FOREWORD

David A. Dow, Director Facility Engineering
Walt Disney Imagineering, Anaheim, California

The Walt Disney organization recognizes the importance of facilities engineering and management. As the company becomes global, more theme parks are being designed and built to keep up with the demand for the Disney product. It has become a monumental task to dream up, design, construct, operate, and maintain the facility assets of the company. Throughout the process, from the early conceptual plan through to the maintenance of the entire physical plant, the goal of every "cast" member is to cater to "guest" satisfaction.

The facilities manager has evolved from being a mechanic in the early 1900s to a highly skilled, multidisciplined individual. Through all of the phases mentioned, the facilities manager must have the same knowledge as the mechanic and must also be computer literate, Internet comfortable, a planner, a scheduler, a motivator of people, an integrator, a problem solver, and probably the biggest change of all, a great manager. To wear all of the hats required, the facilities managers must have the management skills to lead a team of staff that will pull together all of the required facets of their businesses. Now, they probably sit at the boardroom table with the other department heads that make company decisions. The budget for facility management is probably looked at in the most detail and needs to be justified by payback analysis, comparable numbers, and generally, the amount of money every dollar spent will save. This can be difficult in maintenance functions where not performing the tasks can mostly be measured only in problems that may show up in the years ahead.

The Disney experience and approach exemplify the thrust of this book, which is that one must always give more consideration to the individual attributes of modern facilities to succeed in our present competitive business environment. Facilities engineering and facilities management now interrelate as never before. Please come along with us for a moment as we explore the Disney experience. Consider how the Disney experience relates to your own facility experience by substituting "customer" for "guest," "employee" for "cast member," and "process, industry, product, or business" for "show, magic, or attraction." We believe that you will be able to draw parallels to your own situation quite easily.

In its way, the Disney environment sets a standard that any organization must meet. Just as the guests in any Disney environment must be transported into their world of fantasy, employees and customers in any work or commercial environment must be well served to achieve their highest aspirations and to fulfill the missions of the host organizations. Walt Disney Imagineering is the design arm of the Disney organization. Within its hallways, creative departments coexist with the engineering groups, and themed designers and architects mingle with the structural engineers. A synergy exists on campus at the heart of the operation that takes creative ideas and produces new attractions from simple brick and mortar, that immerses the guest into a fantasy location where, for a short period of time, the rigors of ordinary life are left behind. Facility engineers are just one member of this team that is under constant pressure to provide the expected product, also to keep costs down, and to use the most efficient method and technology throughout the process.

Once an attraction is open and the guests are enjoying the magic, the monumental task of operations and maintenance takes over. All attractions must maintain a very high operational rate, similar to many other modern facilities. Attractions cannot be allowed to be inoperative. Guests expect to see certain attractions when they enter a park and any downtime can lead to guest dissatisfaction. Preventive maintenance tasks must be scheduled and cycled periodically, depending on the type of ride or show. All scenes in a show must be fully operational or the show is considered down. (The storyline must be maintained.) When a show or attraction does go 101 (inoperative), crews must be available to repair the problem and bring the facility back on line as soon as practically possible. The readiness of the parks and facilities must all be maintained, as mentioned before, despite the added complications of holding down utility costs, minimizing maintenance crews, and obtaining the best possible replacement parts for the least amount of money.

In today's economy, the shareholders expect growth—growth coupled with saving costs wherever possible. This, of course, cannot in any way compromise the safety and enjoyment of the guests. Growth is not possible without repeat visits from our guests.

Each one of the areas discussed—design, operation, and maintenance—now takes place for the Disney organization on a global scale. Design for each facility may be happening at any one time in almost anywhere in the world. The architect may reside in one place in the United States, and the engineers may be located either in one office or in several offices, in another area of the country. In the meantime, coordination is needed with a ride vendor in Europe and possibly other special effects and show-related items in another part of the world. As the Internet becomes a factor in design coordination and collaboration, a whole new business of e-commerce has developed that provides the project team with methods for pulling the entire package together.

This book pulls together the different knowledge bases of facilities engineering and management and offers a valuable tool to anyone involved in the fast-growing and evolving profession of facility management.

FACILITIES MANAGEMENT

Paul R. Smith, P.M.P., P.E., M.B.A., Chapter Editor
Peak Leadership Group, Boston, Massachusetts

Anand K. Seth, P.E., C.E.M., Chapter Editor
Partners HealthCare System, Inc., Boston, Massachusetts

Roger P. Wessel, P.E., Chapter Editor
RPW Technologies, Inc., West Newton, Massachusetts

David L. Stymiest, P.E., SASHE, C.E.M., Chapter Editor
Smith Seckman Reid, Inc., New Orleans, Louisiana

William L. Porter, Ph.D., F.A.I.A., Chapter Editor
Massachusetts Institute of Technology, Cambridge, Massachusetts

Mark W. Neitlich, M.B.A., Owner, CEO, and Chief Engineer of Chemical Manufacturing (Retired), Chapter Editor
New Haven, Connecticut

Part 1 deals with facilities management. We begin in Chap. 1 by discussing contemporary pressures on organizations and then setting out the challenges for facilities management. In Chap. 1, we also suggest how facilities management can be related to corporate strategy and indicate the need to see facilities management as part of a broader picture of corporate infrastructure. We then look at financial analysis and reporting in Chap. 2, presenting necessary background and concepts, as well as methods of accounting, budgeting, and evaluating projects. We also lay out the new roles of facilities managers in their organizations, indicating how they can create value for their organizations and affect corporate earnings and valuations. Through this, the new facilities manager can become part of the corporation's senior management team. Chapter 3 then gives many new tools to facilities mangers. In Chap. 3, we look at the facility over its entire life cycle, beginning with planning and budgeting and then dealing with the management of design and construction over the entire life cycle of a project. We treat crosscutting facilities management functions like automation and supply chain management. We close Chap. 3 with some important new developments in corporate operations management that will have increasingly strong effects on facilities management.

CHAPTER 1
PERSPECTIVES

Paul R. Smith, P.M.P., P.E., M.B.A., Chapter Editor
Peak Leadership Group, Boston, Massachusetts

William L. Porter, Ph.D, F.A.I.A., Chapter Editor
Massachusetts Institute of Technology,
Cambridge, Massachusetts

INTRODUCTION TO THE FACILITIES ENGINEERING AND MANAGEMENT HANDBOOK

To all facilities engineers and managers:

You spend untold hours compiling information from brochures, professional publications, books, and other sources on how to manage your facilities. This handbook will simplify your job. This handbook is intended to simplify facilities professionals' jobs—and lives—by helping them to:

- Run their facilities better
- Satisfy their customers better
- Incorporate good management practices into their facilities
- Relate effectively to the goals and strategies of their organization
- Coordinate facilities with the management of information technology (IT) and human resources (HR)
- Incorporate computer technologies into facilities management
- Improve their career skills for the next millennium

These are just a few reasons why you will want to own and use this book.

ORGANIZATION OF THE HANDBOOK

This handbook is organized in three parts.

Part I is "Facilities Management." It sets the stage for the handbook, providing the needed background and rationale. This chapter discusses contemporary pressures on organizations and sets out the challenges for facilities management. It suggests how facilities management can be related to corporate strategy and indicates the need to see it as part of a broader picture of corporate infrastructure.

In Chapter 2, we look at financial analysis and reporting, presenting necessary background and concepts, as well as methods of accounting, budgeting, and evaluation of projects. It also lays out the role of the facilities managers (FMs) in their organizations and indicates how they can affect corporate earnings and valuations.

Finally, Chapter 3 looks at the facility over its entire life cycle beginning with planning and budgeting and then dealing with the management of design and construction over the entire life cycle of a project. It treats crosscutting facilities management functions like automation and supply chain management. The chapter closes with some important new developments in corporate operations management that will have increasingly strong effects on facilities management.

Part II is entitled "Facilities Engineering." It includes Chap. 4, "Planning and Programming Process" for buildings and facilities, both new and old. It provides a step-by-step process to enable the FM to capture the owner's requirements and translate them into process and technical baseline requirements for the facility's design and maintenance.

Chapter 5, the largest of the handbook, continues with a discussion of the major systems that support buildings and facilities. Using a systems engineering approach, the major systems engineering topics for facilities are presented, including issues for planning and programming processes; engineering and design processes; construction, modification, and renovation processes; and project management processes. Separate chapters address the following topics:

- Architectural and structural systems
- Electrical systems
- Lighting systems
- Mechanical systems
- Instrumentation and control systems
- Construction processes for both new and renovated facilities
- Maintenance, operations, and assessment of facilities and systems
- Building codes, regulations, and standards including performance-based codes

Part III addresses all types of facilities including buildings and complexes. It includes health care, laboratories, and industrial and manufacturing facilities, as well as colleges, malls, military bases, airports, and high-technology facilities. For each, it highlights the most important systems, the associated management operations, and the problems distinctively associated with that type of facility. The section also stresses the development and management of the infrastructure, and includes other issues particular to multiple buildings in extended environments. Part III does not repeat the work of Part II. Instead, it is devoted to problems that are specific to these kinds of facilities.

Figure 1-1 shows the organization of the handbook. Parts I and II deal with management and engineering issues and are on the vertical axis of the diagram. Part III, on the horizontal axis, deals with facilities. The proportions of the diagram indicate roughly the number of pages in each chapter and part.

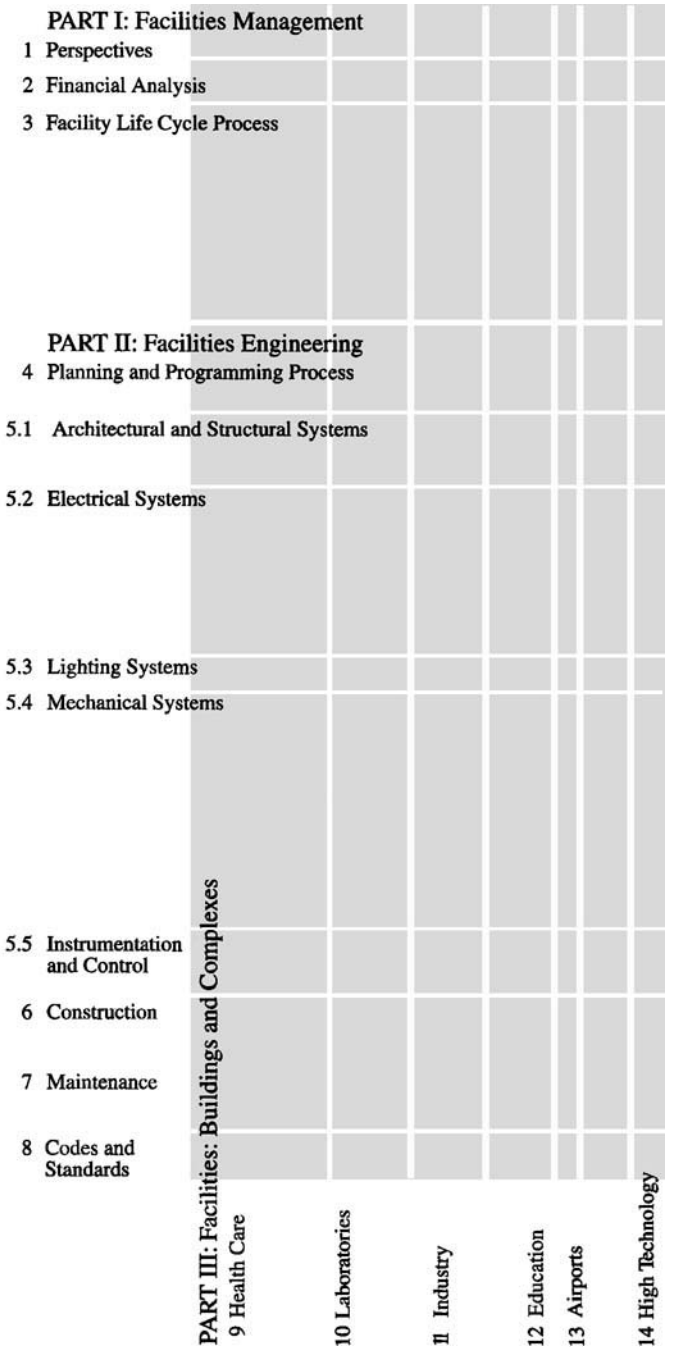

FIGURE 1-1 Organization of the Handbook. Parts I and II deal with facilities management and engineering issues that cut across all facilities and complexes. Part III deals with facilities and includes buildings and complexes. It does not repeat earlier presentation of issues but supplements and refers to them as needed. The distances along each axis in the figure are a rough guide to the number of pages in each section. (*Source: Figure courtesy of Paul R. Smith, Peak Leadership Group, and W. L. Porter, Massachusetts Institute of Technology.*)

SECTION 1.1
INTRODUCTION AND HISTORICAL PERSPECTIVE TO FACILITIES ENGINEERING AND MANAGEMENT

Jack Hug
University of California at San Diego, San Diego, California

Bruce K. Forbes
ARCHIBUS, Boston, Massachusetts

The facilities management profession has changed substantially over the years. As with any successful profession, its vitality has come from dedicated practitioners who have succeeded in gaining positive public support and recognition for the value of professionally managed facilities. All sectors of the economy have benefited from the work of many dedicated and service-minded facilities managers (FMs).

The demands placed on FMs have increased. These new demands are the result of two relentless drivers: (1) increasing complexity and (2) rapid change. The evidence of this manifests itself daily and adds to the challenges that are faced by every FM. Complexity and change will continue to dominate the agenda and propel the profession well into the twenty-first century.

The fact that life has become more complex for the FM is, in itself, no great revelation. The content of this book will help us understand in substantial detail what is at the root of this complexity, and it will fuel the incentive to continuously learn and master the change.

Although the importance of facilities has been acknowledged throughout history, the facilities management profession has not enjoyed the same level of recognition. The FMs, in the early years of modern America and other parts of the world, were clearly working behind the scenes. Throughout history, however, the facilities professional has consistently focused on the management of an asset's life cycle (Fig. 1.1-1).

FIGURE 1.1-1 Facilities managers as stewards of corporate assets. (*Source: Courtesy of Bruce Forbes, ARCHIBUS.*)

To understand today's facilities management profession, it is useful to understand the role played by its predecessors. These earlier FMs were, in every sense, leaders on the cutting edge of an emerging and developing new profession. History has shown that every profession has its own way of doing things and the management of facilities is no exception.

Honoring the past practices of the profession by looking at the way things used to be can provide important clues to significant events that have influenced how things are done today. One is cautioned, however, when looking in the rearview mirror, not to get trapped into thinking that past practices—a return to the "good old days"—are a solution for today's challenges. Honoring the present emphasizes the continuous need to be able to bridge one's actions—and one's thinking—from a solid foundation of relevant past practices to the new realities of today's professional requirements.

The FMs' predecessors saw themselves as optimists who believed that the focus of responsibility and accountability resided with them. They practiced stewardship of the facilities and managed financial and human resources entrusted to them, as if they were their personal assets. They had pride in ownership and pride in workmanship. The physical plant was their baby; the organization was their family. They led by example and, although quite informally, they taught others by coaching and mentoring. Many of these early FMs came up through the organizational ranks. They had performed successfully all of the jobs required by the facilities organization. They were hands-on managers. Many were perceived as the experts. It was in their expertise that building owners invested, trusted, and relied exclusively to make sure that things worked. These early FMs embodied high standards of performance in their everyday activities. They were disciplined and had a strong sense of honor, duty, and obligation. They had no expectations of entitlement, did not draw attention to themselves, and felt they were part of a noble profession.

In his superb book, *The Greatest Generation,* author Tom Brokaw tells the story of a generation of American citizens who came of age during the Great Depression and World War II, and who went on to build modern America. "The war had taught them what mattered most in their lives"[1]; Brokaw continues, "for they had survived an extraordinary ordeal, but now they were eager to reclaim their ordinary lives of work, family, church and community." This profound experience shared by many FMs served as the cornerstone of the profession's solid character traits and service attributes. Facilities management predecessors, for the most part, welcomed their roles at home and at work. They eagerly pursued the development of competencies in the right combination to ensure success. Some of the core competencies addressed by the facilities management professional are shown in Fig. 1.1-2.

EMERGENCE OF THE FACILITIES ENGINEERING AND MANAGEMENT PROFESSIONS

If facilities engineering has a birthplace, our guess is that it was the boiler room. The boiler room and its required auxiliary equipment—its distribution piping systems, water, oil, gas, sewer, steam, condensate and electrical systems—were the most complex, and potentially treacherous, parts of a facility.

In a large building or in clusters of the buildings built in the 1940s and earlier, the boiler room served as the heart of the building operations. Not only did this space (typically located in the bowels of the building) contain the building's life-support systems, the boiler room also served as the central nervous system and the brain. It was a place of mystery and intrigue. It was the home of the building engineer.

The boiler room was off limits to the building occupants, and most building owners had complete trust and confidence in their engineer. The building engineer had ownership, and he (in the old days, it usually was a *he*) was expected to know everything about the building—its construction, its components, where things were located, how things worked, and how to fix them when they did not work. Generally, the building engineer did not have to concern him-

FIGURE 1.1-2 Facilities management core competencies. (*Source: Courtesy of Bruce Forbes, ARCHIBUS.*)

self with housekeeping, landscape maintenance, or even tenant improvements. The job requirements largely emphasized the more traditional engineering skills and competencies. For some, the engineer may have had responsibilities for building hardware, painting, and carpentry, but these were viewed as secondary to the engineering, power plant, electrical, plumbing, heating, and ventilation system responsibilities.

Inside the boiler room, there was no central control room, as is common today. The boiler operators monitored and controlled the steam cycle manually. The operator would make continuous rounds, checking dials and gauges located on the equipment and recording the conditions observed, such as pressures, temperatures, flow rates, and fluid levels. In more modern buildings, pneumatic control technology (developed in the 1940s) was used.

Somewhere inside the boiler room was a space carved out for the building engineer's office. Sometimes, there was a small workshop for maintenance. Rarely was this space designed into the original construction plans; it was usually an afterthought. It was an icon attesting to the innovation and creativity of the building engineer. Hot, smelly, poorly ventilated, noisy, and cluttered with parts, catalogs, and trade magazines—these accurately describe the conditions of the engineer's workspace.

Whenever there was an emergency, the building engineer would be right in the middle taking a leadership role in resolving the emergency. Whether a power outage, a flood, a major steam leak, or a boiler explosion, the engineer was always expected to be in the thick of things, covering the full spectrum of technical issues that today's modern building requires an army of specialists to address.

Facilities management is generally performed within a broad and diverse context of requirements and circumstances. The forces of change throughout history have required the FM to be constantly vigilant, flexible, and adaptable to changing requirements. This inherent stewardship responsibility has been carried forward. Ensuring that the facility remains useful

and functionally adequate continues to be a fundamental part of the job requirement of the contemporary FM.

The fundamental practices of the past have been subjected to continuous change. Practices and procedures that were valid yesterday can easily become invalid and unnecessary in no time at all. For example, many past practices demonstrate that the building engineer was primarily expected to perform in a stable, steady, consistent, according-to-the-book manner, and only occasionally to react to change. Today, however, every successful facilities organization must be designed to respond to change as the norm, and it is even encouraged to create change. Due to the complexities of organizational change, caused in part by the e-commerce phenomenon, the role of the facilities professional will become even more significant. It is expected that real estate, facilities, and infrastructure expenses will consume over 50 percent of an organization's revenue.

During the past several decades, significant events have helped thrust the FM into the middle of things—the energy crisis; population growth; increased environmental concerns; advances in science resulting in new construction materials, methods, and equipment; the recognition of management as a profession; and the impact of technology—all have contributed to the evolution of facilities management as we know it today. Perhaps the most significant changes in the last 5 years have been the e-commerce and business-to-business revolutions. The bricks-and-mortar organizational style that have served us since the industrial revolution is quickly being replaced by clicks-and-mortar and clicks-and-clicks opportunities.

The 1950s and 1960s were significant periods for facilities expansion. The post–World War II boom fueled the need for FMs and engineers. It is difficult to comprehend the explosive growth in all areas of the FM's professional responsibilities. The convergence and interaction of the new forces impinging on facilities management raised the standard by which the FM's performance is now measured (Fig. 1.1-3).

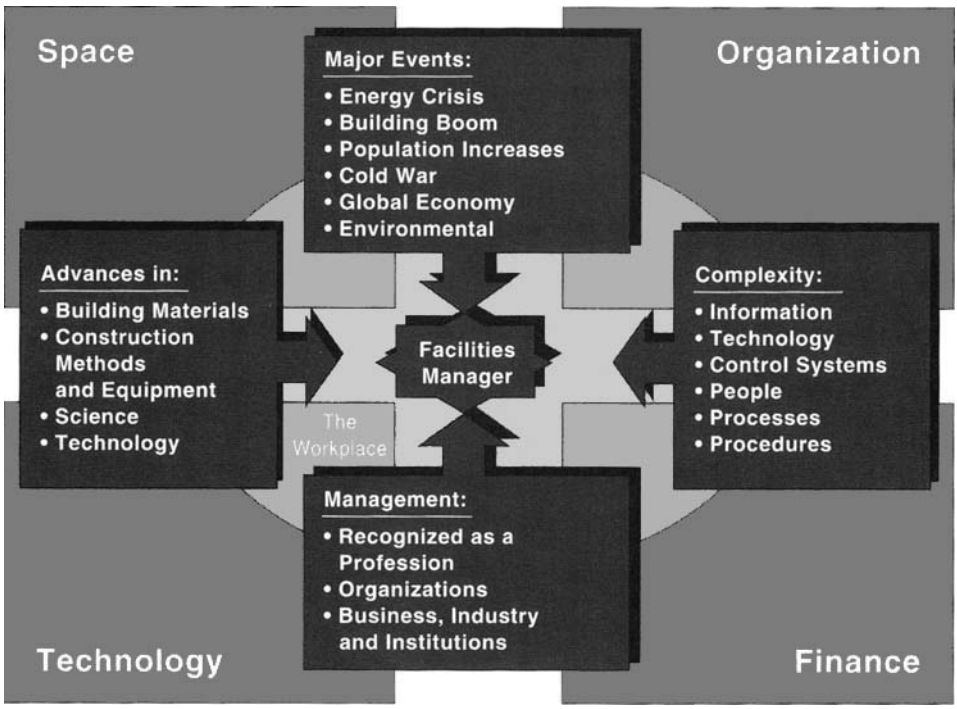

FIGURE 1.1-3 Forces impinging on facilities management. (*Source: Courtesy of Jack Hug, University of California, and Bruce Forbes, ARCHIBUS.*)

Not only has there been enormous growth in all types of new, more complex, and more costly space, but the existing inventory of aging buildings adds a substantial requirement for capital renewal and modernization. Enormous efforts are required to keep the country's institutional, business, and industrial facilities in sound condition.

THE TECHNOLOGY FACTOR

The challenges facing the FM today are awesome. The job has never been easy, but the 1990s have placed more demands than ever before upon the profession. All of the major drivers referred to earlier continue to affect the FM. The most powerful force bearing down on the profession is the quantity, extent, and speed of change in technology.

The facilities management prophet for the year 2000 might proclaim, "When things all around you are changing and you're not, the end is near." The technological shift with its relentless drive during the 1990s is now familiar and we are deeply embedded in the cyber world. This revolution is influencing the type of facility services and the manner in which they are performed. Microchips and computers have been used to create smart buildings, smart systems, smart security, smart access, and smart telephones. The twenty-first century is guaranteed to spawn additional industry-changing innovations. The development of effective infrastructure management enterprises will be critical as facilities professionals help the organizations they serve enter the knowledge age.

Facilities managers are cautioned not to underestimate the impact of this technology. A sudden new world of data communications, local area networks, electronic data interchange, image technology, and the relentless flood of new applications, tools, and technologies are as much a part of the physical plant as are the traditional utility systems. In fact, the data infrastructure not only ranks high in importance with traditional utilities, but also is proving to be one of the most important factors in sustaining business operations, productivity, and profitability. This inexorable fact of life, taking place in multiple facilities organizations around the world, has changed the dynamics of the FM's workplace. A fundamental shift has occurred in the way business is conducted.

STEWARDSHIP, THE FM, AND CYBERSPACE

"Civilization as we know it today owes its existence to the engineers. These are the men and women who down through the centuries have learned to exploit the properties of matter and the sources of power for the benefit of mankind. The story of civilization is in a sense, the story of engineering—the long and arduous struggle to make the forces of nature work for man's good."[2]

The stewardship responsibility that is appropriately assigned to the FM is born out of a long, arduous struggle to make the forces of nature work for the good of humanity. There is a sense of moral responsibility for the care and use of a facility. Today's FM has accepted this responsibility with respect to the principles and needs of those whom the facility is intended to serve. This stewardship perspective has served the profession well, and it will continue to be an important dimension that will help define the future environment of facilities management. Proper maintenance and care of buildings, grounds, and infrastructure demonstrate confidence in the future and recognition of the investment in the physical assets.

We have seen that facilities management is a very broad area of endeavor. It is not regarded in the traditional sense of different branches of engineering such as civil, mechanical, electrical, structural, or chemical engineering. Facilities engineering is a more generalized branch of the engineering discipline. It requires the practitioner to summon many different

kinds of engineering expertise in a cohesive, coordinated, and, sometimes, collaborative manner. Today's FMs come from all sorts of formal and informal educational backgrounds. No credible research has been done that would lead to a conclusion that an FM must be an engineer to be successful. This does not imply that facilities management is not a disciplined profession or that a degreed engineer cannot be a successful FM. Indeed, facilities management requires special expertise and clearly carries with it a very special consciousness and a sense of obligation to serve.

Facilities management is a term of broad application used by those who, with proper preparation and training, are occupied with solving the problems of a wide range of disciplines. It is a profession today from whose ranks its members can be called upon to thoroughly advise on questions involving facilities throughout the world.

In the cyber world of the twenty-first century, FMs will have to acquire new competencies, and specialists will emerge from within the ranks to work with the new information technologies. There will be new possibilities for more effective management of facilities, including much better instrumentation and control. This, in turn, will increase the effectiveness of personnel, and it will greatly increase the efficiency of the organization. The facilities management profession will be transformed.

INTEGRATING INFORMATION TECHNOLOGY

The difference that technology makes in the way we organize, structure, and empower our lives and our workplaces is the most significant determinant in changing the way that FMs deliver services.

There is evidence that increasing numbers of FMs no longer have responsibility for information technology systems management. In facilities across the globe, the failure or downtime of data systems, information technology infrastructures, or computer networks is as critical to a business or industry as an electrical power failure. Currently, only a small number of FMs are charged with the responsibility for these critical systems and infrastructures. Interestingly, the same elements of complexity, reliability, capacity, condition, and flexibility that are present in telecom data systems exist in the utility infrastructure.

Unfortunately for the facilities management profession, the computer network, infrastructure, hardware, and software are largely the domain of a new breed: the telecommunications manager, who does not report to the FM. In fact, this position enjoys equal or greater status in the organization than the FM. Yet, the world of data and information, local area networks, the Internet, and the relentless flow of new software applications, tools, and technologies are as much a part of the physical plant as are the traditional utility systems. It is now a fact of life that data and information technology are proven to be important factors in sustaining successful business operations, productivity, and profitability.

In the transition from the information age to the knowledge age, the components of the new workplace (i.e., space, organization, finance, and technology—and the relationships among them) are in a state of flux. The facilities managers are the most appropriate professionals to provide a leadership role in the emergence and implementation of these new opportunities. Although facilities managers have proven to be highly adept at serving the needs of facility occupants, many observers conclude that some facilities management professionals have a long way to go in their understanding and effective management of the requirements of the knowledge age and its associated technologies and best practices.

This critical assessment of current conditions clearly identifies an area of opportunity for the facilities manager. Now is the time to think strategically and to reposition the facilities management profession—to recapture this critical facilities service. There are risks; however, our experience with other challenges has taught us that if we wait until the path is perfectly clear and the risks have disappeared, the opportunities will have passed as well.

NEW PERSPECTIVES ON FACILITIES MANAGEMENT

Facilities Management Challenges in the New Millennium

The past century has seen the dawn of several revolutions. The industrial and business revolutions have given way to the information and knowledge revolutions. Shifts in the availability of information and increased processing power virtually eliminate information float. Today, information reaches customers quickly, enabling them to become increasingly informed about available alternatives. This means that customers are likely to be less loyal, but more sophisticated and more demanding than in the past. Meanwhile, competitors are delivering innovative products to the marketplace with greatly reduced lead times. Perhaps most important, products and technologies are changing rapidly, making it absolutely necessary for organizations to shorten their response time to new opportunities.

Moreover, competition is not just from within but also from outside traditional business categories, and it often results from innovative redefinitions of such categories. Globalization is occurring in all organizations—manufacturing, service, and hybrid; governmental and nonprofit—with profound consequences for how and where organizations must operate.

Wider issues are also having a direct effect on organizations. The earth's ecosystem is being threatened, many resources are being depleted faster than they are being replaced, and the degradation of the quality of the environment is now a matter of public concern. As a result, the regulatory environment is shifting and standards are rising for the energy performance of buildings, for the environmental standards for its occupants, and for ecologically responsible ways of handling waste materials. New concepts and technologies are emerging that may form the basis for future standards and will influence what organizations purchase, as well as what they produce.

Agility is the characteristic of organizations that can respond successfully to today's market, economic, and environmental pressures for change. For facilities managers, fostering agility requires a high degree of adaptability to provide and manage facilities that can meet the rapidly evolving needs of the organization.

Organizations are responding to these challenges in a variety of ways, including downsizing, outsourcing, and just-in-time procedures. Thus, the collection of activities that constitutes an organization is distributed geographically, and so, too, is the workforce. At the same time, the formation of high-performance, cross-functional teams is increasing throughout the business sector. Cross-functional teams usually consist of people from several locations who depend heavily on communications and information technology, as well as on travel, for needed face-to-face communication. And these teams may operate at all times of the day and night, depending on where the team members are. They may operate simultaneously or asynchronously as information from one group is passed along to another in a different time zone.

Changes of this scope affect the organization's vision, mission, and core values, its management structure and organizational models, its work systems and processes, its performance expectations, and its behavior at individual and group levels. For example, because of the need to draw on talents across the workforce to meet competitive challenges, reward and recognition systems must place increased emphasis on empowering employees throughout the organization and on sharing the risk of failure and the rewards of success.[1] Thinner profit margins, however, are reducing the flexibility of action and leaving much less room for mistakes.

For organizations to be agile in responding to new conditions, *adaptability* is the watchword for facilities managers. Downsizing in one or more locations causes shifts in the use of facilities, forcing onto the market those that are no longer needed. Outsourcing may remove operations from the specialized facility for which there is no other obvious use, and shifting functions from one region to another may force rapid shifts of buildings to new uses. Finally, the workplace of today's organization is changing from the traditional workplace, associated with a single building or location and with a fixed and regular workday. The new workplace requires both cyber and physical space, and it requires that the two types of space be integrated.

Against this background, the most pressing challenges for the facilities manager are:

- To ensure rapid adaptation of existing facilities to new programmatic demands
- To carry out rapid construction of new facilities
- To improve all services and integrate the new information infrastructure
- To enable all facilities to become integral parts of the new workplace of the contemporary organization
- To make these changes consistent with the core strategy of the organization

Figure 1.2-1 summarizes the points just made in this part of the chapter, showing that organizations need agility to respond to the shifting global context and that facilities management must be highly adaptable to enable the organization to change.

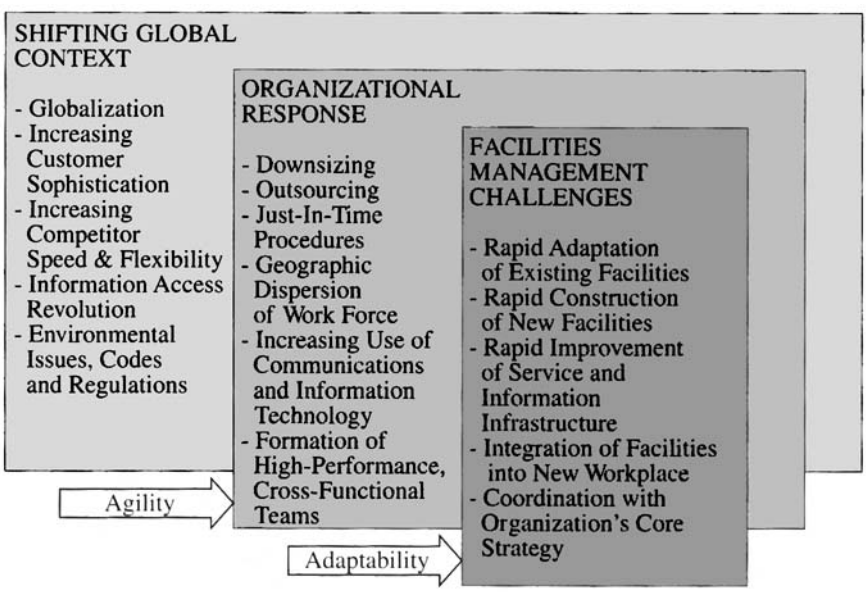

FIGURE 1.2-1 Facilities management challenges. Adaptability in facilities management is necessitated by the organization's need to respond rapidly to the shifting global context. (*Source: Courtesy of Paul R. Smith, Peak Leadership Group, and William Porter, Massachusetts Institute of Technology.*)

Facilities Management and Organizational Change

As most organizations grow, they pass through a series of development phases.[2] Each phase begins with a period of evolution, with steady growth and stability, and ends with a revolutionary period. This is true of all organizations, no matter how fast they grow and regardless of their age. For example, at one phase, centralization practices lead to demands for decentralization. The same organizational practices are not maintained throughout a long life span. Therefore, a company must plan its movement from one phase to the other or its health, growth, and prosperity will be affected. To serve the organization effectively, a facilities manager must be aware of the company's phase of development.

Phases of Growth. Figure 1.2-2 shows five phases of growth for a company.[2] Every evolutionary period is characterized by a dominant management style that is used to achieve

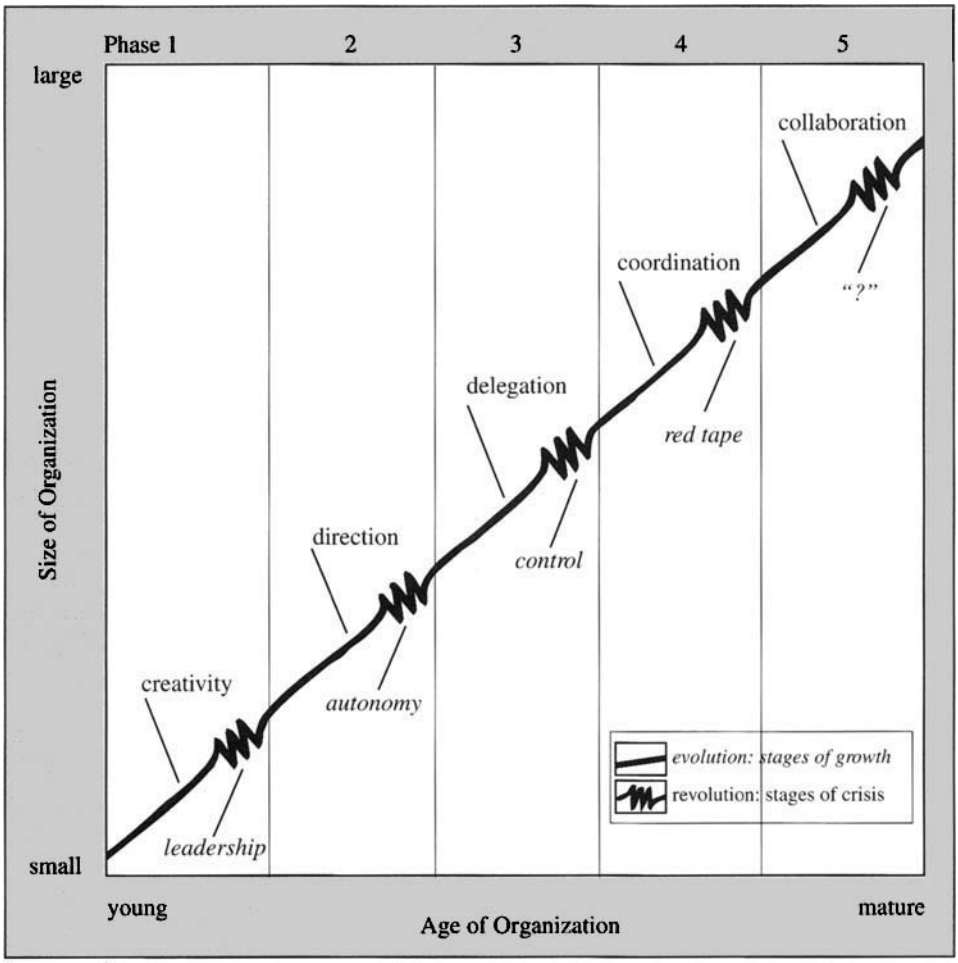

FIGURE 1.2-2 Five phases of growth. The continued successful development of an organization oscillates between evolutionary stages and crises that require new styles of leadership for the next evolutionary stage. (*Source: Courtesy of L. E. Greiner, Harvard Business Review.*)

growth, and it is followed by a revolutionary episode out of which must come a new style of leadership if the company is to continue to grow and prosper. In phase 1, *creativity* is the birth stage of an organization, and the emphasis is on the product and the market. The founders are usually technical or entrepreneurial and tend to disdain management activities. In phase 2, *direction* has a capable business manager installed whose directive leadership channels employees' energy into more efficient growth. During phase 3, *delegation* is provided by installing a decentralized organizational structure that allows the company to grow through heightened motivation of managers at lower levels. In phase 4, *coordination* requires a formal system for achieving greater coordination; top executives take responsibility for initiating and administering the system. Phase 5 calls for strong interpersonal *collaboration* in an attempt to overcome the red-tape crisis.

For each phase, managers are limited in what they can do if growth is to occur. For example, a company that is experiencing an autonomy crisis in phase 2 cannot return to directive management for a solution; it must adopt a new style: delegation. Too often, it is tempting to choose solutions that were tried before but that actually make it impossible for the new phase to emerge.

Self-Assessment. Knowing where you are in the development sequence is important because you need different organizational practices for each of the five phases. Table 1.2-1 lists five categories: (1) management focus, (2) organizational structure, (3) top management style, (4) control system, and (5) management reward emphasis.[2] For example, in the first, or creative, phase, management focus is to make and sell; the organizational structure can be informal; top management style is individualistic and entrepreneurial; the control system is keyed to market results; and the management reward emphasis is on ownership. Contrast this with the last, or collaborative, phase, during which the focus is problem solving and innovation; the organizational structure is a matrix of teams; the style is participative; the control system is mutual goal setting; and the rewards are team bonuses. The task for senior management is to be aware of the phases of growth and to recognize the signs and the time for change in management practices.

TABLE 1.2-1 Management of Growth. Different Management Practices Are Needed during the Different Phases of Organizational Growth and Change.

	Phase of Growth				
Category	Phase 1: Creativity	Phase 2: Direction	Phase 3: Delegation	Phase 4: Coordination	Phase 5: Collaboration
Management focus	Make and sell	Efficiency of operations	Expansion of market	Consolidation of market	Problem solving and innovation
Organizational structure	Informal	Centralized and functional	Decentralized and geographical	Line staff and product groups	Matrix of teams
Top management style	Individualistic and entrepreneurial	Directive	Delegative	Watchdog	Participative
Control system	Market results	Standards and cost centers	Reports and profit centers	Plans and investment centers	Mutual goal setting
Management reward emphasis	Ownership	Salary and merit increases	Individual bonus	Profit sharing and stock options	Team bonus

Source: Courtesy of L. E. Greiner and *Harvard Business Review*

Impediments to Change. The art of managing change in organizations rests in large part on being able to spot the impediments to change and to deal effectively with them. These impediments include the following:

- Resistance to change by individuals and groups, addressed in part by looking more closely at their needs and responding to them and by creating clear indicators of progress
- Lack of consensus, addressed by creating a common vision statement, assembling a broadly drawn guiding coalition, identifying a champion for the changes, and opening the process to wider participation
- Unrealistic expectations, addressed in part only by putting forth alternatives within a defined budgetary frame
- Lack of cross-functional teams, addressed by requiring such teams from the outset of the project
- Lack of team skills, addressed in part by training accompanying the change processes
- Failure to consider information technologies, addressed by introducing them early in the change process
- Too narrow a project charter, addressed by extending the time of project definition at the outset and by providing for project redefinition of scope and priorities as late as possible in the process

Implications for Facilities Managers. These are just some of the issues that may accompany change in organizations. Facilities are often an integral part of change within organizations, and today the facilities manager is increasingly a part of the top management team that addresses and manages organizational change. New facilities need to be designed and renovated to serve the particular phase in which the organization finds itself. Therefore, the facilities manager must be aware of how the organization is changing and where it is in the change process. Recognizing the factors that affect organizational change will therefore help him or her to achieve the organization's objectives.

Recognition of these factors defines the objectives of facilities management itself by:

- Clarifying why changes in work practices are necessary
- Clarifying the link between facilities objectives and corporate objectives
- Incorporating successful change management strategies into facilities management procedures themselves

A fundamental shift to a comprehensive integrated approach, indeed a reengineered process, is required to meet these objectives. This integrated approach takes several forms, each making its contribution to facilities managers' contributions to aligning facilities and corporate objectives. The first is integration between life cycle phases (see Chap. 3), which invites the following:

- Strategies for work efficiency
- Design for construction efficiencies
- Design for flexibility
- Materials chosen in the light of long-term maintenance considerations
- Other strategies, sometimes described as *right-to-left* thinking

This will help the facility manager to meet near-term objectives and never lose sight of long-term facility value optimization. The second form of integration is between disciplines. The facility manager is an organizational coach, dealing with people who are expert in finance, law, design, operations, estimating, construction—the list goes on. These professionals, each with their special wisdom and training, can and will make important contributions to the improvement of facilities, given the right environment and motivation. To get these myriad personali-

ties to work together requires careful treatment of the cultural, personal, contractual, and emotional relationships. The final form of the modern integrated approach is the integrated building system. Designing for integrated mechanical, electrical, control, structural, or other systems can improve construction savings and long-term operational economy.

Facilities Management as Part of Corporate Strategy

Success in the global marketplace requires a business model based on new methodologies and techniques that incorporate evolutionary and revolutionary concepts. Typically, these techniques foster problem-solving and innovation skills; they cultivate collaborative strategies and create the appropriate management and individual reward structures; they engage entrepreneurs and inventors with customers; and they shift from centralized control to mutual goal setting. Moreover, they define strategy and continuously improve performance by creating high-performance work teams utilizing your greatest assets: people, processes, technology, and infrastructure. In general, these techniques tend to hasten the organization's maturation in productive ways.

For years, American Big-Five consulting firms like Arthur Andersen and Ernst & Young have been telling their clients they must align their people, processes, technology, and infrastructure to support the business strategy. They remind their clients that a particular strategy will be different depending on their business environment. Therefore, consulting on productivity improvement could begin by helping you analyze why you are in business today, what the products and services are that you sell to an external or internal customer, and how continuous improvement is implemented.

The consequence for facilities managers is that the systems and processes of the organization, including its physical facilities and informational infrastructure, must adapt quickly to these shifting contexts. Facilities managers must be knowledgeable concerning the factors that underlie them, and they must understand and become an integral part of corporate strategy. We suggest that three ongoing activities make it possible for an organization to achieve success in a changing world: (1) direction, (2) alignment, and (3) implementation. *Direction* is the activity that gives rise to the organization's core strategy; *alignment* gives rise to the organizational strategy; and *implementation* results in the production of products and services (see Fig. 1.2-3).

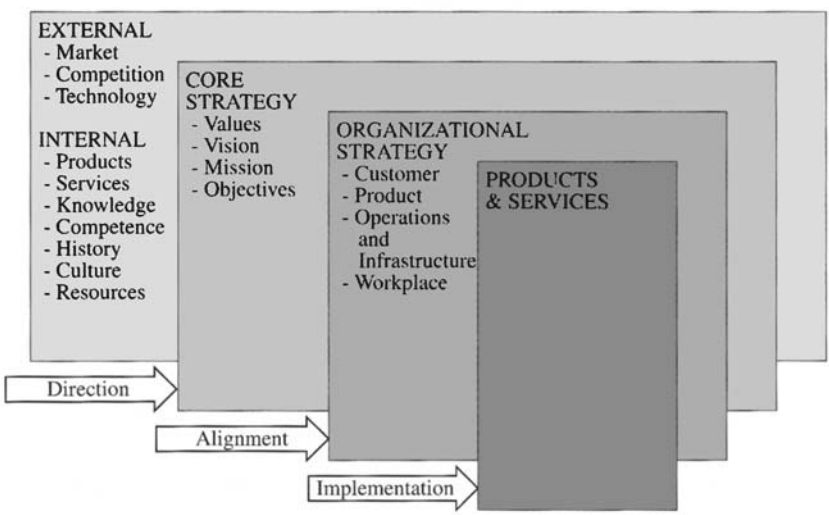

FIGURE 1.2-3 Strategic factors. Direction, alignment, and implementation are the keys to an organization's success. (*Source: Courtesy of Paul R. Smith, Peak Leadership Group, and William Porter, Massachusetts Institute of Technology.*)

Although these three activities are presented sequentially in this text, they actually must occur constantly, each informing the other, to lead to creative transformation of the organization over time.

Direction and Core Strategy. Direction is the activity that formulates the core strategy out of external and internal factors. External factors include the market into which the organization is trying to penetrate, including the customers in that market, their preferences, and their potential; the competition aiming at the same market; and the technologies of the day that affect design, production, and marketing. Internal factors include the firm's current capabilities to produce products and services, its knowledge and competencies, its history and culture, and the resources on which it can draw. Consideration of these factors should give rise to an integrated core strategy.

A core strategy includes values, vision, mission, and objectives. Guided by its core strategy, a company should be prepared to change everything about itself as it moves through corporate life. Otherwise, the world will pass it by. The core strategy contains the elements of greatest permanence—particularly its core values.

Core values are not to be confused with a specific culture or operating principles; they are not aimed at financial gain or short-term expediency. For example, Wal-Mart's number one value is, "We put the customer ahead of everything else . . . If you're not serving the customer, or supporting the folks who do, then we don't need you." A core value is clear, simple, straightforward, and powerful. Successful companies tend to hold tenaciously to their core values.

A. D. Little studied companies that prospered over the long term, such as Hewlett-Packard, founded in 1938; Motorola, founded in 1928; Merck, founded in 1892; and Procter & Gamble, founded in 1837. These visionary companies attained extraordinary success decade after decade, regardless of the change and difficulties facing them. They achieved this by adhering to the same timeless mission, that today's leaders can use, that they developed as a result of preparing themselves for change, along with growth and transformational strategies.

An organization requires fundamental objectives beyond just making money. A company's core objective need not be unique, but it must guide and inspire. Walt Disney captured his core objective when he said, "Disney will never be completed, as long as there is imagination left in the world." Boeing, likewise, can never stop pushing the envelope in aerospace technology. An organization gives direction by formulating and expressing its core strategy and by letting that be its guiding force.

Alignment. The activity of alignment brings external and internal factors into a strong and mutually reinforcing relationship that is guided by the core strategy. Alignment results in an organizational strategy consisting of five major parts that address the customer, the product, the operations, the infrastructure, and the workplace.

The Customer. The customers and their changing buying preferences must be key elements of organizational strategy. Consider how some wholesalers sell used cars in Japan. Until the mid-1980s, vehicles were transported to be sold at live auctions. But only about 45 percent of the products at any given auction were sold, resulting in low efficiency. Fujisaki saw an opportunity to transform the marketplace. He created a proprietary computer and satellite communications system called *AUCNET.* Each week an AUCNET inspector inspects the cars and collects photos of them. The information is digitized, put on laser disc, and shipped to subscribing dealers. AUCNET staffers then moderate an auction that takes place on computer screens all over the country. The purchased cars are then delivered to the appropriate lots.

The AUCNET system has made the physical location of inventory and the actual site of buying cars irrelevant. The traditional face-to-face marketplace interaction between buyer and seller has been eliminated. Now a buyer and seller can meet in marketspace. Consider the implications for space, facilities, and information technology! As indicated earlier, facilities management had to be extremely adaptable to permit the organization to move with agility into its new condition.

The Product. Some companies change from a product orientation to a service orientation without even knowing it. Consider the near demise of *Encyclopedia Britannica,* one of

the best-known brand names in the world. Evans and Wurst report that its sales had plummeted 50 percent since 1990. How is this possible?

The *Encyclopedia Britannica* sells for somewhere in the range of $1500 to $2200. An encyclopedia on CD-ROM, such as Microsoft's *Encarta,* sells for around $50. The cost of producing a set of print encyclopedias—printing, binding, and physical distribution—is about $200 to $300. The cost of producing a CD-ROM encyclopedia is about $1.50.

Imagine what the people at *Britannica* thought was happening. The editors probably viewed CD-ROMs as nothing more than electronic versions of inferior products and toys. When the threat became obvious, *Britannica* did create a CD-ROM version, but to avoid undercutting the sales force, the company included it free with the print version and charged $1000. The best salespeople left, and the company was sold. Under new management, the company is now trying to rebuild the business around the Internet.

Britannica's downfall demonstrates how quickly and dramatically the new economics of information can change the rules of competition, allowing new players and substitute products to render obsolete such traditional sources of competitive advantage as a sales force, a supreme brand, and even the world's best content. Finally, it demonstrates the dangers of not carrying out an effective reassessment of the organization's products, processes, and services.

An effective product strategy requires realignment with the external environment and its windows of opportunity; restriction to a few core competencies in the race to stay ahead of rivals; and alignment of core competencies with the strategy. Alignment may force changes in the core strategy if an organization has developed dysfunctional or outdated approaches to its market. Once again, space, facilities, and information technology had to be highly adaptable in order to support these absolutely fundamental and necessary shifts in organizational strategy.

Operations and Infrastructure. There is nothing remarkable about an organization's effort to coordinate the deployment of different kinds of resources, of course. What *is* new, however, is that "riding the waves of change" means moving beyond notions of coordination alone to include concepts of integration and coinvention. In other words, *agility seems to imply that how work is done and how work is supported need to be considered as one process.* "Not all the time, not every time, but some times."[3]

Operations strategy guides the way the organization goes about its work. It organizes people, plant, equipment, and other resources to implement the objectives expressed in the core strategy. It creates business processes to carry out the organization's objectives. Typically, infrastructure is thought of as supporting operations,[4] but infrastructure and operations may converge and influence one another. Amazon.com provides a good example of the way the infrastructure that was created to market books opened up other marketing opportunities (e.g., toys) that were not included in the earlier marketing plans.

The Workplace. The aim is to create a mutually reinforcing relationship between work practice and the workplace. Over the next several years, the nature of work will continue to change, with powerful implications for changes in the place and style of work as well. Work will be where the worker is, rather than where the place of work is. Work at the end of the twentieth century relies increasingly on information and on digital technologies that permit its easy storage and retrieval. In many industries, work is much more than what is done at one's desk at the place of employment. People work in a variety of settings in addition to the places of work owned or leased by the employer. They work while traveling—in transit and at distant locations, while at the client's office, while at home, and wherever they must work or find it convenient to do so. Moreover, even at the place of employment, many employees are mobile but must stay in communication with people for management purposes or for expertise and with sources of information and computational power.

Wherever they are, employees need access to people and information that are not physically present. The nature of their work, therefore, requires support for information and communication every bit as much as it does for facilities. In relation to these new conditions of work, facilities management has two levels of responsibility that it could assume. It could maintain strict boundaries around facilities, dealing only with the workplace as traditionally understood (i.e., mainly the buildings and service infrastructure owned and leased by the cor-

poration). Alternatively, it could extend its reach into the new workspace, including the required infrastructure. Most obviously, this includes information technology, but the infrastructure for work could also be thought of more broadly as the support for all of the management and other services that help create optimal conditions for work.

Of course, for most organizations, the major places of employment will continue to be centrally important in sustaining work culture, and these are the focus of this handbook. These places are evolving in their own right, however, responding increasingly to the local culture of work and to the highly attractive workplaces that other organizations are creating to compete for talented employees.

Implementation and Infrastructure. The lesson for today's organizations is that infrastructural strategy must be shaped at the highest level of the organization. If it is viewed as a collection of services, typically including space, information technology, human resources, and finance, it must be coordinated and related to operations. It may also be viewed, as in the case of Amazon.com, as creating new organizational capacity, enabling it to open up new markets. Coordination at the highest level is all the more needed.

Figure 1.2-4 is intended to indicate that infrastructural resource strategy should be considered at the same level as all of the other important components of the organization. It should

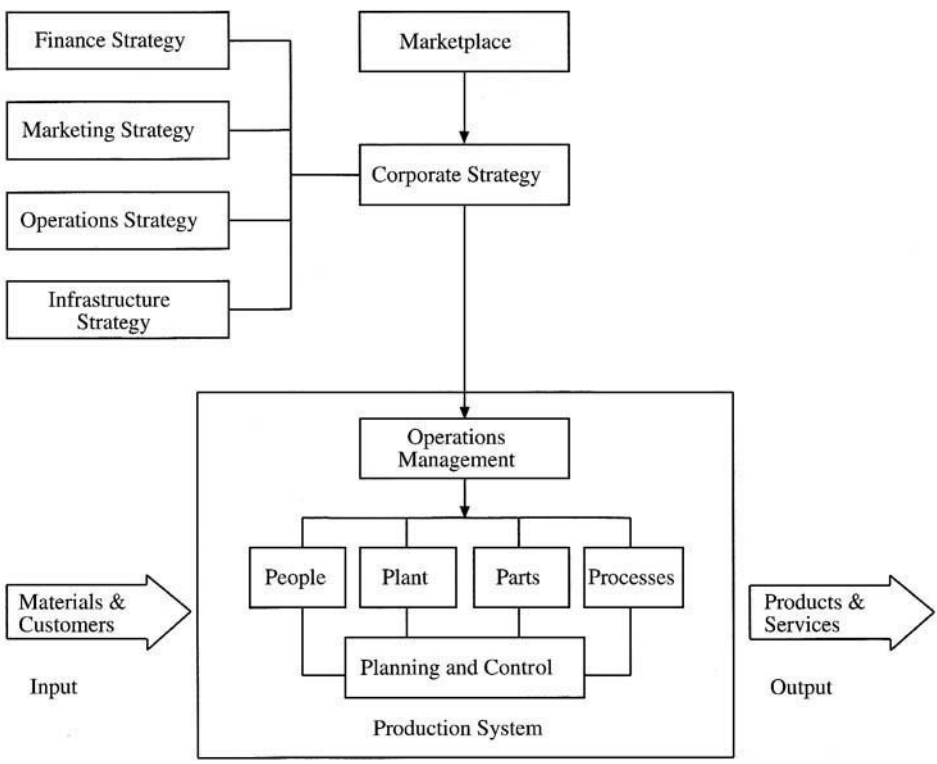

FIGURE 1.2-4 The place of infrastructural resource planning in the organization. Infrastructural resource planning, including space, information technology, human resources, finance, and other areas needs to be carried out at the highest level of the organization to increase its agility in responding to new market pressures and to new ideas. (*Source: Courtesy of Paul R. Smith, Peak Leadership Group, and William L. Porter, Massachusetts Institute of Technology.*)

not be seen just as service. The form this will take for each organization will, of course, be different.

Facilities Management and Workplace Change

Our economy was previously based on economic factors that, in turn, were based on property, plant, and equipment as the primary agents of capital formation. We are entering an economy based on information and knowledge. Therefore, the workforce and all of its understanding, competencies, and sense of social responsibility must become the more important part of the value chain measurement. The implication for facilities managers is to increase the importance of serving the workforce directly as customers in the same way that the corporation must serve its customers if it is to stay competitive. Thus, it is essential that facilities managers see their work as part of the creation of the new workplace, not only the provision of specific services.

The New Workplace. The components of the new workplace include *organization, finance,* and *technology,* as well as *space.* These four elements interact to provide the environment for any work practice (see Fig. 1.2-5). Their interactions can be mutually beneficial or counterproductive. For example, if the space is set up to reinforce working in teams, but neither the organizational nor the financial incentives encourage teamwork, you have an obvious conflict. If, furthermore, the information technology is not there to support teamwork, failure is even more likely. We'll discuss each element briefly and then return to the opportunities to set up more productive relationships among the elements.

Space. Several authors have written perceptively about types of workplaces and have suggested how they may change in the future. For example, for offices, Duffy and his colleagues[5] have described four types of offices: (1) the hive, (2) the den, (3) the cell, and (4) the

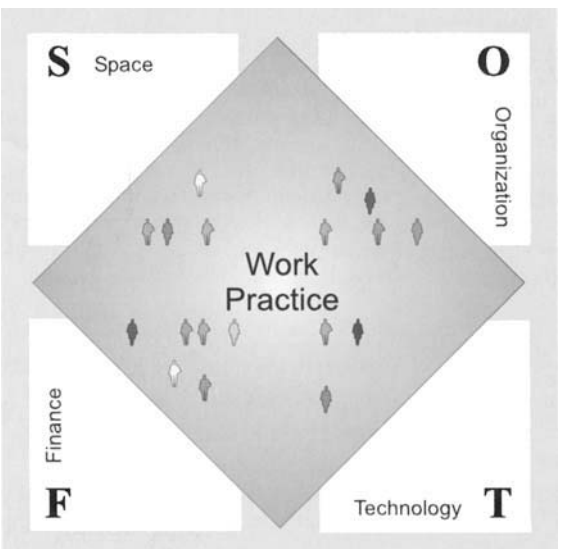

FIGURE 1.2-5 The "SOFT" diagram. Space, organization, finance, and technology must each be designed, and in dynamic relation to one another to create a workplace that supports the core strategy of the organization. (*Source: Courtesy of John Wiley & Sons.*)

club. Repetitive work is associated with the hive, with many workstations, low autonomy, and low interaction among workers. An example might be repetitive backroom work to support banks and other financial institutions. The cell is associated with increased autonomy and might be best illustrated by faculty offices in a college or university. The den is associated with heightened interaction, where most of the work is done in teams—an architectural office, for instance. The club is associated both with increases in autonomy and with increases in interaction; it is exemplified by many research and development groups. Organizations tend to move from the hive to the other types over time, but most medium to large organizations exhibit all four types within their space inventory. In general, organizations have to accommodate an increasing variety of work patterns, including many varieties of telecommuting, and a wide range of types of computing equipment, all of which require more complex and sophisticated information technology support. Space types are increasing in variety as organizations come to understand the great variety required to support service and knowledge work. Many organizations need all four types of space suggested by Duffy: the hive, the cell, the den, and the club.

Two important implications for facilities management flow from this analysis. The first has to do with the type of building that is most supportive of the particular office type, and the second has to do with the heating, ventilating, and air-conditioning (HVAC) systems most appropriate to each. For example, the only office type for which deep buildings are appropriate is the hive, and the only office type for which shallow buildings are appropriate is the club. As the autonomy of the worker and the team increases, and as the needs for interaction increase, HVAC systems have to become increasingly flexible and subject to user control. The raised floor combined with radiative-air systems, increased integration of natural ventilation, mixed-mode systems, and distributed control are all responses to the demands of the new work styles.[6]

Some innovative office buildings are already reflecting these new ideas. The British Airways building at Heathrow, primarily a hive-type office, uses its central atrium to link the control and management functions on the upper floors with the receiving, checking, and briefing of thousands of transient air crew staff each day. In a new factory in the Czech Republic, the offices for management have been placed inside the oval assembly line. Therefore, managers and workers interact on a daily basis, and each can see what the other is doing. Also in that factory, just-in-time deliveries are made from both sides of the building and can be delivered to the assembly line without crossing other operations. The same architect created a so-called main street for the faculty of mechanical engineering complex of Munich University. It contains auditoriums, dining rooms, meeting rooms, and places for casual encounters. These new arrangements result from a deep understanding of the program and a recognition of the need to interact casually, as well as formally, to achieve the mission of the organization. They expand the range of space types and conditions that need to be managed.

Organization. Organizational innovation takes many forms:

- High-performance, cross-functional teams operating largely autonomously
- Multiple-project teams with many individuals playing roles on several teams
- A mixture of stable laboratories and changing project teams that develop new products
- Collaboration, partnerships, and alliances among parts of geographically distant organizations
- Nonterritorial offices where occupancy is handled by hoteling, in which an individual arranges in advance for space to be used for a stated duration.

These new forms may call for new arrangements of space and technology to support the work. One such arrangement is a set of *town commons,* each of which forms a node around which teams form, but among which there can be technologically sophisticated communications. In some traditional research building layouts, laboratories are located in the center with offices along the perimeter. And in a traditional campus model, buildings are linked by the infrastructure of roads, utilities, and services. Activities tend to be segregated by function. In

a recent proposal for a leading research group in a large organization, the focus of the research is located in an innovative node that is networked with related laboratories in other buildings, thus creating a virtual team that is larger than the core team that was spatially collocated. The corridor is transformed into an interactive workplace and news center. Boundaries are blurred between spaces and between functional areas that are traditionally separated; individual offices are replaced by cubicles feeding energy into the Common, fostering collaboration and communication, and encouraging appropriation and use of the shared spaces. The implications for the campus design are profound: multiple linkages, integration of various processes, and sharing of information and services.

Finance. Financial incentives for work have to reinforce the new work arrangements needed for product and idea development. These include point-of-work accounting that recognizes the work where it is done rather than assuming it is done at the main place of employment. And incentives will be created to reward teams, as well as individuals, for successful results.

Other incentives will have to take account of the location and preferences of the customer by rewarding those individuals and teams best able to respond to new and emerging demands. These new distributed financial incentives may change the demand for facilities and other improvements, making the clients for facilities management more numerous and complex than in the past.

Technology. If you think the knowledge revolution is not transforming your business, think again. Economic value is being transformed at lightning speed. In some cases, the information about the product or service can have as much effect on bottom-line profits as the product itself. Information-defined transactions—value creation and extraction in the marketspace—are creating new ways of thinking about making money and, thus, are changing the definition of value creation. Until recently, voice-mail services were available only to large corporations supported by private networks. Today, the services are available at your home as sophisticated voice storage and retrieval systems. They may forward calls, store messages, forward messages with notes attached, and broadcast messages to numerous users, all at the same time. Information technology has also allowed the replacement of a physical product (the answering machine) with an information-based service. With voice mail, the phone companies have identified and exploited tremendous marketspace potential. The answering machine is being challenged by a new service that has no products for the customer to buy and no appliance to maintain, and all charges are included in the phone bill—even though the cost of that service may exceed the amortized cost of an answering machine. Some answering-machine companies are losing out because they didn't see the importance of information-defined transactions.

Companies that do not understand the new technologies will miss opportunities, customers, and new ways of conducting business. Often, the business strategies and systems and technology implementation are not coordinated, resulting in a significant gap between the two. Rather than providing synergy, this gap results in the following issues:

- Lack of clear and consistent overall sponsorship and direction
- Lack of integration among applications
- Large technology investments without adequate returns on investments
- Insufficient coordination among organizational units
- Poor connectivity
- Difficulty with data interface
- Disorganized data storage

Workspace Change Processes and New Perspectives. Because of the rapidly changing market and the increasing need for flexibility and speed in adjusting to new conditions, workplace change processes require a fresh look. Facilities management needs to consider the same set of ideas that corporations are using for product and idea innovation. High-performance teams are necessary to understand the new patterns of work and to suggest how these new patterns are best supported. These teams must be drawn from expertise in facilities manage-

ment, in information and infrastructural technology, in human resources, and in organizational strategy to guarantee fit with the central mission of the organization.

The traditional methods associated with top-down approaches and rigid schedules simply will not do. Success is more likely found by fostering genuine and informed participation in evaluation, design, and decision making.[7] This approach emphasizes collaborative engagement of all stakeholders. It incorporates the informal and spontaneous activities that usually take place outside the traditional approaches and connects them to the workplace-making process. This is accomplished by the addition of activities that are not typical of traditional processes: increased attention to setting up the process of workplace change, and discovering and defining the problems to be addressed; and a focus on building the client and professional teams and on achieving an agreed-upon project procedure and schedule. As contrasted with traditional processes, these activities are best revisited from time to time as the project proceeds. For greater detail on approaches to programming, an essential part of the newer approaches, see Chap. 4.

Facilities Managers' Responsibilities

Facilities managers have two important ways in which they can respond to contemporary corporate strategy.

The first of these is to take their place in the corporate management team. This implies that facilities must be seen as important resources to be deployed in ways that are most effective for the strategic approach under consideration. This may mean considering ways of utilizing facilities that are radically different from the ways they are used today. Also, it will require being able to demonstrate the value of alternative approaches to the use of facilities within a particular corporate strategy.

The second is for facilities managers to use the corporate strategy approach in their own area of the organization. This implies understanding new directions for facilities management, including some approaches now used by top management.

Facilities management sits typically within the operations management area of an organization. It is usually thought of as the support for the production system that permits an organization to create its products from incoming materials and supplies.

An implementation strategy requires a vision for the operations process that establishes and formulates a set of objectives for decision making. This vision should result from and complement the corporate strategy. The strategy should be the basis for developing a plan that establishes a consistent pattern of decision making, resulting in an operational and competitive advantage for the company. Through an operations strategy, an organization can convert its core strategy into an operational plan.

The Implementation Plan. A comprehensive, measurable, attainable, and understandable implementation plan must be developed and shared throughout the organization. It should include assessment of the firm's strengths and weaknesses, performance measures for evaluating results, and a benchmarking plan aimed at achieving best practices. The plan should be developed collaboratively with those who have a valid stake in the outcome. In addition, it should include specifications for changes in all relevant workspace elements: space, organization, finance, and technology.

Redesign Tools. In recent years, performance measures have evolved as a way of checking the vital signs of corporate health. Performance measures are usually classified under the three general categories of cost, quality, and time. Companies are finding out that improving quality and productivity while reducing cost go hand in hand with enhanced customer satisfaction. At the same time, they have found that the best way to ensure external customer satisfaction is to satisfy every internal customer at each step of the process. This is true for both manufacturing and service operations.[8]

Among redesign tools, benchmarking has been used with great success. Benchmarking is the activity by which an organization measures its performance against standards that it

wishes to achieve. There is an accumulating and valuable body of case studies; following is a description of how an organization can provide continuing support. According to Vicki Powers, writing in *APQC*, its objectives should include the following:

- Developing a system that facilitates continuous improvement through regular use
- Identifying areas of excellence and making improvements to reach the level of best practice
- Building a system that can be used in public to demonstrate the value of its services[9]

Powers goes on to distinguish between performance benchmarking and process benchmarking. *Performance benchmarking* is used to analyze relative performance among similar organizations. It typically includes identifying the critical success areas for the organization (or organizational unit), identifying the key performance indicators for each of those areas, identifying the gaps between the organization's performance and the best practices with which to compare performance, and identifying the highest-priority areas for improvement.

Process benchmarking is similar, but it focuses on the organizational means to bring about the needed improvements identified through performance benchmarking. It identifies the organizational processes necessary to bring about the improvements, develops performance indicators, identifies the gaps between these processes and best practices identified as appropriate standards for comparison, and brings about changes in the relevant area.

Both types of benchmarking require the identification of best practices against which to compare the performance of the organization. There is no single best practice, because best for one may not be best for another. Every organization is unique in some way. Corporations have different missions, cultures, environments, and technologies. What are meant by *best* are those practices that have been shown to produce superior results; selected by a systematic process; and judged to be exemplary, good, or successfully demonstrated. Best practices are then adapted to fit a particular organization.[10]

One of the easiest ways to improve your processes and practices is to benchmark yourself against the "best in the class." By finding out what works well somewhere else, you may be able to introduce innovative ideas to improve your organizational unit's processes. For example, facilities managers might focus on the process of space programming, purchasing of furniture and equipment, or contracting for small jobs as the key areas to improve to react more quickly to the formation of high-performance teams, a corporate objective resulting from a performance benchmarking exercise.

One of the most famous benchmarking groups is the International Benchmarking Clearinghouse (IBC) set up by the American Productivity & Quality Center. The blue-chip corporations that make up the IBC pool their information. They provide their corporate vital signs as a basis for comparison. Other corporations may use the IBC information base to compare themselves against the best in the class.

Other redesign tools include reengineering and criteria and procedure lists from many authors.[11] It is essential to choose tools that are convenient to use and easy to reuse over time. Also, it is essential to use commonly understood measures of performance. Any tool, however, must be chosen in the light of the organization's mission and its current circumstances. When an organization is striking out in a new direction, the best practices of others may not be the best standards to use!

Commonsense Rules. No matter what redesign tool you select, you should balance it against the aims of the implementation plan and against common sense. It should be the framework within which you carry out your redesign procedures and your implementation plan (see Fig. 1.2-6). Here are some commonsense rules that are as applicable to the facilities management area as they are to the corporation as a whole:

- Identify current problems and eliminate or rectify the source of the problem.
- Ensure that information and data are available in the first step and in the right format for all subsequent steps.

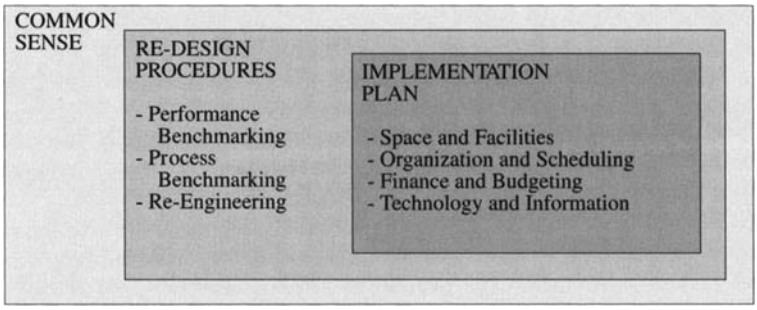

FIGURE 1.2-6 Facilities management's responsibility. Common sense must be the fundamental framework for evaluation and project planning. (*Source: Courtesy of Paul R. Smith, Peak Leadership Group, and William L. Porter, Massachusetts Institute of Technology.*)

- Find the right sequence of activities to occur, and collect information just in time to process it.
- Simplify the process.
- Replace specialist-to-generalist functions by increasing the scope of responsibility of personnel's job descriptions.
- Replace after-the-fact reconciliation with front-end edits, validation, and QA checks.
- Eliminate approval/authorization processes. If still warranted, make them after the fact.
- Make the process logical, rational, and fact-based, and include creative, intuitive, and instinctive elements of strategic insight.
- Implement a clear decision-making process and clarity in the organizational design. The management team must understand the market into which it is selling and create an effective strategy to maximize shareholder value. The corporate strategy is concerned with the intermediate term of a couple years out; the operational management is concerned with the current year.
- Make sure that the strategy has full executive support.
- Expect the development process to make all participants uncomfortable initially, but give them a legitimate stake in the outcome.
- Ensure that the corporation's ambitions and objectives are clearly understood.
- Understand that the corporate strategy development is a learning process that should develop consensus, new insights, and clear communications.

Global and local competition can provide intense pressure to be the best in your industry. To stay the best, you must search out and find the new tools that will keep you ahead of your competition. In making change within facilities management, implement change quickly but "don't outrun your headlights."

9. The American Productivity & Quality Center (APQC) "helps enterprises manage change, improve processes, leverage knowledge, and increase performance by becoming more agile, creative, and competitive. These pursuits require high-quality information, strategies, skills, knowledge, experience, contacts, and best practice. . . . Founded in 1977, APQC is a nonprofit education and research organization supported by more than 550 founders, Clearinghouse designers, and members." From http://www.apqc.org/apqcglan/glance4.htm. See V. J. Powers, "Benchmarking in Hong Kong," *APQC,* no. 11.
10. The APQC created the International Benchmarking Clearinghouse (IBC) as a resource for organizations interested in using benchmarking as a tool for breakthrough improvement. This is based on the premise that all businesses in the world perform essentially the same basic processes (e.g., develop strategies, hire people, purchase resources, make products or deliver services, and bill customers). They all have operational and management and support processes. For further information, see http://www.apqc.org/best/bmk.
11. Another of the strategies for improving organizations is called Business Process Reengineering (BPR). The reengineering trend has had major acceptance in America since Hammer & Champy, the reengineering gurus, issued their book *Reengineering the Corporation: A Manifesto for Business Revolution* (Harperbusiness, 1994). Recently, however, it has also caused a backlash, some of it justified and some guilt by association. Many reengineering efforts have failed in the past. Michael Hammer and James Champy reported a 70 percent failure rate in the efforts they have seen. An added problem in assessing success and failure is that some people use the term *reengineering* for just any downsizing or rightsizing activity that may be a butchering rather than surgical approach for cost cutting. Stowe Boyd, in his article "Business Process and Information Technology," states that the major message to learn from slash-and-burn reengineering is that it is possible, but not necessary, to rapidly inject a process-centered management style into old-style business. And AT&T has a concept called *Integrated Diversity,* which, translated, means plan from the top down for modeling and implement from the bottom up for building. Many authors have listed practical ways of improving management practice. These include Mark Youngblood in *Eating the Chocolate Elephant: Take Charge of Change Through Total Process Management* (Richardson: Micrografx, Inc., 1994), and Steven Rayner in *Recreating the Workplace* (John Wiley & Sons, New York, 1995).

SECTION 2.1
INTRODUCTION

Why is it that some managers always have their pet projects funded, whereas others do not? Could it be that the winners have learned how to speak the language of business and package their requests in the appropriate business context? We hope that reading this chapter will help you articulate and present your ideas in a manner that gets results and helps you communicate in terms that business managers understand.

Many companies have stories about brilliant strategies that were not implemented. Everyone supported the new strategy, but somehow it was not implemented or was implemented haphazardly. The answer lies with managers themselves—or more specifically, with the way managers direct their energies. Managerial energy is the organization's most important and scarcest resource. When new opportunities arise—such as falling trade barriers, deregulation, emerging market changes, and technological breakthroughs—all of these changes tug on management's attention and business resources. Which opportunity should the corporation pursue and why? This chapter focuses on developing a clear and concise business case to drive supportive business decision-making.

Our goals in this chapter are to provide sufficient knowledge (1) to help the facility manager become part of the senior management team, (2) to establish a standard by which facility managers understand the information needed to have a well-run facility, (3) to combine theory and applications, and (4) to provide a document that facility managers find user-friendly. As with Chapter 1, we did not look at other facility management books and try to improve on them. Instead, we started with a blank page and decided, on the basis of our knowledge and experience with executives and financial officers in business today, what the facility manager should know.

This chapter will identify a process that is critical to the success of the facility manager. Each facility manager has (1) a specific role, given the mission assigned, (2) to plan for and align to the future, (3) to be responsible for the plan, and (4) to report the results, given the resources

assigned. This process shows up in many of the things managers try to control. Whether it is a project, a service request, or an annual budget, the manager needs to understand certain key elements within a business context that are part of this process and responsibility.

SECTION 2.2
BACKGROUND INFORMATION

AN OVERVIEW OF FACILITY MANAGEMENT

It took General Dynamics, a major defense contractor, 43 years to increase the value of its stock to $2.7 billion. Netscape Communications accomplished the same feat in about one hour in August 1995, when investors had their first chance to buy the stock on the open market. This fact is amazing, considering that Netscape had never earned a profit at that time and had been giving away its primary product free of charge on the Internet. Why is this example pertinent to facility managers? Understanding the linkage between a company's market value, its publicly reported earnings, and underlying business decisions will help facility managers become key individuals in their organizations.

Facility management has many aspects. Very few industries view facilities management in the same way. Some industries focus on real estate, others focus on property management, and still others focus on asset management in general. A critical part of facility managers' roles is to understand their missions and levels of responsibility. Facility managers are entrusted with a stewardship role over the physical assets and overall security of an enterprise. Generally, their work involves facility planning, use, and design; maintenance and operation of assets; ongoing replacement of assets; and retrofitting and updating of assets as needed over time.

These responsibilities, if central to the day-to-day aspects of facilities management, are sometimes referred to as *core competencies.* Usually there are resources associated with each competency. The role of a facility manager is to plan for and manage these functions and resources.

Effective facility managers should use balanced approaches in dealing with all aspects of their areas of responsibility. Kaplin and Norton established the balanced scorecard approach to ensure that *all* of the resources, including financial resources, are coordinated and focused on supporting the achievement of the organization's overall objectives. Managers tend to focus on issues and easily identifiable work rather than looking at all aspects impacting performance. The balanced scorecard approach directs a manager to consider goals and requirements from the perspectives of the customer, employee, process/technology, and the owner. The internal processes affect how things get done; the customer's perspective helps identify the quality of the work; the innovation and learning perspective focuses on how well the employees learn and advance the mission of the organization; and the owner's perspective typically deals with financial returns. Even though much of the focus is on the financial perspective, ignoring the other perspectives could affect the manager's success. In most cases, accounting for the amount of resources and showing how they were used and managed is a big part of a manager's job.

FACILITY MANAGEMENT FUNCTIONS WITHIN THE ORGANIZATION

Facility management provides an organization with the skills and knowledge to manage its physical assets. This service to an organization impacts a significant portion of any available

resources. Therefore, facility managers need to understand the nature of corporate governance, accounting and its principles, and the general principles surrounding the financial obligations associated with the way a company or institution is organized, the type of industry within which it operates, and what considerations may be specific to that industry. Facility managers live within an organization and typically are responsible for managing depreciable assets or significant costs that a company must use efficiently.

SECTION 2.3
OVERVIEW OF FINANCIAL MANAGEMENT

THE NATURE OF ACCOUNTING FOR RESOURCES

Most of the world's work is done through organizations that deploy resources to meet some specific objective. In doing work, organizations use *human* resources, materials, various services, buildings, and equipment. These resources cost the organization money. To work effectively, the people in the organization need information about these resources. Accounting is a key department in the process to provide this information.

Organizations can be broadly classified into two categories: *for-profit* and *nonprofit.* As these names suggest, the dominant reasons for a corporation's existence are to make a profit and increase the shareholder value, whereas nonprofit organizations have some other reason for existence and, at a minimum, must break even. In the United States, approximately two-thirds of employed persons work in for-profit organizations, and the remaining one-third work in governmental and nonprofit organizations. The objectives of accounting are similar in both types of organizations.

Accounting information is traditionally divided into three categories: *financial accounting, operating information,* and *management accounting,* as described in the following sections.

Financial Accounting

This information is intended for company managers and for parties external to the company, including shareholders (trustees in nonprofit organizations), banks and other creditors, governmental agencies, investment advisors, and the general public. Shareholders who invest in a company want to know the financial health and financial performance of the company. Financial accounting information provides this information using generally accepted practices as a basis. This consistency of financial information allows the general public to review the financial condition, income or loss, and cash flows in a consistent and prescribed manner.

Operating Information

Most of what any company does is captured in internal reports. Personnel hired; time consumed during the day; hours of operation; goods or services received, created, stored, transported, and provided to end users (e.g., customers); and other relevant data regarding

business activities of a company are captured, stored, modified, and reported in one form or another for supervisors, managers, and others to review.

Although the financial accounting systems of a company are built to capture and reflect all of the business activities of the company, financial accounting ignores nonmonetary activities when capturing and reporting. Thus, operating information exists to provide such nonmonetary data along with financial data.

Management Accounting

Managers may not have time to review the details provided in the operating information, so they turn to summaries provided by management accounting information. These summaries are used to plan, implement, and control departments or projects. Examples include fiscal budget reports, reports summarizing staffing head counts, product line sales reports, and other business unit performance reports.

In this chapter and this handbook, operating information and management accounting information together will be referred to as *internal reporting.* Financial accounting will be referred to as *external reporting.*

Before moving ahead with our discussion of financial management and management decision making, let's review a few key terms and aspects of accounting. These terms represent the language used within a company to summarize the financial activities of the business.

Generally Accepted Accounting Principles (GAAP). The foundation of accounting rules and guidelines is a set of Generally Accepted Accounting Principles (GAAP). These principles are currently established by the Financial Accounting Standards Board (FASB). Companies are not legally required to adhere to GAAP as established by the FASB unless they are regulated by the Securities and Exchange Commission of the United States. However, as a practical matter, there is strong pressure to do so. When a certified public accountant (CPA) audits a company, it is to render an opinion as to the company's adherence to GAAP.

Financial Statements. Financial statements are an important management tool for managers. When correctly prepared and interpreted, they contribute to an understanding of a company's current financial health, financial performance, and potential. GAAP require that financial statements include three reports: (1) a balance sheet (sometimes called a Statement of Financial Condition), (2) an income statement (sometimes called a Statement of Operations or Profit and Loss Statement), and (3) a Statement of Cash Flow.

1. *Balance Sheet.* The balance sheet presents a picture of assets, liabilities, and owner's equity of a company or entity as of a specific date. The balance sheet portrays the entity's financial condition or health. The balance sheet is so named because it represents the following equation:

Assets	=	liabilities	+	owner's equity
(resources of the business)		(amounts owed to others)		(amounts owed to the owners)

This basic equation holds at any time, although the amounts assigned to the individual elements will fluctuate by type of business and relevant industries.

2. *Income Statement.* The income statement is a summary of the revenues (e.g., sales) and the expenses (e.g., cost of doing business) and clearly states the net income or loss for a specific period of time. It is very important to understand that the income statement represents a period of time, typically a quarter or a year. The income statement portrays the operating results of a company for the applicable period of time.

3. *Statement of Cash Flow.* The statement of cash flow reports the sources and uses of cash for the same period as the income statement. The cash flow statement consists of three major classifications:

- Cash provided by or used by operations
- ± Cash provided by or applied to investment activities
- ± Cash provided by or applied to financing activities

The sum of these net increases or decreases in cash is shown in this statement.

To be a part of a company's leadership team, a facility manager needs to understand the nature of financial reporting. Understanding how your responsibilities affect the bottom line (e.g., net income) is critical. Most facility management areas represent an expense to a corporation. Knowing the financial impact of resources is important. Accounting is the language businesses use to communicate their performance.

In addition to accounting principles for financial reporting, there are differences stemming from the kind of entity the business is. Financial management is driven by certain accounting principles associated with the ownership structure and the type of industry. Facility managers need to be aware of the way a particular financial management structure can impact the way it functions in the organization.

GENERAL PRINCIPLES OF FINANCIAL MANAGEMENT

Accounting personnel in organizations are not the only individuals concerned with and responsible for the finances and record keeping in a company. Accounting typically is responsible for preparing financial reports using accumulated financial results and activities of the company. The extent and type of financial reporting depends on a number of factors. First, the legal entity typically drives the accounting and financial reporting processes of a business. Second, the type of industry or business has a significant impact on the accounting and financial reporting practices of a company. Third, and finally, a clear distinction must be made and understood regarding the objectives of accounting. The Accounting Department typically is responsible for two basic types of financial reporting, *external* (or *public*) reporting and *internal* (or *management*) reporting. Therefore, financial management is impacted by a company's ownership structure, the type of industry, and key accounting practices.

Ownership Structure Drives Financial Management

The purpose of accounting is to keep in balance the investment (traditionally called *assets* in accounting terms) and financing (traditionally called *liabilities and equity* in accounting terms) activities of a legal entity. What is a legal entity? All businesses that are registered with a governmental body become formal legal entities. Certainly, it is obvious that General Dynamics is a legal entity. But at times, most start-up business ventures are not so clearly "entities," let alone "legal entities."

A legal entity has documents that define its organization, its ownership, its business purpose, its management structure, and its operating policies. These documents are typically the Bylaws, Articles of Incorporation, and Statement of Purpose. The documents create a board of directors that is responsible for managing the business. These documents create the foundation for legal ownership interests and the rights of stockholders. Although not all companies are stock companies (e.g., mutual companies and many not-for-profit organizations), our focus in this book is on companies with stockholder ownership structures.

There are three major types of business organizations: (1) *sole proprietorships,* (2) *partnerships,* and (3) *corporations.* There are also several hybrid forms, such as *limited liability partnerships* (LLP), which are beyond the scope of this book.

Sole Proprietorship. A sole proprietorship is an unincorporated business owned by an individual. This is the simplest form of organization and can be set up with limited expense. If you use your own name and tax identification number, you may not need to register your company with anyone. However, if you use another name, you should register the name in the form of "doing business as" with the state and federal governments. The sole proprietor receives all the profits or losses generated by the endeavor.

Partnership. A partnership is formed when two or more individuals decide to conduct business together in an unincorporated form. Partnerships may operate under different degrees of formality, ranging from an informal handshake to a formal agreement drawn up by attorneys and filed with the state where the partnership was formed. The partnership agreement stipulates who owns what and who shares in the profits or losses of the enterprise.

Corporation. A corporation is a legal entity incorporated by the state in which it was formed. It is a legal entity separate from its owners and managers. Generally, if a corporation has more than 300 shareholders, it must file with the Securities and Exchange Commission of the United States (SEC). This action also allows the corporation to become a "listed" stock or one of the public stock-trading markets like the NYSE. However, it is very important to note that many corporations are "closely held" or subsidiaries of larger companies. These types of corporations typically do not have stock traded on public stock markets.

Sole proprietors and partners have unlimited liability against losses while corporation executives have limited liability.

Type of Industry Drives Financial Management

Have you ever read in newspapers or magazines or heard the news media refer to a company's performance as better or worse than "peers" or "industry norms?" Distinct businesses that manufacture, build, distribute, and/or sell similar products and services are grouped into industries. Obviously, these grouped companies compete with each other at times. But they also pool their collective needs to lobby government actions. However, for accounting and financial management purposes, it is very important to recognize that these industry groups create a natural source of performance comparison. The senior management team of a company typically is acutely aware of how well their financial results compare to those of their peers. Peers are those companies considered similar enough to be grouped in the same industry.

External financial statements are traditionally the source of comparative financial performance. Therefore, a major consideration impacting management decisions, such as a major facility initiative, will be the expected effect on the company's reported financial results compared with those of peers, not just the positive or negative direction of its own earnings.

The potential market value of a company's common stock depends on industry comparisons made by investment banking firms and analysts. The value of a company's common stock is a fundamental component in a free market society that allows the public to invest in companies. The capital markets are the open trading exchanges such as the New York Stock Exchange (NYSE) and the National Association of Securities Dealers (NASDAQ). Today, many small companies are publicly owned (shares of common stock have been sold to the public through the capital markets, and their stocks are traded on one of the exchanges). The external financial statements prepared by a company's Accounting Department provide most of the data used by investment bankers to evaluate and compare financial performance with that of other companies.

The management team must make a range of financial decisions to keep its company growing and prospering. One of the first decisions, the form of the business organization, was made at the company's inception. Other decisions, such as the amount and type of future financing needed, which projects are to be funded in the future, and how to manage cash flow will bring new challenges to the management team of any new or dynamic company. If things go well, at some point earnings will be generated beyond what is needed to keep the organization going, and the company will decide how much of its earnings it will pay out as divi-

dends to shareholders. Most of all, management must be aware of the mission, vision, and goals of the company; how their actions bring them closer to or further from meeting these goals; and how the impact of these actions affects the earnings and therefore the stock price of the company. Performance measures consisting of key financial ratios help the company define and report its goals in measurable terms. Several common financial ratios used to assess a company's health are listed here:

$$\text{Return on equity (ROE)} = \frac{\text{net income}}{\text{average stockholders' equity}}$$

$$\text{Earnings per share (EPS)} = \frac{\text{net income}}{\text{average shares of common stock outstanding}}$$

$$\text{Current ratio} = \frac{\text{current assets}}{\text{current liabilities}}$$

$$\text{Leverage ratio} = \frac{\text{debt}}{\text{shareholder equity}}$$

$$\text{Price to earnings ratio (P/E)} = \frac{\text{market price per share}}{\text{EPS}}$$

Understanding the impact of management decisions on these ratios is very important in gaining the support and confidence of senior management. The financial impact needs to be evaluated as of today, as well as over the future life of the project under consideration. Demonstrating the impact on earnings and financial position from the investment and results of a facility project will go a long way toward gaining acceptance from the executive officers of a company. The following basic example highlights how a modest new facility costing $500,000 to set up can impact reported financial performance:

Example: Purchase of New Facility

New Facility purchase and setup cost $500,000

New facility operating cost $80,000 (annually), excluding depreciation

Current operating results and key balance sheet facts of our example company (before the new facility):

Net Income	$500,000	(annually)
Long-term debt	$2,500,000	
Shareholder equity	$1,500,000	

Key financial results—impact	Calculation	ROE	Leverage ratio
Before the new facility	500,000/1,500,000	33%	1.67 times
Immediately after buying the new facility		N/A	2.00 times
After the first year of using the new facility	420,000/1,500,000	28%	N/A

This example holds all other variables constant, assumes no incremental growth in revenue, and reflects no change in equity or debt pay down.

As you can see, if only the cost of a project is presented to management against historical operations, the result will be a negative impact. This will not typically get the buy-in of senior officers. Thus, the facility manager needs to demonstrate the benefits in financial terms in addition to the costs.

Key Accounting Practices Drive Financial Management

The financial management practices of an organization are closely related to its business planning processes. In theory, the board of directors and its management team periodically prepare a strategic plan that states the company's mission, vision, values, goals, and objectives. The primary benefit of the strategic plan is to focus the efforts of the organization on achieving its goals and identifying significant investments necessary for the company to achieve its goals.

Upon completing the strategic plan, management prepares its annual technology plan, capital plan, and financial budget. This is the culmination of management's planned initiatives translated into the estimated impact on the company's financial statements. The importance of the technology plan is the consideration of the cost of new equipment, facilities, and software. Each defined department or division prepares its annual plans with the associated income to be generated, expenses to be incurred, cash flow created and used, and capital needs. Table 2.3-1 gives an example of how each department in a company may impact the combined financial results.

We can all understand that income represents the sales revenue of the company, and expenses represent costs incurred. But the impact on a company's cash flow and the capital needs of a department or division may need further discussion. The Accounting Department of a company will attempt to identify, capture, and account for the differences between cash and the accrual basis of transactions and events. Cash basis accounting is as it sounds. The accounting entries are made to reflect the receipt and disbursement of cash. The accrual basis of accounting attempts to reflect the economics of business transactions and activities. What does that mean? Economics? What we are referring to is the fact that a sale or expense has occurred without the actual receipt or disbursement of the company's cash.

For example, if a company had only a single transaction before its December 31 year end, what would the company's financial statements show on December 31?

TABLE 2.3-1 Summary Budget Worksheet Combining Departments

	Projected expenses in dollars (cash outlays)					
Departments	Executive	Accounting	Production	Sales	All other administration areas	Total combined company
Expenses						
Salaries	350,000	400,000	1,250,000	500,000	300,000	2,800,000
Benefits	100,000	125,000	350,000	190,000	114,000	879,000
Supplies	20,000	40,000	20,000	50,000	25,000	155,000
Equipment	0	0	0	0	200,000	200,000
Promotion	0	0	0	250,000	250,000	500,000
Other	25,000	50,000	200,000	50,000	325,000	650,000
Depreciation	395,000	615,000	1,675,000	475,000	3,160,000	6,320,000
Total expenses	890,000	1,230,000	3,495,000	1,515,000	4,374,000	11,504,000
Capital cost						
Furniture and equipment	10,000	25,000	100,000	75,000	10,000	220,000
Facilities	0	0	250,000	0	0	250,000
Computers	10,000	10,000	100,000	15,000	10,000	145,000
Other	0	0	0	0	10,000	10,000
Total	20,000	35,000	450,000	90,000	30,000	625,000

Timing	Cash vs. accrual basis example	Accounting entries		
On Dec. 15	Company sells inventory on credit to a customer for $100		Debit	Credit
		Accounts receivable	$100	
		Sales	$100	
On Jan. 15	Customer pays for inventory (30 days later) it bought with no discounts		Debit	Credit
		Cash:	$100	
		Accounts receivable		$100

In this example, the sale is reflected by the company, as of December 31, because the economic transaction, the sale of the inventory, occurred. However, the company reports that it has receivables of $100 on December 31, not cash, reflecting the credit extended to its customer. This is the accrual basis of accounting for the sale.

Again, understanding the timing of cash flows stemming from a major initiative and recognizing the impact of a facilities initiative on the financial statements of a company is how senior officers assess whether to go ahead with a plan.

Capital needs represent the purchase or development of property, plant, and/or equipment. This is clearly very relevant to facility managers and major facilities initiatives. In accounting terms, the difference between an expense and a capital expenditure is the purpose and expected benefit to be derived from the disbursements. Generally, if the benefits to be derived from the expenditures are expected to last beyond one year, it is classified as a capital expenditure. This is also a very important concept that creates another difference between cash and accrual accounting.

Have you ever heard of the concept of depreciation? Of course, we all know that the day we buy a new car and drive it off the auto dealer's lot, it depreciates in value by a large percentage! But what does that mean in accounting terms?

Except for land, most items of plant and equipment have limited useful lives. They will provide services to the entity for a limited number of future accounting periods (e.g., years). Therefore, a fraction of the cost of the asset is properly chargeable as an expense in each of the accounting periods in which the asset provides services to the facility. The accounting process for this gradual conversion of plant and equipment capital cost into expense is called *depreciation.*

We mentioned that capital needs are for acquiring property, plant, or equipment expected to provide benefit to the company beyond one year. Therefore, accounting attempts to reflect this future benefit to the company by providing an annual depreciation expense in the financial statements. The entire cost of the capital item is depreciated over its estimated useful life, even though the typical expenditure (e.g., cash disbursement) is made for the capital purpose in the year acquired or built. Let's look at another cash versus accrual accounting example as it relates to the purchase of a new car.

Example of Cash Outlay and Depreciation

Purchase price of new item	$25,000
Immediate depreciation	50%

If accounting was to record these events, it would look like this:

Purchase using cash	Debit	Credit
Debit automobile	$25,000	
Credit cash		$25,000
Depreciation		
Debit depreciation (expense)	$12,500	
Credit accumulated depreciation		$12,500

The company balance sheet would be impacted as follows:

	Purchase of car	
	Before	After
Assets		
Cash	$25,000	0
Auto	0	25,000
Less accumulative depreciation	0	(12,500)
Total assets	$25,000	$12,500

Wow! What happened to $12,500 of the company's assets? Well, that is what depreciation does to assets. It periodically and consistently reduces the assets for the estimated and expected reduction in value or usefulness. Thus, the company's $25,000 in cash it had previously reported on its balance sheet is now a car worth only $12,500. The company's income statement would have shown an expense for depreciation of $12,500.

This example holds true for the purchase and/or building of any assets of any company. The Accounting Department will use accrual accounting to reflect the depreciation expense of the capital outlay.

A number of business situations will create this type of noncash annual accounting for the economic substance of an event or investment in a capital item such as a plant. In addition to purchasing physical assets, financial statements may include such items as goodwill, which is amortized to expense it over its estimated life. Reserves for bad debt are also established to reflect the fact that certain of the company's accounts receivable may not be fully collected from its customers. Either deterioration or obsolescence limits the useful life of a tangible long-lived asset. Deterioration is the physical process of wearing out. Obsolescence is the loss of usefulness because an improved product or process is developed, styles have changed, or for other reasons unrelated to the physical condition of the asset. The useful life is usually determined as the time it takes the asset to wear out. The time before it becomes obsolete is usually called its *service life.* Other noncash accounting entries include:

- Economic events accrued for in financial statements without a cash outlay or cash receipt
- Sales made on credit terms
- Expected sales warranties (discounts to be provided to customers)
- Expected bad debts (not all sales made on credit will be paid)
- Inventory obsolesce (some inventory will not sell)
- Idle property, plant, and equipment (some assets are not fully used)
- Commitments to buy (contractual liability)
- Excess purchase price versus fair market value (goodwill)

Last, besides external reporting the financial management function of a company includes accounting and reporting internal management information. These reports may (and often do) differ from the external financial statements of the company. Management reports are for internal use and should be confidential. Competitive and other sensitive data about a company's business may be included. These reports need not comply with GAAP (Generally Accepted Accounting Principles). They are developed in a manner that best captures the data critical to management to run its business. Accounting Departments must therefore use the accounting systems to capture and report for internal and external purposes.

Generally, internal management reports are provided to department heads and used in management meetings. However, as we discussed earlier, the impact of a business decision on the external financial statements of a company must not be overlooked.

SECTION 2.4
FACILITY FINANCIAL PLANNING

After the facility manager understands the mission, functions, and resources that have been assigned and has a clear understanding of the type of financial structure and accounting principles needed to be successful in the organization, the next step is to plan and establish financial objectives. It is critical that facility managers understand the importance of planning. To be effective, all levels of the organization need to plan. A summary of planning within facilities management should align with the organization's overall plan. This is especially critical in planning for an organization's use of short-term and long-term financial resources.

Planning is the process of deciding what future actions will or will not be taken. A single plan should be made for the entire organization to show the corporation's health at a glance.

Making the planning process effective and efficient is always a question to management. Does planning pay dividends? Is the effort worth the time and attention? The only way to deal with the changes surrounding business today is to plan. The business professional will always need to plan. A tool to help focus on management's ability to plan is hard to measure, but a qualitative measurement has been suggested that would help measure the effectiveness of planning.

RETURN ON MANAGEMENT

When management's attention becomes diluted or is distracted from looking at too many opportunities, even the best strategy stands little chance of being implemented. So, making sure that management focuses its attention on the best opportunities is the most important thing to look at. Simons and Davila recommend that managers use a new ratio called *return on management* (ROM) that is expressed as follows:[1]

$$\text{ROM} = \frac{\text{productive organizational energy released}}{\text{management time and attention invested}}$$

Like its cousins *return on equity* (ROE) and *return on assets* (ROA), ROM measures the payback from the investment of a scarce resource. In this case, ROM measures a manager's time and attention. Because both the numerator and denominator are estimates, the results are more qualitative than the traditional quantitative measures for ROE and ROA. Nevertheless, by computing ROM for various options, specific clear strategic priorities for the return on time and energy may be estimated to select the most promising option.

The allies of high ROM are defined as:

1. Clearly defining which customers, projects, investments, or activities are beyond the organization's boundaries.
2. Critical performance measures are selected for one purpose—to keep everyone looking at the results that count.
3. Managers all know the critical performance measures, of which there are no more than seven at any time.
4. Managerial processes and paperwork exist only when they add value to the bottom line. Employees know on what and where to focus their attention.

In addition to the planning pressures created by a changing world, other management issues impact an organization's financial areas. In this millennium, the scope and business conducted will challenge those that manage assets.

SECTION 2.5
FINANCIAL MANAGEMENT IN THE NEW MILLENNIUM

Two key issues are exerting a pervasive impact on financial and facility management—the globalization of business and the advent of information technology.

GLOBALIZATION OF BUSINESS

The globalization of business will continue because of several major factors. These include (1) improvements in transportation and communication, which lower shipping costs and make more international trade possible; (2) growing numbers of intelligent consumers who desire high-quality, low-cost products; (3) lowering of trade barriers; (4) deregulation of numerous commodities (i.e., telecommunications and utilities); (5) technological advances that have reduced the cost and time to deliver products and services to the marketplace; (6) global acceptance of the Internet for trade; and (7) the world populated with multinational firms that can shift production to places where production cost is the lowest.

Many manufacturing companies have gone offshore to reduce their labor and material costs, while service companies such as banks, insurance, utilities, accounting firms, telecommunication firms, and consultants are seizing global opportunities to expand their customer bases and better serve their global customers.

INFORMATION TECHNOLOGY

The new millennium will see a revolutionary way of making financial decisions by individual businesses. The Accounting Department's role is changing from that of a number cruncher to partnering with other departments to add value to the financial aspects of its services. All personnel in business must become extremely proficient with technology to access and use the wealth of information available.

The World Wide Web or Internet will challenge the way business is conducted, and firms that fully understand the information highway and learn the new rules of engagement will have an advantage. Videoconferencing will allow face-to-face meetings with distant colleagues, and the Internet will allow real-time simultaneous access to data and information by multiple users.

THE FINANCIAL MANAGER'S NEW RESPONSIBILITIES

Financial managers are chartered with the responsibility to maximize shareholder (or the owner's) value. These are some of their specific roles:

Strategic Planning

The Accounting Department develops a financial plan that complements the strategic plans of the company. This plan should be a living document that is updated continually as the marketplace and business change. The impact on projected financial plans is critical to the success of any facilities project. New facilities initiatives have a direct impact on financial plans.

Partnering with Internal Customers

The Accounting Department's role is changing from a command and control position to one where fellow employees are treated as customers. With this new role, the finance person understands what the needs are and helps provide alternative solutions. This is very important. Developing a good relationship with key personnel in accounting will help the facilities manager as well as the financial person.

Managing Financial Investments and Other Financial Decisions

All businesses are changing in some form every year, typically with sales increases or decreases. As sales levels increase or decrease, these changing circumstances must be reflected in the use of assets, including plant, equipment, inventory, people, land, and facilities. The financial manager is responsible for analyzing the projected company growth and determining how to adjust the resources on a macro level to support the business activities profitably. Should the company get the required resources by taking on debt, equity, or some combination of the two? If debt is used, another major decision made by the Accounting Department is whether it should be long-term or short-term.

How to maintain or improve profit is another major responsibility of the Accounting Department. How much the company should provide as a dividend to its shareholders, and whether it should share profits with its employees, are decisions that involve the Accounting Department, working with the Human Resources Department and other departments.

Coordination and Control

The company must have controls set up to ensure that all parts of the organization are within the financial limits established. Providing a spending budget usually does this. The annual budget process is the best way to initiate discussion and analysis, and to coordinate a strategic initiative. Facilities moves, additions, or changes are strategic initiatives for most companies. They impact communities, incur substantial up-front cost, and generally modify existing cost structures. When the Accounting Department is involved in its budget process, it is a great time to gain an understanding of the financial ramification of a facilities initiative. Thus, the Accounting Department must ensure that budgets are made to require that units remain within these financial limits or have the company's performance objectives changed.

Dealing with Financial Organizations

A continuous flow of money and capital is required to keep an organization going. The financial organization must decide where and how the funds are raised, where and when the company's securities are traded, and when profits are reinvested into the company to maximize profitability.

Risk Management

All businesses face risks from disasters such as floods, storms, fires, loss of power, uncertainty in financial markets, interest rate changes, and foreign exchange rate changes. Purchasing insurance or hedging in derivatives markets can reduce many of these risks. The financial managers usually have a responsibility for risk management and will hedge their assets in the most effective and efficient manner.

SUMMARY

In summary, the *facility* and financial managers are integral in decisions regarding which assets a company will acquire, how the assets should be financed, and determining the required returns on investment to drive overall profitability. If these responsibilities are performed optimally, the *facility manager along with the financial manager* has helped to maximize the value of the firm, and this should benefit customers and employees.

SECTION 2.6
MANAGEMENT DECISION MAKING

Because we now have a general understanding of financial and facilities management in business, it is critical to recognize that the financial aspects of managing a business are only part of the story. This section discusses and emphasizes decision-making from a company perspective. These same techniques and methods should be used when making decisions within the facilities organization. Decision making is a critical part of planning for and managing assets. The use of the S.W.O.T. (Strengths, Weaknesses, Opportunities, and Threats) analysis technique in determining strategic direction is a tool used in dealing with stakeholders' needs. Determining strategic needs is the first step in establishing what kind of decisions management needs to make. Reviewing the role of a senior financial officer helps us understand how involved and focused a facility manager needs to be to understand the business impacts surrounding the decision-making process. How to be a good partner in achieving the strategic needs is critical for strategic success.

The senior financial officer of a company oversees the Accounting Department and other areas of a business. In most corporations, the senior finance officer is called the *Chief Financial Officer* (CFO) and works closely with the *Chief Executive Officer* (CEO) and the board of directors. In small businesses, the senior finance manager may be the owner, or a general office manager who assists the owner or president. In all organizations, financial management involves the nearly daily activities of managing the liquid assets such as cash and investment securities against the payment of current obligations. The second major aspect of financial management addresses the longer-term financial considerations of borrowing to finance a company's operations and investment activities. Last, the finance manager is primarily responsible for analyzing profitability. Forecasting profitability and cash flows are integral in determining borrowing or capital needs. Earlier in the chapter, we discussed the importance of cash versus noncash business activities or transactions. Determining the timing of cash inflows and outflows and managing the borrowing and financing needs are key roles of the senior financial manager.

In addition to financial matters, management decision-making considers the strategic business plan, management incentives (e.g., the rewards earned by management stemming from the results of decisions), social responsibilities, and the situation.

STRATEGIC BUSINESS PLANNING

Strategic business planning typically consists of the following eight major activities:

1. Defining the business mission
2. Analyzing external opportunities and threats
3. Analyzing internal strengths and weaknesses
4. Formulating goals
5. Formulating strategy
6. Formulating programs
7. Implementing programs
8. Feedback and control

In discussions about funding specific projects or tasks, the finance officer focuses the attention of the company on determining the value added by these projects to one of these eight specific activities. Let's briefly review key elements of planning as it relates to a desired facilities initiative.

Business Mission

As mentioned earlier, an organization exists to accomplish something: to make cars, lend money, provide a night's lodging, and so forth. Its specific mission or purpose is usually clear once the business starts. Over time, some managers may lose interest in the mission, or the mission may lose relevance because of changes in market conditions. The mission may also become unclear as the corporation adds new products, services, and markets to its portfolio. Generally, any significant investments made by a company should enhance its ability to achieve the organization's mission.

External Environment Analysis (Opportunities and Threats)

Management should be extremely aware of the business environment in which the company operates. Is it static, dynamic, unknown, complex, simple, or confusing? The business environment will create or eliminate opportunities. The business environment can be threatening to an organization. Senior managers are primarily accountable for monitoring the business environment and directing the resources of a company to take advantage of opportunities and address threats to the company's performance.

Internal Environmental Analysis (Strengths and Weaknesses)

It is one thing to discern opportunities in the environment; it is another to have the competence to succeed in making the most of these opportunities. Thus each business must evaluate its internal strengths and weaknesses. Clearly, the business does not have to correct all weaknesses, nor should it gloat about all of its strengths. The big question is whether the business

should limit itself to opportunities for which it possesses the required strengths or consider better opportunities where it might have to acquire or develop certain strengths.

Goals

Business decisions should not be made in a vacuum but as part of a unified strategic plan for the company's good health, well-being, and success. The goal of most for-profit companies is to maximize shareholder wealth, which translates into maximizing the firm's common stock price typically driven by earnings or opportunity.

Strategy, Programs, Implementation, and Control

Executing the strategic plan requires programs. Typically, programs are developed annually. The purpose of the annual plan is to determine which projects and expenditures should be funded in the upcoming year. The annual plan is to ensure that the company achieves the sales, profits, and other goals established in the annual plan in a manner well-linked to the company's strategy in plan. The last element of the annual plan is control. A typical approach to control is management by objectives. These four steps are involved in the process:

1. Goal setting: What do we want to achieve?
2. Performance measures: What is happening?
3. Performance diagnosis: Why is it happening?
4. Corrective action: What should we do about it?

Managerial Incentives

Stockholders own the company and elect the board of directors, which in turn hires the management team. Management in turn is supposed to operate in the best interests of the stockholders. However, in many companies, the stock is widely held or closely held and leaves a large amount of autonomy to the management team. The incentives for management should be based upon what it takes to accomplish both the short-term and long-term interests of the shareholders.

Companies are increasingly tying management compensation to the company's profit and stock price. Whether incentive plans include executive stock options, performance shares, or profit-based bonuses, they are supposed to accomplish two major goals: (1) provide executives with an incentive to take actions that will contribute to shareholder wealth, and (2) attract and retain managers possessing enough confidence to stake their financial futures on their abilities and efforts to motivate the company to generate profits or accomplish its strategic goals.

Social Responsibilities

One might question whether return on investment is the only thing that management looks at when deciding to invest in a project. The welfare of the employees, customers, and the community in which the company operates are other considerations. For example, building a new facility in an area frequented by endangered animals may be logical but not socially responsible.

SITUATIONS

Situations are the key to all management decision making. What do we mean by situations? Well, we mean that before putting pencil to paper, you need to do your homework. We rec-

ognize that this can be difficult in certain organizations. Politics, culture, fear, and lack of trust can stop the process of gaining an understanding of the situation before you even get going. But the key is perseverance!

The strategic plan, the annual budget and capital plans, public perceptions regarding the company, and recent events such as layoffs, union disputes, management turnover, industry change, and economic pressures can be critical to the timing of a management decision.

Typically, a cost justification is required to gain approval for a major facility change. Such an analysis requires assumptions. These assumptions are always the major sticking points in any management decision. Understanding the situation surrounding the company is crucial to building well-thought-out and logical assumptions. Besides the assumptions, the basic accounting treatment of the business case is also a key area typically leading to a lack of management support. You must not provide the decision-makers with an easy out (e.g., through poor calculations or inaccurate accounting treatment of the initiative). So, understanding the situation and providing an accurate accounting treatment will position your proposal for management approval.

SECTION 2.7
FINANCIAL ANALYSIS

A basic approach to a well-thought-out financial analysis consists of five basic steps: (1) obtaining background and planning, (2) gathering data, (3) analysis, (4) developing conclusions, and (5) making recommendations. The most important part of the planning, managing, and decision-making process is reporting and analyzing how well the plan succeeded. A good information center can certainly make the next projections better and more representative of what is happening. To analyze what is happening, the current status of a number of performance ratios and indicators are used. Common analytical financial tools that help managers evaluate various aspects of the cost/benefit performance of the business include the following:

LIFE CYCLE COST

When a facility manager makes a request to purchase new equipment, the first question might be, "What is the economic basis for the equipment purchase?" Some companies use a simple payback period of two years or less to justify equipment purchases. Others require a life cycle cost analysis with no fuel price inflation considered. Still other companies allow for a complete life cycle cost analysis, including the impact of fuel price inflation and the energy tax credit. These examples are presented to illustrate that when comparing several cost alternatives, you need to ensure that you are comparing apples to apples for an accurate cost assessment.

USING THE PAYBACK METHOD

This method of cost analysis determines the time required for recovering a capital investment from profits or cost savings. The payback method is usually used when funding is limited and it is important to know how fast the investment will be returned to replenish available funds for other projects. The payback period is determined by computing the following ratio:

$$\text{Payback period} = \frac{\text{initial investment}}{\text{after-tax savings}}$$

This method is used to prioritize projects when funding is limited. The advantage of this method is its simplicity. It also emphasizes the cash flow in early years, which is more certain than that of later years. The drawback of the method is that it does not account for the time value of money. This method ignores all savings beyond the payback period, thus penalizing projects that have a long life potential in favor of those that offer high savings in the relative short run. Despite these shortcomings, this method is very helpful as a prescreening technique.

USING LIFE CYCLE COSTING

Life cycle costing is an analytical method of determining the total cost of a system, device, machine, and so forth over its anticipated useful life. Life cycle costing is difficult because one must comprehensively identify all costs associated with the system, not just the initial capital outlay. The costs most commonly included are the negative costs consisting of the initial in-place cost (equipment and installation cost), maintenance cost (personnel and materials), and interest on the investment. The salvage value is an added cost "return" that is used to offset the cost outlay.

Two factors that must be estimated are (1) the expected life of the system or the period after which the system will become obsolete, and, once the life of the system is determined, (2) the effect of interest rates as applied by using one of several expressions for the time value of money. When using alternative methods for particular calculations, the system with the lowest life cycle cost will usually be the first choice. This expression assumes there is little difference in performance among the various alternatives. Other considerations such as installation time and difficulty, pollution effects, aesthetics, delivery lead times, and owner preference may also need to be factored into the decision based on other means/factors. The life cycle cost analysis method still needs judgments about assumptions pertaining to interest rates, useful life, and inflation rates.

NET PRESENT VALUE (NPV) (TIME VALUE OF MONEY)

When a facility purchases a long-lived asset, it makes an investment decision similar to that made by a bank when it lends money. The basic principle is that cash is committed today in the expectation of recovering that cash plus some additional cash in the future. Therefore, when facility managers are deciding whether to purchase long-term assets, they want to know whether the future capital inflows are large enough to make the investment. If we look at a potential investment that projects a cash inflow of $500/year over a three-year period, the result is a total inflow of $1,500. If the investment (outflow) to achieve this inflow is reasonably less than $1,500, the net present value is greater than zero, and therefore it is an acceptable investment. When various project options are compared, the one with the highest NPV is usually selected.

THE TIME VALUE OF MONEY

When making an investment decision, the owners look at their capital and decide what is the best use of it. Should they invest their limited capital in the stock market, buy real estate for resale, or what? Owners know that a dollar received today is worth more than a dollar

promised at a later time. They also understand that in weighing options the risk of losing their investment must be considered. People who invested in the overseas stock market quickly found during the late 1990s that they could lose a substantial amount of their portfolio if the market suddenly drops. For these reasons, a time value of money must be placed on all cash flows into and out of the company.

When a choice is made between alternatives that involve different receipts and disbursements, it is essential that interest be considered. Economic studies in facility management generally involve decisions between such alternatives. When a facility manager is evaluating alternative solutions to a problem, the dollar value must be made comparable. The time value of money allows these comparisons.

Monetary financial transactions look at the cash flows to and from the company. The investment decisions take into account alternative investment opportunities and the minimum return on investment. To determine the rate of return on an investment, it is necessary to find the interest rate that equals payment outgoing and incoming, as well as the present and future values of capital. The discounted cash flow method is used to determine the rate of return.

RISK AND RETURN

Risk is defined as the probability of the course of an unfavorable outcome. Risks are generally classified into two categories: (1) *systematic,* which is the risk outcome from the general market conditions resulting from economic, political, or social changes, and (2) *unsystematic,* which is the risk variability of an outcome caused by events unique to an industry, such as labor strikes, management errors, new inventions, advertising campaigns, shifts in consumer taste, and new governmental regulations.

The four major types of systematic risk are as follows:

1. Operating risk caused by variations in operating earnings before interest and taxes
2. Financial risk caused by a variation in earnings per share that is used as leverage in the capital structure
3. Market risk caused by external elements that affect the economy in general and that may affect earnings
4. Purchasing power risk caused mainly by inflation that reduces the purchasing power of savings or invested wealth

Return is defined as the benefit received from incurring a certain cost. Returns that provide a better benefit for their costs are the most attractive as defined by the equation

$$R = \text{rate of return} = \frac{\text{net benefit}}{\text{cost}}$$

BREAK-EVEN ANALYSIS

A major task of facility managers is to choose financial alternatives. Facility managers want to utilize their scarce funds available for getting the job done in the most cost-effective manner. The following are some typical problems:

1. Whether to contract a certain service or to use in-house crews?
2. Whether to buy certain equipment that is reported to save money in maintenance?
3. Which utility type to buy (gas, oil, or coal)?

4. Whether to purchase or lease equipment?
5. How frequently and in what quantity to purchase stock items?

Break-even cost for a volume of products is calculated from the following equation:

$$\text{B-E-V} = \text{break-even volume} = \frac{\text{fixed cost}}{\text{unit cost contribution}}$$

The break-even point is of little interest to most corporations because their major aim is to make a profit. However, when preparing to start a new production process, you need to understand the break-even point as part of your risk and return analysis.

INVESTMENT DECISION MAKING

To make investment decisions, the finance manager usually follows one simple principle: Relate annual cash flows and lump sum deposits to the same account base for comparison. The six following categories used for investment decisions convert cash from one time to another. Because the company has various financial objectives, these factors can be used to solve an investment issue.

Single Payment Compound Amount (F/P)

The *F/P* factor is used to determine the future amount F that a present sum P will accumulate at i percent interest in n years. If P (present worth) is known and F (future worth) is to be determined, then Eq. (2.1) is used:

$$F = P \times (1 + i)^n \tag{2.1}$$

or

$$F/P = (1 + i)^n \tag{2.2}$$

The *F/P* ratio can be computed by an interest formula, but usually its value is found by using the interest tables shown in Table 2.7-1. Interest rates are compounded annually in these tables. Linear interpolation is commonly used for interest rates falling between the numbers shown in these tables.

Single Payment Present Worth (*P/F*)

The *P/F* factor is used to determine the present worth P of a future amount F invested at i percent interest for n years. Thus, if F is known and P is to be determined, then Eq. (2.3) is used:

$$P = F \times \frac{1}{(1 + i)^n} \tag{2.3}$$

$$P/F = \frac{1}{(1 + i)^n} \tag{2.4}$$

TABLE 2.7-1 Fifteen Percent Interest Factors

Period n	Single-payment compound-amount (F/P) Future value of \$1 $(1+i)^n$	Single-payment present-worth (P/F) Present value of \$1 $\frac{1}{(1+i)^n}$	Uniform-series compound-amount (F/A) Future value of uniform series of \$1 $\frac{(1+i)^n-1}{i}$	Sinking-fund payment (A/F) Uniform series whose future value is \$1 $\frac{i}{(1+i)^n-1}$	Capital recovery (A/P) Uniform series with present value of \$1 $\frac{i(1+i)^n}{(1+i)^n-1}$	Uniform-series present-worth (P/A) Present value of uniform series of \$1 $\frac{(1+i)^n-1}{i(1+i)^n}$

65	8817.787	0.0001	58778.583	0.00002	0.15002	6.666

Uniform Series Compound Amount (F/A)

The *F/A* factor is used to determine the amount F to which an equal annual payment A will accumulate in n years at i percent interest. If A (uniform annual payment) is known and F (the future worth of these payments) is required, then Eq. (2.5) is used:

$$F = A \times \frac{[(1+i)^n - 1]}{i} \tag{2.5}$$

$$F/A = \frac{[(1+i)^n - 1]}{i} \tag{2.6}$$

Sinking Fund Payment (*P/A*)

The *P/A* factor is used to determine the present amount P that can be paid in equal payments of A (uniform annual payment) at i percent interest for n years. If A is known and P is required, then Eq. (2.7) is used:

$$P = A \times \frac{(i)}{(1+i)^n} \tag{2.7}$$

$$P/A = \frac{(i)}{[(1+i)^n - 1]} \tag{2.8}$$

Capital Recovery (*A/P*)

The capital recovery factor is used to determine the annual payment A required to pay off a present amount P at i percent interest for n years. If the present sum of money P spent today is unknown and the uniform payment A needed to pay back P over a stated period of time is required, then Eq. (2.9) is used:

$$A = P \times \frac{i(1+I)^n}{[(1+i)^n - 1]} \tag{2.9}$$

$$A/P = \frac{i(1+I)^n}{[(1+i)^n - 1]} \tag{2.10}$$

Sinking Fund Payment

The *A/F* factor is used to determine the equal annual amount R that must be invested for n years at i percent interest to accumulate a specific future amount. If F (the future worth of a series of annual payments) is known and A (the value of those annual payments) is required, then Eq. (2.11) is used:

$$A = \frac{F[(1+i)^n - 1]}{i(1+i)} \tag{2.11}$$

$$A/F = \frac{[(1+i)^n - 1]}{i(1+i)^n} \tag{2.12}$$

Internal Rate of Return

The internal rate of return (IRR) method computes the rate of return that equals the present value of the cash outflow with the present value investment. Thus if we use any of the previously cited methods to determine the present value of the future years' outlay and the expression IRR = total investment – total inflows, any rate that makes the IRR equal to zero is acceptable, as long as it exceeds the cost of funds for its risk class.

Marginal Cost

Marginal cost refers to variable cost. Variable costs are those that vary proportionately with change in the volume of output. The marginal cost of a product is the cost of producing one additional unit of that product.

It is important to note that simplicity is best with management decision making. It is fine and even desirable to prepare very detailed studies, calculations, and analyses for the justification. *But do not present these detailed computations.* Summarize the financial results and impacts, and provide clear depictions of the impact of the initiative on the key financial performance measures today and over the course of the project.

The enemies of high ROM are:

1. A company has a "sky-is-the-limit" strategy driven by vague or overly broad mission statements.
2. "Politically correct" performance measures are in place that are selected so as to not exclude or offend any constituency in the organization.
3. People are not sure what they are accountable for, or they face so many measures that they are overwhelmed.
4. Planning, budgeting, and controlling systems have lives of their own.
5. Employees have little or no awareness of senior management priorities and performance measures.

BENCHMARKING

Today financial and facility managers need to understand and practice *benchmarking.* Benchmarking is a measurement used to determine the "best in class." Benchmarking is used in two different ways. Equipment like a computer benchmarks the time it takes to complete a certain process. This benchmark measurement, usually in time, is then compared to the performance of similar equipment given the same process. Another approach is to compare the processes used by different industries to get the best results. An example would be the case of an organization that wants to improve pizza delivery comparing the process used by a parcel post service organization to deliver packages all over the world, to determine if the process used by the parcel post organization could help deliver pizzas better. The benchmarking of that process could be viewed as a "best-in-class" process.

Benchmarking in today's facility and financial management profession can be a key to the future. The search to find better ways to carry out business processes and add value is a goal toward which we all must continue striving.

One of the most famous benchmarking groups is the International Benchmarking Clearinghouse (IBC). The IBC founders include AT&T, Arthur Andersen, DRI/McGraw-Hill, General Motors Corporation, IBM Corporation, PriceWaterhouse, and Xerox. These corporations pooled their information to share it among themselves. They provide the vital signs of their corporations as a basis for comparison. In 1991, the American Productivity & Quality Center (APQC) and 86 companies designed the APQC International Benchmarking Clearinghouse membership to help managers find and adapt best practices. Clearinghouse members include hundreds of companies, government agencies, health care providers, and educational institutions. With the clearinghouse's assistance, organizations discover best practices through many forms of benchmarking and learn from one another through network benchmarking studies, systematic knowledge transfer, and sharing outstanding practices.

Additional corporations can and do provide information to populate the information base. Corporations may also use the IBC information base to compare themselves against the best in the class. The IBC basic principle is that all businesses in the world perform essentially the same basic processes (e.g., develop strategies, hire people, purchase resources, make products or deliver services, and bill customers). They all have (1) *operational* and (2) *management and support* processes. The IBC operational processes include eight processes:

1. Understand market and customers
2. Develop vision and strategy
3. Design products and services
4. Design and construct network
5. Market and sell
6. Produce and deliver for manufacturing operations
7. Produce and deliver for services organization
8. Invoice and service customers

The IBC management and support processes are:

1. Develop and manage human resources
2. Manage information
3. Manage financial and physical resources
4. Execute environmental program
5. Manage external relationships
6. Manage improvement and change

These 14 IBC key processes provide the foundation to compare and contrast your process against the best in class. By classifying the operating and management and the support processes in the same way, a standard process for all corporations is created to provide information. Once information is collected consistently for standardization; information within its database can be catalogued, stored, searched, and sorted. Typical questions include information on the following topics against which to benchmark your company:

Best practices: Organizational practices that are noted for innovation, productivity, or effectiveness

Benchmarking studies/interest registry: Registry of business practices from member organizations that they have benchmarked, are currently benchmarking, or want to benchmark

Case studies and articles: Documents including surveys, studies, and potential partners

IW's interactive benchmarking database: This powerful interactive CD-RO database contains performance metrics on the manufacturing practices—and performance results—from 2,800 manufacturing facilities. Use it to view performance metrics based on company SIC, product type, plant size, union/nonunion status, and companies' use of advanced manufacturing practices and technologies such as:

- Empowered work teams
- Supplier rationalization
- Quick changeover techniques
- Just-in-time (JIT)/continuous-flow production
- Cellular manufacturing
- Advanced MRP II
- Strategic outsourcing
- Agile manufacturing strategies
- Total quality management
- Pay for performance
- ISO 9000

SECTION 2.8
IMPLEMENTATION PLAN

A comprehensive, measurable, attainable, and understandable implementation plan must be developed and shared throughout the organization. It should consist of a rigorous assessment of the firm's strengths and weaknesses, performance measures for evaluating results, and a benchmarking plan aimed at achieving best practices.

There is no single "best practice," because best is not best for everyone. Every organization is different from every other organization in one or more ways—different missions, cultures, environments, and technologies. What is meant by "best" are those practices that have been shown to produce superior results; are selected by a systematic process; and are judged exemplary, good, or successfully demonstrated. Best practices are then adapted to fit a particular organization.

In recent years, performance measures have evolved as a way of checking the vital signs of corporate health. Performance measures are classified under the three general categories of cost, quality, and service time. Companies are learning that improving quality and productivity go hand in hand with cost. At the same time, they have found out that the best way to ensure external customer satisfaction is to satisfy every internal customer at each step of the process. This condition is true for both manufacturing and service operations.

Once you have selected the desired criteria, view the performance of plants that match those criteria. Then, analyze how much your facility could benefit in terms of higher productivity, greater efficiency, and decreased costs and product defects.

SECTION 2.9
REENGINEERING

Now that your corporation has decided upon a new strategy, you must decide how to adapt the new strategy to the existing organization, a process sometimes labeled Business Process Reengineering (BPR). The reengineering trend has had major acceptance in America (since Hammer & Champy, the reengineering, gurus, issued their book *Reengineering the Corporation*). Recently, however, it has also caused a backlash, some of it justified and some guilt by association. Many reengineering efforts have failed in the past. Michael Hammer and James Champy reported a 70 percent failure rate of the efforts they have seen. An added problem in assessing success and failure is that some people use the term *reengineering* for just any downsizing or rightsizing activity, which may be butchery rather than a surgical approach to cost cutting. Stowe Boyd, in his article, "Business Process and Information Technology," states the major message to learn from slash-and-burn reengineering is that it is possible (but not necessary) to rapidly inject a process-centered management style into old-style business.

Usually a top-down process model is created of the area under study. This high-level process identification allows you to look at your important processes that are done to accomplish the mission, goals, and objectives of the company. This high-level model should not have any organizational or technology constraint. By definition a process as a collection of sequential and logical activities which when performed add value to the product or service. A process produces distinct deliverables whose quality can be measured. It has a beginning and an end, and is usually repetitive. Processes usually coexist in companies, with two types being most common. One type of process is organized along functional lines, in which the input has its value added to from an output within a single organization. These vertically organized processes are easier to improve because there is no major departmental interface (e.g., word processing) during the process.

When processes span one or more vertical (function such as information systems management) departments, they are called *cross-functional* processes. Usually, with cross-functional processes, no single organization or person is in charge of the entire process, thereby making the process complex. Most large companies have hundreds of processes and thousands of subprocesses.

A critical step is to identify your core business processes. Most companies have defined their core processes. This step is key to beginning a reengineering effort because it helps management to focus on the important areas where work gets done. Some organizations find it difficult to determine their core processes because they tend to think in terms of departments or functions, not in terms of the work they actually do and the manner in which this work is performed. Without a core process, the corporation would cease to function properly. Core business processes should always consider the core competencies of an organization. Process analysis should look at the following considerations: Is the process effective? Does the process output meet customers' and users' needs (products and services)?

The product should be efficient [cost, time frame, and full-time equivalents (FTEs) included]. When one decides to do process REENGINEERING, it forces a fundamental examination of the core purpose of the key processes to be reengineered and may require a major adjustment of many of the ways in which the organization conducts its business.

Considerable effort has recently been devoted to studying manufacturing processes and has resulted in improvements such as just-in-time manufacturing, continuous-flow manufacturing, computer-integrated manufacturing, total quality management, materials requirements, and supply-chain management. Many of the techniques for analyzing manu-

facturing companies can also be used to analyze service companies, although you may need a different set of tools for the analysis. In manufacturing, however, the essential ingredient is the machine and its efficiency, whereas in service companies the key ingredient is people.

Service companies deal with providing services and products in a non-mass-production (nonmanufacturing) environment. The increasing global competition will require that service businesses minimize the "time" it takes to service customers with quality, so as to increase profits. Service companies should look at the human rather than the nonhuman aspects of organizations, in the form of Human Performance Technology (HPT).

Some reengineering projects do not result in downsizing. Instead, they free resources from wasteful or obsolete processes and redeploy them for more important or effective processes. For example, the traditional hospital pharmacy dispensing process of counting pills and filling vials is facing obsolescence from automation. Automated point-of-use dispensing machines and unit-of-use packaging eliminate most of the dispensing work, freeing as much as $200,000 per year in pharmacy resources for clinical roles such as medication management. These new programs, in turn, generate additional savings from improved medication usage and improved patient care outcomes.

Mark Youngblood, in his book *Eating the Chocolate Elephant,* lists 32 ways to improve business processes. Most of these principles have been used by industrial engineers and applied to production problems for decades. However, it is important to list some of them because they are areas where you can get quick results in process improvement:

- Organize multifunctional teams.
- Simplify processes.
- Eliminate duplicate activities.
- Combine related activities.
- Outsource inefficient activities.
- Implement demand-pull.
- Eliminate movement of work
- Eliminate multiple reviews and approvals

The following are some guiding principles aimed at reducing cost and enhancing effectiveness:

- Compress time.
- Align toward customers.
- Organize around outcomes.
- Provide end-to-end solutions.
- Empower people to make recommendations for change.
- Quality is number 1.

SUMMARY

This chapter has explained the financial role of an organization through the eyes of a financial manager. The lesson gleaned from this view should make every facility manager aware of what takes place in a professional business, and more important, what it will take to become part of senior management. This standard of information will assist any facility manager in realizing how roles are shared in an effective organization. There is a melding and sharing of

responsibilities between the facility manager and the financial manager. To be successful in the current business climate, each has to understand the other.

CHAPTER 3
FACILITY LIFE-CYCLE PROCESS

Paul R. Smith, P.M.P., P.E., M.B.A., Chapter Editor
Peak Leadership Group, Boston, Massachusetts

William L. Porter, Ph.D., F.A.I.A., Chapter Editor
Massachusetts Institute of Technology, Cambridge, Massachusetts

In Chap. 1, we describe the evolution of the facilities manager (FM) from the boiler room to the board room! Traditionally focused on the management of facilities over their life cycle, the FM today must rise to contemporary challenges and participate in decisions critical to the future of the organization. Today the components of the workplace include not just space, but also technology, finance, organization, and the relationships between them. And these are each in a state of flux that must be recognized and mobilized to support the mission of the organization. Facilities managers have a leadership role to play in realizing these new opportunities. But to play a leadership role requires that FMs learn more about effective management practices and about the requirements of the knowledge age and its associated technologies and best practices.

Chapter 2 provides sufficient information to (1) help the FM become part of the senior management team, (2) establish standards so that the FM understands the information needed for a well-run facility, (3) combine the theory and the applications of facilities management, and (4) provide a chapter that FMs will find user-friendly.

Chapter 3 identifies processes that are critical to the success of the facility and the FM's role in managing the facility throughout its entire life cycle. And it identifies issues in corporate operations management that facilities managers must increasingly take into account. For each facility, there must be management of planning and budgeting of the design and construction process and then of the facility, once it is in operation. We give special emphasis to the role and to the potential of information technology. We also underline the importance of corporate operations management by discussing some new developments in that field.

Some FMs would question why operations management, facilities management automation systems, and infrastructure management topics are discussed in this book. The answer is that the FM must pay attention to the way the corporation creates value in both the physical and virtual world. Whether it is a project, a service request, or an annual budget, the manager needs to understand certain key elements within the business context that are part of this process and are the FM's responsibility. The FMs of the future must be able to communicate with their peers on computer networks, infrastructure, hardware, and software. They can no longer ignore their information technology and their sisters and brothers down the hall. Rather they must get very close to them, learn their language, and become trained in their technological skill sets and toolkits. They must help them design the new processes, practices, and technological solutions that will help us navigate this complex economic environment and bring eco-

nomic value to all of our organizations, whether industrial, institutional, or commercial buildings. And these solutions are all built on the fuel for this new economy—knowledge.

Now is the time to think strategically and to reposition the facilities management profession. First, it must be closely connected to the mission and management of an organization. And second, it must be closely coordinated with the management of technology, human resources, and finance. Third, it must be prepared to grow and to change, depending on the demands of its particular organization, sometimes incorporating untraditional functions and sometimes forming new management teams and partnerships. These are dynamic times, and there are risks associated with them. However, our experience with other challenges has taught us that if we wait until the path is perfectly clear and the risks have disappeared, the opportunities will also have passed.

SECTION 3.0
OVERVIEW

Kristin Hill, A.I.A.; Cindy Aiguier, John Morganti, and Bonnie Seaberg
International Facility Management Association (IFMA), Boston, Massachusetts

Norman Faucher
Association for Facilities Engineering (AFE), CAC Industries, Inc., Leominster, Massachusetts

Chapter 3 is written to equip facility managers with the tools to succeed in the new millennium. Here you will encounter advanced thoughts and ideas combined with solid industry knowledge. The authors have unleashed information that represents the best of practices so as to empower and excite aspiring facility managers and facility professionals who wish to refine their performance capability.

The chapter is formatted to take the reader through the facility management process as it logically unfolds around a facility project. Section 3.1, for instance, contains information having to do with planning and budgeting, the first steps to getting a facility project underway. Section 3.2 offers insight into the next phase, design and construction. Following these are new developments in knowledge management, in Sec. 3.3, and new developments in operations management, in Sec. 3.4. These last two sections explore the many aspects of facility management encountered after a "project" has been completed and "facility management" has begun.

Chapter 3 does not attempt to provide a step-by-step guide to facilities management. We believe a step-by-step guide would be impossible due to the nature of facilities management. What this chapter seeks to do is to impart the wisdom that facilities management is evolutionary and revolutionary (as discussed in Chap. 1) and is responding to the new technological advances and influences in business today. "Tried and true" can mean outdated and debilitating. Just as it is inefficient today to use an abacus to solve mathematical problems, so too is following a stale formula for facilities management. Traditional methods of approach and operation become the burdens of yesterday.

And so this chapter is also about connection—the connection between technology and change and the way we use each to affect the other. The technological advances in industry,

communication, improved methodologies in manufacturing, financial reporting, and other systems used to conduct business become the catalysts for change. In response to these influences, facilities themselves will undergo change to adapt to the advances. But it does not stop there. The new technologies that are driving the changes in facilities are also providing facility managers and their teams with new tools for planning and budgeting, designing and constructing, managing the change, the knowledge, and the operations. Success for facility managers lies in recognizing these technological forces and employing them to their best effect.

The tidings in this chapter are about a different way to approach a facilities project. Understanding that it is vital to maintain a dynamic program by seeing in new ways, the facility manager today must develop a vision for new possibilities and new methods. Don't make the mistake of believing that this will be easy. It is never easy to sell new ideas. It is human nature to rally against anything unusual or deviant, and change almost always meets resistance. The professional gain that will be achieved by successfully championing this effort will, however, be immeasurable.

The basic tools for accomplishing the facility manager's goals are not radical. Common sense, an unclouded vision of both the present and the future, and commitment to innovation in problem solving are all it takes to recognize needs and set new directions. To facilitate a change in old methods of approaching projects, one must set the course, weigh the potential gain or loss, and see the change through. So read on. This is a brave chapter designed to encourage you to be a changemaker, and to reach for the leading edge. In the new millennium, the facility managers who survive and prosper will be those who foresee, seek, and strive for change.

SECTION 3.1
PLANNING AND BUDGETING

Kristin Hill, A.I.A.; Cindy Aiguier, John Morganti, and Bonnie Seaberg
International Facility Management Association (IFMA), Boston, Massachusetts

Norman Faucher
Association for Facilities Engineering (AFE), CAC Industries, Inc., Leominster, Massachusetts

Planning and budgeting are initial steps in every project, whether sketched on a cocktail napkin or compiled into a multiple-volume presentation. One must begin with the end in mind. Plan and budget for the FUTURE, not to catch up with the past. It is essential to spend the time to produce a solid plan to avoid unanticipated costs and project overruns that will destroy the budget and ultimately threaten the plan. Goals must be clearly identified.

To have a project funded, it is important to know the owner and the leadership. This is the place to identify the principal players and their concerns while keeping in mind the goals of the proposed project. Learning and speaking the language can ensure that you understand the goals, cost, and schedule while moving them toward a successful outcome. The approval process in financing a project can result in both positive and negative outcomes—it is important to know

both! Planning and budgeting defines the level of risk in a potential project. The information in these articles is essential for understanding the project process and the stakeholders' goals.

In these articles you will learn to identify all of the project stakeholders and the impact they will have on the project. Their concerns for the project may range from the contribution it will make to the success of the business, the design and functionality of the space, and the return on capital investment, to the ability to adapt the space for future uses. Each of these concerns carries with it a risk and consequence of failure that must be addressed during the project planning and budgeting phases. One must be prepared to show how a particular project will benefit the company. It is important that the project is aligned with the company's mission and objective statements.

Every stakeholder in the project could be considered a speaker of a dialect of the common project language. The financial and approval process represents a common understanding of the goals, parameters, and structure set for the project during the planning and budgeting phase. During this process, risks are evaluated, negative impacts are mitigated, and positive outcomes are strengthened.

The facility manager's role in the company structure is to provide plans, action, evaluation, correction, and results. Armed with the knowledge of this role and the reality of available resources, the facility manager is prepared to develop a plan and begin to view it in many different ways. Learn how to propose projects successfully and get them approved, so you can move forward with confidence.

ARTICLE 3.1.1
OWNER REQUIREMENTS

Matthew C. Adams, P.E.
Association of Higher Education Facilities Officers (APPA),
Adams Consulting Group, Wellesley, Massachusetts

Facility owners are becoming increasingly sophisticated in their expectations that the "highest and best" methods of management will be applied in their operations. Certain self-improvement criteria now affect departments in all operating areas. There are seven key criteria for empowering a governing or management organization to achieve high performance standards. These interlocking criteria for success substantially increase the ability to achieve operational superiority in all areas affected by managerial actions.

ADHERE TO THE MISSION

The driving purpose of management within any type of organization must always be to direct operations toward attaining its mission. The highest level of accountability to which management can be held is the degree to which executive decisions advance the cause of the organization as a whole. Managers do not operate in a vacuum; their role is to manage operations within their responsibility to advance the highest and best interests of the organization.

It is essential that the organization have a clearly understandable mission statement. Without such a guiding plan, there is no foundation to provide direction to management groups within the organization.

An interesting exercise for departmental managers is to assess the mission-directedness of the management team members by asking them what they perceive as the mission. This can take the form of a written comparison, in which each team member is asked to write down the organization's mission. The responses are reviewed to determine the cohesiveness of the team and the degree to which members are working toward achieving a common mission. A strong team will display significant areas of overlap, if not complete consistency; both with one another and with the organization's formal mission statement. However, if responses vary significantly or if some members are unable to formulate a coherent mission statement, it is time to undertake serious internal work to ensure that the management team members get on track so that they see themselves as accountable for achieving the organization's essential mission.

FOCUS ON HOLISTIC THINKING

The old system, by which management made decisions through a process of representational governance, is being replaced by a trend toward holistic or systemic thinking. Each member of management is expected to look at the operation as a whole and to work toward achieving the mission of the greater entity. When each management team member focuses on the best interests of the entire system, the competition between formerly competing elements will be eliminated, and decisions that better benefit the organization as a whole will be facilitated. Previous procedures by which many executives were expected to "bring home the bacon" for their perceived constituency are being made obsolete by the expectation that management will work for the greater good, as a cohesive team without hidden agendas.

Through holistic thinking, the organization's strategic goals are advanced. Executives will be empowered through their unity of purpose rather than divided by conflicting special interests. This new emphasis on holistic thinking will certainly affect the ways in which the management team is selected—and thereby also affect the structure of the team. In addition, members of the management team will be expected to focus on a mission that will entail a willingness to forego the idea that they have been placed on the team to represent a particular constituency. The resulting management emphasis on holistic thinking will affect all management decisions from budgeting to operational methodology.

In the long run, the particular interests of component groups or constituencies within the organization will be best served by the holistic approach. As the greater interests of the organization are advanced, all of the various components will find themselves in stronger positions.

IMPLEMENT STANDARDS OF MANAGEMENT ACCOUNTABILITY

An effective management team achieves success by evaluating the performance of its members in terms of certain established criteria. These will vary from organization to organization, but include structural measures, such as regularity of meeting attendance and completion of continuing education goals, and such qualitative measures as the ability to contribute to the decision-making process, preparedness for decision-making sessions, and the overall level of support for management policies and activities.

Failure to upgrade the performance of weak managers or to replace them with strong managers can result in a negative dynamic that undermines managerial effectiveness and drives away stronger managers who are eager to be on a winning team.

The composition of the management team must be periodically updated to reflect changing requirements. The need to infuse new skills and new areas of expertise grows stronger as the pace of change increases.

CREATE THE FUTURE

This same trend to ever-faster rates of change means that a successful management team must be prepared to implement forward-thinking techniques and to actively plan and initiate action to cope with all types of progress. A streamlined decision-making process will prove more adaptable to changing requirements than approaches that resist change.

Fear of change lies at the heart of institutional inertia. It is not a new problem but it is one that becomes more critical as the pace of change accelerates. Rather than simply monitoring the past, effective managers anticipate the future. They use resources of all kinds, including valuable managerial time, to create the future, develop new ways of doing things, and envision new paradigms. By utilizing planning, policymaking, and the decision-making process, effective managers concentrate on future requirements.

DEVELOP STRATEGIC INFORMATION

This emphasis on the future requires that effective managers ensure that they receive the kinds of information needed for making decisions that affect the future. Reviewing past performance should require no more than 25 percent of the total information intake. The rest of the information on which managers rely will reflect current and predicted conditions of the operations for which they are responsible. By defining long-range operational policies, it will be possible to develop the kinds of data that will most significantly impact decision-making processes. By controlling the flow of information and emphasizing information with long-range value, leaders will be in a better position to formulate policies for the future success of their organizations.

LET THE MISSION CONTROL THE STRUCTURE

The ways in which authority is divided can work either for or against an organization. Outmoded management structures that have numerous subsidiary organizations or too many members can impede progress because they are not designed to meet changing needs. An obsolete management structure is another example of institutional inertia.

Ineffective management structures can result in either gridlock or conflict as executives strive to reach meaningful decisions. If the existing system tends to drag out decision making because of multiple committees or unclear lines of authority, decision making will be untimely and unresponsive.

Highly effective management teams continually assess and fine-tune their structures to facilitate their ability to accomplish goals. Ideally, management structures reflect functions, areas of responsibility, and strategy.

CLARIFY JOB DESCRIPTIONS

As management structure changes to reflect current conditions, individual jobs within the management team will undergo corresponding transformations. To avoid confusion about who is supposed to do what and how the various responsibilities interrelate, it is necessary to update job descriptions for individual roles.

All members of the management team should have a shared understanding of the group purpose. In addition, each should have an understanding of the particular roles of the indi-

vidual team members. Responsibilities and relationships with other leaders should be defined to increase the streamlining process and to achieve clarity of understanding. Job descriptions for each management role enable members to assess their performance and to improve it as appropriate, based on a clear vision of the standards. In particular, all must understand that the role of the head of the team includes the responsibility for teaching holistic thinking, changing team selection procedures, and spearheading the other operations of an effective managerial team.

ARTICLE 3.1.2
FINANCIAL MODELING

Thomas K. Davies, A.I.A.
Vanderweil Facility Advisors, Boston, Massachusetts

The financial methods, techniques, and tools that organizations employ to manage their large building portfolios are directly correlated with the state of the facilities now and the dollars needed to keep their condition acceptable well into the future. Research exists to support such an opinion, and failure to recognize this concept often leads organizations to defer needed maintenance year after year, eventually paying much higher "balloon payments" down the road to fix building failures, working reactively instead of proactively.* Considering the consequences of doing nothing or little in the way of managing their facilities, it is no wonder that several organizations have elected to go down the path of proactive facilities management to maintain the substantial value of their investments in facilities. A cornerstone of this proactive approach is the financial model.

WHAT IS FINANCIAL MODELING?

Financial modeling is an integral part of proactive facilities management. The process involves a parametric analysis of several variables and is ultimately intended to forecast future costs of maintaining real plant and equipment, to provide a vehicle for understanding the magnitude of the problems at hand, and to provide a foundation of realistic costs and assumptions for building a workable long-term business plan for capital investment in the facilities. The financial model utilizes "baseline" information on the condition of the facilities as one of the parameters. Another parameter utilizes commonly accepted cost models for certain types of buildings. Still other parameters take into account the desired time frame of the analysis, the current age of building components, and the life expectancy of building components.

Financial scenario analysis enables flexibility through dynamically altering variables and estimating the resulting changes in the financial model. Improved financial decisions are facilitated through analysis of accurate baseline facilities information, projections based upon proven models, and established benchmarks.

* Many of the concepts presented in this article represent joint efforts and projects including, but not limited to, the Society of College and University Planners (SCUP), the National Association of College and University Planners (NACUBO), the Association of Higher Education Facilities Officers (APPA), and Coopers & Lybrand. Specific credit is noted to *Managing the Facilities Portfolio,* a publication prepared by the foregoing with contributions by others.

WHICH TOOLS ARE USED IN FINANCIAL MODELING?

Several tools are used in the financial modeling process for facilities. First and foremost is the raw data collected during the Facility Condition Assessment (FCA). Such data provide a fundamental snapshot of the building's condition. The Facility Condition Index (FCI) is the ratio of the cost of remedying facility deficiencies to current replacement value (CRV).

$$\text{Facility Condition Index (FCI)} = \frac{\text{deficiencies}}{\text{current replacement value}}$$

The FCI is a recurring theme in financial modeling. It is the basis of understanding multiple funding scenarios to improve the condition of the facilities and reduce the FCI.

One such tool is the FCI versus Annual Funding graph, an example of which is shown in Fig. 3.1.2-1. For each funding option, this graph illustrates the annual dollar amounts that would be funded under the option and the forecasted FCI that results from that option. Building replacement costs are adjusted annually by the inflation rate identified, 4.7 percent in this case. If the organization anticipates accelerated growth, this rate is reflected in both the replacement cost and the overall FCI, assuming that growth is via new construction. Anticipated new physical plant deficiencies are computed as the sum of two factors. The first is the further deterioration of current deficiencies not corrected, at the backlog deterioration rate identified as 2 percent. The second is a forecast of annual renewal requirements, using a best-fit trend line. The vertical bars indicate annual dollars invested in the building, as marked on the left axis, and the graph lines indicate the effect of this spending on the FCI, as marked on the right axis. This particular graph represents a 22-year forecast, but longer or shorter forecasts can be generated.

Option 1 explores the effects of minimal investment in the building, reflected by 0.5 percent of the facility replacement cost. This minimal funding option is included for comparison only. This funding strategy is unrealistic because it projects an unacceptably high FCI. Options Two and Three take the opposite approach—these establish the FCI desired and determine the funding required to achieve that FCI.

Option 2 determines the funding requirement to maintain the FCI at its current level.

Option 3 explores the improvement of the portfolio, in which significant building improvements are distributed over a 10-year period, bringing the FCI down to an efficient 0.05 level, and maintaining it at this level thereafter.

Another useful tool is the Facility Renewal Forecast graph (see Fig. 3.1.2-2) that illustrates the amount of dollars that will need to be spent to renew the facilities over time. The annual forecast of renewal costs, which is based on the accumulation of the data on the current condition and costs of the building components, is useful for projecting capital funding required to maintain status quo. The moving average of projected annual expenditures and the straight-line trended regression should form one basis of funding justification for ongoing renewal. Finally, long-term average funding requirements provide a rational baseline for average ongoing funding and expenditure. Lower average spending levels translate to increased deferred renewal and increased costs to maintain steady state of facility conditions and functionality.

Yet another tool, the Investment Gains/Losses by Year graph, illustrates the effect of the three funding options shown in Fig. 1 on the value of the physical plant over time, as shown in Fig. 3.1.2-3. Plant value is considered the current replacement value minus the aggregate costs to correct deferred maintenance and deferred renewal.

The comparison of Total Funding and Change in Plant Value graph (see Fig. 3.1.2-4) illustrates a tool for comparing each funding option, the cumulative renewal expenditures to the cumulative change in the value of the physical plant, and permits comparing such dollar amounts across the various funding options.

The Return on Investment graph (see Fig. 3.1.2-5) is based on the preceding graph and shows a return on investment analysis by computing the ratio of (1) the "profit" (i.e., the

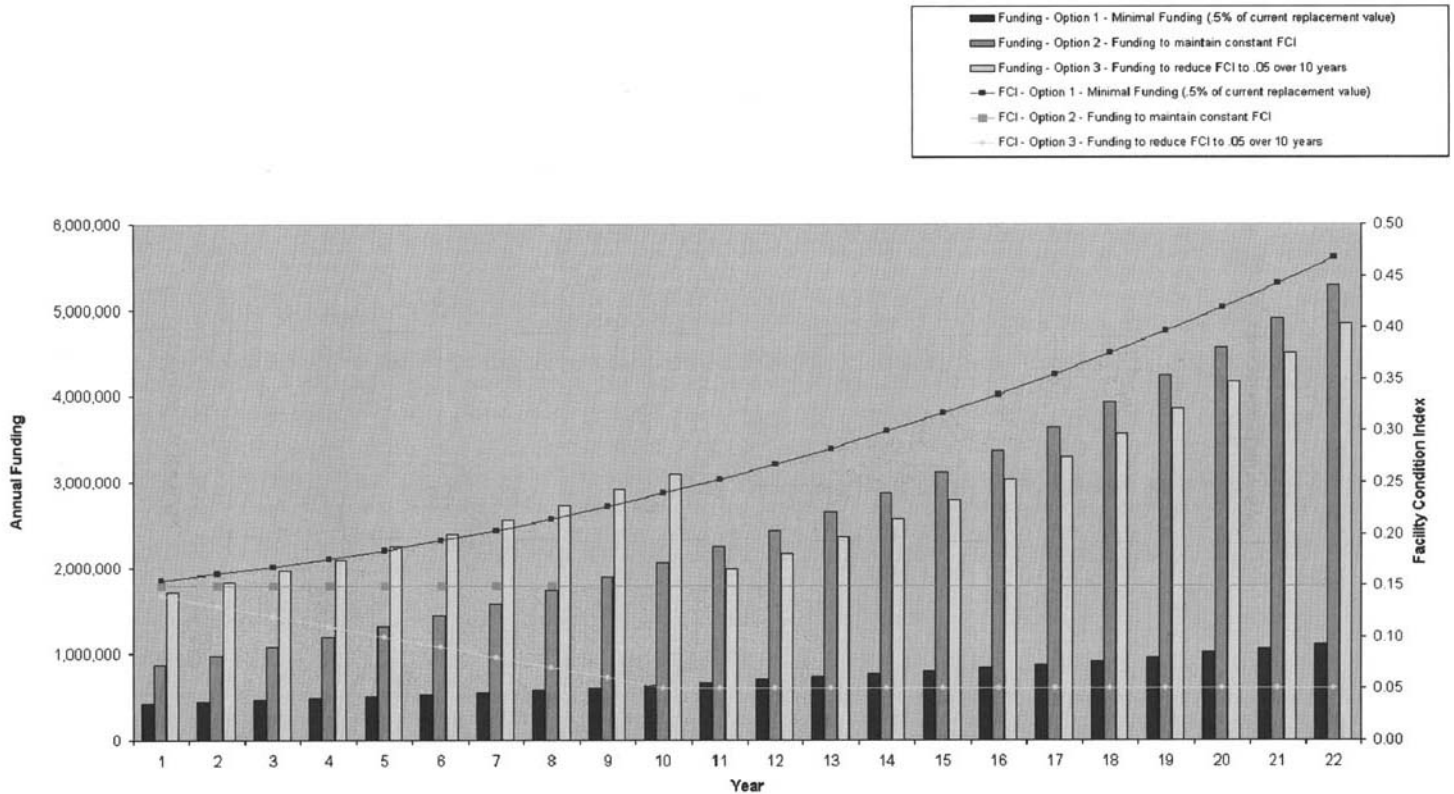

FIGURE 3.1.2-1 FCI versus annual funding graph. (*Courtesy of Vanderweil Facility Advisors.*)

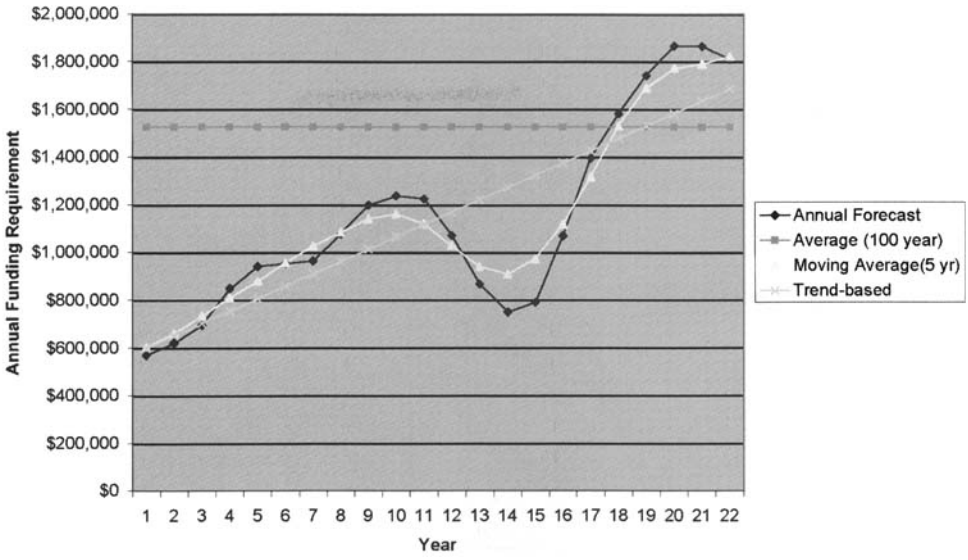

FIGURE 3.1.2-2 Facility renewal forecast. (*Courtesy of Vanderweil Facility Advisors.*)

cumulative increase in value less the cumulative renewal expenditures) to (2) the cumulative renewal expenditures.

These illustrative graphs, coupled with sophisticated facilities management software programs, are the major tools employed in state-of-the-art financial modeling.

WHY IS FINANCIAL MODELING IMPORTANT?

Organizations are increasingly establishing mission statements and business plans for their facilities-related businesses. This is a critically important process, as any business manager knows. Financial modeling of facilities is used to support key decisions regarding the direction of the organization's business plan or mission. The business plan is both rudder and filter, establishing defined criteria against which potential actions can be measured.

The quality of the business plan is often based on key assumptions and factual cost data that have been loaded into the parametric analysis of the financial model. If the financial model uses incomplete or erroneous methodologies or relies on unsubstantiated cost data, the resulting data may negatively influence the organization's business plan. The result could be that the business plan steers the organization in the wrong direction. Consider a typical research university where this "wrong direction" could be made manifest. Say, for example, that the university's financial model fails to accurately depict the true costs for maintenance and renewal. Data from the financial model find their way into the business plan, leading to insufficient funding of campus facilities. The subsequent inability to update 1950s-era laboratories results in degraded appearance and functionality. This in turn leads to declining enrollment—and ultimately the organization's mission of being a premier research university is short-circuited. A sound financial model could have prevented the organization from going in

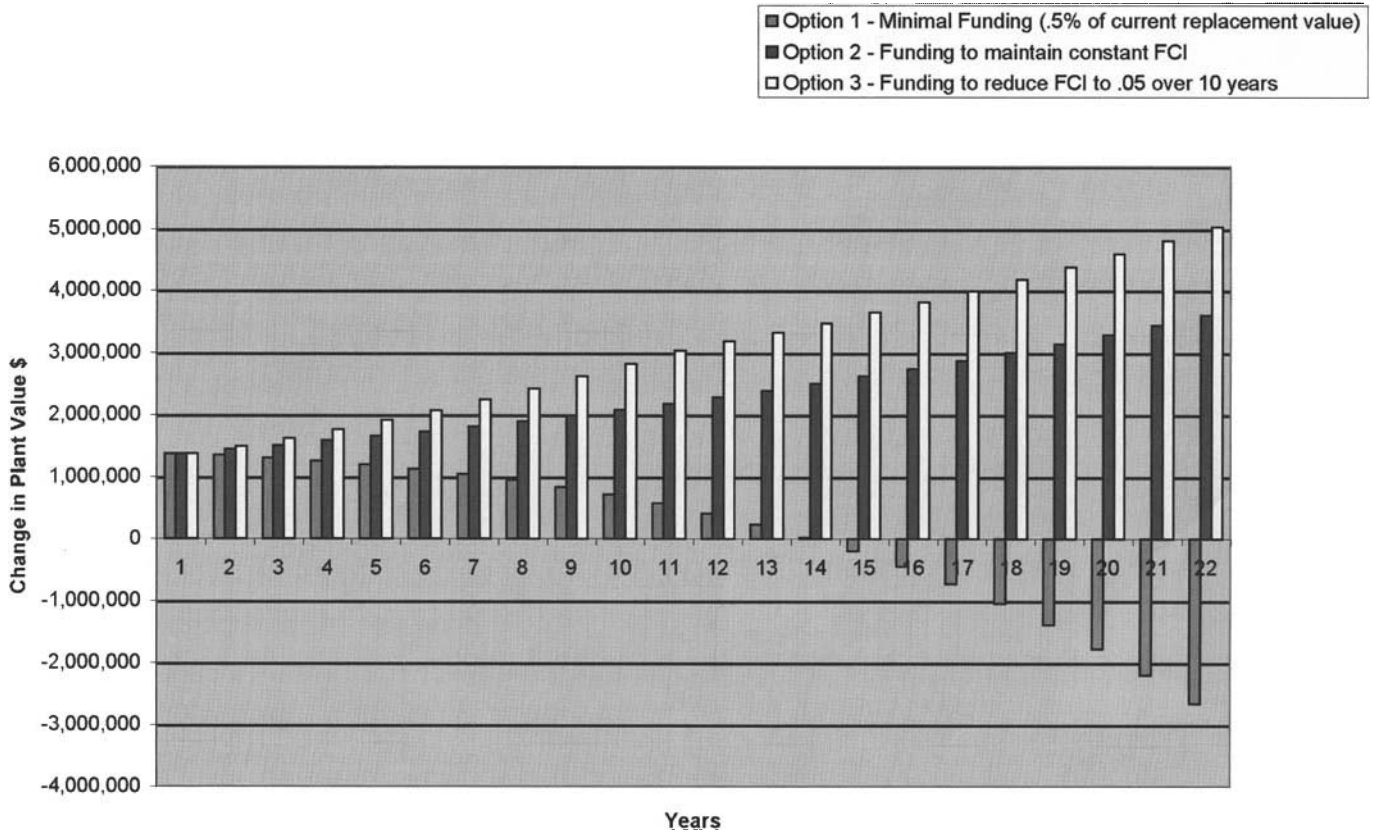

FIGURE 3.1.2-3 Investment gains/losses by year. (*Courtesy of Vanderweil Facility Advisors.*)

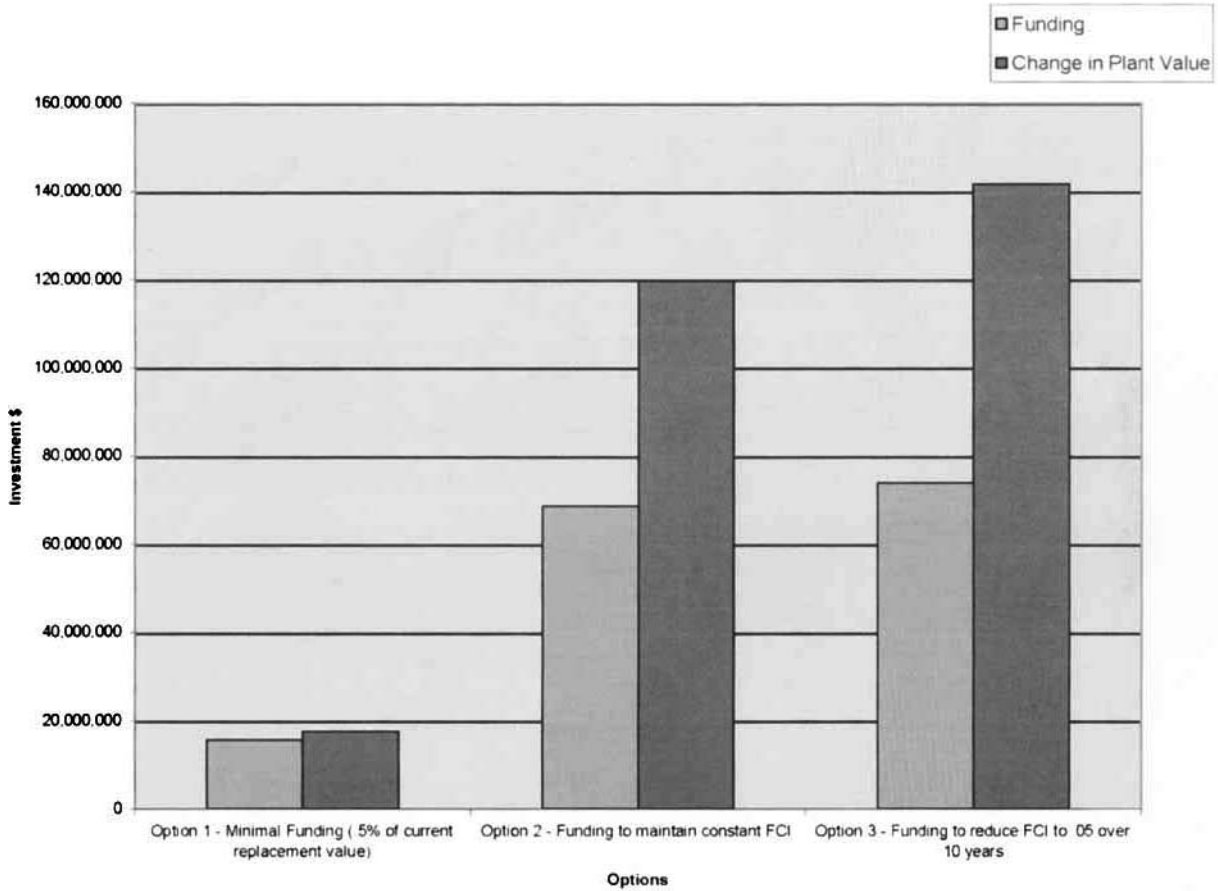

FIGURE 3.1.2-4 Comparison of total funding and change in plant value. (*Courtesy of Vanderweil Facility Advisors.*)

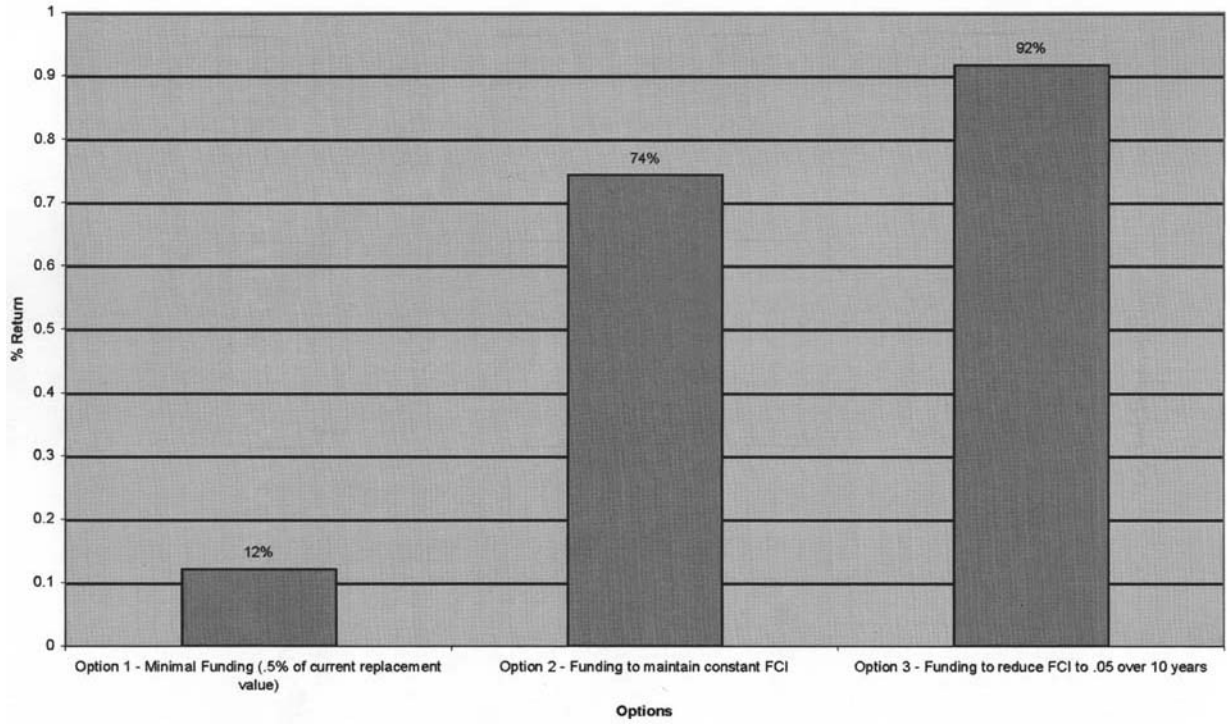

FIGURE 3.1.2-5 Return on investment. (*Courtesy of Vanderweil Facility Advisors.*)

the wrong direction and kept it focused on its true mission and business plan. Financial modeling is at the core of any sound long-term plan.

WHO IS INVOLVED IN FINANCIAL MODELING?

Business and technology shifts are altering the landscape of facilities management. Strategic facilities management is primarily a communication-driven process. Decision support must involve input, planning, and management from several areas, including facilities directors, operational management, and planners. Moreover, the owners of this process must engage in roll-up reporting to and executive direction from CFOs and CEOs. As such, technology plays a critical role.

Web and related advanced technologies have been developed and are being deployed to link strategic facilities management with the organizational mission of the enterprise. Technology is increasingly changing the process of baseline data gathering, capital requirements planning, capital project planning, and project execution. Redistribution of information, capability, and assets is an ongoing process. Software and technology systems that allow several decision makers to be involved simultaneously in cutting-edge financial modeling remain the key to sound planning.

WHAT ARE THE RESULTS OF FINANCIAL MODELING?

Financial modeling allows an organization to see into the future and take action. If properly designed and methodically executed, financial modeling systems can greatly improve an organization's ability to understand, address, and solve complex capital spending plans that are a necessary component of long-term capital planning. Consider the fact that organizations often have a large list of building-related problems to be fixed, but usually only a small list of available funds with which to do the work. The value of financial modeling becomes clear when an organization needs to squeeze the most value out of every facilities dollar. Financial modeling allows the organization to establish funding priorities with scarce resources and to stay on track with the organization's long-term vision.

ARTICLE 3.1.3
FACILITIES MANAGEMENT SYSTEMS

J. Richard Swistock
The Association of Higher Education Facilities Officers (APPA), Alexandria, Virginia

Facilities management systems and processes must be integrated with and support the institution's or company's broad goals. Public or private facilities rarely exist in their own right, and their existence can be justified only by their support of the institution's and company's mission and goals. The exception to this is historic structures and facilities that can properly exist in their own right. The existence of all other facilities can be justified only by their con-

tribution to the larger institutional mission. Preserving tradition and history is an important element in the broad goal of institutions such as colleges, universities, churches, museums, and so forth.

The justification for facilities should frequently be tested against the broader institutional or company goals, and just because a facility exists is not adequate justification to continue owning and maintaining it. Private companies are more likely than public institutions to frequently test the needs for facilities against corporate goals and objectives.

Facilities should be managed as assets, and, as with all other assets, require attention and should provide a positive return on investment. Ideally this return can be quantified in dollars and reflected in financial statements. This may not be reasonable for many public facilities. However, the return on investment in facilities should be expressed in some manner such as more effective use of research resources, recruitment and retention of faculty, or some other identified return.

Many institutions such as public and private colleges and universities do not treat facilities as assets but rather only as expenses, and therefore frequently find themselves owning and maintaining facilities that are liabilities which do not contribute to the institutions' missions and goals.

An integrated facilities system will support the goals of the institution and will consist of master planning; space planning and utilization; facilities construction, renovation, and maintenance; and utilities and building services. Good process management of these systems will assure good customer service to those who use the facilities and good cost-effectiveness in their acquisition, renovation, maintenance, and operation, and in the procurement of utilities and related services.

This article discusses these elements of facilities systems and the related process management for each part of the system required to provide and maintain a productive environment as cost-effectively as possible for users of the facilities.

DEFINITION OF FACILITIES MASTER PLANNING

Facilities master planning is a process that defines the physical requirements needed to achieve the institution's vision, mission, and goals. When the master planning process is done effectively, it leads to cost-effective decisions for facilities development.

The facilities planning process is an extension of the institutional planning process and must acknowledge the needs of institutional constituents and the community in which it functions. This process results in the *facilities master plan,* which defines current facility requirements and makes provisions for future facilities that are likely to be required to support future institutional goals. The facilities master plan usually is a snapshot in time that defines the facilities planning process. The facilities master plan usually has a useful life of two to five years. The process should be continuous, and published plans should be frequently updated.

The facilities master plan contains the following four major elements:

1. Inventory of current facilities, including buildings, grounds, and infrastructures.
2. Currently needed additions, deletions, or major changes to the inventory that are required to support the institution's current goals and objectives.
3. Likely future changes, additions, or deletions to the inventory that may be required as institutional goals and objectives change.
4. Design guidelines that describe the quality of the environment desired, including landscaping, architectural styles and limitations, and specific infrastructural and utility requirements. These guidelines should ensure consistency across facilities while permitting latitude for creative architectural and engineering designs. They can be included in the master plan or clearly referenced if they are consolidated into another comprehensive document.

GOALS AND OBJECTIVES

The goal of the master planning process is to produce a master plan. This master plan, supported by a financial plan, is the road map for institutional facilities development for the next two to five or more years. The master plan document is a vehicle for communication that clearly shows the long-term facilities objectives and the near-term development plans of the institution to all interested parties.

A well-developed master plan is a powerful tool in obtaining community, constituent, and legislative support of management goals and objectives. For this reason, the document must be easily readable, as well as technically complete.

The plan is a starting point for all future development and construction.

Techniques and Procedures

Successful master planning of facilities includes input from major constituents and facilities users, as well as senior management. The process of getting this input is important to ensure future support of the plan. In large institutions with diverse constituencies and facility users, formal meetings or hearings with these groups may be appropriate. This is especially important when public or quasi-public facilities are involved.

Managers and planners must control the input to avoid unrealistic expectations from constituents and users. Boundaries and guidelines for the input procedure must be presented to and understood by interested groups before input from them is received. The boundaries and guidelines are the anticipated financial limits of the future facilities development, the corporate vision and goals for the future facilities, and the legal and physical boundaries to facilities development. After corporate objectives, boundaries, and constituents are identified, user group inputs should be obtained.

Before the final plan is prepared, a conceptual plan that meets corporate objectives and constituent and user needs within the planning constraints should be developed and shared with all those who provided input. At this point, plan developers should seek buy-in concurrence from major users. The greater the buy-in and support at this stage, the better the chances are that the plan will ultimately be fulfilled.

Facilities Inventory

To properly manage facilities as assets, an accurate facilities inventory in a useful, conveniently available form is essential. Inventory methods include facilities maps, building plans, and documentation of infrastructure and building systems and equipment.

Facilities maps locate buildings, roads, parking facilities, and all other ground improvements and physical facilities. Maps should show topographical features and document significant trees, flower beds, historical structures, and other significant items. The mapping system should also locate and document all underground facilities and utilities, as well as property boundaries, easements, and right-of-ways.

Accurate building plans are essential for space management and compliance with fire and other safety regulations. Effective maintenance plans require a complete inventory and location of all building electrical, mechanical, and structural systems and a database for developing equipment histories. The Americans with Disabilities Act (ADA) requires that public spaces are accessible or a plan is developed to provide equal access to all programs and activities. Accurate building plans are essential for developing a comprehensive ADA compliance plan.

Geographic information systems (GIS) are computer-based systems that contain the complete facilities inventory and allow retrieval and presenting of information in several useful formats. These systems are built in layers starting with base maps and building plans, with consecutive layers that display additional information. Because these systems contain digi-

tized information and are stored in computer files, they can easily be updated and kept current. This is a powerful tool that allows exploring various alternatives during the planning and development process. A comprehensive GIS can combine all facilities inventory—including utility systems, property and real estate maps, underground infrastructures, ground topographical features and improvements, and building plans—into a single database.

GIS is a rapidly developing technology that should be considered for all facilities inventory and master planning.

Facilities Needs

Facilities master plans must be carefully linked to corporate and institutional planning. The facilities master plan should clearly indicate the facilities required to support overall corporate goals and objectives. These facility requirements should include prudent deletions from the facilities inventory, as well as additions and new construction.

The facilities master plan must be supported by the corporate business plan to achieve the institutional goals and objectives. The corporate business plan for a university may, for example, envision the expansion of medical research activities and the recruitment of a prestigious medical research faculty. In this case, the facilities master plan must address these facilities needs for expanded medical research facilities.

The facilities changes needed to support corporate goals, objectives, and strategies must be coordinated with the financial plan for developing these facilities. Although facilities master planning is frequently initiated independently of the corporate financial plan, the facilities master plan process will not be fully effective until it is supported by a capital financing strategy and plan.

The fully integrated facilities master plan must support the corporate mission and goals and should be closely coordinated with the corporate business and financial plans.

Design Guidelines

Design guidelines are not necessarily required for effective master planning, but they are essential for effective development and operation of facilities. Including them usually by reference in the master plan helps ensure their integration into the construction that is likely to result from the master plan. Design guidelines ensure consistency with institutional architectural concepts and compatibility with all building and infrastructural systems. Design guidelines document the architectural themes in various zones of the campus or grounds, ensuring that new facilities are consistent with the desired architectural themes. Standard elements such as streetlights, paving types, building finishes, and hardware should be detailed in these guidelines. Landscape details such as species of trees desired on campus or sections of campus should also be specified.

The design guidelines detail building systems that should be specified in all facilities. Such things as campuswide building automation systems, security, and lock and key systems should also be specified. Utility system details (especially local systems such as electricity, steam, or chilled water distribution parameters) should be clearly spelled out in the design guidelines. Central building automation and fire alarm and reporting systems must be clearly identified.

Building systems preferences such as desired roofing systems should be indicated in the guidelines. Proprietary systems in use, such as telephones and master keys, should be specified. Special performance requirements, such as high-reliability utility distribution system designs, should be included.

Many institutions have developed information systems requirements such as size and electrical requirements in telephone and computer/information systems rooms, closets, raceways, and outlets that should be included in the design guidelines.

A well-organized comprehensive design guidelines manual will eliminate many costly redesigns of new facilities and help ensure that user needs are met.

Need for Space Planning and Administration

Acquiring and owning or leasing facilities can be justified only by their value in helping meet the institution's missions and goals. Effective space planning and administration are essential if facilities are to optimally support the institution's mission and goals. Facilities are assets and like all assets must be carefully managed to achieve the desired return on the investment made in them. Space planning and administration are important in achieving this return on investment.

Space Utilization and Cost

Every organization has various space needs, which must be quantified as the first step in effective utilization. Administrative, classroom, laboratory, industrial, showroom/retail, and storage are some common categories of building space. Grounds areas can also be categorized by use. Parking, recreational, residential, storage, access, and "green" are some common categories.

All spaces have acquisition, operating, and maintenance costs associated with them, which should be quantified. Usually the owning and operating costs of buildings are expressed in dollars per square foot. When building space is categorized by use (administrative, research, production, etc.), facilities costs to support these functions can be quantified.

Development, Process, and Standards

To manage and administer building space effectively, an accurate inventory of space is required. The GIS and CAD systems discussed in master planning are effective systems for storing, organizing, and managing building space inventories. Space utilization guidelines allow space managers to make effective decisions for space allocation. These guidelines usually take the form of square feet per unit. For administrative space in categories such as clerical, supervisory, managerial, and senior managerial, standards are frequently expressed as square feet per person. These standards include circulation and support space for the individual person or workstation.

Space guidelines for common office support such as mail and reproduction rooms, conference rooms, and lunchrooms are not usually included in the guidelines for square footage per person. Separate guidelines for such facilities are frequently developed on the basis of the number of people served by the spaces.

All buildings have several categories of space, which should be identified and quantified for effective space management and administration. The following are the major categories of building space:

- *Gross square feet:* The total square footage of a building, including walls (interior and exterior), basements, mechanical, electrical, and other building support spaces, as well as lobbies, stairwells, and hallways.
- *Net square feet:* Usually gross square feet less exterior walls, mechanical, and other building spaces normally not accessible to building occupants.
- *Assignable square feet:* Usually considered net square footage less common areas such as lobbies, hallways, public restrooms, and so forth. This is sometimes referred to as *rentable square footage.*

Space planning and administration is primarily associated with management of assignable building spaces.

Space utilization guidelines should be developed for all categories of building space. The guidelines should be realistic and shared with all space users. Table 3.1.3-1, an example of space guidelines, is published by the Commonwealth of Virginia.

TABLE 3.1.3-1 Space Guidelines for State Agencies Leasing Real Property

Space type		Maximum area (square feet)	
Office space	Pay grade	Private	Open
Offices (excludes receptionists)			
Department or agency head	18 and above	256	
Assistant department or agency head	15–17	192	—
1st level administrator	13–14	168	96
2nd level administrator	11–12	144	96
Other	10 and below	120	64
Note: Field office personnel who are routinely out of the office 50 percent or more of the normal work week shall be restricted to 64 sf per person.			
Reception areas (including receptionist)			
1–4 visitors (peak)			240
Over 4 visitors add (per additional visitor, peak)			20
Conference rooms (per chair, peak)			
First 10		30	
All over 10		20	
Note: Conference rooms shall be shared among work units where possible to avoid excessive space requirements.			
Interview areas		80	80
Testing, training, or hearing rooms (per chair, peak)			
Seminar seating		15	
Auditorium seating		10	
Lounge/break rooms (requires prior approval of the Division of Engineering and Buildings)			
Equipment		60	
Plus (per chair peak)		20	
Furniture/equipment (except personal offices)			
Copier (freestanding)			25
Copy room (including copier)			50
Plan/flat file			25
Lateral file			10
Vertical file (letter)			10
Vertical file (legal)			12
Circulation (to compute total usable space)			
If the total office area is less than 50% open office space, add 25% to the office area.			
If the total office area is 50% or more open office space, add 30% to the office area.			
Note: the aggregate usable area shall not exceed 250 square feet per person without the prior approval of the Division of Engineering and Buildings.			

Application of Guidelines

After realistic space utilization guidelines have been developed, all inventoried space should be tested against the guidelines. Space utilization guidelines are guidelines, not standards, and considerable judgment is needed when applying guidelines to existing spaces. The guidelines, however, can be used as standards when new space is being planned, constructed, or leased.

Successful application of the guidelines requires good communication with all levels of management and with the individuals who occupy or will occupy the spaces in question.

When space utilization guidelines are used with design guidelines, they provide the means to quantify facility requirements during the master planning process. The result is an integrated approach to facilities planning and development that stands the test of meeting the facilities requirements to support the institution's mission and goals.

With accurate and readily available building and space utilization information in the facilities files, managers can build effective maintenance and energy management programs to support the facilities operations in the most effective manner possible.

Documentation and Updating Process

Automated files and GIS inventories make it feasible to update information systems continuously so that current inventory and facility utilization information is always easily available. A formal feedback process to the files is necessary to ensure that an accurate database is maintained. The feedback information is from the following three sources:

1. New construction and renovation information
2. Maintenance files
3. Space utilization and requirement surveys

All new construction and renovation "as built" information must be recorded in the GIS. This is easily done by requiring that construction and renovation designers and project managers provide digitized information as part of the project management and close-out procedures. Final payment to designers and contractors should not be made until such information is provided in the desired format.

As the preventive and corrective maintenance programs are executed, information about any equipment changed and/or replaced should automatically be provided to the facilities database managers. It is important that such information as roof, HVAC system, or electrical system component replacement be documented in the facilities files.

Space usage frequently changes as a result of staffing changes, production and office equipment upgrades, and changes in the work assignments of building occupants. Although most of these individual changes have minimal impact on facilities planning and management, the impact can be significant in aggregate and over time. For effective space utilization and management, these changes should be periodically quantified and compared to space utilization guidelines and building systems capabilities. This information will enable corporate managers to make space reassignments when appropriate and will be important for the continuing master planning process. A convenient method for gathering this information is an annual survey of space utilization that will allow space managers to document any changes in the preceding 12 months.

FACILITIES OPERATIONS AND SERVICES

Objectives

Facilities should exist only to support the institution's missions and goals. The mission of facilities management and operation is to maximize the benefit of all corporate facilities and ensure their continued benefit in the future. Facilities support the institution's goals by providing the most effective environment possible for the people, equipment, and processes that contribute to achieving the institution's mission and goals. Except for those exceptional facilities that have recognized historical or esthetic significance, facilities should be managed as

assets. Investments in these assets should yield quantified returns measured by increased productivity and positive effects on people who use the facility.

The public image of an institution is frequently reflected in its facilities. This is especially true of colleges and universities and other public institutions. Therefore, this image must be reflected in facilities planning, designing, and construction and also in maintenance and operations throughout the facilities' lives.

Because facilities exist to help meet corporate goals primarily through people who use the facilities, effective facilities managers view these people as valuable customers. Routine maintenance activity is more than facilities maintenance; it is customer service. Facilities operations and services include the following:

1. Preventive and corrective maintenance of all buildings and structural, electrical, mechanical, and communication systems.
2. Building services such as housekeeping and in some cases moving, package delivery, and other services.
3. Utilities such as electricity, water, steam, gas, chilled and hot water, and, where appropriate, compressed air and other piped gases. Grounds, parking lots, and all other property should be similarly managed.

Facilities maintenance and building and grounds services are usually overhead costs to the institution and subject to appropriate scrutiny at the corporate level. Therefore, the objective for facilities managers is to provide high-quality facilities services in the most cost-effective manner possible.

Customer Communications

Building occupants and users (customers) ultimately determine the effectiveness of facilities management and operations. Good customer communication with the facilities organizations is critical to good customer service. There are several levels of communication between facilities operations and customers. The communications pyramid (Fig. 3.1.3-1) shows the various levels of these communications. At the top of the pyramid are formal policies, directives, and instructions. This is the most formal level of communications, and communication with customers becomes less formal through the lower levels of the pyramid. However, the amount, intensity, and influence of communications on the effectiveness (or the perceived effectiveness) of the facilities organization increases as communications pass down through the pyramid. The most important communications frequently occur at the base of the pyramid. These communications between facilities management staff who directly provide services (housekeepers, air conditioning technicians, work reception clerks, etc.) and the customers who personally and directly receive these services have the most effect on daily operations and on the effectiveness of the facilities operation.

First-line supervisors and service providers are empowered individuals. They frequently work independently, not under direct supervision, in the presence of customers, and frequently perform tasks that require making judgments and decisions on the spot. First-line workers frequently deal with the concerns of frustrated customers, and in a very real sense they are the facilities management organization in the eyes of the customer at that time. Plumbers or multicraft maintenance persons responding to a call concerning a leaking sink may find anything from a dripping faucet to a flooded restroom. They are empowered to speak for the facilities organization, commit resources, and accomplish the task at hand either well or poorly. Empowerment is by default or through positive means.

Empowerment of first-line workers by default occurs when

1. They have not been given clear guidelines within which to work and make field decisions
2. Management does not keep first-line workers informed of organizational mid- and long-term plans and strategies.

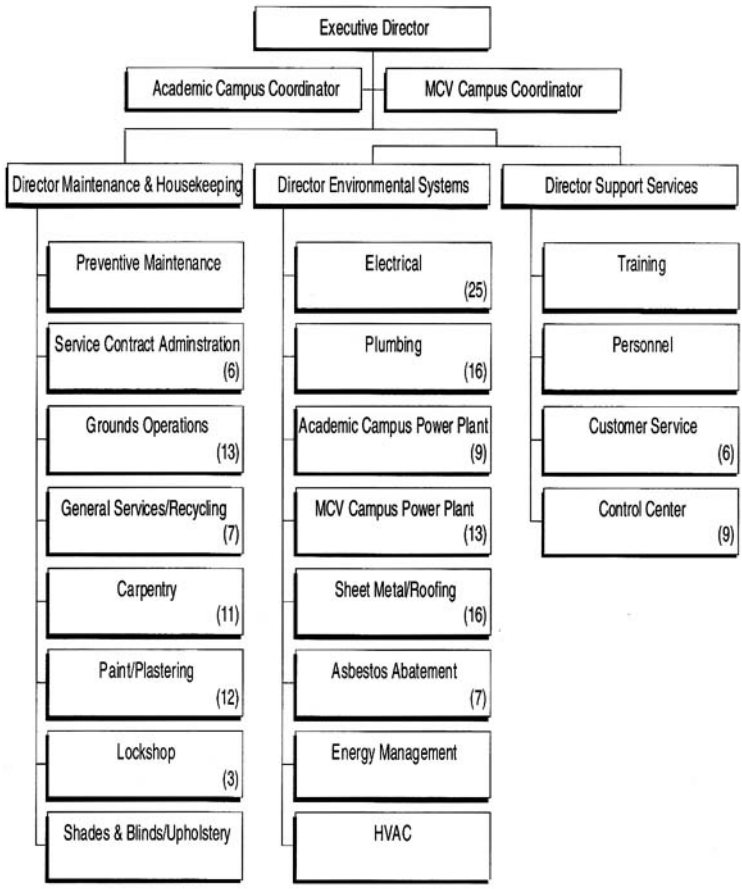

FIGURE 3.1.3-1 Traditional organization.

3. First-line workers have not received adequate technical training to deal with field situations.
4. An atmosphere of distrust exists between management, supervisors, and first-line workers.

When any of these conditions exists, the most likely results will be poor completion of tasks or at least the perception by the customer that the work is poor. Frequently the perception (and sometimes the reality) are that costs were too high. Empowerment by default can exist in any facilities maintenance service organization. Services provided by contract, as well as those provided by in-house forces, are equally subject to empowerment by default.

Because first-line workers are empowered when they are in the field, they must be *positively* empowered if the mission of facilities organization is to be achieved. Positive empowerment increases the probability that the field task will be completed correctly in a timely way and that customers will be satisfied with the results. Positive empowerment of first-line workers occurs when

1. They have a clear understanding of their responsibility and authority.
2. They understand the organization's goals and objectives, and especially the goals and objectives of their unit.

3. Workers are technically competent, have confidence in their ability, and have the proper tools and equipment to do the job.
4. They have confidence and trust in their supervisors and managers.

Training is essential for all facilities management personnel. First-line workers must stay current with developments in their profession, and in many areas such as plumbing, electrical, and air conditioning, they must keep licenses and certifications current. First- and second-line supervisors usually receive a considerable amount of training in managing the workforce and dealing with problem employees, OSHA, and safety requirements. These are the key people who interface daily with customers, and they should also receive training to develop and sharpen their skills in customer relations. From telephone etiquette to empathizing with customer concerns, these people have important interactions with customers and should receive formal customer service training.

Appropriate individuals should be encouraged to continue individual education and earn certificates and even advanced degrees that are work-related. Some tasks involving refrigerants and asbestos require certification before an individual can work with the products in the field. Electricians and plumbers should be required to take tests for and obtain journeyman and master licenses and certifications. Multicraft technicians should be encouraged to obtain all certifications applicable. Although certification is not required for many maintenance tasks, it gives a facilities worker credibility in the field and leads to a more competent workforce that is more likely to respond positively to field situations. When this is recognized, technical competence is complemented with skills in customer relations, customer satisfaction increases significantly.

Skills in customer relations are developed through formal training classes, teaching, and coaching by supervisors and managers. Telephone and other communication skills, appropriate personal dress and grooming, and trust and pride in the organization are all influenced for better or worse by the attitude and behavior of the first-line supervisor.

Many first-line supervisors and lower level managers were field workers before advancing to their current positions. Management must ensure that these individuals are properly trained to lead and empower their subordinates positively.

Middle managers frequently are required to deal with customer frustrations and receive compliments from customers. How well they deal with these situations will significantly affect the perceived quality of customer service in the organization. These individuals should also receive training in customer relations.

Control and Allocation of Resources

Capital construction is almost always specifically funded through direct appropriations, bond issuance, or some other quantified means. Obviously, adequate resources are identified, and fund-raising is specifically planned, or the project will not be completed.

Once construction is complete and construction contracts closed out, resources are required to operate and maintain the facility over its life. Depending on the life planned for the facility, it is not unusual for operating and maintenance costs to exceed construction costs. Some common methods of providing these resources include space rent, continuing governmental appropriations, facility user fees, increased corporate earnings, and benefactor endowments. Some of these, such as rent or lease revenue, are used frequently to service capital debt for the project and to provide resources for operations and maintenance. Predicting these costs can be challenging, especially when future periodic capital renewals and component replacement are considered. Superimposed on this demand for operating and maintenance resources are the possible additional requirements that may occur during the life of the facility. Ten or 20 years ago, few would have anticipated the cost of dealing with chlorofluorocarbons (CFCs) and ADA requirements. Because of these factors, many facilities managers do not have what they consider to be adequate resources to maintain and operate their facilities. As a result, decisions that affect allocations of operating and maintenance resources are con-

tinually being made, and frequently result in deferring maintenance items. It is estimated that in the United States the backlog of unfunded facilities maintenance at colleges and universities is $26 billion.

On a daily recurring basis, facilities managers are allocating resources by setting priorities for work to be done that affect the level of customer service or perceived service. Three broad categories of maintenance and operations compete for available resources:

1. Those that are immediately essential
2. Those required to protect the asset for its planned life and ensure continuous satisfactory facilities performance
3. Those required to maintain the desired level of customer service and satisfaction

Examples of the first category are utility services, elevator certifications, maintenance of building structural integrity, and operation of HVAC systems. Examples of the second category are preventive maintenance, basic housekeeping services, major component replacements such as roofs, air conditioning systems, and compliance issues such as NFPA and building code requirements. The third category may include painting, carpet replacement, higher level housekeeping services, flower bed maintenance, etc. The first category of expenses must occur if the facility is to open its doors and meet its basic function. Very few of these expenditures are considered at all discretionary.

The second category of expenditures allows some discretionary spending by postponing building component replacement or delaying compliance with some regulatory requirements. Generally these expenses can be delayed but not eliminated. Most of the maintenance backlog at colleges and universities falls into this category.

The third category of expenses is usually the most visible to building occupants and is the greatest source of expressed customer dissatisfaction. Allocation of resources between and within the second and third categories is one of the most difficult and at the same time among the most important decisions facilities managers make.

Facilities must be functional and attractive to the individuals who visit and work in the buildings and grounds, and adequate resources must be dedicated to this end. However, basic preventive maintenance and corrective maintenance, major repairs, and component replacement must all be accomplished when required to ensure that the facility is functional during its programmed life.

FACILITIES MAINTENANCE AND SERVICE ORGANIZATIONS

The traditional building maintenance organization at large institutions is made up of applicable trade shops. These shops include carpentry; painting; electrical; plumbing; and heating, ventilating, and air conditioning (HVAC). Additionally, specialty shops such as a locksmith, plasterer, roofer, signage maker, motor rewinding, electronics, and asbestos abatement may be included in the facilities organization. Housekeeping services, ground maintenance, and moving/general labor are frequently part of the facilities operations and service organization.

Many of these shops' functions, especially the specialty shop services, are obtained through contract services rather than from in-house shops. Whether contract specific services or to provide them using in-house staff is one of the most complex decisions made by facilities managers.

In general, consideration should be given to contract services if any of the following circumstances exists:

1. The specialty shop staff is not fully employed on a year-round basis doing specialty work. When specialty personnel perform a significant amount of work outside their specialty

areas, a close examination of shop operating costs will frequently reveal that the actual specialty work could be done more effectively by contract. Examples of this are motor repair and rewinding, furniture repair and refinishing, asbestos abatement, and in some cases, air conditioning and refrigeration repair.

2. Rapidly changing technologies require a continuous reinvestment in specialty training and diagnostic equipment. Examples of this are building automation and HVAC controls, elevator repair, and sign making.

3. Low technology, labor-intensive operations are being performed by people with significant longevity. Some examples of this are housekeeping/janitorial services and routine grounds care. In many of these cases costs will be much higher than with vendor-provided services.

Although many companies provide full-service facilities management services, ultimate management responsibility cannot be contracted out and must rest with the institutional administration. Large institutions with diverse and complex facilities often require a stable, dedicated workforce with intimate knowledge of the facilities to provide the high level of dependable customer service and responsiveness expected. It is more difficult to obtain this level of service from vendors. For these reasons the best mix of vendor-provided and in-house-provided maintenance and building services is difficult to determine.

Zone maintenance is an organizational concept that focuses on the whole building or facilities maintenance and operation rather than on specific systems and components (electrical, plumbing, etc.). This organizational concept is gaining wider acceptance in facilities maintenance and building services. The zone maintenance organization consists of multicraft, skilled facilities maintenance teams responsible for all aspects of facilities and maintenance in a relatively small number of buildings. The team is staffed with multicraft technicians to perform routine preventive and correct maintenance. The team leader is responsible for all facilities maintenance in the zone and has access to specialty shops or vendors, as required. The team leader is responsible for routine maintenance budgets and expenditures. The zone organization replaces the institution's carpentry, electrical, plumbing, paint, and HVAC shops. Specialty services such as roofing, locksmithing, and elevator maintenance are procured as needed by the zone maintenance team leader. These services may be procured from the in-house specialty shops or from vendors. This concept employs traditional competitive market forces to assure high-quality, cost-effective services.

Figure 3.1.3-1 (shown previously) is a typical facilities maintenance organization for institutions with 150 buildings and 4 million gross square feet of space. Figure 3.1.3-2 is an example of a zone maintenance organization for the same size facilities.

Facilities rarely exist in their own right. Most exist to provide an environment in which people pursue their organization's mission and goals. Therefore, facilities managers must understand and respond to the needs of building users in the most cost-effective way possible. In manufacturing and other productive facilities, it is relatively straightforward to define the facilities environment that enhances the production mission and the facilities' unit cost of output can usually be reasonably quantified. In an office, academic, or service environment where the organizational missions and goals are pursued by individuals with fewer measurable output units, it is more difficult for facilities managers to identify and quantify cost-effective facilities management strategies. In this people service environment, facilities managers must establish good communications with facilities users to understand their facilities needs and educate them regarding building and facility capabilities and limitations, as well as the cost of providing the facilities environment in which they function. Because people service organizations do not frequently measure unit output and even less frequently the cost associated with this output, it is difficult to quantify facilities cost per unit of output meaningfully.

In large institutions with many buildings spread over a campus, customer coordinators are frequently employed to optimize the effectiveness of the facilities organization. Customer coordinators are members of the facilities management organization whose task is to help building occupants and users obtain the most effective service possible. Coordinators cham-

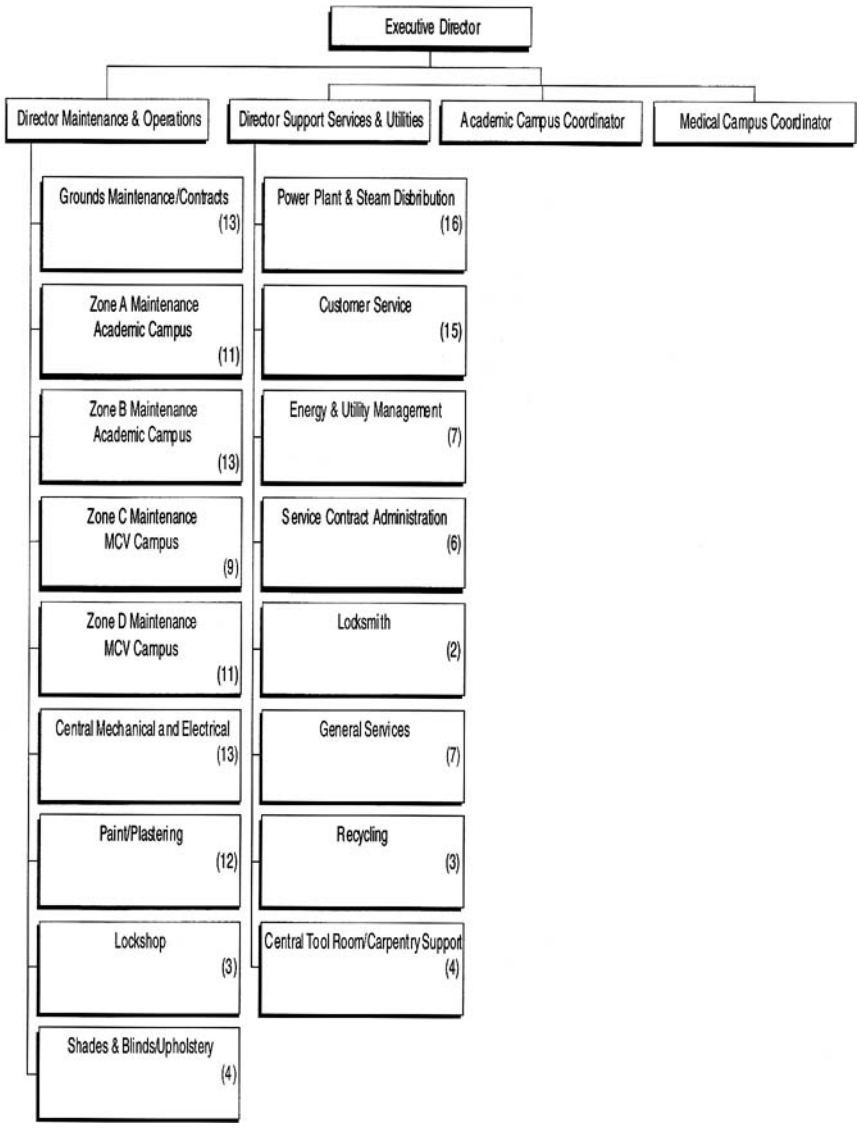

FIGURE 3.1.3-2 Zone maintenance organization.

pion the building users' needs in the facilities management organization and ensure that the individual requirements of building customers are addressed in the facilities management organization. The coordinators educate building users concerning reasonable expectations, limits, and capabilities of the building systems and facilities services organization. Effective customer coordinators maximize the effectiveness of the facilities maintenance and service organization in meeting individual customer requirements.

In a multiple-building campus environment, building managers should be established to work with customer coordinators and expedite communications with the facilities manage-

ment organization. The duties of building managers are collateral duties assigned to an administrator or a business manager of the principal department or unit that occupies the building. The duties of the building manager include the following:

1. Being the principal contact for reporting building systems problems to the facilities management organization
2. Being the principal contact for facilities management to disseminate information to the building occupants concerning such things as utility shutdowns and renovations and design work schedules that may affect building occupants

Building managers and customer coordinators must develop a continuous dialogue that greatly helps in the process of delivering effective facilities maintenance and building services.

Budget and cost management is critical for facilities managers in most effectively providing the best physical environment for building users. After capital investments and construction are completed, realistic budgets must be developed to preserve the facility for its programmed life and to provide the maintenance building services to optimize customer satisfaction in the building. Most facilities are maintained and operated on the basis of an annual budget. Funds for this budget may be appropriated from central sources or may be from rental or lease charges or other sources. Budgets should be identified in each of the three categories that compete for resources as previously discussed. Deviations from this budget plan should be minimized and made very thoughtfully. Such deviations usually result in diversion of resources from basic maintenance to customer desire, and discretionary projects increase the deferred maintenance backlog of the facility. Budget and cost accounting systems should clearly document such diversions, and senior management must address the issue to prevent large increases in deferred maintenance.

Work order systems that are integrated with cost accounting systems will automatically accumulate cost against specific budget line items. Standing and open work orders should not be used. All maintenance and service work should be on specific work orders and should clearly identify the work to be accomplished. Even routine work such as housekeeping services should be accumulated specifically by building, and for large, complex buildings, by subcategories of the building. First-line productive workers should account for all of their time every day against specific work orders. Overhead functions and activities such as training time, allowed time, leave, and tool costs should be accumulated into overhead accounts. Contractual service costs should be accumulated on specific work orders in the same way. Such a system allows management to review organizational cost-effectiveness and to compare it to benchmark costs. Commonly used benchmarks are building maintenance costs per square foot for different categories of space, housekeeping cost per square foot, and overhead cost as a percentage of direct cost.

Facilities Maintenance

Refer to Chap. 7 for several detailed facilities maintenance articles that will complement the following overview. Preventive and predictive maintenance are central to any effective maintenance program. *Preventive* maintenance includes any scheduled maintenance effort that improves the serviceability and dependability of building systems. Preventive maintenance includes periodic maintenance work recommended by equipment manufacturers that ranges from changing filters to periodic equipment overhauls. It also includes exercising and operating equipment such as emergency generators and switchgear on a scheduled basis. *Predictive* maintenance includes examining and analyzing equipment and components to predict specific maintenance or component replacement to reduce the probability of failures. Such activities range from basic tasks such as visual inspection of drive belts and couplings to more sophisticated testing such as current analysis of heat exchangers in boilers, chiller tubes, and drums. Predictive maintenance is included with preventive maintenance when air filters are changed based on measured air-pressure drops across filters and when experienced mechan-

ics decide to adjust the tension on drive belts based on visual and audio observation of drive systems while they are operating. Therefore, preventive maintenance usually includes elements of predictive and preventive maintenance.

A basic automated preventive maintenance (PM) system schedules this work, estimates the task time required, produces detailed work orders, tracks costs, and produces backlog reports of completed PM work. More sophisticated systems will schedule PM work, taking into account manpower availability and production or building schedules; will develop equipment maintenance cost analysis; and will manage inventories of spare and replacement parts. These systems will manage all preventive and predictive maintenance activities from daily visual inspections to multiple-year equipment overhauls. Data from these systems provide a quantified basis for capital replacement programs and predict manpower and equipment needed to maintain equipment most effectively.

All dynamic equipment from sump pumps to elevators and emergency generators should be maintained on a PM system. Equipment such as door closures, piping and plumbing valves and devices, switchgear, panel boards, transformers, and other building system components should be on a PM system to assure maximum system dependability. Roofing systems should be included in the PM system to ensure that rainwater drainage systems are clean and functioning properly and that water is not penetrating roof membranes.

Corrective maintenance is activity to correct malfunctioning or broken system components. This work is frequently identified by building occupants when an obvious failure occurs. Too-hot and too-cold calls, information regarding plumbing or roof leaks, and complaints regarding burned-out lights and doors not closing properly are examples where building occupants identify the need for corrective maintenance. An effective PM program will minimize the need for corrective maintenance, but a responsive service call system is required to meet customer requirements for corrective maintenance.

Scheduled maintenance includes planned work that is usually included in periodic work plans and budgets. This includes scheduled painting, major roof repair or replacement, and replacement or overhaul of other major building system components. When scheduled maintenance and preventive maintenance are not completed as planned, the need for corrective maintenance increases, and eventually a backlog of maintenance requirements accumulates. This deferred maintenance will eventually require major building reinvestments and replacement of building systems. Deferring maintenance when building components are scheduled to be upgraded or replaced in the near future because of service code or other external requirements is the only legitimate reason for allowing deferred maintenance to accumulate. Examples of this include HVAC systems that have exceeded planned life and are scheduled to be replaced with more energy-efficient systems using non-CFC refrigerants, and planned replacement of roofing systems with better insulated systems and modern roof membranes. Except in the case of such planned replacement, deferred maintenance should be minimized.

The Facilities Condition Index (FCI), discussed in detail in Art. 3.1.2, is a measure of the general maintenance condition of a building. It is expressed as a percentage calculated by dividing the total estimated cost of deferred maintenance by the replacement value of the building. An FCI of 5 percent or less is an indication of a properly maintained building. An FCI of 5 to 10 percent indicates that additional maintenance and repair effort are needed, and an FCI of more than 10 percent indicates that the facility is generally poorly maintained and requires a significant reinvestment.

Building Services. From the perspective of a customer and building occupant, housekeeping services are part of facilities services. To be most effective, housekeeping services should be integrated with building maintenance systems. Housekeeping services are frequently provided after normal working hours and provide an excellent opportunity for spot relamping and monitoring of building and security lighting systems. The housekeeping staff can very effectively document and report building system malfunctions ranging from improperly operating door closers to restroom plumbing leaks and malfunctions. When housekeeping operations are integrated into the building maintenance effort, total building services are improved. Refer to Art. 7.1.4, "Environmental Services," for a more detailed discussion of these issues.

Next Page

Solid waste management and recycling operations are most effective when they are part of the integrated facilities services system. The housekeeping staff can perform initial separation of recyclable material at the source. This is especially true for office paper and discarded cardboard. By making best use of freight elevators, loading docks, and spaces normally managed by facilities maintenance operations, solid waste and recycling effectiveness can frequently be significantly improved.

Relocation, moving, and storage services within a building are frequently part of the integrated facilities service system. Most administrative classroom laboratory and medical facilities require frequent relocation of furniture and equipment. To be most effective, these services require close coordination with facilities management, and many building services such as minor painting, electrical outlet relocation, and so forth are part of the complete moving and relocation service for the facility's users.

Minor space renovations are frequently associated with moving and relocation. These renovations should be managed by the facilities maintenance organization to ensure continued compliance with building and fire codes. To provide good, cost-effective facilities service to building occupants, such minor renovations should be integrated into the facilities management systems.

Modern building security involves locking, lighting, and monitoring systems, as well as physical security. Electronic locking systems using various sensing technologies provide a high level of access control and a wealth of security and access control information. To function most effectively, these systems require that doors and door hardware operate properly and that the building emergency power supply is dependable. Good maintenance of the associated building systems is essential to the best operation of these security systems.

Lighting systems, security cameras, and other security devices require dependable building support systems. Therefore, to be most effective, these systems should be part of the integrated facilities management systems.

Utilities. Management of building utilities is an important part of the integrated facilities management process. Utilities often represent a large part of the cost of building operations and maintenance or housekeeping. Modern lighting systems and related controls, automated building management systems, and efficient, optimally managed and operated heating and cooling systems can reduce utility costs significantly. Refer to Sec. 5.5, "Instrumentation and Control Systems," for a detailed treatment of these instrumentation and controls systems.

Facility managers must understand utility and energy markets in order to procure electricity, natural gas, and fuel oil at the lowest possible cost. Refer to Art. 7.1.6, "Fuel and Energy Procurement," for a detailed discussion of this topic. The electric power industry restructuring will offer challenges and opportunities for facilities managers to manage energy procurement more cost-effectively. Natural gas markets have been deregulated in most areas for many years, and facilities managers have considerable flexibility in purchasing natural gas. Where possible, the use of natural gas and fuel oil should be integrated to obtain the lowest BTU cost of energy while ensuring a dependable supply of fuel. Facilities managers would have access to contractor and other physical plant technical support on a reimbursable basis, as required.

- A central electrical mechanical team would manage and provide maintenance for large chilled-water generation systems, large electrical switchgear, fire pumps, emergency generators, and elevators.
- A central support shop with lock shop, roofing, asbestos abatement, and other trade and craft capabilities would be available to support the zones on reimbursable basis, as needed.

Lighting technologies offer many opportunities to reduce lighting costs while improving the quality of light for building users. Some frequently used technologies include converting fluorescent lighting systems from T-12 tubes with magnetic ballast to T-8 tubes with electronic ballast; the use of compact fluorescent bulbs in lieu of incandescent lamps; the use of metal highlight lights and geometric reflector systems; the use of motion and ambient light sensors to switch and dim lights; and integration of lighting systems with building automation systems. Section 5.3, "Lighting Systems," offers a detailed presentation of these issues.

Copyright © 2001 Knovel Retrieved from www.knovel.com

HVAC technologies include high-efficiency chillers and cooling towers, high-efficiency dual-fuel boilers, thermal storage, variable-volume air flows, variable-frequency drives for fan and pump motors, the use of premium efficiency electric motors, and sophisticated building automation systems. Sections 5.4, "Mechanical Systems," and 5.5, "Instrumentation and Control Systems," provide further information on these subjects.

The U.S. Department of Energy sponsors energy star and green light programs to encourage conversion to and use of energy-efficient building components and systems. These programs provide a clearinghouse for information and efficient energy technologies, offer training and education programs about these technologies, and publicize companies and institutions that reduce and manage energy usage.

As the electric power industry moves toward deregulation and competition, facilities managers must position themselves and their companies and institutions to take advantage of the deregulated environment. The pace and details of deregulation vary from state to state, and facility managers should understand how deregulation will affect the electric power industry in their states.

Facilities managers should be familiar with the various rate schedules available to them from their local electric power companies and ensure that electrical energy is purchased at the most favorable rate or rates available.

Natural gas markets have been deregulated for several years, and larger users of gas usually have several options for purchasing natural gas. Dual-fuel boilers using fuel oil and natural gas give the facility manager considerable leverage in negotiating natural gas prices with gas producers, interstate pipeline companies, and local distribution companies (LDC). Some large users can effectively purchase natural gas at the wellhead and pay interstate pipeline companies and LDCs to transport natural gas to the boiler considerably more economically than by direct purchase of natural gas from the LDC. Having the dual fuel capability may also allow negotiation of gas prices directly with the LDC. When dual-fuel boilers are used, it allows facility managers to purchase interruptible gas service at lower rates when they agree to switch to fuel oil at times of extremely high regional or local natural gas demand. When world oil markets are depressed, these depressed prices give additional leverage when negotiating with gas suppliers and LDCs.

Natural-gas brokers are available to help users purchase natural gas at the most favorable prices. When the electric power industry is deregulated, similar opportunities are likely to exist in the purchase of electrical energy.

In some regions and localities, high water and wastewater rates provide an incentive for reducing water consumption and justify investment in water-saving devices. Some localities require water use reduction or other restrictions, adding further justification for controlling water usage and consumption.

Reduced-flow toilets, faucets, and showerheads are available and should always be considered when replacing existing devices. Separate metering of cooling tower makeup water and irrigation water should be considered when wastewater charges are based on water usage. The responsibility for water reduction strategies varies widely with local conditions and regulations but should be considered in integrated management strategies.

Dependability and the need for alternate and backup utilities should be considered in integrated facilities strategies. The use of emergency generation, dual-fuel boilers, alternate electric feeders, and water storage or wells are common strategies to ensure dependable utility services for critical buildings.

SUMMARY

Facilities should exist only to support an institution's or company's mission and goals. A few facilities, such as historic buildings, may exist in their own right. But even these facilities should be integrated into the institution's mission and goals.

Master planning is the process of identifying and quantifying the facilities required and outlining a strategy to acquire and maintain these facilities. Space planning and administration is the process of effectively and efficiently utilizing the facility assets of an institution. Facilities operation is the process of maintaining and operating the facility to the maximum continuing benefit of the institution and its constituents.

Facilities operation is the process that includes facilities maintenance; building services such as housekeeping, moving services, and renovations; and dependable utility services. It is the responsibility of facility managers to provide these services to building users in the most cost-effective manner possible.

Investment in facility assets can be justified only by the return on investment. The return is in the form of a physical environment that facilitates the accomplishment of the institutional mission. Tools to measure this return include facilities investment, operating cost per unit of output, and user satisfaction with facilities services.

ARTICLE 3.1.4
BUILDING LIFE CYCLE— AN INTEGRATED APPROACH

Bart D. Bauer, P.E.
CID Associates, Boston, Massachusetts

Kenneth H. Stowe, P.E.
George B.H. Macomber Company, Boston, Massachusetts

A NEW WAY OF THINKING

Facilities professionals have the opportunity to make profound contributions to their companies when they find ways to contribute *at every phase* of their buildings' life cycles. This can be accomplished by taking an *integrated approach* to the building life cycle—making decisions and taking actions in one phase to improve overall performance in many others. These facility professionals are promoting and defending a philosophy—that every facility investment should produce maximum value. This article focuses on the vital need to consider all phases of a life cycle when investment decisions are made. Some call it "right-to-left thinking."

The need of forward-thinking corporations in the recent past and in the far-reaching future has been and will be to minimize the effects of facility costs on the bottom line. This is accomplished by striving for optimal value from every facility. The well-informed facility manager has the opportunity to participate in value-related discussions at the boardroom level and provide the understanding and information to maximize the facility's value. Maximizing the long-term service of a facility and minimizing its long-term costs generate optimal facility value. The service of a facility is expressed in intangible forms as

- Operational productivity
- Aesthetic value or public image
- Comfort
- Flexibility

The costs show up in these tangible forms:

- Construction capital cost
- Energy costs
- Maintenance and repair

WHAT IS AN INTEGRATED LIFE-CYCLE APPROACH?

The integrated life-cycle approach has one fundamental tenet—that experience at every phase is valuable and that the wisdom gained from many professionals over many phases must be considered.

Reengineered Systems

The enlightened facilities professional solicits input from many experts involved in all aspects of the facility. For example, the design team should receive consistent and mature input from operations, maintenance, construction, and procurement. Input from these areas of expertise ensures that design decisions are not made in a vacuum—achieving short-term goals but sacrificing efficiency in other aspects. Collecting, processing, manipulating, organizing, and presenting the data that are levered into position at the boardroom table are the facility manager's responsibility. The pieces of facility data may have been collected individually for years; the power that the new facility manager has is in combining those individual pieces into a cradle-to-grave facility picture that is all-encompassing.

Similarly, the modern builder is collecting vital electronic as-built computer-aided design (CAD) information, photographs, and testing and manufacturing data during the construction phase for efficient use during operation and maintenance. Changes to the facility during operation are documented in up-to-date CAD libraries to facilitate the design of a future renovation.

Other examples of life-cycle approaches include:

- Integrating the CAD approach
- Investing for flexibility—structure
- Investing for low maintenance and operating costs
- Designing for low maintenance and operating costs
- Designing for the owner's philosophy and risk preferences
- Involving participants from other aspects for decision making

There is additional power in leveraging available technology. During the last 15 years, technology has been used to collect and analyze individual pieces of data, and the technologically literate facility manager could use individual computer applications to prepare presentations based on those individual pieces of data. The additional power of this new integrated approach is found in leveraging the ever-growing body of computer applications, to combine and synchronize data from one application to the next to create models that work across all phases of the building life cycle. An example of this approach is the three-dimensional computer-aided design and drafting (CADD) model that has color references to tie into a schedule, that the architect uses for presentations to the client, that the estimator uses for true quantity takeoffs, that the facility manager uses as living as-builts, and that allows all of the design engineers and construction trades to prepare true, coordinated drawings highlighting physical and scheduling conflicts long before the materials are on-site for installation. Space planners and marketing staffs can use this three-dimensional model to sell the space in the building and an architect

retained to perform tenant fit out as the space turns over throughout the life of the building can use it. Although this example uses CADD as the leveraged tool, the application of technology is not limited to a single computer application or program. Rather it is the combination of the programs and the use of the programs output at all levels and phases that more closely defines the use of technology in this new leveraged way of thinking.

The nature of the facilities professional's challenge is that there will be conflict when decisions are made, and decisions about life-cycle value are no exception. This article is designed to equip you with an approach to facilitate the decision-making process, so that your personnel can reach agreement and communicate decisions in a compelling way.

The Phases of a Facility Life Cycle

The phases of a facility life cycle (see Fig. 3.1.4-1) are as follows:

- *Definition of need*—documenting specifically how an existing facility no longer serves as an optimally functional space for the intended use, and understanding the reasons (e.g., shortcomings or functional failures). Additionally understanding the requirements of a new way of doing business and what those requirements will be into the future use of the building. (This phase is often combined with the program phase into one large phase.)
- *Program*—A set of owner/occupant-defined guidelines or specifications that reflect how the needs defined in the previous phase can be met by a facility. A designer uses these guidelines to set goals with which to guide the process of designing a facility.
- *Design*—The collaborative, creative process that produces a set of documented instructions, both written and diagrammed, that address the program requirements and are used to build a new facility or renovate an existing one.
- *Build*—Procuring, expediting, and constructing the building components to produce the physical entity that was specified in the design phase.
- *Operate/maintain*—The process and time period when the owner-occupant is using the building for its intended use and is doing the upkeep.
- *Decision phase*—The analysis of options leading to a decision to renovate a facility or choose the "end-of-useful life" option. This phase is reached when the overall cost of using a building equals or exceeds the value received from the occupancy or the value of building a new facility in its place. This decision requires reentry into the facility life cycle either through a total renovation of the existing facility or construction of a new one.

These phases and their associated costs make up the life cycle of a component of a specific building, a group of components of a building system, a facility as a whole, a group of facilities that comprise a campus, or a group of facilities scattered on sites across the globe that is owned and operated by a single organization.

Communication

The key to the new integrated approach is achieving a global view. The global view encompasses all stakeholders—all critical players at all phases of the facility life cycle. The methodology to realize this and to achieve success is communication among all the stakeholders. All stakeholders must be involved early in the process and remain engaged throughout the entire life cycle. Lessons learned and life experiences are the conduit for the value realized from the integrated approach.

The stakeholders include the owner, bankers, limited partners, architect and engineers, contractor, estimators, production management personnel, and subcontractors. Critical to the success is the involvement of the tenant and the building maintenance team. All of these

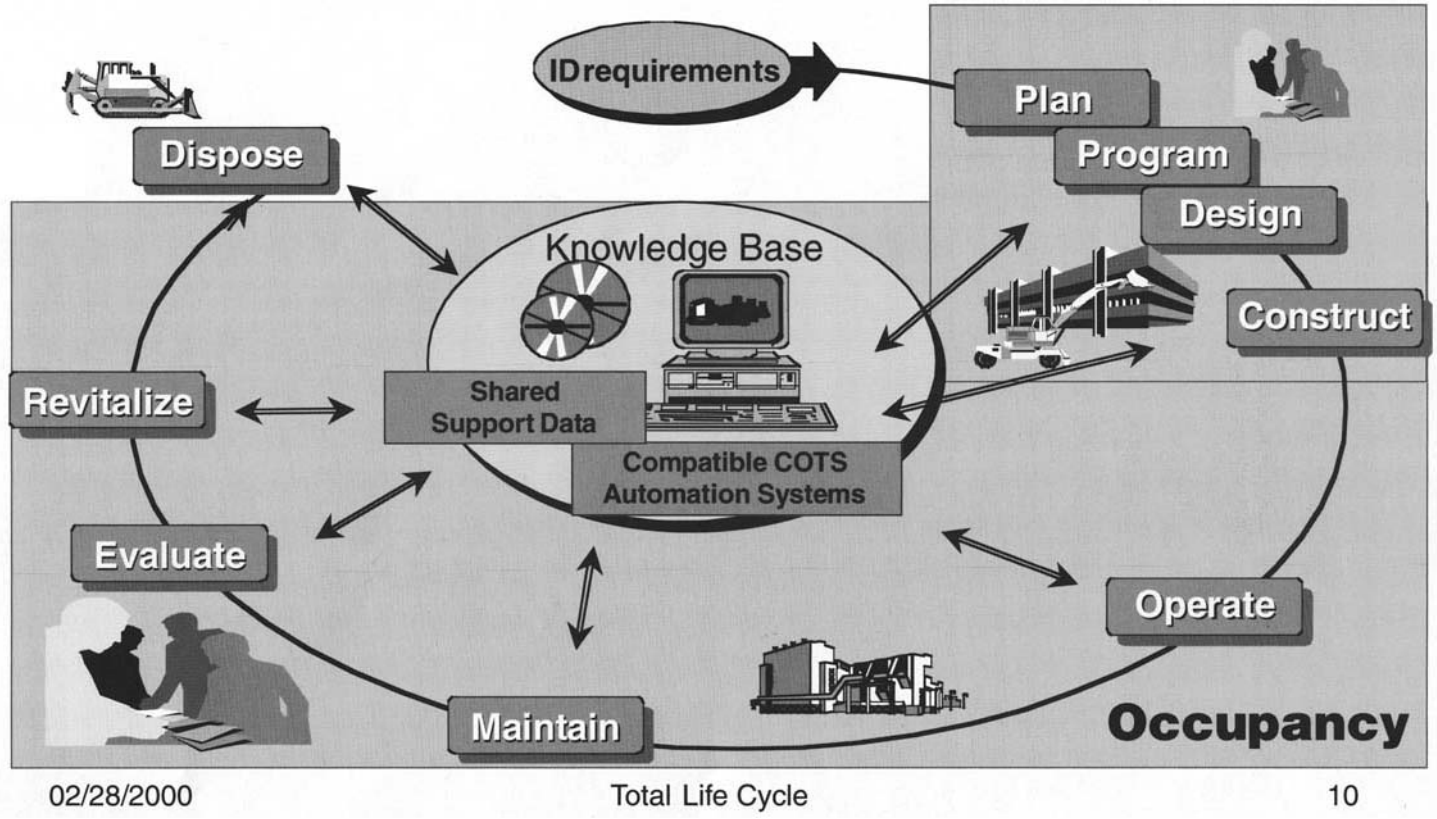

FIGURE 3.1.4-1 A facility life-cycle model. Information collected by many people can be useful during many phases. (*Courtesy of Bart D. Bauer, P.E., CID Associates, and Kenneth H. Stowe, P.E., George B.H. Macomber Company.*)

stakeholders must be involved in the process at the earliest possible moment. Why? Let us revisit the one tenet of the integrated approach—"That experience at every phase is valuable and the wisdom gained from many professionals over many phases must be considered". The combined value of all of the wisdom and knowledge will create the closest-to-perfect facility imaginable. This wisdom appears in many forms when the opportunity is presented to all of the stakeholders:

- The contractor shares in the planning phases with realistic estimates and schedules that come from real-world experience.
- The maintenance team ensures that the products and materials are compatible with the staff's knowledge and experience and are durable and maintainable with the user group in mind.
- The architect is a working member of the team, rather than an adversary, and participates with the contractor and subcontractors to find and resolve conflicts preemptively.
- The owner presents a fully coordinated team and project to investors, and the project team can respond to the owner's concerns about time, scope, or money because all of the team members are aware of the project restraints.

The earlier in the process this wisdom is shared, the more value the wisdom has. The more value the wisdom, the less likely that the project team will spend time on costly tangents with no real chance of success. The less time wasted, the faster and more efficiently the facility is produced, reducing financing costs to the owner, general condition costs to the contractor, and allowing the design team to move on to the next project. So, there is a direct financial benefit to all the stakeholders who participate in an integrated approach.

The integrated approach is not something that requires a Ph.D. in computer technology. Any project team in any corner of the world can adopt advanced communication strategies. Project teams can be formed, and work together around a conference table or a pile of sand and share wisdom. As project teams become broader and more disciplines and areas of expertise are introduced, they no longer center geographically around the client's home office, and as the team members are selected for their expertise, not their geographic office locations, computers can be used to make these distances and logistical problems disappear. Transferring CADD files over the Internet, videoconferencing, redlining drawings from remote facilities, e-rooms, and bulletin boards are all tools that facilitate an easier implementation of the new integrated approach. Additionally, the power and speed of computer technology allows for fast and accurate generation of different scenarios such as different phasing plans, floor plan layouts, and schedule priorities. The power of the technology is also used by combining applications, such as linking the schedule, the budget, and CADD drawings, so that each is updated by the mouse stroke in the other application.

Life Cycle Costs—The Story

For any facility produced in the modern age, the overall financial picture of life-cycle costs throughout its life can generally be grouped in the following six broad categories:

- Design, or *soft* costs
- Initial construction, or *hard* costs
- Indirect expenses
- Operating and maintenance expenses
- Capital replacement costs for replacing building components
- The cost of money, or the interest paid on the monies expended

According to Alphonse Dell'Isola, author of *Value Engineering: Practical Applications,* during the life of a building, these costs break down into the percentages shown in Fig. 3.1. 4-2 (see Ref. 1).

Every facility and every facility operational system is comprised of individual components. All of these individual components have varied but fixed life expectancies, usually referred to as *expected useful life* (EUL). A well-designed project will have facility and system components whose life expectancies complement other related building components or the owner's maintenance philosophy. An example of failing to integrate the components of a building system would be the use of polyvinyl chloride (PVC) masonry flashing that has a short (5 to 10 year) life expectancy in a brick wall that has a 75 to 100+-year life expectancy. An example of building components that can be integrated with the philosophy of an owner who is a long-range thinker and wants to lower the cost of life cycle maintenance would be the use of masonry for exterior sheathing. If, on the other hand, the owner has a short-range financial focus, then maybe an exterior insulation finish system (EIFS) that has a 15-year life expectancy would be used.

During the course of a system component's useful life, there are costs associated with it. These costs are generally divided into initial purchase costs (which is a component of the overall facility construction budget), operating and maintenance costs, and finally capital replacement costs (see Fig. 3.1.4-3).

The operating and maintenance costs of building components can be generally divided into routine and nonroutine maintenance and capital expenditures. As an example, the routine maintenance costs for a HVAC system may include preventive maintenance such as replacing filters. The nonroutine costs include replacing a belt when one breaks, or recharging the refrigerant. Capital replacement may be the replacement of the compressor. In a facility design that is well integrated, both routine and nonroutine maintenance can be predicted and will be evenly spread out over the expected useful life of the building.

At each capital expenditure, a decision process is undertaken. The facility manager questions whether there is still value in renovating the unit by replacing the belt. In this case, the belt is definitely a small cost compared to the cost of replacing the entire machine. When a compressor breaks down and needs to be replaced, the decision process is again visited: Is the

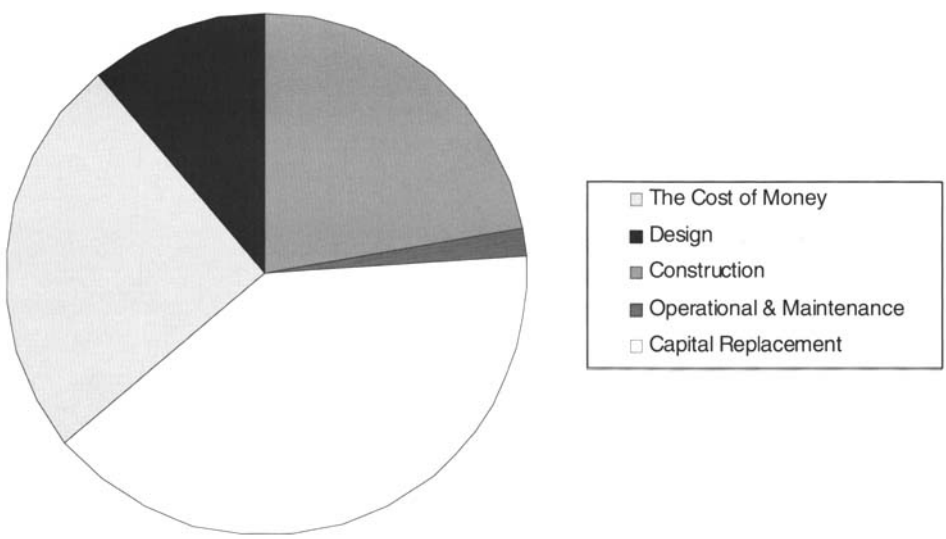

FIGURE 3.1.4-2 Distribution of expenses. Cost breakdown for a facility's life cycle. (*Courtesy of Bart D. Bauer, P.E., CID Associates, and Kenneth H. Stowe, P.E., George B.H. Macomber Company.*)

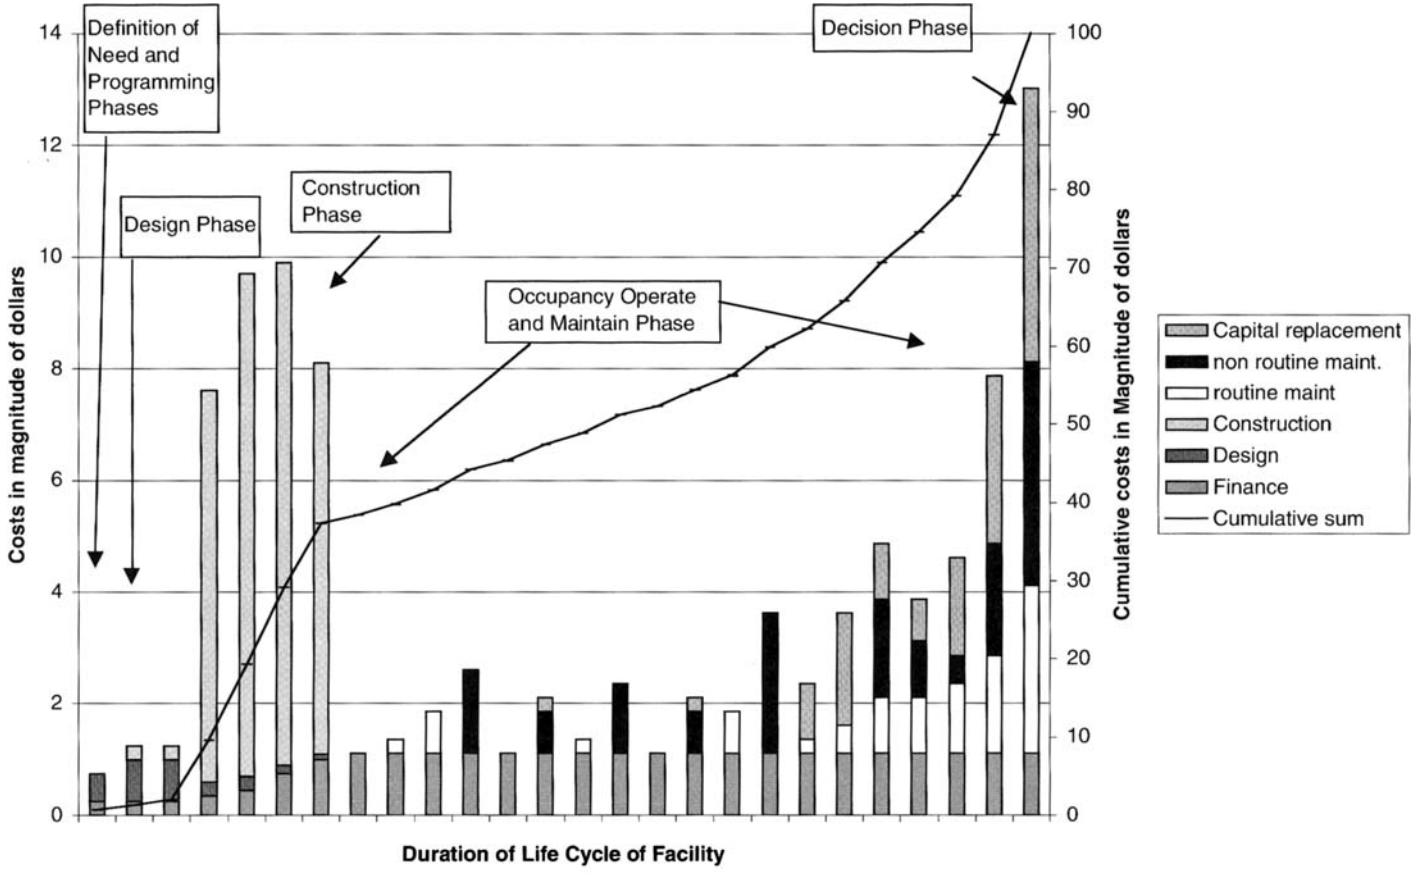

FIGURE 3.1.4-3 Distribution of costs during a facility's life cycle. (*Courtesy of Bart D. Bauer, P.E. CID Associates, and Kenneth H. Stowe, P.E., George B.H. Macomber Company.*)

cost of the compressor equal to the replacement or the value received from the entire unit? No. Therefore, the unit is renovated again. When the compressor breaks down again, and the belt is worn and frayed, the case in which the unit is housed is rusted and can no longer keep the weather out, the fan blades are rusted, the bearings need to be replaced, and the motor needs to be rewound, then the final decision phase is reached: Should the unit be replaced or totally rebuilt? This is the end-of-life decision that is the last phase of the life cycle.

No matter, however, whether the focus is short-range or long-range or whether the facility is well integrated, it eventually reaches a point of diminishing financial returns. Then it becomes worthwhile to evaluate the alternatives of building a new facility. This decision is based upon the cost effectiveness or the return on an investment to replace major pieces of capital equipment versus investing those monies in a new facility. This is potentially the final stage of a facility's life cycle.

In our HVAC example, all of the previous costs have covered work and parts within the confines of the original box and cover. No matter how many times those internal components are replaced, there is a point at which the basic structure of the HVAC unit decays and must be replaced. This is a major capital outlay. Before this time, an analysis may have determined the cost-effectiveness of repair or replacement, but once this major structure has deteriorated, a major capital outlay is the only option. The facility manager can choose to buy a new unit or to totally rebuild the current unit.

No matter what the life expectancy of a facility, whether it is a masonry building with a 100+-year life expectancy or a building with shorter life-span components, there is a time at which that facility reaches the end of its useful life. This does not mean that the facility is standing one day and collapses the next. Rather this is the point at which the majority of the major systems require considerable capital maintenance; routine maintenance has grown in scope and costs; and nonroutine maintenance has occurred so frequently that it is bordering on routine. This point in a well-integrated facility project can be predicted on the basis of an understanding of escalating maintenance costs, end of useful life (EUL) of the major components, and the usage and related physical depreciation of the facility. That escalating expense is shown in graphical form in Fig. 3.1.4-3. A conscious decision must be made at this end-of-life point.

Based upon philosophy, facility performance, capital funding, and risk and benefit analysis, the options presented are to renovate the existing facility or move and build a new facility. There are benefits and consequences to each decision, as shown in Table 3.1.4-1.

If the decision is made to renovate the existing facility, then the facility manager and owner essentially have the opportunity to reenter and start the life cycle over again. Needs are

TABLE 3.1.4-1 The Decision to Renovate or Build New

Decision	Possible benefits	Possible negative consequences
Renovate	These are discussed in chapter 6, and include the following: Working within the existing shell, even in a total rehabilitation, is often less expensive than new construction. When working with the existing facility, generally there are no new property acquisition costs. The existing location is a known entity to employees and clients alike.	It may be more difficult to institute new technology and industrial methodology in an existing facility. Even in a total rehabilitation, some existing building fabric remains, and therefore all capital planning cannot assume time zero as an age as in new construction.
Build new	All components of the facility fabric are new, and life-cycle capital planning can start at time zero. New locations, new images, and building around new and current technology are possible.	Additional costs are incurred for land acquisition, moving, and employee and client orientation.

assessed, and a program is established to understand the scope of work that is required to rejuvenate the building.

There are other ways for a facility manager to reenter the life cycle that are unrelated to the end of the facility's useful life. If the current technology has changed so dramatically that the product can no longer be produced in a facility of the current design, the functionality of the building has become obsolete despite the fact that the building components have not exceeded their EUL. Or if the user has added so many employees or developed new business units, it is possible to exceed the facility's capacity, and therefore the usefulness of the facility must be reevaluated again based on functionality, rather than on the basis of EUL.

CONCLUSION

An integrated approach to the life-cycle performance of a facility can make a huge difference in the net value of a facility engineer/manager.

ARTICLE 3.1.5

CORPORATE LEASING, DESIGN, AND CONSTRUCTION: A PROJECT MANAGEMENT APPROACH FROM THE TENANT'S PERSPECTIVE

Scott S. Tibbo
International Facility Management Association (IFMA), Boston Massachusetts, and Expense Management Solutions, Inc., Southboro, Massachusetts

AN OVERVIEW OF FACILITIES PROJECT MANAGEMENT FROM THE TENANT'S PERSPECTIVE

In today's dynamic business environment, a company's need for office space can change rapidly, and it is essential that the corporate real estate department be prepared to respond to the business challenge of effectively managing the company's real estate transactions while still meeting the corporate goal of controlling occupancy costs. Because most real estate portfolios today, for both small and large corporations, tend to be comprised of leased office space rather than owned building assets, it is critical that the team that represents the tenant use an

effective transaction process. This article provides an overview of the major steps in a typical real estate transaction, and provides insight from a tenant's perspective into proven project management methodologies that engender up-front planning, organized communication, and informed decision making. Table 3.1.5-1 summarizes the major phases and tasks within the process in a matrix format.

Phase I: Project Initiation/Needs Assessment

Initiate the Project. When the initial request is made to the corporate real estate (CRE) department by an end user group to obtain more space or to modify an existing office environment, it is essential that CRE obtain clear direction as to the size, length of term, and business need for this new requirement. It can be very beneficial to establish a standard project initiation process that involves a formal sign-off on the scope and intent of the new project by the requesting department's senior management. Without this end user management control in place, the CRE department could invest significant effort and cost in pursuing a new space requirement, only to find out later that the end user's senior management did not support or agree with the original direction. A simple, one-page project initiation form that is approved by the requester and their senior management can help minimize these occurrences.

Analyze the Current Environment. Before proceeding to discuss the new space requirement, it can be very beneficial first to evaluate and confirm the conditions and costs of the end user's current environment. In addition to providing CRE insight as to how the existing space has been performing, it will establish an internal benchmark that both CRE and the end user can use to compare the quality and cost of any new space alternatives. This assessment of the current con-

TABLE 3.1.5-1 Summary of Transaction Process

• Project initiation • Analyze current environment • Review real estate market • Define business needs & strategy • Develop project schedule • Define project team • Update client on schedule and project team	• Confirm staffing and space needs • Detailed market search • Complete property tours • Issue RFPs • Analyze RFPs • Test-fit drawings • Due diligence • Develop/ compare occupancy costs between options	• Issue counterproposals • Summarize proposals • Detailed financial analysis • Issue recommendation memorandum • Obtain approval • Negotiate lease • Confirm design and construction terms	• Design development • Construction documents • Integrate I/T • Incorporate furniture and equipment specs • GC prequal • Bidding & award • Construction phase • Install furniture and cabling • Move-in activities	• Punch list • Reconcile accounting • Issue close-out report • Complete project evaluation • Finalize project files • Enter data into real estate management system • Transition files to lease administration • Monitor occupancy issues

ditions should confirm how the space is being utilized, identify any environmental or property management concerns, and clearly document the full occupancy costs of this current space.

Review the Current Real Estate Market Conditions. Based on the general information provided in the project initiation form, CRE can research the current market rental rates and space availability within the desired geographic area. This market data, in addition to the information gathered on the current conditions, can be very instrumental in conducting strategic discussions with the client regarding specific long-term space needs.

Define the Business Needs and Confirm the Real Estate Strategy. After the information previously mentioned has been gathered and evaluated, it is recommended that CRE share and review that data with the end user. This would be followed up by a meeting or conference call with the requester and a senior management representative to discuss the specific business and real estate needs for this new space in greater detail. Specific direction regarding site location, image, access, visibility, employee demographics, and so forth is critically important so that the CRE team clearly understands the situation before it begins a detailed space/real estate search.

Develop a Preliminary Project Schedule and Establish the Project Team. Once CRE has obtained this baseline information and project direction from the client, there should be sufficient information to develop a project time line (schedule) that outlines the subsequent phases of the project and the anticipated amount of time needed to complete each major phase. It is helpful if CRE can establish and publish schedules in a standard format for all clients and members of the project team. At this point in the project, it is recommended that CRE establish the expanded core team that will be responsible for supporting the execution of this transaction (project manager, architect, engineers, leasing agent, information systems coordinator, etc.). It is also recommended that CRE issue a contact list that includes all of the core team member names, addresses, phone numbers, e-mail addresses, and so forth.

Phase II: Analysis of Options

Confirm Staffing and Space Needs. Before conducting any detailed market search, it is essential that CRE first confirm their long-range staffing and space needs with the end-user group(s). This information should be clearly detailed and summarized within a standard programming document. Quite often, this information is gathered and evaluated by a space planner or architect who has met with the key client contacts, on-site, to evaluate their current work environment and discuss long-range space needs. Depending on the size of the organization, the department's senior management may want to approve this long-range staffing and space need information.

Conduct a Detailed Market Survey. Once the project team has a clear understanding of the space needs, along with the specific real estate criteria already gathered, it can commence a detailed market search to identify all available property locations within the defined search area. Using a standard set of selection criteria, such as building type, access, visibility, rental rate, ownership, floor-plate design, and so forth, the team can establish a "long list" of properties available that may meet the requirements and qualify for a property tour.

Complete Property/Site Tours. At this point, representatives from the core team (e.g., project manager, tenant rep, architect) should conduct facility tours of all long-list properties with the building owner's representative to evaluate how these facilities meet the defined needs. Based on the team's assessment of the property tours, a "short list" of potential buildings should be confirmed for further evaluation.

Issue RFPs to Selected Sites and Landlords. Detailed requests for proposals (RFP) should be sent to the owner's representatives from each short-listed building. The RFP should request information on critical lease issues such as space availability, term, rent, operating expenses, tenant fit-up allowances, building systems, ownership, other tenants in the building, and so forth.

Analyze the Requests for Proposals. Once all of the RFPs are completed by the building owners/representatives, it is important that all members of the core team have an opportunity to review the detailed responses. Quite often, the tenant representative will compile a matrix document that summarizes the major deal points and building features to help compare, on a line-by-line basis, the qualitative and financial differences between the various building candidates. If critical pieces of information are missing or appear inconsistent, invest the time to obtain clarification at this point in the process. Based on the detailed review, the team should have sufficient information to reduce the list of buildings under consideration to three primary choices. It is very important to keep at least two to three options open and in play until a final recommendation has been accepted by the client and all critical lease terms are negotiated and approved by both parties.

Complete Test Fits and Building Due Diligence. In addition to considering the business and financial terms of the various lease proposals, it is valuable if the tenant can develop some preliminary "test-fit" drawings to define more accurately how much space will be required in each prospective facility. The project designer or architect can often quickly develop these test-fit drawings from the approved staffing and space program documents already gathered. In addition to indicating how much usable square footage will be needed in each location, it will help define the total rentable square footage per location, which can vary dramatically, depending on the building's configuration. These test-fit drawings are also helpful in determining how much new construction, or use of existing architecture, will be required in each of the facilities. This information is critically important in developing probable cost estimates for tenant improvement expenses and for evaluating how well each building fits the space requirements. It is also highly advisable at this point in the process to engage a team of engineering consultants on the tenant's behalf to fully evaluate the quality and performance of the base building infrastructure for each of the buildings under consideration. These studies may include examination of all major mechanical, structural, electrical, and fire protection systems, including life safety and Americans With Disabilities Act (ADA) accommodations, the telecommunications infrastructure, and the amount of lighting in the designated parking areas. It is critically important to recognize any major building issues that may exist along with their associated costs and risk factors early in evaluating prospective buildings—before short-listing or any lease negotiations.

Develop Full Occupancy Cost Models. It is essential that a comprehensive occupancy cost model is completed by the core team before any recommendations are made to the end-user group. These financial models should take into account the proposed rent and operating and common area maintenance costs over the term, including escalations and real estate taxes.

The models also need to include all soft costs related to design and engineering fees, tenant construction costs (minus any tenant improvement allowances provided by the landlord), plus any additional costs for signage, security, moving, telecommunications infrastructure, or any landlord management fees that may be required. Determine whether your Finance Department requires that you include any "cost of capital" or internal financing charges related to capital outlay. Also factor in any holdover penalties or duplicate rent from your current location and any landlord management fees, if involved. These financial models should determine for you a total annual occupancy cost and the total commitment over the lease term. It is also helpful to compare the average "occupancy cost per person" among the various options. Comparing the true total occupancy costs among the building alternatives is the best approach. The decision on which building to lease should never be made on basic rent alone.

Phase III: Internal Approvals and Lease Negotiation

Issue Counterproposals. Based on the qualitative and financial comparisons that have been completed at this point and the needs of the business unit, the project team should be able to define the top two locations that best meet the overall requirements. It is advisable to keep at least two options "in play" and to continue to refine and negotiate business/lease terms in the event that one of the space options is leased to another tenant or if a deal falls through. This is also a good time to research and leverage any incentives that the landlord, community, or the state/regional economic development sector may have to offer your company (e.g., tax relief, parking concessions, energy discounts).

Complete Financial Analysis. Once the final evaluation for each building has been completed and cash flows have been calculated for each option, summarize the results in a matrix format to be used as a financial exhibit with the recommendation package that the project team will issue to the internal customer.

Issue a Recommendation Memo. Present the results of the process in a standard memorandum format for the client that summarizes the defined primary business objectives, the research completed, the building options considered, and a recommendation as to which location best meets the defined criteria, including the cost considerations. The recommendation memo should include the detailed financial model along with descriptions of the building, location maps, and copies of the test-fit drawings. If there are multiple business units involved in the deal, it is helpful to break out each unit's pro rata share of the total project costs.

Obtain Senior Management Approval. Issue the recommendation memo to all necessary levels of management within CRE, finance, and the business unit(s) that requested the project and clearly communicate which level of management needs to approve the transaction and in what time frame. It is very helpful if the organization can have preestablished approval authority levels for new transactions based on the size of the financial commitment.

Review, Negotiate, and Execute the Lease Document. Once internal approval has been confirmed for the preferred location, the project team, along with legal counsel, should finalize all financial and business terms related to the lease document. Make sure that the team members who represent the design, engineering, and construction aspects of the project have the opportunity to review and approve any lease language or exhibits that relate to design, construction management, schedule, access to the site, landlord allowances, square foot calculations, and so forth, before executing the lease.

Phase IV: Design, Construction, and Occupancy

Complete Design Development. Although information regarding staffing and space needs were gathered earlier in the process and preliminary layouts were generated during the test-fit stage, it is advisable at this point to have the design team reconfirm the initial requirements with the end users to make sure there have not been any major changes in their business plan that would impact space needs. This is also the point in the process when the specific details of the space plan should be finalized with the user group. It is imperative that the design team understands how each specific unit functions, what its ideal work flow arrangement is, and that it also understands how the various departments function as an organization. Those work-flow needs along with their unique conference, filing, and equipment requirements need to be effectively incorporated within the space plan design. The final design development documents need to effectively represent an office environment that enhances the functional work-flow needs of the user group; otherwise the result will be an ineffective, unproductive workspace.

Finalize the Construction Documents. Once the design development phase is complete, the expanded core team can be engaged to coordinate a full set of working drawings and specifications that will be used for bidding, permitting, and construction. It is essential that the architectural and engineering disciplines have thoroughly examined the existing conditions of the proposed space and understand how the building systems are intended to operate, so that their modifications and improvements represent logical, constructable, and efficient designs. Any building system modifications should also be reviewed with the landlord's building management and approved by an authorized representative of the owner. For example, if there are postoccupancy mechanical problems in cooling the tenant space, it is very advantageous if the tenant can establish that all HVAC modifications to the space were coordinated and previously approved by the owner, who is ultimately responsible for operating the base building systems in accordance with the heating/cooling/fresh air requirements referenced in the lease document.

Integrate All I/S Telecom Requirements. Make sure that all IS/telecommunications infrastructure requirements are incorporated into the plans and specifications. Incorporate any special I/S requirements related to building access (T1 line, fiber, dual feeds), conduit for riser cabling between floors, uninterruptible power supply (UPS) needs for the computer/server rooms, and generator backup requirements for critical equipment.

Complete Furniture and Equipment Plans and Specifications. Coordinate all electrical and/or mechanical requirements for tenant furniture and equipment with the architects and engineers. Make sure that power supply, circuitry, and installation methods for the furniture system are clearly defined in the drawings. Also make sure that all ancillary equipment such as fax machines, printers, and copiers are specifically located on the floor plan and that all special electrical or HVAC requirements are engineered and included in the original bid set. This will help avoid last-minute scrambles during the weekend of the move and will eliminate costly change orders.

Bidding and Award of Construction Contract. Depending on the location, size, complexity, and schedule for the project, the tenant may elect to contract the actual work in one of several different acceptable methods. Stipulated sum, cost plus fee, guaranteed maximum price, and design build are a few of the more common approaches, and in some cases the tenant will elect to have the landlord manage the entire bidding, award, and construction phase. In any case, it is advisable that both the tenant and the landlord mutually agree on the short list of contractors who are proposed to bid the work.

Regardless of which method is used, the following are a few key factors for success:

1. Make sure that the construction documents are clear, accurate, and as thorough as possible. Weak drawings can result in change orders, delays, and performance issues.
2. Take the time to prequalify the contractors who are proposed to bid the work. Consider each firm's financial resources, annual volume, experience with similar type work, qualifications of the proposed project manager and superintendent, and the company's overall reputation for completing work on time, within budget, and in a professional manner.
3. When evaluating the final bids, carefully review the major cost components among the bidders and note major variances by trade or any exclusions that may indicate a problem area within the drawings. Make sure that the project schedule is clear and demonstrates that the contractor can accomplish the work within your required time frame.

Construction Phase. Once the bid has been successfully awarded and all permits and contracts have been approved, it is very beneficial to conduct a construction kickoff meeting where the client (whether it be the tenant or the landlord) meets with the primary contacts from the construction firm (GC) to discuss schedule, process, and project administration. Quite often the GC will include representatives from the major trades including mechanical,

HVAC, electrical, and plumbing. If possible, it is also advantageous to include representatives regarding furniture installation, floor covering, security hardware, and voice/data wiring to incorporate their particular coordination issues into the overall master schedule and to agree on sequencing and the way these various trades will integrate on the job site.

At the kickoff meeting, it is also important to communicate to the contractor who is authorized (by the tenant's organization) to direct changes in scope (i.e., the project manager from CRE, not the end user) and to establish a clear process for identifying, pricing, and approving change orders. During the construction phase, it is essential that the tenant has some representation at the weekly project meeting with the contractor, whether it be an internal CRE project manager or a representative from the tenant's architectural (or construction consulting) firm. Close monitoring and documentation of construction progress including schedule, budget, outstanding issues, and request for information is essential. With today's technology, it is also possible to require that the contractor digitally photograph construction progress and/or site issues and forward these images electronically through a project site on the Web. At the conclusion of the construction phase, it is also very important to have the contractor produce a project manual that includes a contact list for all major trades for follow-up work/warranty issues, copies of the certificate of occupancy, any operational and maintenance guides, HVAC balancing reports, and important information that the owner, end-user contact, or CRE may need to refer to in the future.

Complete Furniture and Cabling Installation. Toward the end of the construction phase, it is important to confirm that the installation of systems furniture and voice/data wiring are being installed according to schedule, leaving sufficient time for punch-listing the furniture installation and testing all voice/data wiring connections prior to move-in activities. Make sure that base plate power is in place for the ancillary printers and fax machines and that all outlets for large copier machines have the appropriate plug configurations installed.

Move-In Activities. At this point, if all of the subsequent phases of activity have been completed properly, the site should be readied for move-in activities that typically involve relocation of boxes, computers, equipment, filing cabinets, and assorted support furniture. In addition to communicating all moving requirements to the employees involved, it is important to make sure that all move-in activities are coordinated carefully with building management regarding loading dock and elevator access, security, trash removal, and cleaning. It is also advantageous to have an electrician and cabling installer on site or on call in the event there are some critical last-minute electrical or telecommunication wiring needs that must be completed before the start of business the next day.

Phase V: Project Closeout

Complete Punch Lists. In the event all punch list items have not been completed by the contractor, furniture installer, or cabling installer, these remaining activities should be documented, prioritized, and scheduled for immediate completion. Holding back on the final payment is often the best leverage for getting these completed in a timely manner. Before making final payments, also make sure to obtain all lien releases from the general contractor to ensure that all subcontractors have been paid in full and do not have any outstanding claims that could cause them to place a lien against the building, which in turn could place your lease in default.

Reconcile all Project Accounting. As all of the final payments to contractors, suppliers, and consultants are being finalized, be sure to reconcile final costs against your contracts with each party, challenge and reconcile any outstanding change orders, and collect any landlord allowances due. Compare your final project costs with the budgeted amounts, identify any variances, and determine why each variance occurred.

Issue Project Closeout Report. You should generate a final project close-out document that summarizes for CRE management, as well as for the end user/business unit management, all final costs against the budget numbers presented when the project was approved. Summarize the activity completed, the basic terms of the lease (abstract), critical notification dates (notice to terminate, expansion options, etc.), final project costs, and explanations of variances.

Complete a Project Evaluation. It can be very helpful if the project team conducts a brief conference call with the entire core team when the project is completed, to discuss the degree of success of the project and to identify what worked well and what did not. This information should be shared with other members of the CRE department to help share "lessons learned" with the goal of continuous improvement. It is also recommended that someone from CRE obtain input from the end users regarding how they felt the project management met their needs and expected levels of service.

Finalize the Project File. It is essential that all critical documentation relating to the project, including contracts, financial data, specifications, drawing file references, customer approvals regarding changes in scope, and copies of payment applications are organized in a project file that will be maintained in a central filing area within Corporate Real Estate.

Enter Critical Data into CRE Facilities Information Management System. Once the project closeout is finalized, all critical legal or financial data regarding this project should be entered into a central (CIFM) database where this information can be accessed and reported on to assist with internal portfolio/lease management responsibilities. This information will be essential for CRE in tracking and strategically managing critical lease dates, rental rates, escalation schedules, square footage under lease, excess space, opportunities for consolidation, and so forth.

Postoccupancy Evaluation. Approximately six months after the users have occupied the new space, it can be very beneficial to follow up with the end-user group to seek input as to how well the overall space is meeting their needs. A standard survey can be utilized that seeks feedback regarding satisfaction with individual workstations, ergonomics, the adequacy of common support areas, any positive or negative impacts on work productivity, and general questions regarding how well the building is being maintained and the responsiveness of the property manager.

ARTICLE 3.1.6
PROPERTY LOSS PREVENTION

John Bender
FM Global, Johnston, Rhode Island

Though designated corporate individuals deal with providing a business with property and liability insurance, no one is better positioned to maintain business continuity than the facility manager. And these days, if a business of any kind suffers an unanticipated interruption, the likelihood of regaining its former status is in jeopardy because of competition being what it is. It is, therefore, incumbent on the facility manager to understand the threats against the business and to take appropriate action to prevent, or at least minimize, the possibility of property loss.

VULNERABILITIES TO PROPERTY DAMAGE

Fire and Other Perils

When facility managers stand on the hill overlooking their property and ponder all the threats to their business, one that may come to mind is fire. This is because fire happens so often and gets so much press. And, despite the relatively recent rash of natural hazards that have doomed so many businesses, property insurers still find that fire causes the most losses. Of course, to have a fire, there have to be the elements of the fire triangle: ever-present oxygen, fuel, and the ignition source. So, as easy as it sounds, to avoid a business-threatening fire loss, one has to manage combustibles and control their ignition sources. The property insurer can assist you with both measures.

To manage combustibles, one has to know what and where they are, plan carefully for their safest storage configuration, and protect them adequately. Control of ignition sources is much harder. Table 3.1.6-1 shows ignition sources in order of severity. Note that *electrical* has been the leading ignition source for years. How do you control that? It boils down to installing adequate overcurrent protection, testing the protection, and maintaining the electrical system. Hot work, formerly known by the more restrictive term *cutting and welding,* is number two on the list. Did you know that over one-half of the fires that were started as a result of hot work were the responsibility of contractors? Therefore, to control this, you have to manage not only the in-house operations, but watch over the contracted operations as well.

Another in the top 10 of ignition sources is arson. Arson includes not only the usually thought-of "burning for profit," but also intentionally set fires for other reasons like the disgruntled employee who just got laid off or the pyromaniac who loves to watch things burn. How can that ignition source be managed? Well, it comes down to security. Did you ever ask yourself how easy would it be to get into your facility unnoticed? Would your employees recognize and challenge nonemployees? Do you leave piles of combustibles like pallets next to the building for an arsonist to light? This ignition source *is* manageable.

Now, how about the other perils that were alluded to. Over the last decade, there have been tremendous property losses due to such things as winds, earthquakes, freeze-ups, floods, and building collapses due to snow accumulation or rain ponding due to poor drainage. Why are so many of these natural hazards happening lately? Well, weather patterns have changed. And businesses have changed too, choosing to locate in storm-prone

TABLE 3.1.6-1 1989–1998 Fires and Explosions by Probable Cause*

Probable cause	No. of losses	Gross loss ($U.S.)
Electrical	1,497	$787,354,883
Hot work	565	696,302,342
Hot surface/radiant heat	597	482,883,379
Arson/incendiary	759	362,930,132
Spontaneous ignition	313	285,533,985
Exposure	232	225,647,028
Friction	289	223,008,409
Burner flame	238	176,255,610
Overheating	487	140,149,881
Smoking	280	122,107,182
Overpressure	64	116,851,760
Combustion sparks	136	70,116,310
Static electricity	77	46,141,023
Lightning	69	23,080,895

* Losses reported to Factory Mutual Insurance Company.

areas. Construction has changed with the advent of synthetics and a preference to install pre-engineered metal buildings.

Hurricane Andrew taught about weak roof construction and failure to shutter or otherwise protect glazing. The early 1990s floods in the Midwest found unnoticed vulnerabilities as many businesses were quite unprepared for the magnitude of water damage that resulted. Unpredictable earthquakes took their toll in this decade, and we learned about the devastating aftereffects when unleashed gas caught fire while protection systems lay hopelessly damaged and unable to protect. Unusual weather patterns brought freezing temperatures to areas not built to withstand them and the result was devastating. Industries quickly learned to avoid winter shutdowns and have a protection plan ready at all times. The heavy snows of the early 1990s collapsed many weak buildings, causing reevaluation of the capability of roofs to hold the weight. And plans were developed to keep the excess cleared off.

There is another loss potential to think about. Is there any possible exposure from the property adjacent to yours? How vulnerable are neighboring facilities to property loss, and if there is a problem, will it affect you? If there is a threat, you need to plan for it. Suppose, for instance, that the company has a building very close to yours. You know there are hazardous processes within and there isn't any automatic sprinkler protection either. The side of your building that faces theirs has lots of windows. You might consider eliminating the windows on that side of your building, knowing there is a high probability of uncontrolled fire from next door. That would be good planning.

Equipment

Once you've inventoried the threats to your property from fire and natural hazard perils, consider what can happen to your business if key equipment ceases to function: Loss of steam due to boiler malfunction; loss of cooling due to a compressor, chiller, or cooling tower failure; loss of electrical power because of a weak cable or failed circuit breaker; a production line down because a gear set failed and there is no spare; a press part cracked that should have had nondestructive examination but didn't, or. . . . How vulnerable is your equipment? Is the protection the best it can be, and is it regularly tested and maintained? Are operators formally trained and empowered to take quick action to minimize an impending failure?

A facility manager has to evaluate all of these business threats, and others. Then, perhaps with the help of the property insurer, the threats must be prioritized by likelihood and potential impact. Each needs to be evaluated further to determine if protective measures are in place to prevent and/or control losses. Finally, employees need to be made aware and trained to do their part—all with the backing of the highest levels of company management.

Management sets the tone and imbeds the loss prevention culture through its policies and procedures, and through its personal follow-up by everyone on the management team. Employees, once educated, play key roles in emergency response, protection system maintenance, and generally watching over the facility for threats of any kind.

PROTECTION PROVIDED

Prevention and Control

At this point, you should be either elated or concerned, depending on how many of the vulnerabilities you've considered before. Providing a suitable degree of protection against the threats we've just discussed will require some professional help. Perhaps the best organization to turn to is your property insurer whose trained loss prevention engineers are in a good position to help you evaluate your needs.

There are two elements of protection that you must consider—prevention and control. Prevention measures should stop a property loss from happening in the first place, but there also has to be a control function to take over quickly if a loss does happen and minimize the effects.

Effective protection depends on both the peril (fire, flood, etc.) and the contributing factors that are unique to the business being protected. For instance, let's say you are in the paper manufacturing business and looking at fire prevention and control. Fire in the woodyard is prevented by the arrangement of the raw stock and taking measures to prevent smoking and other ignition sources from starting a fire. The control aspect is perhaps some monitoring towers ready to deluge a fire if it starts. However, the monitoring towers are useless without the proper water supply. The dry ends of the paper machines require some sort of automatic sprinkler protection that is adaptable to the higher temperatures, but the prevention aspect is how clean the area is kept. The warehouse has its own automatic sprinkler needs based on the type of paper, how it is stored, and how much there is. The prevention in this case is the proper storage, perhaps using electric instead of internal combustion fork trucks, and a robust antismoking policy.

On the other hand, if you are managing a public building, chances are that the sprinkler requirements will be less robust, but there are pressure needs (adequate water on the 60th floor) and standpipe locations to consider. If you have to retrofit an existing building, there are aesthetics to deal with. For prevention, there are such things as need of a smoking policy, daily refuse removal, strict policy on space heater use (and other appliances), infrared scans of the electrical system, and a good electrical testing and maintenance program.

Now you have a prioritized list of perils that are likely to affect your facility at one time or another. You should take each of the perils, make two columns labeled "Prevention" and "Control," and begin to fill them in with necessary measures. Keep in mind that both prevention and control contain human factors, too.

During the Planning Stage

The best time to consider loss prevention and control is when a new facility is in the early planning stage. Considerations include where best to site the structure, what construction methods and materials are best given the location and function, what installed fire protection will best protect the facility based on the processes involved, and many other related concerns (e.g., insurance company plan review, protection during construction, building code compliance, using materials and methods approved by standard setting institutions, etc.). Protection can be very affordable as a percent of the building cost when considered during the planning stage. This is the time when your property insurer should be working with you on the project.

Change as Circumstances Change

If the facility and/or equipment is not new, you are in a maintenance mode. However, you should view each change that takes place in your building use or the processes contained within as a threat to property loss prevention or control. For example, to enhance productivity, you took a two-week shutdown to exchange a production and a storage area. However, the automatic sprinkler protection in each area was never considered in the changeout. You may have just compromised protection for your finished goods because the automatic sprinkler system, designed for its former use, may not have the proper strength for the type of material now being stored in the new location.

Another example—after a recent merger, the entire workforce underwent a tremendous change and ultimate downsizing. However, you never checked the adequacy of your emergency response organization after the changes. Only after a devastating fire might you dis-

cover that only one-half of the positions were covered, and by ill-trained people at that. Property loss prevention and control must be a consideration after every change, no matter how small. Failure to do so will result in a false sense of security and a more severe loss if and when a loss occurs.

THE HUMAN FACTOR

The term *human factor* encompasses a vast area, starting at the very top of the organization and involving every person. Policies and procedures related to property loss prevention and control are a human factor. Communication up, down, and sideways is a human factor. Learning from incidents so they never happen again is a human factor. Other human factors include educating all levels as to perils and protection, empowering employees to take action to protect assets, designing and constructing proper buildings and equipment, and managing contractors. Human factors need to be periodically assessed and corrective action planned when deficiencies arise. On average, 70 percent of property losses have a contributing factor that is related to human factors. This is simply stated as *actions or in-actions of people on all levels that either cause a property loss or contribute to its severity.*

Emergency Response

One of the most important parts of human factor planning is emergency response, or how employees are organized and trained to combat an emergency situation. No matter how hard you try to manage prevention, there will be inevitable incidents. How quickly and properly these are dealt with will determine the severity of the loss. To get there, one has to revisit the original prioritized peril list and think about how to respond to the most important or most likely ones. For instance, a planned response to a fire will surely involve someone designated to call the fire department. It should also include someone to make sure the automatic sprinkler control valves are open, that the fire pump (if installed) is running, and maybe even tackling the fire (but read your OSHA regulations first to make sure you are aware of the requirements).

If your facility is vulnerable to flood or surface water, do you have people trained to respond? Do they have the proper supplies they need? Do they know how to use them? How about an approaching hurricane if you are on the East Coast or an earthquake if you are on the West Coast? It is up to you to determine to what degree you plan to, but there is no substitute for a trained and organized response. And it needs to be kept up to date. Data on previous losses clearly shows that an inadequate or ineffective response can make a loss greater than 10 times more severe than the situation where the response is both adequate and effective.

Maintenance of Protection

All of this may be for naught, however, if there is a failure to maintain what was put into place. Why do things deteriorate? Protection systems are, for the most part, passive. And they do not directly contribute to the end product or bottom line. What happens, therefore, is that dwindling resources get devoted to producing the end product, often at the expense of the needs of the protection system maintenance. It takes belief and determination to keep a reasonable level of maintenance on both the hard systems, like automatic sprinkler protection system components, and people programs, like emergency response, that keep the facilities loss-free. It usually takes higher management backing to prevent protective system maintenance from being the backlog. An ill-maintained system or human element program cannot be counted on to work when needed.

Contingency Planning

Contingency planning is evaluating possible scenarios and planning for those that are most likely to occur. If you are sited next to a river that has overflowed its banks twice in the last 50 years, a contingency plan for flood is very much in order. The plan would allow for emergency response but would go beyond that. Basically, a contingency plan is designed to maintain business continuity in the face of a probable outage. Your contingency plan may include moving equipment and supplies or using a competitor's facility or obtaining raw product from alternative suppliers. Contingency planning can, and should, be used on a smaller scale, too. For instance, if a spare part for a key machine is not kept in stock, a contingency plan would list where to get the part, how to transport the part, and how long the suspected outage would be.

PROPERTY INSURANCE

Now that the vulnerabilities to your business have been discussed in terms of property loss causes and their prevention and control, you should be aware that more than likely, your company has a degree of property insurance. Having property insurance does not relieve the facility engineer from pursuing a realistic level of loss prevention and control. However, insurance is limited and can never bring back customers lost because of a business outage caused by a property loss. And there may be a sizable deductible that will surely impact the bottom line. Here is a brief primer on property insurance.

An insurance policy is a contract in which one party (the *insurer*) agrees for a price (the *premium*) to reimburse another party (the *insured,* or *policyholder*) for loss that is caused by insured events. Insurance policies usually specify items such as, but not limited to, the following:

- The location (where the insured property is located)
- The item(s) to be insured and for what occurrence
- The amount of insurance purchased
- The premium
- The *deductible,* if applied (the specified amount of an otherwise insured loss that must be sustained by the insured)
- The length of time, or *term,* for which the policy is issued
- The exclusions and restrictions (no policy covers all property for all possible occurrences)

Insurance coverage may be described in terms of the following:

- *Perils.* Specific events that may cause loss (e.g., fire, explosion, wind, hail, lightning, or equipment breakdown).
- *Exposure.* The vulnerability to damage or destruction by some peril.
- *Hazard.* A condition or activity that increases the probable frequency or severity of loss.
- *Endorsement.* A document attached to a policy that modifies its terms.
- *Exclusions.* Policies or endorsements may contain these, which limit the scope of coverage.

The facility manager should be aware of the property insurance coverage for their facility(ies) so they can better plan their loss prevention and control strategy. What specifically is covered? More important, what is not covered? What is the deductible, or, in other words, how much of the risk has the business chosen to assume itself? This could be significant. Often, properties are underwritten as *highly protected risk* (HPR). This means that the business being insured has exhibited genuine interest in loss prevention by management and employees, is appropriately protected, manages its human element programs, and maintains

a high level of interest in property protection in general. All businesses should strive to be classified as an HPR.

You should work as closely as possible with your property insurer. Pay attention to their findings made during evaluation visits. Seek their advice any time a process, machine, or building undergoes change, no matter how insignificant it may seem. When new construction is planned, the insurer should be notified at the earliest opportunity so that they can advise on appropriate siting, construction, and protection. The facility manager is in a key position to ensure that the business is not interrupted by an unanticipated property loss.

ARTICLE 3.1.7
VALUE IN RISK MANAGEMENT

Robert W. Fitzgerald and Leonard D. Albano, Ph.D., P.E.
Worcester Polytechnic Institute, Worcester, Massachusetts

As values in buildings increase, risk management is becoming an increasingly important element in a comprehensive facilities management program. Value includes the quality and performance of a building in terms of user satisfaction and changes in user needs, life-cycle costs, and delivery time. Value is in the systems that comprise physical facilities, in the information base housed within the facility, and in the impact of facility downtime on the well-being of a company and its employees. Risk may arise from natural forces such as earthquakes, tornadoes, hurricanes, and floods. Risk may also be caused by man-made influences such as fire, explosion, sabotage, and terrorism. This article describes a process for developing a risk management program. Although the general process may be applied to all natural and man-made hazards, fire hazard is used here as the model for study.

ELEMENTS OF THE PROCESS

A program to improve fire prevention or fire protection in a building commonly originates from a fire department inspection that identifies conditions that do not meet regulations. Alternatively, the program may be a response to an insurance carrier's evaluation of the status of the building's operations and the existing loss exposure. Often, the corrective action recommended by an insurance carrier is related to changes in premiums, so a cost analysis may be incorporated relatively easily. This type of analysis merely relates the cost of corrective action to the change in the insurance premium. Rarely does the analysis incorporate the change in risk as a result of the physical changes in the building. The fire risk process outlined in this article relates an engineering analysis of risk to decision making and value. The process enables management to evaluate the mix of alternative options in accepting the risk, transferring the risk through insurance coverage, and reducing the risk through changes to the building or the facility operations.

The complete process is described by the following seven elements:

1. Understand the problem.
2. Define the building.
3. Analyze incident scenarios to understand the performance of the building.
4. Characterize the risk to people, property, and operational continuity. The risk to the environment and to neighbors can also be incorporated into this evaluation.

5. Evaluate prevention effectiveness.
6. Structure a decision analysis.
7. Evaluate alternatives, and decide the best course of action.

Understand the Problem

The most important part of a risk management program is to understand what is at risk from the consequences of the hazard. For fire risk, one first identifies the value contained within the building. A convenient technique is to use a space utilization plan and to identify the cost of a complete loss of each room or designated space with regard to people, property, and mission or operational continuity. For example, one would value the replacement cost of the contents of a room or space. The replacement costs include both the contents and the room (building) structure itself. For operational continuity, the value of the loss of the facility in terms of production downtime, loss in market share, business interruption, or other factors that are sensitive to the operational continuity of the facility would be shown on the space plan. The risk to humans is more difficult to quantify in this manner. Therefore, this identification typically describes the number of individuals and their physical characteristics when in the space.

Second, when the value of the contents and operations of the facilities have been identified, their sensitivities to the products of the disaster are described. For fire, one would describe the sensitivity of the contents and operations to flame–heat, smoke and toxic gases, and water. For example, some materials may be very sensitive to only a small rise in temperature or to the corrosive effects of the gases that are released by a fire. Computer software and data storage may be particularly sensitive to the products of combustion. In any event, the sensitivity of the contents and operations to the natural products of the fire must be identified.

A third important part of identifying and understanding the problem is a description of the type of loss that management is willing to accept. For example, is the loss of the complete contents of Rooms A and B acceptable but the loss of only accounts receivable or data storage in Room C unacceptable? Is a two-month downtime in the operations of Space D acceptable but a one-day downtime of Space E unacceptable? Again, an analysis of the space utilization plans will provide a cost-effective and efficient way to understand the potential value of losses and the special sensitivity that some spaces will require. Because it is possible to *harden* selected spaces against hazards without necessarily providing the same protection to the remainder of the building, the building can be adapted to accommodate selected protection, if one understands the nature of the problem.

Define the Building

Defining the building means identifying the physical structure and all of the components that influence the hazard. For example, for a fire risk, building definition includes the type and location of detection and notification instruments, the coverage provided by automatic suppression systems, the ease or difficulty of fire department access, and the location of barriers to the passage of flame–heat or smoke and toxic gases. An existing building is usually easier to describe in terms of the existing active and passive fire defenses. The responsible designers are expected to provide this information for a new building being designed. Although this description is not difficult, it is essential for the subsequent evaluation of building performance.

Evaluate Performance

Predicting the performance of a building for specific fire scenarios is a necessary part of the risk assessment and management program. A series of fire scenarios is identified to understand the building and its performance. An important aspect of this analysis is to recognize

that prevention measures may fail. Do not incorporate prevention effectiveness into this analysis. The goal is to identify the likely outcome from an ignition and established burning. Corporate management must understand what can happen when prevention fails. This puts prevention and what happens after prevention fails into perspective.

Fire performance may be organized into three major components: (1) flame–heat movement, (2) smoke–gas movement, and (3) structural frame performance. Each of these components may be evaluated independently. The results of each analysis are then incorporated into the risk characterization described next. The evaluation of each component is discussed.

Flame-Heat Movement. The evaluation of flame-heat movement involves the following factors: fire growth potential, automatic sprinkler system, fire department extinguishment, and barriers.

Fire Growth Potential. Evaluation of flame-heat movement starts with an estimate of the relative potential for fire growth in the space. Some spaces make it very difficult for a fire to grow, whereas other spaces have conditions in which the fire growth potential is very great. A general classification that gives an indication of the fire growth potential posed by the interior design of the space is a first step in describing the relative hazard posed by the combustible contents and their arrangement. The fire growth potential also gives an indication of the type of fire that the active and passive fire defenses are expected to resist.

Automatic Sprinkler System. The most common and effective fire defense for many types of building operations is the automatic sprinkler system. Refer to Art. 5.4.7, "Sprinklers and Fire Protection," for a more complete treatment of this important subject. No other fire defense can demonstrate the success of automatic sprinkler systems in controlling unwanted hostile fires, but these systems require care in installation and maintenance. The quality of an automatic sprinkler system can be evaluated to a certain extent by assessing its reliability and design effectiveness. The reliability of a sprinkler system depends on ensuring that the water control valves are open when a fire occurs and that water will reach the fused sprinklers in a timely manner. Valve supervision and company attitude are the major factors that influence the control valve condition. The reliability of the exhausters or accelerators of dry pipe systems, as well as pump design and continuity of power supply, are the main influences on water movement to the fused sprinklers. Design effectiveness involves several considerations. One is the temperature sensitivity of the sprinkler to the fire growth. In addition, the water supply must be sufficient to maintain control and limit fire spread until manual suppression can complete extinguishment. The influence of building elements (e.g., partitions, furniture, air conditioning ducts, or beams and joists of floor systems) on water discharge is another major consideration. A well-designed sprinkler system can be rendered ineffective by occupants or contractors who are not sensitive to the importance of allowing the sprinkler spray pattern to control the fire.

Fire Department Extinguishment. Manual suppression by a community fire department is another way by which a fire can be extinguished. The analysis of fire department extinguishment involves comparing two time lines. One is the expected time of fire growth, that is, what is the expected time for fire propagation? The second is the accumulated duration for the following sequence of events: fire detection, notification of the fire department, fire department arrival at the site, and application of first water to the fire.

The time for detection depends on the size of the fire, the flow path from the fire to the detection location, and the sensitivity of the detector. Detection may involve human sensitivity, instrument detection, or both. The selection of the detection system should be consistent with the needs of the building, and is discussed more completely in Art. 5.5.4, "Fire Alarm Systems." For example, smoke detectors are sensitive to the airborne particles released during combustion. Heat detectors may either respond to a fixed temperature felt by the detector or to a rate of temperature rise over a relatively short period of time. A variety of specialized types of detectors are available to sense fires in industrial occupancies.

The delay between detecting and notifying the fire department often is a major determinant of the success or failure of manual suppression to limit the fire to small areas of a building. Delayed notification will enable the fire to grow large, requiring the local fire department

to change from an aggressive attack to a defensive mode of fire fighting. Thus, the time for suppression and the amount of damage are directly related to the time between detection and notification. Detection and notification may be greatly influenced by the availability of humans in the process. Consequently, two different fire department suppression analyses are normally done. One is for a building that is occupied and the other is for the same building unoccupied. The time for detection and notification and the amount of damage that can be expected can differ significantly, depending upon the occupancy condition.

After the fire department arrives at the site, the time to first water application depends on how much time the firefighting forces need to complete the following sequence of activities: size up the situation, determine the best strategy for allocating resources, develop the water supply, lay the attack lines through building obstacles, and apply water to the fire. In addition to the challenges imposed by reduced visibility and smoke, the building and site design and the community's firefighting resources affect the time to first water application.

The time to first water application will give a good indication of the amount of damage that can be expected, and this damage estimate is the final part of a fire department analysis. Damage is influenced predominantly by the fire size at first water application. Larger fire sizes require more hose lines and a reliable water supply. The water flow provided by the local community will depend upon the staffing and equipment that is available at the fire scene, as well as the source of supply water. Supply water may be provided by underground piping and hydrants or may be drafted from unfrozen ponds or streams. If neither of these sources is available, water must be transported to the fire by tankers.

Barriers. The remaining part of a flame-heat analysis involves the effectiveness of barriers to delay or prevent fire propagation. Note that the term used is *barrier effectiveness,* not fire resistance. During the early stages of a fire, the fire resistance of barriers is not as significant as their status in protecting openings. Open doors allow fire to propagate into the next space regardless of the fire resistance of the barrier. Consequently, openings for doors, windows, and ducts are important factors in evaluating the effectiveness of a barrier to prevent or delay fire propagation into an adjoining space. Barriers are also important in assisting sprinkler and fire department suppression. Containing the hot gases of a fire will enable the sprinkler system to control the fire more effectively. Barriers are also an important ancillary feature in manual fire suppression. They prevent rapid fire propagation from space to space, and they enable the conversion of water to steam to become an effective heat absorption factor in extinguishing flames more quickly.

Smoke-Gas Movement. The airborne products of combustion require an analysis separate from the flame-heat movement because the speed and ease of spread are so different. Most individuals who have not been involved with a large fire do not realize the speed with which a large volume of smoke is produced. Visibility is reduced or completely obscured very quickly. It is not uncommon for individuals to comment about how dark the space becomes and how disoriented a person can become in these situations.

It is possible to estimate the volume of smoke that is produced. The architecture of the building, obstructions to airflow, and air movement from air-handling systems influence the movement of smoke in a fire. Beyond the room of origin, smoke flows to other spaces along the paths of least resistance. The objective of a smoke movement analysis is to estimate the time in which target spaces become untenable. Therefore, one must identify the target space and the concept of an untenable condition.

A target space may be an exit access or an exit if one were evaluating the time for egress. The target space may also be a room with equipment that is sensitive to the corrosive gases of a fire. In either case, the target space beyond the space of origin should be identified to enable an estimate of the time before the space becomes untenable.

The definition of an untenable condition can be more difficult. The most convenient definition is expressed in terms of visibility, that is, what is the maximum distance that one should be able to see in a smoky condition? Ten feet? Twenty feet? Across a room to the next door? The definition of an untenable condition should be specific and based on the activities in the

building. An untenable condition for sensitive equipment may be defined in terms of the corrosive products that are produced in a fire. This type of definition is more difficult to apply. However, recognizing that some equipment is sensitive to the corrosive products of combustion is often sufficient to make the building operators aware that a fire in remote spaces may cause unanticipated consequences to operational continuity and property protection. The engineering and design aspects of systems intended to mitigate the effects of smoke are presented in Art. 5.5.5, "Smoke Control Systems."

Structural Frame Performance. The third major part of a building performance analysis involves excessive deflection or collapse of the structural frame. A fire that continues to burn will cause deterioration of the structural frame. A structural analysis can provide an estimate of the likelihood that the structure will remain in place for the duration of the fire.

Risk Characterization

After an estimate of the building performance is made, the risk to people, property, and operational continuity may be characterized. The risk to the environment and to neighbors can also be incorporated into this evaluation if desired. A risk characterization estimates the likelihood that people, contents, and operations will be threatened by a fire. The process must recognize when people and too many products of combustion (i.e., an untenable condition) are present in the same space at the same time. Similar evaluations of combustible products are used to characterize the risk to equipment, computer software, data, and other storage.

Evaluate Prevention Effectiveness

Fire prevention was not incorporated into the process at the intuitively logical position before the building performance evaluation. This omission is intentional because management must recognize the outcomes to the building, its occupants, and its operations when prevention fails. Often, when the consequences of an unwanted ignition are recognized, the importance of fire prevention takes on a completely different value.

Fire prevention consists of two major parts: preventing ignition and preventing established burning. Ignition prevention is the traditional way of viewing fire prevention. However, from an engineering viewpoint, the initial part of a fire from ignition to a flame about 10 inches high (which is called *established burning*) is very fragile, and the behavior of the fire during this stage is difficult to predict. In addition, most small fires are extinguished by occupants if they happen to be in the vicinity of the fire. Room fire analysis starts at established burning and estimates future outcomes because these are much easier to predict after the flame reaches about 10 inches in height.

Fire prevention also incorporates the occupant in an evaluation. This has an advantage because building performance can be separated from occupant characteristics. This separation simplifies the analytical process and provides a better understanding of building performance. For example, any initial suppressive actions by an occupant can be clearly established and evaluated. A value analysis of prevention and initial occupant extinguishment activities can be assessed more easily.

Structure a Decision Analysis

A risk management program includes a decision analysis to organize the study so that it provides value. A decision analysis includes three parts: (1) identifying the alternatives, (2) selecting and structuring the type of analysis that is most appropriate for the needs of man-

agement, and (3) evaluating the alternatives. Risk management generally considers three alternatives for addressing risk. The first is to accept any losses that may occur. This is normally the approach for the military and other governmental properties. Business decisions also incorporate this alternative in the form of insurance deductibles. A business may be able to write an insurance policy with a deductible of $5,000, $50,000, $500,000, $5,000,000, or more. Each of these approaches has implications as both a business loss and an expense (in the form of insurance premiums paid to an insurance carrier).

A second alternative involves transferring risk by purchasing insurance. As noted in the previous paragraph, premium expense is related to the deductible of the policy. In addition, the influence of the loss of contents and the cost of business interruption can be more clearly defined because of the information that was obtained during the identification of the problem (i.e., the first part of the process).

The third alternative involves changing the risk by changing the building through the incorporation of different active or passive fire defenses. The cost of each of these alternatives can be identified clearly. The effectiveness would be understood by the engineering evaluation, which is the third part of the process.

A decision analysis would identify the mix of these three alternatives, along with the cost, expense of losses, and the probability of performance that relates to any particular alternative under consideration. Business management practices of decision analysis offer techniques for structuring and identifying values for the possible outcomes. These can be expressed in terms of expected monetary value or utility value.

Decide the Best Action

The final step in the process is the shortest because it is based on understanding all that unfolded during the previous parts of the process. Management can decide to accept the building as it is or to change the building by incorporating different fire defenses. When management opts for building changes, an additional analysis may be useful to identify the changes and their cost-effectiveness. Chapter 2 presents useful guidance for conducting financial life cycle cost analyses. Alternatively, management may decide to accept losses or to buy different insurance coverage. Regardless of the decision, it will have been made with a better understanding of the risk and more appropriate management of that risk.

Closing

The design of any facility involves trade-offs among a variety of factors, including life-cycle cost, delivery time, operations, architectural image, and risk due to natural and man-made forces. In many instances, levels of risk can be traded against capital investments, insurance premiums, and the expenses that result from loss of functions. To make informed decisions, facility owners and managers must understand each source of risk, such as fire, earthquakes, hurricanes, explosions, and terrorism; the consequential risks to human safety and the value of the facility; and the economic impact of alternative solutions for managing risk. In addition, the design team must communicate the results of their engineering analyses and use a systems-based approach so that interfaces and interactions between building subsystems are included in the decision process. For example, significant drift of the structural frame during an earthquake may be tolerable from the standpoint of life safety, but the resulting impact on the building's nonstructural systems may produce life-threatening fires and unanticipated losses of function. The process described in this article enables an enterprise to understand the risks inherent in the design, construction, and operation of facilities and to make more informed decisions for managing that risk. The understanding that unfolds during the study enables the consideration of a wide variety of alternatives for changing the risk and the inclusion of the facility's value in the decision process.

ARTICLE 3.1.8

THE NEW FACE OF THE PROJECT TEAM MEMBER

Donna K. Burnette and David Hutchens
Paradigm Learning, Tampa, Florida

Read the following project management case study carefully. A quiz will follow! Ready? Here's the scenario: In the Chevron Corporation, a project team was commissioned to manage the design, funding, and building of a large plant to manufacture a product that was in great demand and offered significant margins. After many months of work, the project team finally completed the project—ahead of schedule and under budget. The plant was opened to great fanfare, and the project team celebrated its achievement.

Got it? Here's your one-question quiz: Was the Chevron project a success? (Take your time answering. No one's looking over your shoulder.)

By now, you may have suspected that the question contains some hidden trick. You're right. The fact is that you have not been given enough information to evaluate the success or failure of the Chevron project. A correct answer in this case would have been to ask for more information about the larger organizational context or to inquire about what happened next. Okay, so the above exercise was a little manipulative. But it illustrates a common trend in project management: the tendency to evaluate project success too quickly, too narrowly, or to use short-sighted criteria. The traditional measurement criteria of schedule, budget, and quality, on their own, may no longer be sufficient.

Case in point: Let us return to Chevron for the rest of the story. Very soon after its glorious opening, the Chevron manufacturing plant failed and was sold. As it turned out, the market for the high-demand, high-market product was volatile and prone to change quickly. And change it did. Had the project team considered the possibility of this market change, they surely would have explored the option of shelving the project altogether.

Now, which criteria would you use to determine success? If you were to consider only the traditional criteria of budget and schedule, you would have concluded that the project was a smashing success. But if the criterion value is added to the business, the project failed abysmally. And here we can observe the need for project team members to begin thinking about their work in different ways.

But isn't such market forecasting the responsibility of leadership? Isn't it unrealistic to expect that kind of strategic thinking from our already-stressed, neophyte, project team members? Perhaps that was once true. But the world has changed.

A NEW WAY TO THINK ABOUT PROJECTS

In the new world of work, the familiar project has become a very different entity. Carl Pritchard, PMP and Principal of Pritchard Management Associates, has lectured and written extensively on the subject of project management. He sees many new trends in project management, not the least of which is the changing profile of the people who are being called upon to lead projects. "What I see in the classroom is interesting," he says. "It's an amalgam of old-timer project managers who have been doing it for years without any formal pro-

cesses. They're in there with a lot of new folks who are just entering the practice. In many instances, these new people are joining project management on the heels of success they had in some other part of the organization. They were pulled off some organizational effort, and management is now looking for a new home for them. Poof! They're expected to be project managers."

What's behind this new trend of putting more and more people on a rapidly growing number of projects? Pritchard suggests that one major cause is the nearly obsessive concentration on the customer that has become the focal point of organizing for so many businesses. This intense customer focus will require a special touch in fostering new processes and relationships. And that touch is going to come from individuals who can marshal and control resources and who can recognize when a project is faring well—and can also tell when it needs more intense time and attention.

One would be hard-pressed to complain about a customer service orientation. But the new sense of urgency is thrusting a lot of people onto project teams who are not fully equipped. Many still are learning "the hard way"—let 'em learn it on the fly and hope they don't foul it up. At the very least, many are being trained in the basic principles and tool of PMI's Project Management Body of Knowledge (PMBOK).

But how many are being trained to ask the kinds of questions that could have prevented the painful Chevron fiasco?

> "We should be training our project teams to be more. They need to be entrepreneurs. Consultants. Even agents of change."
>
> *—Carl Pritchard, PMP*

If you're thinking PMBOK is enough grounding, think again. Those are implementation techniques—a great place to start, but hardly a full toolbox. More is needed. Pritchard agrees. "We should be training our project teams to be more," he says. "They need to be entrepreneurs. Consultants. Even agents of change. We need to build the confidence of these individuals to serve the organization with a willingness to affect change without apology and to implement change with an understanding of all those it will affect."

The profile of successful project teams is changing. Now, success will require the people on those teams to take on new skills and responsibilities that include the following:

- Strategic, big-picture thinking
- Continual reassessment of the risk and opportunities throughout the project
- Sensitivity to all critical stakeholders and sponsors
- An environment of openness and trust

Strategic, Big-Picture Thinking

As the Chevron project team members learned painfully, projects do not exist in a vacuum. In the end, the project teams that deliver value to the organization will be those who are keenly attuned to the organization's strategies and objectives. Lynne Hambleton, Manager of Learning Systems at Xerox, concurs. "I'm aware that many organizations measure project success using the traditional criteria—like time, cost, scope," she says. "But that just doesn't fly in our culture, where quality is important and our Malcolm Baldridge award continues to set a legacy for excellence. Those traditional criteria just don't get us there. That's why at Xerox, our projects must always speak to value provided whether that's value to Xerox or to the client. We make it clear that project teams must offer solutions that support strategy. That's a lot more complex than the old way of thinking."

Continual Reassessment of Risk and Opportunities

The project team may be doing things the right way—but are they still doing the right thing? That is the kind of question that characterizes today's new breed of project managers.

At Xerox, project team members are trained to assess both risks and opportunities continually, from the inception to the completion of the project. "Just about everyone involved in the project is asking questions like what's going on in the larger context? What could derail our efforts?" says Lynne. "Project team members certainly ask those questions. And the operations side of the team is definitely asking those questions a lot because they'll be the ones running the effort after the project is done. They are constantly held accountable because they're going to be living with it."

Sensitivity to Critical Stakeholders and Sponsors

Nothing scintillating here; it is in all the basic texts. Yet the critical process of managing stakeholders continues to be ignored. It is the oldest story in the books: The project was delivered skillfully, but a key stakeholder was left out of the process . . . and the project choked. It is sobering to realize that these stakeholder interests are almost never hidden. In fact, they are often quite overt. But if the project team members do not ask, their interests will not be spelled out in the statement of work or the contract. The make-it-or-break-it criteria never even show up on the project team's radar screen.

Pritchard offers this example:

> I met with my contractor just this morning to talk about the addition we're adding to our home. He hammered me with all the right questions. "Who will I talk to?" "Who might I talk to?" "Who will sign the changes?" "Who will be around the day they place the Porta-John?" They were great questions! The barrage was almost too much for me. I started thinking about the many project managers who would rather put off those difficult discussions until later, after the relationship develops. But my contractor is building our relationship now. He's not wasting time. As a result, he's going to have a very clear understanding of my expectations—just as I will have a clear understanding of his.

Trust and Openness

Perhaps it is the many technical tools of project management—the risk assessment grids, the Gantt charts, the budget sheets—that lull well-intentioned project teams into the mistaken belief that their role is itself technical. But success is not built exclusively on deadlines, budget, and quality. Remember, there are people involved here. And the wheels of relationships are greased by those old nonquantifiables of trust and openness.

Pritchard agrees. "Project management has long been a somewhat furtive practice where we [the practitioners] take it upon ourselves to 'hide' extra money and time without letting the customer know we're doing it and why," he says. "Honest project management is going to be the successful project management over the long term. Some organizations cannot support overt communication about risk, time and cost slippage, and team relationships. Those organizations should be out of the project management business in the not too distant future."

> The "skill-building" approach to project management is giving way to a new paradigm: the culture-creation approach.

Ripples of Change

The "skill-building" approach to project management is giving way to a new paradigm: the culture-creation approach, in which project management is a holistic process, nurtured by the organization's shared beliefs, attitudes, and infrastructure.

But cultures can be slippery. How does one create a culture where project team members enthusiastically embrace the new attitudes, beliefs, and skills that lead to success? At Xerox, it is a matter of education. And not just the dry flip-chart-and-lecture kind of education; Hambleton immerses people in the subject in the most compelling way of all—experientially. Using a learning simulation called Countdown®, a strategy game for project teams developed by Tampa-based Paradigm Learning, Lynne equips project team members in a low-risk, high-involvement learning environment. "Countdown has proven to be a marvelous tool," Lynne confirms. "It introduces people at Xerox not just to the skills and tools of project management but also to the culture for creating value-added solutions. It is teaching project team members at Xerox what it means to be a consultant and a strategic partner."

As more and more companies begin to embrace this strategic partner approach to project management, success stories are emerging and offering a tantalizing glimpse at the possibilities. At AT&T, project team members from many divisions are brought in at the earliest conceptual planning stages of an effort. At Bell Atlantic, formal reporting processes have been established to ensure that project teams have the ongoing involvement of critical stakeholders. And at NCR, team members begin assessing opportunity and risk on day one . . . and continue until completion.

To be sure, at each of these organizations, the traditional tools of PMBOK are still firmly in place. So what distinguishes them from others? Look a little deeper, and you will find some new assumptions at work: Project work teams are most enabled when members see themselves as leaders, strategic partners, and entrepreneurs. And leaders, partners, and entrepreneurs are developed only when organizations embrace employees as whole people.

As is often the case with success stories, the victory arises not in the tools but from human beings. Now *there* is an assumption worth embracing.

The Learning Connection

So how does one communicate new principles about project management in a way that leads to a culture shift? Based on her own experience with Paradigm Learning's Countdown® simulation, Xerox's Lynne Hambleton offers some suggestions:

- Make it active. There is still a place for flip charts and PowerPoint presentations in classrooms of corporate America. But adult learning theory confirms time and again that people learn by doing. At some point, put away the flip chart and get people on their feet.
- Make it fun. "Let's face it. Project management is a pretty dry subject," confides Lynne. "I have the most success engaging learners when they're having fun. That was one big reason the Countdown simulation worked so well at Xerox. It was fun."
- Make it practical. After engaging people in the fictional world of the learning simulation, Lynne's work is only half done. The next critical piece is connecting the experience back to the reality of daily work. How can we actually practice what we've learned? How do we actually do this in our work?

If you do not tie it back, people will not ever own it.

SECTION 3.2
DESIGN AND CONSTRUCTION PROCESS MANAGEMENT FUNCTIONS

Kristin R. Hill, A.I.A.; Cindy Aiguier, John Morganti, and Bonnie Seaberg
International Facility Management Association (IFMA), Boston, Massachusetts

Norman E. Faucher, C.P.E.
Association for Facilities Engineering (AFE), CAC Industries, Inc., Leominster, Massachusetts

The largest investment of capital, personnel, and time culminates in the design construction process. In turn, this is where the greatest problems can occur. Facilities management departments can be negatively impacted when expenses get out of control, because a large portion of the costs managed by them are tenant and capital improvement expenses. Adequate procedures, standards, systems, and controls need to be addressed by a solid effective team that can deal with the many complicated issues that will arise. The design and construction process is the most volatile of all the processes and could have the greatest impact on the financial stability of the facility.

Knowing what constitutes the process and service of a facility keeps you on track for initiating the design of the facility; function follows form. Knowledge of objectives, requirements, and the specifics of different types of facilities is your guide to that design. Realize that the driving forces for these goals are the advances in technology, communication, and financial reporting. This paves the way for the tools necessary to succeed in the new millennium. The goals and objectives should focus on the true life cycle of the facility. Maintaining control of the goals and objectives as processes aids the definition of the investment and payback of the facility's life cycle. Ultimately, you can control that which you can define or measure.

Equally important are the roles of your design team. How do they accomplish these roles and responsibilities? Which type of contract is most appropriate for the project? A contract can take on many forms; knowing which one or which part best serves the project goals and objectives will enhance your position.

Learn to assemble a great team with knowledge of the advantages and disadvantages of the players and where and how they interact. What are the tools necessary to manage these players, architects, engineers, construction managers, and general contractors? Keep in mind that the success of the project depends on the players as they relate to a unified team.

Change is inevitable within the design process, but managing it brings about a controlled change. It is important to be able to identify the project baseline and learn how to facilitate changes. A controlled change can lead to a cost-effective design. The entire project team must understand the change process.

Know what documents are required to start up the facility; what records, policies, and requirements are needed to maintain the facility. Keep accurate records on the procedures that have been formulated by the design team. This enables a smoother transition from construction to commissioning to occupying the facility. Remember, design and construction, like all projects, have an end—not an end in itself but a signal of closure that sets the agenda for the informational management and operational management of the facility.

ARTICLE 3.2.1
THE PROJECT MANAGEMENT PROCESS

Paul R. Smith, P.M.P., P.E. M.B.A.
Peak Leadership Group, Boston, Massachusetts

Kenneth H. Stowe, P.E.
George B. H. Macomber Co., Boston, Massachusetts

William Duncan, P.M.P.
Project Management Partners, Lexington, Massachusetts

Successful project management depends on clear communication. All participants must share a common understanding of the terminology they use if problems are to be avoided. Yet project management's diverse roots have led to many different "dialects." Consequently, project-related exchanges are foggy at best and dangerous at worst if we do not appreciate that different people may use the same term to convey a different meaning. This article is written as an overall description of project management. Most facility managers have projects ongoing throughout their facility's life cycle. These projects may be subcontracted to third parties. However, once completed, the revised facility must be taken back and operated by the facility manager. Therefore, there is a continuous flow of information between the project manager and the facility manager.

For the facility manager who faces a renovation, restoration, or new construction, balancing competing goals relating to scope, cost, and schedule is part art and part science. Project management is a vital contribution to achieving the highest value from facilities investments. Project management involves a group of activities that mesh together; action in one activity affects others. These interactions often require trade-offs among project objectives, goals, and missions. In this article, the reader will be presented with all of the knowledge areas that must be integrated to manage a project. We begin by explaining the basic behavioral aspects of a project and later give detailed information about how to run a project.

BEHAVIORAL ASPECTS OF A PROJECT

What Is a Project?

Projects are the way persons or organizations define related jobs that perform work to create deliverable(s). Projects can be used to do work in any of the life cycles of a facility, from conception to closeout. Usually, they are temporary undertakings to create unique products or services. By being temporary, projects have definite beginnings and endings. By being unique, there is some distinguishing way in which the product or service differs from similar products or services.

Projects are performed at all levels of the organization. They may involve a single person or many thousands of people. Projects may require less than 100 hours to complete or more than 10 million hours to complete. Projects are often critical components of the performing organization's business strategy. In facility engineering and management, a project can be, for example:

- Preparing a plan for the feasibility of developing a product or service
- Creating a cross-functional team to determine the conceptual design of a facility
- Preparing the design basis, drawing, specifications, and contracts to construct or modify a facility

Because the project is unique, we will spend the majority of our discussion on defining and managing a project.

What Does "Temporary" Mean?

"Temporary" means that there is a definite beginning and a planned ending. The beginning of a project is usually after a contract is authorized or when your supervisor gives you the authority to spend money on a task or group of tasks. A project ends when you complete the customer's requirements to their satisfaction, or it is completed when you determine that the project must stop because the final results cannot provide the scope of the work within the constraints of the costs and the schedule. The results of projects need not be temporary. The Egyptian pyramids are an example of projects that have lasted for millenniums.

Products or Services

Projects provide deliverables that are measurable, attainable, and unique. Even though something was done before, it still can be unique. A second pyramid built by the Egyptians could have been unique and a project, even though one had already been built. It contained a process including the initiation, planning, execution, control, and closeout of the project.

What is Project Management?

Project management describes an organizational approach to the management of ongoing operations. Project management is the application of knowledge, skills, tools, and techniques to project activities to meet or exceed stakeholder needs and expectations from a project. Project management is necessary throughout the entire life cycle of a project.

What is a Project Manager?

A project manager (PM) is an individual responsible for managing a project. The PM is an organizer of the project. A PM is a single person who can work through others to accomplish the objectives of the project. The PM must coordinate and motivate people who sometimes owe their allegiance to other managers in their functional areas. In addition, the people who work on a project frequently possess specialized knowledge and skills that the PM lacks. The PM must often function in an environment that has many uncertainties. Even so, budgets, schedules, and resource constraints are usually imposed that create pressure on both the PM, who has limited authority, and on the project personnel whom the PM supervises.

Areas of Authority for Project Managers

The role and responsibility of a project manager depends on the type of organizational structure adopted by the corporation. The following are some typical areas of authority for project managers:

- Customer contact
- Project scope definition
- Project management plan (PMP) preparation
- Change control
- Resource allocation
- Staffing assignments and selection

Project Sponsor

Any successful project has a senior manager who champions the project. As a minimum, this sponsor must provide the following support:

- Believe in the cause of the project
- Knock down all roadblocks to the project's success
- Appoint and empower the project manager
- Define the project scope and boundaries
- Ensure project buy-in at management levels
- Ensure that resources are provided in a timely manner
- Resolve major policy issues
- Police sustained adherence to constraints
- Provide guidance and direction for key business strategies
- Support the project team in the resolution of cross-functional issues
- Stay informed about the project's status
- Deliver regular positive feedback to the team on performance versus expectations.

Tools for Successful Project Managers

There are many tools for gaining and maintaining control over a project that a PM can use, including the following:

- Having a project (senior level) sponsor
- A written statement of authority
- Sufficient rank to deal with the project personnel and stakeholders
- Access to decision makers on the topic of the project
- Communication skills and use
- Progress reports
- Knowing hidden agenda (if applicable)

Why Care About Project Management?

For the business community to succeed in a world that demands lightning-fast response to rapidly changing markets and economic conditions, we need to become project experts. As consumer markets undergo radical political and social change more frequently, more and more of the work we do is done in a project mode.

Project management is the only tested, cohesive management approach that allows you to pull a team of experts together rapidly, focus them on a specific job, disband them when they are finished, and start all over again as soon as a new need arises. An effective project manager system enables project teams to deliver the highest-quality products and services possible in the shortest time and at the lowest cost.

FORMAL PROJECT MANAGEMENT

Project management was a successful methodology in the construction and engineering world long before the business world discovered it. For decades, the U.S. Navy, Department of Defense (DOD), and Department of Energy (DOE) have actively contributed to the tools and techniques required for good project management. Their work has standardized the behavior of project managers throughout the United States and also in technology transfer throughout the world. American industries in aerospace, shipbuilding, construction, and telecommunications have benefited from this technology.

The Project Management Institute (PMI) is an international organization that is concerned with developing and disseminating good project management practices. PMI issues its *Project Management Body of Knowledge* (PMBOK) to assist users within the project management profession. The PMBOK includes knowledge of proven and widely applied traditional practices, as well as knowledge of innovative and advanced practices that have seen more limited use.

PMI's guide defines five major process groups in project management, as shown in Fig. 3.2.1-1 and defined as follows:

- *Initiating process.* Based upon the fact that projects have a beginning phase, there must be well-defined project goals, objectives, deliverables, and team spelled out in a project charter.
- *Planning process.* Devises and maintains a workable scheme to accomplish the work and the business needs for the project by defining the major activities and producing a project plan.
- *Executing process.* Coordinates the resources to carry out the plan and manage the constraints of deliverables, schedule, and budget.
- *Controlling process.* Ensures that the project objectives are meet and that the constraints are not exceeded before corrective actions or change controls are initiated.
- *Closing process.* Formal acceptance of the project deliverables brings the project to an orderly end. Documents are archived, and retrospective reviews of lessons learned are conducted.

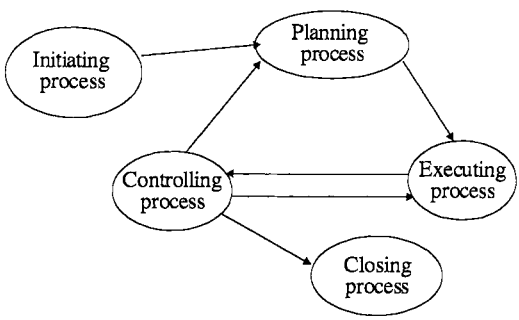

FIGURE 3.2.1-1 Links among PM process groups. [*Courtesy of the Project Management Institute (PMI).*]

The process groups are linked by the results they produce such as the product or service of one process to feed another process. The arrowheads shown in Fig. 3.2.1-1 illustrate the direction of information flow among the process groups. The processes overlap each other and are not sequential, as is shown in Fig. 3.2.1-2.

These five process groups are not one-time events that stand alone without any interaction. The levels of interaction and activity overlie and vary with the processes, as shown in Fig. 3.2.1-2. The end of one process group may provide input to another process group that requires deliverables to be accepted (such as a project charter approved) before the planning process can begin. The five processes repeat themselves in each phase of a project, as shown in Fig. 3.2.1-3.

The PMBOK also has nine knowledge areas. Each knowledge area includes the activities and processes required to ensure the following:

- *Project integration.* This knowledge area ensures that the various other knowledge areas of the project are properly coordinated.
- *Scope management.* Includes the processes required to ensure that the project includes all work required to complete the project successfully.
- *Time management.* Includes the processes required to ensure timely completion of the project.
- *Cost management.* Includes the processes required to ensure that the project is completed within the approved budget.
- *Quality management.* Includes the processes required to ensure that the project will satisfy the needs for which it was undertaken.
- *Human resources management.* Includes the processes required to make the most effective use of the people involved in the project.
- *Communication management.* Includes the processes required to ensure timely and appropriate generation, collection, dissemination, storage, and ultimately disposal of project information.
- *Risk management.* Includes the processes for identifying, analyzing, and responding to project risk.
- *Procurement management.* Includes the processes required to acquire goods and services outside of the organization.

Figure 3.2.1-4 is a cross-reference among the five processes of a project and the nine areas defined in the PMBOK. The project management outputs/deliverables of each process are

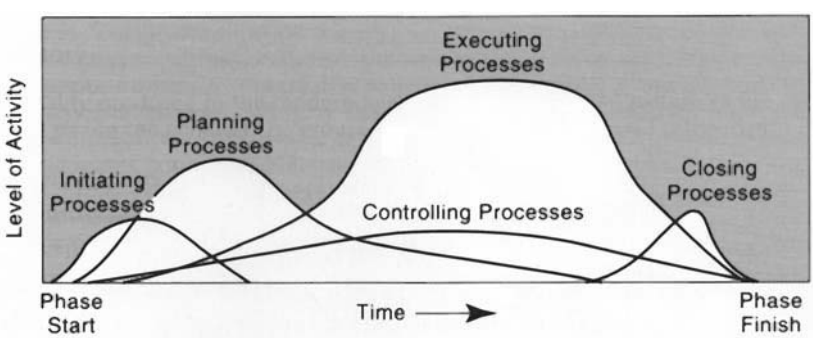

FIGURE 3.2.1-2 Overlap of process groups. [*Courtesy of the Project Management Institute (PMI).*]

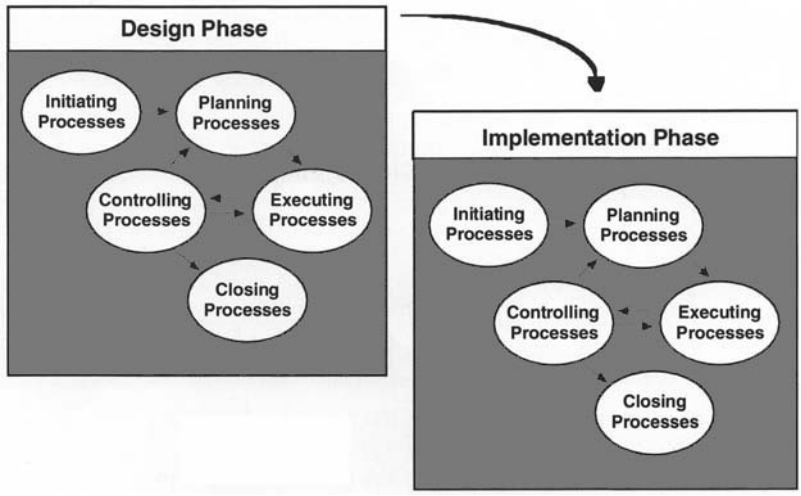

FIGURE 3.2.1-3 Process groups repeat. [*Courtesy of the Project Management Institute (PMI). Chart adapted from* A Guide to the PMBOK. *Used with permission. Copyright 1998, Project Management Partners.*]

shown as a separate box after the knowledge areas at the bottom of each process. For example, the deliverable of the initiating process is a project charter. The five process processes of a project just defined are further described in the following paragraphs:

Facility Phases

Article 3.1.4 discusses six major facility phases, or life cycles, which include the following:

- Definition of need
- Planning and programming
- Design
- Construction (build)
- Operate/maintenance
- Decision for next use

Each of these phases has five process groups called:

- Initiating
- Planning
- Execution
- Controlling
- Closing

These five groups are discussed in this article. The reader should also refer to Art. 3.1.4 for a discussion on the six facility phases.

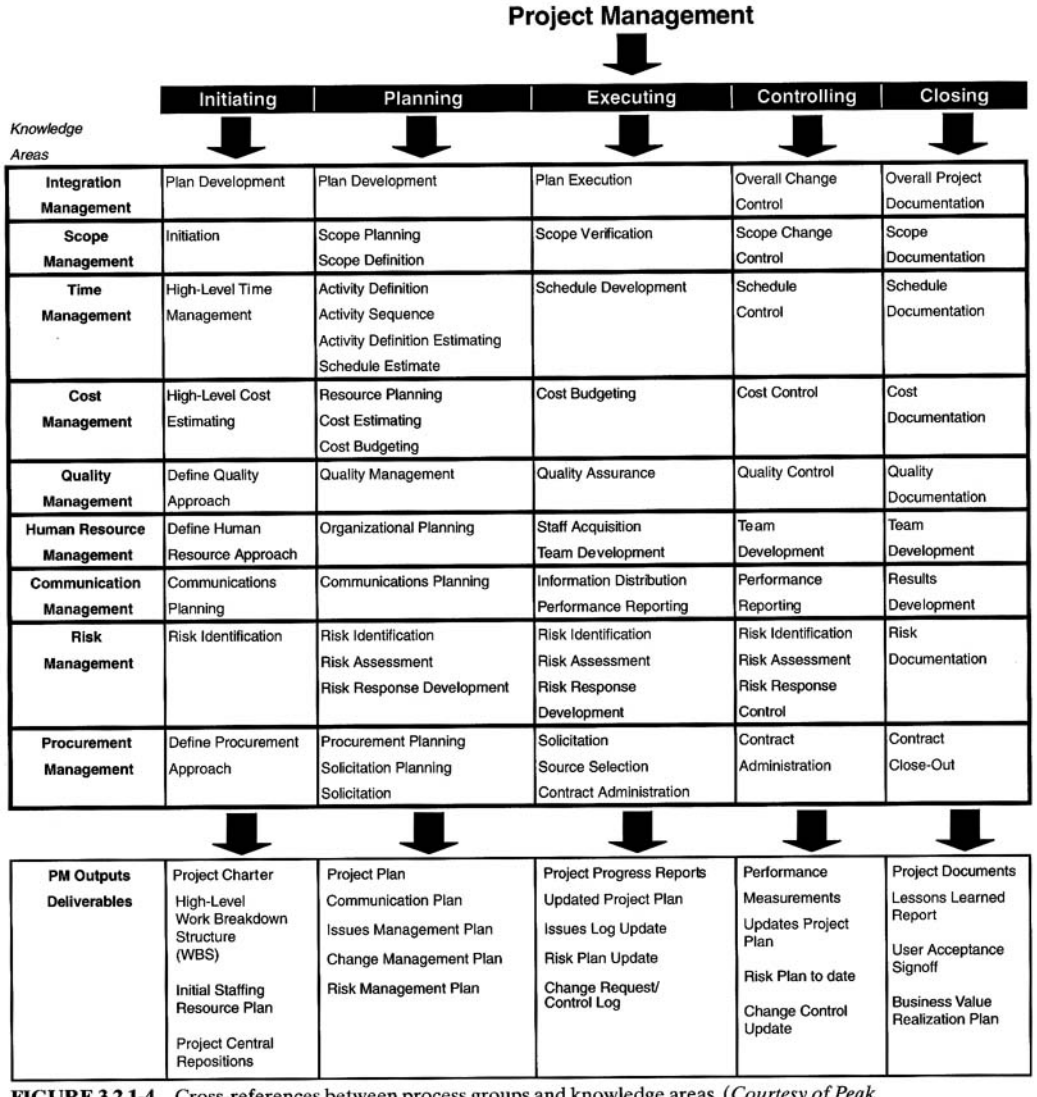

FIGURE 3.2.1-4 Cross-references between process groups and knowledge areas. (*Courtesy of Peak Leadership Group and Project Manager Partners.*)

Project Initiating Process

The initiating process identifies the project assumptions and the project objectives, products, and services to be delivered, and produces a project charter. The inputs to this process phase are the project business case, corporate policies and procedures, and lessons learned from previous projects. The process reviews and analyzes the inputs and identifies, in the project charter, the major actions to produce the project deliverables such as a definition of the business sponsor, project title, project objectives, statement of value, scope of the work, order of magnitude estimates, key deliverables, assumptions, major risks and constraints, desired time frame and sponsor approval.

Stakeholders and Their Potential Conflicts

During the project initiating process phase, all stakeholders should be identified and made part of the project team. The project team gets its lead from the financial sponsors (executive sponsor) of the project. They are likely to be looking for a specific financial performance from the facility, often described formally in a pro forma financial statement that describes the financial performance of the investment. There are the users, who will be dedicated to the functional and the aesthetic performance of the facility. These two groups can often be at odds—users demanding "bigger, better," and sponsors demanding "less, leaner." There is the operations group, which will be looking for operational and maintenance efficiency, perhaps many years, even decades, hence. There is the environmental/building codes "audience," whose demands can conflict with both sponsors and users. Finally, there is the project team—charged with developing consensus among all of the stakeholders on what to achieve, when, how, and with what resources, and also charged, of course, with executing the plan. Other potential conflicts include

- Speed versus waste
- Speed versus ongoing operations
- Cost versus quality
- Capital cost now versus operational efficiency later
- Fiscal phasing versus cash flow
- Aesthetics versus cost and/or schedule
- Environment or code upgrades versus user needs

The list of potential conflict can go on indefinitely. The project manager must work with all stakeholders to resolve or minimize conflicts and keep the project moving forward. Methods appear later in this article for refining the plan so as many as possible of the stakeholders benefit and so that the conflicts are successfully resolved.

Project Planning Process

The planning process produces a comprehensive project plan that identifies the activities necessary to produce the required deliverables of products and/or services to the customer. The plan identifies and manages all knowledge areas of the project, including integration, scope, time, cost, quality, human resources, communications, risk, and procurement, as shown in Fig. 3.2.1-4. The project charter defines the level of detail with which each of these knowledge areas will be addressed in the project. Because changes happen throughout a project, a requirement in the planning process is to monitor the execution process to ensure that the project stays on track with the project charter. Any proposed changes must be compared with

the project plan to ensure that scope creep (work done outside the project charter) is not allowed without client approval of the changes.

To define and present the project scope, time, and cost, the project manager must structure the work that is going to be performed. There are numerous methods that can be used to further define the statement of work and to understand the customers' requirements for the scope of work. One method used by many professionals is to create a work breakdown structure.

Work Breakdown Structure. Many projects involve a large number of activities. Therefore, planners require a tool to determine exactly what work has to be done, so that they can estimate how long it will take to accomplish the various elements of the project. A work breakdown structure (WBS) is a hierarchical listing of what must be done during the project. A WBS may be in the form of project life-cycle processes (design, construct, commission, closeout), functions (engineering, information systems, manufacturing, construction), or deliverables (main building, annex, infrastructure, landscaping), or a combination of these types. The WBS preparation shown in Fig. 3.2.1-5 is a major first step in planning the project. The WBS preparation is often developed to establish a common understanding of the project scope between the PM, the stakeholders, and the customer. The WBS usually includes the necessary information to define major work deliverables. The WBS approach can provide definition and structure to the work that the project team will provide and helps prevent misunderstandings. In some cases, for project definition clarity, the WBS defines work not in the scope of work or follow-up work.

A WBS is developed in flow chart form as in Fig. 3.2.1-5. A WBS is a method of creating a project plan that subdivides work into hierarchical units of tasks or deliverables, work packages, and units of work. Each element within the WBS serves as an item or subtotal in the budget and as an activity or summary bar in the schedule. There are numerous levels in the WBS, and each one gives more detail to support the higher-level elements of the project. Each item in the WBS is given a unique identifier; collectively, these are called the *code of accounts.* The items at the lowest level of the WBS are often referred to as *work packages,* as shown here:

Level 10—Company
Level 20—Authorization
Level 30—Control
Level 40—Work Package

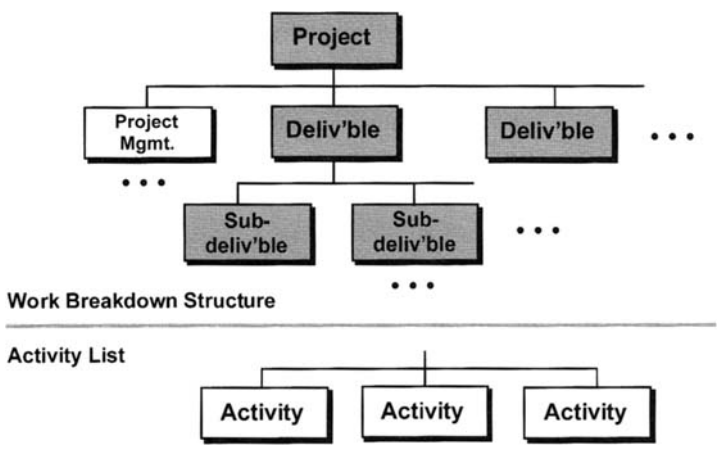

FIGURE 3.2.1-5 The work breakdown structure (WBS) types deliverable or activity. [*Courtesy of the Project Management Institute (PMI). Copyright 1998, Project Management Team.*]

The WBS should be prepared in conjunction with the scope of work; should include the entire scope of work; and should be developed to the level of detail where responsibility for performance is assigned. Responsibility for each element of a WBS should be established.

A WBS dictionary uses the terms identified in the WBS so that a common language is spoken on the project. Once the language is standardized, information for follow-up activities such as work package development and descriptions, resource loading, and other planning information regarding schedule dates, cost budgets, and staff assignments is consistent.

Work from a WBS can be displayed in a pictorial form, with color schemes to show information such as the actual 3-D work, processes of the project, or even schedules for the project, as shown in Figs. 3.2.1-6 and 3.2.1-7.

Defining Work Scope. Many projects are unsuccessful because they fail to define structure and do not communicate what the customer really is willing to pay for. When a project is initiated, the following information should be addressed in a project overview:

Project overview:

- Current status, described today
- End status: a description of the process after the requested project is completed

What:

- Customer requirements, statement of work
- Project scope: identify all of the tasks and deliverables included in the project
- *Project objectives.* Overall goals of the project
- *Project outcome.* Target deliverables/results of project
- *Project constraints.* Cost, schedule, and so forth; limits of the current project
- *Key assumptions.* Information that defines the project scope

Why:

- *Business case.* Business objectives of the project
- *Business benefits.* Summary of the business benefits of the project, including financial and tangible benefits

When:

- *Start date.* Project initiation target date
- *Start date drivers.* Factors impacting the start date, such as key resources
- *Key milestone location.* Certain date or time when the status of the project or deliverable is required
- *End date.* Project completion target date
- *End date drivers.* Factors that impact the completion date, such as Year 2000 and government deadlines

Who:

- *Project sponsor(s).* Senior management overseeing the project
- *Process owners.* Process users impacted by the project
- *Lead users.* Lead people who will participate in the project and provide functional expertise
- *Key users.* Other user participants

How:

- *Alternatives.* A summary of the different methods by which the project could be implemented
- *Recommended approach.* Proposed solution to the project

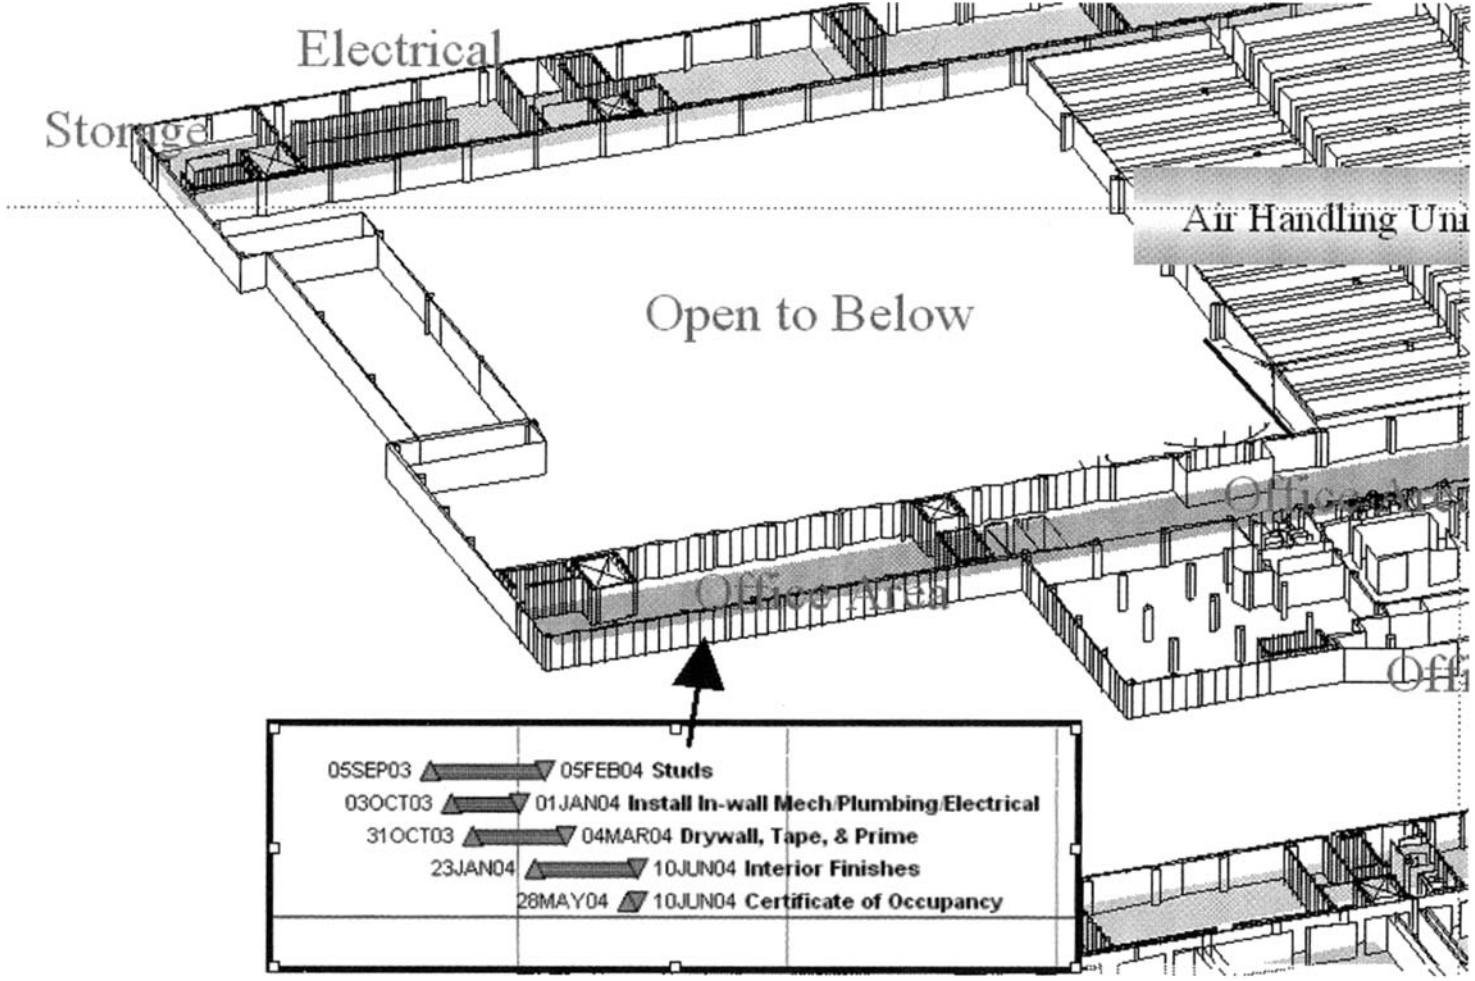

FIGURE 3.2.1-6 Pictorial way to illustrate work. (*Courtesy of the George B. Macomber Company.*)

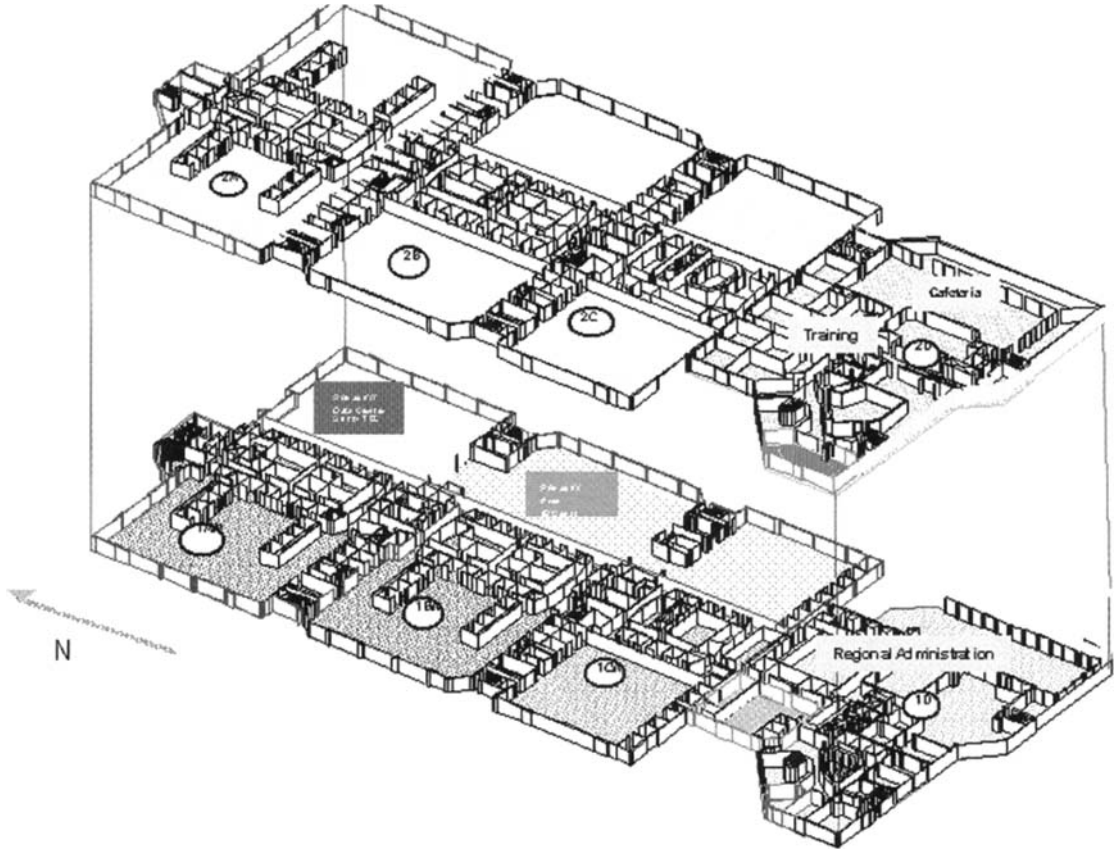

FIGURE 3.2.1-7 Pictorial work scheduling technique. (*Courtesy of the George B. Macomber Company.*)

- *Project work plan.* A high level project work plan, including primary project tasks and milestone dates
- *Deliverables.* Description of project end results (reports, programs, documents, products, and services)
- *Risk management.* The risk management strategy to be used during the project
- *Change request.* The method for gathering issues and change requests

Early communication with the customer is important for each work activity to ensure that both sides understand the work scope sell. People can have different interpretations of descriptions and varying levels of technical expertise, so it is important that you communicate up front what you understand the customer requires and what the deliverables of the project mean to the project team, and that you get the customer's responses.

Work Package Development. Work is usually defined in a work package that organizes the work task or groups of tasks. Each work package includes detailed schedules, resources, and assumptions. When applicable, standard work packages planning procedures with documentation forms should be developed companywide.

Detailed work package planning involves clearly defining and planning the detailed scope, schedules, and costs for specific elements of the work. In addition, detailed resources planning and budgeting occurs at the work package level. (See the previous discussion on WBS for work package definition.)

It is considered a best practice to use work package planning to establish a basis for scope statements and a basis for the detailed cost and schedule estimates. Commitments from the performing organization can be easily documented on the work package activity assignment section.

Project Schedule, and Cost. All projects have goals and limited time, space, money, equipment, and intellectual resources with which to achieve them: Rigorous project management, often described as part art and part science, is a vital process for managing unique jobs or activities that have clearly defined scopes, costs, and schedules. The project scope is the most important of the three factors to define. The cost and schedule are the constraints under which the scope must be defined and managed, and sometimes they require readdressing the scope.

Organizational Structure. All of the resources required to accomplish the work described in the WBS must be clearly identified and scheduled. Often, when the lines of authority need to be clarified, the team should make an *organizational breakdown structure* (OBS). Detailed resources requirements and availability of those resources should be identified before schedules and budgets are formally established and commitments are made. The following are examples of resources:

- Labor (by discipline, skill, organization, number)
- Computer (including special software)
- Materials and supplies
- Physical facilities
- Support services (recruiting, training, and administration)

Resource planning and optimization should be based on detailed cost estimates coordinated with performing organizations. Resource planning such as that shown in Fig. 3.2.1-8, provides the basis for work task managers, as well as for functional organization managers, to plan their resource needs for the project's duration.

Preliminary resource planning can be critical. For instance, functional managers or suppliers may need to be contacted early to ensure availability of personnel, equipment, or supplies.

Enterprise Resource Planning. Project resource demands often compete for resources required elsewhere in the company. Doctors are needed to attend hospital project planning

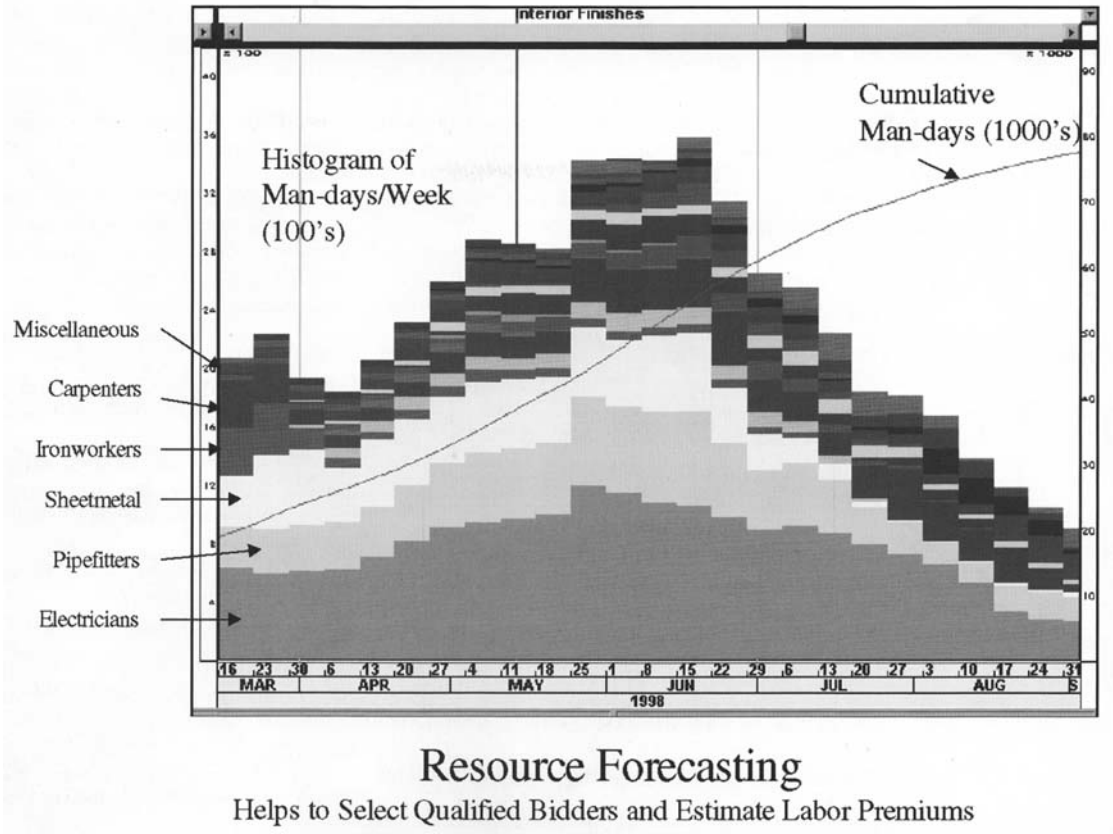

FIGURE 3.2.1-8 Resource forecast loading. (*Courtesy of the George B. Macomber Company.*)

meetings. Production managers are needed to attend design and construction meetings. These conflicts give rise to a need to carefully design the project organization and clarify how much time the project team can expect from these resources. Decisions need to be timely and often require understanding complex inputs. There is no substitute for taking the time and having the skills and experience to digest the matters involved. The skills of the project team must be addressed in all processes of the project to ensure that the right persons are on the job at the right time.

Schedule and Time Techniques. There are two principal methods for estimating the time that project activities will take. The *backscheduling* technique sets the date of completion and then forces the project to fit the available time. Backscheduling is often dictated by legal, regulatory, or market factors. However, some deadlines are selected arbitrarily without taking cost and quality implications into account. This unstudied development of milestones can be very costly to organizations and demoralizing for the project team. With the backscheduling method, managing project resources is critical, and controlling time rigorously is advisable. There are times when backscheduling may be the only option. Unfortunately, accepting a time period because it is "mathematically necessary" can produce unrealistic project completion dates and in reality can be too costly to meet. Also, this method may cause undue stress within the organization to meet the deadline.

Forward scheduling estimates the time for each activity and estimates a project completion date from these estimates. This approach usually produces more realistic project completion

dates. However, there is always the possibility that excessive time will be padded into the schedule.

Time Contingency. One method of dealing with tight schedules is to acknowledge the risk of missing any one of many critical dates in a project schedule and to create a time contingency. Many professional planners consider planning with time contingency (at the end of the schedule) just like a budget contingency to allow for unknowns.

Tools and Techniques for Documenting Activity Sequencing. Activity sequencing looks at the proposed tasks and can use two types of diagrams, namely, *activity on node* and *activity on arrow.*

Series Versus Parallel Processing Activities. When two or more activities can take place in the same time period, the process is called a *parallel process.* When only one activity occurs at a time, it is called *series processing.* Parallel processing saves time, but there are times when a series process cannot be avoided. However, changing a work method may create a parallel process from a series process. For example, traditional home construction methodology dictates that you cannot build a roof until you put in the foundation. However, if you use a prefabricated home kit, the roof can be assembled and ready to install before the foundation is laid.

PERT. The Program Evaluation and Review Technique (PERT) was originally used by the U.S. Department of Defense (DOD) Research and Deployment Team for the Polaris submarine project.

PERT Estimates. PERT uses three estimates of duration—optimistic, pessimistic, and that most likely to increase the accuracy of the estimate. In estimating durations, many projects suffer from one or another party's subjective interest in the project. Some estimates are unrealistically low (the head-in-the-sand estimate)—often a result of someone who wants the project to move forward or who wants (too much) to win a bid. Some estimates are grossly overestimated (the sky-could-fall estimate)—the result of a risk-averse person or party. The best estimate is one that is factual, accurate, and objective.

CPM. Critical path scheduling consists of analytical techniques to plan and control a project. The critical path method (CPM) is quite similar to the PERT method. The basic forms of PERT and CPM focus on finding the longest time-consuming path through a network of tasks as a basis for planning and controlling the project. A good CPM planner creates and/or facilitates the creation of a network of related activities. The activities are related to predecessor and successor relationships with *lag.* Lag, the term to define whether the start or finish of one activity is related to the start or finish of another, may be zero. Firms that offer project planning and control software often have excellent documentation and training programs that introduce CPM.

A good CPM network is a model that forecasts the way the project will perform and as such has the following characteristics:

- The scope is well defined.
- Tasks are discrete and are related accurately.
- Resources are modeled that may impact project performance.
- The model has a database structure that honors the project work breakdown structure so that activities can be sorted, filtered, and colored for effective presentations and summaries.

Slack Time. Total slack is working time that an activity can slip without affecting the end date or any critical milestone. Slack time is a valuable piece of information. If the project is moving forward according to schedule, activities that have slack time can be postponed. Then,

effort can be directed toward other more critical activities. There are two kinds of slack time, *total* and *free.* Total slack is the total nonscheduled time available for the activity. Free slack is the amount of working time an activity can slip without affecting any other activity.

To calculate a slack time, one must calculate four time-values for each activity as follows:

- *Early start time (ES).* The earliest possible time the activity can start
- *Early finish time (EF).* The early start time plus the time to conduct the activity
- *Late finish time (LF).* The latest time an activity can finish without delaying the project
- *Late start time (LS).* The latest time an activity can start without delaying the project

The total slack of an activity is the lesser of (LS – ES) and (LF – EF).

DESIGN—AN INTEGRATED APPROACH TO REFINING THE SCOPE DOCUMENTS, BUDGET, AND SCHEDULE

Schedule Baseline and Optimization

The most effective way to build a schedule so that it is realistic and so that the project team will perform at a high level is to create a "first-pass" baseline that is a solid network and has the entire team's buy-in as a starting point. In this schedule, all activity durations are acceptable to the team, and activities have realistic relationships. Milestones are established in this baseline schedule as a definitive way to break down the project and allow "at-a-glance" comprehension of the schedule. This baseline schedule (and its implicitly and explicitly implied means and methods) is the basis for a comprehensive baseline estimate of project costs. Attention is drawn to time-variable costs (e.g., staffing, office trailer rental), and seasonal costs (cold weather protection, erosion control). These costs bear watching as the team analyzes options.

Then, optimization analysis follows (usually, but not always accelerated) to achieve the earliest economic completion. The critical activities are established and their durations and relationships are tightened. Each "element of acceleration" is analyzed for its impact on cost, quality, and safety. A strategic team is also engaged to consider the value or "earning power" of the completed project and may be empowered to increase the budget if the increase can show a favorable return on investment.

Resource Loading and Leveling

The project team's job is to anticipate when resources may not be available to accomplish activities. When resources are potentially scarce enough to constrain the pace of a project, resource loading of the activities on the schedule is vital. These constraining resources may be a selected trade (like pipefitters), a material (such as concrete from a batch plant), a piece of equipment (such as a crane), or cash.

Resource Leveling. When resource demand may exceed resource availability, activities often need to be postponed to reduce or flatten the demand. Professional project planning software will allow resource loading and automatic leveling and will postpone activities with lower criticality or priority to reduce demand for critical resources during peaks. If resource-leveling algorithms are employed, they should be used with a measure of caution because they only "reason" as well as the model has integrity. For example, if an activity does not have the correct successors and as such has an inaccurate amount of slack, the algorithm may postpone an activity that may greatly and adversely effect the completion date.

A good method of resolving disagreements between stakeholders about how much to accelerate a schedule is to drive all inputs to a net present value and optimize. The chart in Fig. 3.2.1-9 is an illustration of a project analysis to determine whether the August 1 project deadline is justified when all time-variable costs are considered: the expediting, the general conditions, and the revenue and compromises for each completion date.

Gantt Charts. Gantt or bar charts are graphical displays of schedule-related information. In this type of chart, activities or project elements are listed down the left side of the chart, dates are shown across the top, and activity durations are shown as date-placed horizontal bars. Gantt charts are to scale, and therefore unlike PERT charts, the actual duration can be determined by glancing at the timetable. Activity sequencing and whether activities run in series and parallel are easily recognized at a glance, as shown in Fig. 3.2.1-10.

Presenting Complex Data. Often, bar charts and Gantt and PERT diagrams are inadequate communication vehicles. The audience may be unskilled, uninterested, or unwilling to take the time to digest a complex schedule. Then a visual image can be worth a thousand words. Here, a single graphic conveys to the user community where the processes begin and end, when they begin and end, and what the status of the adjacent spaces will be when the user takes occupancy. The result can often be that the users understand more of what to expect and what their obligations are.

Project Execution and Control—Measuring Progress as the Plan Is Executed

The project plan is never static. Every day brings reports of progress, questions, delays, new information, and so forth. The project progress is measured against the plan on a formal and regular basis. Milestones (discrete, measurable, and undebatable progress points) should be built into the schedule to make the comparison of plan versus actual progress very easy. If these milestones represent design releases, they should be defined with a clear set of deliverables. These points can be used to reward the project personnel formally or informally. The frequency of reporting progress should be at the project team's discretion but in any case should be at least monthly. When projects are very dynamic and very tightly scheduled, the frequency may be weekly or even daily. More frequent updates are often easier to accomplish because the information is fresh.

Updating the schedule for the greatest accuracy and making progress payments sometimes requires measuring *earned value.* Earned value is used to protect the owner's interests and to counter any confusion that may enter the discussion around "percentage completion." An activity may be 50% complete in terms of duration, because mobilization and setup time can be extensive, but may be 10% complete in terms of the quantity of material in place. For payment and productivity calculations, the earned value, defined as the completed quantity in place divided by the total quantity multiplied by the value of the activity, may represent an important difference.

Project Status Meetings

Weekly status meetings provide a forum in which participating project team members can communicate with one another. Status meetings allow for discussion of essential issues relating to the project and provide an opportunity for project team members to communicate with each other to ensure understanding of status, issues, and upcoming plans. In addition, the status meetings allow for issues with cross-project area categories to be discussed by parties involved within the project area, allowing for common understanding and joint definition of resolution.

Project meetings are usually conducted on either a Friday afternoon or Monday morning, depending on the number of active projects and the availability of the meeting location. The list of invitees should include the following:

Cost Benefit Analysis of Alternative Project Completion Dates				
For the Schedule Completing:				
Affected Budget Line Item	**01- Jan**	**01- Mar**	**01- May**	**01- Jul**
Construction Expediting Contingency	$ 902,000	$ 740,000	$ 520,000	$ 400,000
Design Expediting Contingency	$ 120,000	$ 90,000	$ 50,000	$ 25,000
General Conditions-variance from baseline	$ 25,000	$ -	$ 40,000	$ 80,000
Fees on Acceleration Costs(variance from baseline)	$ 6,510	$ -	$ (6,600)	$ (9,750)
Net Present Value of Revenue Impact-(variance from baseline)	$ (230,000)	$ -	$ 230,000	$ 460,000
Other Time/Cost Variables	$ 22,000	$ -	$ (36,000)	$ (11,000)
Total	**$ 845,510**	**$ 830,000**	**$ 797,400**	**$ 944,250**
	$ 230,000	estimated net value of operating month at completion

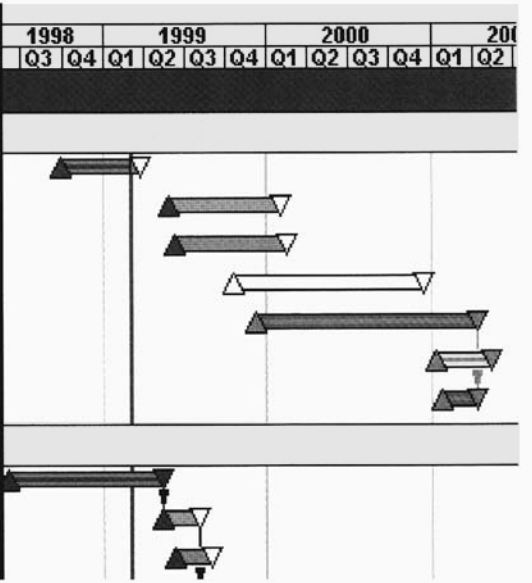

FIGURE 3.2.1-10 Project activity controlling. (*Courtesy of the George B. Macomber Company.*)

- The project management team
- The functional lead for the project area
- At least one representative from each outside party associated with the project
- Any project area participants whose areas are currently active and may have input into the status meeting
- A representative of the project management office, if applicable

Each of these should be invited to the weekly status meeting, but the status group should be kept as small as possible to minimize the impact of the meeting on the participants' progress. The status meeting should cover the following topics:

- A walk-through of the status report to identify accomplishments since the prior week and to highlight deliverables missed and their possible impact
- Identification of issues related to project areas and assignment of responsibility for resolving them
- Identification of cross-project area issues and assignment of responsibility for bringing these issues to the PM
- Discussion of project logistics among team members
- Plans for the upcoming week and arrangement of upcoming meetings

Status meeting minutes should be taken and issued within one working day. The minutes should include the following items:

- A list of attendees and those invited but not in attendance
- A distribution list for meeting minutes
- A summary of key points discussed
- Highlights of accomplishments since the previous week
- A summary of tasks for the coming week, and assignment of responsibility for each task
- Identification of issues and follow-up items discussed but not resolved during the meeting, and assignment of a person to resolve and report the findings
- Modification to key project milestones or the project schedule from the prior week or resulting from the status metering
- A summary of overall project goals for the coming week

Project Management Status Meetings

Project Management Status review meetings bring the entire team up to speed on the progress since the last status meeting. The management review meeting is usually conducted on a regularly scheduled basis (i.e., monthly basis) using the information from the project weekly status reports. The meeting should have an established agenda that includes the following topics:

- Project objectives
- Scheduled deliverables
- Original project timeline
- Original project budget
- The team: resource utilization
- Current project status: includes work completed, deliverables provided, and client perceptions

- Status against budget and timeline
- Key milestones going forward
- Lessons learned
- Open issues

Version Control

As the schedule and scope options are embraced and each is analyzed for the impacts on cost, multiple versions will be published and can confuse the audience and the team members. Version control is a simple naming of versions to eliminate confusion among various published schedules. One easy to follow method is to name the first acceptable baseline "Version 1.0," and label each succeeding version with small changes 1.1, 1.2, and so forth. When a delay, a substantial change, or a schedule is published to a wide or high-level audience, the schedule is named "Version 2.0." Version control gives rise to an important type of report called the *variance report.* It defines the actual or "current forecast" dates for each activity, the "as planned" dates of the baseline or "target," and the variance or difference between the two.

Issue Resolution Strategy

One of the primary roles of the project area managers is identifying, tracking, and resolving project issues, including issues that may change the project scope. A key factor for success for the effort is the development and use of a standard issue tracking and resolution strategy (see Fig. 3.2.1-11). Issues should be identified and communicated through the use of issue communication strategy.

The project issues should be maintained in an issue tracking system. The issue tracking system, which may be custom-developed or purchased, will allow storing issue information in a database that has multiuser entry and retrieval capabilities. Project lead persons should be able to enter resolutions or actions against the issues and to change issue status.

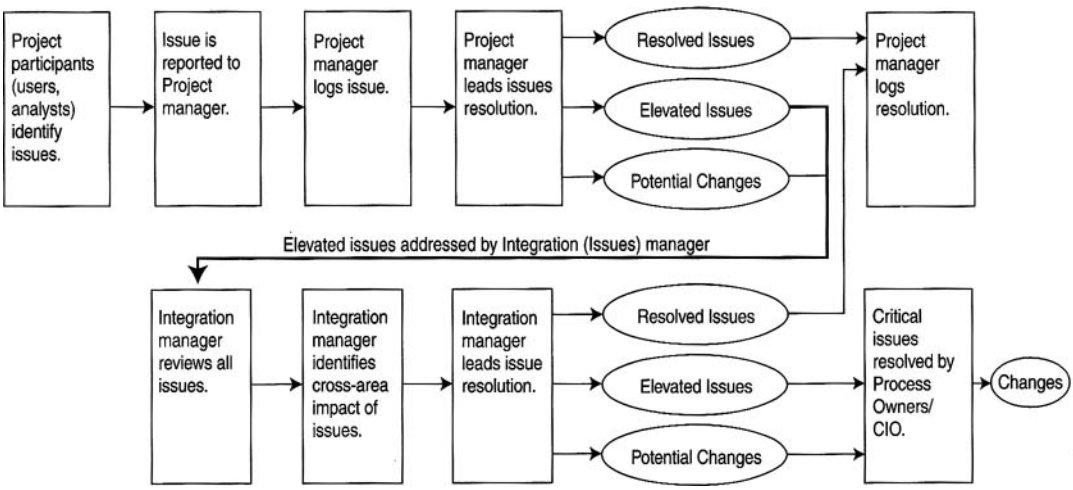

FIGURE 3.2.1-11 Issue resolution process. (*Courtesy of Peak Leadership Group.*)

Change Management

In some cases, issues and their resolution, including changes in cost and effort, will impact the project scope and timeline. These types of issues can be identified as potential changes during the issue resolution process. The change management process is similar to the project initiation process. When the resolution of an issue requires a change in the project, the change management process is initiated. Based upon the analysis of the pros and cons of implementing the change, it may be approved, revised, or the issue resolution may be modified so that the change may not be required. For more details, see Art. 3.2.2, "Change-Control Process."

Project Closeout

The closing process documents the outcome of the project. Products and services are delivered, actual project results are reported, project contracts are closed out, personnel are reassigned, and project lessons learned are documented.

The input to this process includes the final (last) approved charter, final project plan, and project results. The results usually contain the final project status report and final earned value analysis (EVA). A checklist of final actions should include the following items:

- Close out and settle contracts
- Resolve any remaining action items
- Provide final project accounting information, including invoice details and billable expenditures
- Conduct a lessons-learned meeting with the project team
- Document successes
- Document opportunities for improvement
- Communicate results to all stakeholders
- Update the lessons-learned database
- Generate and archive final project documentation
- Produce final scope, cost, quality, and risk documentation
- Produce final as-built documents
- Provide final performance information
- Provide performance feedback to all members
- Provide final documentation to project sponsor, owners, and management for approval

Occupancy is an important phase of a successful facility project. It involves planning, resource analysis, milestone definition (what is the condition of the facility that is acceptable for the owner's equipment, furniture, personnel, etc.), packing, move planning, and control. It often involves weekend and off-shift work. It is the phase that, if unsuccessful, can soil the reputation of a solid project team because it is the most visible phase to many users. If it is treated as an integral part of the project planning and execution, the likelihood of success can be greatly enhanced.

For a discussion of construction and commissioning, see Chap. 6.

In some cases, issues and their resolutions, including their cost and effort, impact a project's scope and time line. These issues are identified as potential changes during the issue tracking effort (see Art. 3.2.1, "The Project Management Process").

A change-control process ensures that facility changes are identified, controlled, and integrated into the facility's system. The steps for this process are evaluating, coordinating, implementing, and documenting the changes. This process maintains consistency among the design requirements, the physical facility's configuration, and its documentation requirements. Change control is the most important process in ensuring that the facility has accurate documentation; as such, change control is usually the first process to be worked on when a facility wants to regain configuration control.

When establishing change control, the facility manager should have established, up-to-date, facility baseline documents. Examples of baseline documents include the master equipment list, as-built master facility drawings, a master facility drawing list, change-control documents, as-built specifications, approved vendor data, operating procedures, and operating and maintenance manuals.

PROCESS STEPS

The first step in the change-control process is to identify, as soon as possible, the change that needs to be tracked, so as to assess the impact of the change on risk, cost, coordination, and time. Those changes that are critical to the facility, costly to purchase or maintain, and/or are complex to manage should be the top priorities. The larger the facility complex or the more numerous the locations, then the more items that should go through this process. In this process, the benefit of tracking the change should outweigh the efforts to produce the change. Keep necessary documentation of the change to a minimum to avoid excessive and unnecessary paperwork.

The second step is maintaining the change-control process. The facility manager is responsible for maintaining this process and should use a system for logging and tracking the steps of the change. This can be a facility change form, a document revision request, a drawing change form, or a construction interface document. These forms can provide a means of formal review, evaluation, and approval of the proposed change.

The third step is configuration management control. This step assures that with the change, the physical facility maintains its conformance with the design and that both the physical facility and the design requirements are accurately reflected in the documents. Configuration management control provides supervised change and integrates information about the facility into a structured, usable format (see Fig. 3.2.2-1, Steps 3.1 through 3.8, for more detail).

The fourth step is implementing the approved change.

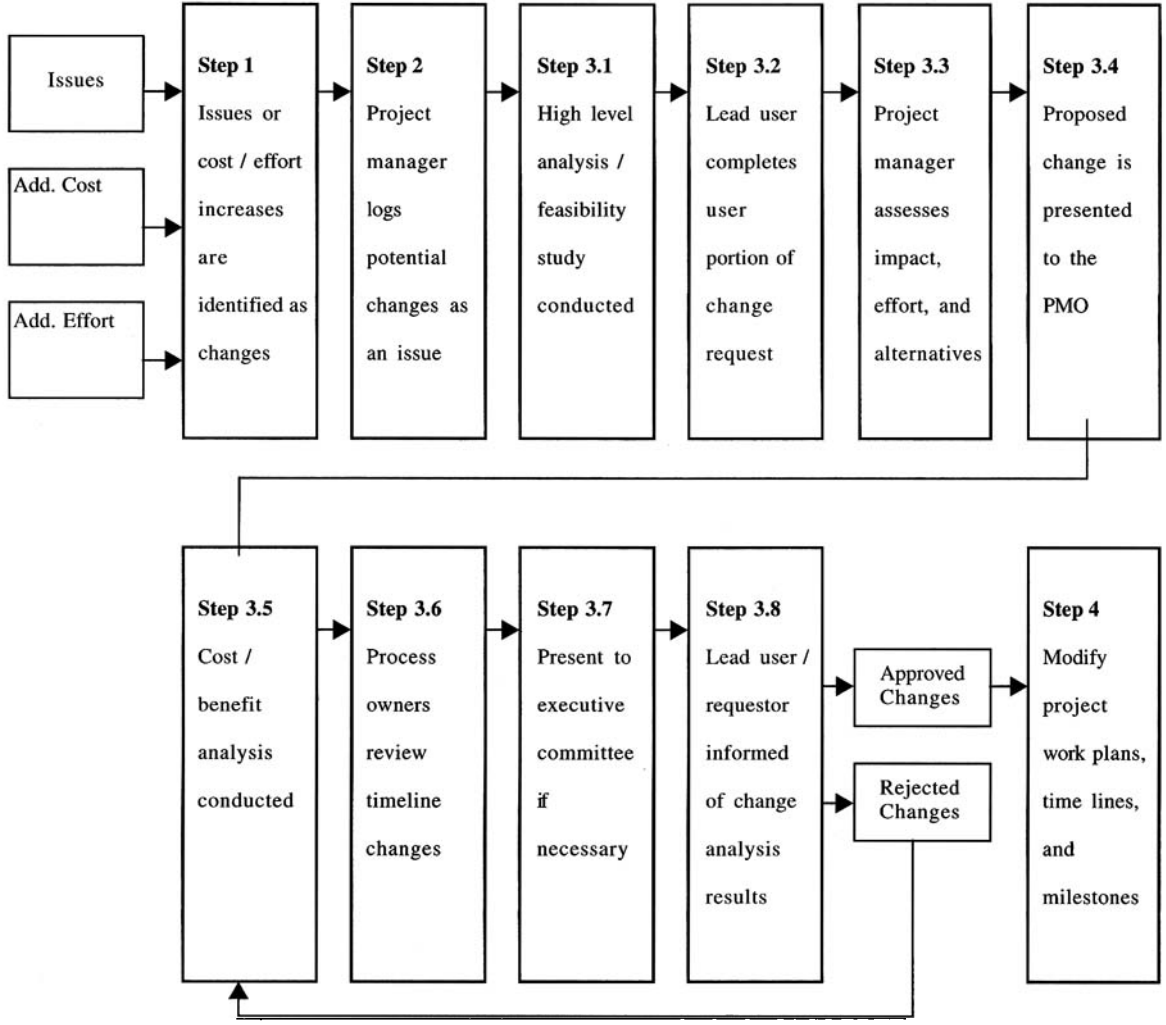

FIGURE 3.2.2-1 The change-control process. (*Courtesy of Paul Smith, P.M.D., P.E., M.B.A., Peak Leadership Group.*)

TYPES OF PROJECT CHANGES

Figure 3.2.2-1 is a high-level diagram that illustrates the control of project changes. The following are some common types of changes and the reasons for tracking them.

Facility Modifications

Facility modifications that alter the facility's equipment or structure need to be consistent with the design, need to list acceptable substitutes, and need to consider maintenance and repair requirements. A list of structures, systems, and equipment critical to the facility operations should be identified.

Maintenance Changes

Maintenance changes alter the facility's maintenance process. Maintenance personnel are the best source for maintenance changes and should be encouraged to submit changes via this change-control process. The facility manager should be cautious and make sure that plant personnel clearly understand the difference between a "change" and "routine maintenance." Maintenance activities that change the facility need to be evaluated for consistency with facility requirements by ensuring that safety and reliability have not been downgraded or compromised and that the change conforms to the design, construction, and operational requirements of the facility. Routine maintenance activities that involve routine repair or restoration of the facility (like-for-like replacement) without altering the physical or functional characteristics need not be evaluated for consistency with design. Any deviation, such as manufacturer equivalent substitutions, changing torque values on a mechanical seal, changing O-ring material, changing glue type on a control component, and so forth, should be evaluated as a maintenance change.

Procedural Changes

Procedural changes (such as in operating procedures) result from a modification and need to be evaluated to ensure that they do not violate the design and safety limits established for the facility.

Document Only Changes

These changes to specifications, vendor data, manuals, and so forth do not affect hardware but alter the accuracy, intent, or context of the facility's documentation. Changes to these documents should be reviewed to ensure that they do not alter the design, regulatory, or operational limits of the facility. The level of approval of the change in these documents should be consistent with the level of the original document approval, unless the change is nontechnical (such as correcting misspelled words). Take care not to alter trade-specific terminology when attempting to correct misspelled words.

Software Changes

Changes to software include the basis for safety analysis, design information, facility configuration, supports of the facility process system, or changes to software used for technical or

safety decisions. This software requires a formal evaluation of the basis and an evaluation of its impact on performance, customer requirements, and safety before implementing the change.

Operational Changes

These are changes that deviate from the procedure established for start-up, normal operations, or the shutdown phases of facility operations. An example of an operational change is adjustment in instruments and equipment set points that have secondary effects on engineering considerations such as reductions in safety margins and response time. Additionally, lifting leads, jumpers, and other temporary modifications need careful attention. When established operational limits are exceeded, this could also damage or reduce the qualified life of equipment/components or cause potential accidents.

Safety Questions

These are changes that did not review safety issues. An example is a change made to a facility that reduces the margin of safety, increases the probability of a serious accident, or introduces a possibility of a type of accident not previously identified.

Training Changes

These are changes in hardware, maintenance practices, procedures, documents, software, or operational techniques that require updated training. The form of training can be formal classroom introduction, required reading of a text or manual, on-the-job training, prejob briefings, computer- or video-prompted introduction, self-paced workbooks, and so forth. A written record should be established and maintained by the facility training coordinator to ensure that the required training update has been completed. Dates should be established for completion of training to ensure that the training is done in a timely fashion. The required training for each job title should be in written form. Each employee's personnel file should document completion of this required training.

Minor Changes

These changes include spelling, grammar, punctuation, and inconsequential textual content, changes to personnel positions or procedural title changes, and updating the facility management system document matrix. These changes can be exempt from the same level of review and approval as the original document. The facility manager can authorize these minor changes. The revised minor changes should be distributed to the same personnel as the original document.

Technical Review

These are changes to an approved baseline item that must be reviewed and approved by the "design authority" for that system or process to ensure consistency with the design basis. Technical reviews may be performed by organizations other than the engineering unit, such as maintenance or operating personnel, if they have access to the design basis via a "design envelope" that established preapproval limits or constraints within which changes can be made without exceeding design requirements. If a proposed change is not consistent with the design requirements, then the engineering unit must be consulted. Technical reviews and approvals of changes to the documents previously mentioned should be the same as required for the original issuance of the documents. The changes should be implemented upon receipt of the required approval.

MANAGEMENT REVIEW OF CHANGE

Facility management should review proposed changes to the scope, cost, and schedule of the project to verify that adequate technical reviews have been performed and documented. Management can prevent changes to the project baseline, except as directed and when changes to the project effort are agreed to. All changes to the project scope, cost, and schedule shall be documented and approved in accordance with the requirements defined in the operations program management plan. Management should approve changes before implementation. Changes made before the required approvals are given should be prohibited for safety reasons. The only exception is for minor corrections.

DOCUMENTATION OF CHANGES

Once a document change has been approved, all relevant documents affected by this change shall be identified, modified, and updated in a timely manner. Documents such as those required to operate the facility shall be updated before returning the facility to operation. Facility personnel should document and review the approved changes to the project baseline documents as soon as practical during the normal course of design, construction, and operation.

ADDITIONAL POINTS OF CONTROL

The following areas must be attended to in a successful change-control process.

Technical Vendor Control

Procedures should be established to ensure that important vendor activities and information are consistent with the facility's requirements. The control management program requires reviewing and approving vendor procedures before work commences or imposes the use of facility procedures for work conducted at the vendor's facility. The facility manager is to define when vendor work has been completed satisfactorily and is ready for information turnover with established acceptance criteria to the facility personnel. After turnover, vendor information can be kept current and available by including it in the document control center. Vendor data on systems, equipment, components, or items associated with the facility's operation are available from the manufacturer. Document Control shall receive, catalog, and store all important vendor data for retrieval. Vendor data consists of: shop and fabrication drawings, operating and maintenance instructions, installation procedures, installation instructions, user manuals, training materials, warranties, spare parts lists, parts availability, and operating life expectancies.

Information Equipment Databases

Document Control should maintain information on all systems, equipment, and components that are critical to the facility's operation in one central configuration management database, which may be a hard-copy file. The database will provide updated and consistent information on systems, equipment status, and maintenance to facility management and the project personnel. The database can be based on the facility's comprehensive equipment list, master equipment list, vendor data, and key drawings.

Computer Software Configuration Management

Software configuration management applies to any computer programs, procedures, rules, and associated documentation and data that are essential and critical to the design, analysis, evaluation, assessment, operations, and process control of the facility. Software users must manage and control computer software during its entire life cycle. This is particularly significant in software used for technical decisions.

Configurational Management Procedures and Training

When new projects or tasks are initiated, the facility manager should identify appropriate procedures and engineering standard practices that must be complied with by the project.

Records Management and Document Control

Record management ensures that activities affecting the life cycles of records are planned and managed. These actions ensure compliance with applicable federal, state, and company policies and requirements. Records are broadly defined as papers or other documentary materials. Regardless of their physical form, records are worth preserving temporarily or permanently. The records provide proof of the facility's performance.

Quality Program Plan (QPP)

The facility's Quality Program Plan identifies program requirements, personnel responsibilities, and authorities to provide required quality assurance for operating the facility. The QPP can be organized around the American Society of Mechanical Engineers (ASME) procedure NQA-1 18-point criteria.

Environmental, Safety, & Health (ES&H) Requirements

ES&H design requirements are necessary to (1) prevent or mitigate the consequences of hazards (e.g., toxic or chemical hazards) to personnel off-site, on-site, and local to the facility; (2) provide worker health or industrial safety; and (3) protect the environment. ES&H design requirements are established to comply with safety regulatory requirements imposed on facilities by agencies such as the DOE, EPA, OSHA, and other federal, state, and local agencies that regulate environmental protection, worker safety, and the health and safety of the public.

Mission Requirements

Design requirements critical to the mission are necessary to prevent or mitigate substantial interruptions in facility operation or severe cost impact, or are necessary to satisfy other facility mission considerations. All operations will be conducted in a manner that minimize the impact on the environment.

Design Basis

The principal design requirements for the facility should be established and documented. The following are some documents that can be used to create the design basis:

- Functional and operational requirements
- Design reports
- Engineering design files
- "As-built" drawings
- System descriptions
- Component specifications (when available)
- Master equipment list
- Safety analysis reports/technical safety requirements
- Environmental permits
- Operating and maintenance procedures
- Emergency plan/RCRA contingency plan
- Vendor data

ARTICLE 3.2.3

DIFFERENT TYPES OF DESIGN AND CONSTRUCTION AGREEMENTS

Christopher L. Noble, Esq., and Heather G. Merrill, Esq.
Hill and Barlow, Boston, Massachusetts

There are many ways of structuring the design and construction team for a renovation or new construction project. Various options, including construction management and design/build, are described in Art. 6.2.1, "Construction Documents." In this article, we focus on the traditional system, under which the owner contracts first with an architect or engineer (the "A/E") to design the project and then contracts with a contractor to build it. We focus on the various types of business arrangements that the owner can make with these key members of the team.

A/Es should always be engaged under written contracts, which can take the form of simple purchase orders or more complicated design agreements, depending on the scope of the project and the A/E's services. The most basic form of business arrangement with an A/E involves payment by the hour. If either the project or the scope of the A/E's services is undefined, this may be the only appropriate method of compensation. The hourly charges may be based on flat rates for various categories of personnel or may be expressed as a multiple of salary or "direct personnel expense" (which includes mandatory and customary contributions and benefits). The multiples used by different A/E firms range from two to three times direct personnel expense; two and a half times is the most common.

An hourly fee permits owners to purchase and pay for only the services they desire. However, if the owner is not able to maintain control over the amount of time that is spent by the A/E, it is possible for costs to get out of hand. Conversely, the owner may be tempted to exclude the A/E from some meetings and tasks to save money, when the A/E's participation would actually be useful and efficient in the long run.

When the project and scope of work are sufficiently defined, it may be appropriate to add an upset limit to the A/E's hourly compensation. This system is not preferred by A/Es because it imposes upon them the risk of cost overruns without giving them the opportunity

to benefit from efficiencies. Although the owner may believe that it is advantageous to retain the benefit of "savings," this benefit may be illusory because the A/E has no incentive to spend less time than is reflected in the fee limit. Shared savings clauses that are common in construction contracts are virtually unknown in A/E contracts.

A lump-sum fee is often more satisfactory to both the owner and the A/E if the project and the scope of services permit. A lump-sum contract is easier to administer because it does not involve detailed time sheets and justification of hours spent. Progress payments are based on a percentage completion of documents or services. Because of the simplicity of the lump-sum fee arrangement and the relative absence of minor disputes if the fee is appropriately matched with well-defined services, the professional relationship between the owner and A/E is enhanced.

A percentage fee represents a compromise between open-ended hourly charges and a fixed lump sum. Under this arrangement, the A/E is paid on the basis of a percentage of estimated or actual construction cost. Some owners believe that a percentage fee arrangement gives A/Es an incentive to load a project with expensive components, resulting in an increase in the A/E's compensation. In most cases, however, a competent cost estimating and control process minimizes the risk of self-serving manipulation by the A/E.

Methods of compensation are limited only by the creativity and imagination of the parties. Sometimes, for instance, the major variable will be the size of the project, in which case the A/E can be paid a certain amount per square foot. Other contracts employ "blended" methods, such as hourly rates for initial planning services, and full design services are provided for a percentage fee that is transformed into a lump sum when a firm construction cost estimate or guaranteed maximum price is established.

A typical construction contract consists of several parts, including an agreement, general conditions, drawings, and specifications. The basic business terms are usually defined in the agreement, which will state the basis of compensation, the time and method of payment, the time for completion, and such items as special incentives or liquidated damages. As with A/E agreements, construction contracts can be based on several alternative methods of compensating the contractor.

The lump-sum (stipulated sum) agreement is nearly always used when the contractor is to be chosen by competitive bidding. It has the advantage of relative certainty as to price, provided that the drawings, specifications, and other contract documents contain sufficient detail to define fully what the contractor must do and provide. Administration is also relatively easy because payments to the contractor are typically based on the percentage completion of the various components of the work, as shown in a schedule of values agreed upon at the beginning of construction, instead of on the basis of the contractor's actual verified costs. Under this type of agreement, the contractor bears the risk of cost escalation, inefficient work, and miscalculation of cost, but also stands to profit from his or her own efficiency and skillful purchase of materials and choice of subcontractors.

The cost-plus fee agreement is often used when the contract results from negotiation between the owner and the contractor either before or after the completion of detailed drawings and specifications. Under this system, the owner reimburses the contractor for the contractor's actual cost of performing the work and pays him or her either a fixed or percentage fee to cover overhead and profit. Although drawings and specifications are not necessarily well defined under this type of agreement (and it is often used when the exact scope of construction work is not known in advance), defining in detail the types of expenses that are reimbursable as allowable costs and those that must be absorbed by the contractor as part of the fee is very important. Items in question might include certain field office costs, the salaries of certain supervisory personnel, and the cost of correcting damaged or negligently performed construction work. A cost-plus fee agreement may be more difficult for an owner to monitor and administer than a lump sum agreement because of the need to verify hundreds of claimed costs, not just the percentage of completion of the project.

In a typical construction project, it is common for contractors to subcontract a large percentage of the work. These subcontracts are typically bid on a lump-sum basis. Payments to

subcontractors under these lump-sum subcontracts constitute reimbursable costs to the general contractor under his or her cost-plus agreement. Therefore, it is not uncommon for a purportedly cost-plus contract actually to consist of several lump-sum components. Indeed, fixing these lump sum subcontract costs by bidding or negotiation provides a significant means of protecting the owner against open-ended cost overruns in a pure cost-plus contract.

When the scope of the project is sufficiently defined, an owner may want a cost-plus contractor to agree that the cost and fee together will not exceed a guaranteed maximum price (GMP). Establishing a GMP creates risks for the contractor similar to those encountered under a lump-sum agreement, without the related opportunity to make additional profits if additional costs are lower than expected. To provide an incentive to the contractor to run the job efficiently and to keep costs down, a *shared savings clause* is often added to a GMP agreement to provide a bonus to the contractor that is equal to some percentage of the amount by which the contractor's actual costs and fee are less than a prenegotiated GMP.

The unit-price agreement is appropriate in specialized situations where the type of work is defined but the quantity of work is not. Contracts for excavation and site work may be let on a unit-price basis because the exact quantity of ledge, for instance, is not known in advance. It is also common to provide that some allowances in an otherwise lump sum contract will be made on a unit-price basis if the work that is subject to the allowances can be easily measured or quantified.

With these basic alternatives in mind, the facilities manager can develop the most appropriate business terms to procure design and construction services. There is no "right" way to structure these arrangements. Any one of them may be best for a specific project.

ARTICLE 3.2.4
IMPROVING PRODUCTIVITY THROUGH INTEGRATED WORKPLACE PLANNING[1]

Joe Akinori Ouye, Ph.D.
Gensler, San Francisco, California

Members of the R&D Workplace Performance Consortium*

Many planners who deal with aspects of the workplace, whether they are technologists, organizational change planners, or facility planners, realize that the workplace has to be planned comprehensively. They have come to this realization because they are motivated or driven to make significant changes in group productivity, workplace-related costs, or both, and these changes can no longer be realized by changing only a single aspect of the workplace. Improv-

* Members include 3Com, Adobe Systems, Bay Networks, Cadence Design Systems, Cisco Systems, Hewlett-Packard, Netscape Communications, Octel Communications, Oracle, Sun Microsystems, Tandem Computers.[3]

ing productivity is especially problematic because it is the resultant of many variables, just one of which is the physical workplace. To improve organizational productivity, it is necessary to plan multiple aspects of the organization. This realization has all the symptoms of a classic paradigm shift: The basic definition of the problem has changed, and we are faced with a lack of solutions, techniques, processes, and even expertise to address them.[2]

This article describes an approach to planning workplaces in an integrated fashion by defining, analyzing, and improving key aspects of an organization to improve its performance. It also addresses the issues that characterize this type of problem:

- How do you define better productivity or performance?
- At which level should you attack the problem?
- Who should be involved in defining and solving it?
- What is the role of leadership?
- How do you measure success?
- What are the obstacles to implementation?

This article is based on the efforts and experiences of the members of the R&D Workplace Performance Consortium, comprised of a select group of high-technology firms centered in the Silicon Valley, that have been wrestling with and in some cases dealing successfully with these issues. Although the consortium members share many issues with other "non-high-tech" companies, they are at the forefront in dealing with performance. Because of the competitiveness of their businesses, they are willing to embrace new approaches to the workplace to support or enhance performance or to achieve other strategic advantages.

WHAT IS PRODUCTIVITY?

If we are trying to improve knowledge-worker performance, it is necessary to define it. The definition by the American Productivity and Quality Center is "the relationship between what is put into a piece of work and what is yielded (output)."[4] The application of this broad definition presents a challenge because everyone defines output differently, especially the "knowledge worker" whose work is characterized by intangible, ill-defined, and uncountable outputs, processes, linkage to the company's strategic objectives, performance criteria, and high independence."[5] Finally, the quest for some kind of generic measurement(s) of group performance is a further challenge.

As we reviewed the organizational performance literature, it soon became obvious that each situation is unique and that performance must be defined in terms of the goals and objectives of the specific group versus the individual. In corporations today, generally the group (whether it be called a "department," "group," or "team") is the basic work unit. Management goals and objectives are defined by groups, and because of the interest in quality management techniques such as process improvement, performance is increasingly measured by groups. The American Performance and Quality Center recommends that performance be defined in terms that are most relevant to the groups' outputs and that a "family of measures" be used. "To determine how well an organization is functioning, its leaders must not restrict their focus to just one indicator—one individual, one department, one product, one process, one expenditure, or one measure of success. They must examine an entire family of measures."[6] Using this approach, performance includes a wide group of indicators that may include the excellence of the product or service, alignment with the budget, keeping on schedule or achieving rapid time-to-market, and customer satisfaction. For example, the performance of a software engineering group may be based on the perceived quality of the software, the group's ability to stay within the budget, timeliness (keeping on schedule), and customer satisfaction.

WHAT AFFECTS PERFORMANCE?[7]

The following elements directly or indirectly affect individual performance, and by extension, affect team performance ranging across the spectrum of the workers' physical and social environment:

- Personal factors
- Organizational/management factors
- Process-related factors
- Technology factors
- Physical environment

Personal Factors

- Technical competence in performing the job
- Motivation to work, especially because "the work of knowledge professionals happens inside their heads"
- Compensation, recognition, leadership, physical environment, and just about anything else that affects mood
- Work Strategies: taking initiative, networking, self-management, teamwork effectiveness, leadership, fellowship, perspective, show-and-tell, and organizational savvy

Organizational/Management Factors

- Participation in determining how employees are managed and the way their workspaces are arranged
- Independence and initiative in doing work
- The lack of obstacles to effective work, for example, adequate resources and tools, a clear mandate, and lack of interference
- Clear performance expectations and feedback to keep workers on track and from going on unproductive tangents
- Few and focused meetings and the lack of interruptions to concentrated, focused work
- Compensation and incentives

Process-Related Factors

- More effective and efficient processes, supported by the right kinds of technologies

Technology Factors

- Production tools: computers, appropriate software, printers, scanners, and copiers
- Communication tools: telephone, fax, modem, networks, and videoconferencing

- Automation: computers and other technology to duplicate and even enhance processes performed by workers; for example, workflow software that automatically pulls and sends information as necessary in a work process

Physical Environment

- Spatial comfort: the most important physical factor that affects performance (includes the amount of workspace, adequacy of storage, furniture, and equipment arrangement, furniture comfort, and ergonomics)
- Control of general office noise levels, distracting conversations, equipment noise, and other audible distractions
- Privacy, including phone privacy, visual privacy, and freedom from interruptions
- Air quality: air movement, air freshness, ventilation, odors, humidity, and warmth
- Lighting: brightness, absence of glare, colors, and daylighting
- Support space: availability and adequacy of quiet rooms, large and small meeting rooms, resource centers, and lounge areas

INTEGRATED WORKPLACE PLANNING APPROACH

Because performance is affected by many factors in the workers' environment, it is necessary to design the workplace comprehensively by considering the various factors as a system (see Fig. 3.2.4-1). This is not a new idea. More than 35 years ago, Eric Trist and Fred Emory coined the *sociotechnical systems* (STS) approach, which "considers every organization to be made up of people (the social system) using tools, techniques, and knowledge (the technical system) to produce goods or services valued by customers (who are part of the organization's external environment). How well social and technical systems are designed with respect to one another and with respect to the demands of the external environment determines to a large extent how effective the organization will be. Thus every organization is a socio-technical system, but not every organization is designed using the principles and techniques that have come to be a part of the socio-technical systems approach."[8] Much of the efforts of STS proponents has been to improve work-group performance in manufacturing settings and has not reached out extensively into knowledge-worker performance.

The STS perspective has and is being used by researchers such as Professor Wellford Wilms of the UCLA Graduate School of Education and Information Systems to understand how teams perform effectively in settings ranging from the new United Motors plant in Fremont, California, to Hewlett-Packard's R&D laboratories.[9] Wilms used ethnographic research methods, integrated his team into various organizations, worked alongside the employees at their jobs, and made detailed observations of what people said and did. He found that although some teams manage to work in spite of the context, whether it be the management culture or tools and processes, teams that thrive do so because their social and physical environments provide nurturing conditions for them.

Professor Franklin Becker at Cornell University describes a similar approach as the "Integrated Workplace Strategy," a way of "rethinking how work was being done and creating organizational, technological, and workplace solutions that supported the way work could be done effectively."[10] This approach views the workplace as an "organizational ecology" that "considers these elements of a workplace system as part of an integrated workplace strategy that defines a total workplace in two distinct ways: through the scope of the physical settings considered and through the social process used to plan and manage—and link—the physical settings through time."[11]

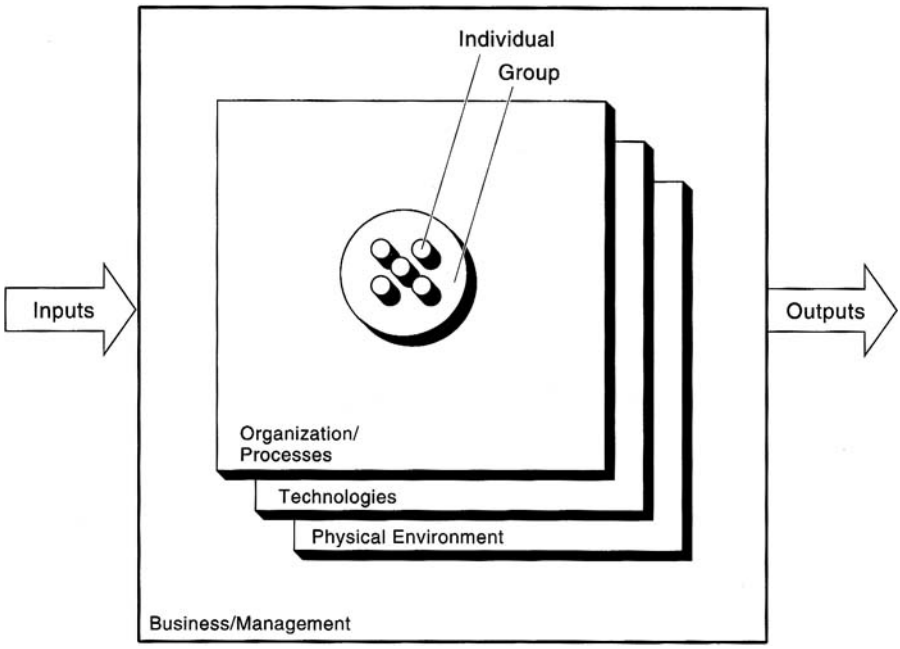

FIGURE 3.2.4-1 Workplace as a system. (*Courtesy of* The Competitive Workplace, *by Joe Ouye and Jean Bellas.*)

And so, settings (and work settings in particular) have been long viewed as systems of people, things, and their relationships that need to be planned as systems to achieve the goals of the group—although successful applications of this approach have been "spotty and results mixed."[12] But recently, as corporations have continued to push for greater performance and more value from their assets, there has been a surge of interest in considering the place of work, the real estate and facilities location and characteristics, as an important part of the ecology or system. This approach is especially relevant as corporations explore new workplace approaches by rethinking how, when, and where people work.

NEW INTEGRATED WORKPLACES

Planning an integrated workplace can result in solutions that change the physical work setting and also parameters such as behaviors, processes, technologies, and other resources to achieve the goals of the planning effort. Each of the resulting solutions is idiosyncratic. There is no single approach or ideal integrated workplace or "office of the future." Any such endeavors are doomed to fail because approaches must vary to suit different corporate intents and different group goals, objectives, and constraints. But these solutions do share common themes:

The Personal Workplace

Specific characteristics of the personal workspace are driven by the functional needs of the occupant for high performance and by the informal organizational culture. This is contrasted to "space standards," which define personal workplaces by organizational or group status. In addition, the change of behavior is considered a "design variable," for example, promoting

behaviors for an open office environment: lower voice levels, no use of speakerphones, using other support areas for confidential conversations or focused work, or redefining what in fact is really "confidential" or "private."

Multiple Work Settings

More focus is placed on supporting the productivity of individuals and groups in areas other than the personal workplace. Information technologies continue to support workers with information, whether data or voice, whenever and wherever the worker is working.

Informal Interaction. Promoting informal interaction recognizes that productivity results not only from individual work and formal interactions but also that really important gains often result from spontaneous, informal interchange.

Teaming and Remote Teaming. Groups are changed from hierarchical or individually based organizations to team-based organizations, and team rooms, project rooms, and more meeting areas of varying levels of formality or informality are provided.

Alternative Workplace Strategies

Although telecommuting, hoteling, office sharing, and virtual officing are appropriate mostly for workers such as consultants, auditors, and salespersons who spend a great deal of time out of the office, most corporations are exploring or piloting these radical strategies.

Whole Life Needs

Supporting high performers means making their lives simpler and better. Free soda, abundant lunches, espresso and cappuccino bars—the attention paid by these companies to make their workers happy sometimes seems to be at the point of spoiling them.

THE INTEGRATED WORKPLACE PLANNING PROCESS

Planning the workplace for performance and dealing with all of the disparate elements as a system is a radical departure from simply "planning a space" or dealing with each element separately. Going through a process that systematically considers the business context and workplace elements (as outlined in the following paragraphs) is highly recommended. The process necessarily includes tools and techniques from diverse fields, such as organizational analysis, sociotechnical systems analysis, strategic planning, and facility planning.

1. Establish Goals and an Approach to the Project and the Project Team

Meet with the overall leadership and, second, meet with the specific group to define the overall direction and goals, the planning approach, the schedule, and to identify the appropriate team members. This step is important and difficult because of the scope of possible changes and the elusive level of the problem.

The composition of the planning team is often the most important early decision. It must include individuals whose scope of responsibilities encompasses the range of possible workplace changes. Its membership should involve leaders who have the authority to change business organization and processes, information technologies, human resources, and real estate and facilities. Often, additional expertise such as corporate risk, taxation, and purchasing should be engaged.

2. Define Desired Organizational Goals and Outputs

This may be based on an organizational business plan, interviews of key managers, or a workshop, and should focus on the performance goals and objectives of the organization. It is not unusual for the organizational business plan to be nonexistent, far too sketchy to be of much use, or simply outdated, and it must be defined in this process. For many fast-moving high-tech companies, the rule "If it's written down, it's out-of-date," usually holds. But at the lower organizational levels, such plans are increasingly outcomes of continual quality management or other similar processes, and this process can capitalize on them. Existing organizational goals and objectives have the advantages of (probably!) prior buy-in and historical metrics, which can be the basis of measuring organizational performance.

3. Understand and Assess the Existing Organization and Workplace

The existing organization can be understood by reviewing its structure (the organizational chart), its business processes, and its job designs.[13] Process mapping of groups, tasks, information flows, skills, and resources is a way to gain this understanding. A tour of the existing space, a review of floor plans and technology plans, and interviews with key individuals will provide information about the workplace and other softer aspects such as communication patterns, morale and motivation, and management style. A group can be understood by using an organizational profile map that maps the characteristics of a group against a range of organizational, technological, and work-setting variables. The resulting group profile can be readily compared against other profiles within the organization.

4. Identify Obstacles to Improved Performance

Critique the existing organization and workplace by identifying obstacles to performance goals and objectives. Obstacles may be caused by any elements of the organization or workplace. Again, the proper level of the problem has to be respected. It may be true that the president of the company is an "obstacle," but changing that condition is probably outside of the scope of your mandate! Most obstacles may also be perceived as opportunities. For example, the obstacle "There is a lack of cross-group interaction" suggests the opportunity "Improve cross-group interaction."

5. Develop, Evaluate, and Select Workplace Options

Create workplace options that capitalize on the opportunities identified. Some workplace options may resolve multiple obstacles and capitalize on multiple opportunities. For example, a central meeting hub could support more serendipitous interactions, informal group meetings, and meetings of the entire group. The options should be evaluated using the criteria previously developed. Cost analysis should include harder costs such as technology facilities/equipment and services, and also softer costs such as increased work hours due to process improvements. These latter costs usually have to be estimated, and if so, should be discounted very conservatively in anticipation of "doubting Thomases." Other costs, such as tax implications, training costs, and insurance/corporate risks that are not normally considered may have to be included.

6. Implement the Planned Changes

The implementation plan should identify key management and organizational support, training, and personnel/human resource issues. The implementation plan establishes the appropri-

ate steps, specific tasks, resources, and timing. The changes may be piloted with a smaller subgroup to evaluate its effectiveness before rolling it out to the entire group, or in some cases, it may be a full implementation program. A communications plan to inform and involve workers in the change is critical. The failure of many efforts in workplace change is the failure to communicate, rather than the failure to develop a good solution.

7. Evaluate the Results

Monitor and evaluate the results of the workplace changes. The evaluation should consider the impacts of the changes on the group's performance, the effectiveness of the workplace in supporting performance, and satisfaction with the planning process itself. This step is expanded in, "Measuring Performance."

OTHER CONSIDERATIONS

The integrated planning process has some unique characteristics that make the planning processes very "wicked"[14] and fraught with difficulties:

Redefining Performance

The parameters for defining "better performance" vary from company to company and from group to group. As John Igoe, Director of Real Estate and Property Development of Octel notes, "Octel is more interested in performance than sheer square footage reduction. . . . The goal is not to cut space usage; the goal is to make the employee more productive." In Octel's case, the driving force is the need to be first in the market, and the time to achieve this has decreased dramatically in recent years. As Igoe relates, "The life cycle of a typical product in the '50s was 10 years, in the '80s 5 years, now it's 6 to 8 months." Frank Robinson, Vice President of Corporate Real Estate and Services for Tandem Computers, has similar concerns. "We're faced with the challenge of reducing time-to-market for our products. The time frame that used to be 24 to 36 months has been pushed back to 18, 12, sometimes 9 months. Unless the time taken to assemble the group in their workplace shrinks too, we (i.e., Corporate Real Estate and Facilities) become a stumbling block."

In the case of Tandem Computers' sales group, better performance equates to more time spent with the customers. "The key for our sales and service people [formerly] was to bring a customer back to our computer showroom to sell hardware," says Tandem's Frank Robinson. "Today the customer doesn't care what the box looks like. He has a problem. He needs a solution to the problem. Our people are spending far more time out with the customers understanding what the problem is. The offices have changed not because we dreamed up a way to change their world, but from our saying 'Let's take a look at how they're doing their jobs today.' "

Debra Engel, Vice President for Human Resources and Corporate Services at 3Com, is redefining and extending performance beyond the normal realm of specific group outputs to include more sophisticated meanings. An example is the concept of *organizational capability,* which is the ability of the organization to incorporate and instill superior values, superior experience and knowledge, superior learning, and superior processes and systems.

Organizational capability is another edge to differentiate companies from their competition. It is an aspect of visionary companies that "build an organization that fervently preserves its core ideology in specific, concrete ways. . . . Visionary companies translate their ideologies into tangible mechanisms aligned to send a consistent set of reinforcing signals. They impose tightness of fit, [and] create a sense of belonging to something special through practical, concrete items."[15]

Defining the Level of the Problem

Integrated workplace planning can include high business and organizational planning and change efforts, such as reengineering and business process improvement. Although these possibilities should not be automatically excluded, the danger is that they may be beyond the authority of the client group or project mandate and the capabilities of the planning team and may diffuse the efforts of the planning team. But ongoing efforts in business planning and change can be leveraged with great effectiveness, especially because the physical aspects of these changes are very often overlooked.

Setting the Goal of the Process

Keep the goal of the workplace planning in mind, which is, most of all, to support the group's mission or business plan. It is not to cut costs or even to develop an alternative workplace strategy, although they may result! As Igoe of Octel observes, "Octel is more interested in performance than sheer square footage reduction. The goal is not to cut space usage, the goal is to make the employees more productive." The planner should not have any preconceptions about the solution, because the solution may be to do nothing or to improve the social aspects of the group, without doing much to technologies or the workplace. Garcia of Adobe concurs, "Facilities people sometimes want to be evaluated on the basis of costs. A lot of facilities people don't spend enough time with the rest of the organization, besides simply saving money on real estate or operating the facilities because they're not participants in some of the other kinds of decisions. If you spend a large portion of your time thinking about increasing performance, at the end of the day people will look at you as having a contribution to solving these problems."

Planning for Change and Unpredictability

Most high-tech companies (maybe all!) are faced with increasing rates of change and turbulence in their business environments. They in turn are forced to react with corresponding speed and unpredictability. Groups and teams are organized and reorganized; groups grow at high but unpredictable rates; and workers are moved constantly (as much as one and a half or more times per year, based on the total number of moves divided by the total number of employees—what is known as the "churn rate"). Abe Darwish of 3Com, a company that has been growing at 30 to 40 percent per year recently and experiencing 110 percent churn, recommends, "[You have to] anticipate the future and prepare for a high degree of churn. Design your facility for change. You can't rule out change; you have to be prepared, from operations to design; you have to be ready from the beginning." All this is expensive and unproductive. It is expensive to change furniture, technologies, and carpets. In some companies, it may cost as much as $2,000 to $3,000 per employee per move! Because it may take from one to two days to accomplish moves, the costs of unproductive time can be even higher, not to mention the time it takes for the workers to settle into their new spaces and become comfortable and effective again. All this, notwithstanding impacting group performance in time-to-market and scheduling. Hewlett-Packard, San Diego, has reduced the average time per move from 11 hours to just about 3 hours at one of its new R&D buildings. The productivity saving is far more because the disruption to the relocated engineer is much greater—in the range of 40 to 60 hours per move! Given that the churn rate is about 300 percent per year and that there are 400 workers, the saving of productive time is about 48,000 to 72,000 hours per year. This was achieved by "universal planning" (i.e., planning and designing space for changes by anticipating them). Workstations, furniture and equipment, technologies, and other resources are designed to accommodate most future possibilities and are standardized (or "universal"). Therefore, moves are reduced to "box" moves rather than reconfiguring the workplace and all of its components.[16]

Participation

No one likes to be "planned at" or even "planned for," especially when the plans involve changing important aspects of their lives. IBM summarily notifying some of their workers that they no longer had personal space and had to work out of their homes or share hoteling space is an example. Although successful from the viewpoint of reducing real estate costs, this action had far more damaging costs in terms of human relationships. Most significant workplace changes involve meaningful changes in a worker's life—management styles, evaluative methods, communication patterns, work location, information technologies, hardware/software, and personal "territory." Darwish of 3Com is convinced of the importance of employee participation: "You enhance your performance if the business unit fully participates in the solution. You can't use one solution and apply it universally. Part of performance enhancement is getting the user involved in space, information systems, and human resources planning. What that means is that we, as facilities solution providers, can't expect to provide a solution and enforce it universally. You have to customize it. You have to have buy-in." Although businesses may not subscribe to the ethical view that it is the users' "right" to participate in decisions that affect their lives, those businesses should heed the advice that employee participation informs the process for a better solution and also makes it far more likely that the participants will be motivated to make the necessary changes for a successful outcome.

Thoroughness

When you start changing parts of a complex workplace ecology or sociotechnical system, many adjustments may have to be made to stabilize the new system. It is important to thoroughly consider all of the possible factors that may be upset by the changes. For example, in the case of a telecommuting program at a major interstate bank, the payroll tax consequences had to be seriously considered because many of the telecommuters would be working at their homes, which are located in a state other than where the corporation pays payroll taxes.

Cultural Change

The fact that people do not like to change should not be underestimated. Change is painful to most, even if they know it might be better for them! As mentioned before, participation in the planning of the change makes a big difference. Full participation in the change process is ideal, but it is usually not possible for all affected workers to participate. And so constant communication to all involved is necessary so that they can at least understand why the workplace is being changed, how it is being changed, and the extent and timing of the changes. As Tandem's Robinson cautions, "If you view it as a real estate project, you're only going to get so far. You have to view it as a workplace solution project. Real estate is the easy part, the technology is more difficult, and the human behavior side is the hardest. Never take for granted [the resistance to] behavior changes."

Leadership

Leadership from the top can make all the difference in changing the workplace. Leadership is not telling workers what to do but rather motivating and showing them what to do. In other words, to "walk the talk." When Pacific Bell wanted its executives to give up their private offices in order to increase the density of the headquarters, there was little enthusiasm until the CFO decided to "walk the talk" and move out to a cube. After his move, it was a race between the other executives as to who would be the next out on the floor. Needless to

say, this was an important symbolic gesture because spaces of other workers were being changed to shared, teamed, or hoteled spaces. "Leaders are no more or less than a manager of transitions."[17]

Measuring Performance

The measurement of performance and the contribution of the workplace to performance have been perceived as major stumbling blocks by the R&D Workplace Performance Consortium. If you can't measure the improvements, it is very difficult to convince management to invest monies in the change of the workplace when those funds could be spent for more marketing or R&D. As Ann Bamesberger, manager of planning and research for Sun Microsystems, observes,

> Where [achieving buy-in] gets tricky is proving that these changes have actual value. Gaining credibility. Nobody expects direct causal linkages. We should expect some intervention that we are responsible for, [which] is at least intuitively linked to some enhanced business outcome.

It would be ideal to have measures of group performance that can be taken from readily available information (i.e., information that is collected in the course of doing business anyway). As an example, Eric Richert, Director of Design and Construction of Sun Microsystems, uses the proposed "Information Productivity Index" (IPI), which is proposed as an index of the value added of information systems to a company. The IPI is defined as follows:

$$\text{Information Productivity Index} = \frac{\text{net income} - \text{costs of equity}}{\text{total costs of sales, general operating and administration and R\&D}}$$

Unfortunately, we remain far from agreement on any similar measure for productivity and workplace effectiveness.

In the absence of such an ideal measure, we have been exploring a technique developed by the American Productivity and Quality Center (APQC), the family of measures approach described earlier. These measures can be defined quantitatively or qualitatively. One is not necessarily better than the other. Logically, all quantitative measurements ultimately have to translate to a qualitative scale to have meaning. For example, how much "better" is beating the budget by 10 percent versus 15 percent? This can be determined only by assigning a value scale to being 10 percent and 15 percent under the budget.

Performance can also be defined in terms of direct and indirect measurements. Some desired characteristics of products or outputs of a group work process can be measured directly, or characteristics of the group, which correlate to performance, could be measured to determine performance. For example, the lack of interruptions and distractions may be an indicator of the performance of knowledge workers who require "flow."

Correlating improvements of organizational performance to specific changes of the workplace is another difficulty. It is clear that because workplace performance may be the result of many kinds of changes (new management, processes, technologies, desks, chairs, etc.), as we described, correlating specific workplace changes to performance is impossible because there are too many intervening variables. But because we are assuming that performance results from the interplay of many factors, perhaps the point is to see how and if performance was improved as a result of applying all these factors, instead of trying to understand the impact of an isolated factor.

Performance and workplace improvements can be visualized as lying along two axes. The first axis measures the change in performance, using the APQC approach. The other axis quantifies the group's assessment of the performance of discrete characteristics of the work-

place. If group performance and perceived performance of the workplace both improve, we can be fairly confident that the changes as a whole contributed to improve performance. For example, if too frequent interruptions were identified as a barrier to better performance, and if changes were made in the workplace to deal with it, and the group perceived that there were indeed fewer interruptions, then those changes probably contributed to improved performance.

Actually measuring performance and workplace improvements resulting from workplace changes is a rarity. This is not because of lack of interest but rather due to the inexperience or lack of expertise in performance and workplace measurement techniques of those dealing with workplace changes. It is still regarded by some noted researchers in the field of workplace planning as "not relevant" because of the measurement difficulties and the improbability of correlating performance to specific workplace changes.

These researchers' views notwithstanding, a few companies have had success dealing with this difficult area. At Hewlett-Packard, as part of their Headquarters Renewal Project, the performance and satisfaction with changes in the workplace were evaluated using pre- and postmove surveys of 122 workers.[18] The following changes were included:

- Increasing the overall density and team spaces by sacrificing independent, personal space
- Updating and thoroughly utilizing integrated information technology and taking advantage of state-of-the-art adaptable workstations

The results are convincing that both performance and satisfaction with the workplace environment were significantly improved.

Performance was measured using three indicators (ranging from "excellent" to "poor") that rated the group's performance in the following areas:

- Producing quality services and products
- Producing services and products in a timely manner
- Producing services and products within budget

The perceived performance in all three parameters increased in the range of 30 to 32 percent.

Satisfaction with the workplace was surveyed in the categories of personal workspace, meeting spaces, and technology. The perceived change in satisfaction with the workspace varied from 0.25 on a scale of 3 to 5, but respondents were uniformly more satisfied with the changed workplace. The greatest perceived change was with the meeting spaces (39 percent), followed by personal workspace (38 percent), and then technology (31 percent). Among the specific indicators, improved ergonomics and work surfaces were rated significantly better than the others, whereas the adequacy of the workspace was last.

These results are not surprising, because the main business change driving the workplace changes was the emphasis on facilitating teamwork and cross-group synergies. Increasing teaming and meeting areas were emphasized at the expense of individual workspace areas. The quality of the furnishings, equipment, and technologies of the individual workstations were significantly improved.

We can conclude that performance was significantly improved, along with satisfaction with the workplace. Although we cannot say certainly that the workplace changes led to the improvement in performance, we are fairly confident that they did because these changes were specifically addressed toward eliminating barriers to better performance.

Challenges to Implementation

Improving workplace performance in this integrated fashion is difficult to achieve in the corporate environment. First, organizational issues are not usually tackled in an integrated fashion. They are not defined as problems in that way, nor are integrated solutions sought. Second, an

integrated approach to organizational performance does not typically have a corporate "home" or champion. For example, the information technology group will address it as an information problem, human resources will address it as a personnel issue, and real estate/facilities will address it as a physical issue. Third, we do not have a good way of defining problems and solutions in a way that cuts across disciplinary boundaries. These problems can be solved to some extent by working with cross-functional project teams to integrate and leverage corporate-wide initiatives, for example, linking technology initiatives with initiatives to reduce real estate occupancy costs. But a hopeful sign is that some of the leaders in these disciplines are beginning to understand, appreciate, and even advocate the necessity for an integrated workplace approach.

Case Studies

The following paragraphs summarize three case studies from a forthcoming book by Joe A. Ouye and Jean Bellas, entitled *Competitive Workplace.* The book describes how to transform the workplace into a competitive tool to lower costs, accelerate the time-to-market of products and services, infuse companies with creativity, and increase the flexibility and productivity of the organization:

AT&T Global Services. Vice President of AT&T Global Services Richard Miller had a vision of transforming his sales organization by streamlining his account management processes. The critical needs were to increase the exposure of the sales team to both existing and potential customers and to increase the synergy between his team members.

This vision was achieved by changing team organization and processes and supporting them with new technologies and physical workplaces. Teams were consolidated from multiple locations, so that they were no longer separated by account and function. There were two major profiles of workers: those comprising the administrative team, who worked from the office 100 percent of the time and represented 30 percent of the team, and those making up the sales and technical teams, who worked from the office for 40 to 75 percent of a typical workweek. The administrative team led the other teams, energized the sales team, and set quality standards for the marketing responses. The sales and technical Team sold products and services primarily by "face time" with the customers. The team members were out of the office for 25 to 60 percent of the time. Between client meetings, they needed a place to "touch down" to generate new appointments, follow up on old appointments, and get recharged with ideas and energy.

The space of the new sales centers was reduced by 50 percent by reducing office sizes by 30 percent and by having the sales team share offices at a ratio of one workstation to every three salespersons. A portion of the new space was dedicated to encouraging interaction among staff members—a "Café Break Out" functions as the "kitchen," where staff members can informally meet for coffee and casual conversation. The space is peppered with more than 40 percent more small- to medium-sized meeting rooms (see Fig. 3.2.4-2). All meeting areas, including the Café Break Out, are equipped with network connectivity for group work and with overflow space for individual work.

The prototype is being replicated through the Creative Workplace Strategy initiative, consolidating almost 200 sales centers throughout the country. Since consolidating, the Rick Miller group produced the highest revenue in AT&T in both 1997 and 1998. The group credits this success directly to meeting the needs of the sales team and the new processes, technology systems, and physical workplaces that responded to those needs.

Lucent Technologies' Project Atlas. Lucent Technologies' Project Atlas is an ambitious effort to "transform their R&D culture and workplace." Launched shortly after Lucent Technologies split from AT&T, Project Atlas (see Fig. 3.2.4-3) was to enhance the productivity of the R&D team and, at the same time, reduce real estate costs of 12.5 million square feet of R&D space to fund the improvements.

The project assembled the following information:

FIGURE 3.2.4-2 AT&T floorplan. (*Courtesy of* The Competitive Workplace, by *Joe Ouye and Jean Bellas.*)

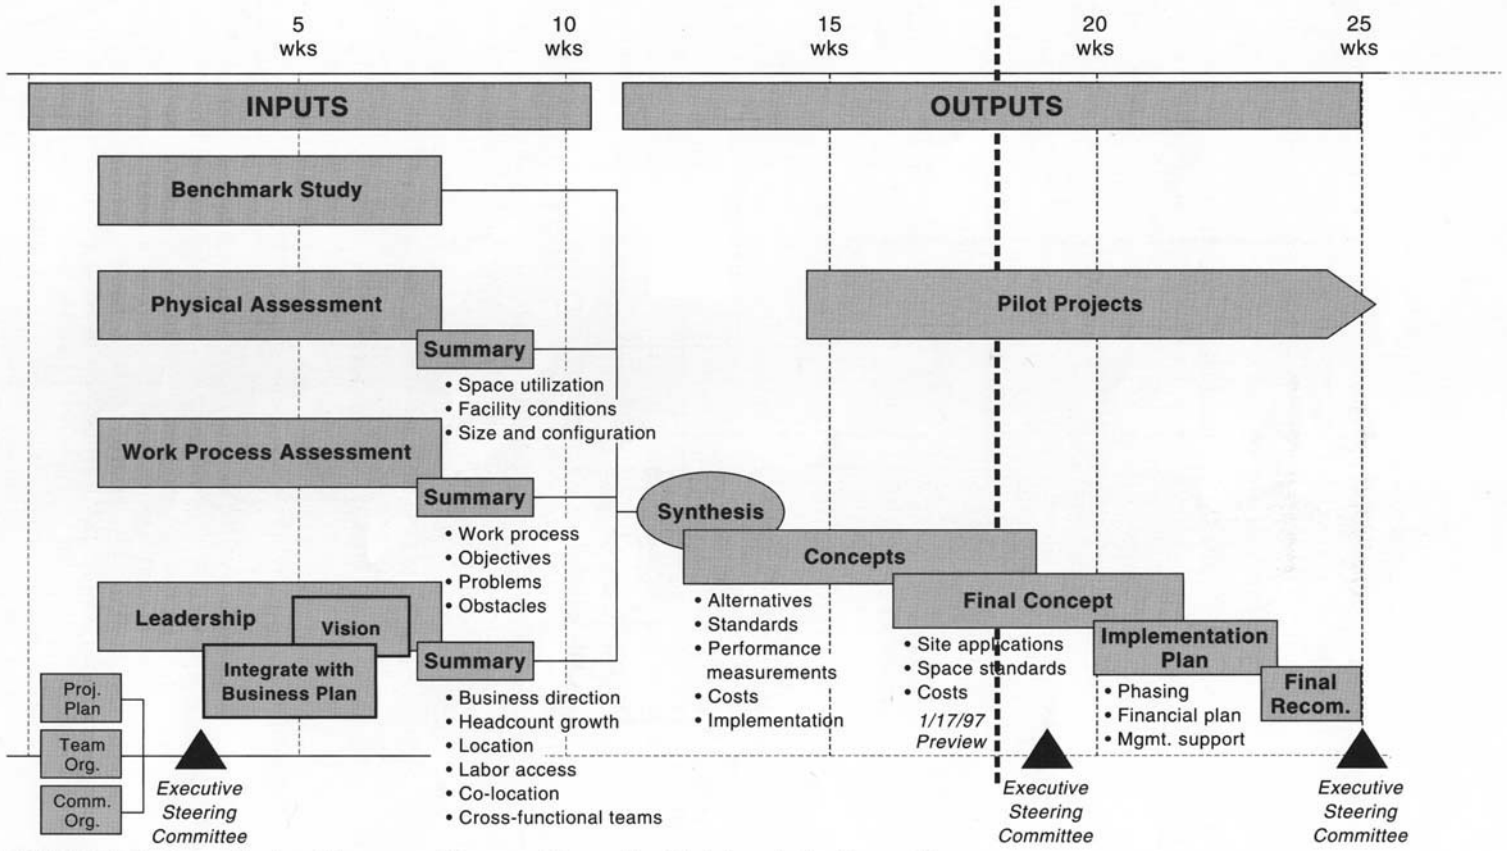

FIGURE 3.2.4-3 Lucent Project Atlas process. (*Courtesy of* Competitive Workplace, *by Joe Ouye and Jean Bellas.*)

- A benchmark of Lucent competitors' use of space
- An assessment of existing conditions
- Discovery of user needs by analyzing business drivers and work processes
- Development of planning and design concepts and evaluation of their costs and benefits
- Field testing in multiple cities
- A full-scale, phased-implementation program

Workplace planning was conducted concurrently with the planning of new supporting information technologies comprising the "Communication, Computing and Collaboration" project.

The solution supports both individual and group productivity because it was found through focus groups of R&D engineers that projects typically go through cycles of both intensely individual and group collaborative work. R&D engineers are housed in shared offices (see Fig. 3.2.4-4) that can be also used as collaborative team areas. The shared offices are enhanced with liberal amounts of team areas and conference rooms. Workers from multiple groups can gather and meet casually at strategically placed "Café Lucents."

The new workplace optimizes companywide resources by using advanced communication, computing, and collaborative technology. As a side benefit, the new workplace showcases Lucent products, performance, and company image.

The new workplace dramatically reduced operating expenses. The projected cost saving on a 10-year net present value basis is $200 million. This consists mostly of reducing the cost of relocating team members by 90 percent by standardizing workstation technology and furniture, and of 20 percent savings in space costs.

Prudential Customer Services. Faced with dramatic changes of its business environment, Prudential was forced to rethink its way of doing business and radically change the delivery of customer services. The solution was to make fundamental changes in the customer services processes, supporting technologies, and the workplace.

The customer services strategy consolidated more than 25 existing service centers into 5 major sites to reduce redundancies among the service centers and to improve service delivery. Local presence was no longer essential, and many customer service tasks were routine and could be automated. An investment in technology allowed the company to consolidate services, greatly expedite service delivery, and significantly reduce the costs of the customer service function. In the new model, customer service agents have higher levels of technical skill, education, and training so that they can deliver increased levels of information to the customers, including future product offerings beyond claims processes, such as various loan programs, investment consulting, and portfolio management services.

A real estate strategy was coupled with the customer service strategy to reduce overall occupancy costs. The strategy consolidates existing service centers into five existing locations and disposes of the excess properties or gets out of the excess leases. The new workplaces (see Fig. 3.2.4-5) are highly interactive, extremely efficient, and supportive. The new centers include six Imaging Centers to receive and digitize all incoming mail, creating a complete electronic database of customer communication. The data is then accessible from the centralized database by the customer service representatives while they are on the phone with customers.

Ultimately, the project involved more than 30 phases, each averaging about 250,000 square feet. More than 1.5 million square feet were renovated within the first 14 months. Seven thousand workers were relocated into their new homes.

As a result of this workplace transformation, the performance of the workers has improved 40 percent in the daily number of claims processed. Prudential is also continuing to grow into a financial services organization with marketing continuing to feed new services into the Prudential system. The initiative was extensive and expensive, but it positioned Prudential to absorb growth and to lead the financial services industry by positioning its products, the quality of its service, and a streamlined delivery system.

ARTICLE 3.2.5
FACILITY LIFE-CYCLE MANAGEMENT TOOLS

Bruce Kenneth Forbes
ARCHIBUS, Inc., Boston, Massachusetts

INTRODUCTION

Facility life-cycle management is not a new application area of facilities management. In fact, many consider it one of the core competency areas in which all facilities professionals should be knowledgeable. Driven by downsizing, outsourcing, reengineering, mergers, acquisitions, e-commerce, and the virtual office, effective facility life-cycle management is discussed in corporate boardrooms around the world. Directors are asking facility professionals to educate them about the costs and opportunities of effective facility life-cycle management and the total costs of ownership (TCO) of corporate assets. Life-cycle costs are constantly evaluated and presented regularly to directors worldwide. Directors are realizing that a good understanding of the management of facility life cycles can mean the difference between a profitable quarter and a very profitable quarter. Thus, the facility professional's access to directors and corporate boardrooms is becoming more and more prevalent.

The depths of facility life-cycle requirements vary, but most boards have directed the facility professional to deal with such areas as capital consumption, energy use, technology deployment and access, asset use and renovation, capital projects, infrastructure management, systems and material replacement programs, and financing.

In an integrated facility life-cycle management environment, FM life-cycle benchmarking and FM life-cycle best practices analyses address numerous areas of concern. These are 10 of the more common areas explored:

- *Capital investment costs.* Initial construction costs, cost of money, cost of delays, opportunity costs
- *Repair and replacement costs.* Costs of repair and restoration activities (people, time, and materials)
- *Maintenance costs.* Predictive, preventive, demand, proactive (people, time, and materials)
- *Renovation, alteration, and improvement costs.* Costs of changes required to meet the changing needs of a facility's users and its customers
- *Lost revenue.* Costs of not undertaking appropriate life-cycle activities
- *Basic operating costs.* Costs of the day-to-day facility activities (heating, ventilation, air-conditioning, electricity, telecommunications, IT infrastructure, and utilities)
- *Occupancy and use costs.* Costs of people, materials, and supplies required to perform and/or enable normal facility management and occupancy functions
- *Financing costs and project liabilities.* Costs of equity and costs of capital (bridge financing, short-term and long-term credit expenses and opportunities)
- *Disaster containment and contingency planning.* Costs of disaster management and containment, as well as contingency planning (backup facilities and alternative delivery systems)

- *Technology realization costs.* Costs of ensuring competitive technological access and empowerment for the users and customers of a facility (how to enable access of the "latest and greatest" technological innovations)

Strategic capital planning and management are other key elements of effective facility life-cycle management. Facility life-cycle management optimizes the performance of spatial and nonspatial assets by deploying condition assessment surveys, optimized maintenance management, regulatory compliance, risk management, project bundling, and effective capital program justification and allocation. In their striving to create customer value, facilities professionals who participate in life-cycle management programs address such areas as life safety, risk mitigation, downtime minimization, and effective asset selection, procurement, redeployment, use, and disposal.

Condition assessment is common to all life-cycle management programs. FM automation and visual infrastructure management solutions enable FM professionals to manage an asset's life cycle more efficiently by allowing rapid access to alphanumeric reports, graphics, and floor plans (see Fig. 3.2.5-1).

The following are the top 15 areas reviewed in a facility's life cycle with visual infrastructure management tools:

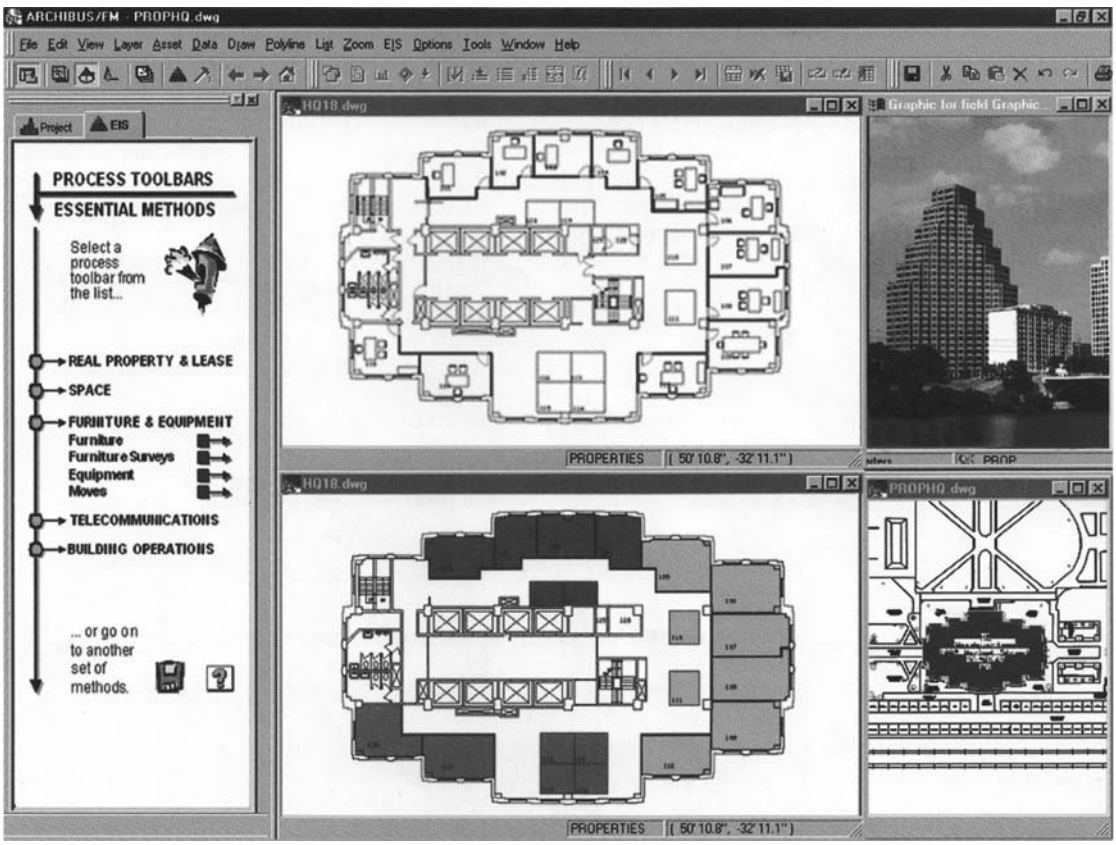

FIGURE 3.2.5-1 Life-cycle management is readily facilitated with FM automation and infrastructure management solutions. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*).

- Foundations
- Substructure
- Superstructure (floor and roof construction, stairs)
- Exterior closure (exterior walls and fenestration)
- Roofing
- Interior construction (partitions, interior finishes, specialties)
- Conveying systems (elevators, escalators, conveyors)
- Mechanical (plumbing, HVAC, fire protection, special mechanical systems)
- Electrical (service and distribution, lighting and power, special electrical systems)
- Equipment (fixed equipment, furnishings, special construction)
- Site work (site preparation, utilities, improvements, and off-site work)
- Special infrastructures (telecommunications, cables, and wireless systems)
- Special activity and functions (move management, hoteling, room booking, etc.)
- Soft infrastructure (space, organization, technology, and finance management)
- Asset exposure, special needs, and disaster management (direct, indirect, third party)

THE TECHNOLOGICALLY-DRIVEN LIFE CYCLE OF FACILITIES

To understand and manage a facility's life cycle, a facilities professional must have a vision and an understanding of the technological changes that affect that facility. Keeping up with the exponential rate of technological change will be one of the greatest challenges faced by facilities professionals in the new millennium. New technology is driving obsolescence, and obsolescence is considered a primary cause of facility failure and subsequent business failure. Bearing in mind that there is an opportunity with every business failure, it is important to identify both the opportunity of facility-related failure and the opportunity for facility-related success. Any discussion of technology-driven facility lifecycles is most likely to be obsolete in two or three years. At best, we can only identify trends, opportunities, and pitfalls to avoid.

During the next decade, facilities must become enablers of technologically changed corporations and institutions. As such, the facility manager must be able to rapidly adopt and employ technologies and realize the opportunity inherent in technology-driven facility life cycles. An individual facility's life cycle will be controlled by four business criteria (as illus-

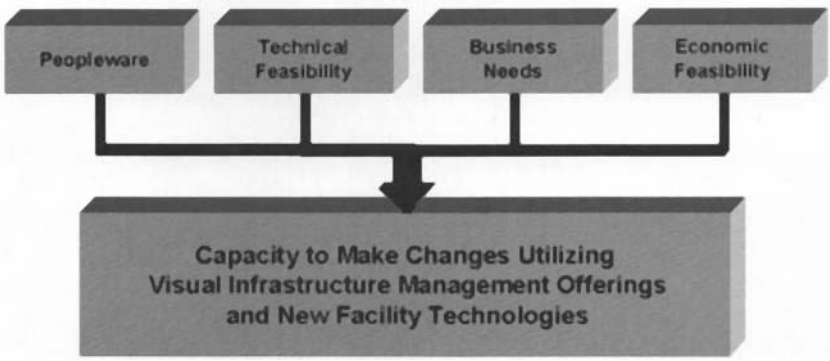

FIGURE 3.2.5-2 Four business criteria affect business life cycles. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

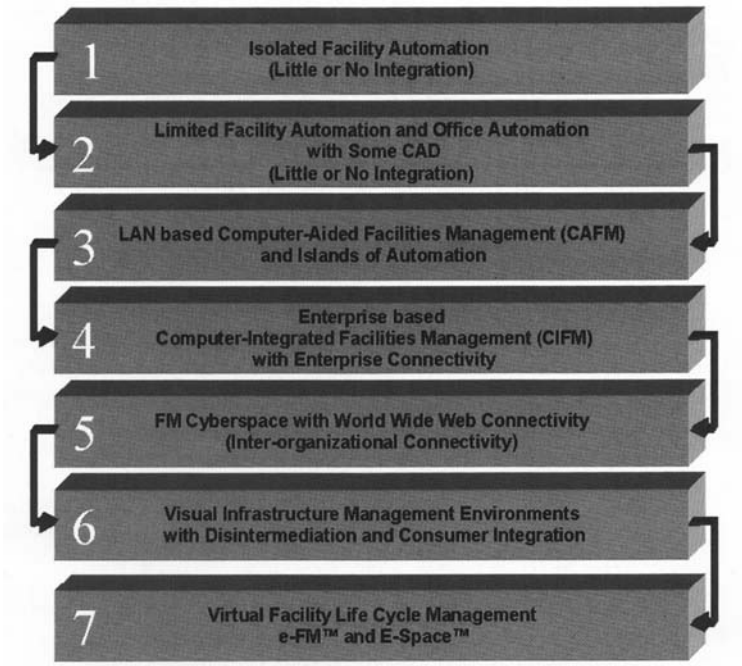

FIGURE 3.2.5-3 Seven generations of automated facility life-cycle integration and management. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

trated in Fig. 3.2.5-2) and by its capacity and/or ability to be reshaped using FM automation and infrastructure management offerings and new facility technological enablers.

Figure 3.2.5-3 lists seven levels of technological integration that have proven beneficial in enabling facility professionals to deliver superior facility life-cycle management services.

ARTICLE 3.2.6

HOW FIT ARE YOUR FACILITIES? PERFORMANCE MEASUREMENTS AND FACILITIES INFORMATION TECHNOLOGY

Joseph Milando
FIT Technologies, Newton Upper Falls, Massachusetts

Measure twice, cut once, is the well-known carpenter's adage. We intuitively grasp the wisdom that it is wasteful, time-consuming, and costly to take action without proper measurements. Trying to squeeze savings from bricks and mortar without proper measurements is like building a house without a tape measure.

How do you measure the performance of your real estate and facilities? What are your key financial indicators? How do you measure maintenance performance or space utilization? The only way to measure is with timely, reliable information. Timely and reliable information sounds so simple—but in reality it takes planning. Like building a building (or renovating an existing structure), you need to gather the requirements, conceive the solution, and communicate the idea before starting construction.

Most of us could benefit from a little improvement in our personal fitness routine. Similarly, most organizations can benefit from a facility fitness program. Many companies vastly undervalue the financial impact of proactive investment in facility information systems. Facility information is the lifeblood of a facility fitness program. You cannot measure fitness or progress without information.

This article covers conceptualizing, prioritizing, and designing a sound information system to support your facility fitness program and demonstrate the recurring value of facility management (see Fig. 3.2.6-1).

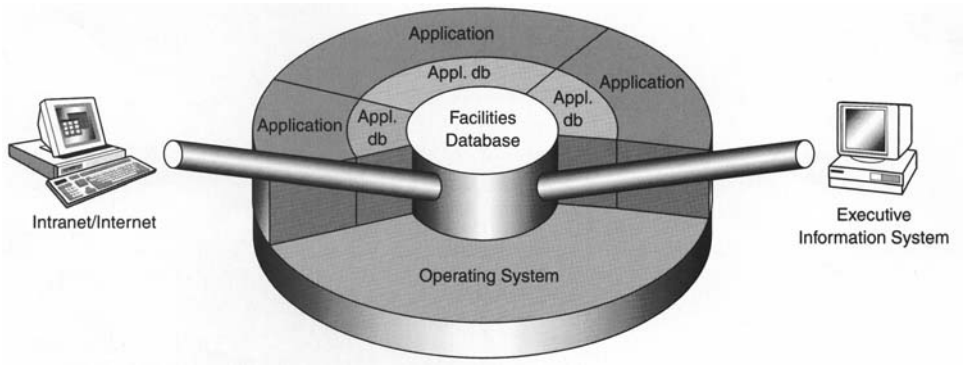

FIGURE 3.2.6-1 Who needs information? What information do they need? How do they need it delivered? Where does/should the information reside? Who maintains each category of data? (*Courtesy of Joseph Milando, FIT Technologies.*)

WHERE DO I START?—GOALS

Start at the end and work your way to the beginning (called *right-to-left thinking*). Since knowledge is the key to intelligent decisions, ask yourself what knowledge you need to make sound decisions. Who else needs information, and how does it need to be delivered to them? By working with the end result in mind, you will stay focused.

Define Your Goals

In facilities management as in fitness training, you will find that a vaguely worded goal (like "become more fit") is not going to drive you toward any worthwhile result. You need to have specific goals, and most likely there will be multiple goals and they will be interrelated. A set of exercise goals might be to lose 15 pounds in the next three months, to be able to run 5 miles in less than 40 minutes, and to achieve a resting heart rate of 64. Notice a few things about these goals:

1. They all rely on specific measurements comparing "before" and "after." (One needs to establish baseline measurements.)
2. The goals are based upon knowledge of what constitutes fitness for that person. Appropriate weight, heart rate, and so forth (industry standard performance metrics).
3. They take into account a vision of realistic progress for that person (assessment of the level of progress that is achievable).

To achieve sustainable fitness, one needs to establish complementary goals in various categories; dietary, scheduling, and goals for each specific exercise. Just as fad diets don't last over the long term, quick fix information projects don't stand up to time either.

Set three goals in each major information category. For illustrative purposes (see Fig. 3.2.6-2), I have divided facility information goals into segments where commercial applications exist. These may not be the best categories for your needs. The choice of categories is unique to each company, because they are related to many variables: the size of the organization (people, revenues, square feet), the number of buildings, the use of space, centralized versus decentralized control, owned versus leased properties, the level of technical sophistication, the core business of the organization, existing information, and other considerations. The figure may help you identify your key categories.

Triage

People generally have short memories and little patience for long time horizons. The best path to wide-ranging success is usually through demonstration of incremental smaller successes. By demonstrating results, you solidify your reputation and the requisite support to continue your plan. You need to rank your goals based on value, risk, and political considerations. These are three primary considerations:

1. What is the value of the goal in both financial and political terms? Who will make or save money? When will gains be recognized? Who will benefit politically? Who would oppose this goal? Would the organization or personnel assignments change?
2. How much will it cost over what period of time? What is the initial investment? Will recurring investment be needed? What level of staffing is needed?
3. Your intuitive assessment of the likelihood of success must consider the people required to cooperate, the availability of data, and the simplicity or complexity of the project.

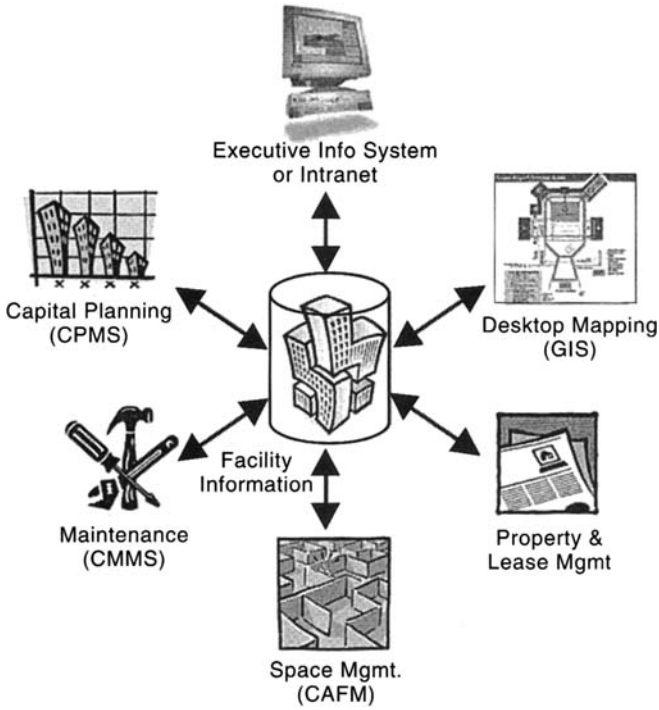

FIGURE 3.2.6-2 Facility information goals segments. (*Courtesy of Joseph Milando, FIT Technologies.*)

To assess these considerations you may wish to use a matrix. At this point, remember that you are just trying to prioritize goals, so don't get caught up in too much detail. (See Table 3.2.6-1.)

Other items to consider for your matrix include

- Dependency information—goals that need to be accomplished first
- Who needs the information?
- How often is it needed?
- How accurate is the source data?
- Who is responsible for maintaining the source data?
- Where are the data? How do you collect the data?
- What technologies support the collection and distribution of the information?

FUNDAMENTAL CONSIDERATIONS

By now, you may be anxious to start your project. But before you do, a little caution is necessary. Here are two fundamental rules that many overlook in their desire to achieve success.

TABLE 3.2.6-1 Ways to Identify Your Goals

Item	Space options	Maintenance options
Goal	Reduce usable square feet per person 5% over 18 months	Increase ratio of preventive maintenance to reactive maintenance by 15% in 18 months
Benefit/value in both financial and political terms	Financial—cost reduction of X, avoid cost of move, avoid X capital expenditures Political—enhance new COO's stature, avoid move	Financial—business production without mechanical failures, increase revenue 1%, reduce operating costs 5% Political—improve image of FM dept., increase employee satisfaction
Budget (cost) over time	Capital investment of X, with X per month to monitor and maintain	Capital investment of X with X per month to monitor and maintain
Likelihood of success considering people, availability of data, and the simplicity of the project	Very high—considering new corporate directives, staffing, and widespread recognition of the issue	Medium—cultural change is required, need buy-in from union, fits with FM department looking to change image

1. The Mousetrap

Achieving a realistic balance between efficiency and effectiveness is the golden rule (see Fig. 3.2.6-3). Just because a system can track very detailed data doesn't mean you should do so. I have seen organizations itemize more than 20 departments in order to split the cost of an 8-square-foot closet rather than simply sharing it among the 22 departments on the floor. The annual cost of the closet was less than $250. Did it matter whether it was split among 20—or 22—departments? I call tracking more information than is worthwhile the "mousetrap." Set practical guidelines to avoid this trap.

Conversely, one can err on the side of shortsightedness, not capturing the extra 5 percent of work that will provide whole new functionality (e.g., while performing a survey to update architectural plans, missing the opportunity to note vacant spaces for planning purposes).

2. The Value Chain

Performance measures rely on information. Reliable information is the result of a continual process of renewing the data. Therefore, unless everyone who needs to participate in the

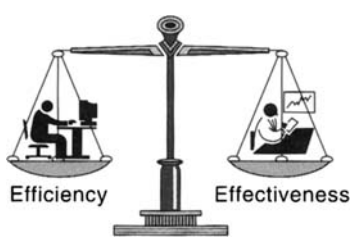

FIGURE 3.2.6-3 Keep efficiency versus effectiveness in balance. (*Courtesy of Joseph Milando, FIT Technologies.*)

information chain gains some benefit from their participation, the data will become unreliable over time. Let's face it, everyone has more work on their plate than they can perform. Shortcuts will be taken wherever possible. However, people will usually not shortchange tasks that benefit them.

DEFINE YOUR SPECIFIC REQUIREMENTS

By stepping through the process described, we have already done a great deal of our work and have certainly thought through the beginning of a plan of attack. But, in the analogy of the carpenter's rule, we are still not ready to cut the wood. We know we are going to build a house, and we know how big it will be and how many rooms it will have, but we still need the design and to communicate that design on paper.

Start again with the matrix, but make sure you consider all of the items (including those listed after the sample matrix). This time list every piece of information required. Consider who is responsible for maintaining each data component and how often it needs to be refreshed. Wherever possible, refresh as infrequently as practical. You can always increase the frequency as the kinks are worked out. At the end of this process, you will understand each piece of required data and how the information needs to flow.

Data Definitions

This step is critical to the long-term integrity of your data. Simply list each allowable name within each data category. This serves three functions: it tests your logic, it communicates a standard definition that everyone will use, and it controls data creep. I have seen organizations that did not tightly control and define their room types. During a period of years, new room types were created to suit personal tastes. Over time, more than 430 room types existed. Obviously, no one could get any real information from such an expansive and widely interpreted list. Keep in mind that you may have to adjust your list upon system selection, but you should perform this exercise before system selection if for no other reason than that it helps you to understand the right system for your needs.

System Selection

Now you are in a good position to evaluate systems and the technology available on the market. Comparing and selecting systems is beyond the scope of this document. But it is usually a good idea to get your information systems group involved along with someone who has set up these types of systems before.

Project Plan

Because each system differs in its setup and operation; it is best to select your system and technology platform before detailing your implementation plan. Your project plan transforms the requirement specifications into the tasks and milestones needed to get to your goal. Devising a good project plan is also beyond the scope of this document, but a few reminders are warranted.

Break the project into small, discrete, manageable sections. Establish milestones and deliverables. As you reach each milestone, communicate your success. The idea is to break the project into pieces so that you can consistently achieve small successes. It is easier to monitor progress and forecast schedules that way, and most important, momentum is maintained and sometimes accelerated.

SUMMARY

Applications of facilities information technology have traditionally been introduced through individual grassroots initiatives, often doing nothing more than expediting manual tasks. Each application is for the most part its own island, often duplicating data from other systems. The result is multiple systems, disparate databases, duplicated and erroneous data, and most important, the inability of information to flow throughout the organization.

The Possibility

An ongoing convergence of technologies (e.g., Internet, Intranet, databases, open architecture) is transforming every aspect of our lives—including the way facilities information systems transform our work. The ability to build and maintain immensely valuable facilities information systems is becoming easier every day. Before starting or revising your system, step back and try to envision the entire need for information within real estate and facilities. If you start with the end in mind and prepare a plan before purchasing and implementing a desired change, you will shift the burden of much data maintenance back to where it belongs. The overall effectiveness of the entire organization will be increased. And most important, you will have reliable information to monitor facility fitness and make strategic decisions.

ARTICLE 3.2.7
MANAGING THE MAGIC

Frank Addeman
Walt Disney Imagineering, Los Angeles, CA

> Whatever we accomplish is due to the combined effort. The organization must be with you or you don't get it done . . . In my organization, there is respect for every individual, and we all have a keen respect for the public.
>
> —*Walter Elias Disney*

IT TAKES MORE THAN "PIXIE DUST" FOR A PROJECT MANAGER AT WALT DISNEY IMAGINEERING TO MANAGE THE DESIGN AND DELIVERY OF A MAJOR ATTRACTION

Walt Disney Imagineering (WDI) has always been the Walt Disney Company's best-kept secret. The reality of a project at WDI is that managing and delivering the magic requires all of the fundamental project control tools and processes typically found in other industries to define and organize the project scope and deliver a quality project within budget and on schedule. The budgets are tight, the schedules are aggressive, Disney standards for design quality and guest experience are high, and the project teams are spartan. Although no ambitious organization can bat 1.000, WDI has an extraordinary track record for delivering projects on budget and on schedule. Creating the magic involves many components, from blue-sky conception to design and implementation, and finally opening the attraction. Don't be fooled. The work doesn't stop there; it just begins in another arena, presenting these new projects to Disney audiences around the world.

So how does a WDI project manager manage the design and delivery of a major attraction? It takes more than "pixie dust" to focus the wide spectrum of Imagineering *dreamers* and *doers* and turn an unproven concept that may initially defy the laws of physics into a cost-effective and reliable attraction that meets guest expectations on Opening Day. In addition to the project challenges found in other industries, creating a major attraction at WDI involves two further unique complexities that must be fully understood and integrated by the project team for a successful delivery.

THE WDI PROJECT ORGANIZATION

The first unique difference is that WDI is in the entertainment industry and its project organization is similar to that for film production, with both a producer and a director who share project responsibilities. Each project team has a show producer who is responsible for the creative vision and a project manager who is responsible for project delivery. Second, WDI projects mobilize a wide range of specialized talent—residing in over 100 specialized work groups in multiple locations—that must be fully integrated and sequenced during the project's life cycle.

These Imagineering specialists are assigned to functional divisions and support each project when their specific skills are required at various points in the project life cycle. Some of the specialized talents required to deliver a major WDI attraction include writers, artists, model makers, sculptors, set designers, artificial foliage designers, lighting designers, special effects designers, audio/video designers, show/ride mechanical engineers, show/ride electronic software engineers, show production and tooling specialists, show animators and programmers, rockwork designers, graphic designers, facility engineers for each discipline, architects, landscape specialists, film production specialists, interior designers, themed carvers, and themed painters. Each of these specialty groups must be engaged at the appropriate time and must provide a timely deliverable to another group to keep the project on track. For example, creating a complex AUDIO ANIMATRONICS figure involves more than two dozen different specialists residing in different groups that must work in sequence from the initial figure movement sketch through a fully functional figure in an Opening Day scene.

Walt Disney Imagineering uses a decentralized project matrix organizational structure to provide the diversity of talent to achieve a large portion of the project scope. It is neither practical nor cost-effective to attempt to dedicate this talent only to one project. A large portion of the work is performed by Imagineers working in more than two dozen separate locations. The WDI functional divisions include Creative Development, Architecture and Facilities Engineering, Show/Ride Design and Production, Theatrical Design and Production, and Finance and Project Controls.

The projects require timely and accurate reporting to maintain cost/schedule visibility in a rapidly evolving project/division environment, as the project matures through its life cycle. A project team is assembled and empowered to be responsible and accountable for achieving the objectives for each individual project. Division work groups are authorized to perform defined work scopes for each project.

One of the biggest challenges for the project team is coordinating the many specialized performing work groups, which adds a very complex dimension to project coordination. To monitor work performance, each performing work group must have consistent and clearly stated objectives and a well-defined and measurable scope of work assigned. By establishing what is to be "accomplished" or "delivered" and who does it, the project manager can maintain the schedule and budget and identify deviation from the original plan.

Each specialized WDI work group can perform work at multiple times on a project during the design or implementation phase of the life cycle. In turn, each division work group must support multiple projects at any time. Most work is performed in a location different from that of the team. Each functional work group within each division is responsible and accountable for achieving the correct creative and technical solutions within its area of responsibility

and expertise for each project. Each division provides the appropriate support personnel, including managers and technical specialists, to support the project team.

The most challenging aspects of the project and division management matrix are (1) tracking budgets and (2) scheduling performance for each work group from project inception through each phase of the life cycle to completion. Project scope and continuity are controlled using a standard WDI project work breakdown structure (WBS). The WBS identifies the theme park, land, attraction, major components, and divisions of work. This structure provides the project team with a basis for evaluating where the project is today and, most important, what remains to be done.

An overview of the WBS Level 5, Project division of work (DOW) is shown in Fig. 3.2.7-1. The show and ride portion of the DOW is unique to WDI and is the common denominator for cost and schedule control and communication between the projects and divisions. A division management summary report could be for one DOW, such as DOW 41, Animated Figures, for all projects currently authorized. A project summary could be for all show components of the project for the full project life cycle, including DOW 41. The DOWs are assigned to three major work categories: facility, show, and ride. Facility design and construction scope are organized by the CSI standard for consistency within the construction industry. Show and ride components are assigned to DOWs that were created for WDI. Each show component is assigned to scenes within each attraction to coordinate production and installation sequences with the building construction.

The Project Team Challenge

If you were a project manager for an automotive manufacturer in Detroit, and you were asked to design and build a new high-performance car that looks great, exceeds all of the current safety standards, and is less expensive than last year's model, and were asked to find a way to deliver it one year early with an 800,000-mile warranty, would you accept the challenge?

Many of the Imagineering project teams are required to meet similar objectives when new show or ride technology is required for their attraction. The project financial pro forma is tight. The schedule is usually aggressive, supporting an Opening Day requirement. The attraction needs to receive a high guest satisfaction rating. The show components and ride need to last 20 to 30 years and operate up to 20 hours per day, seven days a week.

So how does a project team meet all of these objectives? It takes a blend of "pixie dust"; an experienced core team that knows where the risks are; world-class talent in each specialty area; proactive communication among the project team, divisions, and contractors; and lots of sweat. Compared to other industries, the project controls staff that provides cost and schedule control is spartan. Realizing that the effort to control cost and schedule increases with the level of reporting detail required, the project manager must limit the level of control detail to the high-risk areas and use high-level reports for the lower risk scope.

To stay on budget and schedule, the team needs to avoid design reiterations by identifying timely design deliverables when they are required for efficient design. For example, the heat load for a pyrotechnic special effect must be finalized before the HVAC can be designed. The size and movement of a large AUDIO ANIMATRONICS dinosaur must be finalized before the building structural, mechanical, and electrical loads can be designed. The energy profile of a ride must be finalized before the show set and facility can be designed. A complex attraction could easily have more than 1000 design deliverables to maintain the design schedule.

Casting the Project Team

Before joining WDI, I worked for a large design and construction firm. Our project teams, typical of the heavy construction industry, consisted of a project manager, project engineer, construction manager, and a project controls manager. Even though the projects were all

LEVEL 4	LEVEL 5
WORK CATEGORY	**DIVISIONS OF WORK**
Facility Design/Construction (16 codes)	• 02 Site Work • 03 Concrete • --- • 16 Electrical
Show Design/Production/Installation (23 codes)	• 41 Animated Figures • --- • 44 Special Effects • 45 Projection Hardware • 48 Audio Software • --- • 51 Show Lighting • 55 Rockwork/Shotcrete • --- • 64 Theatrical Rigging
Ride Design/Production/Installation (13 codes)	• 71 Load/Unload Conveyance • --- • 74 Track/Flume • 75 Vehicle • --- • 79 Ride Control Software

Schedule activities and logic ties are required for each component within each Division of Work as they are sequenced between 6 to 24 different WDI work groups.

FIGURE 3.2.7-1 At Walt Disney Imagineering, the work breakdown structure (WBS) division of work (DOW) is the common denominator for cost and schedule control and communication between projects and divisions. The DOWs are assigned to three major work categories: facility, show, and ride. Facility design and construction scope is organized by the Construction Specifications Institute (CSI) standard for consistency within the construction industry. Show and ride components are assigned to DOWs that were created for WDI (© *Copyright Walt Disney*).

much bigger and required more resources, the number of specialty groups required was less than one dozen. The WDI project team is organized to support the special demands placed on the project manager to provide an entertainment project and manage the diversity of talent required. The WDI project team has a project manager, a show producer, project core team members, and project control team members.

Project Manager. The project manager (PM) is the focal point for the project team and has full accountability for project results. The PM is the project facilitator and must have the ability and visibility to deal with problems and obstacles from a single, coordinated viewpoint over the total project. A PM must have sufficient influence to ensure that the division priorities support the project requirements. The PM assigns work to the divisions and must resolve priorities with each division manager to support the project schedule.

Show Producer. The WDI show producer is responsible for directing the creative vision throughout the project's life cycle. The show producer represents the Creative Division's executive management on the project team. The show producer manages the intent of the show design from conceptual design through project completion and reconciles operational and budget trade-offs, when required, to meet the project's creative objectives.

Core Team Members. The core team for a major attraction typically consists of an architectural and engineering manager, a ride project engineer, a show program manager, and a construction manager. The project core team members are the communication conduits between the project and their respective divisions. They are responsible for project leadership, decision making, and delivery for their respective scopes. They have dual reporting relationships. They report to the project manager in their roles for accomplishing the project objectives and to their respective functional managers for professional execution of their creative or technical responsibilities in support of the project. They are accountable for project-related work performed by their respective divisions or outside vendors and contractors. They report to both their project manager and their respective director/manager regarding cost, schedule, and technical status.

The project core team members are also responsible for their respective divisions' scope/strategy, plans, schedules, budgets, and design intent. They work with the project team and their division directors to identify their respective division's scope and deliverable requirements for each funding phase and to ensure that the creative vision is achieved.

For successful project delivery, core team members must ensure that the project goals are understood and committed to by their respective division managers and performing work groups and that each work group's schedule is integrated into the project master schedule.

Project Control Specialists. The project team also has project control specialists who report to the project manager for project direction and to their division director for functional direction. The project control specialists include a project estimator, project planner/scheduler, project financial analyst, and a contract manager. They support both the project manager and each one of the project core team members with project control services for both division authorized work and outside contractors and vendors.

PROJECT DELIVERY

Each new attraction evolves through five phases, from a potential new idea through Opening Day. The project life cycle establishes the duration of each phase and the framework for each schedule. An overview of the project life cycle and key milestones is shown in Fig. 3.2.7-2. A unique challenge for a WDI project team is blending creative and technological innovations with Disney storytelling. "Concept" is the evolutionary phase that is used to ensure that an attraction can be designed to integrate the story line into three dimensions through feasible

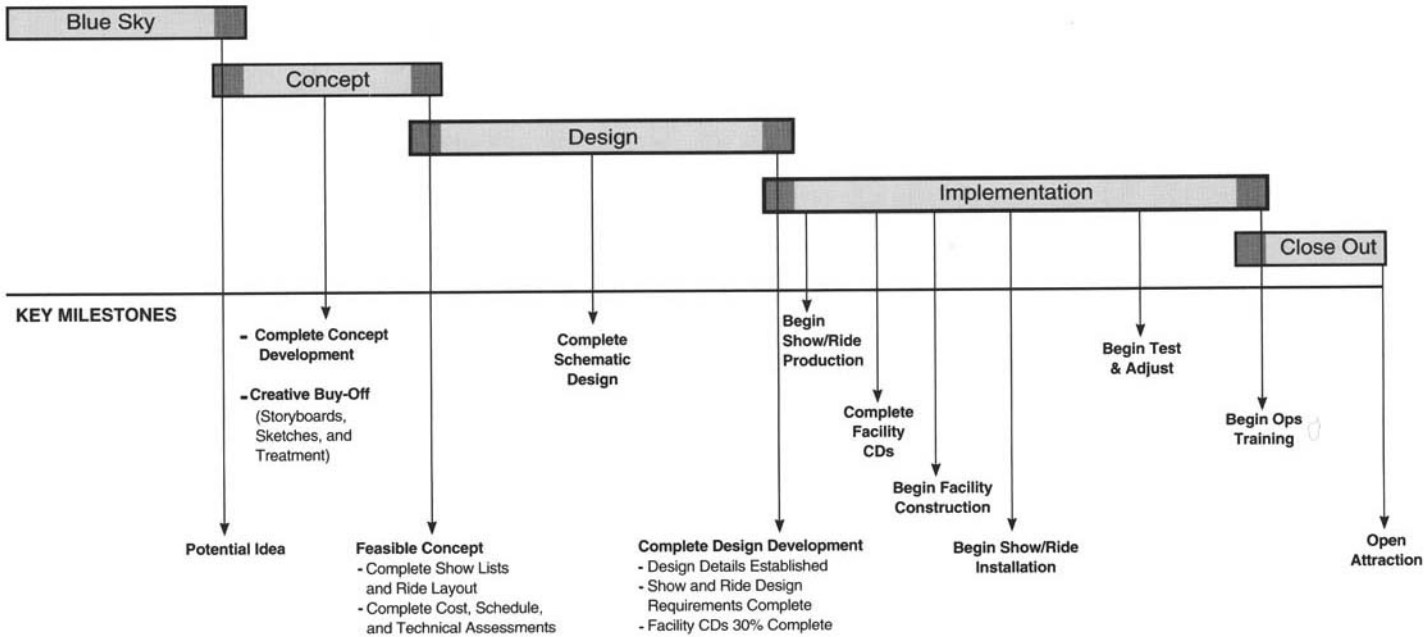

FIGURE 3.2.7-2 Each new attraction evolves through five phases, progressing from a potential "blue-sky" idea through Opening Day. The project life cycle establishes the duration for each phase and the framework for each schedule. *Concept* is the evolutionary phase that is used to ensure that an attraction can be designed to integrate the story line into three dimensions through feasible technology. (*Courtesy of Walt Disney Imagineering. © Copyright Walt Disney.*)

technology. This is the time required to develop a recommended unproven concept into a feasible concept that supports the budget pro forma.

The design phase includes the *schematic design* and *design development* stages. The schematic stage is used to finalize the building and show/ride layouts and to select the appropriate show/ride systems. The design development stage must lock down all of the design details including equipment location and functions.

The implementation phase includes the final design of facility contract documents and show/ride production documents. During this phase, all of the design scope must be completed and appropriately defined in the contract bid documents. All of the work unique to WDI, such as themed construction finishes and ride technical performance requirements, must be well-defined. The contract drawings, specifications, samples, and special conditions must clearly define the work scope for each potential bidder, how it needs to be accomplished, and when it needs to be performed. This is a key transition point for the team. This phase also includes show and ride production, facility construction, show and ride installation, and test and adjust.

The concept and design phases are the most challenging phases for the project team to manage because design is not locked down until implementation. These phases place special demands on the project manager to manage the diversity of specialized talent required, to maintain the creative intent, and to avoid negative impact on the project from design reiteration. The project team must complete these phases on schedule to optimize its implementation budget and schedules. The scope and strategy for these phases must be clearly defined by the project team, and the performing divisions must understand the key project milestones and critical schedule interfaces. WDI deliverable guidelines are used to help each project team establish the appropriate deliverables to achieve the objectives for each stage. They provide a consistent framework between each project and performing division. Producing too many consecutive stage deliverables too early may result in major rework; underachievement of the required stage deliverables may result in errors or omissions. The team needs to avoid both of these scenarios to optimize its budget and schedule.

PROJECT PLANNING AND SCHEDULING CONTROL

The project team must develop a fully integrated project master schedule to successfully deliver the project. The project master schedule must be fully integrated into all of the division work group schedules to support a coordinated work effort and ensure that performing organization resources can support the project's objectives. To do this, the project master schedule must be realistic and sufficiently defined to support communication among the project, the division's performing work groups, and each contractor. It must also provide a quantifiable base for performance measurement. As the project evolves, the scope, strategy, and schedule are expanded.

Project/division integration is achieved by developing sufficient DOW detail to provide a common denominator for both the projects and division work groups to plan and show the status of the work scope progress. The project master schedule must identify the appropriate phase deliverables and objectives to avoid design reiterations and to minimize design errors and omissions. Show/ride design must be planned and sequenced to ensure that it does not impact facility design. All project and division schedule activities must contain a consistent coding structure to support project and division management sorting and selection requirements.

The project manager must establish the schedule goals, conditions, and requirements in harmony with the project team members, division management, and contractors. The master schedule is developed within the framework of the project's life cycle and is expanded during each phase by the project planner/scheduler and the project team, using the most current project scope documents. Working with the project team, the project planner/scheduler integrates all project-related schedules into one overall project master schedule to ensure that all work scope is addressed at the appropriate time.

The project master schedule is a critical path method (CPM) logic schedule that identifies key project milestones and critical interfacial points. It provides the project team, division management, vendors, and contractors with an intermediate level of detail, required times of performance, interrelationships, and project schedule objectives. Key project schedule milestones are identified in the project master schedule to ensure that senior project and division management mutually understand schedule goals.

The project team members and the project planner/scheduler must coordinate the schedule development with the responsible work groups to ensure that detailed work plans are properly integrated and that the appropriate need dates are verified. This helps the team identify schedule conflicts among the various work groups. The project manager must ensure that all detail division schedules are integrated within the framework of the project master schedule. The project planner/scheduler identifies the key interfacial points among the performing organizations and determines the project's critical path and work priorities.

Conflict Resolution

Conflicts are inevitable within any matrix organization. The diversity of disciplines required for delivering an attraction increases the magnitude of interfaces and potential scope, schedule, and financial conflict. Most WDI project conflicts are resolved through timely communications between the project core team members and divisional work groups.

The project manager must resolve conflicts between the project team and divisions or among the core team members before they impact project delivery. Critical unresolved conflicts must be elevated to the portfolio project vice president and divisional vice president for appropriate executive management action. Projects for each geographical portfolio are reviewed monthly by senior management of WDI. Any unresolved conflicts that may impact Opening Day are addressed for his resolution as part of the project update process.

SO, HOW DOES A PM LEAD THE TEAM TO SUCCESS?

At the end of the day, the project manager has to successfully deliver a major attraction and also has to examine the principles it took to get there. No one will ever explain this, nor will it ever be put in any type of manual or job description; however, the project manager's key ingredient to success is to remember that he or she is not only managing the project but the human aspect as well. The other elements that fit into this recipe would be to:

- Influence the team through open communication
- Anticipate risks and have a backup plan ready
- Proactively interface with the division managers and work groups to ensure they share the project's goals
- Work closely with the project team to resolve conflicts
- Proactively maintain a healthy balance between budget, schedule, and quality
- Lead the team with passion, conviction, and courage

I believe it was best said by one of the best project managers at the Walt Disney Company:

> Courage is the main quality of leadership, in my opinion, no matter where it is exercised. Usually it implies some risk—especially in new undertakings. Courage to initiate something and to keep it going—pioneering and adventurous spirit to blaze new ways, often, in our land of opportunity.
>

ARTICLE 3.2.8
RETHINKING THE ARCHITECT OR CONTRACTOR SELECTION PROCESS

William C. Ronco, Ph.D.
Gathering Pace, Inc., Bedford, Massachusetts

Daniel Gainsboro, President
Genesis Planning and Delphi Construction

Facility managers readily acknowledge that the main problem in any construction project is communications. However, when they interview architects, contractors, and engineers, facility managers usually neglect communications issues or even ignore them completely. They examine scale models and drawings, review slides and graphs, and study reports and columns of numbers. They fail to explore the candidates' track records in the communications issues that determine project success.

The roots of many of the problems facility managers have with design and construction begin in the interview process. Too often, traditional methods for interviewing and selecting architects and contractors portray little about the interviewees' skills and track record in management and project communications. Candidates who have weak or difficult histories in communications slip through the interview process unnoticed while selection committees study their slides.

The selection process for architects and contractors naturally focuses facility managers on the building. Have you ever built this kind of building? What did it look like? What did it cost? Can you make it look a little more like this? Could you accommodate that? What would it cost? Following this natural line of questioning provides only a small part of the information clients need to know. Questions about experience with buildings provide the baseline, but they do not touch the problem areas.

Selecting an architect based on the look of the buildings that his or her firm designed is like buying a car based on a picture in a magazine, not considering its reliability or its operation. Your buildings committee can devise an excellent list of questions that explore the building and also the process of communications required to get it built. How will the architects communicate with you? How will they involve your input? How will they work with a committee that has internal disagreements, a client base that does not communicate well? How will they manage their own internal turnover?

Following the tenets of "behavioral interviewing," it is also important to ask questions following particular guidelines. Ask no hypothetical or "what if" questions such as:

- What would you do if you disagreed with a client?
- What do you think is an ideal building?
- Of which jobs are you proudest?
- Do you have any weaknesses?

These classic interview questions provide interesting, often fascinating responses. Perhaps that is why they are classics. However, the responses to hypothetical or "what if" questions in no way predict what the respondent will actually do in the situation. Instead, ask questions based on real events.

Effective questions do a better job in predicting what the respondent will do because they explore what the respondent has already done. Effective questions follow this format (also see Table 3.2.8-1).

TABLE 3.2.8-1 Effective Questions for Selection Interviews

Don't ask hypothetical questions: What would you do if . . . ? Don't ask speculative questions: What is your view of an ideal building? These questions yield responses that are interesting but provide no prediction of behavior.	Do ask questions about real events. Use this format: Tell me about a time when you_____. What did you do? What were the results? Based on past behaviors, these questions better predict future actions.

- Tell me about a time when you ____.
- What did you do?
- What were the results of what you did?

Here are 10 questions that facility managers find reveal useful information about candidates in the design and construction process. After each question, the interviewee asks, "What are some actions you took?" and "What were the results of those actions?"

The statements all begin with the phrase, "Tell me about a time when you . . .":

1. Went over budget or beyond schedule
2. Disappointed a customer
3. Disagreed with a customer
4. Disagreed with other members of the project team
5. Had to work with an organization such as ours that does not communicate effectively with its members?
6. Had to work with an organization such as ours that includes some departments that do not get along with each other
7. Had to move key staff off a project
8. Had a client who would not get involved enough in the project
9. Had a client who got too involved in the project
10. Had to work with a project team that had one weak player

We find that few architects and contractors come to selection interviews prepared to answer these questions thoughtfully. Actually, we have seen some architects and contractors who took offense at facility managers who even raised these questions. Needless to say, those are candidates to be concerned about. Many candidates find that they have to return to their offices to gather information to address these questions.

Some architects and contractors cannot answer these questions because they have not really thought about them.

This approach to selection has strong potential for facility managers in design and construction and also in the following areas in which they must select a candidate or a partner:

- Job interviews
- Outsourcing service providers
- Preferred vendors
- Contractors of any kind

In all these cases, it is clear that facility managers must ask these questions and also ensure that candidates provide excellent answers. As long as communications problems impact design and construction projects, it is important for facility managers to understand and manage them in the same way that they understand and manage technical issues.

ARTICLE 3.2.9
ENVIRONMENTAL COMPLIANCE AND MANAGEMENT SYSTEMS

Joel Higginson
Advantage Engineering, Wakefield, Massachusetts

OVERVIEW OF ENVIRONMENTAL COMPLIANCE MANAGEMENT IN MODERN FACILITIES

Since the authorization of the USEPA in 1970, the burden on designers, managers, and operators to build and continuously run their facilities within the framework of local, state, and federal environmental regulations has become increasingly challenging and complex. The Federal Environmental Code, Section 40 of the Code of Federal Regulations, has grown from just over 10,000 pages in 1990 to over 17,000 pages in 2000, and updates and proposed changes to the Federal Code are printed daily in the Federal Register. It should also be noted that the federal regulations are the minimum standard to which our facilities must be managed. State and city codes must be at least as stringent as the federal regulations, and they are often more restrictive.

This article provides a general strategy for managing environmental compliance at your facility. The approach that is described herein is broad and generic. Because of differences from facility to facility, and especially between different types of institutions and industries, not all sections of this article will apply to all facilities. Beyond the scope of this article, it is the responsibility of facility management to identify the specific regulatory requirements that apply to their facility.

All of the regulations that comprise a facility's federal environmental compliance responsibility can be found within the following legislation (Acts):

- *Clean Water Act (CWA).* Regulates chemical, biological, and particulate pollutants in sewage, industrial effluent, navigable waters, and stormwater runoff.
- *Clean Air Act (CAA).* Regulates pollutants from combustion sources, manufacturing processes, and storage systems.
- *Toxic Substances Control Act (TSCA).* Regulates chemical raw materials (primarily imported and new materials) and certain existing materials which represent an "unreasonable hazard."
- *Superfund Amendments and Reauthorization Act (SARA).* Enacted to minimize the potential of a disaster similar to the chemical release disaster in Bhopal, India, SARA is the umbrella act which covered EPCRA and which modernized and strengthened CERCLA.
- *Emergency Planning and Community Right to Know Act (EPCRA).* Regulates facilities that store and use greater than threshold amounts of hazardous materials; provides emergency planning information to communities; requires annual usage and release reporting.
- *Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA).* Regulates processes for identification and cleanup of contaminated (hazardous waste) sites and for responses to spills of hazardous materials.
- *Resource Conservation and Recovery Act (RCRA).* Regulates hazardous waste generation, storage, transportation, treatment, and ultimate disposal.

In addition to the regulations that enacted under each of the preceding Acts, the federal government and state agencies frequently issue "policies," "guidance documents," and "guidelines" that augment, reinforce, or supplement their legislation. Complying on a day-to-day basis with the "letter of the law" is a legal requirement, yet it is also a formidable task. This article presents a strategy for implementing and maintaining compliance and discusses the issues of importance to facility manager over the life cycle of the facility.

DEVELOPING A STRATEGY FOR ENVIRONMENTAL MANAGEMENT

A successful environmental management system (or program) depends on two key things—*awareness* and *ownership.*

It is generally very easy to tell within minutes of walking through the "nonpublic" (service, maintenance, waste collection and disposal, or utilities) areas of a facility how strong its "culture" (with respect to environmental compliance) is. Companies and facilities that practice reactive environmental management are certain to have more frequent and more serious noncompliance issues than those that are proactive in style.

Awareness of the regulatory responsibilities, requirements, and limits under which a facility must operate in order to remain in compliance can only be attained via continuous education and training. Sources of educational and training materials for facility management include federal, state, and local agencies, independently operated agency hotlines, trade associations, industrial and institutional journals and trade publications, business and industry associations, equipment vendors, suppliers, and consultants. Awareness training should be "pushed" by facility management to each appropriate organizational level of the workforce.

Ownership of compliance responsibilities must be clearly delegated via job descriptions and enforced via their presence in the individuals' performance review program. A compliance program that is designed to establish responsibility for certain environmental activities at the *lowest* levels of the organization will generally create the appropriate culture for successful environmental management.

GETTING STARTED WITH OR RESTRUCTURING AN ENVIRONMENTAL MANAGEMENT PROGRAM

The easiest way to get started is to select a team of people from a geographic *and* functional cross-section of the facility to brainstorm all of the "things" that affect the facility's ability to be "in compliance." The number of "things" may vary in number from 12 or 13 for a simple office building to hundreds for a complex manufacturing facility or institution campus (see Table 3.2.9-1).

Grouping the "Things" into Appropriate Compliance "Modules"

The foundation for effective environmental compliance management begins with a system with concise, coherent structure, which takes into account the following elements:

- Personnel who manage the process that has the potential to contribute to pollution
- Personnel who use the process
- Personnel who maintain or supply the process
- The form of the potential pollution and the way in which it enters the environment

TABLE 3.2.9-1 Compliance Issues for an Office Building

Past history of site
Site contamination
Leaking underground storage tanks
Air emissions
Fossil-fuel-fired boilers, incinerators, emergency generators
Wastewater
Sewer connection permit
Hazardous waste and hazardous materials handling
Light bulbs, batteries
Fluorescent light ballasts
Cooling tower and boiler water treatment chemicals
Solid waste management
Waste management and reduction programs
Fuel storage
Underground storage tanks
Refrigeration management
Chlorofluorocarbons
Ammonia
Spill prevention, control, and countermeasures
Fuel oil storage
Hydraulic oil (elevators)
Electrical transformers (PCBs)

The "modular" approach results in a program structure that localizes compliance issues and breaks them down into easily understandable and manageable activities. Shifting gears to a manufacturing environment, an example of modules for a light manufacturing facility may consist of the following:

- *Water pollution control module.* Takes into account discharges of industrial wastewater that may include suspended solids, toxic contaminants such as heavy metals and organic toxics, BOD (biochemical oxygen demand), FOG (fats, oils, and greases), temperature, and pH
- *Air pollution control module.* Takes into account emissions from fuel-fired devices such as boilers, heaters, incinerators, dryers, and ovens, and from manufacturing processes such as coating and painting systems, reactors, baking ovens, and so forth
- *Hazardous waste and hazardous materials handling module.* Relates to the proper disposal of hazardous waste materials and the proper storage, handling, and reporting of hazardous chemicals that are used on the manufacturing site
- *Solid waste management module.* Deals with the management of solid waste streams that leave the facility, and includes waste minimization, substitution, elimination, and recycling
- *Spill prevention, control and countermeasures (oil spills), and stormwater pollution prevention module.* Takes into account storage systems, stored materials, and raw materials deliveries that could result in a spill of oily material into the environment (e.g., storm sewers, soil, roadways)
- *Underground storage tanks.* Relates to the potential for spills from underground storage tanks and piping systems.

A Specific Module Example for a Manufacturing Facility—Identifying Compliance Activities

The module teams should meet to define the specific activities that should be managed in order to ensure compliance. Each module can be effectively managed by implementing 6 to 12 simple management activities. For example, most water pollution control modules can be managed by producing and maintaining the following eight module "tools":

- *Site map with discharge points.* The module team should locate and identify on a site plan the sources and discharge points for process wastewater as well as sanitary wastewater. Care should be taken during the site review to identify for elimination any cross-connections which may allow sanitary wastewater to enter a process wastewater pretreatment system; sources of noncontact "once-through" cooling water (which unnecessarily increases the hydraulic loading on downstream treatment processes); drains from "clean" roofing (which should discharge into stormwater systems); and floor drains in manufacturing areas which bypass wastewater pretreatment systems.
- *Permit or registration summary.* Identify by discharge point whether the discharge requires a permit or a registration. Local regulations, ordinances, and sewer authority guidelines should be reviewed, as they may contain more stringent requirements than federal and state regulations.
- *Summary of permit obligations.* The module team should review the facility wastewater discharge permit and prepare, for management review, a two-page summary of permit obligations. Once a permit is obtained, *most* permit holders quickly lose track of all but the most significant of their compliance obligations. The permit summary should include a listing of what pollutants are controlled (BOD, TSS, FOG, pH, etc.); a summary of the "controlled" parameters (daily wastewater flow, process throughput, hours of operation, pretreatment system functions, and so forth; a summary of record-keeping and reporting requirements; operator licensing requirements; noncompliance notification procedures, phone numbers, and timing; and permit renewal requirements.
- *Compliance and operations data filing system.* The module team should ensure that records and reports are being properly completed, and that they are maintained in an active file for the mandatory records retention period. Records should include discharge monitoring reports; analyses performed by outside laboratories; qualifications documentation on outside laboratories; manufacturing production records (if permits restrict operations); and preventive maintenance and repair records for equipment and control systems.
- *Site accountability listings.* The module team should decide in advance and make generally available to employees on each shift the appropriate chain of command for managing and reporting noncompliance issues on a shift-by-shift basis.
- *Incident reporting action plan.* Facility management and the module team should establish a decision tree or flow chart to identify proper incident-reporting protocols for notification of regulatory agencies as well as corporate headquarters. The plan must include 24-hour emergency notification numbers. One of the most horrifying experiences that corporate senior management can have is to turn on the television to a "live report" from outside one of their facilities.
- *Licensing and certification requirements.* If operator licensing is required, the module team should put in place a system to ensure that annual training requirements are planned for and achieved and that recertification examinations are scheduled and successfully completed.

Record Keeping

The single most important compliance management activity is record keeping. Each facility is obligated to prepare and maintain records that demonstrate its compliance with environmental regulations. Records are the principal tools that regulatory agencies use to determine

whether a facility is meeting its obligations. By simply reviewing the filing system, a good field inspector can tell within 15 minutes whether a facility understands and is managing its compliance obligations. A good record keeping system should include:

- *File system index.* A single point of information that describes the filing system.
- *File location summary.* A "file locator" which identifies where each type of information is filed. As a general rule, it is recommended that a facility's active environmental files be maintained in a single location, and that limited access be provided to personnel on each shift. For example, current (monthly) boiler or fuel documentation may be maintained in the boiler room, then subsequently filed in the main file location.
- *Separate location for archived files.* Files that are maintained beyond the minimum statutory records retention requirements (in some cases a corporate requirement) should be maintained in a separate locked location. These files are not part of the facility's regulatory compliance requirements, and they should therefore not be treated as such.

Program Review and Evaluation

Facility environmental compliance programs must be periodically monitored by or on behalf of senior management to ensure that they are being maintained at an acceptable level.

ENVIRONMENTAL COMPLIANCE OVER THE LIFE CYCLE OF A FACILITY

Environmental management is a process that must be implemented and maintained throughout the life cycle of a facility. Facility owners and operators are responsible "from the cradle to the grave" for the emissions, discharges, and wastes that are generated at those facilities. Therefore, compliance issues must be planned for and managed from facility planning through facility closure. Permitting processes often lie on the critical path of facility construction or modification plans. This section addresses some of the issues that must be addressed at each stage of the facility's life cycle.

Site Selection Regulatory Issues

Site selection issues include principally *site condition assessment* and *environmental impact assessment.* Site assessment is a site condition and data review process designed to identify historic uses, review reported soil and groundwater contamination in the region, and evaluate the likelihood of contamination originating onsite. Environmental impact assessment ensures that the intended development and use of the site will not create unacceptable impact on the local environment.

Site Assessment (Phase I/Phase II). "Site Assessment" is a very specific process for identifying and evaluating risks at a particular location. Site assessments are frequently required by lending institutions on mortgage acquisition or refinance and by insurers on new coverage or increased limits coverage requests. Although the American Society for Testing Materials (ASTM) has developed site assessment specifications, there is great variability in the level of information that the lending institutions and insurers require.[1,2] A Phase I site assessment addresses observed and recorded site contamination issues. A Phase I assessment is therefore a screening process. The minimum Phase I site assessment requirements generally consist of three elements:

- *Environmental database review.* Several vendors offer environmental database review and report services. The database reviews identify contaminated sites; leaking underground storage tanks; major generators of hazardous waste; hazardous waste treatment, storage, and disposal facilities; landfills and incinerators; and sites of major spills in the vicinity of the subject site.
- *Local department records review.* A local review consists of reviews of the planning board (historic site plan approvals); building department (ownership, historic use, significant construction and demolition projects); and fire department (underground tank and hazardous materials storage registration) records.
- *Site visit.* The facility walk-through identifies visible signs of contamination and environmental risk. Key objectives of the site visit are to identify signs of significant spills and leaks; presence of asbestos, lead paint, and PCB's; and evidence of inadequate compliance management.

A Phase II site assessment[3] is generally ordered if there is a significant potential of site contamination and if additional testing and analyses are required to determine the extent of the contamination. Significant contamination can range from issues such as lead paint chips on the surface of the ground (identified and characterized via a soils analysis) to serious soil and groundwater contamination (often from the disposal of industrial chemicals into old septic systems or from a previous history of leaking drums stored onsite).

Environmental Impact Assessment. The "environmental impact assessment" process originated with the National Environmental Policy Act (NEPA), Article 22-1. This act required federal agencies, departments, and installations to prepare environmental impact statements on proposals for legislative and other major federal activities that have the potential to significantly affect the quality of the natural environment.[4] Many states have adopted the environmental impact assessment process (or various parts or reconfigurations of it) as a means of creating a forum for public input and comment on projects that have the potential of causing significant impact on the region or community. Typically the process, which is triggered by a myriad of potential impacts (including deforestation and loss of natural habitat, wetlands and drainage basin modification, traffic, noise, lighting, impact on community services and infrastructure, air quality, and others), requires the applicant to evaluate the impacts for the preferred project configuration as well as for less intrusive or less impacting alternatives. This process can have a tremendous impact on the site selection process, as it may drive a proposed project to a different location, or it may result in the rejection of the project in its entirety.

SITE PLANNING REGULATORY ISSUES

Specific site-related projects (whether they be new "greenfields" projects, conversion of existing property to an alternative use, or addition to or modification of an existing property) are regulated under state, county, and local programs. Site planning activities, which generally come under the purview of elected and/or appointed boards, encompass things such as zoning (the establishment of specific land use patterns, criteria, and requirements), wetlands protection, community impacts (including traffic, noise, lighting, air emissions), and the availability of utilities and services.

Zoning

Zoning is the process whereby county or local officials regulate land use via a predetermined definition of permissible uses and land use restrictions within the community. Zoning is intended to be protective of the interests of the community as a whole. The zoning process typically addresses the following issues:

- Land uses (which are typically listed as permitted or not permitted within certain sections of the community)
- Density of development (by regulation of minimum lot size; establishment of requirements for the minimum setback distance of facilities, structures, and paving from streets and property lines; and by potentially regulating the specific location of a building within the property boundaries)
- Community impact (by addressing issues such as traffic, air emissions, noise, and lighting)
- Infrastructure impact (including electric power, potable water, and natural gas availability; impact on community safety and educational services; site access; impact on existing roadways; and wastewater disposal issues and alternatives)

Applicants who initiate the zoning process should be aware of the fact that this process will result in the discussion and review of alternatives to the proposed plan, and applicants should prepare to address justification to support the preferred project configuration during the zoning review process.

Requests for exemptions, exceptions, or waivers to specific requirements within the zoning approval process are generally handled by a separate site plan approval authority, or by an appeals board process.

Wetlands Protection

Wetlands issues are regulated at the local level, frequently with oversight and even active involvement at the state level. Wetlands are important to the ecology for several reasons. They provide accumulation volume and settling capacity to prevent downstream damage and pollution, they provide habitat for wildlife, and wetlands plants perform treatment of wastes.

During the initial stages of the project development process, the owner and the site engineer must make a determination of the location and boundaries of wetlands on the project site (and perhaps on adjacent sites if the project has the potential of impacting them). Although wetlands determination requirements vary from state to state, wetlands determinations are generally based on plant species, hydrology, and soil type. Wetlands impacts originate from two sources—the impact on wetlands that must be moved, reconstructed, or replicated due to the construction of the facility and its access roadways; and the impact of stormwater runoff storage requirements on existing wetlands and storm drainage systems. Most states now limit the project's postconstruction runoff to less than or equal to the preconstruction runoff. This means that the additional runoff that is caused by impervious structures such as building roofs and paved areas must be stored onsite and released to existing offsite drainage systems in a controlled manner.

The board, commission, or agency that is responsible for managing the wetlands permitting process will frequently require the applicant to submit alternative analyses to the baseline design in order to ensure that the permitted project will minimize impact on the wetlands.

Community Impacts

Air emissions, noise, and lighting issues are administered at the county or local level via "nuisance ordinances." Nuisance ordinances are often based on subjective evaluation of the impact of the site and its operations on abutters and other nearby residents. Some of the considerations that an owner may make when evaluating a particular site are:

- Direction of prevailing wind and impact on facility odors that may be carried to surrounding properties

- Facility operating schedule and placement of noisy or brightly lit operations on the side of the facility that has the least impact on neighbors
- Site topography, vegetative screening, and access roadway design to minimize impact on neighbors

Availability of Utilities and Services

Potable water may be extracted from the ground by the facility owner, or it may be delivered via a municipal supply system. In either case, the facility's initial as well as proposed water requirements (to accommodate growth) may have a significant bearing on site selection. Aquifer studies and pumping tests can be performed to determine the ultimate capability of the aquifer to support the desired extraction quantities and rates. Owners who are dependent upon extracting potable water from their own site should evaluate surrounding operations to rule out or minimize the potential risk of groundwater contamination due to leaks, spills, or catastrophic events at nearby properties. Owners who plan to rely on municipal potable water supplies should inquire during the project planning activity about the community's ability to meet initial as well as projected water needs.

Of equal importance is the ability of the community to provide treatment of the wastewater from the facility. Nonmanufacturing facilities may estimate the amount of sewerage leaving the facility based on the number of employees occupying the facility and on additional activities such as operation of a commissary or laboratories. Manufacturing facilities may estimate and characterize their wastewater based on similar operations and on the proposed manufacturing system's material balance. The U.S. Environmental Protection Agency (USEPA) has developed categorical wastewater pretreatment standards for some specific industries that generate high-strength wastewaters. The categorical standards define the amount of treatment required at the manufacturing site prior to discharge of the wastewater to a publicly owned treatment works (POTW). The cost of wastewater treatment can be a significant line item of a facility's annual operating budget. In fact, wastewater disposal fees and surcharges may represent a significant negotiation opportunity during a new facility siting process.

REGULATORY ISSUES DURING FACILITY PLANNING AND CONSTRUCTION

During the preconstruction and construction phases of a project, the owner or the owner's representative must be cognizant of the types of proposed activities that may require permits. Some of the permit requirements may have a significant impact on facility design, and others may fall along the critical path of the construction and startup schedule. The types of permits that must be considered include stormwater discharge associated with construction activity (in the case of disturbance of five acres or more of land with the potential to discharge soils and contaminants into stormwater systems and waterways); flammables storage licenses and permits; treated wastewater discharge; stormwater discharge associated with industrial activities; hazardous waste storage; and combustion systems and manufacturing processes operating permits.

Stormwater Discharge (Construction)

Any construction project that will disturb over five acres of land, and that will discharge runoff into an ocean, lake, river, stream, or wetland must obtain an NPDES (National Pollutant Discharge Elimination System) permit. (Discharge into a storm sewer system that subsequently discharges into a waterway or a wetland is considered to be the same as directly

discharging into the waterway or wetland.) The NPDES permit will require two things—a pollution prevention plan and installed mitigation measures. Typical mitigation measures include controls to stop the runoff of fine soils and silt (erosion and sedimentation controls) and discharge flow controls (detention basins) which control the volumetric flow of stormwater from the site. The application process for an NPDES permit for stormwater discharge associated with construction is a simple process, and does not generally impact the project schedule. Most facilities choose coverage under existing general permits.

Flammables Storage Permits and Licenses

Permits and licenses to store flammable materials are managed at the state or local level, and permit requirements vary widely. For this reason it is important to determine prior to beginning facility construction what the local authorities are willing to permit. For example, a community with a high groundwater problem may prohibit the installation of underground storage tanks, and the facility plan will have to account for aboveground fuel storage in a room or vault. This may have an impact on the footprint of the proposed building.

Treated Wastewater Discharge

If the proposed facility will be responsible for pretreating the wastewater or for completely treating it to discharge standards, the type of treatment system and its real estate requirements for the proposed initial operation as well as for planned expansion must be taken into account when planning the site layout. Planning should take into account strategies for holding or recycling wastewater so that operations will not have to be shut down in the event of an upset in the treatment system. If the facility proposes to discharge treated wastewater directly to a waterway, the permit application must be submitted at least 180 days prior to initial wastewater discharge.

Stormwater Discharge (Industrial)

A facility that discharges stormwater that has had the potential of contacting raw materials, work in process, finished products, wastes, or equipment and machinery which may contaminate that water, must obtain a NPDES permit for discharge of the stormwater. As with the wastewater treatment NPDES permit application, this permit application must be submitted 180 days prior to startup of the facility. This requirement encompasses facilities that discharge via any "conveyance" (swale, berm, pipe, channel, etc.) into a waterway or wetland or into a storm sewer system which subsequently discharges to a waterway or wetland. Facilities that unload raw materials in unsheltered areas, discharge exhaust from dust collection devices to the roof, or discharge compressor condensate with trace amounts of oil are considered to "have the potential" of contaminating the stormwater. The facility owner may wish to design the facility to perform all activities and to release all discharges within protected (roofed and drained) areas in order to eliminate the need for participation in this permit program.

Hazardous Waste Handling and Storage

Facilities that generate hazardous waste (as defined by the Resource Conservation and Recovery Act—RCRA—40 CFR Part 270) must apply for an EPA ID number and must store and dispose of the waste material in accordance with the regulations. Facilities that propose to treat, store, and dispose of their hazardous wastes (TSDF facilities) must submit a two-part RCRA permit application 180 days prior to *commencing construction* of the treatment, storage, and disposal systems.

Combustion Systems and Manufacturing Process Permitting

Three types of air emissions permits must be considered during facility design and construction, and must be implemented prior to constructing a new facility or modifying an existing facility. Each of these permits is dependent upon the size and scope of operation of the proposed facility as well as upon the air quality status of the region in which the facility is to be located. Under the 1990 Clean Air Act Amendments (CAAA), nearly all air emissions are subject to permit requirements. The individual states have been delegated the authority to issue and administer air emissions permits on behalf of the EPA. Therefore, although each state's program includes as a minimum all of the federal program requirements, individual states may enact more restrictive regulations.

The federal Clean Air Act Amendments regulate a variety of emissions that are categorized as "air toxics" as well as a set of six "criteria pollutants." The criteria pollutants include nitrogen oxides, carbon monoxide, sulfur dioxide, particulate matter, lead, and ozone. The standard for ozone emissions (which is a major component in photochemical smog) is actually enforced by monitoring volatile organic chemicals and chlorofluorocarbons.

The National Ambient Air Quality Standards (NAAQS) have been established to define maximum levels in the environment of the criteria pollutants above which human health is at significantly increased risk. Through a system of data collection, monitoring, and analysis, EPA has defined regions of the country as being either *nonattainment* (meaning that the region has not reduced air pollution below the maximum program levels), or *attainment.* As one might expect, the permit process in nonattainment areas is more restrictive than that in attainment areas.

The Clean Air Act Amendments are also written around two tiers of facilities—*potential major sources* and *minor sources.* Potential major sources are facilities which "have the potential to emit" greater than "threshold amounts" of pollutants. The potential to emit is defined as how much of any given criteria pollutant the facility would emit if it operated at full capacity for 24 hours per day, 365 days per year. The threshold amounts of pollutants differ depending upon whether the region in which the facility is to be located is in an attainment area, a moderate nonattainment area, or a severe nonattainment area.

The New Source Review (NSR) program mandates two types of permits for "potential major" sources—*preconstruction review* permits and *prevention of significant deterioration* (PSD) permits. Any new "major source" or any major source that is proposed to undergo a significant modification in an area which is nonattainment for one or more of the criteria pollutants must apply for a preconstruction review permit. Preconstruction review permits are administered by the state environmental agencies, and they may take up to a year or longer to obtain. Clearly, such a permit will fall along the project's critical path, and it must be considered and initiated at the very beginning stages of the project. Proposed new facilities or existing facilities which are undertaking significant modifications and which are located in attainment areas, must file for prevention of significant deterioration permits. The objective of PSD permits is to ensure that the region in which the facility is located remains an attainment area after startup of the facility. PSD permits can take up to a year to secure also.

A third type of permit, the *operating permit,* also called the "Title V" Permit, is an umbrella permit that has been issued to all facilities which are potential major sources of air toxics or of any one of the criteria pollutants. Operating permits establish facility-wide emissions limits, define criteria for limiting operations of the process or facility, establish monitoring and recordkeeping requirements, and specify criteria for reporting exceptions or exceedances.

In addition to the permits just specified, state environmental agencies and local air quality control boards may require *plan approval applications* for systems or processes that are above a certain size. Plan approval applications are a mechanism by which the permitting authority can regulate nonmajor processes. Plan approval applications typically have a 30 to 90 day approval window.

REGULATORY ISSUES DURING FACILITY OPERATION

Each of the environmental permitting requirements described here carry through into the operation of the facility. The permit restrictions, reporting, and record keeping that were established prior to construction must be implemented and followed throughout the course of facility operation. Permit renewals must be expeditiously filed. For example, most NPDES Permit renewals require that an application be filed 180 days prior to expiration of the current permit.

The facility manager must be aware of the requirements of the initial facility permits. In fact, it is recommended that facilities prepare a two- or three-page summary of the key points and obligations of each permit, and periodically review both the summary and the permit.

The following issues will trigger new permitting or regulatory compliance activities after initial startup and operation of the facility.

Process Changes or Expansion

A change in fuels or a significant change in raw materials used, process conditions and capacity, or operation of manufacturing processes must be evaluated for its impact on licenses and permits. Typical areas to be reviewed include wastewater (NPDES permits or sewer connection permits), air emissions (operating permits or plan approvals), and flammables storage licenses.

Flammables and Hazardous Materials Storage

Once a facility is in operation, it must comply with the requirements of the Community Right-to-Know Act of 1986, also known as Title III of the Superfund Amendments and Reauthorization Act (SARA). This program includes three key elements—*emergency planning and release notification, community right-to-know reporting,* and *toxic chemical release reporting.* Under Emergency Planning and Release Notification, any facility that stores more than the "threshold planning quantity" of substances that are listed as "extremely hazardous substances" must prepare a process hazards analysis. This plan requires the evaluation of potential effects of a release and the development of a plan for notification of response agencies and sensitive receptors. EPA's *risk management plan rule* requires facilities that handle, store, or use any one of 139 hazardous chemicals at or above the listed threshold quantities to prepare a detailed hazard assessment, an integrated prevention program, an emergency response program, and an overall management system. Furthermore, the facility must coordinate its risk management plan (RMP) with the local emergency planning committee (which is comprised of local first-response agencies).

Community Right-To-Know Reporting requires any facility that stores over 10,000 pounds of any material for which it is required to keep a material safety data sheet (MSDS) or over 500 pounds or the threshold planning quantity (whichever is lower) of an "extremely hazardous substance" to report information on how and where the material is stored to the state emergency response commission (SERC), the local emergency planning council (LEPC), and the local fire department. This reporting must be renewed annually prior to March 1. Toxic Chemical Release Reporting (TRI) requires any facility that uses directly in its manufacturing process over 25,000 pounds (or which uses in "ancillary processes" over 10,000 pounds) of "listed chemicals" to report annually to the EPA the amounts used and the amounts released to the environment. TRI reporting must be made annually prior to July 1.

Hazardous Waste Management

Hazardous waste regulations are complex. The key elements to proper hazardous waste management are to properly define the facility's generator category (conditionally exempt small

quantity generator; small quantity generator; or large quantity generator), to properly store the waste (in strong containers made of compatible materials, segregating reactive materials, with secure access and proper signage, having adequate ventilation, and with a means of contacting and communicating with personnel outside of the storage area), and to properly manage the waste disposal paperwork. The generator of a hazardous waste is obligated to receive and maintain copies of the shipping manifest from the transporter and from the final treatment or disposal site, or to report absence of the documents within a statutory time frame. Improper management of this paperwork is one of the most frequently cited violations during a regulatory inspection.

REGULATORY ISSUES ASSOCIATED WITH CLOSING A FACILITY

The responsibility for environmental compliance extends through the entire life cycle of a facility—from initial planning and site selection through decommissioning. The owner/operator of a site or a facility must therefore be concerned with the condition of the site upon departure from the site, as well as with its subsequent deterioration. Responsible facility management would suggest that adequate documentation of the condition of the facility and site upon closure is appropriate. The following are among the types of issues with which facility management should concern themselves:

- *Asbestos and lead paint.* As long as the facility remains under the control of the owner/operator, that entity is responsible for exposure of people to these contaminants. Therefore it is encumbent upon the owner to secure the facility against unauthorized access to areas in which these contaminants may be present and to make available any knowledge of these contaminants to construction or demolition crews.
- *PCBs.* Older transformers, switches and capacitors, and even some hydraulic systems may contain cooling oils which are contaminated with polychlorinated biphenyls. When contained within the devices, this material presents minimal risk to humans or to the environment. However, their release constitutes both a potential health risk and a potentially significant cleanup expense. Therefore, owners/operators should consider removing contaminated systems from the facility upon decommissioning or, as a minimum, securing these systems from unauthorized access and vandalism.
- *Oils and maintenance chemicals.* Fuel oils, lubricating oils, coolants, and other maintenance chemicals above and beyond any quantity which is necessary to maintain the integrity of the decommissioned facility should be removed. If the facility is to be demolished, underground tanks should be closed and tank closure documents should be secured.
- *Wells.* If the facility has operated an onsite water well, the well should be tested to document its condition upon closure of the facility, and appropriate measures should be taken to prevent unauthorized access to the well.

In summary, common sense should prevail with respect to closing a facility. Facility management personnel are encouraged to perform a risk analysis ("what-if" assessment) on facility closure issues.

OVERVIEW

In today's working environment, change is constant. As changes occur, they invariably affect the physical office. The need to accommodate company growth, improve business processes, enhance the company image, or even reduce space due to company downsizing are reasons for change—change usually manifested as an office reconfiguration or relocation.

There are many complexities to bringing such facility projects from concept to reality. A number of people and a great many details must be coordinated. Landlords, architects, contractors, furniture vendors, security, telephone and data system installers, and movers all play a part in a facilities change or relocation.

This article explores the process of facility change and/or relocation and provides the facility manager with a checklist that will be useful for ensuring that no aspect of a project is overlooked.

HIRING AN ARCHITECT

The first step in making a facility change is identifying the need for it. Once this is done, the business of making the change typically involves the services of an architect. Depending on the size or scope of the project, the architect may be hired through a bid process.

Programming

Once hired, the architect will work with the owner and other designated parties to establish the project requirements, timetable, and budget.

Next, the specific client needs are assessed. Through a series of interviews with appropriate staff members, an analysis of activities is conducted to establish the client's operating procedures, space requirements, communications relationships, and present and future functional needs.

If the project involves relocation to another site, the following predesign activities ensue:

- Site evaluations for relocation and comparisons of prospective sites
- Lease negotiations (typically do not involve the architect) (see Art 3.1.5, Corporate Leasing Design, and Construction)
- Feasibility studies
- Preliminary block plans

If the project is a renovation of an existing site, then the architect will set about inventorying the existing site conditions. As part of a feasibility study, the architect also reviews code compliance to determine building limitations and design parameters.

To complete the programming phase of the project, the architect will prepare a summary analysis of the programming findings and issue this to the owner for sign-off approval.

Schematic Design

The architect then enters into the schematic design phase of the project, whereby schematic layouts are produced to communicate preliminary concepts for group clustering, furniture layout, and circulation. Color, finish, and materials selections are explored in this phase, and a preliminary cost estimate is also established. Several owner reviews and architectural revisions can be expected before arriving at an approved layout and finish selections.

Design Development

With approvals in place, the architect moves on to the design development phase. Drawings and documents are developed to include more detail with respect to the size and character of the interior design and proposed work. A more complete project budget is formulated as the plans illustrate actual counts of items for specification.

Contract Documents

The contract document phase of the project involves the development of working drawings, necessary documentation for the build-out of the new or renovated space. Along with the drawings, schedules and specifications are produced that detail particular items in the plans such as doors, hardware, finishes, equipment, and so forth. Upon completion, contract documents are sent out to bid to secure a general contractor and/or obtain pricing for finishes, furnishings, equipment, and custom items. These documents ultimately become the "contract" for the awarded general contractor, as well as the instrument used for securing building permits.

Contract Administration

The final phase of the project for the architect is contract administration—a required duty of the architect as mandated by most building codes. Here the progress of construction is monitored to assure compliance with the architect's drawings. Contractor submittals in the form of shop drawings, product data, and samples are reviewed and approved. Change orders are also prepared as necessary. When construction is complete, the architect walks through with the contractor to note any deficiencies in construction. This "punch list" is followed until the architect and the owner are satisfied with all resolutions.

Other Project Aspects

The facility change or relocation project does not begin and end with the architect alone. As previously mentioned, there are many aspects to these projects, all of which must be coordinated carefully and at appropriate intervals to assure project success.

Furniture. When a facility change involves new furnishings for which corporate standards do not already exist, research and evaluation of prospective furniture lines must be con-

ducted. Aesthetics, ergonomics, and price are only some of the points for consideration in selecting furniture. (See Art. 3.2.11, "Furniture Specification," for more information.) The process, in fact, can become fairly lengthy and involved. Because furniture lead times can sometimes run up to 16 weeks, it becomes necessary to begin the research and evaluation as early in the project as possible. The process will include the following elements:

- Development of workstation "typicals" and furniture standards
- Tour of furniture dealer or manufacturer showrooms (as well as local installations) to view furniture being considered
- Preparation and evaluation of bid package for furnishings
- Institution of product mock-ups for in-house evaluation
- Unbiased evaluation of potential furniture purchases, comparing performance criteria, cost, availability, flexibility, long-term maintenance, and residual value

The following are other furniture issues that must be coordinated during the various phases of the project process:

- Physical inventory of existing on-site furnishings to determine whether any existing pieces are appropriate for reuse in the new plan. The size, finish, and condition of each piece must be carefully evaluated. When reuse is contingent on refurbishment, a financial analysis must be performed to evaluate the cost-effectiveness, contrasted with the likely diminishing life expectancy of the older pieces.
- Furniture disposition. When reuse is not an option, resale opportunities should be explored. Used furniture has become a big industry over the years, and competitive brokerage networks exist that can quickly bring products to the market, sometimes using the Internet and e-mail to broadcast digital images of their inventory. However, should supply and demand determine that old, unused pieces have no residual value, the disposal of these items may include donation or simple discarding.
- Reuse of furniture from inventory when applicable. This process is sometimes facilitated if and when companies maintain an accounting of their warehoused inventory using a bar code system. Bar coding allows the owner to know quickly what is in inventory, its source, location, condition, and cost center.

Once it has been determined if and where existing furnishings will be reused, the information must be incorporated into a plan. From there, the following activities must take place to complete the furniture aspect of the project:

- Submit the approved layout to the furniture vendor for quotation.
- Ensure the review of furniture vendor drawings and specifications for accuracy before order entry.
- Track the purchase orders for furniture.
- Coordinate and track the schedule for delivery and installation.
- Oversee the delivery and installation to ensure that items are damage-free.
- Oversee the punch listing of furniture and expedite the resolution of all items, including missing, damaged, or incorrect products that cannot be installed per the approved plan (see Fig. 3.2.10-1).

Security. Very often, facility change or relocation projects involve security considerations. If the company has an in-house security department, a representative will meet with the users to identify security requirements, risk levels, internal security needs, security devices (e.g., card

Item	Station/Room	Description	Notes	Status
1	1	Tighten 42″w panel to worksurface (bracket)		Completed 5/3
2	5	Missing 2-way connector base cap		
3	5	Tighten seam between 36″w & 48″w worksurfaces		Completed 5/3
4	5	Missing finished end base cap		
5	7	Alternate recep locations-"X" to be under corner w.s.		Completed 5/3
6	8	Secure finished end		Completed 5/3
7	12	Tighten 42″w panel to worksurface (bracket)		Completed 5/3
8	15	Missing finished end (include top cap)		
9	26	Straighten run at 48″w & 30″w panel		Completed 5/3
10	26	Adjust base at 2-way connector		Completed 5/3
11	30	Replace torn finished end w/left-over in better condition		Completed 5/3
12	31	Tighten seam between 36″w & 48″w worksurfaces		Completed 5/3
13	1217	Missing Allsteel 2 high 36″w lateral file	Shipped damaged— Candy DeLuca making freight claim Replacement to be located *either* between stations 5 & 7 *or* 56 & 58	
14	58	Broken key in pedestal cylinder	Cylinder to be replaced	
15	1208	Missing business accessories visual board	Reference purchase order 409-25

reader locations, CCTV camera locations), staff access issues, and operational issues to develop a security plan. This information must be forwarded to the project engineers and architect before initiating construction drawings. Refer to Art. 5.5.3, "Security Systems," for a detailed discussion of this topic.

Telephone/Data. User needs involving equipment locations, as well as the origins and destinations for telephone and network lines, must be coordinated with the company's telephone and data vendors. The vendors in turn coordinate with the architect to ensure that the requirements are incorporated into the new design. Refer to Art. 5.5.6, "Telecommunications and Data Distribution Systems," for a detailed discussion of this topic.

Project Phasing

Project phasing and the temporary fitting out of "swing space" often becomes a planning consideration in a facility change. To allow a company to continue to conduct business throughout a renovation, swing space is located or created to accommodate staff who will be displaced from the area or phase to undergo change. Much planning must go into the temporary relocation of these individuals. For example:

- Existing furniture configurations must be modified to provide new work areas for the displaced individuals. This often requires the services of the furniture vendor, electrician, and furniture installers.
- Existing telephone and data systems must be modified to provide continuous service to the swing space.
- Common files, equipment, and individuals' personal belongings must be packed, tagged, and moved.
- Furnishings remaining in the vacated area must be torn down and put into storage or otherwise disposed of before the renovations commence.
- Any artwork or signage must be removed and stored.
- Plants must be relocated out of the area of renovation and into new, compatible locations.

All of these efforts must be coordinated and project strategies must be implemented to accomplish the temporary move within a time frame that works within the overall project schedule.

Premove. As the project schedule for construction nears a close, a number of activities should be performed in advance of moving in to ensure that both the move and initial occupancy transpire as smoothly as possible:

- Notify plant vendors of new location.
- Coordinate with building management for building signage and/or directory update.
- Coordinate with computer manufacturers, or the owner's information systems department, to move all computers, printers, scanners, and plotters.
- Coordinate with copy machine company to move all copiers.
- Arrange for final cleaning before moving in.
- Coordinate with proper party to have company telephone directory updated with new phone numbers and locations.
- Notify mailroom of location change.
- Ensure that restrooms are clean and stocked with adequate paper supplies.
- Coordinate for security coverage during move-in.
- Ensure that all employees will have access to the new space beginning on the move-in date.

Move. When the design and construction of the new space are complete, the process of moving in can begin. In planning for the physical move, the sequence of activities can be broken down into four phases.

Phase 1.[1] Survey furniture, equipment, and contents to be relocated to determine the following:

- Load factors based on the inventory of relocatables
- Material requirements (i.e., cartons, bins, conveyors, Masonite, and Koroflex)
- Packing and unpacking requirements at origin and destination

- Manpower requirements at the origin and destination
- Vehicle requirements
- Supervision required at origin and destination
- Inventory of data processing equipment to include manufacturer, model, vendor, dimensions, weight, noting whether owned or leased
- Disassembly/assembly of desks, shelving, and library stacks
- Time frames for all relocation activities by location, floor, and department to anticipate and establish the relocation timetable.

Phase 2. Hire a moving company.

- Select qualified moving companies to receive the bid package.
- Prepare bid package for moving services.
- Evaluate bids and contract for moving services. Analysis will include consideration of a mover's ability to perform the services required in accordance with the anticipated schedule, based on their trucks and personnel. A thorough check of references should be conducted, specifically noting the mover's performance on jobs of similar size and scope.
- Negotiate contract with the chosen bidder.

Phase 3. Establish client user group involvement as a system for reporting and communication:

- Produce and distribute a move instruction manual for appointed move coordinators.
- Produce moving instructions for affected staff.
- Assist with "purge campaign" of obsolete documents.
- Develop the scope of work and logistics for electronic data processing (EDP) relocation with the appointed move coordinator for the data processing group. This will include its own timetable to anticipate pre-moves, special packing, preparation, take down, start up and the scheduling required to relocate effectively without disrupting the data stream.

Phase 4. Preparation and start-up of moving activity.

- Conduct move meeting with staff and movers.
- Prepare detailed move plan and schedule, including the names and phone and pager numbers of all key contacts (see Fig. 3.2.10-2). Distribute the completed sets to the move coordinators and the mover's foremen.
- Act as a liaison between the client and the landlord (both present and new landlords, if applicable).
- Ensure that all vendors provide landlord(s) with the proper certificate of insurance.
- Ensure that all vendors understand the guidelines for doing work or making deliveries into the building to be occupied.
- Ensure that all vendors understand the guidelines for doing work in or taking items out of the building to be vacated.
- Resolve in writing the egress and ingress points of the move—lobbies, loading docks, platforms, and so forth—at all origins and destinations.
- Confirm mover reservations for elevator use.
- Schedule building security and/or an elevator operator, when necessary, for after-hours deliveries and installations.
- Walk the finished space with movers and installers to note any existing damage that is the responsibility of the contractor.

Date	Time	Vendor	Floor	Description	Contact	Company/ Position	Number
Friday 4/10	reg hours	Property Services/ International	12	Doug Stills and Bob McCarthy to coordinate to box contents of (3) Steelcase bookcases & (1) forms storage unit from wall opposite stations 83 & 85	Bob McCarthy Doug Stills	Property Services Green Co International	(617) 123-3008 (617) 123-3047

FIGURE 3.2.10-2 (*Continued*)

- Coordinate the delivery of boxes, labels, bins, equipment, carriers, and so forth, and supervise "materials positioning" by floor, department, and area so as not to disrupt the work environment.
- Survey the items labeled by staff to ascertain that only appropriate items are moved.

Postmove. The following activities should be conducted immediately after moving in:

- Ensure that all product and moving tags are removed from the furnishings.
- Ensure that all instructional tags are retained and available for user review.
- Coordinate the removal of empty moving boxes and any remaining debris.
- Coordinate the installation of artwork.
- Walk through the vacated area to ensure that nothing is left behind.
- Coordinate the reconnection of fax machines.
- Coordinate the connection of PC and computer equipment; verify network connection.
- Ensure that security equipment is in proper working order.

Closeout. Project closeout is the final step in completing the facility change or relocation process. Activities to be performed as part of project closeout include the following:

- Schedule product demonstrations between vendors and user groups. In response to the need for offices to be "ergonomically correct," chairs, keyboard trays, work surfaces, and so forth are being designed with a multitude of adjustments to reduce the risk of workplace injury. Users need to be made aware of and properly instructed in the use of these features.
- Administer postoccupancy evaluations. Postoccupancy evaluations (POE) provide a measure of project success. They determine user satisfaction with the overall project, process, furnishings, and team performance. The instrument for evaluation is typically a questionnaire followed by a meeting, both designed objectively to elicit unbiased responses (see Fig. 3.2.10-3). The information gathered offers valuable insight for future projects and possible project process improvements. A POE should be conducted no sooner than six weeks after moving in, to allow users to become adjusted to their new environment and to allow time for issues to surface.

Execution

From beginning to end, the time frame for making a facility change will vary greatly, depending on the scale of the project and the number of affected individuals. A small change involving only furniture could take under a month to plan and execute. A change that includes space renovation usually takes longer, involving more items with lead times and requiring greater coordination of trades. Likely to be longer still is the project that involves relocation to a new site being built-out to suit the client's needs. These projects can run anywhere from 6 to 7 months up to a year or two in duration.

Good project coordination will bring methodology to the project process to assure a logical and systematic approach to the accomplishment of the facility management objective. As the process unfolds, the following activities should take place as part of project coordination:

- Conduct regularly scheduled project meetings with all project stakeholders such as the architect, contractor, client representative, security planner, telephone and data system planner, landlord, and when appropriate, the furniture vendor and mover. Project meetings become a vehicle for monitoring the schedule and discussing relevant issues. Items that require action must be firmly established and monitored to ensure that the responsible team member provides follow-up in a thorough and timely manner.

I DESIGN PHASE

A. HOW DID THE DESIGN MEET CLIENT NEEDS?

B. DID THE DESIGN PROCESS USED ASSIST THE CLIENT IN UNDERSTANDING THE IMPLEMENTED SPACE AND FURNISHINGS?

C. TEAM OPINION OF PRE-CONSTRUCTION ACTIVITIES.

D. HOW COULD PRE-CONSTRUCTION PROJECT MANAGEMENT ASSIST THE ARCHITECT IN THE FUTURE ON COORDINATION OF THE DRAWING SET?

II CONSTRUCTION PHASE

A. DISCUSS CONSTRUCTION SCHEDULE—IMPACT ON THE ARCHITECT OR CLIENT.

B. DISCUSS COMMUNICATION DURING CONSTRUCTION PHASE.

C. DISCUSS ANY ISSUES ON PRODUCT SPECIFICATION, I.E.: LIGHTING, CEILING, CARPETING, AND FINISHES.

D. COMMENT ON SUBCONTRACTORS/CONSULTANTS ON PROJECT.

E. DESCRIBE ANY COST SAVINGS ACHIEVED.

III FURNISHINGS & VENDORS

A. COMMENT ON MANUFACTURER AND DEALER PERFORMANCE.

B. DESCRIBE ANY AREAS TO ACHIEVE FURTHER COST SAVINGS.

C. DISCUSS ANY ISSUES WITH THE ACTUAL MOVE AND INITIAL OCCUPANCY.

FIGURE 3.2.10-3 Sample questionnaire used to conduct a postoccupancy evaluation.

- Provide a review of the architect's space plan and programming requirements to ensure that client needs are satisfied.
- Monitor to ensure that all coordination and reviews of the construction documents have occurred at appropriate intervals to meet the project schedule.
- Correlate team member schedules. Although each discipline creates its own schedule, it is important that they be correlated to identify potential conflicts. The careful and proper sequencing of activities is essential to avoiding trade disputes—costly propositions in terms of jeopardizing schedules and incurring additional labor charges.
- Conduct site visits to monitor the progress and quality of the interior work.
- Track purchase orders for fixtures, furniture, and equipment (FF&E). Missed lead times can put the project schedule at risk.
- Coordinate and track the schedule for FF&E delivery and installation.
- Oversee FF&E delivery, installation, and placement to ensure that items are damage-free.

CONCLUSION

The success of a facility change and/or relocation project is determined by the ability of the architect's plan to satisfy the users' needs and also by the successful implementation of the project process. Strategic planning and careful project coordination are paramount in ensuring a smooth transition into a new space.

ARTICLE 3.2.11
FURNITURE SPECIFICATION

Cindy Aiguier and Michael Clancy
IOI, Inc., Boston, Massachusetts

OVERVIEW: FURNISHING THE OFFICE FACILITY

Within the last two decades, awareness of the relationship between a well-furnished facility and the enhanced effectiveness of the physical work environment has been increasing. This relationship can be most easily understood by recognizing the negative effect a poorly furnished work environment has on employee morale. This condition is typically manifested in a loss of enthusiasm, motivation, and productivity among employees. It usually results in high employee turnover at great expense to the company.

In today's world, it is necessary for the work environment to meet ongoing requirements for change, growth, and improvement. To do so, facility managers must learn the skills of inte-

grating the facilities and the work process. The selection of appropriate furnishings is an important factor in meeting this challenge.

This article explores the many considerations a facility manager will have in furnishing an office environment. Although the focus here is on an office facility, the general information presented applies to all types of facilities.

IMPORTANT CONSIDERATIONS IN FURNISHING THE OFFICE FACILITY

Company Image

At a glance, the style, color, pattern, and arrangement of furnishings in a company's office facility send a message about its culture. They may project an image that is conservative and traditional, or perhaps one that is young and innovative. Proper furnishings improve a company's image by communicating such things as accomplishment, competence, credibility, and efficiency. Before any new furniture purchases are made, a facility manager should determine whether the selections communicate the desired image.

Work Process

The physical place should facilitate effective operations and for this to happen the furnishings must assist the work process. Therefore, the FM must have a clear understanding of the nature and functions of the company and its employees.

Basic Human Needs

Individuals who occupy the workplace have basic human needs that must be acknowledged when furnishing a facility. These include the need for both physical and psychological comfort. Physical comfort is achieved when the selection of furnishings incorporates anthropomorphic considerations, provides good support to the body, and allows tasks to be conducted with ergonomic correctness. Psychological needs are addressed by providing furnishings that allow for territoriality, personalization, and group interaction.

Budget

The furnishings budget will affect the way the company image is established, the way the work process is supported, and the way basic human needs are met. Although large budgets allow greater choices of aesthetically pleasing and functionally efficient furniture, small budgets can still provide furniture that meets the basic criteria. When limited resources are a determinant in selecting furnishings, it is important to reconcile the value of items that are initially inexpensive because of reduced quality. These items will have a shorter life expectancy and likely a higher long-term cost of ownership.

TYPES OF FACILITIES

The furnishings selections have a direct relationship with the type of facility a company seeks to create. A facility may be comprised primarily of private offices, open plan systems furniture (workstations), or some combination of the two, depending on some or all of the following factors:

- *Profession.* Members of some professions, such as lawyers, accountants, human resource professionals, engineers, project managers, and scientists, require more privacy for confidentiality or simply for concentration. Private offices best support their needs.
- *Corporate style.* Hierarchical organizations may use private offices as a symbol of status or reward, whereas flatter organizations may wish to avoid such symbols.
- *Facility flexibility.* Open plan systems furniture environments are less expensive to build and easier to reconfigure. They do not involve coordination with building systems such as HVAC and fire sprinkler heads, nor do they require architects, building permits, and so forth.
- *Financial implications.* The tax implications of systems furniture differ greatly from those of a private office build-out. For example, a 10% investment tax credit is extended for furniture and equipment purchases in the first year, and, because they are considered personal property, they qualify to be treated taxwise as a depreciating asset. Office construction, by contrast, is taxed on appreciating assessed values. Another financial consideration concerns potential company moves. A private office build-out must remain behind, but systems furniture can move along with the company.

ALTERNATIVE OFFICING STRATEGIES

Work styles or alternative officing strategies (AOS) also impact the way in which a facility is planned and furnished. "Telecommuting," "hoteling," and "teaming" are some of the new strategies that companies are adopting to increase employee performance, improve productivity, decrease the rate of employee turnover, and reduce real estate investment. (See Art. 3.2.4, "Improving Productivity Through Integrated Workplace Planning," for a more detailed discussion.)

Telecommuting

Enabled by today's technology (fax machines, pagers, laptop computers, cellular phones, modems, e-mail, and voice mail), *telecommuting* describes employees who work from home while staying connected to the office. This AOS offers many benefits to a company. By allowing people to work when and where it is more comfortable for them, talented people, who previously may have had to drop out of the workforce because of competing outside commitments (such as child rearing), no longer have to do so. And as the flexibility in their schedule makes employees feel more valued, productivity tends to increase. "Telecommuting" also helps companies comply with the federal Clean Air Act by reducing employees' work-related use of motor vehicles.

Hoteling

The Chicago-based professional services "Big 5" firm Ernst & Young pioneered the alternative officing strategy of *hoteling.* With hoteling, employees' individual desks or workspaces are eliminated, thereby encouraging them to spend more time working out of their clients' offices. When it occasionally becomes necessary for the employees to work on-site, they call ahead to schedule a place to work.

Teaming

The idea behind *teaming* is that by creating a more open, collaborative environment, employees are enabled to exchange ideas and information more freely. With this dynamic, a company

can benefit by realizing fewer repeated mistakes and less time wasted, as individuals wait for answers. As a result, a company may experience such positive outcomes as reduced product development time.

OPEN-PLAN LAYOUT/SYSTEMS FURNITURE

Systems furniture was and continues to be designed to integrate furniture and the office facility as a direct response to the work process (see Fig. 3.2.11-1). By providing a high level of efficiency and productivity with systems, companies better manage the dynamic nature of the work process. The communications effectiveness of company staff is improved with the open plan, and work flow between individuals and departments is simultaneously facilitated. Additionally, systems furniture offers these other advantages:

- More flexible and readily accessible energy and communications distribution to better accommodate technology. Some systems offer power and data access above the work surface that is particularly helpful for laptop computer use (see Fig. 3.2.11-2).
- The use of vertical space provides greater storage in a smaller footprint thereby allowing companies to decrease the amount of space required per person (see Fig. 3.2.11-3).
- Systems panels define an employee's territory and create individual work environments that may be personalized (see Fig. 3.2.11-4).

PRIVATE OFFICES

Although systems furniture has revolutionized work environments and brought down a great number of private office walls, private offices have not and are not likely to disappear entirely. There are many reasons for this, not the least of which is that the private office answers two psychological needs: one for territory, the other for status. For some professionals, such as lawyers, accountants, engineers, and program managers, the private office as a status image is also essential to maintain credibility with their clients.

The furnishing choices for the private office are most typically freestanding case goods comprised of a desk (standard, L-shaped, or U-shaped), credenza, and vertical storage unit. A table and chairs for conferencing and/or a soft seating group sometimes accompany them.

Less common but not unusual is the trend to using systems furniture in enclosed offices. Technology has sprouted many young companies (particularly in the computer industry) within which hierarchy and status is intentionally avoided. In these flatter organizations, there tend to be fewer private offices. However, where they do exist for privacy or security, it is likely that the occupants previously worked in systems furniture environments and have come to rely on the support of the furniture to facilitate the work process. A back wall of hanging product provides greater flexibility than case goods and incorporates the principle of verticality to support more work activity.

TASK SEATING

Task seating is perhaps the most important furnishing item within an office facility. It affects nearly every individual within the office and has tremendous impact on those whose jobs have them seated for the greater part of the day. When a chair is uncomfortable, there is inevitably

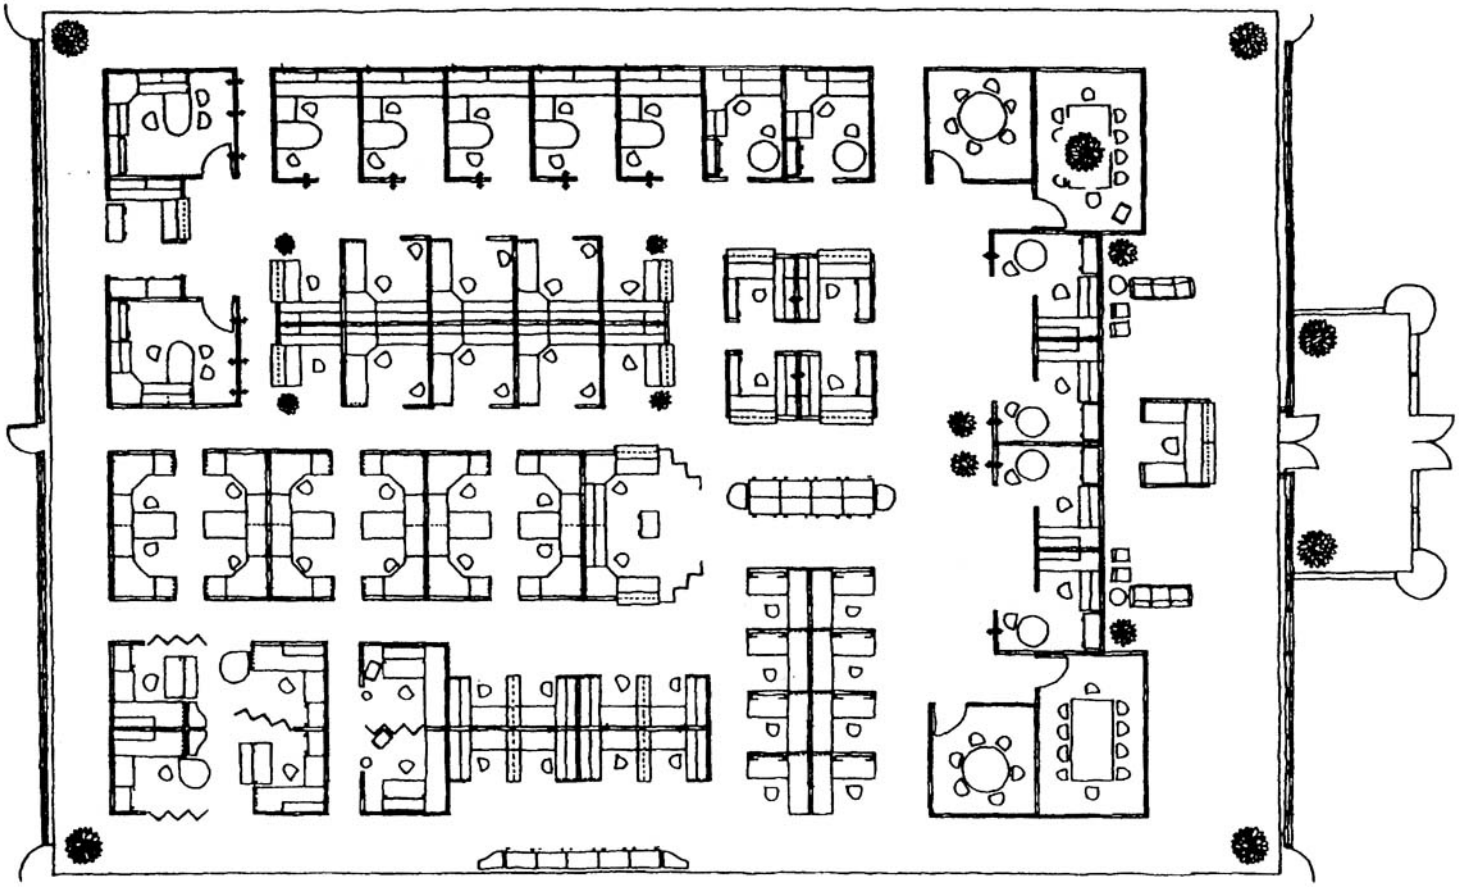

FIGURE 3.2.11-1 Systems furniture environments can be designed to support varied work styles and work processes. (*Reprinted with permission of Herman Miller, Inc., Zeeland, MI.*)

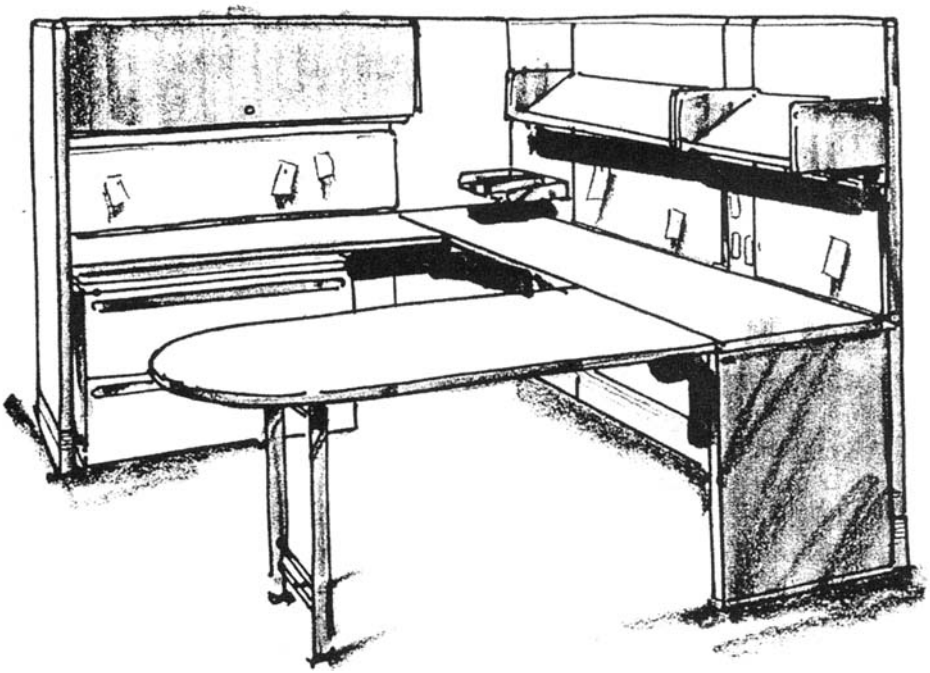

FIGURE 3.2.11-2 Power access is conveniently placed above the work surface. Additional attributes include a peninsula work surface that allows for both a conference area and space to work with an adjacent computer. (*Reprinted with permission of Herman Miller, Inc., Zeeland, MI.*)

a loss in productivity. Individuals find that they must get up and walk about to relieve themselves of the stress and strains caused by their chairs.

Statistics show that bad chairs increase absenteeism and insurance claims, and the latter consequently increase a company's insurance rates. In fact, lower back pain caused by poor seating is the leading cause of absenteeism in the United States and is responsible for $14 billion a year in medical claims, according to Dr. Stover Smith of the Harvard School of Public Health.[1] Additionally, many circulatory problems are attributed to the sometimes hard, flat seats on task chairs. The seat can result in 85 to 100 pounds per square inch of pressure on the thighs. Capillaries begin to restrict blood flow at only 20 pounds per square inch.[2]

In response to these concerns, manufacturers have introduced many chairs labeled "ergonomic." (Ergonomics is the study of the relationship between human physiology and the physical environment.) These chairs are designed to support the body in a variety of positions. All "ergonomic" task chairs are not equal, and a facility manager should carefully consider the following when evaluating seating:

- How well does the chair respond to changing body postures? A chair must respond with the user to changing job functions, social encounters, and intrinsic body shifts.
- How well does the chair provide support to the following body areas: back (including lumbar), seat, thighs, and arms?
- Do the contours of the chair evenly distribute weight loads?
- Does the chair have edges that will not restrict blood flow?

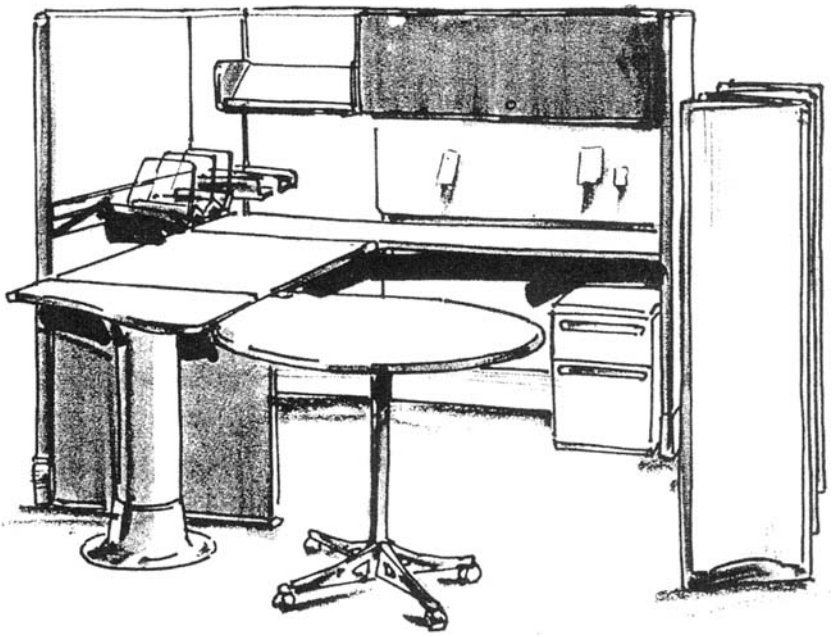

FIGURE 3.2.11-3 The use of vertical space allows for many storage opportunities. Note also the use of a screen to provide selective privacy as well as the two freestanding tables that serve both as auxiliary work surfaces and meeting space. (*Reprinted with permission of Herman Miller, Inc., Zeeland, MI.*)

Passive Versus Active Ergonomics

The industry has developed two types of ergonomic task chairs: *passive* ergonomic and *active* ergonomic. The essential difference between the two is that a passive ergonomic chair responds to changing body postures without much manual adjustment. Conversely, an active ergonomic chair has a number of knobs, paddles, and/or levers to control such things as forward tilt, seat depth, back angle, arm width, and arm height. Both types of chairs are typically offered with either manual or pneumatic height adjustment, and unless cost is the overriding factor, pneumatic height adjustment is recommended for its ease of use.

GENERAL CONCERNS THAT AFFECT FURNISHINGS PLANNING AND SPECIFICATION

Ergonomics

An increasingly important issue, ergonomics goes beyond chair adjustability. A rise in ergonomically based, job-related health problems such as cumulative trauma disorders (CTDs) and vision difficulties has seen a subsequent rise in the number of insurance claims and lawsuits. To alleviate some of the risk involved with intense computer use that leads to these conditions, facility managers should consider the following elements:

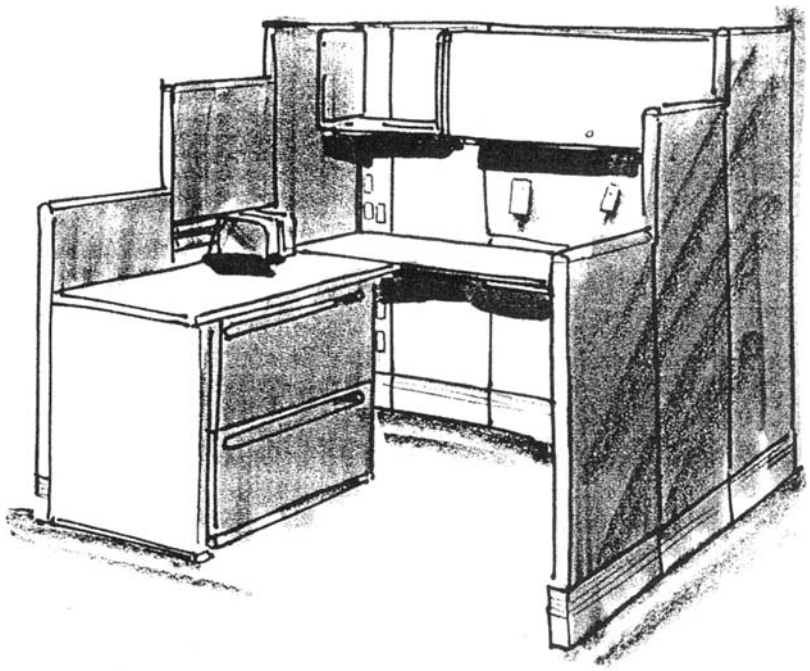

FIGURE 3.2.11-4 This semiprivate workstation has varying panel heights that define territory while simultaneously adding visual interest and opening up the office. (*Reprinted with permission of Herman Miller, Inc., Zeeland, MI.*)

- *Keyboard height.* The surface should be between 26 and 28½ inches high and be adjustable.
- *Computer screen glare.* The reduction of glare is typically accommodated in the lighting design or furniture layout and orientation.
- *Angle of video display terminal (VDT).* Such things as monitor lifts or split work surfaces will allow a user to vary the distance or angle of a VDT to provide visual variety. This in turn will promote relief from sustained viewing at a set position.

Fire Code

Many cities and states have specific flammability codes that regulate the specification of furniture. It is essential that furniture be specified to meet all applicable code requirements.

The California Technical Bulletin 133 (CAL TB 133), in effect since October of 1975, is the widely accepted standard by which furniture is tested for approval to meet a minimum fire standard. CAL TB 133 is a full-scale fire test for furniture manufactured for use in public buildings. The standards do not specify how to construct furniture, but only how it should perform when tested by the following procedure: A finished piece of furniture (never single components) is placed in a 10 × 12 × 8 foot chamber and is tested by applying a gas flame for 80 seconds. Thereafter, measurements are taken to determine the rate and amount of heat generated, the temperature of the testing room while the furniture is burning, the smoke opacity, the amount of carbon monoxide generated, and the mass loss of the furniture after one hour or until the fire is completely extinguished.

The Americans With Disabilities Act (ADA)

The ADA was enacted in 1992 to regulate the removal of barriers for the physically disabled. It requires that all employers provide "reasonable accommodations" to individuals with disabilities unless doing so would result in "undue hardship." Although the ADA does not detail particular rules for compliance, it can be expected that over time it will evolve to become more specific and restrictive. This should be a consideration for the layout of the facility and also for the selection of furnishings. Versatility and adjustability become criteria for products that respond well to the needs of disabled individuals. For instance, facility managers should consider the following:

- Desks or work surfaces that are adjustable in height and angle
- Desks or work surfaces that have a minimum knee-well width of 30 inches to ensure accommodating the width of most wheelchairs[3]
- Desks or work surfaces that have a minimum knee-well depth of 19 inches to comfortably accommodate a wheelchair with footrest[4]
- Matte or eggshell work surfaces, as opposed to glossy ones that pose difficulties for individuals with perceptual disabilities
- U-shaped handles that have enough clearance on the inside to permit ease of use by individuals with manual limitations

Furniture Standards Program

Facility managers may wish to consider establishing a furniture standards program. Many companies, particularly larger companies with satellite locations, institute such programs that define the allowable square footage for each level of office or workstation; the manufacturer, model numbers, and finishes of furnishings items; the size and selection of workstation components; and the cost allowances for furnishings items. These programs can be advantageous because they ensure a level of equality for personnel with similar functions or titles in different departments or locations while also providing a consistent corporate image in various office locations. Other merits to standards programs include:

- Predictable cost and square-foot requirements to assist in long-range planning
- Savings through volume purchasing
- Minimal inventory and simplified purchasing procedures for frequent changes in layout
- Lower design fees

There are, however, some disadvantages to standards programs. Consider the following:

- Office standards limit design expression in the facility.
- A poorly conceived standards program can result in the perpetuation of bad design.
- Rigid programs may not address unique individual needs.
- Furniture finish standards may not coordinate with building finishes.

Fabrics and Finishes

In specifying furnishings, fabrics and finishes should be chosen carefully to assure that furnishings last many years without looking dated. A fabric's appropriateness should be evaluated as it relates to the following:

- *Abrasion resistance.* Typically rated with a double rub count known as the Wyzenbeek method. A fabric is considered durable if it withstands 15,000 double rubs.
- *Lightfastness.* Of particular concern if furnishings are located near a window or other natural light source. Fabric testing is performed with a machine called a Fade-O-meter that measures color loss at intervals of 20 hours. A fabric is considered to have a minimum rating at 80 hours' exposure without color loss.
- *Stain resistance.* Teflon- or Scotchgard-coated fabrics have greater stain resistance. Also consider the manufacturer's recommended method of cleaning.
- *Color.* Soiling can be expected to show over time if a fabric choice is too light.
- In considering the use of COMs (customer's own materials) for upholstered items, the advantages and disadvantages should be weighed against one another. For instance, use of a COM allows for unique design expression and perfect color matching or coordination with other elements of the workplace. However, the use of COMs can increase product lead times because furniture production is often delayed pending receipt of the fabric. There is also a greater potential for fabric discontinuance that will affect future furniture orders, and the extra step in the ordering process may create greater complications.

PROCURING OFFICE FURNISHINGS

Method of Procurement

Office furniture is typically priced at "list" and sold through office furniture dealers at a percentage off "list," otherwise known as "net." Many factors affect the discount amount that a dealer will extend on purchases. The dollar volume of the order, the anticipated volume of future orders, the profit margin inherent in the product for sale, and the ability and willingness of the manufacturer to extend a deeper discount to the dealer are all considerations.

In procuring furnishings, a facility manager may issue a request for proposal (RFP) to several dealers for the items that the company wishes to purchase. It is important that this RFP include delivery and installation pricing, because these figures can vary greatly between dealers and will have an overall impact on the purchase price. Alternatively, a facility manager may choose to forgo the RFP process and negotiate the furniture purchase directly with a selected dealer.

Another method of procurement is leasing, which offers the advantages of conserving capital, preserving credit lines, and greater financial flexibility. A lease may or may not be structured to include an option to buy.

MANUFACTURER/DEALER SELECTION

The selection of furnishings is as much about the manufacturer as it is about the product itself. Particularly in the case of systems furniture, the commitment to both the product line and the manufacturer is a long-term one. Therefore, it is important to consider the following elements:

- The manufacturer's proven record in the marketplace
- The manufacturer's financial stability
- Product nonobsolescence policies
- Product warranty
- Point of shipping and associated charges

- Product lead times
- Quick-ship program for projects requiring a rapid turnaround

A manufacturer's furniture line can be either *open* or *closed.* An open line is one that any furniture vendor may represent. A closed line, however, is represented only by select dealers designated by the furniture manufacturer. Because systems furniture lines are generally closed, the selection of a furniture manufacturer will often predetermine the furniture dealer with whom a company will work.

The role of the furniture dealer is to act as a liaison between the purchaser and the furniture manufacturer, facilitating the product order, delivery, and installation process. This role is key to the successful implementation of a furnishings plan, and a dealer's strength and financial stability should be carefully evaluated prior to establishing a relationship. As part of this evaluation, a facility manager should consider a dealer's strength as it relates to level of service and committed follow-up; breadth of service offerings; and ability to control installation, project management, and communications (customer service). For companies that have satellite offices, it will be important to note whether a dealer network exists that may provide service to remote sites.

The relationship between a company and the furniture dealer will extend beyond the initial furnishings purchase. Such things as service issues, the need for additional product, and, in the case of systems furniture, the need for layout reconfigurations will invariably arise. Therefore, a dealer should also be evaluated for its ability to offer the following services:

- A maintenance contract for the installed product
- The ability to refurbish or reupholster the product
- Warehousing and inventory management of customer product
- Trade-in allowances on systems product
- An inventory of recommended touch-up paint, miscellaneous hardware, and replacement parts

CONCLUSION

Furniture must satisfy a wide range of needs, not the least of which is to effectively and efficiently support the company work process. Other functional and practical considerations include comfort, adjustability, durability, aesthetics, and cost. In specifying furniture, it is important for the facility manager to focus on the details of the particular furnishing items and reconcile them with the various selection criteria. Along with changes in culture, technology, and business processes, a well-planned and furnished facility is a contributing factor in helping a company achieve its organizational and business goals.

ARTICLE 3.2.12
PROJECT COMMUNICATIONS AND PROJECT MODELING

Kenneth H. Stowe, P.E.
George B.H. Macomber Co., Boston, Massachusetts

Bart Bauer, P.E.
Edwards and Kelcey, Boston, Massachusetts

The modern facility manager's ultimate goal is to reduce cost and maximize product life-cycle performance. Can today's high technology enhance a project team's performance? The answer is yes—but not without a thoughtfully reengineered communication process and an integrated philosophy of teamwork across all aspects of the project.

For participants to communicate successfully, the process must be as rapid, effective, efficient, and seamless as possible. The conventional process of hard copies and mail, and of traveling to meetings and coping with unreturned phone calls, is a slow and inefficient way of communicating to all members of a project team, be they owners or accountants, builders or suppliers, designers or users. In this dawn of a new age, it will become increasingly more costly to follow the old linear process of draw, print, package, mail, evaluate, comment, return, revise, analyze, and then finally choose a direction. Technology has provided the opportunity and the power to reengineer the communication process to reduce time and errors and increase value and flexibility. Additionally, this use of technology provides a competitive advantage to all members of the project team who are participating in an integrated philosophical and technological approach.

To understand the reengineered communication model, we must agree on what the components of the communication process really are. We believe that there are three separate elements of the process. The first element is who is communicated with and when; the second, how are they communicated with; and the third, what is communicated.

The value of teamwork has always been appreciated. Traditionally, however, the team was composed of a limited number of members in a finite geographical area and in related disciplines. However, the efforts of building the best project team for any facility should not be limited by geography, disciplines, or an intentional restriction of added value through the sharing of knowledge. An argument can be made to increase the number of members on a project team and, in fact, to adopt a global view—a new philosophy—to involve any individual who is related to the facility from its conception to its ultimate demise, during the formative period of a facility development project. Let us reinforce that here. To communicate efficiently about any item related to any aspect of the project, representatives from all phases of the project life cycle must have the opportunity to participate. Only then is the highest value achieved.

Technology has provided a tool to facilitate these new project teams. The facility manager should be able to build the team for a diversified owner using the best consultants, designers, and contractors. This may draw individuals from tremendous distances and varied collaborations. By using electronic innovations designed for communication and data sharing, the opportunity is available today for the facility manager to reengineer the communication process to involve all the parties.

Once the team has been built, it is critical that its members effectively communicate ideas and concepts, as well as data, throughout the process. Many project teams now elect to use a shared, secure Web site for vital data storage and for advanced communications. The data

include master schedules, computer-aided design files, specifications, drawing and submittal logs, site photographs, meeting minutes, requests for information, change orders, daily field reports, and so forth. Sharing eliminates duplication and inaccuracies. Immediate access speeds responses to questions from the site or elsewhere. Elements of the project data that are related can even be "threaded" for better understanding of complex interactions.

Sharing project data has a positive influence on a team. When the entire team observes a request for information being submitted, and when and how it is answered, this sharing increases the sense of unity, accountability, and responsiveness. The team can collaborate with pictures, computer-aided design (CAD), even videos and animation, with fewer time or geographical limits. Other members can comment or intervene if necessary, so that decisions are made quickly, with more participation, and accordingly, with more commitment. Faster, more informed decisions lead to faster time-to-market projects.

INTEGRATING THE MODELS

Creating one secure site for current and archived project information opens the door to computer-integrated construction modeling. This is an integrated approach that streamlines workflow and connects the models that reflect current or explored forecasts of the project plan. An example of this type of integrated models is to create quantity reporting from intelligent CAD models. These data inform the cost model, which generates manpower estimates by trade. These labor projections inform the schedule durations (through crew-size projections). The schedule generates overall project durations and timing, which in turn derive important time-variable costs for the estimate.

Efficiencies of Combining CAD and the Extranet

Sharing project data often results in more accurate models because more sharing means more input into the design effort. This often comes in the form of constructability input, phasing requirements, and cost-saving ideas. Three-dimensional features of the CAD model derive greater value because they reach a greater audience earlier in the process. Nongraphical enhancements to CAD models (e.g., manufacturing data and links to specs) generate efficiencies. The CAD model serves as the trade and vendor coordination vehicle that provides an electronic as-built.

An example of this occurred when the project Web site for one project team enabled CAD to provide efficiencies well beyond design. Centerbrook Architects, working from their Connecticut office on the $20-million phased renovation project at Dartmouth College in Hanover, New Hampshire, posted CAD files to a project Web site. The owner, consultants, and construction manager (CM), located in three other states, had immediate access to them. The construction manager, the George B.H. Macomber Company, downloaded the CAD files, performed some cost and schedule analyses, and posted some very advanced products back to the project site (see Fig. 3.2.12-1).

This collaboration achieved five positive results:

- Faster distribution of the drawings, and savings on printing, packing, and shipping
- Faster and more accurate development of the estimated quantities
- Three-dimensional color output (see Fig. 3.2.12-1) for better understanding of the estimate and the CM's assumptions
- Faster distribution of the estimate and schedule
- Graphical presentation of the phasing and essential dates

Following are more specific examples of the way each segment of project communications can be improved by using the technological tools that are available today.

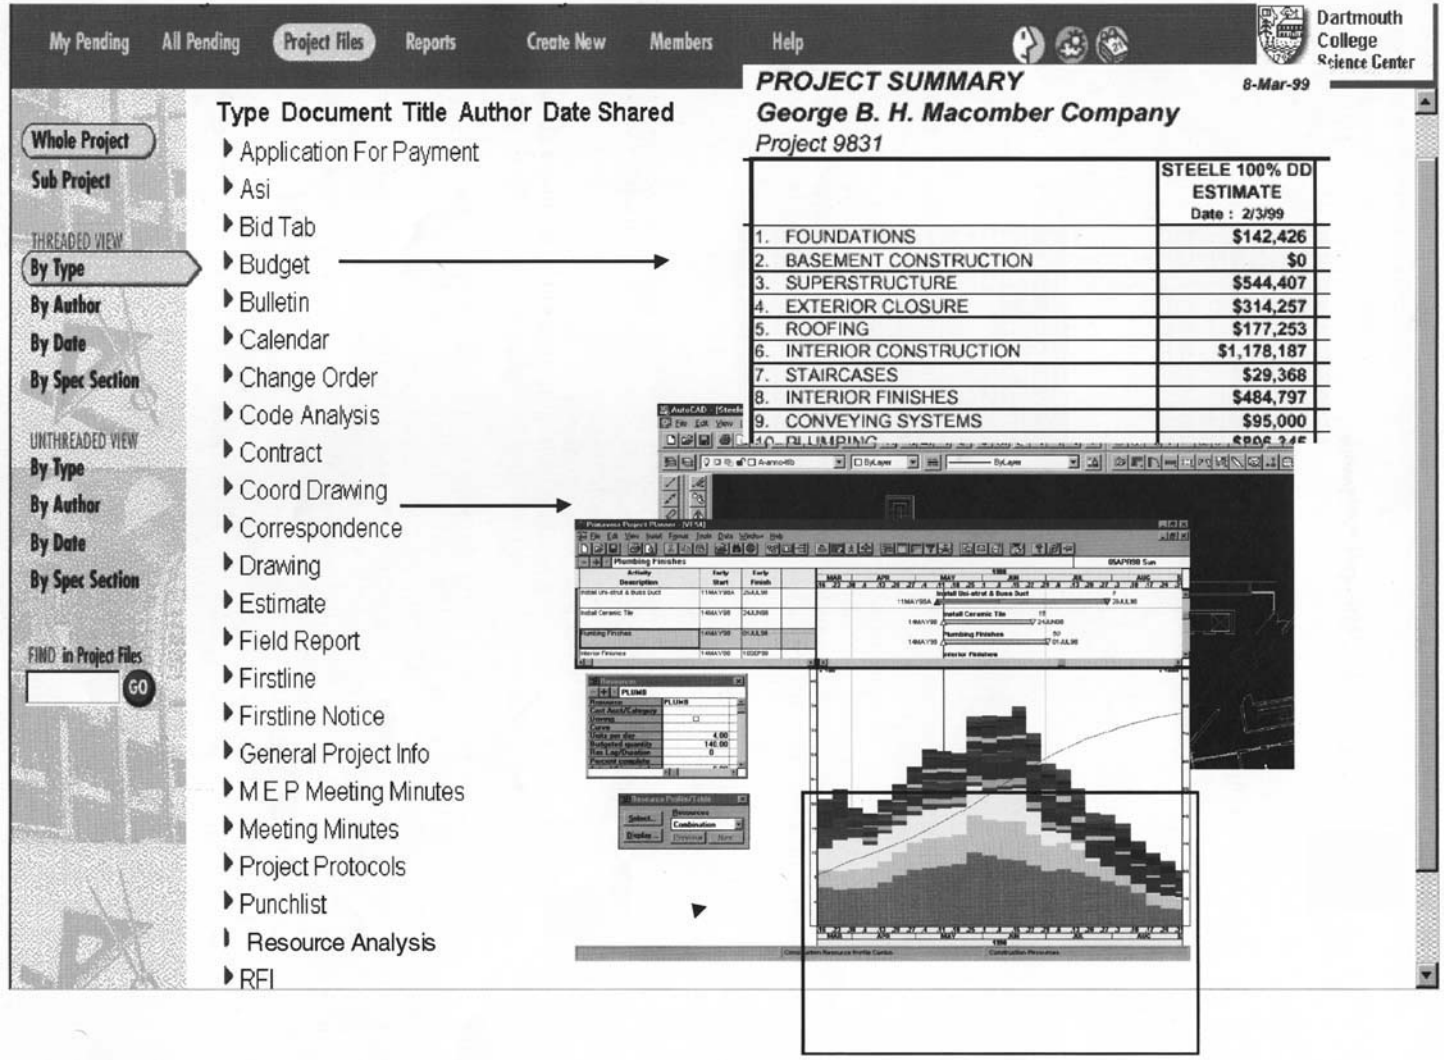

FIGURE 3.2.12-1 Project Web site allows project team members to secure access to shared information. (*Courtesy of Ken Stowe, George B.H. Macomber Company.*)

Sharing CAD Files. Designers create an electronic design file on CAD that contains an enormous amount of knowledge from a group of design professionals. The construction management team now has the ability to analyze costs and schedules directly from this rich database of design details. CAD files should be sent electronically, and detailed estimates should be taken directly from these electronic files. Schedules can be attached and linked to these estimates, and an initial project plan—received within a few days—will contain a compound document that fully represents the full cost and schedule implications of the project.

Using Advanced Planning Software. One way to save owners time and money is to develop a comprehensive plan by using advanced critical path method (CPM) scheduling software, such as Primavera Project Planner. To use this software strictly for construction activities wastes its power and potential. Instead, teams should use this technology to create a single database of activities that includes program decisions, design, procurement, construction, commissioning, owners' equipment, and occupancy details. The schedule should be loaded with resources to anticipate which subcontractors have the requisite forces and will be invited to bid.

Due Diligence. A comprehensive analysis is vital for a company in assessing the purchase of property. For example, a building is selling for $22.5 million, and renovating will require the investment of an additional $50 million and take 12 months to complete. The company is desperate for room to expand and wants to know if it should purchase the property.

This investigation includes an analysis of the roof, HVAC and other skeletal operational systems, the exterior facade, the interior layout, the presence of asbestos and other potential environmental hazards, site evaluation, traffic assessment, insulation, telecommunications data, structural integrity, flexibility, and accessibility compliance.

Consulting experts working individually in each field could require 12 weeks to compile the necessary data by conventional means. Much is at stake in such an analysis. Cost, schedule, risks, and assumptions all need to be factored in. However, the turnaround time of this due diligence effort can be reduced to four weeks. This means that purchase, execution, and occupancy can be achieved earlier.

Expedite Decisions with the Internet. The Internet is an agent of dramatic change in the world of design and construction. It is the vehicle for improving turnaround time for construction and design projects. Consider these time-savers:

- Web use facilitates communication as a team. Arranging a meeting through e-mail and integrating scheduling options can be accomplished very quickly.
- Most e-mail transmission is instant. Instead of a number of missed telephone messages among five team members and checking everyone's schedule, e-mail allows immediate communication and immediate response. A meeting that formerly took two days to arrange can be scheduled in less than an hour.

On-Line Project Web Sites for Communications. The Internet allows project meetings to take place on-line. A secure project site allows a team of architects, engineers, designers, and construction consultants to transmit their portions of the design to a site where all other team members can view them and make recommendations.

Consensus can be reached in hours instead of days, and action can be taken immediately. More deadlines can be met through this new technology and more options can be analyzed. And no members of the project team had to leave their respective offices for this meeting.

The ability of a large audience to provide input simultaneously from their desktops dramatically increases the ability to get the right design direction from the start. This increases the reliability of the initial budget and extends the amount of time you will have to look for creative cost saving.

The Competitive Advantage

Ultimately, every day that you reduce in planning and construction is a day of potential revenue from your employees or tenants, once the facility is operational. Shorter schedules also reflect savings in interest on construction and bridge loans and shorten the time to market for your product, the facility. Combining teamwork and technology in your construction project can create a significant competitive advantage.

SECTION 3.3
FACILITY MANAGEMENT FUNCTIONS

Kristin Hill, Cindy Aiguier, John Morganti, and Bonnie Seaberg
International Facility Management Association (IFMA), Boston, Massachusetts

Norm Faucher
Association for Facilities Engineering (AFE), Boston, Massachusetts

In the introduction to the design and construction process phase, it was indicated that the completion of the design and construction phase does not signal the end of a project for the facility manager (FM). In fact, it can be considered a beginning—the beginning of the use of the facility. It is here that the knowledge transfer and management functions begin.

All of the requirements and associated documentation need to be assimilated and made available to all facility stakeholders. Moving forward, FMs will have to look at all of the knowledge-related systems in an integrated format. This information needs to be accessible by other departments such as administration, human resources, information systems, and finance. The goal should be to funnel the information from all of these groups together so that each may extract the information needed for decision making. Well-assimilated information will enhance the communication and synergy among all of these groups.

The following articles will show you the tools to assess where you are, to determine where you want to go, and to help you select the tools to aid your passage through the facility's life cycle. Driven by advancements in technology, changes will continue to occur in business products, processes, and procedures that will affect the facility. Facilities management becomes the means for coping with the changes that will occur during the facility's life cycle. It becomes a process for controlling the effects of change. These changes will begin a new cycle of planning, budgeting, design, and construction.

ARTICLE 3.3.1
COMPARISON OF FM AUTOMATION SYSTEMS

Denis R. Cormier
Facilities Management Solutions, Inc., San Diego, California

This article addresses the process and elements for comparison and selection when considering various computer-aided facilities management (CAFM) systems. Before discussing the process and elements of comparison and selection, it may be useful to briefly review some of the more obvious reasons for a business to consider acquiring and implementing a CAFM system:

- To manage and control assets proactively whether they are buildings, building systems, machinery, equipment, computers, or people
- To optimize the business process of managing facilities by measuring and controlling the total life cycle cost of ownership of assets
- To increase productivity and efficient utilization of assets

"Find a way to improve productivity and provide more useful and timely information at less cost. Business as usual just isn't good enough anymore." This message is heard more and more frequently from corporate senior managers as they try to contend with higher real estate and facilities costs. When you consider the total life cycle cost of facilities (buildings and infrastructure) of a corporation, you soon realize that facilities are its second most costly asset. Human resources (employees) are the most costly asset. The extent to which a corporation proactively measures and manages the performance of this dynamic tool, which we call facilities, will to a large extent contribute directly to a corporation's profitability and competitiveness.

In 1995, Arthur Andersen LLP conducted an in-depth study of corporate real estate. One of the significant findings of the study was that corporate senior management generally views real estate (facilities) as a "cost of doing business," rather than a strategic "tool" that can be managed and that can significantly impact how effectively a corporation competes in its respective market.

Historically, corporations have viewed facilities as static shelters to house employees and equipment. In addition, there are usually few processes, if any, in place to measure how effectively they are using their facilities. As a result, corporations often evolve and find occurrences of several areas of clutter filled with unused, abandoned, or obsolete assets (furniture, machines, and equipment) throughout their facilities. In addition to using space ineffectively, the lost revenue from not properly disposing of or redeploying surplus assets is just one of many examples of lost opportunities.

Fortunately, CAFM technology provides a method for dynamically and proactively managing corporate assets. However, the purchase of CAFM software alone will not ensure success in managing corporate facilities. The key to the success of any software solution is proper integration and implementation that closely mirrors well-defined processes. It cannot be stated strongly enough that the processes of your company should dictate the appropriate CAFM solution and not the reverse! For this reason, you must take the time to document your current processes, sometimes referred to as *process mapping.*

One fundamental objective of any process analysis is to provide the ability to create and access information that is commonly understood and shared by everyone who is affected by

processes in the organization. To accomplish this analysis, a business process model is created (refer to Art. 3.4.3, "Quality Assurance Practices," as a template). These are the four elements of this process model:

1. "What Is"
2. "Should Be"
3. "What to Do"
4. "How to Do It"

Each of these elements has four critical components:

1. "Inputs"
2. "Outputs"
3. "Controls"
4. "Supports"

In addition, the process map must include all feedback loops that provide updates of a given process.

After completing a process model, you will achieve the following:

1. Clearly understand the existing processes within various departments and organizations.
2. Determine what resources (people, equipment, software) are involved in various processes and thus learn who will be affected by the chosen CAFM system and who will need to be trained in using CAFM.
3. Identify what legacy systems and platforms are used and how CAFM will either extract data from or input data to these legacy systems.

Before investing in CAFM technology, a business must build an intelligent strategy that outlines the performance metrics of the software. In other words, what elements do you want to measure to demonstrate clearly whether the organization is improving? A thorough needs analysis and an assessment of existing processes and procedures will usually enable a business to obtain these elements.

When evaluating a CAFM system, it should be viewed as a decision-support tool. When this tool is properly chosen, integrated, and used in the business process of a company, it can ensure that all of the key elements of your business—people, facilities, and equipment—are working to the best advantage for corporate goals and objectives.

A CAFM system in its simplest form is a huge repository of data that is designed for use as a decision-support tool. Collecting data, whether in a personal computer, mainframe computer, or computer client server, just for the sake of collecting data is of no value to anyone. Only when the data can be easily converted to meaningful reports (graphic or tabular) for use as a decision-support tool has CAFM achieved its goal.

Accurately compiled data can be used to generate reports that clearly illustrate such things as:

- Space planning and forecasting
- Asset management reports
- Changes in space use
- Space chargeback reports
- Change and cost of churn
- Change in personnel requirements relative to work load

An effective CAFM system provides critical decision-support information easily and quickly to anyone in the organization who needs the information in a visual or graphical format or a numerical data format.

Corporations have critical and possibly redundant information residing in various computer systems, sometimes called *islands of information,* that are controlled by various departments. The best CAFM solutions are designed to break down barriers between sources of information. Eliminating islands of information and redundant databases is the hallmark of a well-designed CAFM solution.

To the extent that a company proactively manages its facilities and assets, enabling it to anticipate both internal and external changes, there will be a direct benefit in positioning the company to be more competitive in the marketplace.

METHODOLOGY

The process of evaluating and ultimately selecting an appropriate CAFM system for a corporation can be quite simple or complex, depending on the needs expressed by the various departments that are affected by the CAFM system. If the intent is to have a stand-alone, PC-based CAFM system used primarily within a facilities department for such things as space planning and move management, then the evaluation and selection can be fairly straightforward and can be accomplished by relatively few people—probably members of the facilities department. This is sometimes called a *bottom-up* approach, where just a few modules of a total suite of CAFM software are deemed necessary. However, if a more global enterprise-wide system is warranted, where several departments such as Human Resources, Finance, Real Estate, or Information Technology will be affected, then a more *top-down* approach is probably warranted.

If a top-down approach is viewed as the preferred method, then it is strongly advised that senior management be involved or at least well apprised in the early stages of needs assessment, as well as system definition and specification. Senior management needs to understand clearly the philosophy and intent of any enterprise-wide CAFM system and must support the goals and objectives if any system is to be successful.

The methodology of evaluating and selecting a CAFM system should address as many departmental and organizational process and procedural issues as possible. Try to anticipate and plan for a tool that is functionally flexible and technically robust enough to respond to the specific needs of the facilities department and also to the needs of several other departments, as well as other applicable sites.

In this context of a broad scope for the potential impact of any chosen system, a bottom-up approach can be risky. For example, perceived ease of use for one or two specific departmental processes can lead a team to overvalue system characteristics for a department and undervalue those factors that are critical for enterprise-wide implementation.

The following list outlines the specific methodology steps:

- Project plan
- Functional requirements analysis (needs assessment)
- Technical requirements analysis
- CAFM system recommendations and implementation strategy
- System implementation and testing (pilot application test)
- System-wide transition and training (documentation)
- Evaluation and periodic corporate-wide communication of milestones and achievements

A project plan must be developed to establish the goals and objectives, priorities, and time schedules. The plan should include team members, roles and responsibilities, and milestones.

The next step is to conduct a comprehensive functional requirements analysis using a systematic business process/work flow approach. Sometimes, this is called documenting *what-is* conditions, or documenting *reality*. This is usually done by personally interviewing individuals from various departments who might use a CAFM system or whose business processes could be affected by a CAFM system. Some corporations have well-documented processes and procedures manuals that can be referenced during the interviewing process. Unless a corporation is very diligent in maintaining its procedure manuals, it is quite likely that the actual processes and procedures do not necessarily mirror what is written in the manuals. Quite often, documented processes and procedures do not exist. The resulting report would typically define current business processes in the form of various flowcharts. The report should also point out any inconsistencies between actual procedures and documented procedures. Any functional overlaps, as well as redundant processes, within departments or between departments should also be pointed out.

The technical requirements analysis provides information related to any existing automated tools that are used and what specific data are accessed, how frequently, and by whom. Examples of these are CAD software, personnel databases, fixed asset ledgers, etc. In addition, all legacy computer systems and associated software and platforms should be documented.

The collective knowledge that is gained from both the functional requirements analysis and the technical requirements analysis should be included as part of the evaluative criteria to identify and recommend a specific CAFM suite of tools that are best suited to the needs of the specific corporation.

This is generally achieved by developing a customized matrix that compares the features and benefits of various CAFM software packages in relation to the specific needs that were identified in the functional requirements analysis and technical requirements analysis. However, this "feature comparison" approach focuses attention on a list of features and tends to divert attention from the key, subtle reason for evaluating features in the first place: namely, successful implementation of a CAFM system that improves business results. Products that look equivalent in features may have drastically different records in being used effectively over a period of years to accomplish business process improvements. The only effective means to avoid this mistake in evaluation is to do a thorough job of interviewing several existing user references to the short list of CAFM systems that seem to provide the best job. If possible, contact references in a similar industry and similar facility size.

COMPARISON OF CAFM SYSTEMS

Before discussing the various elements in the comparative tables, note that this is just an illustration of the way a matrix can be used to assist in selecting a CAFM system. The elements and format of any product comparison matrix should be tailored to your company's specific requirements. Furthermore, the data fields are merely depicted as an example and may not represent the latest version of the respective CAFM software provider's product offerings. In addition, the material presented should not be construed as an endorsement of one CAFM solution over another. The information is presented only for illustrative purposes.

Tables 3.3.1-1 through 3.3.1-4 help to categorize and compare the features that are offered in each CAFM software package. The tables have been separated into these four segments:

1. Key features summary
2. Modules and tools summary
3. Technical information summary
4. Cost information summary

TABLE 3.3.1-1 Key Features Summary

Features	SPAN-FM	Aperture	FIS	FM:SPACE	ARCHIBUS/FM Oracle
Maintain drawing accuracy and validity	Space analysis module	Space manager module	Facility inventory manager module or facility drawing coordinator module	Space module	Space management module
Enterprise level functionality	Y	Y	Y	Y	Y
Modular construction	Y	Y	Y	Y	Y
Acceptable RDBMS (Oracle, Sybase, SQL Server)	Y	Y	Y	N	Y
Client–server	Y	Y	Y	N	Y
LAN/WAN	Y/Y	Y/Y	Y/Y	N/N	Y/Y
Ability to import/export AutoCAD (DWG and DWF)	Y	Y	Y	Y	Y

The features that are listed in Table 3.3.1-1 are some of the more important items for consideration, such as drawing accuracy, enterprise level functionality, modular construction, random database management system (RDBMS), client/server capability, local area networking (LAN), wide area networking (WAN), and AutoCAD import/export ability. Additional features could be added to this table in accordance with the needs that are determined to be important to your corporation.

The features listed in Table 3.3.1-2 state the various modules and tools that are offered with the various CAFM software packages. In addition to the basic module that is offered with each package, a suite of modules and tools can be purchased initially or at a later date, depending on the needs of the corporation. If the corporation chooses to implement an enterprise-wide CAFM system, then most if not all of the modules would be purchased. If a more localized solution is preferred, then fewer modules would be purchased. Some of the modules available are lease management, move management, strategic space planning, maintenance management, accounting/chargeback, communication/cable management, and HR personnel management.

The features described in Table 3.3.1-3, "Technical Information Summary," address primarily system-level specifications, such as platform, network access, native database support, database connectivity, user interface, security, reports, file formats, and interoperability.

Finally, Table 3.3.1-4, "Cost Information Summary," lists the retail prices of the various modules of each CAFM system. The prices vary depending on how many concurrent seats or licenses need to be purchased.

Using the information provided in Tables 3.3.1-1 through 3.3.1-4 a thorough evaluation should be made emphasizing scalability of software, cost of software, cost of training, cost and ease of software integration, cost of software maintenance, and after-sale support.

The resulting recommendation should be accompanied by a standard return on investment (ROI) analysis. The ROI should attempt to reflect and quantify quantitative savings, to the greatest extent possible. Some of the quantitative savings to be realized are reduced operational cost due to automating routine manual procedures, reduced occupancy cost due to increased efficiency in space usage, and implementation of a space chargeback system. In addition, reduced maintenance cost and reduced cost associated with churn and relocation should be considered. The recommendation should also include the implementation strategy and associated time schedules.

The system implementation and testing or pilot test should interface various data tables and provide sample interfaces and output formats. Menu-driven windows and floating control boxes should be provided in a *drill-down,* clear and easily understood layout. A report writer and query builder should be provided with plain English terminology. Once the pilot test is

implemented and proven, then system-wide transition should proceed along with proper training of all CAFM users as well as process and procedures documentation.

Finally, the CAFM system should be evaluated periodically to ensure that the information and resulting reports provide useful and timely information that supports the corporate strategic decision-making process. As with any change, some will embrace change, and some will resist it. For this reason, the implementation team should publish periodic corporate-wide bulletins stating the various milestones, achievements, and successes of the CAFM system. Use all means of advertisement available (e.g., company newspapers, display exhibits at various visible locations throughout the company, management presentations, and banquets with successful team members). By making heroes of those employees who embrace change, reluctant employees will begin to participate.

SUMMARY

A well-defined and well-integrated CAFM system can significantly contribute to the goals and profit objectives of a corporation as a strategic decision-support tool. To ensure successful CAFM implementation, certain essential elements must be adhered to. If an enterprise-wide CAFM system is deemed appropriate, the understanding and commitment of top management is extremely important. Also, just as important, there must be a commitment to the adherence to data stewardship and the integrity of data to ensure continuous improvement and efficiencies. If the individuals who use the CAFM system lose confidence in the integrity of the data and the reports generated by the CAFM system, it will eventually be abandoned.

ARTICLE 3.3.2

THE GREAT GLOBAL INFRASTRUCTURE RESOURCE MANAGEMENT GAME: HOW TECHNOLOGY IS CREATING NEW VALUE PROPOSITIONS IN INFRASTRUCTURE MANAGEMENT FOR THE TWENTY-FIRST CENTURY[1]

Nancy J. Sanquist, CFM, IFMA Fellow, Associate AIA
Peregrine Systems, Inc., San Diego, California

We all thought we knew what value meant. At one time, the ultimate symbol of a business that had the greatest market share in its industry was the large, monolithic corporate headquarters with the most expensive real estate space in a large city. The gigantic high-rise screamed to the world from its lofty perch that it was the most valuable company in the world (think of Philip Johnson's monument to AT&T looming over trendy Madison Avenue in New York City in the 1980s). Following suit, properties all over the globe were gobbled up at incredible costs to the delight of the real estate community.

Something incredible happened a few years later across town, however, on the trading floors of the New York Stock Exchange. Analysts began to award "most valuable player" in the market to companies that no longer cared about making statements through their real estate holdings. Stockholders applauded as the cybermarketspace exploded. Now, a bookstore that has less than $1 million in real assets has a higher market capitalization than its two biggest competitors, which are burdened with a combined real-asset portfolio worth more than $1 billion. Amazon.com's prosperity is reflected in its Web site where shoppers can fill their virtual shopping carts full of the latest best-sellers and click to another Web page to find information about the company and its associative communication links.

That shopper no longer cares what the corporate headquarters looks like and probably does not even know where the building is. The nature of value is shifting before our eyes between physical place and virtual space, and some of us are only beginning to understand what that means for all of our futures in the workplace. It does not mean, at least at this Internet time, that places are going to disappear into the virtual reality. What it does mean is that the value that we have put on places and their relationship to the value of our companies has changed forever.

This change in the creation of value is affecting those of us who were trained to design, manage, and maintain the physical space of an organization, although many are unaware of it. What do we do now that cyberspace is changing that value proposition? How do we understand this new concept of value in today's chaotic and revolutionary economic climate?

We must be aware of some clear patterns emerging that we need to understand in facility management and real estate. We can no longer ignore our information technology (IT) sisters and brothers down the hall. Instead, we must get close to them, learn their language, and train in their technological skill sets and tool kits. We must help them design the new processes, practices, and technological solutions that will help us navigate this complex economic environment and bring value to all our organizations, whether governmental, educational, or business. And these solutions are all built on the fuel for this new economy—information.

Those of us who can create it, use it, optimize it, and synchronize information with other groups, both within and outside of our corporate walls, will be players in the great global infrastructure resource management game. Companies will be attracted to our knowledgeable and networkable skill sets, and we will be rewarded highly and attracted to (and stay with) those organizations that know how to create value in this new world.

WHAT IS VALUE?

The *Wall Street Journal* posed an insightful inquiry in the August 20, 1999, "Money and Investing" section, in an article about the problem of defining value in the investment world: "Does anybody know what *value* is?" The answer is far from simple in this new economic climate. Its simplest definition is the return on investment (ROI) to stakeholders in the organization, stockholders, communities, employees, and suppliers. This ROI must be calculated now in two worlds—the physical and the virtual.

The physical world is composed of the organizations that invest significant capital to acquire the people who inhabit a myriad of places and use lots of things while they create ideas that bring in the capital to fuel corporate growth. And all of these resources are planned for, acquired, deployed, and maintained until the end of their life cycles when they are no longer needed by the organization. We think of infrastructure resource management (IRM) as the mortar that connects the virtual resources with the physical resources to create value (Fig. 3.3.2-1). True IRM unites the unique disciplines of the enterprise service desk, asset management, real estate, facilities, and fleet management through common shared data. It addresses all aspects of organizational infrastructure from IT, including both computers and telecommunications, to the buildings and real estate assets that house the technology and

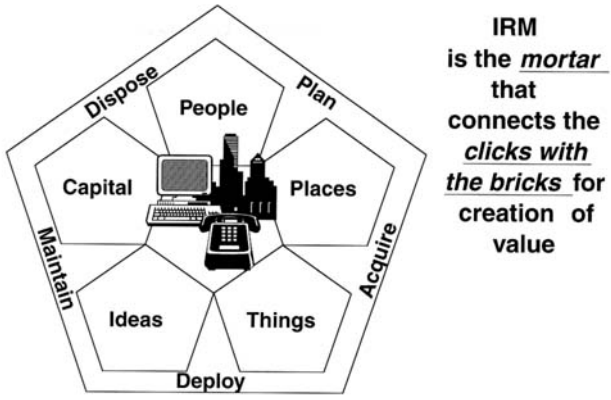

FIGURE 3.3.2-1 Infrastructure resource management (IRM).

people of the organization to the transportation fleets that serve the organization (Fig. 3.3.2-2). The merging of these disciplines results in a more thorough understanding of the impact of events and change upon the investment decisions of an organization.

This is particularly apparent in those organizations where all of these assets have begun to play a greater role in the strategic game plan of their business. Arthur Andersen understands the value of assets in the new business model:

> Businesses are their assets, all of their assets—tangible and intangible, owned and unowned . . . successful business models will combine both old and new economy assets. In fact, it is the combination and interaction of the various assets that will determine economic outcome.[2]

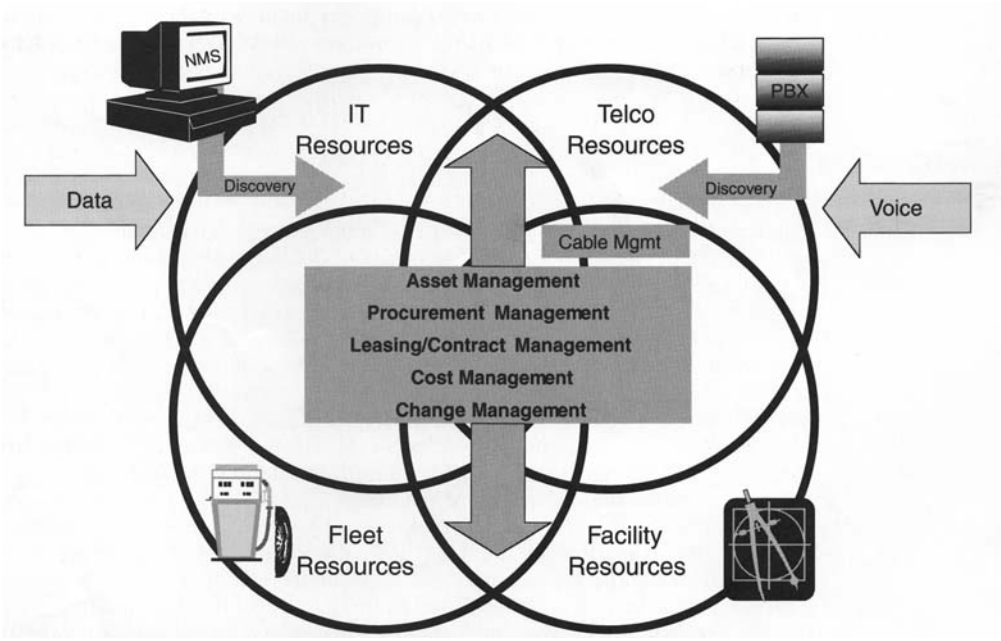

FIGURE 3.3.2-2 Components of IRM.

The e-business tsunami that is impacting the way we review all of our asset portfolios is all about using improved connectivity to optimize the performance of the entire business. And this connectivity is connecting the "clicks and the bricks." Amazon.com is a perfect example of a business that requires a new asset mix. Although it has rejected any off-line retail infrastructure, it has had to invest heavily in the physical world because its business model requires massive warehouse operations like the 800,000-square-foot structure built in Georgia. Location is critical to the immediate distribution of Amazon's products to its customers.

Corporations, universities, hospitals, K–12 institutions, and government agencies are all questioning their existing investments in physical places versus new investments to expand their reach into virtual space. And the plays they make on their particular game boards cannot be made intelligently unless they have the most accurate baseline information on all of their infrastructure. Then, they can benchmark with other organizations, share best practices, and determine what the most critical activities for creating value should be. And the only facilities management and real estate (RE) groups today that are truly playing on this value creation game board are doing it with sophisticated asset repositories and business reporting tools linked to the IT organization.

Boeing

Take the example of Boeing. In the early 1990s, Boeing was under great pressure from its shareholders to respond to the financial problems that were created by deregulation, declining aircraft orders, and divestment in space exploration. By the latter part of the decade, its vertically integrated business model of design, engineering, and manufacturing under hundreds of millions of square feet of roofs had catapulted them into the no-profit zone. At the same time, operating costs were escalating. A new management group was summoned to fix the problems.

Boeing announced its new "flight plan" in the spring of 1999, and it was not about scheduling its fleet of planes. It was a plan to create value for shareholders, customers, and employees. It was a performance-based strategy designed to substantially improve revenue growth, profit margins, and asset use. In doing so, Boeing was announcing a major change in the way the aerospace business measured success. It was turning its focus away from its former concentration on increasing the performance of its major carriers with no consideration of cost in the desperate race to space.

The aerospace giant had finally figured out (like the other industrial manufacturing titans in the automobile, steel, and appliance worlds) that they had to focus on value-based, market-driven cost reduction to compete in the global aerospace game. This was highlighted in an address given by its chief operating officer (COO), who identified cost as the most pressing problem and the "new frontier" in the aerospace business. The COO had now become a change leader for Boeing in its new race to increase value for its stakeholders and decrease costs for its global operations. And it could not begin to make the decisions it had to without state-of-the-art management technology.

New Processes for the Change Leader in Value Creation

Peter Drucker, still our guru of business at 90+ years, has described this new role of the change leader for the twenty-first century, which is to "make the present create the future." The new processes that this leader must adopt include practicing

- Organized abandonment
- Organized improvement
- Exploitation of success

The change leader in infrastructure management must consciously identify, analyze, and abandon any of yesterday's assets (including people, places, and things) that do not produce

results. To practice organized abandonment, every asset must be analyzed to determine what it costs the organization. According to Drucker,

> For management purposes there are no "cost-less assets." There are only "sunk costs," the economists' terms for buildings and other fixed investments. The question is never: "*What have they cost?*" The question is "*What will they produce?*" And assets that no longer produce except in accounting terms, that is, assets which produce only because they appear not to "cost" anything, are not assets. There are only sunk costs.[3]

Therefore, as we look at implementing technology, the discussion we should be having should (1) concentrate on cost savings (be they reductions in occupancy costs in FM and RE or reductions in support and procurement costs in the IT world) made by implementing electronic tools and (2) focus on the productivity increases that can be gained when we hang on to the most valuable assets for our strategic missions and sink the nonperformers. When we engage in this type of discussion, we are out of the accounting realm into the economic world of creating value.

Only after abandoning these nonperformers can we seek to make improvements to those that are still valuable to an organization. Drucker discusses drawing from the Japanese *kaizen,* or continuous improvement, at this stage. These improvements to products, processes, services, and technology all depend on accurate information to determine the most significant best practices to apply to the organization.

One interesting example of determining best practices and creating standards is the work of the United Kingdom's Central Computer & Telecommunications Agency (CCTA), the agency that supports the English government in managing information. The CCTA created a methodology to codify best practices for IT services, called the Information Technology Infrastructure Library (ITIL). The ITIL is the only global comprehensive documentation on best practices for IT service management. Now used by hundreds of organizations around the world, it includes best practices for the entire life cycle of the infrastructure, including help desk, problem change and configuration management, contingency planning, and accommodation specification (including environmental and electrical requirements). Infrastructure planning and management tools are now incorporating the ITIL best practices into their product offerings.

Once performance metrics are identified for benchmarking and value scorecards and wins are identified, successes of the group can be exploited within the organization and also in the outside world. Boeing did just that on July 16, 1999, when the results of its own value scorecard for 2Q 1999 were announced to the press. Boeing described four metrics chosen to measure the organization's performance. Two of these metrics involved facilities: facility consolidation and overhead reduction. The Boeing CFO proudly exploited their success in abandoning real estate and consolidating operating groups into 122 million square feet and in reducing overhead by $600 million. Boeing's change leaders presented the results of their value-based performance initiatives to their shareholders, which included reducing overhead and occupancy costs.

The next section addresses specifically how new facility management, real estate, and ITs are allowing our profession to enter a new phase in its evolution as we learn innovative ways to create value in physical place and virtual space for all of our organizations. We can all play in the great global value creation game.

THE FOUR STAGES OF VALUE CREATION

In this section, we explore how the new change leaders in infrastructure management must act more like chief infrastructure officers (the new definition for CIO). They must determine a technology strategy and then the financial justification for these tools that are required to

enforce this strategy. Then, they can use the technology to analyze, measure, abandon, and improve the valuable assets in which their organizations have invested to play on the board of the great global value creation game.

To understand how this relates to our world of facility management and real estate, I describe how these processes relate to the introduction and implementation of electronic systems for the following:

- Collecting data (electronic and manual)
- Planning strategy and scenario
- Acquiring
- Tracking
- Monitoring
- Managing
- Maintaining
- Disposing
- Reporting (graphic and alphanumeric)
- Benchmarking, scorecarding, and simulation dashboarding
- Integrating with enterprise resource planning (ERP) systems
- Linking graphics (CAD, GIS, photos, and videos)
- Creating virtual communities

In fact, without installing and implementing the systems just listed, the change leader cannot be successful. Performance cannot be measured, and it would be impossible to determine the value of any changes to business processes made to improve the infrastructure leader's role in supporting the mission and strategies of an organization. To organize improvement, the following four-stage framework has been defined that allows a change leader to move from one stage to another by introducing new management technologies and processes (Fig. 3.3.2-3).

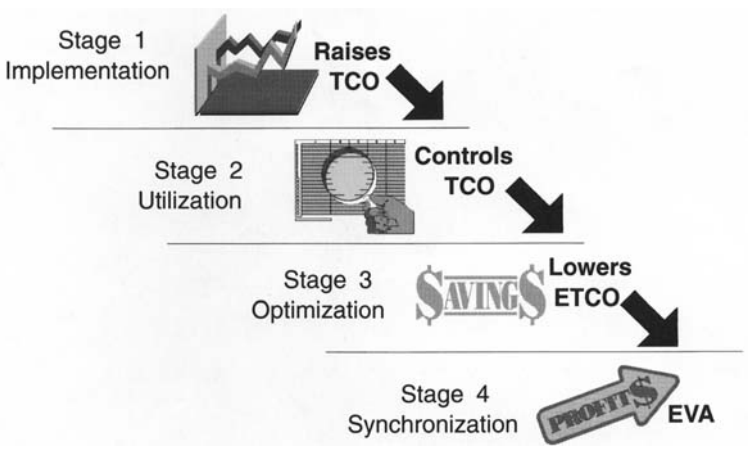

FIGURE 3.3.2-3 Four stages of implementing an IRM system. (*Source: Gartner-Group.*)

Stage 3. Optimization

Stage 4. Synchronization

The first two stages are very reactive environments where IT, FM, and RE manage the infrastructure from their separate organizational silos. In Stage 1, it has already been determined that the infrastructure is business-critical, and there is a need to lower the total cost of ownership (TCO) and occupancy while increasing the quality of service to the customers (the employees of the organization). The organization has determined its automation requirements and justified the investment by using automatic ROI calculators.[4] However, due to the fact that each of the separate groups is separately applying technology without coordination, the initial investment is much larger than attacking the problem in a holistic fashion.

In Stage 2, information is available about the existence and condition of the entire infrastructure resource portfolio—answering the questions, "How much do I own and lease?" and "Where are these assets located?" These are critical baseline data that can serve for internal and external benchmarking. It gives management information as to whether the resources are doing what they should for the maximum success of each of the business units.

After the results of the benchmarking activities have been compiled in Stage 2, Stage 3 is the point where the change leader can move out of a reactive environment into one where strategic planning can optimize the infrastructure resources in each of the respective RE, FM, IT, and telecommunications groups. This is the stage when the TCO finally starts to decrease because of

- Lower real estate costs due to implementation of best practices such as alternative work settings, hoteling, consolidation, and sale and lease back
- Cost recovery due to disposition of sunk assets (e.g., buildings, leases, computers, networks, software, etc.)
- Lower costs of telephony due to accurate call accounting

True IRM occurs in Stage 4 where IT, Finance, HR, RE, FM, Fleet, and Telecommunications are all linked electronically. There are strong linkages particularly with the ERP systems (Fig. 3.3.2-4). Real-time data are collected from one application and fed into another for mon-

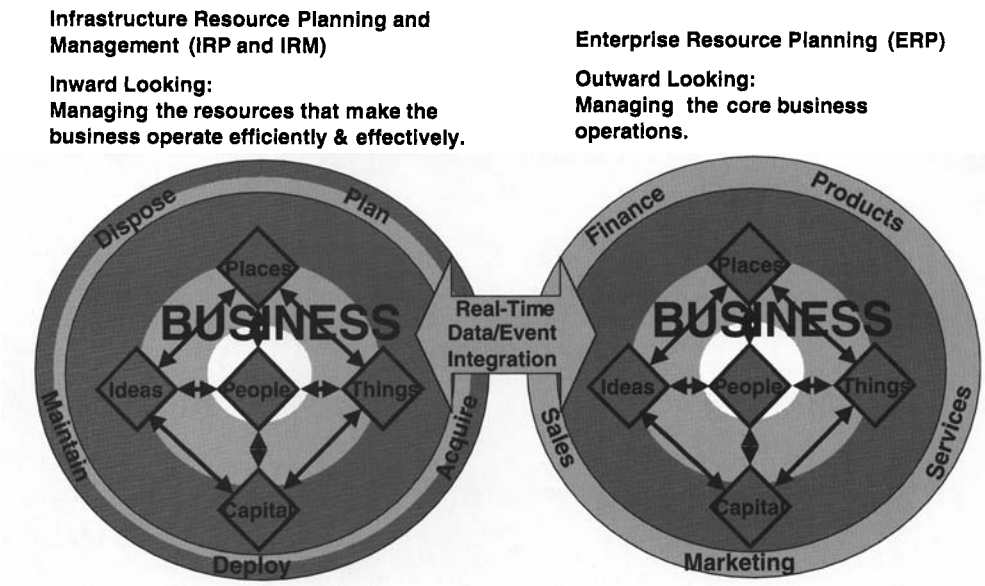

FIGURE 3.3.2-4 Infrastructure resource planning (IRP) integrates with enterprise resource planning (ERP).

itoring the state and condition of the infrastructure from building, data management, and telephony systems. At this stage, true financial benefits can be contributed to the bottom line of the business as measured by net present value analysis or real options pricing. We have moved from an accounting discussion in the first two stages to economic dialog in the last two stages. This is the point where the true value of integration is realized for the stakeholder. These four stages are depicted in Figure 3.3.2-5.

Stage 1: Automation

After you have determined your requirements and justified the investment, you can begin to automate new business processes. The major force behind this stage is cost reduction. Information is captured in one or two repositories from many disparate sources (both graphic and alphanumeric) by each separate silo master of the organization (i.e., FM, RE, and IT). Interfaces and gateways have been established with other groups such as human resources and finance. This short-term view can be accomplished in 1 to 4 months, and assets and resources are still perceived as expenditures and costs to the organization. There is an average of 100 percent churn in this stage and approximately 15 percent of underused because there is no space or asset planning, only a space and asset inventory.

Stage 2: Utilization

After the initial stage, you can move to the second stage where now you can use this information to look at your infrastructure from a global viewpoint (or however large your universe is) and start cutting occupancy costs. This is a space and asset utilization stage where you are look-

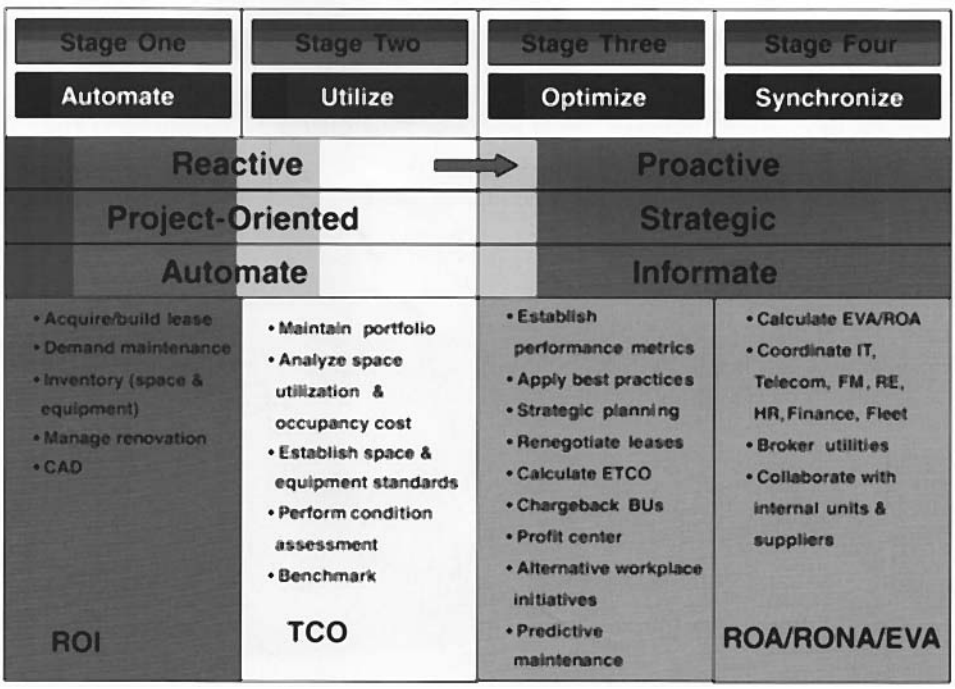

FIGURE 3.3.2-5 Financial impact of IRM.

ing at overall efficiency and effectiveness and establishing policies, procedures, and processes to maximize your portfolio by benchmarking with other groups both within and without the organization. The American Productivity and Quality Center (APQC) has determined that more significant cost savings can occur from internal comparisons than from external benchmarks.

This is the stage for defining how your costs will be reported. It is suggested that you use the Workpoint Accounting System to determine the true costs of the bricks-and-clicks infrastructure provided to support the knowledge worker. This is an accounting standard issued by the Institute of Management Accountants in mid-1997 that includes a chart of accounts and describes categories of IT costs and investments, as well as costs incurred for investment in the physical infrastructure. It was created by the Institute of Management Accountants and is entitled "Practices and Techniques: The Accounting Classification of Workpoint Costs." In this stage, the IT group will use this classification scheme for their TCO, and the FM and RE organization units will account for building and equipment costs (TCO). In the next two stages, they will be brought together for the enterprise total cost of ownership (ETCO), as defined by Mike Bell of the Gartner Group (Fig. 3.3.2-6).[5]

These data are used as accurate baseline data for the third stage, where you can begin strategic planning, benchmarking, and determining what your own value scorecard will look like to measure your performance in optimizing the infrastructure portfolio.

Stage 3: Optimization

In Stage 3, the benchmarking activities that have been performed in Stage 2 are now allowing management to identify the areas where best practices need to be applied. These practices can help to lower the TCO and provide even more superior service for the knowledge workers to help them increase productivity and stay within the corporation. The third stage is the point where you can begin to do what Drucker calls "organized abandonment" and to dispose of "slump" assets. Other more creative activities include examining workplace transformation to enable a true virtual integrated enterprise [VIE (also defined by the Gartner Group)] in the last stage of development.

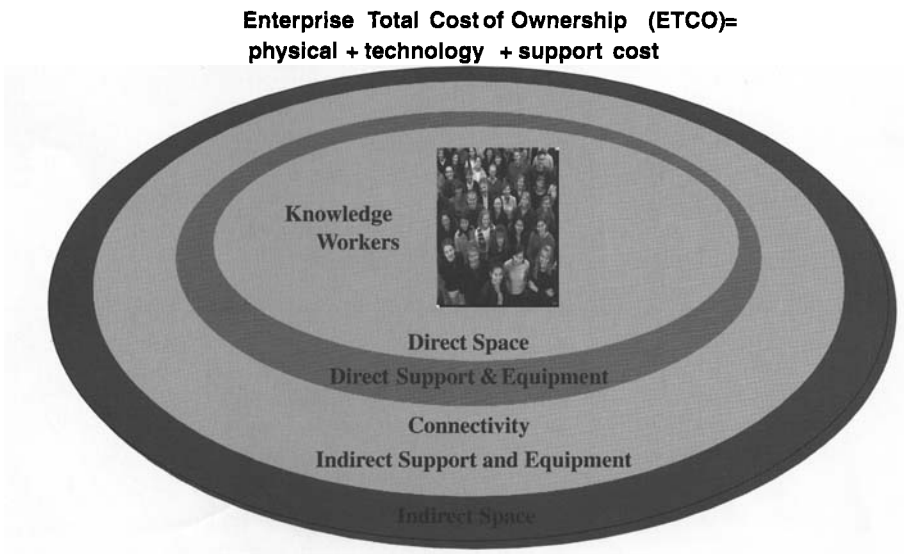

FIGURE 3.3.2-6 Enterprise total cost of ownership (ETCO).

Stage 4: Synchronization

As e-business continues to claim resources in every type of organization, this stage is where chief infrastructure officers have now integrated all of their IT applications to synchronize the VIE.[6] The GartnerGroup has defined *VIE* as follows:

> . . . global trends have spawned new business challenges, including enterprise agility, a relentless focus on core competencies and processes, a redefinition of the value chain as flowing backward from customer requirements to the enterprise, instantaneous response and latency (speed rules); the ability to scale resources and infrastructure across geographic boundaries, a "plug and play" IT infrastructure with componentized architectures and an interoperable applications portfolio. In short, as we enter the new millennium, the traditional business model is changing into a new hybrid structure, combining the local dominance of "bricks and mortar" infrastructure with the agility and scalability of digital infrastructure—what we call the VIE.

In this VIE environment, as organizations such as Sun Microsystems and Procter & Gamble combine their IT, FM, and RE functions to decrease the cost of selling and general administration divided by sales revenue (SGA) and to increase the productivity and retention of their workforces globally, they centralize their infrastructure planning and management activities.

The Methodology for Measuring Performance in the Four Stages: The Balanced Scorecard

We are all being held accountable for value creation. But how is this measured? How can we be sure that we have the right road map for applying new technologies and business processes to create the greatest value for our shareholders?

One methodology that has been used successfully since the early 1990s is the Balanced Scorecard.[7] The creators, Kaplan and Norton, designed a management system to link an organization's missions and long-view strategies with short-term action plans. They saw that a company's competitive strength is based "on information, their ability to exploit intangible assets has become far more decisive than their ability to invest in and manage physical assets."[8] Therefore, the Balanced Scorecard measures financial performance, customer satisfaction, internal business processes, and innovation. The Association of Physical Plant Administrators (APPA) has embraced this methodology for physical plant directors of the university community. Jack Hug of the University of California at San Diego has applied the Scorecard to his facility operations:

- *Financial performance.* To ensure financial integrity, to demonstrate stewardship responsibility for financial and capital assets, and to provide services efficiently, productively, and cost-effectively.
- *Customer satisfaction.* Perform "great customer service."
- *Internal business processes.* Implement processes that meet operational requirements and make it easy for customers to receive great service.
- *Innovation and learning.* Create a workplace where people love to come, where they are encouraged to grow and prosper, and where everyone is treated with respect.[9]

Recent research conducted by the APQC, directed by Doug Christianson, relied on the Balanced Scorecard to report on the critical issues underlying space utilization:[10]

> Although financial performance measurements such as efficiency ratios are important, they should not be the only factor affecting space utilization decision. The goals of real estate and facility management include more than just cost cutting. The challenge for corporate real estate and facility management officers is to provide a work environment that increases employee productivity and retention while maximizing the return on the organization's real estate portfolio.

Information technology must be added to this concept because the performance of the increasingly computerized integrated workplace is being measured in its support of the intelligent organizational networks necessary in the new "e" business space.[11]

One can use the Balanced Scorecard as a measurement system in each stage of value creation. To measure specific examples of total life cycle asset management, the work processes can be divided into the following categories:

- General administration and management
- Real estate (acquisition and disposition)
- Planning, design, and construction
- IM maintenance and operations
- Energy management
- IRM asset management
- IRM procurement

As we move from stage to stage in implementing systems in each of these areas, financial discussion will change from an accounting to an economic perspective, improvements in customer satisfaction will move from faster response time to increased productivity, internal business processes will leap from tactical improvements to strategic decision making, and innovation will change from mere automation of processes to new ways of doing business. And these are just some of the ways by which we can navigate this complex value proposition.

CONCLUSION

This article has described how you can navigate from separate distinct silos of activity in the first two stages of systems implementation to integrated asset management that we call *infrastructure resource management* (IRM).

Already, new business processes are being defined by organizations such as KPMG, which has created an infrastructure resource planning (IRP) practice.[12] Just as the Big Five created extremely lucrative practices building on the expertise required for implementing ERP systems, which have changed the physical and virtual supply chain for the core business of an organization, IRP processes will be the next critical movement. These IRP processes will support the changes required to support the complex environment of the technological and physical infrastructure in both old- and new-economy businesses. The question is: Are you creating or destroying value on your own IRM game board?

NOTES

1. A variation of the title of a talk given by Dr. Kjell A. Nordstrom, Assistant Professor, Director Institute of International Business, Stockholm School of Economics, Sweden, at the European IFMA World Workplace in June 1999. The game board concept is attributable to the recent work of Michael Bell at The GartnerGroup. Portions of this article appeared in IFMA's *Facilities Management Journal* (January/February 2000), 22–32.

ARTICLE 3.3.3

LEVERAGING THE FACILITIES MANAGEMENT TECHNOLOGY INFRASTRUCTURE: ALL ASSETS ARE CREATED EQUAL

Eric Teicholz
Graphic Systems, Inc., Cambridge, Massachusetts

It is hardly a surprise that organizations are spending more and more of their resources on their information technology (IT) infrastructure. Not so long ago, this infrastructure encompassed only the hardware and software associated with mainframe computers and the networks that connect terminals to those mainframes. In the 1980s, PCs entered the equation. In the 1990s, the IT infrastructure has expanded to include everything from laptops, palmtops, intranets, extranets, collaborative Web sites, mobile phones, pagers, and personal digital assistants. Given the nature of progress, it is anachronistic to think that facilities managers will continue to control their IT infrastructures independent of other business units.

Indeed, there has been a term coined to describe the growing technological interconnectedness of a company's individual units: *Infrastructure management* (IM) refers to managing the life cycles of all assets within an organization. The goal of IM is to minimize the cost of that asset for the organization as a whole [i.e., the "return on asset"—an increasingly popular facilities management (FM) benchmark]. To accomplish this, IM needs to know about people, locations, and assets—the traditional domain of computer-aided facility management/computer-integrated facility management (CAFM/CIFM). What traditionally has *not* been the domain of CAFM/CIFM systems are calculations for the cost of that asset over time (the life cycle of the asset) and how effectively it is being used to support strategic corporate business objectives. To perform these calculations, new types of interfaces must exist between FM

and other mainstream corporate systems, and new business management processes must be established to which all organizational units adhere.

What is key about IM management is that it is done for the organization as a whole—not just the FM department. To optimize return on assets (ROA), the organization must treat all assets alike throughout that organization, and standards must exist for computers and also for data, telecommunications, applications, and even the work processes for managing assets over time.

The implications for FM are profound. It means that FM data must be linked to real estate, human resources, IT, and all aspects of finance and procurement. It means that FM technology systems must function as a part of a whole and that the goals of FM technology must be synchronized with those of the organization as a whole.

THE BEGINNINGS OF IM

Infrastructure management embodies concepts that have arisen as management wakes up to the strategic importance of IT and its influence on all aspects of an organization's business. No business unit, facilities management included, is immune from the centralizing force of IT.

Information technology is already the largest capital expense in many corporations today (it amounts to 7 percent of revenues and 14.2 percent of expenses for service industries), and investment in IT is growing at the rate of 3 percent per year. The corporate/organizational IT infrastructure increasingly reaches across IT to all business units. Because of the potential benefits of IM, however, IT increasingly incorporates these areas:

- PCs and all aspects of computing devices (e.g., laptops, palmtops)
- Communications and telecommunications protocols and vendors
- Vendors and other types of data of corporate-wide interest
- Internal and external Web technology, including the Internet, intranets, and extranets
- Benchmarking and financial metrics for cost-benefit analyses
- Various aspects of mission-critical work processes, such as procurement and financial management

The number of centrally managed technology-based functions is growing, and organizations are increasingly trying to understand and manage the risks and returns of such investments.

THE EFFECT OF IM

The FM cause-and-effect relationships between IM investment, risks, and rewards are just beginning to be understood and quantified. However, enough case studies and feedback are available to reach this conclusion: Organizations that understand such relationships and invest heavily in IM will receive more business value and ROA than those that do not.

For the facilities manager, it means that the role of FM technology will change as IM is better understood and accepted by organizations. It means that an asset (whether a chair, a PC, a paper clip, cabling, a painting, or an entire building) will be processed by the same technology and with the same benchmarks and work processes that are used throughout the rest of the organization. It means that the support structures (e.g., HR, finances, real estate, IT, and purchasing) required for corporate strategic decisions will all use the same technology and business processes and probably even report to the same management. Now, every resource for which an organization is responsible (whether leased or owned) will be part of an integrated strategy that affects the entire life cycle of that asset. In the IM environment, understanding the life cycle of assets from purchase to disposal is critical.

As IM centralizes business functions and processes, it means (at least in larger organizations) that CAFM/CIFM vendors will also be required to integrate with enterprise resource planning (ERP) systems and vendors. Mainstream "mission-critical" systems that control the tasks of purchasing, finances, HR, and IT (typically the domain of ERP vendors) need to share information with FM systems to provide the spatial and financial information required by management. Vendors such as Oracle, PeopleSoft, SAP, and Bain are already working with FM vendors to enable such integration. The line separating FM and ERP technology is still somewhat fuzzy and constantly changing. A number of potential scenarios are possible that would make this line clearer (at least at a particular time):

- ERP vendors might focus on mainstream enterprise-wide business processes, and facilities managers would manage the environment in which these business processes take place.
- ERP vendors might try increasingly to develop FM and real estate functionality within the ERP environment.
- ERP vendors might increasingly partner with FM vendors to provide comprehensive integrated solutions.

Finally, IM will affect how internal and external customers from all business units interact with information. The model of a single point of interface has appeal because it provides a unique location for all organizational data. Thus, the current functionality of help desks that are popular with many existing computerized maintenance management systems (CMMSs) would be expanded to aid the customer with problems associated with all assets. There would perhaps even be a single help desk that would serve all business units within an organization.

Although the benefits of IM for the facilities and real estate manager are just beginning to be understood, some value can be anticipated. Effective IM deployment and management will

- Provide a single repository of information about all occupants, locations, and assets that an organization owns or leases
- Capture, track, and potentially calculate the impact of an asset on an organization (which, in turn, will minimize downtime and expenses) as long as that asset is owned by the organization
- Minimize the cost and time of moving employees, assets, and systems of an organization from one location to another
- Enable deploying new FM and real estate technologies and applications throughout an organization
- Provide much more rapid integration of FM and real estate data with HR, IT, and financial systems
- Leverage the large investment made in ERP systems
- Facilitate defining, collecting, and reporting of financial and operational benchmarks that are consistent throughout the organization

THE FUTURE OF IM

As mentioned, organizations have so far ascertained that investment in IM yields business value and better understanding and control of assets. However, there are trade-offs in just how much centralization should take place in hardware, software, communications, Internet, data, benchmarks, business processes, and so forth. The risk and return of IM are not clearly understood. For example, firms that have more integrated and comprehensive infrastructures can introduce new products faster; however, IT systems and related procedures tend to be complex, and therefore, it takes longer to integrate new technologies and applications into

the existing infrastructure. For the facilities manager, technology is constantly changing. Technology vendors are just beginning to move their applications to the Internet on a real-time, transactional basis. New technologies such as workflow and collaborative Web sites have been applied only recently. High-speed Internet, chips embedded in assets, and interoperability are just a few years away. How much will these technologies be influenced, and possibly be slowed, by organizations that have heavily integrated infrastructures? How will different types of investment in IM affect the ROA? No one really knows at this point.

Nevertheless, there is an obvious trend toward increasing investment in an organization's technological infrastructure. It is also clear that the definition of this infrastructure involves more than just hardware, software, and networks. The definition of IM is embracing more functions, including aspects of applications software, Internet and related technologies, databases, benchmarks, profit-and-loss calculations, and even entire business processes. Anything that is required outside of a specific business unit is fair game for IM.

This common organizational integrated technological environment encompasses people, assets, and spatial (locational) data—all of which are critical to the facilities manager. As facilities data are increasingly merged with other corporate data for strategic needs (e.g., occupancy cost calculations, outsourcing analysis, and ROA), the trends toward centralization of IM will continue. Centralized purchasing and e-commerce on the Internet mean that facilities assets will likewise be centrally purchased.

The role of the facilities manager in IM is currently fluid. The role to be played by traditional CAFM vendors vis-à-vis ERP vendors is likewise dynamic. What is clear is that the facilities manager must understand the implications of IM for facilities management and must anticipate the ways in which the traditional functions of space and asset management will be affected by this centralizing force.

ARTICLE 3.3.4

FACILITIES MANAGEMENT AUTOMATION AND INFRASTRUCTURE MANAGEMENT

Bruce Kenneth Forbes
ARCHIBUS, Inc., Boston, Massachusetts

This article is a primer on facilities management (FM) automation and infrastructure management (IM). It bridges the gap between management practices and the application of technology. Issues raised in this article will benefit all facilities professionals and their allied affiliates, no matter what their level of FM automation and IM experience.

Now, FM professionals are using hand-held computers (also known as palmtops), smart chips, cellular connectivity, and bar codes to decrease paperwork, increase quality, and handle larger workloads. Thanks to cutting-edge technology, world-class procedures, benchmarks, best practices, software, and e-commerce, the facilities planning and management field is undergoing a remarkable transformation. Advanced FM automation solutions, IM enterprises, and cyberspace universes for FM have become a reality.

During the last three decades, the FM automation industry has been defined, clarified, realized, and reengineered. Some of the by-products of this process include best-of-class standards and procedures and best practices for the facilities management professional. During this time, the marketplace has been educated about the financial and personal benefits of FM

automation. The digital economy of FM automation is evolving rapidly. Comprehensive graphical user interfaces make FM automation solutions easy to understand and use (see Fig. 3.3.4-1). In just 5 minutes, executives can learn how to access information about assets on their sites or anywhere else in the world.

Facilities management automation and IM improve FM knowledge management. The unique needs of dynamic global economies and reengineered business environments are requiring inventive responses. Timely access to corporate information can determine the quality of strategic decision making. Facilities management knowledge management will be used to create unlimited opportunities. The technological aspects of FM knowledge management embrace automation tools, processes, procedures, and best practices for managing corporate assets and will have a direct impact on an organization's effectiveness, efficiency, productivity, and profitability.

Facilities management automation and IM technologies are critical management tools of the virtual networks and enterprises that are vital to the new e-business, e-commerce, and business-to-business (b2b) delivery environments. Yet, for many CEOs and other senior executives, finding easy-to-use resources that help bridge the gap between general management practices and the base FM disciplines and core FM competencies has been a daunting challenge. Among the numerous benefits of deploying FM automation and IM solutions is the ability to use graphical drill-down techniques to parse through billions of pieces of data, information, and knowledge. An executive who has minimal training can use a few clicks of a mouse to locate specific information in a real estate and property abstract, departmental occupancy report, or suite lease expiration report by graphically drilling down and reviewing a desired report (see Fig. 3.3.4-2). The immediate access to strategic information and knowledge is often cited as the executive's top reason for using these systems.

Why You Should Read This Article

This article offers a nontechnical reference to the world of FM automation and IM. By reading it, one can learn how to rapidly deploy FM automation solutions and IM enterprises, implement FM best practices for FM automation, save time and money, and realize greater productivity and profitability.

Facilities professionals are involved with thousands of different activities and would greatly benefit from FM automation and IM if they perform any of the following tasks:

- Real estate acquisition, use, redeployment, maintenance, and disposal
- Long-range facility planning
- Strategic master planning
- Facility financial forecasting and budgeting
- Acquisition, use, redeployment, maintenance, and disposal of assets
- Renovation and/or new construction
- Architecture/engineering planning and design
- Interior design, space planning, workplace specifications, furniture and equipment installation, and space management
- Telecommunications and cable management
- Human resources (HR), security, and general administration
- Predictive, preventive, and demand maintenance
- Mergers and acquisitions

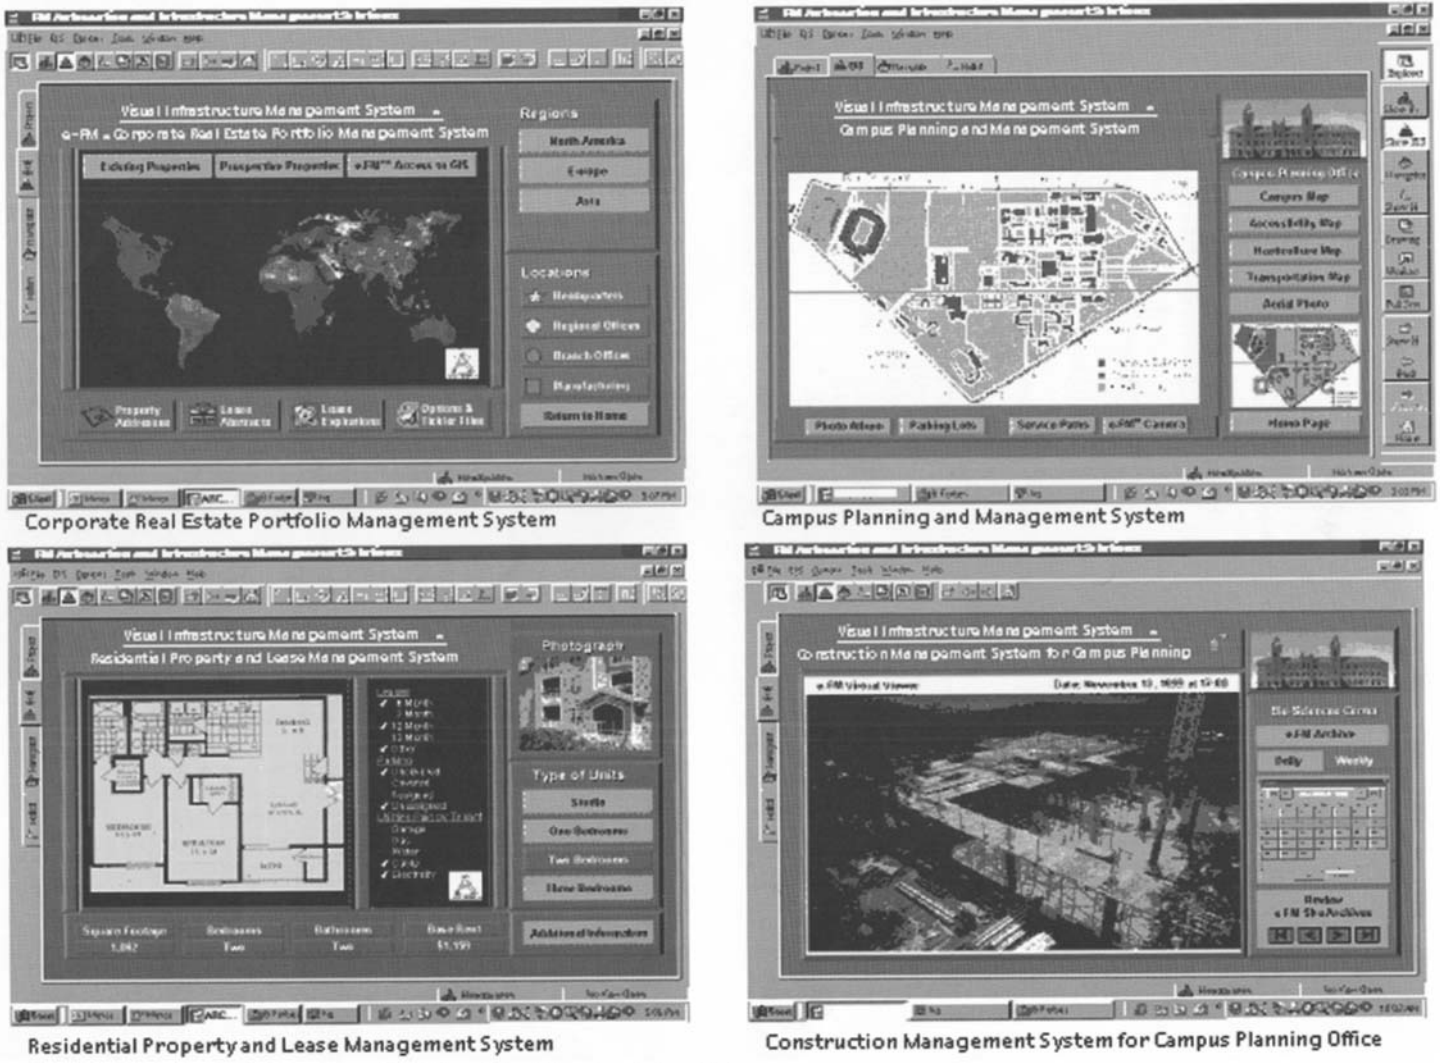

FIGURE 3.3.4-1 The digital economy of FM is rapidly being shaped by e-FM, e-space, e-commerce, and cyberspace universes for FM. Executives can establish immediate links to their favorite reports, financial analyses, help desk, construction site, work request system, and more. (*Courtesy of Rice University and ARCHIBUS, Inc.*)

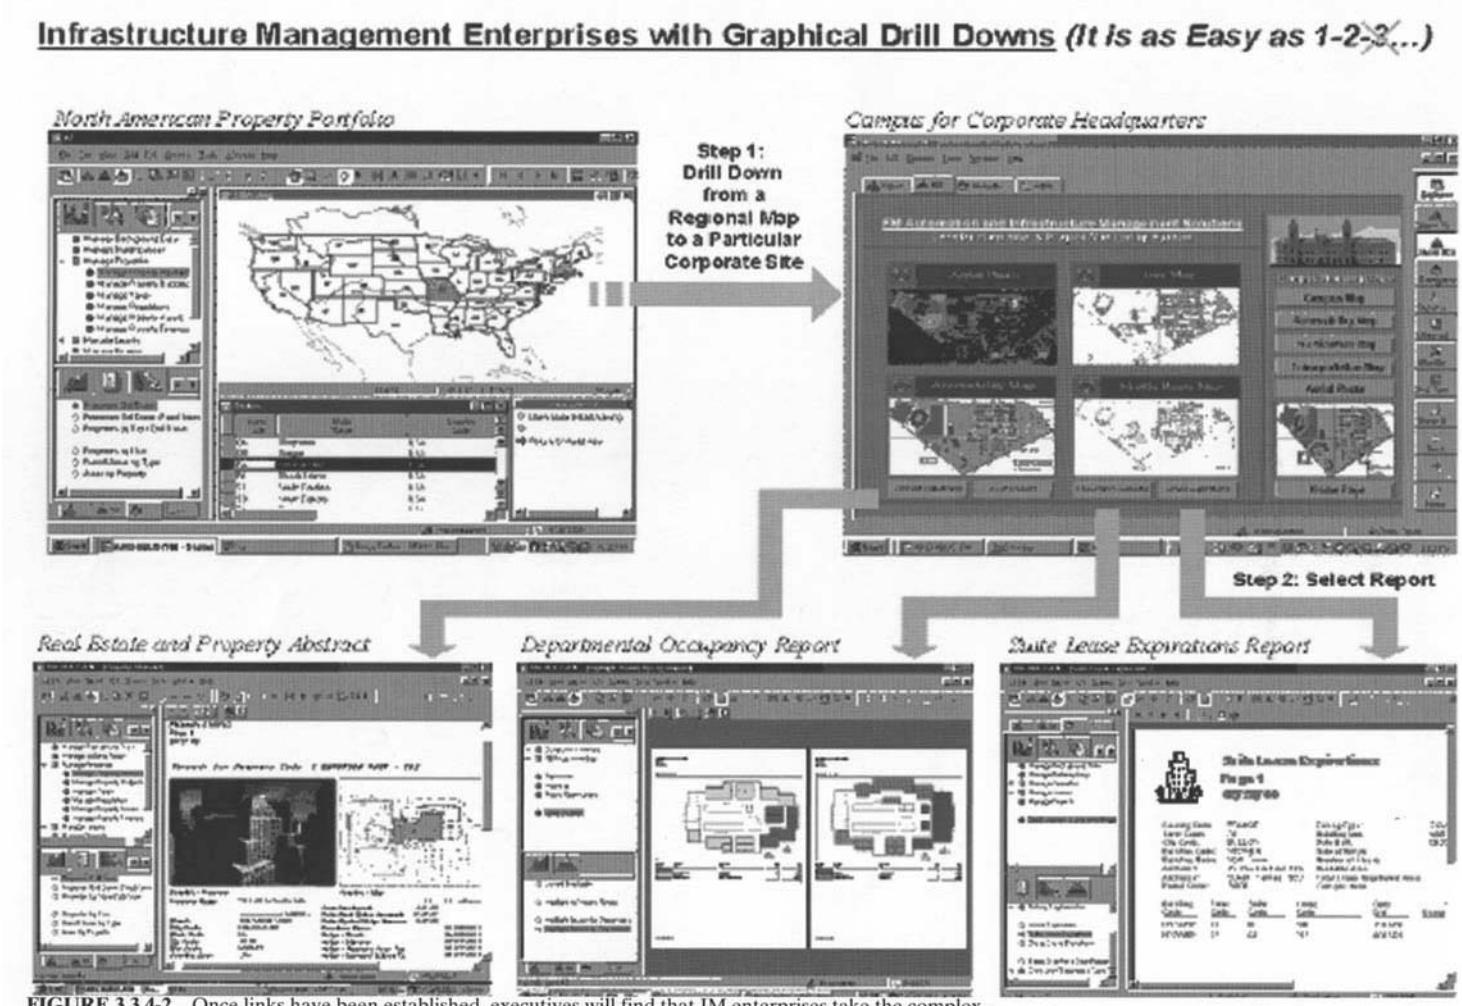

FIGURE 3.3.4-2 Once links have been established, executives will find that IM enterprises take the complexity out of FM automation, making digital economy inexpensive, fast, easy, intuitive, complete, and only a mouse click away. (*Courtesy of Rice University and ARCHIBUS, Inc.*)

THE COMMON ACTIVITIES ADDRESSED BY MOST FM AUTOMATION APPLICATIONS

Facilities management automation deals with the full life cycle of assets. Facilities management automation is currently being used in all of the areas listed previously. The common activities addressed by most FM automation applications include planning, design, acquisition, use, maintenance, redeployment, and disposal. The primary FM automation application areas that are addressed by commercial off-the-shelf solutions include real property and lease management, strategic master planning, space management, CAD overlays with design management, furniture and equipment management, telecommunications and cable management, building operations management, and IM connectivity with Web interfaces and executive information systems (see Fig. 3.3.4-3). When considering where to start to implement FM automation, it is advantageous to review each of the tasks shown in Fig. 3.3.4-3 and determine their relevance to your organization.

BENEFITS OF FM AUTOMATION: TOP REASONS FOR UTILIZING FM AUTOMATION SOLUTIONS

In 1998, a survey of facilities engineering and management professionals revealed what are considered the top benefits of using FM automation (Table 3.3.4-1).

Strategic managers stressed increases in productivity and profitability as the primary drivers for FM automation within their organizations. Business managers cited comprehensive analytical tools for better decision making as a primary benefit. Operations managers use FM automation to reduce costs and get things done more quickly, easily, and efficiently. Administrative and corporate services utilized FM automation to rapidly develop and implement corporate policies, tools, standards, guidelines, FM benchmarks, and FM best practices.

MANAGING TOTAL COST OF OWNERSHIP EFFECTIVELY

Today, an industry-wide dilemma exists: People are looking for panaceas to solve their automation problems. They assume that if they invest in FM automation solutions, all of the problems will be solved. But the reality is that once you make that purchase and commitment to FM automation, you have just begun. To make an FM automation solution work for your organization, you must address a wide variety of issues, and you must make informed decisions that allow your expectations to meet your reality. You must manage the *total cost of ownership* (TCO) effectively.

INFRASTRUCTURE MANAGEMENT ENTERPRISES

In this new millennium, your FM automation solutions must also connect with thousands of information silos and other islands of automation. Infrastructure management enterprises will be able to provide a framework for integration and connectivity. Such integration and connectivity can greatly reduce the TCO. In world-class IM enterprises, the "islands of automation" and "information silos" are assembled, integrated, and accessed via a variety of user interfaces.

An IM enterprise (an example is shown in Fig. 3.3.4-4) is considered a core competency of a virtual-based bricks-and-mortar, clicks-and-mortar, and clicks-and-clicks organization.

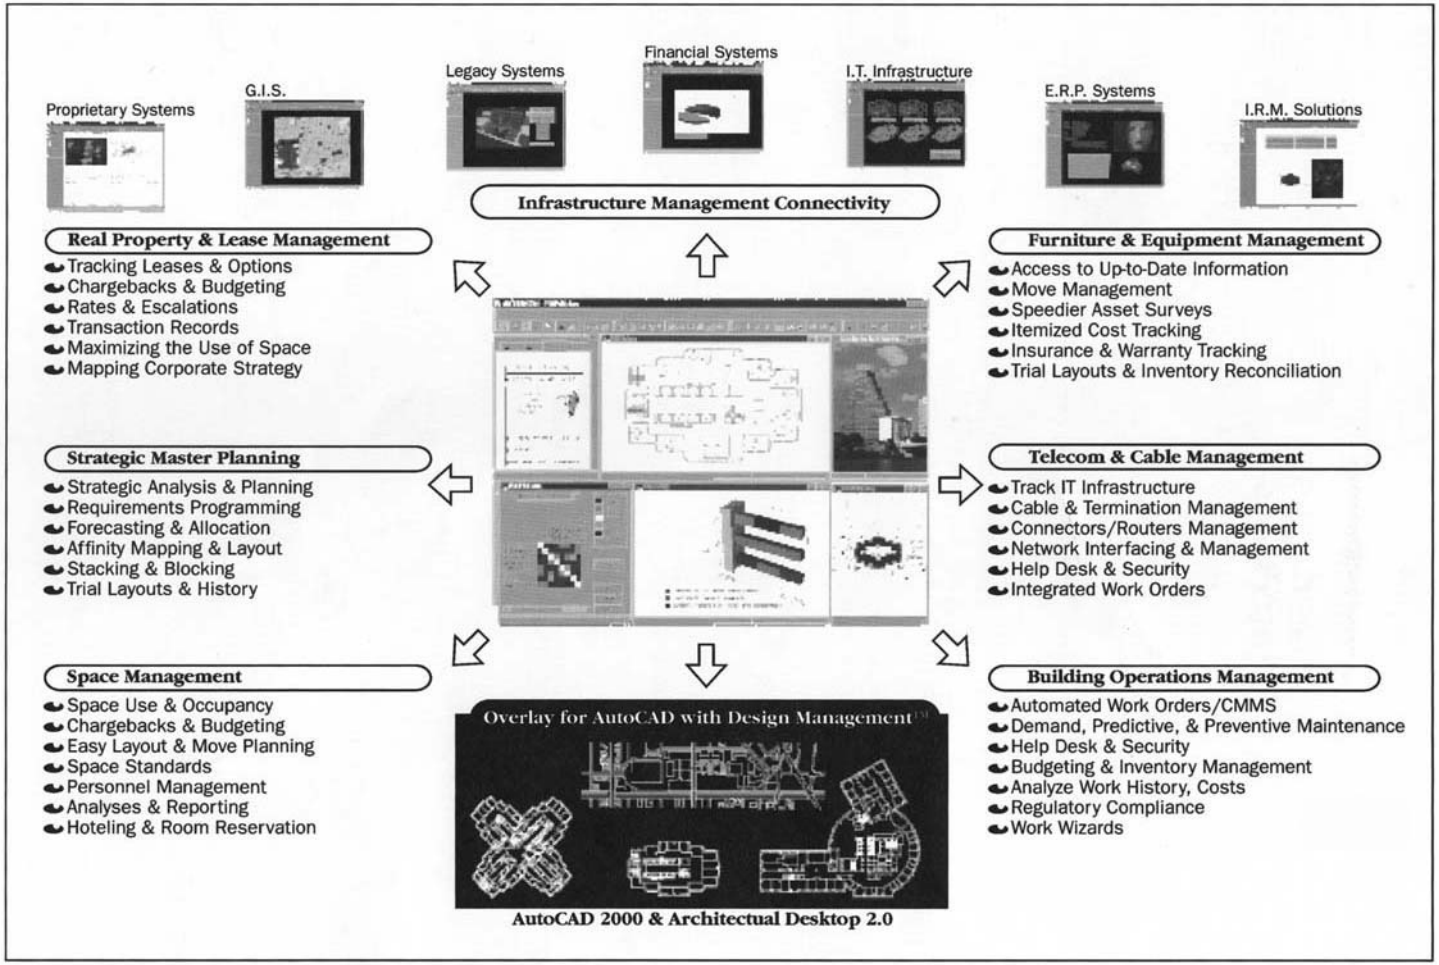

FIGURE 3.3.4-3 Islands of automation and information silos are connected and integrated within FM automation solutions and IM enterprises. The primary application areas are real estate, strategic master planning, space management, CAD overlays, F&E management, telecom, and building operations. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

TABLE 3.3.4-1 Top Reasons for Implementing FM Automation and IM Solutions

FM automation improves	FM automation increases	FM automation reduces
Benchmark data	Accuracy	Asset management costs
Corporate archives	Accountability	Churn rates and vacancies
Corporate knowledge	Asset use and management	Information bottlenecks
Customer satisfaction	Connectivity	Need for new space
Customer value	Control	Portfolio overhead costs
Effectiveness	Efficiency	Redundancy costs
Management	Profitability	Training costs
Responsiveness	Productivity	Training time
Service delivery	Reliability	Vacancy costs
Quality	Responsiveness	Underused assets

Facilities planning and management organizations can successfully create connectivity between their FM automation solutions and the numerous solutions for automation used throughout their organizations. Infrastructure management enables FM professionals to rapidly combine the data, information, and knowledge that has been stored in information silos or that exists in the various islands of automation. Some of the seamlessly integrated applications include the following:

- FM automation solutions
- Enterprise resource planning (ERP) systems
- Building automation systems
- Information technology (IT) infrastructure systems
- Computerized maintenance management systems (CMMS)
- Help desk and telephony systems
- Numerous other automation systems of the new millennium
- Simple return-on-investment (ROI) worksheets for FM automation and IM solutions

There are hundreds of reasons why FM automation has been proven to be a successful tool for facilities professionals. The most-often-cited reason for using FM automation is that organizations often spend up to 50 percent of their revenues in the acquisition, use, maintenance, redeployment, and disposal of assets. These organizations can realize up to 34 percent savings in these costs by effectively implementing and using FM automation.[5] In Table 3.3.4-2, the worksheet following is representative of a simple ROI analysis created for FM automation and IM solutions. This worksheet is based on presentations made at numerous World Workplace conferences, IFMA Best Practices Forums, local IFMA Chapter roundtables, IFMA Computer Applications Council discussions, and the American Institute of Architects—Professional Interest Area for Facilities Management seminars and workshops.

AUTOMATION IN THE TWENTY-FIRST CENTURY

We are rapidly evolving from a marketplace economy to a marketspace economy, courtesy of the opportunities afforded us by e-commerce, e-business, and b2b offerings. Virtual networks will be empowered by IM solutions that

- Are designed for people (providing user interfaces for casual, intermediate, and advanced users)

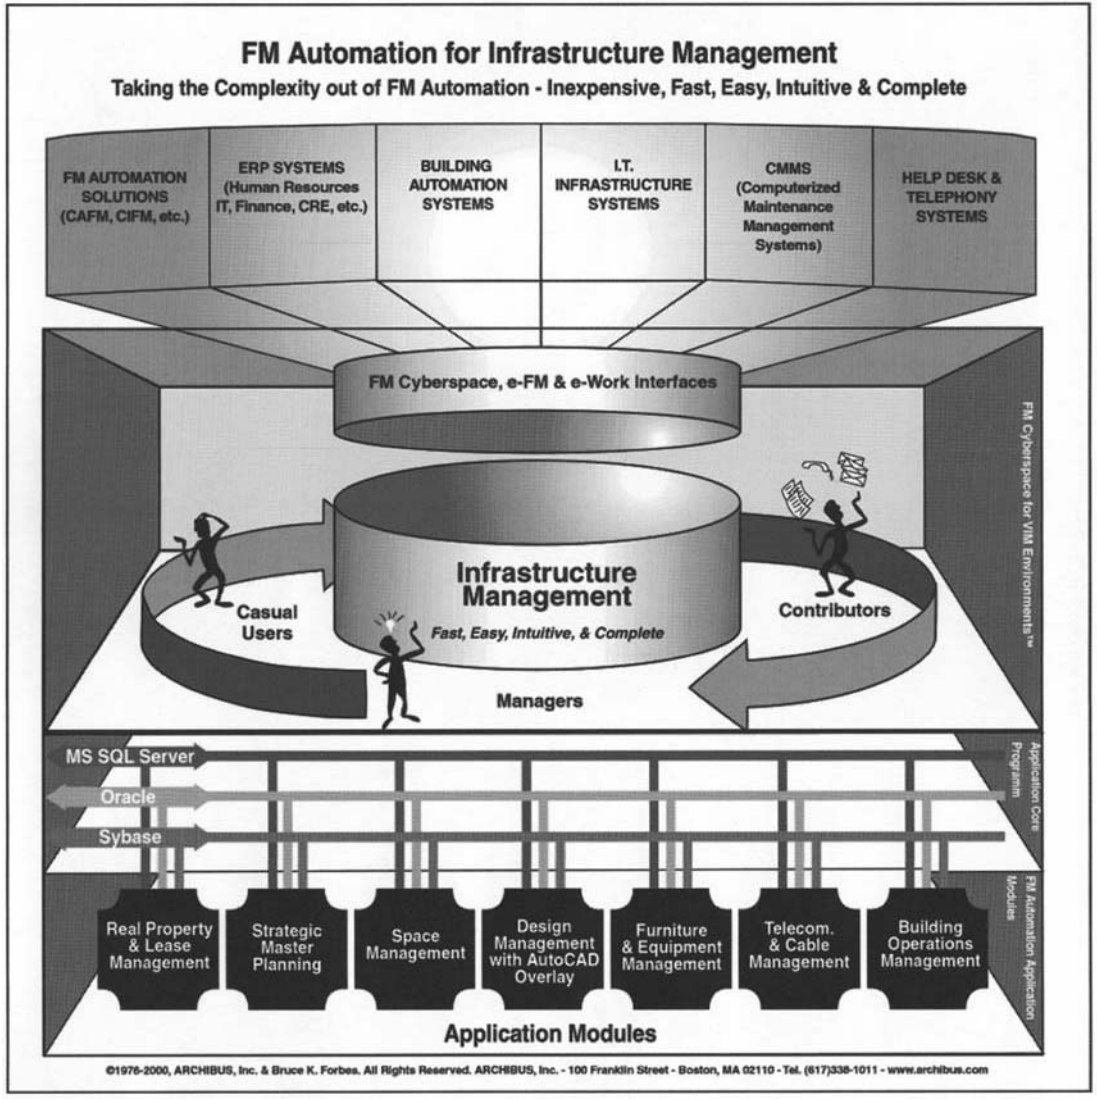

FIGURE 3.3.4-4 Hundreds of systems can be seamlessly brought together in enterprises (of which only a few have been depicted in this diagram). Some of the application categories for the systems more commonly connected include FM automation, ERP, building automation, IT infrastructure, CMMS and BOM, and help desk and telephony. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

TABLE 3.3.4-2 Simple ROI Worksheet to Determine Whether Your Organization Should Consider Using FM Automation and IM Solutions

	Small corporation	Medium corporation	Large corporation	Your organization
AA. Annual revenues of a corporation:	$5,000,000	$50,000,000	$500,000,000	(Estimated revenue)
BB. Facilities and asset-related expenses: Costs associated with the acquisition, use, maintenance, redeployment, and disposal of a corporation's assets (50% of a corporation's revenues)	$2,500,000	$25,000,000	$250,000,000	(Line above times 0.5)
CC. Estimated savings by effectively deploying and using Facilities Management automation and IM solutions (34% of a corporation's facilities-related expenses)	$ 850,000	$ 8,500,000	$ 85,000,000	(Line above times .34)
Estimated automation costs				
Number of square feet managed	25,000	250,000	2,500,000	
A. Total background data capture costs (sq ft × $1.80)	$ 45,000	$ 450,000	$ 4,500,000	
Number of employees and outsourced FTEs* on-site	50	750	10,000	
Number of assets per FTE on-site	12	24	36	
Total number of tracked assets (FTE × number of assets)	600	18,000	360,000	
Asset mgmt. and base maint. costs ("B" × $1.65 × 12 mos)	$ 11,880	$ 365,400	$ 7,171,200	
Recommended FM automation staff				
(1 person for 1,000 FTE on-site @ $60,000/yr)	$12,000	$ 45,000		
(5 persons for 10,000 FTE on-site) @ $300,000/yr)			$ 300,000	
Miscellaneous hardware, software, Internet/ Intranet expenses, customization, training	$ 25,000	$ 325,000	$ 500,000	
Estimated total FM automation expenses (A + C + D + E)	$ 93,880	$1,185,400	$12,471,200	
G. Estimated total ROI (CC–F) (realized over 3 years)	$756,120	$ 7,314,600	$72,528,800	
H. Estimated loss sustained by your organization every 90 days that you do not invest in suitable FM automation and IM solutions (CC ÷ 12 months). Typical payback period is less than 6 months.	Quarterly loss if not automated $ 70,833	Quarterly loss if not automated $ 609,550	Quarterly loss if not automated $ 7,083,333	
The inability to act can cost you millions . . .				

* Full time equivalents (employees) (FTE).

- Enable users to save a tremendous amount of time
- Address the TCO issues
- Provide for seamless integration
- Incorporate the latest and greatest technologies and the legacy systems that helped get organizations where they are today

Real-World Savings as Revealed in FM Automation Case Studies

There are hundreds of reasons for creating FM automation initiatives in your organizations. Following are some of the more frequently cited reasons:

- Better management of legal and safety issues
- More rapid completion of projects
- Better maintenance of equipment and assets
- Expedited modernization programs
- Gains in capacity, productivity, and profitability
- High ROI
- Better rent negotiations
- Energy management and savings
- Reduced telecommunications costs
- Reduction of needed space and facilities
- Better procurement methods and pricing
- Savings in labor rates and resource costs
- Increased productivity and profitability
- Reduced churn rates, move, and construction costs
- Reduced architectural, engineering, and interior design costs
- Tax reductions and abatements
- Reduced costs of building operations and maintenance
- Reduced furniture and equipment costs
- Reductions in personnel disruption costs and labor costs
- Incalculable savings of time
- Opportunities for personnel reduction
- Better control of information

Infrastructure management solutions will be accessed via a variety of user interfaces. These interfaces are process oriented and are easy to understand. Using these interfaces, a casual user can be trained in only a few minutes to use cyberspace universes for FM, executive information systems, and FM hot lists.

WHAT IS FACILITIES MANAGEMENT?

Facilities management is the practice of coordinating the physical workplace with the people and the work of the organization; it integrates the principles of business administration, architecture, behavioral, and engineering sciences. Facilities managers oversee assets (e.g., buildings, furniture, equipment, and computers) throughout their life cycles. The life cycle of an asset typically includes its acquisition, use, maintenance, redeployment, and disposal.

WHAT IS THE FACILITIES MANAGEMENT PROFESSION ABOUT?

Simply stated, the primary concern of the facilities management profession is planning and protecting the life cycle of assets and all things relevant to an asset's life cycle. The timely, pro-

ductive, and profitable acquisition, use, maintenance, redeployment, and disposal of an organization's assets are the prime directives. The relationship of spatial and nonspatial assets changes as an organization evolves from the traditional bricks-and-mortar organization, but the need to manage an asset's life cycle remains consistent.

WHAT IS FACILITIES MANAGEMENT AUTOMATION?

Automated facilities management solutions typically encompass creating, maintaining, and distributing FM data, information, knowledge, and wisdom. These are the primary areas addressed:

- Properties and real estate (parcels, plants, buildings, campuses)
- Physical assets [furniture, fixtures, IT infrastructures, equipment, building infrastructures (including structural, HVAC, mechanical, life safety, emergency, electrical, technical, and plumbing systems), in addition to signage, civil and geosubsystems, and interior and exterior envelopes and walls]
- Spatial assets (financial management analysis and control systems), personnel, and organization (employees, department staffing, vendors, contractors, and workflow processes and procedures)
- FM best practices and procedures
- FM core competencies
- FM benchmarks

State of the Art in Review

COTS Deployment Is "Hip," and Proprietary Solutions Are "Not." Organizations such as the GartnerGroup and Daratech report vast increases in FM automation and IM activities. In the near future, it is estimated that there will be more than 250,000 users of enterprise-based FM automation and IM solutions and 3 million users of cyberspace universes for FM environments. The enterprise solutions will most likely be 95 percent commercial off-the-shelf (COTS) solutions versus 5 percent proprietary and/or heavily customized solutions. The Chief Information Officer (CIO) of the U.S. Navy recently cited numerous benefits of COTS solutions and their deployment in the U.S. Navy. A recent Department of Defense (DoD) mission statement for an enterprise software initiative program reads, "The objectives are to save money and improve information sharing. The initial focus will be on COTS products."

One of the first decisions that an organization pursuing FM automation will have to make is whether its FM organization should buy COTS solutions for FM automation and IM. Historically, most Fortune 1000 FM organizations have opted to create their own FM solutions and invest heavily in customization and proprietary software development. Today, due to staffing, monetary, and time constraints, the same FM organizations are selecting COTS solutions with little or no customization. The ROI in such cases is obtained in less than 1 year, compared with the proprietary systems of the past, which took up to 3 years for an ROI.[6]

ROI Evaluations for FM Automation and IM. A particular organization's ROI for FM automation and IM will vary, depending upon the type of system(s) acquired, level of integration, available financial resources, staffing, and implementation time frames. Now, most corporations are acquiring one or more commercial off-the-shelf (COTS) systems (where the normalized ROI can be less than 1 year compared with a 3-year ROI for proprietary systems). Most organizations use an evaluation matrix when selecting solutions that are appropriate.

The placement of a particular product offering on the "ROI evaluation matrix for FM products" will vary client by client. The ROI evaluation matrix shown in Fig. 3.3.4-5 shows the results of an evaluation of 14 FM automation and IM products, which was done for a product manufacturer that had multiple sites in multiple countries. Criteria for evaluation included examining FM automation costs and the various aspects of FM automation functionality.

FM Automation Costs

- Hardware and software acquisition, implementation, maintenance, and upgrades (the initial software and hardware is only one-seventh of the total cost)
- Training, verification, and support costs
- Personnel costs (direct and indirect)
- In-house and outsourced services for surveys, field verification, data input and verification, customization, legacy system conversion, etc.

FM Automation Functionality

- Extensive graphic user interfaces and ease of use
- Relational access to activities rather than hierarchical
- Integrated report modules, integrated computer-aided design/area network (CAD/AN)
- Environments and robust applications and procedures
- Open-architecture, modular, scalable, enterprise-access-enabled, legacy-system-compatible, and virtual workgroups
- Web access via Internets, intranets, and extranets
- Computer-based training, active agents, and FM objects

Today, it is commonplace for FM organizations to use more than one system. Many will use cyberspace universes for FM with their corporate IT infrastructure to create connective mechanisms for integrating COTS solutions, legacy systems, and proprietary systems. It is estimated that great savings can be realized by effectively deploying and using a COTS solution.

Criteria for Selecting an Appropriate FM Automation Solution

No matter what your business size, an FM automation solution is usually available in a wide variety of configurations and in a range of costs for you and your organization. You can work with a vendor, consultant, IT professional, and/or fellow FM professional to determine which solution would best suit your needs. The criteria examined during the selection of an FM automation solution include but are not limited to the following:

- The size and number of properties and facilities managed
- The types of space and the costs of management (manufacturing, educational, offices, etc.)
- The numbers of people and the annual and quarterly churn rates
- The size and capability of the facilities department and the nature of their business partner relationships (the extent to which outsourcing and outtasking is used)
- The management of facilities-related factors (including people, time, costs, integration, and technology)
- The extents to which standards are enforced and inventory is managed
- The technical and computer competency of staff and outsourcing agents
- The workloads and the management requirements

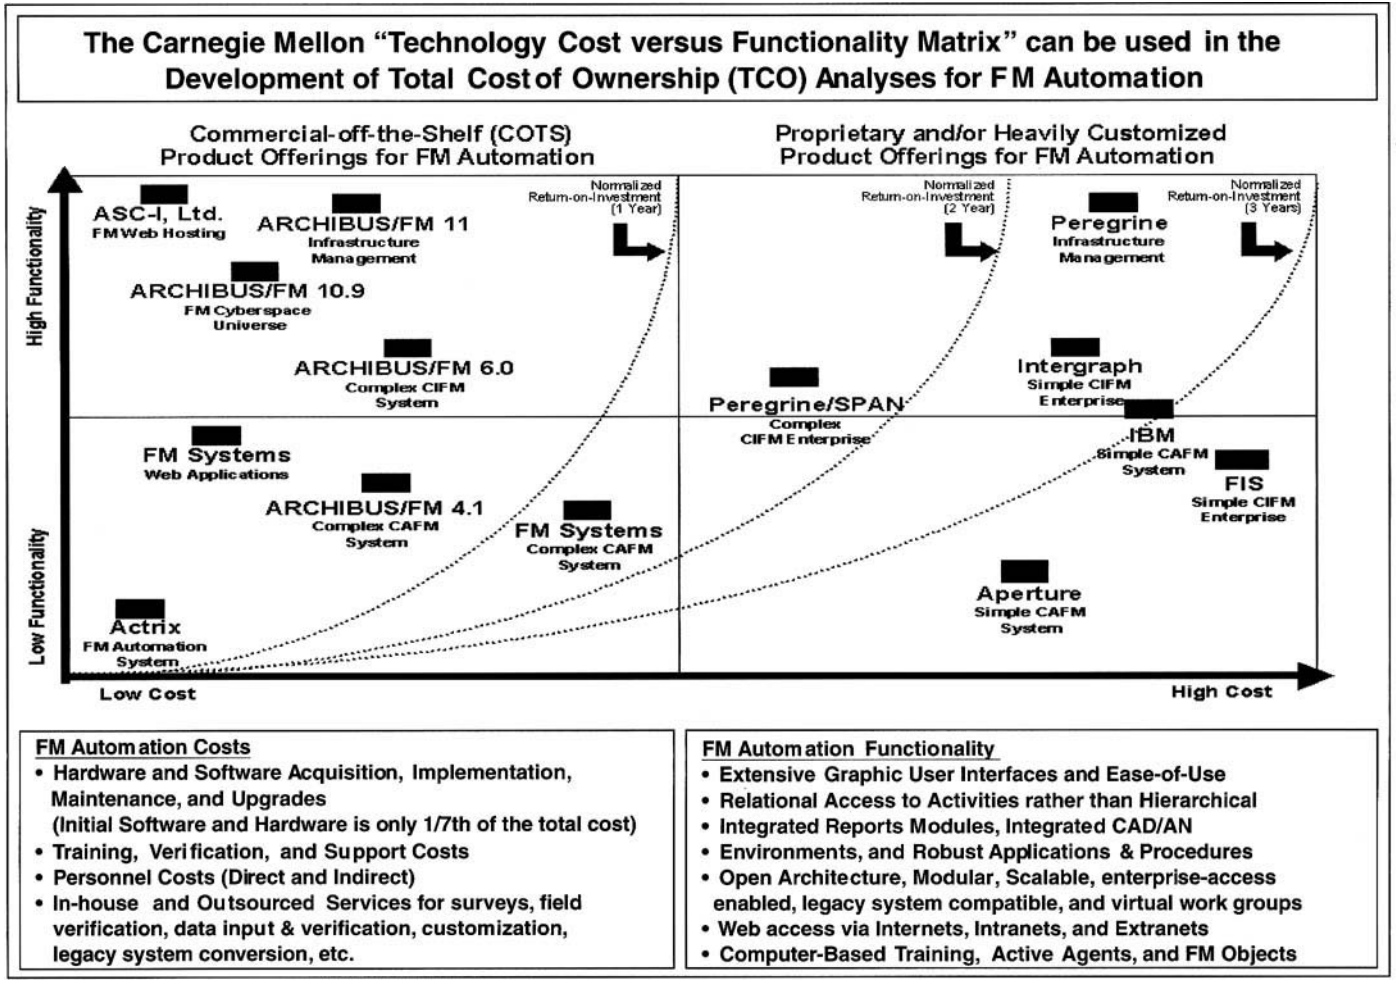

FIGURE 3.3.4-5 The return-on-investment (ROI) and the total-cost-of-ownership (TCO) will vary depending upon the type of systems acquired and implemented. However, it appears most corporations are acquiring one or more commercial off-the-shelf (COTS) systems (where the normalized ROI can be less than 1 year as compared with a 3-year ROI on proprietary systems). The placement of a product on the "FM Product ROI Evaluation Matrix" will vary client by client. The sample shown here is an evaluation of 14 products that was done for a product manufacturer with multiple sites in multiple countries. Based on this matrix, a company would evaluate their ROI needs and select one or more of the options available to them. (*Courtesy of Carnegie Mellon University and Facilities Management Techniques, Inc., January 2000.*)

Facilities management automation programs are generally available in these three categories:

1. The Stand Alone or Express Offering (for organizations with small or limited budgets)
2. The Enterprise Offering (for organizations with more substantial budgets and assets)
3. The Cyberspace Universes for FM Offering (for organizations of all sizes and all budgets)

How to Select the Right Tools for the Job. Selecting appropriate FM automation and IM solutions is a critical activity. Most organizations have eclectic "hybrid" solutions. Solutions exist for organizations of all sizes and capabilities. Consultants and friends who have done this before are great for helping you out in this area. If no one is available, you might begin by answering the three questions that are shown in (see Fig. 3.3.4-6). Having answered these questions, you may be able to determine the appropriate FM automation solution(s) for your organization. This worksheet is based on presentations made at numerous World Workplace conferences and IFMA Best Practices Forums.

Open Architecture, Scalability, and Modularity. Facilities management automation implementations that are oriented to cyberspace universes for FM and IM are, typically, designed with open architectures, scalability, and modularity. As an organization's FM automation activities expand, applicable legacy systems should be readily integrated with other offerings. Facilities management automation and IM solutions enable the integration of corporate databases readily with express or stand-alone, enterprise, and cyberspace universes for FM offerings (Fig. 3.3.4-7). Typically, corporate databases are used to connect information silos and islands of automation.

The Virtual Opportunity: Extending Classic Wide Area Networks and Enterprise Networks into E-FM and E-Space

As an organization expands its virtual network of employees and business partners, a high degree of feature integration over the wide area network (WAN) can be realized with suitable Intranet, frame relay, and ATM capabilities. In the near future, virtual private networks (VPNs) will become readily available to most facility organizations and will be the technology conduit to and from IM solutions (see Fig. 3.3.4-8). It is likely that these VPNs will be a required part of your corporate strategic IT initiatives.

Infrastructure Management with Cyberspace Universes for FM. There are, typically, three components of an IM solution: FM automation application programs, FM automation database management engines, and FM legacy systems integration and connectivity.

FM Automation Application Programs. Facilities management automation application programs usually fall into these seven application areas:

1. Real property and lease management
2. Strategic master planning
3. Space management
4. Design management
5. Furniture and equipment management
6. Telecommunications and cable management
7. Building and operations management

FM Automation Computer-Aided Design Engines. Facilities management automation products use a variety of computer-aided design (CAD) engines. Most FM automation and IM offerings have external links to one or more CAD products. The more advanced solutions have created seamless CAD interfaces or overlays with their product and/or have OEM CAD solu-

Selecting the Appropriate FM Automation and Infrastructure Management Solutions

	What size is your organization?	What do you want to do?	What solution is right for you?
	Small business with under 500 people setting up our first FM Automation Solution We do not have an IT Department or IT Specialist Portfolio Size: Less than 100,000 sq. ft.	• Provide basic capabilities • Help business expand • Keep track of critical assets • Outsource FM Web site activities	• Express Products • Stand-Alone Product Offerings • FM Web Central
	Medium-size business or department of a larger corporation expanding our FM Automation Activities We have limited access to the IT Department Portfolio Size: Less than 573 Million sq. ft.	• Provide additional capabilities • Help business expand • Keep track of critical assets • Build upon existing data, information, and knowledge • Build FM Web site	• Express Products • Stand-Alone Product Offerings • LAN-based CAFM Systems or Client/Server-based CIFM Enterprises • FM Web Central
	Medium to large corporation seeking to achieve strategic competitive advantage using FM Automation We have an IT Specialist and an IT Department Portfolio Size: Unlimited	• Provide advanced capabilities • Help business expand • Keep track of critical assets • Build upon existing data, information, and knowledge • Expand FM Web site • Develop Visual Infrastructure Management Solution	• Express Products • Stand-Alone Product Offerings • LAN-based CAFM Systems or Client/Server-based CIFM Enterprises • FM Web Central

FIGURE 3.3.4-6 Selecting the appropriate FM automation and IM solutions is a critical activity. Most organizations have eclectic "hybrid" solutions. There are solutions for organizations of all sizes and capabilities. (*Courtesy of ARCHIBUS Solution Centers, Ltd. and Facilities Management Techniques, Inc.*)

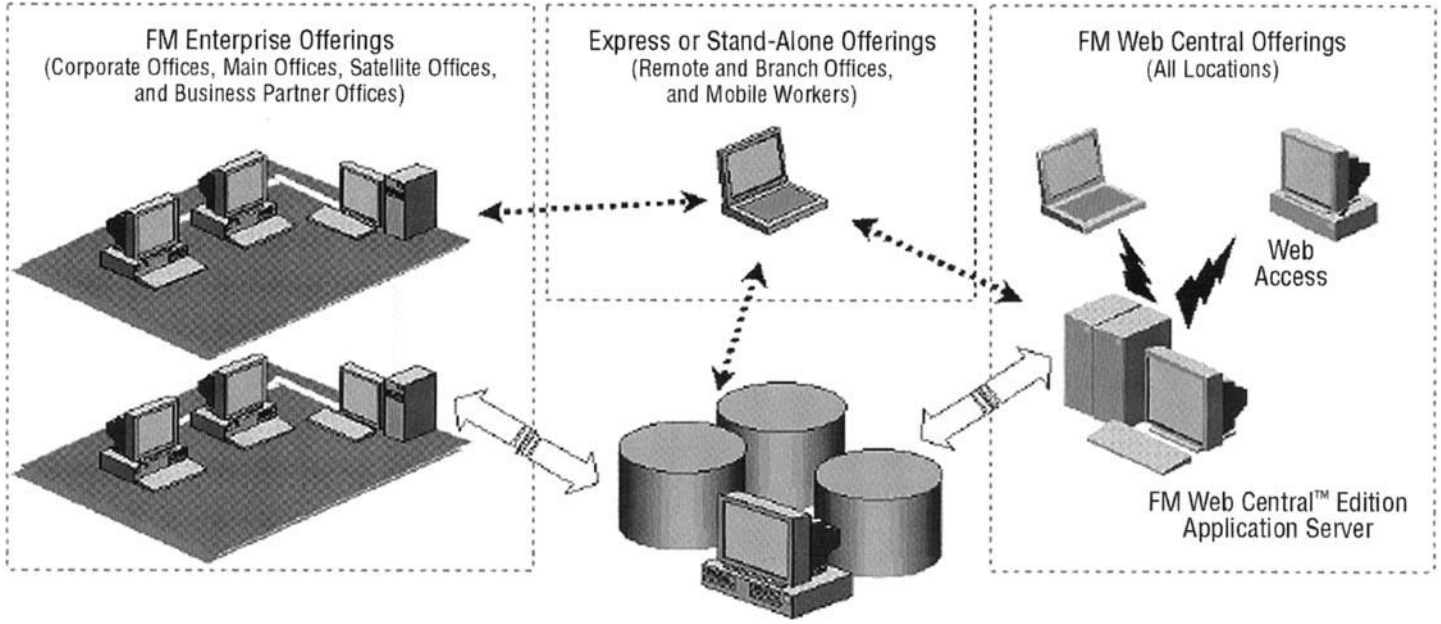

FIGURE 3.3.4-7 Advanced FM automation solutions are modular, scalable, have open architectures, and are readily integrated with existing legacy systems. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

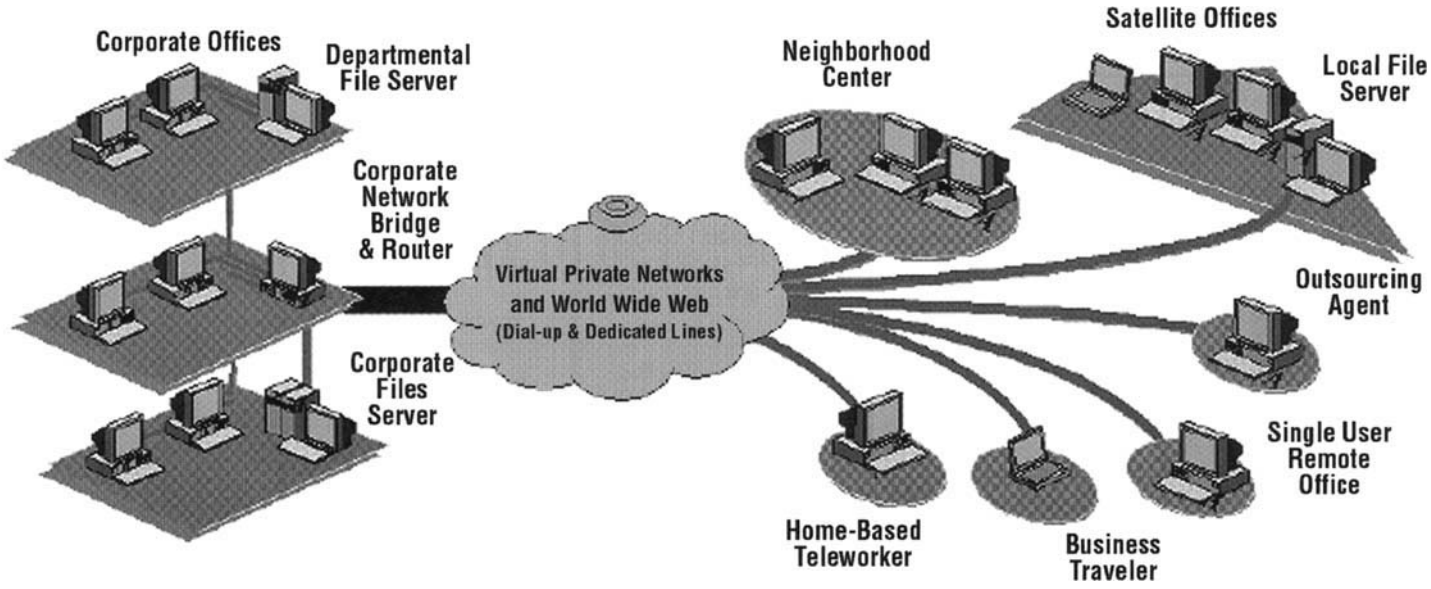

FIGURE 3.3.4-8 Virtual private networks (VPNs) will enable facilities organizations to connect with associates and business partners throughout their buildings and campuses, as well as throughout a city, region, nation, and around the world. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

tions actually embedded into their offerings. In the United States, some of the more frequently used CAD systems are AutoCAD®, Integraph® and Microstation®, Visio®, AutoCAD LT®, AutoCAD Sketch®, and Actrix®. Internet and intranet tools for CAD are being rapidly developed. At this time, some CAD product developers offer free downloads of their CAD-viewing software products. One system that has become very popular is Autodesk's Whip™.

FM Automation Database Management Engines. Facilities management automation products use a variety of database management engines. They range from Microsoft Access® for stand-alone applications to MS SQL Server®, Oracle®, ARCHIBUS/FM®, or Sybase® for the enterprise offerings. Cyberspace universes for FM applications can retrieve and deposit data, information, knowledge, and wisdom to a variety of database management engines.

FM Automation Legacy System Integration and Connectivity. Facilities management automation systems can extend their reach through connectivity with other existing legacy systems and islands of automation. Typically, more than 42 percent of the data and information used in FM automation can come from such existing applications and their associated databases.

The Top Twenty Reasons Why FM Automation Fails

There are many reasons why FM automation has failed within some facility organizations. Some of the top reasons include the following:

- FMA-IM red tape and bureaucracy
- Ineffective FMA-IM management teams
- Lack of proper FMA-IM direction
- Lack of clear FMA-IM goals and objectives
- Lack of tools to achieve goals and objectives
- Lack of suitable FMA-IM value postulates
- Lack of baseline FM data and FM information
- Poor FMA-IM "expectations" management
- Mismanagement by FMA-IM teams
- Anxiety and fear of achieving goals
- Unrealistic FMA-IM goals and expectations
- Poor FMA-IM training and refresher courses
- Lack of FMA-IM audits and reviews
- Poor FMA-IM communications
- Lack of suitable FMA-IM resources and time
- Poor FMA-IM business planning
- Lack of FM best practices and benchmarks
- Lack of FMA-IM knowledge workers
- Poor integration and data mining
- Lack of buy-in for FMA-IM activities

A Brief History of FM Automation

Some of the first uses of computers in the 1960s were for creating data for asset management and financial reporting. Now, we consider that there have been these eight generations of FM automations (see Fig. 3.2.4-9):

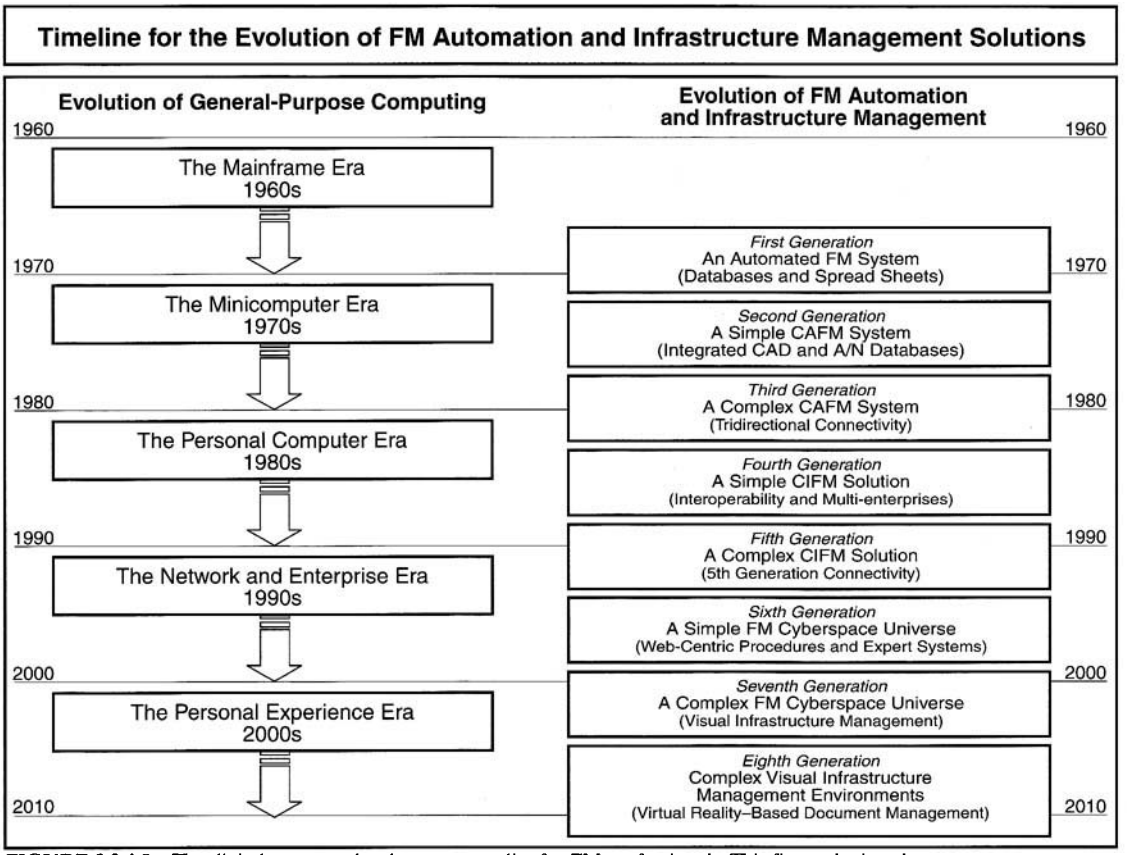

FIGURE 3.3.4-9 The digital economy has become a reality for FM professionals. This figure depicts the evolution of computer technology and FM automation. (*Courtesy of ARCHIBUS Solution Centers, Ltd.*)

- *First generation.* Alphanumeric applications such as spreadsheets and databases (with limited or no CAD system connectivity)
- *Second generation.* Simple CAFM systems [stand-alone or local-area-network (LAN)–based bidirectional connectivity between CAD and A/N databases—a change in a CAD drawing was automatically reflected in the A/N database and vice versa]
- *Third generation.* Complex CAFM systems (stand-alone or LAN based tridirectional connectivity between A/N databases, CAD, and visual display databases such as photographs and video files)
- *Fourth generation.* Simple Computer-Integrated Facilities Management™ (CIFM™) enterprise solutions (stand-alone, LAN, and/or enterprise-based solutions with interoperability and multienterprise connectivity)
- *Fifth generation.* Complex Computer-Integrated Facilities Management Enterprise Solutions (stand-alone, LAN, and/or enterprise-based solutions with interoperability and multienterprise connectivity and/or CIFM-to-CIFM enterprise connectivity at a local, regional, national, and/or global level)

- *Sixth generation.* Simple cyberspace universes for FM (e-commerce enabled Web-centric offerings with expert systems and best-of-class processes and procedures for the FM executive)
- *Seventh generation.* Complex cyberspace universes for FM with connectivity to IM enterprises and cybermedia applications for FM [e-commerce enabled Web-centric offerings with expert systems and best-of-class processes and procedures for the FM executive with limited connectivity to ERP and infrastructure resource planning (IRP) systems]
- *Eighth generation.* Complex IM environments (virtual by design, e-commerce-centric Web offerings with expert systems, artificial intelligence, and best-of-class processes and procedures for the FM executive: The IM environment provides extensive connectivity to legacy systems, IT silos, and data warehouses found in such systems as ERP, help desk, and IT infrastructure systems)

Significant Milestones in the History of FM Automation

Although numerous significant milestones exist in the history of FM automation and IM, it is helpful to examine the generations of FM automation products against similar metrics (see Table 3.3.4-3).

How FM Automation Integration and Utilization Improves Effectiveness, Productivity, and Profitability

The net result is that FM automation significantly increases productivity and profitability. Now, the three most commonly implemented FM automation systems include computer-aided facilities management (CAFM) systems, computer-integrated facilities management (CIFM) enterprise solutions, cyberspace universes for FM, and IM environments (see Fig. 3.3.4-10). These technologies are changing the way companies do business.

The CAFM systems combine the power of nongraphical and graphical databases. A CAFM system enables you to organize and access data and information that is critical for managing your assets—from office space to furniture and equipment, from real estate to strategic master planning, and from telecommunications and cable management to computerized maintenance management. These CAFM systems are usually configured as stand-alone systems or on LANs.

The CIFM enterprise solutions go a step further and extend the reach of your FM data, information, and knowledge enterprise-wide to provide the information that strategic and business managers within your organization need to make better planning and policy decisions. The CIFM enterprise solutions are usually configured for enterprise-wide access, but they are also available for LANs and stand-alone configurations with enterprise connectivity.

Cyberspace universes for FM combine the power of FM automation technologies such as CAFM systems, CIFM enterprise solutions, information management resource solutions, and ERP solutions with new millennial technologies and best practices into a globally accessible depository of FM data, information, knowledge, and wisdom. The expert systems and knowledgeware cultivated within cyberspace universes for FM enable executives to incorporate relevant best practices and benchmarking applications into the daily activities of their organizations.

Infrastructure management environments seamlessly integrate and combine the power of numerous corporate silos of information management and yield collective FM data, information, knowledge, and wisdom. Typical stand-alone automation silos might include CAFM systems, CIFM enterprises, cyberspace universes for FM, ERP and IM systems, IT infrastructure systems, building automation systems, CMMSs and building operation management systems (BOMSs), help desk and telephony systems, legacy systems, and finance/administration systems.

TABLE 3.3.4-3 A Historical Perspective of FM Automation and IM Solutions

Generation of FM automation products	Stand-alone applications	Stand-alone applications	Integrated CAFM systems	CIFM enterprise solutions	Infrastructure management and cyberspace universes for FM
The five paradigms of computing	Mainframe era Batch processing	Minicomputer era Time-shared environment	Personal computer era PCs and work-stations w/networking	Network and networking with client/servers	Personal-experience era Digital nervous systems
Years	1960s	1970s	1980s	1990s	2000s
Computer location	Computer room "fish bowls"	Terminal rooms	Desktops	Mobile	Virtual
Users	Experts	Specialists	Grouped individuals	Groups	Individuals
Primary directives	Calculate	Calculate and access	Calculate, access, and present	Calculate, access, present, and communicate	Calculate, access, present, communicate, and mind meld
Data	Alphanumeric	A/N, text vectors, and CAD	A/N, CAD, fonts, and bitmaps	A/N, advanced CAD, fonts, and graphics	A/N, advanced CAD and graphics, audiovisual, and virtual simulations
Connectivity	Peripherals	Peripherals and terminals	Peripherals terminals, LANs, and WANs	Peripherals terminals, LANs, WANs, RANs, SANs, GANs, and client/servers	Peripherals, terminals, LANs, WANs, RANs, SANs, GANs, client/servers, and virtual area networks (VANs)
Languages	Fortran, Basic, and COBOL	Fortran, Basic, COBOL, PL/1, and RPG	Fortran, Basic, C, Visual Scripting, and LISP	C, Visual Scripting, LISP, C++, and Java	C, Visual Scripting, LISP, C++, Java, and ActiveX FM Objects™
Applications	Customized	Standardized with moderate customization	Generic applications with moderate customization	Commercial off-the-shelf (COTS) with minimal to moderate customization	COTS with minimal customization, E-FM™, E-Space™, CFM™, and FM Cyberspace™
Application costs	$500,000 to $2,000,000	$50,000 to $200,000	$5,000 to $100,000	$2,500 to $50,000	5 cents per transaction to $25,000

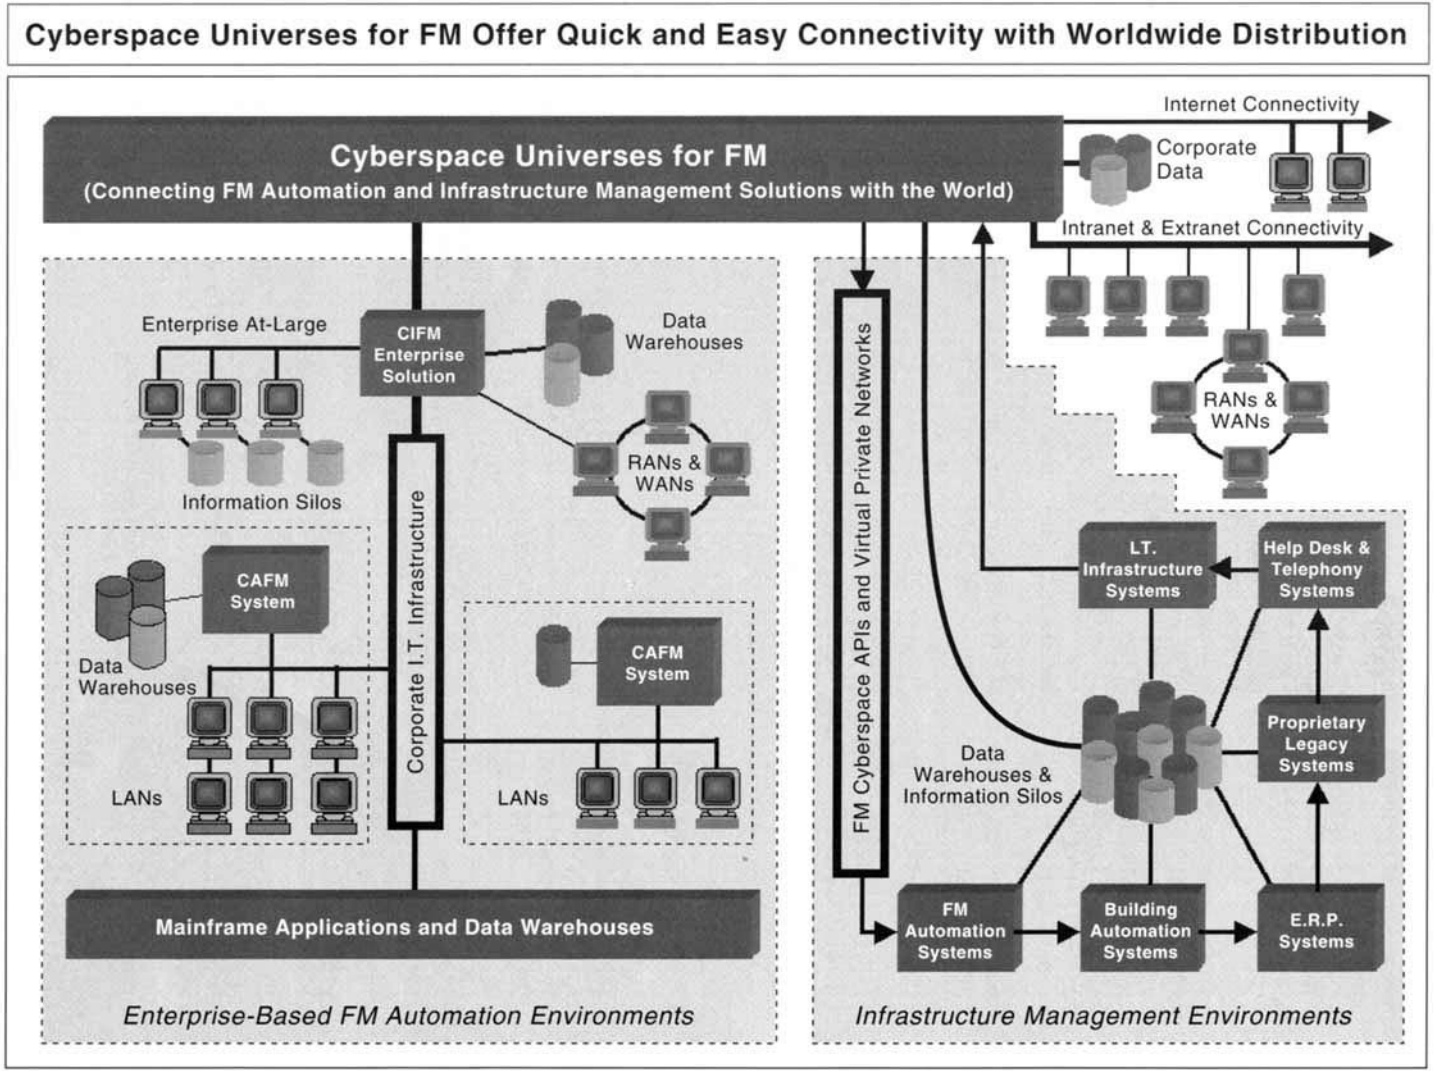

FIGURE 3.3.4-10 Cyberspace universes for FM provide seamless connectivity (to FM automation and IM environments) and the TCO is reduced. Such connectivity enables the rapid deployment of automation with full connectivity to exiting legacy systems such as CAFM systems, CIFM enterprises, ERP systems, IT infrastructure systems, and help desk and telephony systems. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

FM Automation—Easy and Intuitive to Use

Familiar Microsoft Windows™ conventions, such as toolbars, pull-down menus, multiple windows, and dialog boxes make working with FM automation easy. Comprehensive and context-sensitive, on-line help systems can support your learning process. Other special task-oriented menus, called FM automation *navigators* and *process toolbars,* provide intuitive interfaces. Just as the names suggest, the navigator and process toolbars guide you step-by-step through complex FM procedures, showing you where to start, what information to enter, and what types of reports you can derive from the information. Many industry-specific FM methodologies and reports are already built into FM automation, so you can put your information to work immediately.

Seamless Integration. The core application of FM automation software typically links a facilities database with associated CAD drawings, so that changes cascade automatically throughout the system. This activity ensures the accuracy of your data, reduces errors, and eliminates file duplication. The application modules allow you to work simultaneously with multiple facility drawings and data tables. You can even perform all of your FM tasks from within CAD, computer-aided design and drafting (CADD), geographic information systems (GIS), and document management systems.

Dynamic Reports. Based on user experience, FM automation software providers have developed literally hundreds of preformatted reports that meet the needs of a wide range of users. These reports and database queries come built into many products—simply point and click to select the information you need. You can then easily fine-tune the style and content of your reports using a standard dialog interface.

FM Automation for the World Wide Web

Facilities management automation for the Web is the foundation of cyberspace universes for FM. Best-of-class Web technologies have been expanded into a powerful extension of the CAFM, CIFM, ERP, IRM, and customer relationship management (CRM) environments. Inexpensive and easy to use, cyberspace universes for FM enables you to expand the connectivity of FM automation to anyone, anywhere, who is connected to your corporate intranet or the Internet at large, via the World Wide Web. Anyone who uses your organization's facility information will benefit from the use of FM automation for the Web. Unlike other versions of FM automation, cyberspace universes for FM enables the most casual of users to learn quickly how to interact with the applications. Training time is only a matter of minutes.

THE TOP SEVEN FM AUTOMATION APPLICATION AREAS

Facilities management automation environments are typically built around *application control programs,* or *cores,* with *application modules* that address various FM issues. Facilities management automation enterprises also offer a variety of *enterprise access interfaces* or *user interfaces that are visual* for both the creators and consumers of FM data, information, knowledge, and wisdom. You can put together any combination of these elements to fashion the ideal CAFM-CIFM-cyberspace universes for the environment in your organization.

Real Property and Lease Management Applications

Facilities management automation real property and lease management address the needs of commercial property managers, corporate lease managers, building owners, and tenants,

enabling you to record detailed real estate and lease data and to use the information to produce valuable reports and analyses. You can track real-world conditions, such as the impact of lease terms on chargebacks, along with time-dependent elements, including options, escalations, or terminations. You can model complex real estate and lease holdings on a national or even global scale and summarize their revenue potential and performance. A wealth of tools is provided for performing detailed cost tracking, budgeting, and sophisticated financial analyses of your properties.

Tracking Leases and Options. You can easily track important lease provisions and stay on top of activities that have potentially costly repercussions, such as hazardous material abatement or responding to tax assessment or lease notifications.

Chargebacks. You can develop chargeback strategies that model the subtleties of real-world conditions and allow you to charge back costs to buildings, leases, or departments. You can designate certain charges to be applied, or not, according to the negotiated terms of each particular lease.

Budgeting. You can create budgets for properties, buildings, leases, departments, and accounts for categories you define, and you can model your initial budget on your actual costs, on last year's budget, or on costs projected from recurring transactions, such as regular lease revenues or payments.

Maximizing the Use of Space. By integrating intelligent CAD plans with your real estate database, you can accurately model your holdings and determine how efficiently space is being used. You can create occupancy plans to highlight vacant, rentable space, for example, or reclaim lost space that is currently not included in any negotiated lease area.

Mapping a Corporate Strategy. With accurate property and lease profiles in hand, corporate executives can monitor the profitability of each property, lease, or building, and make more cost-effective decisions: What did maintenance cost last year, and should we outsource it? What portion of our expenses was due to a high tax rate? We are considering selling off one of our divisions; what is the total asset and liability summary for the property that that division occupies? For answers to these questions and more, decision makers can turn to real property and lease management applications.

Strategic Master Planning Applications

In the power-packed world of mergers and acquisitions, strategic master planning has become a necessity in valuing and repositioning an organization's assets. Strategic master planning applications extend and expand the power of planning from your FM organization to your boardroom. Professionals who manage a single property, a campus, or a diverse portfolio of buildings sprawled across a city or region will gain tremendous benefits by using the techniques and methods incorporated in strategic master planning applications. Value for facilities professionals is created even while dealing with the complexities of downsizing, mergers, acquisitions, and expansions. Strategic master planning divides the tasks of the strategic master planning process into five areas of activity that may be used individually or collectively to optimize business assets and efficiency: (1) requirements programming, (2) forecasting, (3) allocation, (4) layout, and (5) history.

Requirements Programming. Inventory the data you will need to formulate your organization's strategic planning goals. Data may include departmental affinities, square footage needs, types of space required, duration of need, and so on.

Forecasting. Make informed decisions about future space needs based on those of each department. The data collected during the requirements programming phase of the process allow you to forecast with confidence, using built-in methodologies and user-defined variables.

Allocation. Space is allocated on the basis of your organization's various business goals. One of the most useful automation features available to the facilities manager, the *stack diagram,* is typically available within the allocation activity.

Location. Once you have determined how to best allocate available space, the next step is to design an optimal layout that defines the location of each organizational unit on each floor. One of the most widely used methods for laying out a floor plan is *blocking.* Blocking is based in part on automatically generated stack plans and trial layouts.

History. Maintaining a historical record of the way space was used in the past is very useful in planning for future space requirements. It can provide "snapshots" of your space inventory at various times during your organization's evolution. This activity also enables you to compare trends in the usage of space during different periods.

Space Management Applications

Facilities management automation space management applications enable you to create and maintain an accurate and up-to-date record of all areas in your buildings (a living electronic inventory of your space) and how they are used. By integrating your facilities data with CAD drawings, business graphics, and picture files, FM automation allows you to organize and analyze space information in various ways. Reports can be products that will help your organization make the most of its assets. Users can determine how efficiently space is being used, identify rentable or leasable areas, calculate space costs and chargebacks, and create quick tenant or employee occupancy plans.

Take Control of Your Space. Facilities management automation space management applications make it easy to develop intelligent databases and drawings that track the use of space within your buildings.

Choose the Right Chargeback Method. Once you have developed a space inventory and associated the areas with cost centers, tenants, or other organizations within your company, you can determine how much space each group uses and bill them accordingly.

Analyze Your Data with Predefined Reports. Built upon the experience of thousands of FM operations, the FM automation space management applications typically provide a multitude of preconfigured reports and analyses that immediately allow you to study and interpret your data. You can draw up occupancy plans and determine usable and rentable areas, calculate space efficiency rates or the average area per employee, perform space planning exercises, and more.

FM Automation Overlays for CAD and GIS. Common to most FM automation environments today are supplemental tools, such as FM automation design management overlays that empower CAD- and GIS-based facility drawings and data. Now you can create facility drawings, develop asset symbols, register them in a database, and perform asset symbol edits and database updates—all from within CAD and GIS environments—by using the latest "active objects" drafting tools. These tasks, along with the specialized architectural drafting tools and database tables of the FM automation design management overlays (*overlays*), enable facility managers, architects, and interior designers to create and maintain facility record drawings easily.

Seamless Integration. The features of elegant overlays are indistinguishable from built-in CAD and GIS commands. By adding a series of pull-down menus to a CAD or GIS system's

own menu bar, overlays enable you to connect to a project database that contains your facility information and to perform FM tasks. From within a CAD system, for example, you can connect to an FM automation project, create a room polyline, and assign it intelligence, such as a room number and department assignment. This information, along with the polyline's area, is posted directly to the Rooms table of the project database.

Powered by Reactors or Expert Systems. With reactors and expert systems, such as the ARX™ or "AutoCAD Runtime Extension™" for AutoCAD™, the overlays can react directly to notification of events sent by the CAD system. This means that the overlay knows when you load a drawing, save a drawing, or edit, copy, mirror, or erase asset symbols. For instance, if you use the CAD system's copy command to copy an autonumbered furniture item, the overlay automatically creates a record in the database and links it to the new drawing item. Then, if you generate a furniture standards inventory report in the FM automation environment, it will reflect this change.

Asset Symbols Possess Facility Intelligence. Room, group, furniture, and equipment asset symbols know what type of facility object they represent and assume the correct behavior when copied, mirrored, or erased with typical CAD commands. What is more, for asset symbols located within a group, room, or other boundary, you can infer the values of the enclosing boundary. You can also apply values set for the entire drawing, such as building and floor codes, to new asset symbols that you create.

Furniture and Equipment Management Applications

Furniture and equipment assets represent a substantial investment for any organization and can have a direct impact on productivity. This is why the effective management of these assets is vital to your bottom line. Using the simple, but powerful, inventory tracking capabilities of FM automation furniture and equipment (F&E) management applications, you can easily monitor the cost of your assets, calculate depreciation and churn rates, plan moves of furniture and equipment, and more. Bar code support and built-in forms for surveying your assets help you develop and maintain a useful and reliable inventory of information that will enable you to make better planning and policy decisions.

Access Up-to-Date Information. At the core of effective asset management is the need to maintain a historical record of the disposition of your assets—their condition, location, employee, and cost center assignments. By providing easy access to this information in data tables and CAD/GIS drawings, F&E management allows you to define and enforce corporate standards, plan moves, and produce a variety of reports.

Easy Layout and Move Planning. Visualize a variety of new layouts by rearranging or adding asset symbols to your CAD floor plans. Then, create reports that compare the move and acquisition requirements of each proposed layout to determine the most effective plan of action.

Speedier Asset Surveys. Gathering inventory information can be tedious and time-consuming, but F&E management speeds the process by providing built-in survey forms. It also supports bar code technology for faster, easier, and more accurate data entry. Bar coding and chip implants for F&E management are becoming commonplace.

Itemized Cost Tracking. Furniture and equipment management allows you to track financial data throughout the life of an asset: its original value, current value, accumulated depreciation, and, when sold, the gain or loss on the asset. From this data, you can create a variety of summary reports according to cost center, property type, and so on.

Insurance and Warranty Tracking. Locating insurance information for any asset is as simple as entering the item's bar code. Instantly, you have access to its policy value and expiration

date. You can also determine appropriate insurance coverage by running a risk management report, comparing an asset's insured value against its original, current, and replacement value.

Track Assets Alphanumerically and/or Graphically. You can document your F&E assets only in the database or link them to block definitions added to your CAD drawings.

Telecommunications and Cable Management Applications

Voice and data communications are the lifeblood of business today, making the maintenance of this vital infrastructure a mission-critical task. Facilities management automation telecommunications and cable management applications enable you to create a living, electronic inventory of the physical cabling and telecommunications network connections in your facility. With easy access to detailed and up-to-date connectivity information, you can draw network plans, troubleshoot problems, or move employees with minimal disruption.

Track Your Infrastructure. There is no need to create a complete cable inventory before you begin to reap benefits from a telecommunications and cable management application. Its flexible design allows you to start tracking your network connectivity immediately, at any level of detail, and build gradually on the information. Create an inventory of all of your telecommunications devices and their connections. Identify devices by physical and logical LAN or WAN segments and by their levels in the hierarchy of the overall network.

Speed Cable Connections. Seamless links with CAD drawings through the FM automation design management overlays enable you to speed your work considerably. You can quickly determine where to lay new cables through a cable distribution network, find open ports on existing equipment, trace the connections from one device to others in its path, highlight devices based on criteria such as type or status, and more. You can also connect devices in your drawings simply by clicking on one and then the other. Interactive queries instantly pull up data for equipment, cables, and their connections. Database queries can graphically trace a particular network device or all devices that would be affected by a given action.

Maintaining Your Infrastructure. Managing your telecommunications and cables allows you to maintain the most up-to-date databases and drawings of all telecommunications devices and their links for data and voice networks.

Building Operations Management Applications

Facilities management automation building operations management applications are often comprehensive, integrated CMMSs that help keep your facilities running smoothly and minimize your operating costs. With fast and easy access to critical facilities information, you can more efficiently document and monitor maintenance or repair work, schedule employees or outside contractors to perform the work, maintain an accurate inventory of supplies, and budget the costs. A variety of predefined reports allows you to analyze maintenance histories and expenditures to help you prepare for future demands on your facilities.

Automated Work Orders Speed the Process. Communication is the key to keeping your facilities operating at peak efficiency. By using electronic work requests and work orders to report, track, and analyze problems, you can manage all of the tasks involved in a timely fashion. Anyone in an organization can request work, check on the status of a job, or report on its progress simply by clicking on an icon and entering information in a dialog box. Built-in forms help you process work requests quickly by assigning priority ratings and scheduling resources. Tracking the status of ongoing maintenance work allows you to maximize productivity and resolve backlog issues (see Fig. 3.3.4-11).

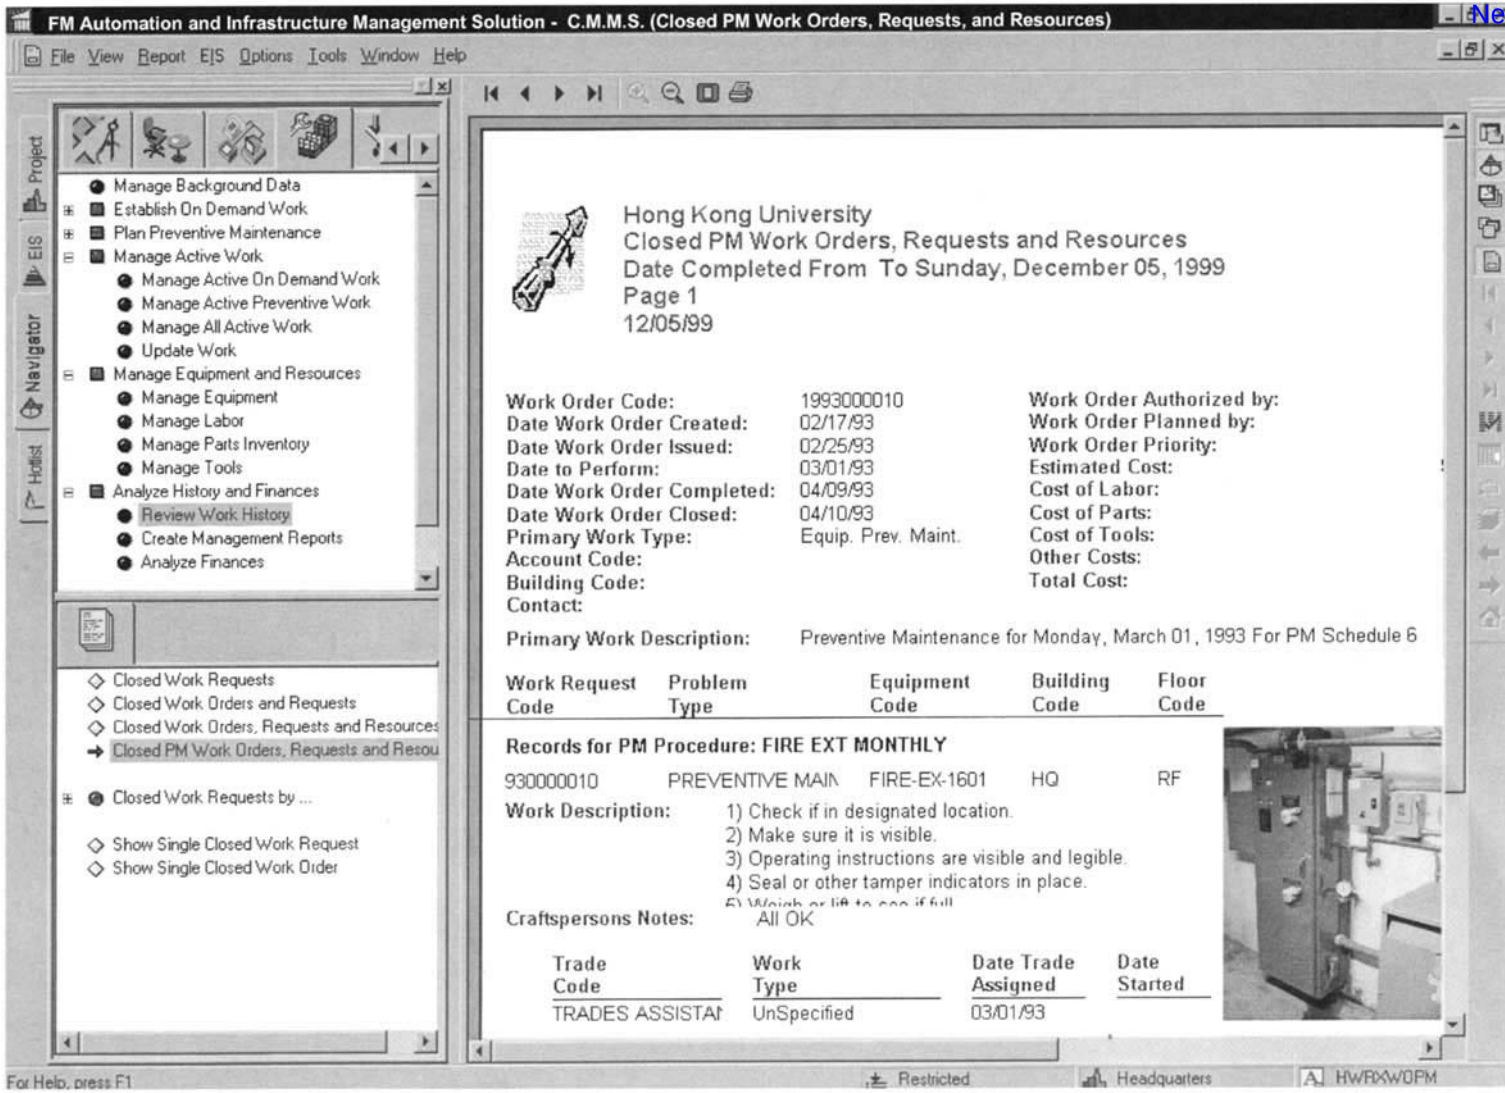

FIGURE 3.3.4-11 FM automation application: screen capture from a "Building Operations Management" application work session (Management Review of Work Requests and Work Order Resolution). (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

Maintain Peak Efficiency with Preventive Maintenance. Automatically scheduling regular preventive maintenance (PM) procedures is the most efficient way to prevent costly breakdowns and downtime. Built-in methodologies can help you schedule regular maintenance or housekeeping tasks at fixed or floating intervals and adjust the schedules to manage conflicting demands on your resources. You can also define complete PM procedures, step-by-step, as well as generate automatic work requests.

Manage Equipment and Resources Effectively. Cost and availability of equipment and resources can impact many of the operating decisions you make every day. By tracking detailed information on your equipment assets (including location, usage, parts, warranty, and service information), you can generate many ad hoc reports and queries. Tracking workloads and labor availability can help improve the efficiency and performance of your labor force, and maintaining an adequate inventory of spare parts and tools ensures that sufficient resources are available when you need them. You can even use bar code technology for easy, accurate data entry.

Analyze Work History Costs. Building operations management helps you learn from experience, so that you can forecast future operating costs and requirements and support your long-term facilities plans. Various reports allow you to review and summarize work histories, analyze labor usage, and generate cost expenditure reports by buildings, departments, or cost centers.

Comply with Regulations. Flexible data collection and customization allows you to maintain data pertinent to EPA and OSHA regulations. Track equipment lockout or tag-out status, mean-time-between-failure or repair (MTBF/MTBR) statistics, or performance histories, and establish PM procedures in compliance with regulations.

Working with Drawings. If you choose to use CAD drawings with building operations management to show graphical locations of maintenance problems, you have several options for developing your information. Start with existing CAD drawings or create new facility drawings, using the application's simple drawing tools to outline room areas and insert equipment asset symbols, or use facility drawings already developed with the space management or F&E management applications (see Fig. 3.3.4-12).

INFRASTRUCTURE MANAGEMENT STRATEGIES FOR ENTERPRISE WEB CONNECTIVITY

Facilities management applications on the World Wide Web serve as a foundation for cyberspace universes for FM. The world of technology-based best-of-class Web technologies is being expanded into a powerful extension of CAFM and CIFM environments. Inexpensive and easy to use, Internet/intranet applications enable you to expand the connectivity of IM and ERP information to anyone, anywhere, who is connected to your corporate intranet or the Internet at large, via the World Wide Web. In the next few years, Internet/intranet applications will become a critical part of Infrastructure Management™ systems.

In Search of Value for Your Customers

Creating value is increasingly more difficult for facility managers who face corporate and organizational challenges. Their internal customers are more price conscious and knowledgeable about buying FM-related services and products, they face tighter deadlines and need more timely information about their corporate real estate assets, and they are more uncertain about their futures and their facility's needs.

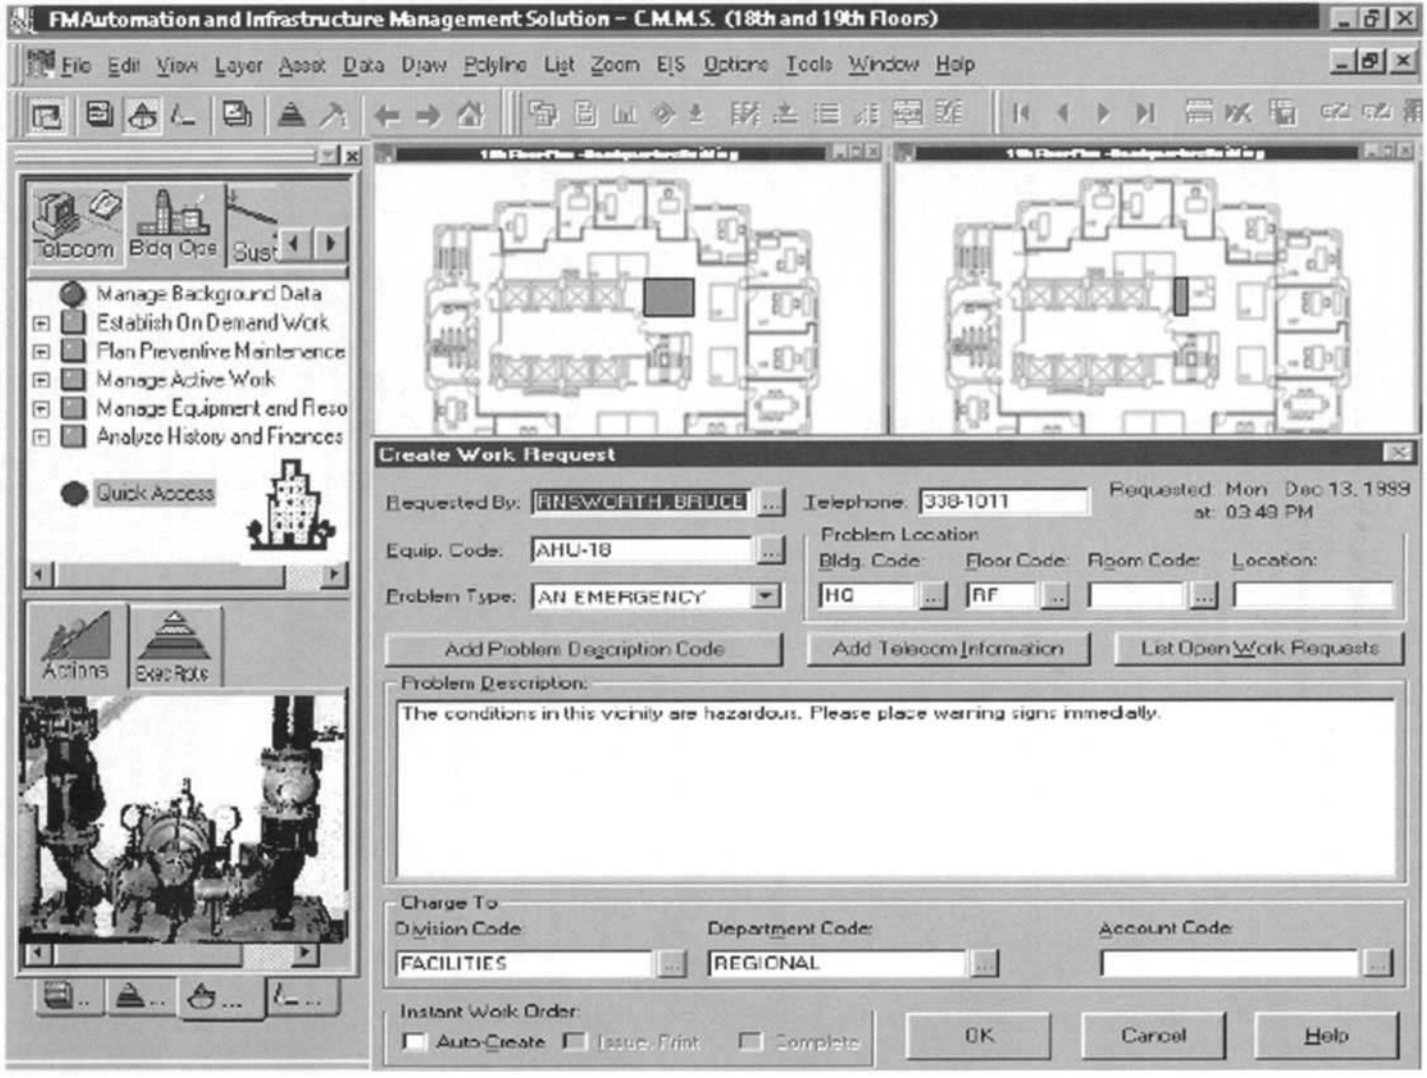

FIGURE 3.3.4-12 FM automation application: screen capture from a "Building Operations Management" application work session (Create a Work Request). (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

By Web-enabling their facilities, FM professionals (FMers) can hone their company's competitive edge with business processes unconstrained by time zones or distance. They can communicate their FM vision to the corporation at large, accurately assess conditions throughout their facilities to make the best use of resources, and collect the critical data the company needs to execute its business plan. Internet/intranet applications enable a facility manager to become a key, visible, dependable player in the strategic planning process. Activities previously available only in enterprise solutions are now finding their way to the Web (see Fig. 3.3.4-13).

Forging a New Role with Internet/Intranet Applications

Facilities management cybrarians create value by intelligently using cyberspace universes for FM. They are the "caregivers," facilitators, composers, and orchestra leaders of FM data, information, and knowledge, and they are the creators of FM wisdom. Facilities management cybrarians and their teams work in a place now known as *cyberspace universes for FM.* At the heart of cyberspace universes for FM is a depository and control center of FM automation data, information, knowledge, and wisdom. It is a repository for the accumulated knowledge and wisdom of one's peers and for the experience of one's organization. Instant access to this repository is through a variety of user interfaces. Similar to the user interfaces found in enterprise-based FM automation solutions, which require training, cyberspace universes for FM versions require only a 1- to 5-minute consultation to learn how to use and produce the same result in many cases.

The Key to Success Is Communication

As soon as data are entered into an Internet/intranet application, updated information and active work orders are immediately available to anyone who needs them. Field personnel can call up active work requests in their area on a laptop hooked to a mobile phone. At a meeting in the boardroom, the facility manager can instantly access answers to unexpected questions. Through increased communication, Internet/intranet applications facilitate the creation of value in the enhanced understanding of key issues at headquarters, in the review of branch office requirements, or in the accelerated responsiveness of field personnel. Through Internet/intranet applications, facilities managers can keep their fingers on the pulse of their facilities, while at the same time decreasing the FM department's cost to respond.

Extend Your Organization's Competitive Edge

By connecting your facility to the World Wide Web, Internet/intranet applications will extend your company's competitive edge with business processes not constrained by time zones or distance. It will change the way you do business and give universal access to up-to-the-minute facility information, instantly, anywhere in the world, 24 hours a day, 7 days a week. Internet/intranet applications can serve as a help desk for your customers' self-service information. It will increase the accuracy of your FM information by enabling remote data collection and increase your control of the global enterprise by integrating information from headquarters, regional offices, and branch offices (see Fig. 3.3.4-14). In this example, the FM automation system has combined data and information from an HR system (photographs and personnel profile) with the facilities information (floor plans, F&E databases, telephone and e-mail directories, etc.) to create an "employee—locate and highlight room" report.

Use E-Commerce Tools to Communicate Your Vision

Just as the Web makes your company globally visible, Internet/intranet applications will make your corporate FM efforts globally visible and instantly accessible. Use the Web to promote your FM department's efforts, advertise your capabilities and internal services, and promote

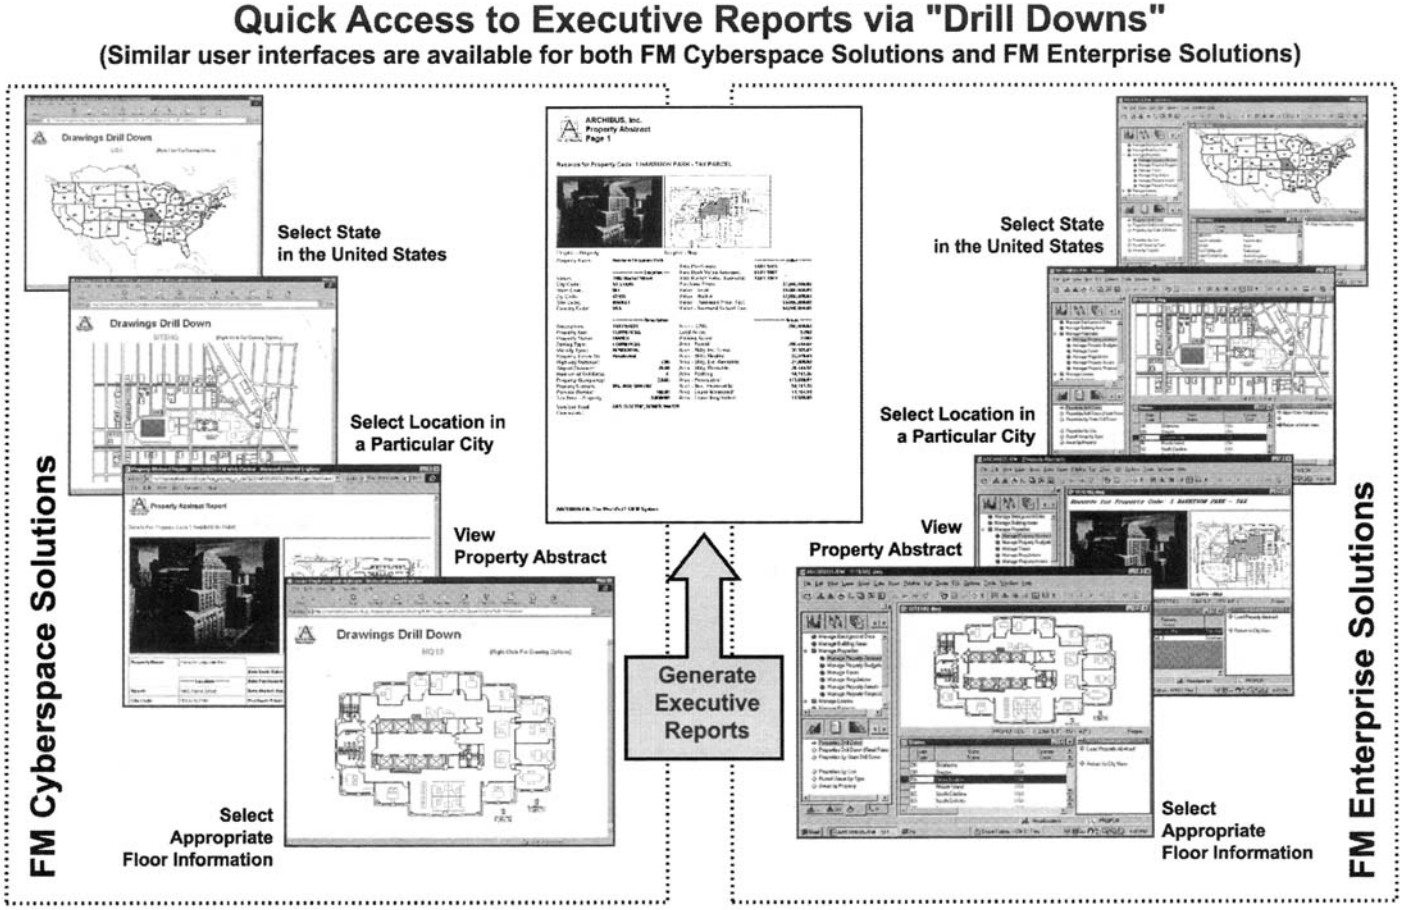

FIGURE 3.3.4-13 Infrastructure management environments enable executives to drill down for corporate information using either enterprise-based executive information systems or Web interfaces. Both systems yield fast, intuitive, accurate information in a timely manner. It is as easy as 1-2-3. . . . (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

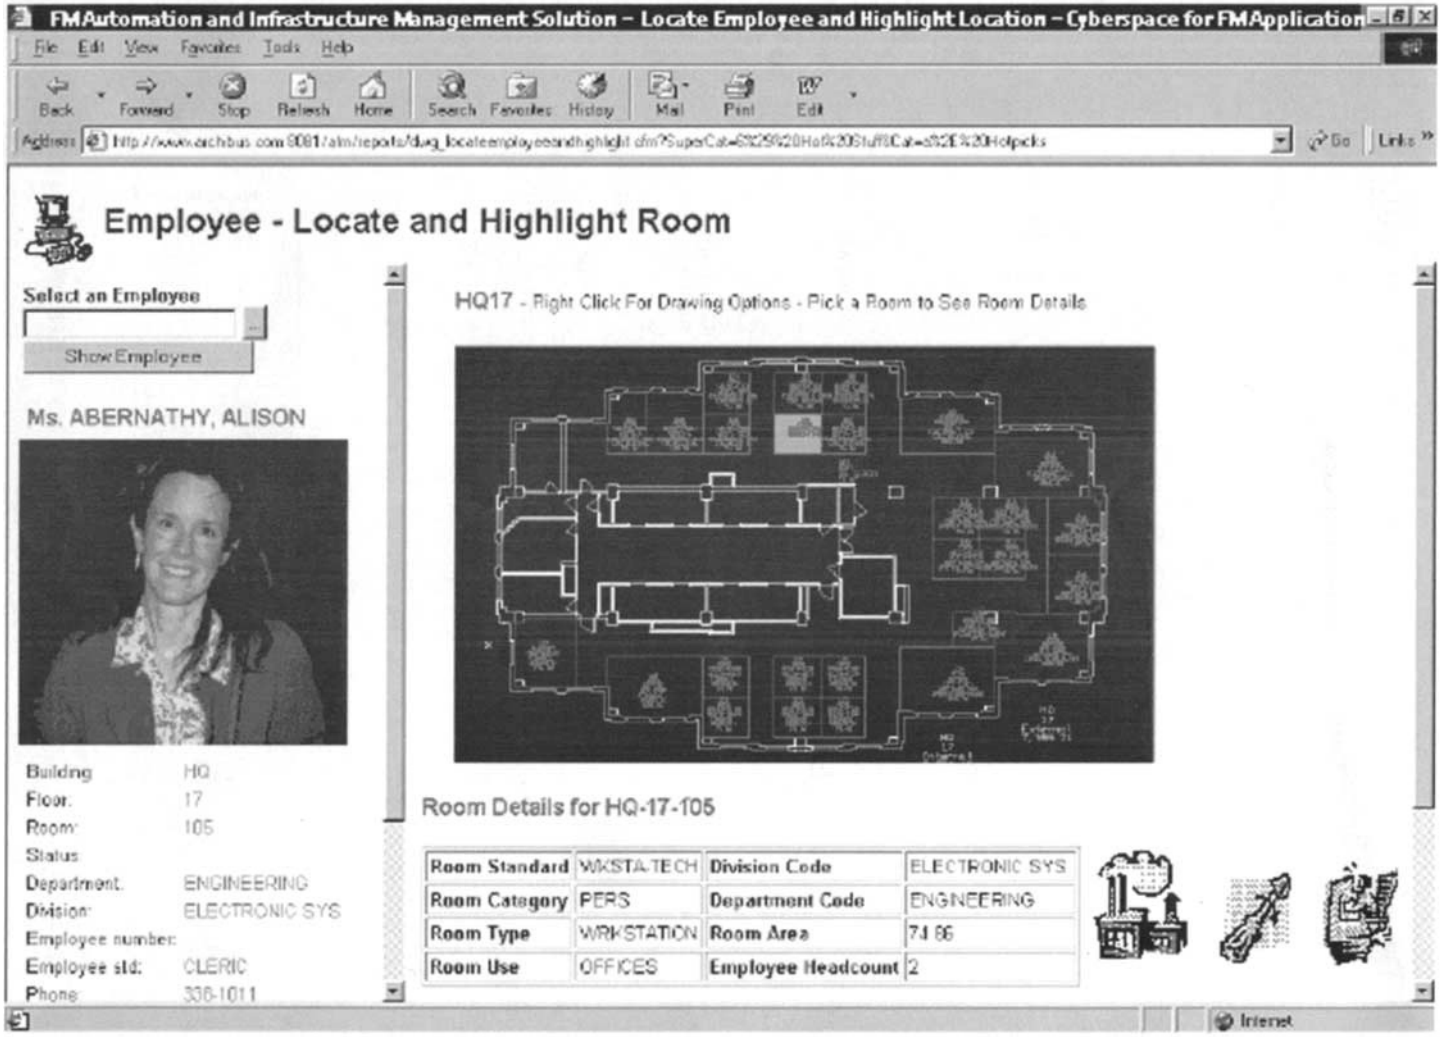

FIGURE 3.3.4-14 FM cyberspace offerings enable connectivity to hundreds of blue-chip software packages via the Internet. In this example, the user can view an AutoCAD drawing showing an office location, SAP HR data, and ARCHIBUS chargeback data simultaneously. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

and enforce your working practices. Use Internet/intranet applications to communicate your FM vision to the corporation at large. Accurately assess conditions within your entire organization to make best use of corporate resources and collect the critical data your corporation needs to execute its business plan. Internet/intranet applications will make you a key, visible, dependable player in the strategic planning process.

Seamless Interface into Your Corporate Web Strategy

Internet/intranet applications are designed to interface into your corporate Web, which has been developed by your corporate MIS department, and leverage their resources. Internet/intranet applications can be entirely open; you can link them to any corporate intranet page; you can use any Internet/intranet application's dynamic form or report on your own Web page. Internet/intranet applications are your productivity powerhouse for dynamic publishing of large numbers of drawings and structured FM data. If there is a report you need that is not provided, you can, in minutes, publish any Internet/intranet application's view to dynamic pages, complete with drill-downs and paging of large results. Internet/intranet applications put all the technological pieces together, so you get the glory (see Fig. 3.3.4-15).

Who Can Benefit from Using Internet/Intranet Applications? Anyone who uses your organization's facility information will benefit from using Internet/intranet applications. Internet/intranet applications do everything that IM systems can do, from anywhere in the world.

Facility managers can access their facility information anywhere, anytime. They can provide users of facility information with self-service mechanisms that enable them to access information or make work order requests, for example.

Field personnel can easily and efficiently pick up work order requests from remote locations, saving them time and helping them determine what tools are needed for a job before they arrive. Branch office personnel can access home office information in real time.

Strategic planners can immediately provide themselves with the historical information they need to make important planning decisions.

Purchasing managers can verify invoices against inventories and track back orders.

Human resources managers can develop occupancy plans and locate vacant space for new hires.

Building owners can determine rentable areas and bill tenants for the space they occupy, plus their share of common areas.

Corporate real estate managers can track detailed lease characteristics, such as options, payments, and prorated taxes.

Accountants can use space data to charge departments for the areas they occupy, plus their share of common areas.

Risk managers can evaluate assets to obtain adequate insurance coverage.

Tradespeople, maintenance staff, and building tenants can take advantage of remote access to facilities information.

REPORTING CAPABILITIES OF FM AUTOMATION SOLUTIONS

The greatest strength of FM automation lies in its phenomenal reporting capabilities. Based on more than 2 decades of experience, FM automation software providers have developed literally hundreds of formatted reports that have been designed to meet the needs of a wide range of users. To illustrate the value that FM reports can offer your organization, a few key reports from each of the FM automation applications are shown in Table 3.3.4-4.

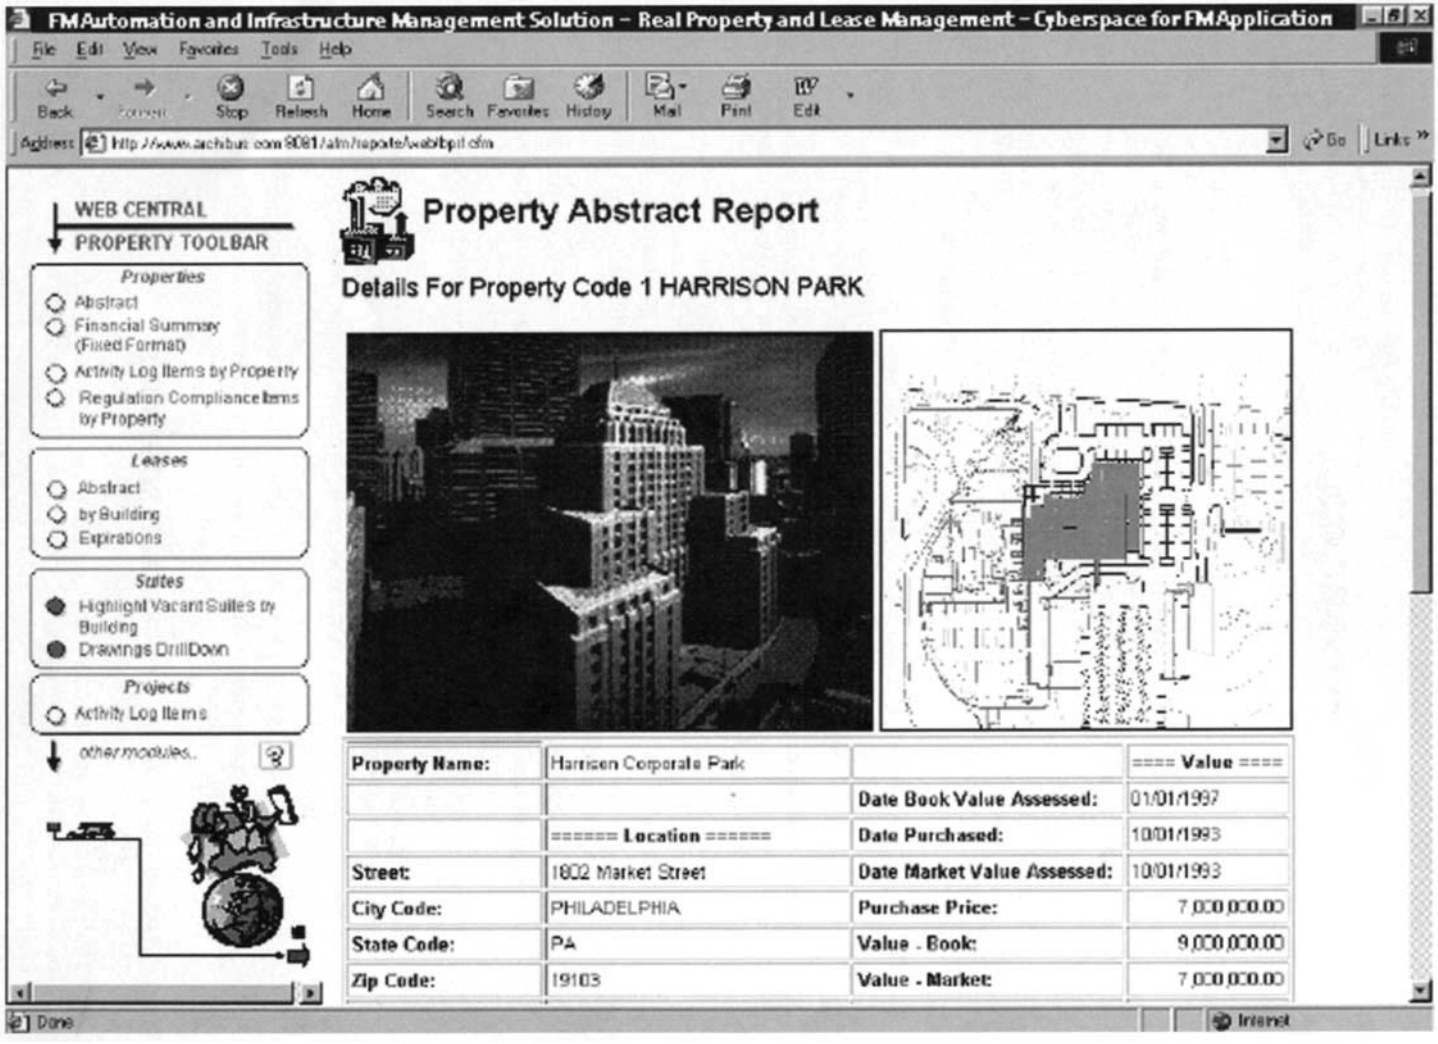

FIGURE 3.3.4-15 Visual user interfaces (such as the FM Web Central Process Toolbar shown) enable rapid training. With just 5 minutes of training/tutoring, corporate real estate executives, CEOs, CFOs, and CIOs can readily access real estate information and hundreds of other reports and analyses. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

ARTICLE 3.3.5

FACILITIES MANAGEMENT AUTOMATION AND INFRASTRUCTURE MANAGEMENT AUDITS

Bruce Kenneth Forbes
ARCHIBUS, Inc., Boston, Massachusetts

In the area of facilities management (FM) automation and infrastructure management (IM), there are four "audits" that are beneficial to facilities organizations.[1]

1. *The needs assessment and opportunity audit.* This is an examination of an organization to determine the business and operational needs it has for deploying automation. If there is a need, an opportunity audit is performed to determine if the circumstances are conducive for an organization to undertake FM automation and/or IM activities (see later section entitled "Core Competency Areas as They Relate to FM Automation and IM Opportunities").
2. *The technology audit.* A survey and audit of existing/legacy systems and proposed technologies is conducted. The processes for these technologies and the use by the various departments within an organization are evaluated, analyzed, and documented.
3. *The management audit.* An exploration of management groups to determine their knowledge, expectations, and understanding of FM automation and IM.
4. *The implementation audit.* This is an examination of the implementation procedures and practices to determine areas of concern and/or opportunities for improvement.

There are numerous reasons why your organization should conduct FM automation and IM audits regularly. Following are some of the most often stated reasons:

- Increased quality of delivered systems
- Improved development productivity

- Reduced development cycle time
- Reduced development costs
- Increased usability of systems
- Improved alignment of systems to support corporate strategies
- Increased return on investment (ROI)
- Increased human–computer interaction
- Increased partnering results
- Creation of world-class FM value

CONSULTING PROCESS FOR AUDITS: FORMAT AND DEPTH OF THE AUDITS

The format and depth of exploration during an audit will vary from organization to organization, but most audits undertake similar activities. The consulting process for FM automation and IM audits is shown in Fig. 3.3.5-1. The figure highlights the five parts of an audit process mapped against the client's and the consultant's documentation of activity requirements and tasks. Audits should be part of any strategic planning process. The audit is a bridge between management and FM automation and IM leadership teams. The five stages of an audit might be

1. *Definition stage.* Frames early client discussions into articulated sets of expectations and commitments.
2. *Structure stage.* Analyzes the expectations and commitments to structure an approach to engagement.
3. *Gathering stage.* Uses explicit and implicit approaches to gather data, information, and knowledge, and summarizes it into findings.
4. *Synthesis stage.* Synthesizes the results of the data, information, and knowledge gathering into documents, which focus on client opportunities and the ramifications of acting or not acting.
5. *Buyin stage.* Uses the synthesis-stage documents, the consultant's FM knowledge and wisdom, input gained from interactions with client and gathering activities, and an understanding of change management to assist the client in achieving buyin.

Each activity requirement and task can be broken down into a series of subactivities and subtasks. A detailed data gathering activity matrix for FM automation and IM audits is shown in Fig. 3.3.5-2.

FM Automation and IM Needs Assessment and Opportunity Audit

Typical audits include the following roles:[3]

- Identify the needs to be addressed in the audit.
- Document the prescribed process to be undertaken and the expected benefits.
- Structure and schedule activities to be undertaken.
- Select participants and areas to be audited.
- Provide roundtables, interviews, and reviews of legacy information.
- Establish groundwork and foundation activities.

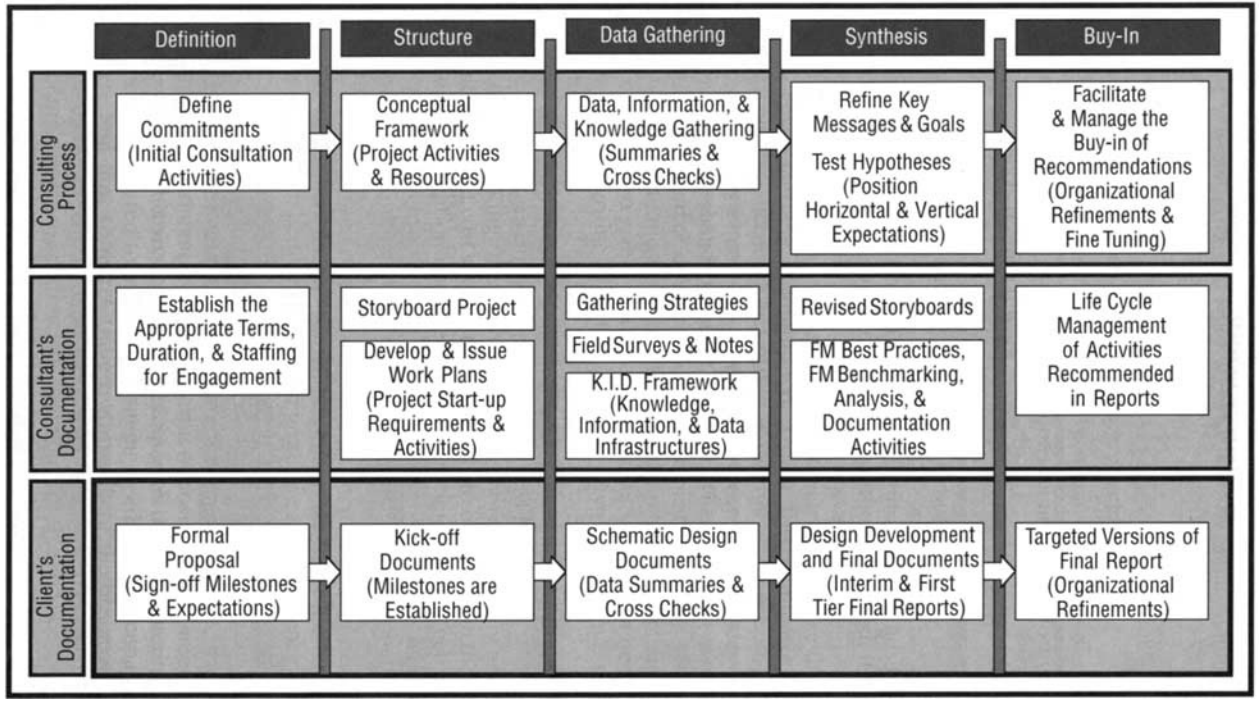

FIGURE 3.3.5-1 The consulting process for FM Automation and Infrastructure Management Related Audits: The Five Primary Stages in an Audit Process as mapped against the client's and the consultant's documentation requirements/tasks. (*Courtesy of ARCHIBUS, Inc.*)

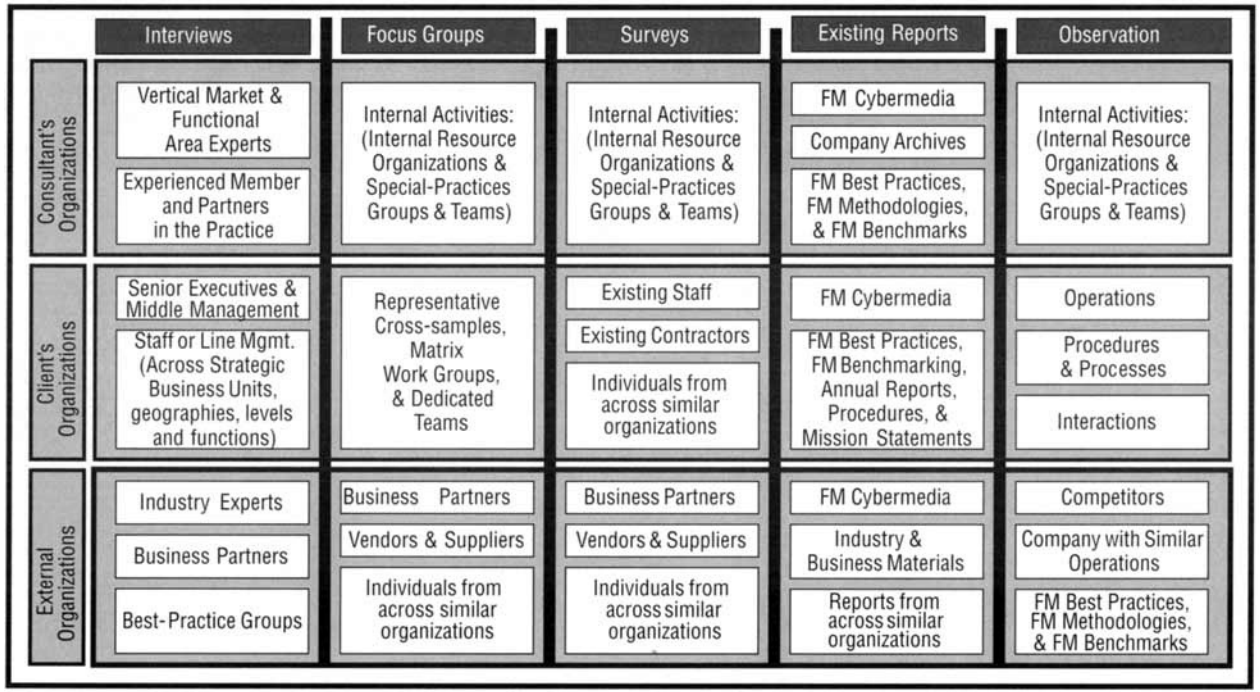

FIGURE 3.3.5-2 Detailed data gathering activities matrix for FM automation and IM audits. (*Courtesy of ARCHIBUS, Inc.*)

- Conduct audit.
- Review data, information, and knowledge.
- Prepare a written document.
- Submit document and publicize applicable findings.
- Implement action items and prepare for next audit cycle.

Having determined the processes and procedures to be undertaken during the audits, your FM automation and IM leadership team is ready to begin.

Needs Assessments and Opportunity Audits Are a Great Place to Start

The process of implementing a computer-aided facilities management (CAFM) system, computer-integrated facilities management (CIFM) solution, cyberspace universes for FM, or IM enterprise poses challenges to even the most well-managed facilities operation. You can easily take advantage of the knowledge and experience of experts in the field. One of the best places to start is an assessment and opportunity audit of FM automation needs.

Assessment of FM Automation Needs

The goal of this procedure is to determine the requirements of an organization for managing its physical assets and facilities processes. An organization should establish milestones to be cyclically reviewed during FM automation and IM audits. These are the six standard milestones for FM automation acquisition:

1. *Awareness of pain.* Begins when you become aware of some level of dissonance between what is and what could be.
2. *Articulation of symptoms.* Requires articulating and defining symptoms, which begin to limit what can constitute a solution or an opportunity.
3. *Envisioning the solution.* Is complete when you have "bought the concept" that a specific service will reduce the dissonance.
4. *Review of available suppliers.* Begins with shopping for the consultant who can best provide the specific service you require.
5. *Definition of technical requirements.* Requires articulating and defining technological requirements, which begin to limit what can constitute a solution or an opportunity.
6. *Selection of business partner.* Is complete when one service provider meets the criteria and demonstrates the ability to optimize your preferences.

Typical Assessment/Audit Activities. The analysis usually involves 1 or 2 days of an on-site visit followed by 1 or 2 days of analysis and reporting. The following areas will be addressed:

Preliminary assessment. Before the on-site visit, communication is initiated to establish some guidelines and structure for the on-site visit and involves the following:

- Identifying and prioritizing FM needs
- Collecting any relevant materials that the organization can provide to demonstrate current methods, data, reporting, capabilities, controls, processes, and support organizations
- Establishing an initial analysis approach and milestones
- Analyzing corporate and organizational strategies and processes

Analysis of current FM resources and opportunities. The first stage of the on-site visit includes the following key activities:

- Analyzing current FM capabilities and training requirements
- Evaluating processes, procedures, reporting, and presentation requirements
- Reviewing current space and asset standards and FM benchmarks
- Understanding the relevant business issues that need to be addressed

Investigation of data requirements. The next major area of review includes:

- Evaluating current data models
- Understanding the FM organization's current core competency
- Examining current data sources and translation requirements

Analysis of data access and reporting requirements. Maximizing the benefits of the information provided when implementing FM automation and/or IM solutions is analyzed by the following:

- Examining additional reporting benefits
- Analyzing executive information needs
- Identifying key methods and procedures
- Evaluating data flow requirements
- Investigating additional distributed information benefits to other organizational units

Implementation plan and analysis report. The resulting analysis report incorporates the following tasks:

- Translating conceptual requirements into deliverable entities
- Establishing the key system parameters and components
- Identifying key tasks and milestones
- Determining an action plan and timeline alternatives
- Defining ongoing technical needs
- Periodically reviewing core competency areas as they relate to FM automation

Using external consultants to develop and implement regularly scheduled audits and review activities is recommended.

FM Core Competency Areas as They Relate to FM Automation and IM Opportunities

Facilities professionals need competency in numerous areas. The following areas are readily identifiable for FM automation and IM:

- Real estate and property management
- Best practices and environmental management
- Strategic planning and project management
- Benchmarking and facility functions
- Finance and administration
- Quality assessment and operations management
- Marketing and communications
- Operations and management

Each FM organization should develop its own matrix of automation goals and milestones, based on its FM core competency areas. The FM automation and IM applications, which the organization has decided to implement, should be highlighted and monitored (see Table 3.3.5-1).

To Create or Not to Create Your FM Automation Solution

Facilities management organizations can pursue a variety of application development strategies. During the various audits and needs assessments, your organization should determine its strategy for FM automation and IM deployment.

TABLE 3.3.5-1 Each FM Organization Should Develop Its Own Automation Targets Matrix Based on the "The Primary FM Competency Areas" and Those FM Automation Applications That the Organization Has Decided to Implement

Competency areas	Core competencies to be addressed with FM automation	Real estate	Space mgmt.	F&E * mgmt.	Telecom mgmt.	BOM *& CMMS*	FM WEB activity
Real estate and property management	1. Manage and implement the real estate master planning process.	X	X				X
	2. Manage real estate assets.	X	X				X
Best practices and environmental factors	3. Develop and implement practices that promote and protect health, safety, security, and the quality of work life, the environment, and organizational effectiveness.	X	X	X	X	X	X
	4. Develop and manage emergency preparedness procedures.	X	X	X	X	X	X
Strategic planning and project management	5. Develop facility plans.	X	X	X	X	X	X
	6. Plan and manage all phases of projects.	X	X	X	X	X	X
	7. Manage programming and design.	X	X	X	X	X	X
	8. Manage construction and relocation.	X	X	X	X	X	X
Benchmarking and facility functions	9. Plan and organize the facility function.	X	X	X	X	X	X
	10. Manage personnel assigned to the facility.		X	X			X
	11. Administer the facility function.	X	X	X	X	X	X
	12. Manage the delivery of the facility function.	X	X	X	X	X	X
Finance and administration	13. Manage the finances of the facility function.	X	X	X	X	X	X
Quality assessment and innovation management	14. Manage the process of assessing the quality of services and the facility's effectiveness.	X	X	X	X	X	X
	15. Manage the benchmarking process.	X	X	X	X	X	X
	16. Manage audit activities.	X	X	X	X	X	X
	17. Manage development efforts and innovation.	X	X	X	X	X	X
Communications	18. Communicate effectively						X
Operations and maintenance	19. Oversee building system A-I-O-M.*	X	X	X	X	X	X
	20. Manage the maintenance of interiors.	X	X	X	X	X	X
	21. Oversee F&E A-I-O-M.	X	X	X	X	X	X
	22. Oversee grounds and exterior elements A-I-O-M-D.*	X	X	X	X	X	X

Source: Adapted by ARCHIBUS, Inc. from *Competencies for Facilities Management Professionals,* IFMA.
* AIOM, ; AIOMD, ; BOM, building operation management; CMMS, computerized maintenance management system; F&E, furniture and equipment.

- *Make.* Engineer a new solution.
- *Update.* Maintain an existing solution.
- *Renovate.* Reengineer an existing solution.
- *Buy.* Purchase a new commercial off-the-shelf (COTS) software solution and customize it.
- *Integrate.* Assemble a new solution from available components.
- *Outsource.* Commission outside development skills with particular responsibilities.
- *Postpone.* Provide other solutions first, based on priorities.
- *Offload.* Enable end users to meet their own computing needs.

Now, existing legacy systems, islands of automation, and information silos have made hybrid solutions very common. Currently, the purchase of COTS software solutions is the most popular alternative in MIS departments. Such groups often cite time and cost savings as primary factors.

FM Automation Requires a Full Range of Support Services

Successful FM automation requires that the facilities professional acquire a full range of support services. Some of the more common services available include:

- *FM automation reviews.* The resources, information, and equipment necessary for FM automation may already exist in your organization. If you have already invested in data collection, software, or hardware, an FM automation consultant or services provider can provide a number of strategies for optimizing these resources.
- *Database creation and verification.* Organizations are generally prepared to maintain their facilities data, but they often need help with the initial process of collecting, entering, and verifying that data. Such intensive data entry projects might support furniture and equipment (F&E) audits or space occupancy inventories.
- *Database creation guidelines.* When different individuals in different departments or outside vendors enter data, it is vital to maintain a consistent format suitable for automatic processing, such as issuing queries. Database guidelines help enforce standards and ensure that everyone enters data in the same way.
- *Drawing translation.* Your FM automation provider can help you extend the usefulness of your existing data by converting paper drawings or drawings from an older CAD system into facility record drawings and integrating them into your FM automation system.
- *System customization.* If your organization has specific reporting needs, your FM automation provider can help you determine which pieces of information are critical and configure your FM automation system accordingly.
- *Design, implementation, and management of enterprise access system.* Increase the value of your facility information by making it more accessible to upper management. Your FM automation provider can help you develop a graphical and alphanumeric model of your facility that provides point-and-click access to strategic information, using any of FM automation's enterprise access solutions.
- *Web-based and professional service organization resources.* There are numerous on-line services that let you connect with other FM automation users, dealers, FM professionals, professional organizations, and technical support personnel over the information superhighway.
- *Telephone technical support.* This is readily available from numerous friendly, knowledgeable, and responsive FM automation customer support teams. A technical support contract can be purchased from the numerous FM automation software and service providers.

- *FM automation users' groups.* Your local FM automation users' group offers the perfect forum for sharing information and experiences with other users in your area. Members of the FM automation community from around the world typically gather annually at International FM Automation Users' Conferences for several days of educational sessions, workshops, and industry forums.
- *Workshops and seminars.* Workshops and seminars that are frequently held in locations across the country and around the world offer free software demonstrations and useful insights designed to help you make the most effective use of FM automation tools.
- *Checklists.* Develop checklists for the numerous audits, reviews, and implementation activities. For examples, see Tables 3.3.5-2 and 3.3.5-3.
- *FM automation work teams.* Perform regular, ongoing FM work using FM automation.

TABLE 3.3.5-2 The IM Master Audit Checklist

✓	Activity	Description	Purpose
	1.0.0	Executive summary of master audit (identify purpose of proposed activity).	Management overview of activity to secure executive management buyin.
	1.1.0	Identify IM activity components.	Software, hardware, technology applications, procedures approaches, methodologies, and previous experience, FM Benchmarks™, FM Best Practices™, and FM Value Matrices™.
	1.2.0	Identify the primary, secondary, and future activity areas.	Integrated support programs, facility management, project management, corporate services, security, finance, accounting/procurement, etc.
	1.3.0	Identify real estate, property, and assets that are to be managed (identify common asset traits and needs).	Distinguish among manufacturing, back-office space, leased versus owned properties, and assets, etc.
	1.4.0	Establish working teams for IM activities.	Review current methods and procedures. Set objectives. Identify base IM needs analysis. Identify and prioritize projects.
	1.5.0	Technology audit.	Review existing systems, IT benchmarks, and their integration.
	1.6.0	Opportunity audit.	Identify goals for IM activities: Improve processes, encourage local/regional/global consistency, match appropriate software with tasks, limit and/or avoid duplication of effort, offer greater flexibility, provide cost-efficient solutions, a variety of user interfaces for easy use, etc.
	1.7.0	Business audit.	Identify best-practice activities and benchmarks for application areas: real estate and lease management, strategic master planning, space management, design management, project management, F&E management, telecommunications and cable management, BOM and computerized maintenance management, finance and administration, ERP, and IM.
	1.8.0	Management audit.	Identify group of IM decision makers. Identify group IM goals. Identify business issue IM drivers. Develop benchmarking techniques. Identify expectations and wish lists. Develop evaluation techniques.
	1.9.0	Executive audit.	Review all of the previous activities.

TABLE 3.3.5-3 The IM Implementation Checklist

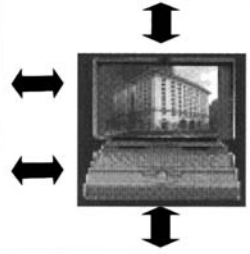
✓	Activity	Description	Purpose
	2.0.0	Executive summary of IM implementation activities.	Management overview of activities.
	2.1.0	Identify IM project support business plan.	Needs analysis and business objectives. Budgeting and staffing. Justification of IM (ROI, ROE, ROA, etc.). Risk assessment.
	2.2.0	Identify the primary and secondary implementation activities.	Projects support. Implementation benchmarking. Pilot projects (comprehensive or incremental). Supplemental activities.
	2.3.0	IM technologies design and implementation practices.	Identify COTS, proprietary, customized, and personalized offering requirements with suitable integration.
	2.4.0	Establish working teams for IM activities.	Project sponsors. Business project manager. Business subject matter contributors. IM technical project managers. IM technical experts. IM implementation experts. IM communications liaison. IM systems administrator. IM trainer. IM Web master. IM activity leaders. Casual Infrastructure Users™. Infrastructure Contributors™. Infrastructure Managers™.
	2.5.0	Project management and risk assessment.	Identify open issues and risks. Predict failure rates and identify fixes. Failure mitigation and contingency planning.
	2.6.0	IM requirements and analysis activities.	Business needs and conditions models. Business requirements and expectation models. Project management models. Technical requirements models. Data warehouse and use models. Knowledge and wisdom management models. IM sequencing and sign-off activities.
	2.7.0	Evaluation and reimplementation analyses.	Buy, build, customize, and integrate solutions. Evaluate and select vendors. RFI/RFP models and evaluation. Sign-off activities.
	2.8.0	Derivative IM change management activities.	IM targets. IM-driven organizational changes. IM change agents. IM opportunities.
	2.9.0	Executive implementation audit.	Review all of the previous activities. IM corrective maintenance. IM preventive maintenance. IM predictive maintenance. IM proactive maintenance.

- *FM automation project team.* Knowledge workers drawn from different FM functional units for the purpose of strategic planning, implementing, and managing FM automation and IM solutions.
- *FM automation management team.* Responsible for the overall performance of the automated facilities function and the organizations it serves.
- *FM automation ad hoc network.* Informal collections of individuals, groups, and business partners connected by shared interests, purposes, or goals that affect FM automation and IM.
- *Parallel development teams (for CIFM activities).* Special FM-related task forces responsible for coordination, problem solving, and improvement-oriented tasks.

Five Phases of Cyberspace Universes for FM Development and Deployment

The fast-track phases of transforming a business with cyberspace universes for FM solutions, the Internet, and IM offerings was found on the Internet and presented at an FM automation user's conference (see Fig. 3.3.5-3).[1] The five fast-track phases are as follows:

1. The Foundation Phase (Month 1)
   Planning your strategy
   Building an organization and infrastructure
   Stakeholders and Inter/Intra/Extranet Strategy
   Creating an on-line personality and branding strategy
   Publishing your content (includes link strategy)
   Using advanced Internet technologies
2. The Exploitation Phase (Month 2)
   E-mail, fax, and phone communications
   Research the competition
   Research market trends and customer requirements
   Create a free educational resource or educational delivery mechanism
   Establish business relationships worldwide
   Find the lowest-cost item for all purchases
3. The Business Extension Phase (Month 3)
   Interacting with stakeholders
   Using instant and automated interactive strategies
   Extending the reach of your corporate databases
   Extending the reach of your corporate applications
   Linking into back-end work flow processes
   Managing corporate intellectual capital as an asset
4. The Business Innovation Phase (Month 4)
   Embracing/capitalizing on the Internet and IM economy
   Building a community environment
   Proactively reaching out to your stakeholders
   Conducting commercial transactions
   Building Web traffic and activity
   Reengineering your business processes



Activity	1st Month	2nd Month	3rd Month	4th Month
Strategic Planning	- Executive Interviews - Focus Groups - Document Findings - Create Mgmt. T.F.	Present Findings		
FM Automation and Infrastructure Management Opportunity Audit	- Identify Products - Conduct Audits at Existing Sites	- Site visits to Manufacturer and clients where appropriate	- Conduct Pilot/ Feasibility Audit - Pilot Legacy System connectivity activities	- Post-Pilot Audit and Evaluation - Select Products, Services, & Suppliers
Design Implementation	- Develop Processes - Meet Op. Mgmt. Team - Develop Electronic Workshop/Backbone	- Collect Data & Info. - Consolidate Findings - Initial Planning	- Review Findings with Op. Mgmt. - Approve Findings - Develop Roll-out	
Design Technology	- Design Core Data Architectures - Hire Independent Service Providers	- Build Background Databases - Coordinate all Bldg. & Information Sys.	- Conduct Audits and Accept Submissions	
Orientation/Education	- Establish CIFM™ Orientation and Education Task Forces	- Define Requirement of the Task Forces - Define Goals	- Peopleware Tools - Training - Town Hall Mtgs. - Handbooks	- Implement Programs
Communications/P.R.	- Establish Comm./PR Task Forces - Define Goals, Roles, and Responsibilities	- Design Comm/PR Tools and Formats (Hot Lines, Web-site, newsletters, etc.)	- Implement Comm/PR Activities (Status Reports, Ed., feedback tools, etc.)	- Implement and Evaluate the Communications and P.R. Programs

FIGURE 3.3.5-3 Fast-tracked implementation plans for FM automation and IM solutions require careful planning. (*Courtesy of Bruce Kenneth Forbes, ARCHIBUS, Inc.*)

5. The Strategic Transformation Phase (Month 5)
   Meeting the needs of the global community
   Targeting micromarket segments
   Creating customized content for individual visitors
   Exploiting electronic channel strategies
   Introducing new channel layers
   Aligning with corporate partners

ARTICLE 3.3.6
THE INTERNET, E-COMMERCE, AND FACILITIES MANAGEMENT

Eric Teicholz
Graphic Systems, Inc., Cambridge, Massachusetts

This outernet article is about the Internet. The Internet has already dramatically altered facilities management (FM) and the ways in which FM practitioners interact with their design consultants. This relationship will undergo a dramatic change again because of the rapid deployment of e-commerce.

FM TECHNOLOGICAL EVOLUTION

Computer-aided facilities management (CAFM) goes back almost 30 years when vendors such as ARCHIBUS (www.archibus.com), FM:Systems (www.fmsystems.com), SPAN (www.peregrine.com), Drawbase (www.drawbase.com), and Aperture (www.aperture.com) started

linking databases to computer-aided design (CAD) programs to perform facility-related functions such as tracking space availability and physical assets, including furniture and equipment (F&E). Occupancy drawings that depicted the physical location and departmental organization of staff were developed by getting this information from human resources (HR) or information technology (IT) groups and entering it into the CAFM system.

As computers became more powerful and CAFM more mainstream, vendors evolved along two paths: either they developed additional FM applications (work, real estate, cable management, and space planning), or they built links to established third-party software packages that performed these functions. A facility manager might, for example, use a CAFM vendor for CAD drawings and tracking space occupancy while using a second software vendor for space needs forecasting or to generate stacking and blocking diagrams. A design consultant who worked for such a client would have to provide electronic drawings compatible with the CAFM system being used. Because more powerful databases became available in the early 1990s, it became possible to disperse software applications and databases throughout an organization. This, in turn, eliminated much data redundancy, sped up processing time, and made it easier to access other non-CAFM systems and databases. It meant, for example, that CAFM software, operating on a facilities manager's desk, might access HR or financial data from different departments over a network and use this data for occupancy or project management purposes.

THE INTERNET

In the mid-1990s, CAFM vendors initially adopted the Web as a simple reporting mechanism. The CAFM output reports were generated in HyperText Markup Language (HTML) and posted on corporate intranets. These static reports were somewhat clumsy because they had to be posted on the intranet site and then accessed by remote users. The data was only as current as the last posting.

Reports soon became dynamic using technology that enabled generating the report in real time by interacting with the CAFM software directly. In this manner, a user of the corporate intranet would download the latest version of the data when required by a particular application. Again, intranets were deployed to distribute dynamic reports and drawings, if the network speed was sufficient. In short, the intranet was still used as a reporting mechanism. To maintain integrity, the software was still centralized and tightly integrated. The Web's most fundamental advantage, the ability to effortlessly and dynamically link disparate multiple sites together (e.g., clients, consultants, contractors, and subcontractors), was still not being used.

It continues to be difficult and expensive to link different external software programs to CAFM systems on the Internet. Most CAFM vendors try to control the Web environment of their software and do not link very well to other Web-based software. This software model is becoming increasingly unworkable because new vendors are increasingly offering stand-alone FM software applications on the Internet. Stand-alone Internet applications that have appeared recently include vehicle (fleet) management, space planning and forecasting, help desk and maintenance work management, furniture layout, asset management, room scheduling, energy management, and construction project management. These software applications are fragmenting the FM function itself in many organizations because providing these functions is so easy and inexpensive on the Web that much FM functionality is shifting to non-FM professionals. For example, VISIO 2000's (www.visio.com) FM software modules are available for just a few hundred dollars. According to the company, more than 1000 copies of its software are purchased daily on the Web.

This migration of third-party stand-alone Web applications is impacting current CAFM vendors because of overlapping functionality and a very different cost model for Web-based products (people do not seem to want to pay for information provided on the Web). Seeing this trend, some CAFM vendors are trying to incorporate some of the stand-alone applica-

tions (i.e., FIS's support and use of VISIO 2000 as a front end to their software). In the long run, however, the Web-based applications are likely to pose a threat to traditional CAFM vendors unless they also change their Internet software architecture. Architectural design consultants (see the case studies following) also need to adapt to this new model.

Project/collaborative Web sites represent another major impact on the way facility managers and their design consultants are doing business and using FM technology. Currently, more than 60 software vendors offer project Web site software—primarily for managing construction projects. These sites traditionally offer document management services and track project information such as drawings, specifications, requests for information (RFIs), various logs, and so forth. The Web sites link the design consultants with the client, engineers, contractors, and subcontractors. These Web sites make data available to corporate users on their intranet as well. For example, HR might want to know what staff is affected by a move; finance might want to track project costs for financial control and capital planning purposes; and business unit managers might want access to floor plans that affect their staff.

Right now, software vendors are charging for project Web site software or are renting software functionality and hosting the software on their computers. However, the valuations of .com companies are based on how many people (called *eyeballs*) visit and use a particular site. This is again changing the financial model in the way vendors charge for software and information. This was dramatically illustrated recently when Autodesk spent an estimated $50 million developing *Buzzsaw.com* that gives away free project Web software simply to get the design industry to use the Autodesk portal. Thus, architects, clients, and contractors all use construction project and document management software provided free of charge by a vendor.

Again, the Internet is playing an increasing role in controlling who accesses, uses, and manages FM data. There is a transition in who is performing FM functions and how that function is being performed. Functions that were traditionally the domain of facility managers are being increasingly performed by both internal and external (e.g., design consultants and service providers) groups.

E-COMMERCE AND FM

To use Internet parlance, we are entering a business-to-business (b2b) application service provider (ASP) world. Financial venture capital funds that fuel Internet start-ups are betting on the b2b, rather than business-to-consumer (b2c), ASP model. The projected numbers are significant: In 1998, b2b revenues were $12 billion, of which services accounted for $1.4 billion [there is no breakdown for architecture/engineering/construction (A/E/C) services]. In 2002, there will be $131.2 billion of b2b commerce, and services will account for $18.4 billion of that figure. This represents more than a 10-fold increase in e-commerce services in 4 years! Project construction Web sites, for example, will share documents; construction materials and services will also most certainly be purchased on-line; and manufacturers will be literally bidding on-line for the business.

To draw a parallel, General Motors and Ford, icons of what the *Wall Street Journal* calls "the Old Economy," announced plans to establish on-line bazaars for all of the goods and services they buy—everything from paper clips to contract manufacturing. The motivation is to cut costs—billions over their current procurement processes. All suppliers will have to go through their sites by the end of 2001. In the A/E/C services world, literally hundreds of companies are being formed that are trying to be the e-marketplace, where it is possible to bid on and procure building supplies from manufacturers worldwide.

The Internet will continue to exert an ever-increasing influence on how we do business. Design consultants need to understand b2b ASP implications and be ready to host design and other services for their clients who are linked to e-commerce sites.

ARTICLE 3.3.7

THE ROLE OF E-COMMERCE AND BUSINESS-TO-BUSINESS ELECTRONIC MARKETPLACES IN FACILITIES MANAGEMENT

Bruce K. Forbes
ARCHIBUS, Inc., Boston, Massachusetts

Traditional procurement organizations and their procedures will be subject to review and reorganization in the new millennium. Current procurement techniques can be labor-intensive and time-intensive, thus driving the costs up and driving down participation by the end user or customer. Once a request is made, the end user has little or no involvement in the procurement process. As such, the end user is not always happy with the buyer's selection of vendors or sellers (see Fig. 3.3.7-1).

In the next few years, thousands of facility professionals will embrace the opportunities afforded them by e-commerce. The collaborative and connective tools of e-commerce will change life, as we know it today, forever. One of the most promising areas of e-commerce is

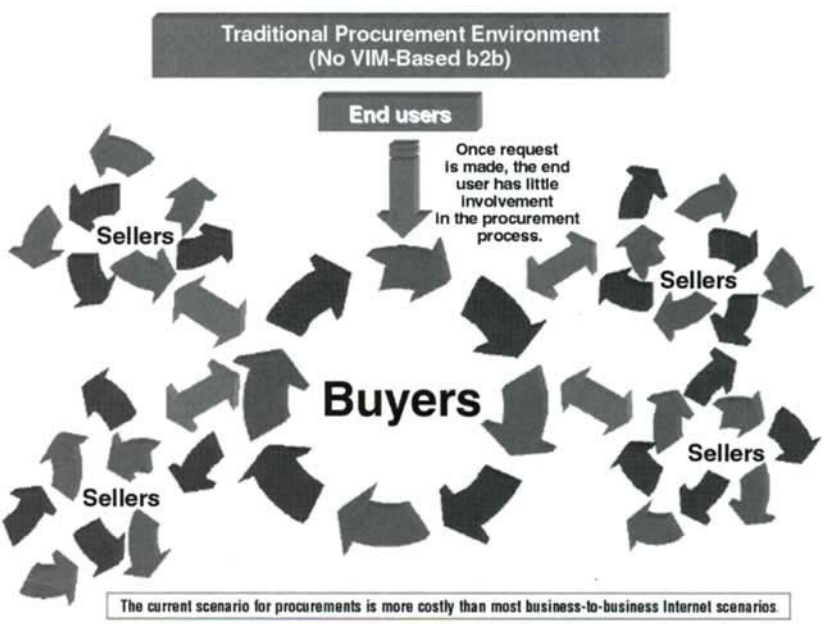

FIGURE 3.3.7-1 Traditional procurement procedures in most companies as they exist today. Buyers must work with a vast array of suppliers to realize great pricing and optimal terms. (*Courtesy of ARCHIBUS, Inc.*)

the business-to-business (b2b) electronic marketplace where end users, buyers, and suppliers have increased access to data, information, and knowledge. Their purchasing processes will be streamlined and they will benefit from leveraged, virtual, on-line sales opportunities. Buyers will benefit from productivity and profitability gains that can be realized by working electronically with public marketplace suppliers and the private network of contracted suppliers (that your organization may have opted to create and use).

INTERNET PROCUREMENT SAVES TIME BY A VARIETY OF METHODS

- Shortened procurement cycles
- Automated purchasing, procurement trails, and routing
- Instant supplier information and communications
- Comprehensive connectivity with legacy systems such as finance and operations
- Comprehensive purchasing activity reports

INTERNET PROCUREMENT SAVES MONEY IN NUMEROUS AREAS

- Through corporate and associative aggregate buying power created throughout your company and your affiliates
- Better prices in competitive bidding scenarios
- Corporate knowledge about suppliers, just-in-time delivery options, etc.

ELECTRONIC MARKETPLACES AND INFRASTRUCTURE MANAGEMENT WILL STREAMLINE PROCESSES

There are three participants in the electronic marketplace—the end user, the buyer, and the seller. The *Internet procurement enterprise* facilitates the electronic collaboration of all interested parties. Participants will use the e-commerce tools of the day to increase productivity and profitability for their respective organizations. In an electronic marketplace where the facilities professional also uses infrastructure management (IM) solutions, the entire process is streamlined from requisition to payment, and on to the various stages of the life cycle of a particular asset. Hundreds of systems can be brought together in IM and Internet procurement enterprises. Buyers benefit from the one-to-many opportunity created by using e-marketplace tools. Better prices and saving time are but a few of the benefits (see Fig. 3.3.7-2).

From the Buyer's Perspective

These are some of the components of an electronic marketplace:

- *E-business sourcing.* Find suppliers by keywords, product searches, product interactions and mapping, and/or SIC codes. Sort via filtering and rating systems.
- *Competitive bidding.* Request bids from the public marketplace suppliers and the private network of contracted suppliers. Send out, receive, and analyze information electronically.

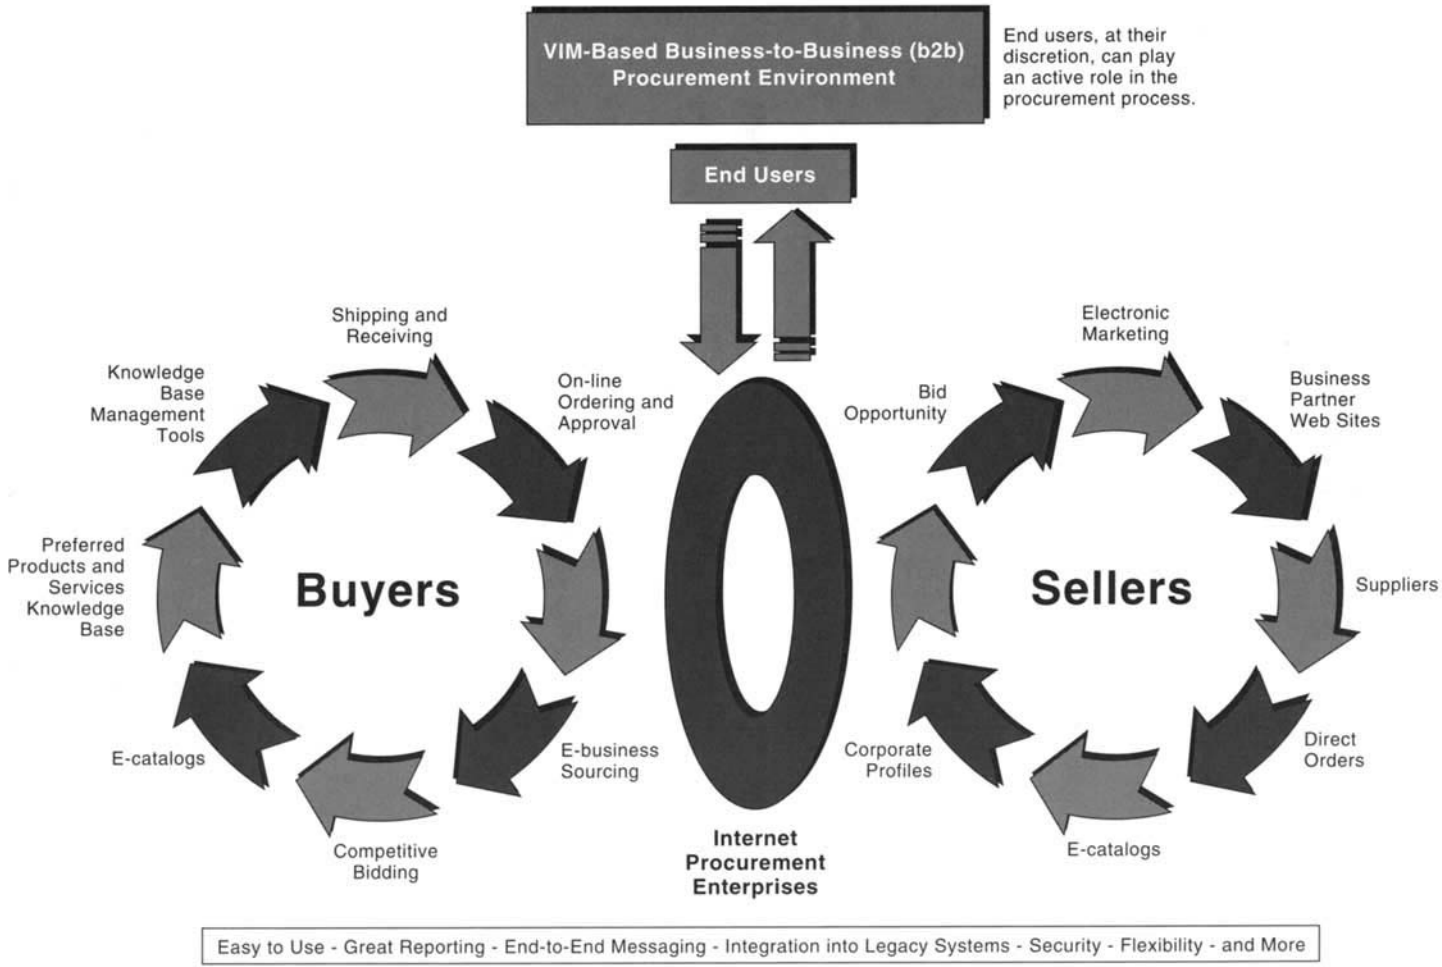

FIGURE 3.3.7-2 Hundreds of systems can be brought together in visual infrastructure management solutions and Internet procurement enterprises. Buyers benefit from the "one-to-many" opportunity created by the utilization of e-marketplace and e-work tools. Better prices and saving time are but a few of the benefits. (*Courtesy of ARCHIBUS. Inc.*)

- *E-catalogs.* Search, review, and analyze electronic catalogs from suppliers. Use "shopping cart" techniques for subsequent acquisition activities.
- *Preferred products and services knowledge base.* Frequently used services or acquired products can be grouped and prioritized. Create "hot pick" list for convenience when ordering.
- *Knowledge base management tools.* A knowledge base of relevant management data, information, and knowledge is collected for creating timely reports and analyses. Archiving of knowledge base materials is automatic and accessible via electronic audit trails and document management systems.
- *Order processing, shipping, and receiving.* All relevant information is passed electronically to the appropriate parties. This includes, typically, the shipping agent coordination and package deployment.
- *On-line ordering and approval.* Create purchase orders automatically for those items put into the shopping cart. "Paper work" is facilitated electronically and via e-mail. Electronic marketplace approval and control systems are used to ensure contract compliance.

From the Seller's Perspective

These are some of the components of an electronic marketplace:

- *Bid opportunity.* Suppliers can work with the buyers and submit bids electronically. Buyers typically feel that electronic submission is usually more responsive and saves time.
- *Electronic marketing.* Electronic marketing can be an effective way to market an organization's products or services. Electronic marketplace suppliers can use Web sites, "hot site links," and E-marketing tools.
- *Business partner Web sites.* Business partners can link their sites to appropriate private network partners and can also be accessed through public vehicles. Web sites can be used for buyer collaboration and information dissemination.
- *Suppliers.* Sellers can also become buyers in the electronic marketplace. Sellers should require their suppliers to be engaged via the electronic b2b tools of the day.
- *Direct orders.* Suppliers can receive, review, and process orders electronically. Payment can also be made electronically.
- *E-catalogs.* Suppliers can provide information electronically for buyers. Purchases can be facilitated via shopping cart techniques.
- *Corporate profiles.* Suppliers can share relevant information with buyers concerning their companies, their products, and their services.

The use of the electronic marketplaces by facilities professionals is still new, but there is little doubt that its presence will be lasting and significant in the years to come. The connectivity provided in cyberspace for facilities management (FM) by IM solutions will enable universal access to new tools offered by the e-marketplace and e-commerce. Buyers, sellers, and end users all benefit from connectivity and information sharing between applications.

RESTRUCTURING FOR E-COMMERCE, FOR FM CYBERSPACE, AND FOR IM

Restructuring for e-commerce, for FM cyberspace, and for IM requires careful examination of the evolving role of the FM cybrarian in organizations that must respond to dramatically changing FM and IM environments. We need to explore how and why FM cybrarians' roles

are changing and clarify the impact of that change on managing and administering facilities and infrastructures. The main focus of an FM organization must be on people, processes, technology, time, organization, and, ultimately, the quality of customer care and service. All of this is strongly influenced by the existence of FM cybrarians and their leadership capabilities. Infrastructure management will enable even the most casual of users to rapidly access and use advanced reporting capabilities.

THE "E-OPPORTUNITY"—ARE YOU READY?

E-FM, e-space, and e-business are dramatically and suddenly changing the way the world does business. These automation-based environments will provide new insights into ways business leaders can use process and technology to achieve new efficiencies, create new value, and attain goals previously beyond reach. It is through these e-opportunities that you will be able to examine the competitive threats that come with new business models and to see how new and old competitors will use these environments to outpace their slower-to-react counterparts. As e-pioneers and e-architects, you must explore the wealth of opportunities and threats, as well as the best practices available through Internet technology.

MASTERING THE WEB WITH INFRASTRUCTURE MANAGEMENT

Cyberspace for FM: The Apex of Enterprise Resource Planning and Management in the New Millennium

E-commerce is coming to a company, institution, or organization near you. The results will be all-encompassing. The rapid acceptance, deployment, and use of Internet and intranet technologies, as well as their repercussions on business, is one of the more remarkable innovations and paradigm shifts of the late twentieth century. The consequences to facilities professionals and the organizations and people they serve are also significant.

In the near future, those organizations that are currently transforming themselves and becoming e-commerce-centric, will need as little as 25 percent of the real estate, fixed assets, personnel, and traditional infrastructure that they currently require. By 2005, up to 75 percent of the facilities professionals currently employed by these organizations will have been laid off, forced into early retirement, or, at a bare minimum, retooled. At this time, opportunities within cyberspace for FM are among the best options for facilities professionals seeking alternative careers. Cyberspace for FM combines the power of automation technologies [e.g., computer-aided facilities management (CAFM) systems, computer-integrated facilities management (CIFM) enterprise solutions, and enterprise resource planning (ERP) software] with new millennial technologies and best practices. Such systems are readily transformed into globally accessible depositories of FM data, information, knowledge, and wisdom.

The "tools of the trade" will vary, but all will be enablers of e-commerce and b2b commerce. Facilities management knowledge workers will gain access to information and knowledge through public switched networks (PSNs) that have global access, and application service providers (ASPs) will facilitate virtual private networks (VPNs). The World Wide Web, virtual communities, critical and secured corporate knowledge, E-FM and E-IM universes, and opportunity will all become available via electronic commerce infrastructure for E-FM and E-VIM (see Fig. 3.3.7-3).

A state of co-opetition exists when organizations, which are typically thought to be competitive, establish a domain of cooperation to solve a particular problem or challenge. Cyberspace for FM is becoming the infrastructure of choice, as organizations attempt to deliver co-opetition-based solutions. The individuals who act in FM cyberspace as project managers might also be known as FM cybrarians.

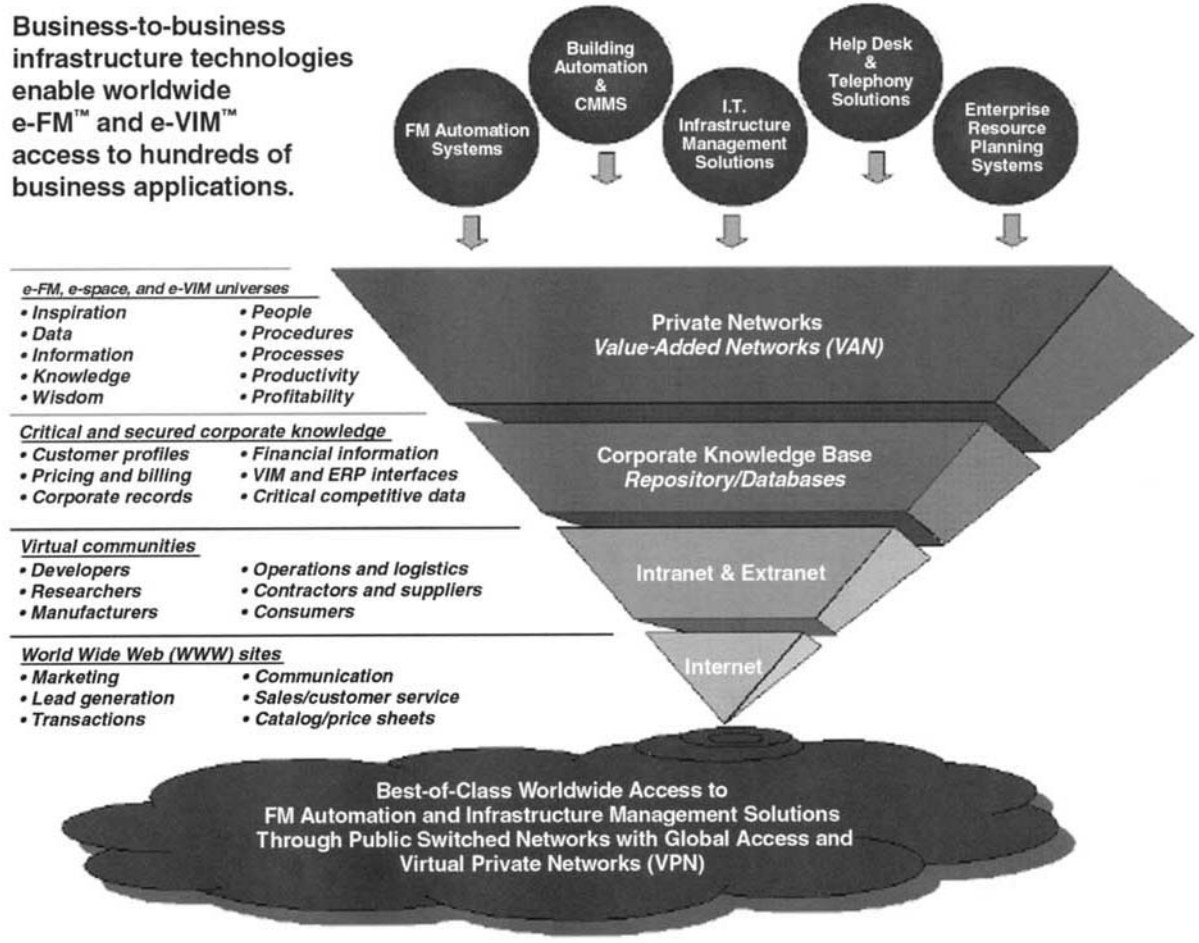

FIGURE 3.3.7-3 Visual User Interfaces™ in FM Cyberspace™ will address an FM organization's portal and content needs. E-commerce infrastructure for e-FM™ and e-VIM™ will enable even the most casual of users to utilize and gain access to FM Data, FM Information, FM Knowledge, and FM Wisdom™. (*Courtesy of ARCHIBUS, Inc.*)

Cyberspace for FM and IM Should Lead Your Organization into the Twenty-First Century

Cyberspace for FM (CFM) (also known as *FM cyberspace*) is being universally accepted as the FM knowledge workers' (also known as *FM cybrarians*) opportunity of a lifetime. In 1999 alone, it was estimated that more than 250,000 new users of CFM technologies would come on line. By 2005, the number of CFM users is expected to exceed 100 million.

CFM enables the rapid assembly, analysis, organization, distribution, and consumption of facilities and operating data, information, knowledge, and wisdom. Although the challenges are great, the costs of establishing such a system are typically one-tenth those of traditional CAFM systems and CIFM enterprise solutions. CFM access will typically cost less than $100 (U.S.) per user per year.

Unique to CFM are user interfaces, which enable even the most casual users to gain rapid access to knowledge. User interfaces can be quickly designed to provide universal access to thousands of applications and hundreds of ERP options. It is expected that CFM and e-space will be accepted and serve as a knowledge infrastructure at all of the successful e-commerce organizations of the new millennium.

Facilities professionals must look for and employ all available technologies that will improve every key corporate function with which they are involved—real estate and lease management, strategic master planning, space management, nonspatial asset management (furniture, equipment, and so forth), telecommunications and cable management, and building operations management (BOM). The help desks and service offerings must be Web-centric. The corporation of tomorrow must successfully intertwine CFM with finance and administrative activities, sales and marketing, human resources (HR), information management, manufacturing, and distribution.

CYBERSPACE FOR FM: THE TECHNOLOGY TOOL OF CHOICE FOR STRATEGIC EXECUTIVES

Computer-aided facilities management and CIFM offerings were representative of the facilities professional's desire to reengineer processes, redeploy resources, and save money by streamlining operations. Cyberspace for FM will be instrumental in an organization's revenue growth, creation of universal awareness, and delivery of informational access to its partners, shareholders, stakeholders, and customers.

Why is CFM so important? It is the executive's user interface to enterprise solutions. Facilities management knowledge workers are enabling the organizations they serve to optimize their basic product and service offerings. Information can be readily communicated and shared in CFM at a fraction of the cost. In the digital economy of tomorrow, knowledge is readily transmitted via enterprise solutions and accessed via a variety of user interfaces for CFM.

Cyberspace for FM command centers will be similar to those of NASA's Mission Control—data are collected and rapidly distributed via user interfaces that have been designed for the casual user, the in-betweener, and the advanced user, alike.

Competition in CFM will be fierce. There are currently many software developers and systems integrators providing software and services for the FM automation, IM, and ERP markets.

The Internet and intranets are fostering a paradigm shift in the way business will operate in the new millennium. Web-centricity is a critical requisite of tomorrow's digital economy.

- *CAFM systems.* Deal with the management and costs of "what has been" and "what is."
- *CIFM enterprise solutions.* Deal with "what has been," "what is," and "what can be."
- *CFM universes.* Deal with "what has been," "what is," "what can be," and also a vast array of expert systems, ActiveX environments, and decision-support systems. These systems can

help strategic business managers determine "what should be done," "with whom," and "what will happen, if . . ."

E-Space: A Critical Part of the E-Commerce Revolution

The one-two combination of CFM and ERP solutions enables broad integration and extensive expansion of FM knowledge works. Innovation, through the e-space sharing of digital economy–based knowledge and wisdom, will be a trademark of the twenty-first century.

BUILDING BLOCKS FOR THE FOUNDATION OF CYBERSPACE FOR FM

The Creation of "CFM Buzz"

Key to creating CFM will be spawning an appropriate "buzz" level—by making it the "talk of the town." Peer-to-peer acknowledgment of the power of CFM will act as a technological enabler. If each FM professional recommended the participation in CFM to five other FM professionals and they, in turn, did the same . . . in no time the vast majority of FM professionals would become catalysts for successful CFM.

Participate in CFM Strategic Master Planning Activities

Audits are critical to the success of CFM and serve as a basis for strategic master planning. Some of the more common CFM audits are management, technology, opportunity, implementation, financial, and return on assets (ROA).

Stratification of CFM

Stratified offerings empower casual users, in-betweeners (facilitators), and advanced users to benefit from CFM. A variety of user interfaces make it easy to become a player in CFM. Horizontal and vertical offerings should complement each other in CFM.

Using CFM to Address Unique Needs

Cyberspace for FM must address both the common and the unique needs of its participants. The expansion of the information highway was the call to action 10 years ago, but now the creation of CFM universes must be the call to action for the new millennium. The unique demands of today's business environments require the rapid creation, deployment, and consumption of FM information and knowledge.

Knowledge About Internetworking

Internetworking, via the Internet, intranets, extranets, and so forth, will become commonplace and critical in the formation of CFM universes. Local area networks (LANs), remote area networks (RANs), global area networks (GANs), cellular area networks (CANs), and satellite area networks (SANs) are but a few that link together PCs, workstations, and personal computing devices so that they can communicate and share information. Some of the

technologies deployed in these solutions include adapter cards, hubs, bridges, routers, Ethernet switches, and ATM switches. Facilities management cybrarians should understand basic technologies and be aware of proper "netiquette."

Basic Requirements for Creators of CFM Universes

Various requirements should be imposed upon the creators of your CFM universes. Some of the more common include perpetual increases in the speed of network transmission, advances in the state of networked applications, empowerment of the mobile and virtual workforce, creation of global infrastructures for information distribution and services, demand for open standards, continuous commitment to evolve as the next generation of technology becomes a reality, network management interoperability, and constant undertaking of appropriate CFM audits.

Client/Server Computing in CFM

In client/server networking, personal computers, workstations, and other personal computing devices are linked to communicate and share FM data, information, knowledge, and wisdom. Typically, there is at least one facility-centric server computer connected to the rest. The server houses many of the centralized and scalable applications and databases. Client/server software includes: operating systems; databases; development environments; programs that enable connectivity via the Internet, intranets, and extranets; network management; and program development environments. Client/servers act as part of the foundation for CFM.

FM Cybrarians: Catalyst (Relationship Builder) Between Technologists and Businesspeople

The risks of serious disconnects between technologists and business managers are a primary concern for FM cybrarians. Technologists are often so enmeshed in their technocentricities that they forget that their raison d'être is to serve the needs of the business, the company's shareholders, stakeholders, and customers. Facilities management cybrarians can help both sides understand and function in CFM, thus giving the organization, which they all serve, a competitive advantage.

CFM and the Advantages of Personal Productivity Suites

Personal productivity software should be available to FM professionals today as stand-alone offerings or in suites—collections of programs grouped with seamless interfaces. General office and FM-specific suites enable the rapid deployment of data and information between applications, thus enabling the FM cybrarian to derive FM knowledge and wisdom more quickly.

Multimedia Technologies in CFM

Multimedia technologies in CFM include the integration of alphanumeric data, audio, graphics, animation, video, neural networks, image recognition, and virtual reality data. Advances in CFM require the use of new and improved multimedia technologies in stand-alone, client/server, and web-centric applications. Videoconferencing, chat rooms, enhanced training, design simulations, and next-generation cellular connectivities are but a few of the multimedia applications in CFM.

CFM—Never to Be a Bleeding-Edge Technology

In a day in which fuzzy logic, nanotechnology, neural networking, and virtual reality simulation are quite common, FM cybrarians must develop realistic approaches to CFM to ensure that it never becomes identified with *bleeding edge.* Historically, technologies developed outside the bounds of commercial viability have been created at universities and research labs. Cyberspace for FM was created in commercial space, with the immediate benefit of commercial, market-tested gains in productivity and profitability.

New Millennial Technologies Applied to CFM

There will be millions of new technologies that will impact CFM in the new millennium. Some of the more interesting near-term applications include: hand-held electronic devices; natural language interfaces, like speech and pattern recognition; ActiveX FM objects; high-definition display and communication devices; smart manufacturing; virtual reality–based holograms; e-commerce; e-FM; and e-space.

CFM as a Catalyst for Paradigm Shifts

In the new millennium, CFM will most assuredly serve as a catalyst for paradigm shifts within any organization. Cyberspace for FM will impact an organization's technologies, marketing programs, organizational structures, finances, alliance activities, mergers, acquisitions, and business models.

Characteristics of Highly Effective CFM Management Teams

Organizations that flourish in CFM seem to have CFM management teams that demonstrate numerous technocentric and personal characteristics. These leaders are noted for their vision, charisma, strategic thinking, and ability to execute; they act as enablers for high-caliber recruitment and retention of staff; and they have a solid footing in reality.

Financial Resources Required for CFM

To be successful, the FM cybrarian must ensure that suitable financial resources are established and maintained for the digital universes being created in CFM. Beyond the FM domain, FM cybrarians must be constantly vigilant about their organization's business plan, cash flow, debt burden, revenue and earnings consistency, and the proportion of revenues from recurring sources. In short, to serve the business, the FM cybrarian must know the business.

The Human Being and CFM

Cyberspace for FM cannot exist without human beings. The digital world and its associated nervous circuitry cannot be a substitute for human contact. Cyberspace for FM, however, offers tomorrow's facilities managers the ability to extend the scope, continuity, and even the quality of their interactions with other FM professionals and the customers they serve. Long-term relationships are not usually formed via digital nervous systems but only extended and expanded. Through CFM, the ability to complement, reinforce, and enhance relationships becomes universal. Cyberspace for FM is based on the human being's need for acquisition, analysis, and distribution of FM data, information, knowledge, and wisdom. The "FM net"

offers much, yet human beings must determine what kind of effect CFM will have on them, their organizations, their customers, and society at large.

The Digital Nervous System as CFM Matures

Today, it is estimated that 90 percent of all documents in U.S. businesses are created and/or stored electronically. Yet, it is still difficult for people to gain rapid access to them, and printed media are still the "preferred" way by which people communicate with each other. Although e-mail is rapidly changing our mode of interaction, how many e-mails are printed by force of habit each day? The personal computing revolution combined with the various Net offerings will truly enable us to have information at our fingertips and, subsequently, to do something substantial with it. The CFM du jour, where Active-X, FM objects, and infinite bandwidth are connected to every point on the globe and throughout the universe, is only a few years away.

The High-Five Version of CFM Boot Camp

The World Wide Web and its associated nets are still in their infancy. By the year 2000, more than 300 million people will have access worldwide. Facilities management cybrarians must address the so-called High Five questions that are associated with CFM. Perpetual in nature, common in need, the answers to these questions must be constantly reviewed.

1. What can CFM do for me and for the FM organization to which I belong?
2. What can CFM do for my company and the customers I serve?
3. How do I quickly, productively, and cost-effectively continue to be immersed in CFM?
4. How will I do business in and throughout CFM?
5. How do I optimally create, maintain, and use CFM?

INITIATIVES FOR REALIZING CFM SUCCESS AS FM CYBRARIANS

As we enter the new millennium, CFM is a reality! But a decade after its public debut, we are only at the beginning of the journey through the CFM universe. Today, hundreds of thousands of people are already tapping into this universe. By 2005, it is hoped that more than 300 million people will have benefited from the power of CFM. Cyberspace for FM has become a reality because of countless technological innovations and the FM professionals who are willing to step outside the box and become pioneers in the realm of their organization's digital nervous systems via CFM. To date, the following are some key observations about CFM:

- The customer is at the center of the CFM universe.
- Superior products and processes must be at the core of CFM.
- For CFM wisdom to be unique, FM data, information, knowledge, and wisdom must be complete and timeless.
- Cyberspace for FM will be most successful in virtual communities.
- Facilities management cybrarians must perform CFM audits (opportunity, implementation, technology, management, etc.) if CFM is to be successful.
- Cyberspace for FM thrives in strategic master planning environments and requires effective management.

FM BEST PRACTICES AND BENCHMARKS FOR CFM—SOME THOUGHTS ON THE DEVELOPMENT OF A COMMERCIAL OFF-THE-SHELF PRODUCT STRATEGY FOR ENTERPRISE WEB CONNECTIVITY FOR AN FM ORGANIZATION

CFM COTS Products

Web-based commercial off-the-shelf (COTS) products should be the foundation of CFM. Best-of-class Web technologies can be expanded into a powerful extension of the CAFM and CIFM environments. Inexpensive and easy to use, Web-based COTS products enable you to expand the connectivity of your CAFM and CIFM environments to anyone, anywhere, who is connected to your corporate intranet or the Internet at large via the World Wide Web.

Use E-Commerce Tools to Communicate Your Vision

Just as the Web makes your company globally visible, a Web-based COTS product will make your corporate FM efforts globally visible and your information instantly accessible. Use the Web to promote your FM department's efforts, advertise your capabilities and internal services, and promote and enforce your working practices. Use this technology to communicate your FM vision to the corporation at large. Accurately assess conditions within your entire organization to make best use of corporate resources, and collect the critical data that your corporation needs to execute its business plan. A COTS product can make you a key, visible, dependable player in the strategic planning process.

Seamless Interface into Your Corporate Web Strategy

Web-based COTS products are designed to enhance your corporate Web and management information system (MIS) departments and leverage their resources. They should be entirely open, linkable to any corporate intranet page, and allow you to use any dynamic form or report on your own Web page. A Web-based COTS product can be your productivity powerhouse for dynamic publishing of large numbers of drawings and structured FM data. If there is a report you need that is not provided, in minutes you can publish any view to dynamic pages, complete with drill-downs and paging of large results. The product puts all of the technological pieces together, so you get the glory.

Who Can Benefit from Using Web-Based COTS Products?

Anyone who uses your organization's facility information will benefit from the use of Web-based COTS products.

- *Facility managers.* Can access their facility information anywhere, anytime. They can provide users of facility information with self-service mechanisms that enable them to access information or request a work order, for example.
- *Field personnel.* Can easily and efficiently pick up work order requests from remote locations, saving them time and helping them determine what tools are needed for a job before they arrive.
- *Branch office personnel.* Can access home office information in real time.
- *Strategic planners.* Can immediately access the historical information that they need to make important planning decisions.

- *Purchasing managers.* Can verify invoices against inventories and track back orders.
- *Human resources managers.* Can develop occupancy plans and locate vacant space for new hires.
- *Building owners.* Can determine rentable areas and bill tenants for the space they occupy, plus their share of common areas.
- *Corporate real estate managers.* Can track detailed lease characteristics such as options, payments, and prorated taxes.
- *Accountants.* Can use space data to charge departments for the areas they occupy, plus their share of common areas.
- *Risk managers.* Can evaluate assets to obtain adequate insurance coverage.
- *Tradespeople, maintenance staff, and building tenants.* Can take advantage of remote access to facilities information.

For the Facilities/Asset Management and Services Industries

Facilities management cybrarians have come to recognize that the most important part of the job is to process, filter, and prioritize FM data, information, knowledge, and wisdom by using technology that quantifies and focuses it precisely. Systematically networking CFM leads to the timely creation of FM wisdom.

Creating an Information and Knowledge Advantage for Your Customers

Cyberspace for FM solution technology is designed to give companies an unparalleled ability to retrieve the information and knowledge they need, wherever and whenever they need it. This information and knowledge advantage, more than any other, is what will separate the winners from the losers in facilities, asset management, and its allied professions.

The Purpose of CFM

Professionals in FM and the allied professions are constantly looking for an edge in their ultracompetitive markets. The pursuit of normalized FM benchmarks and FM Best Practices™ has led professionals to realize that the old rules no longer apply: Advantage does not lie purely in economies of scale or in cutting-edge product development. Facilities management organizations and the companies they serve separate themselves from their competitors in today's economy on the basis of their ability to swiftly gather, manage, and act on relevant business information and knowledge. Facilities master planning is a critical component, and rapidly collecting and disseminating information through the World Wide Web are the realities of doing business in the new millennium.

Facilities management cybrarians have a common goal: to help clients in their facilities, financial, and professional services organizations become more competitive in automated asset management by using Internet and related technologies to retrieve, filter, sort, and deliver strategic information. To accomplish this mission, FM cybrarians develop and manage strategic intranet portals for senior executives, analysts, and managers who need to have the right information at the right time to increase productivity and profitability.

Facilities management cybrarians must combine technology, information management skills, and a high-level understanding of finance and industry to manage a world of information and knowledge for their clients. They recognize that, although the Internet dramatically changes many business processes, existing processes need to be understood and modified carefully to maintain safeguards, confidentiality, and security. Facilities management cybrari-

ans take great pride in the professional quality of their CFM-based products and services and have an uncompromising determination to achieve excellence in everything they undertake.

Elements of Comprehensive Cyberspace for FM Offerings

Content Management. The primary function of CFM is the seamless integration of internal resources and external information. Using the flexible Explorer/Navigator (Navigator) platform and an extensive array of vendor-specific APIs and procedures, a CFM solution is uniquely capable of rapidly delivering an intelligent access point for diverse data and information. Such information and knowledge management affords managers, analysts, and executives the simplicity, speed, and accuracy necessary for effective decision making. One example of content management for a real estate portfolio manager might be the access to a building's performance in a single report or "FM snapshot." In such reports, information is gathered from multiple sources. Required information might be gathered from a corporate financial database and a multimedia file of photographs and videotapes. Calculations might be based on data derived from municipal tax ledgers and portfolio cost escalation monitoring systems. Market valuation might be extracted from yesterday's local real estate journal.

Hot Lists. Facilities management cybrarians work with their clients to identify important content suppliers for inclusion on the customized Navigator (called a *hot list*). Once identified, sources are tagged, prioritized, and integrated into a customized management system that allows single, intelligent searches, and efficient, user-friendly access to all available information. One user of hot lists might be a corporate space planner. By selecting a single action item on the hot list, the corporate space planner can query the corporate database to gather data and establish chargeback information for a particular building. The query results in the generation of alphanumeric and graphical information. A report, such as "Highlighted Rooms by Department by Floor" is rapidly created for each of the floors selected in a particular building.

Custom Interfaces and Personalization Tools. A CFM solution also offers high-level interactive capabilities. Users have access to interface customization options, enabling individual interfaces and search tools. These tools allow smart and individualized data presentation. In addition, users can create, edit, and distribute documents or objects across the network, allowing the CFM solution knowledge management system to be a dynamic tool that becomes ever more customized in response to the client institution's needs. In this example (see Fig. 3.3.7-4), a "dialog box" for collecting information about the creation of a work request has been created. This custom interface enables the user to extract known information from the corporate building operations systems and denote their perceived sense of urgency. Training to use such an interface is typically only a matter of minutes.

Dynamic Learning. A CFM solution allows and encourages clients to continuously update and adapt content to meet specific needs. Client-selected Web sites, research information, and other resources are dynamically included in the hot list system. In conjunction with custom client interfaces, the hot list is a constantly growing, flexible system that consistently adapts itself to the needs of each user. A facilities manager who is concerned about completing active work requests can construct an iterative query environment for dynamic learning (see Fig. 3.3.7-5). In this case, a facilities manager can connect and associate information from several systems to assess the status of a particular work request. A report such as "Active Work Requests by Floor Plan" can be created with a single click of a mouse. Through cellular connectivity, the facilities manager could determine if particular staff members had completed activities, their locations, the parts that were consumed, and the ability to be redirected to a project other than those assigned to them at an earlier meeting. Graphical queries are considered extremely helpful in such dynamic learning situations.

Virtual Libraries. The World Wide Web has now become the largest repository of information available in the world, and tens of thousands of sites provide valuable, precise, and timely data. Market-moving data, such as U.S. inflation and growth statistics, are now released first on the Internet. Countries around the globe are posting economic information; markets such as NASDAQ are publishing valuable information on listed companies; and markets and companies themselves are posting a plethora of information for investors on their Web sites. The digital economy has become a reality.

OPPORTUNITIES IN THE NEW MILLENNIUM

The ability to execute business strategies based on rapid analysis of available information is vital to any executive or analyst. As a result of the growth of PC and Internet/intranet/extranet usage, the number of electronic news and information retrieval services is exploding. In CFM, FM cybrarians can potentially offer every imaginable type of content and data. They may, unfortunately, toss all of the content haphazardly on the virtual laps of their users. Different approaches to categorization, entitlements, symbology, and ActiveX FM objects force users to waste crucial time locating relevant information. Publishers develop Web-based platforms, and many aggregate a number of different sources, but the problem of information overload for senior executives will ultimately be addressed at the company intranet level and on the user's desktop—not by content providers.

A CFM solution offers a quick and effective solution for managing content and data on the strategic intranets that are being developed for senior executives. It provides a robust, scalable system that is focused on delivering value to the user that can be easily customized and rapidly deployed at a reasonable cost. Figure 3.3.7-6 highlights some of the single-click reports that can be generated by a typical COTS Web offering for corporate executives. In this example, hot list access has been set up to provide immediate and personalized user access to selected reports and analyses, such as sample drill-downs for "Departmental Stack Plan," "Highlight Vacant Rooms by Building," and "Furniture Standards and Allocation Reports."

The Benefits of a CFM Solution

- Seamless integration of internal research, news, and analysis with external feeds from any electronic source.
- Central management and monitoring of external sources of data and information for usage tracking and cost control.
- Ongoing management of content, connections, and technology to ensure ongoing improvements, quality, and freshness of information for satisfied executive intranet users.
- Flexible taxonomy for mapping content in industry, country, company, and event-driven categories to external information services.
- Proprietary symbology mapping to external identifiers for all content sources; API management and contextual delivery for any internal or external information service.
- Intelligent access to valuable information on the World Wide Web developed especially for financial executives and managers including company, industry, and country data.
- Hot lists for the casual user.
- CFM is fast, easy, intuitive, inexpensive, and available.
- CFM enables rapid gains in productivity and profitability.

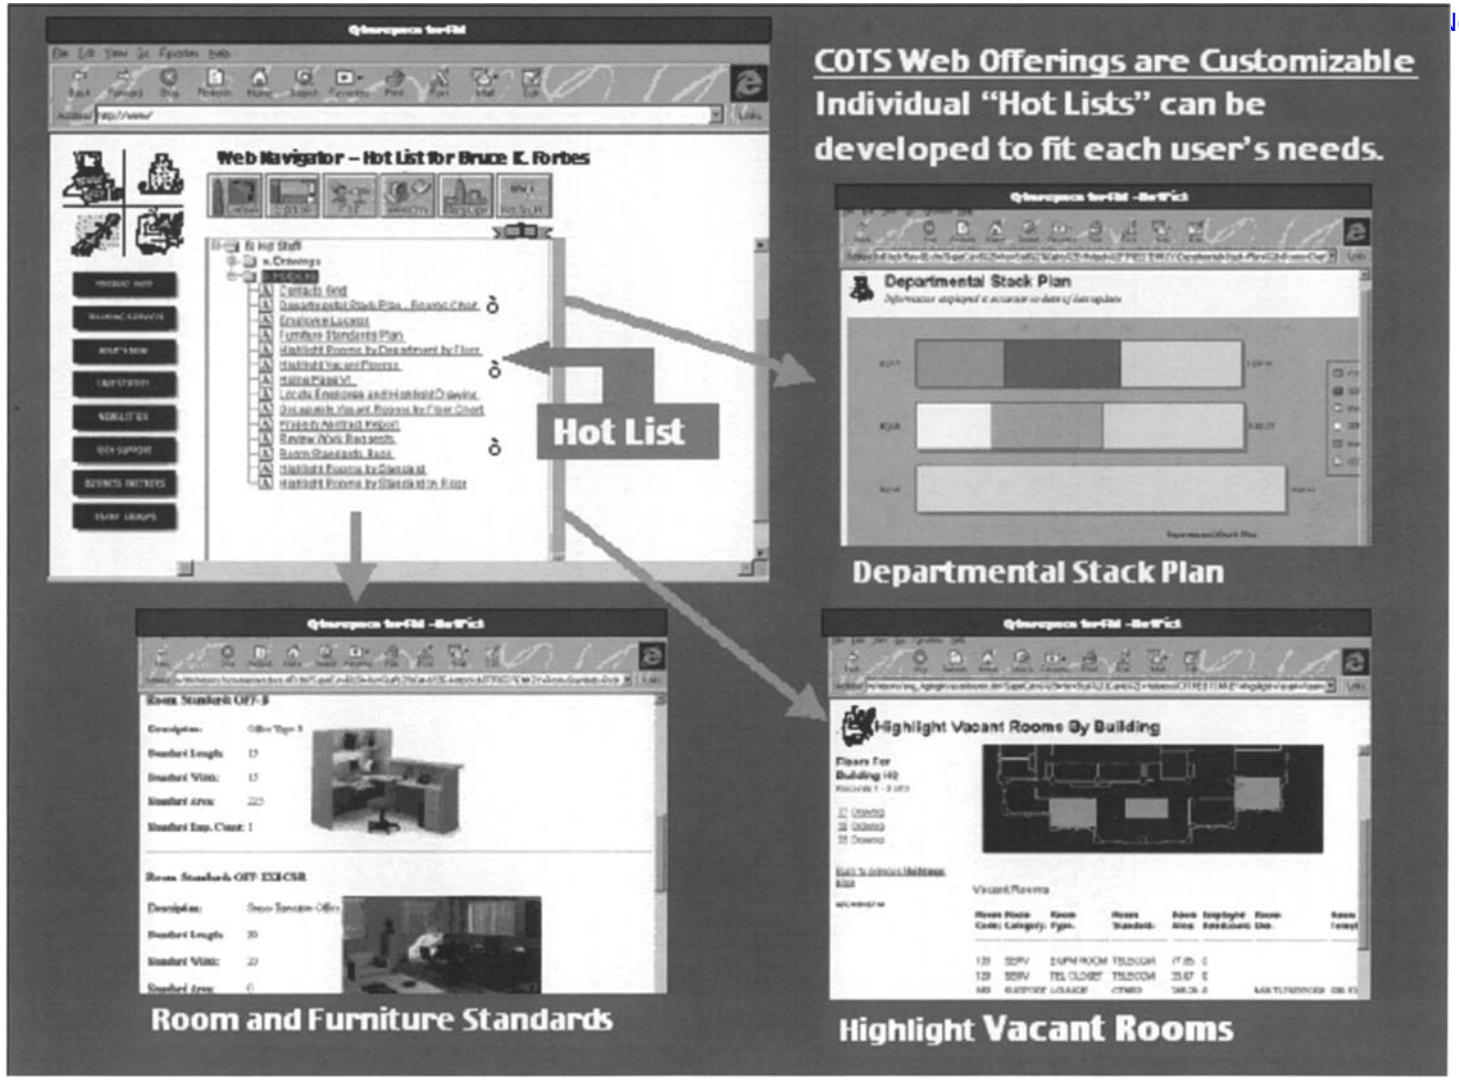

FIGURE 3.3.7-6 COTS Web offerings are customizable. Users can create their own "hot lists" which can provide immediate access to selected reports and analyses. (Sample drill-downs: "Departmental Stack Plan," Highlight Vacant Rooms by Building," and "Furniture Standards and Allocation Reports"). (*Courtesy of ARCHIBUS, Inc.*)

HOW TECHNOLOGY IS REENGINEERING FACILITIES MANAGEMENT PROCESSES

Harold Feinleib
Vincent Iannucci
Robert Trenck
Aperture Technologies, Inc., Stamford, Connecticut

Take a close look at your organization. Are your facilities management (FM) processes up to the challenge of global competition? If your FM activities are not running perfectly, then your existing processes may not be working as well as they should. It is likely that they need to be examined and reengineered.

Applying today's technologies properly can transform a process that causes you angst into a process that makes you a hero. Global competition demands near perfection of an organization's products and services. It also demands perfection from its FM operations.

One facility manager recently described his organization's space configuration process as a "nightmare." Another said his company's quarterly chargeback process used to take more than 3 months to prepare. Both used computer and network technologies to reengineer their respective firms' processes. As a result, they have become strategic players within their organizations.

Consider a well-designed automobile assembly line: Everything runs like clockwork along an immaculate, organized path. Parts are delivered at precisely the right moment to precisely the right place, so that a perfect product drops off the end of the assembly line. Not just once, but time after time.

This does not happen by accident. It happens because every aspect of the process has been examined and designed to work flawlessly.

Now, imagine a well-designed FM department where all processes also run like clockwork: Space needs are always forecast accurately for the entire organization. New space is always ready when new hires arrive. Resources are always available just in time to meet business managers' changing demands.

In a smoothly running organization, maintenance and repairs are tackled in a timely manner. Chargeback reports are always accurate and on time, and management information is always available when requested. This is not a dream. The vision of having all facilities resources available at your fingertips can be a reality. Whenever you need a current floor plan or a list of occupants or resources, you can access it instantly and accurately.

Extend the vision one step further by seizing the ability to communicate this pertinent information to business managers in a form that they can grasp and analyze immediately. You do not have to pinch yourself. It can happen at your company. It is not a dream. Can your FM

department run like this? If you do not examine and reengineer your FM processes, then the answer will be, "Probably not."

So, how do you know what to do? There is no set formula designed to tell you a system makeover is needed, but you will know it when you see it. Failing processes have these distinct, recognizable symptoms:

- Projects run slowly.
- Things seem to be more difficult than they should be.
- Pulling together information requested by management is a disruption.
- Getting management to make key decisions seems to take forever.
- Too many projects require rework.
- Move-ins are not as smooth as you would like.
- Your customers are impatient with your department.

Although the immediate reaction to process disintegration tends to be, "We need more people," hold off on the hiring, and quickly assess your organization. It is more than likely that the problem can be found in already-established processes.

When you reengineer a process, you are seeking to minimize the number of transactions it takes to get something accomplished. Doing this eliminates unnecessary transactions between people and accomplishes others in just one exchange.

Think about how e-mail has totally reengineered the process of communicating. In the past, a message was handwritten or dictated. Then, it was typed, edited, retyped, copied, addressed, and mailed or delivered to each recipient.

Now, we can write messages in a form that can be easily manipulated. It is just as easy to send the message to a group as it is to an individual, and it can be sent and received instantly. The steps of handwriting, dictating, editing, retyping, copying, mailing, and delivery have been eliminated.

By changing the process, e-mail has made communication dramatically more efficient. The same dramatic changes can be applied to your FM processes.

The value of making these processes work more effectively and more efficiently reaches far beyond the direct cost savings that are likely to occur within the FM department. Now, the parts of the organization impacted by an inefficient process get what they need when they need it, enabling them to fulfill their business missions. This increases the entire organization's competitive ranking in the global marketplace because better decisions are made and things happen faster.

MANAGING SPACE

Of all of the diverse activities that facilities managers oversee each day, space management stands out as one of the most crucial in terms of positive reengineering. Modern organizations run somewhat like factory assembly lines. Space is the raw material that keeps things moving. It must be reconfigured to meet the changing needs of its occupants. Additional space must be delivered on time to match the growth needs of the business. The lack of space should never hold up the execution of business objectives. An excess of space, however, is a waste of money.

Facilities managers walk a fine line. Managing space requires short-, intermediate-, and long-term planning and processes that support efficient decision making and execution. For the short and intermediate term, it is critical to keep space working optimally for its occupants. This includes assigning offices to new employees, moving people, reconfiguring space to accommodate business requirements, producing accurate chargeback reports, and keeping everything in good working order.

The space management process seems straightforward, but it is actually quite complex. You need to assemble a great deal of diverse information and then communicate it and evaluate it. Many decisions must be made. Numerous activities must be coordinated. It is no wonder that this process rarely runs smoothly. Many times, when a space request reaches the FM department, it has already passed the point where FM can satisfy the need in a timely manner. A slow, inefficient space management process will only make matters worse.

Space requests trigger a process that includes a series of planning sessions with the requesting business managers. To prepare for the meeting, the facilities manager will typically carry out these actions:

- Gather information from various sources regarding the people, furniture, network communications, and special requests involved in the move.
- Request or print computer-aided design (CAD) drawings of the affected areas.
- Walk the space to see what actually exists and adjust the CAD drawings.
- Mark information and changes directly onto the CAD drawing (cross out walls and write in people names, department names, and floor areas) to reflect the proposed changes that satisfy the space request.
- Present the marked-up CAD drawings to the business manager who is unable to understand the hand-drawn blueprint presented.
- Spend time going between the business manager and the CAD operations as the drawings get closer and closer to a workable solution.

As this occurs, the requirements usually change, requiring still more interactions. And, as you may have guessed, the process is not problem-free. Stumbling blocks occur when the facilities manager

- Does not know when people are being hired
- Does not know when departments will run out of space
- Cannot determine where space exists to figure out where to put new employees
- Spends too much time gathering data about who is involved in the change, at what levels they are, what furniture and network connections are needed, and whether there are any special requirements
- Relies on CAD-based construction drawings that rarely show the detail required for effective space management, such as actual space use, current occupants, network services present, and security arrangements
- Presents plans to business managers using CAD drawings that are hard or even impossible for the business manager to understand, particularly if there are hand-drawn changes
- Finds difficulty in coordinating the requirements of different department managers to lay out and outfit each space effectively

These, however, are not insurmountable problems. All can be addressed with reengineering and the proper application of technology.

REENGINEERING THE PROCESS

Imagine a space management process that not only minimizes the number of transactions but also one where all the steps happen smoothly! This process would be defined by three major capabilities of the facilities manager:

1. The ability to provide accurate, timely information about all facilities resources
2. The ability to clearly communicate ideas and proposals to business managers
3. The ability to communicate quickly and concisely with service providers who need to set up the space

An efficient process starts with an accurate up-to-date base of information. If the database is not kept current, information will need to be gathered every time a change is considered. This will build up and cause delays and confusion. Eventually, the process will break down.

FM'S COMMITMENT

The information system is the heart of the process, but it is not a silver bullet. The system provides a structure for the facilities manager to succeed, but to achieve success, the FM organization needs to make a commitment to success. First, FM itself must own and operate the system. It is critical that the FM organization controls all aspects of the system. It cannot afford to rely on anyone else to do this for them. Facilities management owns the process, so FM should own the system. For example, a company's chief financial officer (CFO) has announced that a new formula must be used to determine departmental chargebacks. Facilities management must respond to this directive. It can do so quickly when it has its own system and, thus, the ability to make the change in the system.

Facilities management cannot rely on a management information systems (MIS) department, an outside consultant, or even a software vendor to keep the system operational. Facilities management must choose a user-friendly system that its staff can maintain and manage within its own department. It should not be one designed for CAD professionals, architects, engineers, or database administrators. It must specifically take into consideration the needs and functions of the FM organization.

Second, FM must organize and take responsibility for keeping the data current. Processes can be streamlined by tracking space needs and uses with up-to-date space management drawings and data. For example, it is FM's responsibility to ensure that all workers are included in the system. This includes employees (both on-site and off-site), temps, consultants, and contractors. It is not enough to tie the system to a human resources (HR) system because the HR system knows nothing about on-site contractors and consultants.

The FM department cannot rely on the CAD or engineering department or outside consultants to keep this information up to date. If it does, delays and slow turnaround of information will certainly occur when decisions need to be made. Additionally, the information will not be formatted effectively for good management decisions.

This does not preclude CAD or engineering from having an important role in facilities planning. It means that these departments do the work they are best suited to do—creating specification, design, and construction drawings. Computer-aided design and engineering do not know who occupies the space, nor do they understand your customer's needs. You should not expect them to be responsible for maintaining space management drawings or providing information for planning decisions. That is FM's job.

Third, an effective FM must present information in a way that business managers can grasp quickly. Business managers do not have time to worry about space needs. That is FM's job. They expect that FM will clearly communicate space proposals back to them in a way that is easily understood. Business managers do not know how to read or interpret blueprints and CAD drawings. In most cases, it is not necessary, especially if FM is doing its job efficiently.

If information is presented using blueprints or CAD drawings, then the process will require an interpretive step. This wastes time. If the information, instead, is presented in col-

orful and clearly labeled drawings, business managers can quickly understand the proposal. Then, the business managers and the FM can become a team to solve space requirements, leading to fast customer buyin.

THE NEXT GENERATION: VISUAL INFORMATION SYSTEMS

Attempts have been made in the past 20 years to automate facilities information, but only recently have a number of factors allowed such technology to become successful in practice. These factors include powerful desktop computers with high-resolution graphics; user-friendly, feature-rich software that permits FM administrators to get the job done properly; and a common method (Web browsers) for anyone to access drawings and data using intranets.

In the past, computer-based solutions tried to tie existing CAD products to database systems. Because these products were not FM-driven (nor were they necessarily database-friendly), they often required the support of MIS or an outside consulting organization to customize, administer, and modify software. And these CAD-based products also required a CAD specialist to make all graphic changes. The results usually fell far short of needs and expectations.

The latest improvements in technology have given birth to new software systems—visual information systems—that can be used directly by FM without relying on CAD departments or MIS personnel. Because FM personnel maintain these systems, the time to make changes decreases along with the costs of those changes.

In a visual information system, an easy-to-use drawing system is combined with database management. Objects in a drawing are tightly integrated with the data that describe them. The integration is so tight that variances in data values can change the way the object appears on a drawing. For example, offices can be color-coded based on department assignment or by occupancy. This new approach to space management allows FMs and business managers to visualize new ways to get the most out of existing space using meaningful graphics and data designed to communicate information to executive and department managers. As a result, alternative proposals can be quickly communicated and easily understood by all.

In developing alternatives, facilities managers and business managers can move people and furniture configurations on the drawings. This can even be done during planning sessions to see the effect immediately—leaving little open to interpretation down the road.

Many facilities managers assume that they can accomplish this with CAD drawings. But CAD was designed for people who design things to convey specifications to people who build things. It is great for architects and engineers to create construction drawings for contractors to use in estimating and construction. But CAD falls far short in conveying easily understood, actionable, management information. It is like using a spreadsheet to do the work of a word processor; it can be done, but the results will fall short of expectations.

Computer-aided design floor plans do have an important place in the process: They form the basis of a visual information system. This system adds intelligence to CAD drawings with a database that describes the objects in the drawings. The original CAD base-plan drawings become reference drawings. Any change is reflected immediately—and automatically—in the visual information system.

Surprisingly, a visual information system is also the best way to communicate with architects and outside contractors—the very people who rely so heavily on CAD to perform their duties. The clear visual information conveys the purpose of each and every proposed space, an invaluable tool for professional designers, contractors, furniture dealers, network installers, and electrical technicians. Such a system can help contractors do their work faster, with no misunderstanding or miscommunication.

FACILITIES INFRASTRUCTURE MANAGEMENT

Maintaining a current data and drawing database has many ancillary benefits. For instance, departmental chargeback reports can be produced at any time. Because data are always current and accurate, the streamlined chargeback process includes only the amount of time required to print the report. In fact, browser and intranet technology even eliminate the need to print the report. Business managers can see their current space charges on line in real time any time they wish.

For maintaining space, a visual information system simplifies specification of materials needed for routine repairs. Every object in a drawing has specific data associated with it. Unique information about equipment and systems, such as manufacturer, model number, installation date, and warranty, can help in both repairs and preventive maintenance (PM) because it is easy to see where the maintenance will be performed.

Other departments can also use visual information systems. Data communications, security, electrical, and mechanical, for example, can simply tap into the system and add their area-of-interest objects on new drawing layers. Managers can also track building contents such as PCs, printers, copiers, telephones, and mechanical equipment with ease.

Consequently, organizations can deploy visual information systems as enterprise solutions that coordinate all facilities and technology infrastructure into one system. This enables everyone who maintains part of the infrastructure to see—and better understand—the plans made by other members of the infrastructure team.

THE PROOF IS IN THE PROCESS

At one well-known Fortune 100 corporation, the FM department manages 8 million square feet of space, housed throughout 40 buildings in a campus environment. In the days before installing a visual information system, staffers described their space reconfiguration process as a nightmare. Using hand-rendered changes on CAD drawings, they simply could not communicate reconfiguration plans clearly to business managers. There was little customer agreement because the customer could not understand the impact of the recommended changes. Additionally, the turnaround of CAD updates resulted in too much time between planning meetings.

Installation of a visual information system solved the crisis. In 5 months, the department had more than half the campus up and running on the system. Today, all 8 million square feet are operational in a system that is entirely maintained by FM.

The company's FM process focuses around building managers who oversee space maintenance and reconfiguration for a specific portion of the campus. Managers tap into the visual information system to plan changes and maintain their portions of the system.

When they prepare for planning meetings and other related activities, the building managers distribute colorful drawings that clearly show how each space is to be used. They even make last-minute changes to drawings and data during the planning sessions with business managers. This enables making decisions rapidly and creates strong customer buyin. Thanks to the successful implementation of a visual information system, the FM department's reputation has changed from being an information bottleneck to a strategic department that efficiently meets the challenges facing the business.

REENGINEERING THE CHARGEBACK PROCESS

The real estate department of a large computer manufacturer tracks 300 facilities that comprise 4.5 million square feet. The department is responsible for providing business managers with chargeback information. In the past, the staff used CAD drawings and handwrote perti-

nent information into each office space in the drawings, including the occupant's name, the department in which the office was located, and the total square footage. These data were entered into the CAD system and then extracted as a file. Then, the business managers reviewed and verified the data and then sent them to IT for validation and compilation. If a name had been misspelled or had been entered incorrectly or a department designation had changed, the data would be rejected.

Completing such a lengthy process took 40 people half of their work time and cost the organization more than $1 million annually to produce. The reporting cycle took more than 3 months to complete, only to have the chargeback information challenged by many business managers who found errors in the data.

To make matters worse, the business managers wanted to receive accurate chargeback information quarterly, rather than annually. Obviously, this was impossible because the reporting process itself took longer than the desired reporting cycle!

They needed a system that would retain one central repository for all facilities information, a system that could be used by everyone in FM. And, most important, one that was easy to learn and use.

A visual information system offered the business and facility managers a workable solution. Seven zone managers use the system to maintain the drawings for all 300 locations, streamlining the process and eliminating administrative clutter.

The system restored the integrity of the reporting process. Because the company now has accurate quarterly reports produced, it has saved upward of $1 million a year in direct costs to produce the reports. By empowering zone managers with a visual information system that they can use to track personnel moves, the way FM is viewed in the corporation has improved dramatically.

RETURN ON INVESTMENT

The success of a visual information system is nearly ensured when you have the backing and commitment of your executive management. Receiving this commitment is contingent on a favorable return on investment (ROI). The ROI for implementing a new process hinges on three questions:

1. Who is impacted?
2. How are they impacted?
3. What is the cost of the impact?

Give the *who* question a lot of thought, and you will soon see how spearheading a reengineered, efficient FM process makes you a financial asset to your organization.

Let us take our first example where space planning was a nightmare. Who was impacted? Certainly, the business manager who made the request. Also, the people directly affected by the request. How are they impacted? The delays may cause them all to spend too much time with the space change, reducing their productivity.

What is the cost of the impact? Multiply the number of days lost by the contribution of each employee multiplied by the number of employees who are moved each year. If the employees such as salespeople produce revenue, the number could be staggering. This could have a large negative impact on the organization's financial results and its ability to compete!

This nightmare process can easily cost the organization millions a year and be the source of lower employee morale and lower employee productivity. Now, you can see how this nightmare process negatively affects earnings and hence the CFO, the COO, and even the CEO!

What about our chargeback example? Business managers need to control their resources, but if they do not receive accurate and timely chargeback reports, then they cannot control

one of their largest budget items. They feel out of control and frustrated, which affects their ability to manage their other resources. This leads to a negative effect on corporate operations and on financial results. Again, the CFO, COO, and CEO are affected, not to mention every department and manager between you and the CEO!

FM MORALE

Thanks to this newest form of computer-aided facility management, facilities managers can make a difference in an organization by providing pertinent information quickly and effectively to all customers. Best of all, they finally know that they are making a difference to the organization. This, in turn, raises the esteem of the entire FM department. Moreover, senior executives begin to view the FM organization as more professional because they now see how it contributes to the business mission.

A visual information system can help you to reengineer your FM processes. It places ownership for space planning in your department's hands, helps you reduce your dependency on expensive consultants, streamline the planning process, and communicate more effectively with business managers. This can lead to strong decisions. The direct and indirect cost savings associated with reengineering the space management process can be dramatic. Obviously, cost savings will vary by organization, but the principles reviewed here can be applied to any organization.

Reengineering the FM process can bring dramatic bottom-line results and transform FM into a strategic player. The key is quickly providing executives and department managers with the information they need—in a format they can understand—so that facility decisions can be made faster and more effectively. Armed with the power of this latest technology, members of the FM department will become strategic players, raising their esteem in the eyes of management and peers.

The Characteristics of a Visual Information System

Achieving the unique benefits provided by a visual information system requires a set of important design principles, all of which work together to produce a powerful, cohesive capability. A visual information system designed to be used by FM has these characteristics:

- Does not require professional programmers to customize or modify it. Facilities staff can modify the system to meet the organization's changing needs.
- Is easy to use, so FM can make changes directly in the drawings without requiring CAD operators.
- Allows FM to tie drawings and data together.
- Offers easy access and navigation through drawings and data.
- Features a built-in report writer, so FM can create or modify reports.
- Runs reports against objects in drawings by highlighting objects.
- Runs reports against one or more drawings.
- Moves objects from one space to another, automatically updating the database.
- Can easily access and update data in industry standard databases.
- Accesses drawings and data live over the organization's intranet using a Web browser.
- Accesses drawings and data in a client/server environment over a TCP/IP network.
- Controls access to drawings layer by layer, so different groups can work on the same set of drawings.
- Easily integrates with other applications, such as computerized maintenance management systems (CMMS) or bar code systems.

- Designed to be an information system.
- Has friendly, easy-to-understand graphics.
- Can instantly color-code drawings based on data.
- Can change text on drawings as underlying database information changes.
- Provides information to management in a clear and understandable form.
- Discloses layers of information progressively.
- Locates personnel and equipment easily, no matter in which drawing they are, over the organization's intranet.
- Customizes applications by placing buttons on the drawings that automatically perform predefined functions such as running reports.

ARTICLE 3.3.9

GETTING THE MOST OUT OF INFORMATION TECHNOLOGY PROJECT CONSULTANTS

Joseph Best
Project Management Services Inc., Atlanta, Georgia

Scott Maddern
Integris, Billerica, Massachusetts

You cringe when you think about it—a project that you wholeheartedly sponsored and for which you stuck your neck out to convince other stakeholders that it had "the right stuff" crashes and burns just a few months after its launch. You're in good company.

A recent study by The Standish Group indicates that project failure is a pervasive reality among information technology (IT) executives and reveals that

- Forty percent of IT projects are canceled before completion.
- Thirty-three percent of the remaining projects are challenged by cost and/or time overruns or changes in scope.
- Failed and challenged projects together cost U.S. companies and government agencies an estimated $145 billion per year.

Why do so many projects get off track? There are myriad reasons, but one common factor is mistakes in hiring and managing consultants. Many sponsors unwittingly set their projects up for failure by not establishing clear guidelines up front to determine how to discern when it's the right time to bring in outside help, what to look for in consultants before hiring them, and how to manage consultants effectively once they're on board.

With big money and your management reputation on the line, here's how you can avoid making costly mistakes in working with consultants on your next IT project.

DETERMINE WHEN A PROJECT REQUIRES OUTSIDE HELP

Bringing in consultants before you've fully used your existing resources can be demoralizing to your staff. It conveys to in-house project team members that you think they're not competent enough in their core skills to contribute effectively to the project. Therefore, maintain morale by hiring consultants only when the project's scope makes it necessary. How do you tell? According to Ralf Leszinski, a McKinsey & Co. alumnus and executive vice president of Atlanta-based Project Management Services, Inc., there are five signs:

1. *Your company doesn't have the in-house expertise.* You have no one on your core management team who has the expertise required to manage the project.
2. *Your company lacks the capacity to lead a new project.* You may have the skill set within your company but can't free them up in time to address a critical project.
3. *You need to accelerate the progress.* Suppose you have a new software product ready to go, but the associated systems to control the sales are 3 months behind schedule. If you're at full capacity, bringing in the right consultants will help you expedite the process and diminish loss of potential revenue.
4. *The project's revenues exceed expenditures.* The project will create an additional revenue stream that overcomes its costs.
5. *A project component doesn't fit your core delivery structure.* In other words, gaining knowledge in a particular area is not going to enhance your overall business model. After the project is completed, you can easily part with that knowledge because it's not something you're interested in carrying forward in your company.

KNOW WHAT YOU'RE LOOKING FOR

Once you've determined that it's the right time to bring in consultants, how do you identify who would be a good match for your project? What criteria should you look for? In addition to the standard quantitative issues such as the firm's financial strength and capacity, look for the following qualitative factors as you interview prospective consultants.

What is their track record? Have they done similar work before? Remember to pay for the consultant's knowledge, not training.

Are they open about their failures? There's nobody out there with a perfect track record. Ask about their projects that did not go well. When something went wrong with a project, how did the consultant respond? What steps were taken to salvage the project? What did the consultants learn to prepare them for the next time?

Do they initiate a discussion of your success criteria? Look for consultants who ask you questions like, What is your definition of *success* for the project? If we were to go in and do exactly what you want, what would the postproject environment look like? If the consultant is not clear about your objectives up front, expect to make several time-consuming and money-consuming adjustments down the road to get things back on track. Define success criteria, and keep them in focus throughout the project.

Are they concerned about what drives the profitability of your business? For example, a solution might meet the project's objectives, but if it's too costly, it will have a negative impact on your bottom line. Look for consultants who suggest solutions that meet a particular need and also enhance your company's overall performance.

What is the firm's core competency? Suppose that the project involves several different components: a strategic portion, a tactical portion, specific technical expertise, and so

forth. Find out which component the consulting company can handle best, as opposed to looking for a one-stop-shop firm. Why? No firm can be excellent in all facets of a project. Instead, try to match the consultant to the specific project component, or hire a lead consultant as a general contractor who has access to the best coders, network designers, trainers, and so forth.

Whom will you get once the project begins? Beware of a bait-and-switch situation. Many consulting companies show up with their top guns and then supply the client with second stringers after the project starts. Make sure that the contract specifies who will be on your team when the project is launched.

Will the key consultants be around for the long haul? Take steps up front to ensure that the consultants whom you hire will stay with your project until completion (see the sidebar, "Keeping Consultants on the Project").

Before you meet with candidates, design an evaluation matrix by putting four or five (or whatever the number) consultants' names on the top with the previous criteria listed on the left-hand side. During the interview, jot down your observations for each category, and before it's over, ask for a list of three to five references whom you can contact by phone to verify information. After you've completed the interviews and contacted references, look at your notes and incorporate a grading system (e.g., 1–10, 1–5, or whatever works best for you) to codify how comfortable you feel about a consultant in a specific category. Then, add up the scores. In this way, you have the data you need at a glance to compare apples with apples.

INITIATE THE RELATIONSHIP

Once you've decided whom you should contract, how do you ensure that the relationship starts on the right foot? Here are five tips:

1. Notify all team members that you've selected a consultant, and give the reasons behind your decision. Explain to staffers that the consultants will provide necessary support to the team as a whole, while acknowledging the heavy existing workload for employees. In this way, you cause in-house team members to view the idea of bringing in outsiders in a positive light, and you cultivate good morale in the entire team.
2. Identify what facilities, communications, and technical requirements the consultants have, and line them up ahead of time. Consultants may need a laptop, software, access to key information, or even office space. When you address these requirements up front, you help the consultant get off to a good start. Otherwise, you're paying for wasted billable time as you scramble around to equip consultants after the meter has started running.
3. Communicate project expectations, goals, objectives, key milestones, and risks in a formal document (i.e., a project charter) to optimize team performance.
4. Obtain commitments from all project team members before the project begins. Require that your team members stand up in a formal session and commit to their deliverables, as outlined in the project charter. This action solidifies the team members' resolve. Otherwise, you risk project failure because of one or more people who lack genuine commitment to fulfill their project responsibilities.
5. Make sure that consultants understand your standard reporting processes. This is to help you assimilate the data easily and reduce the chances of miscommunication that could hinder the project's progress.

MAXIMIZE THE RELATIONSHIP

Okay, you've done your due diligence by finding the best consultants that the project requires and by getting things started on the right foot. Now, how do you manage the relationship effectively over the long haul to keep the project on track? Here are five guidelines:

1. *Cultivate a project environment in which consultants can report actual status.* Reward honesty when you ask project heads about their status. If the person who is behind is ridiculed, you're not going to get the true status in the next meeting. Instead, provide help, guidance, and additional resources (e.g., equipment, software, human capital, etc.) to get those consultants back up to speed.
2. *Make consultants feel like part of the team.* Consultants work best when they feel a sense of ownership and pride in the project that makes them to want to do whatever it takes to make it successful.
3. *The company should put in the same effort as the consultants.* Part of maximizing the relationship is managing the consultants. If the project is behind, for whatever reason, your resources need to work side by side with the consultants to ensure that the consultants have correct information about your internal structure and to manage the team as a whole to keep the project on track. If the consultants are working on Saturdays to catch up, you and the staffers should be working with them to make the project a success.
4. *Be attentive to the project and project team.* Project status reporting, maintaining schedules, and other supervisory functions are hard work and take you away from core project activities. But if you neglect to review people's status carefully, sooner or later, the consultant will realize it and be more inclined to cut corners or lag behind schedule—and you won't know until it's too late.
5. *Review the project success factors periodically with consultants.* In this way, you and the consultants will stay focused on completing priority tasks, as opposed to being sidetracked by other interesting but less important activities, and will keep the project moving on schedule.

Your decisions in hiring and managing consultants can make or break a project. Therefore, do your homework up front. Make sure that you have a genuine need for consultants, know what to look for, and take steps to maximize the relationship once you've hired them. In this way, you can make informed decisions that boost your project success rates—and your company's bottom line.

KEEPING CONSULTANTS ON THE PROJECT

Although ultimately you can't control people's lives, you can take steps up front to increase the likelihood that the consultant you hire will stay with your project to completion. Here's how:

- When interviewing prospective consultants, ask about their short- and medium-term goals. If the consultant says, "After I get enough knowledge, I'd really like to get out and start my own company," that person might not be around next year.
- If the consultant is under a noncompete agreement, see if you can get a copy of it. The noncompete agreement should include time limits and specify what clients, geographic regions, and services are involved. If it is a tough, enforceable contract, the consultant can't just jump ship to the next employer who offers $5 more.

KEEPING CONSULTANTS ON THE PROJECT (*Continued*)

- Try to secure the person to a project performance bonus that's paid out at the end of the project.
- Require that the consultant sign a nondisclosure agreement (NDA). The NDA should include signatures of the individuals assigned to the project; a clear definition of what constitutes *confidential information*; the rights, restrictions, and obligations of the consultant who receives the information; and the term for which the agreement is in effect.
- Make a provision in the contract that reserves for you the right to review the replacement and specifies that the consulting company will cover the knowledge transfer of the replacement. So if the firm's lead expert leaves, for whatever reason, they do not bill you for time until the replacement is as knowledgeable as the key person who left.

OUTSOURCING: THE KEY TO CONTROL OVER THE ENTERPRISE

Although no one can deny the tremendous benefits of open, client/server computing, few would embrace its corresponding set of complexities. Multivendor madness adds to the complexity of a network, and to IT management's headaches.

According to THG's Information Technology Benchmark, the average company has more than 100 IT hardware, software, and services vendor relationships. With desktop systems, operating systems, and applications frequently supplied by different vendors, the multivendor atmosphere can rapidly grow chaotic. Information technology management holds the responsibility of ensuring harmony across the network. Although the drive toward standards-based open systems has helped, sorting through the complexity is still a major challenge.

Companies that deal with such issues of complexity have found that outsourcing is a sensible remedy.

In addition to complexities, cost is a major challenge. One of the most common problems of client/server technology is the unanticipated expense of deploying such a solution. Rolling out a distributed computing environment brings with it numerous "hidden" costs—maintenance, training, and support—all of which are integral and critical to the ongoing success of the environment.

Outsourcing can deliver a number of cost benefits, as functions such as operations and maintenance become the responsibility of the outsourcing company. For example, implementing an outsourcing strategy allows a business to control its staff costs on a long-term basis.

Personnel Resources and Shortages

It is hardly a surprise to anyone in the business today that, as the demand for and complexity of IT services continue to increase, the experienced labor pool continues to shrink. The nation faces an overall shortage of IT staff skilled in the latest technologies, and the turnover of the existing pool is enormous. Add to this challenge the fact that IT personnel account for about 52 percent of total IT spending, according to Compass America, a leading performance consultancy. The net result? Companies and organizations pay more than one-half of their IT budget for people they have trouble finding in the first place—and holding onto in the second. Then how does this allow the company to remain even moderately ahead of the technology curve?

Add Strategic Repositioning

In addition to complexity, cost, and personnel shortages, today's IT manager also has to confront the Net—most significantly, the growing demands from top management to leverage it, so that the company becomes a competitive e-business. That means that IT is, effectively, no longer the purview of the IT department, but rather a critical, strategic element that affects the entire future of the organization.

There is light at the end of this tunnel, however. Corporations that choose client/server outsourcing over the traditional in-house approach are positioning themselves to achieve considerable benefits. By investing in an external team of IT professionals, a company can achieve new balance in its technology operations. The outsourcing team is more able to deliver higher service levels, and it can also do so while managing corporate costs better. Day-to-day operational needs are met by the outsourcing partner, and internal IT personnel can focus on the requirements driven by the company's core business. Additionally, IT management is free to concentrate on deploying technologies that enhance the company's competitive position and long-term growth.

IS YOUR CAFM SYSTEM PREPARED FOR TODAY'S NEEDS?

Yolanda Hill
Facility Information Systems, Inc., Camarillo, California

It is most beneficial for facility management (FM) and real estate directors to provide access to enterprise data via a standard intranet Web browser. Enterprise-wide solutions need to provide business intelligence to the staff for day-to-day decisions in multiple locations and often across multiple time zones. Secure intranets allow distributing and receiving mission-critical information anywhere at any time. Before such an implementation, the organization needs to be able to identify computer-aided facility management (CAFM) solutions that are designed to provide the desired information and match the scale of the enterprise database.

Let us examine some of the factors that need to be considered when evaluating and purchasing a CAFM system. First and foremost, a CAFM system must integrate with databases across the entire enterprise to support decision making, problem solving, and planning. Implemented correctly, the system will become a central source of information to authorized participants involved in strategic, tactical, and operational processes during the life cycle of a facility.

The system should also support document and work flow management with technical document management systems (TDMS). Integration with TDMSs ensures that drawings, maps, leases, property documents, and all associated reports are interactively accessible by appropriate participants in every phase of the life cycle.

Many CAFM vendors have rushed their applications to the Web using proprietary and outdated or new and risky technologies in Web deployments. Often these applications do not port to the Web without time-consuming and expensive customizations or ongoing migrations to current technologies and platforms. Many CAFM systems in the marketplace cannot secure the back-end databases nor can they integrate easily with other systems. Often such

systems contain features to secure access via forms or screens and leave the back-end database exposed to casual or deliberate tampering.

To determine the readiness of any CAFM application, several critical requirements must be addressed in depth:

- Is the CAFM system built on a current, proven technology?
- Does the database management system (DBMS) scale up to manage very large amounts of data in a secure environment? Can the system be deployed on multiple client/server operating systems? Does the system provide complete functionality and features, including access to computer-aided design (CAD) drawing and geographic information systems (GIS) map data in a Web environment?
- Does the system provide options for secure integration with other corporate or vendor applications?
- Do reporting requirements easily serve the needs of all levels of planning, management, and operation? Corporations that own or lease facilities that have several million square feet of space need the power, integrity, and functions of a system that can answer these questions affirmatively and then provide all of these options.

Is the CAFM System Built on a Current, Proven Technology?

Large FM and real estate organizations need a core system that can be integrated on the Web and in client/server environments throughout a large complex organization. To date, only Oracle development platforms have successfully met this requirement by providing the ability to develop in a variety of languages, including JAVA and XML, as well as its own PL/SQL language. Many DBMS vendors claim the ability to store processing logic in their databases, but Oracle remains the leader in this approach to data management. Only those CAFM vendors that employ 100 percent current technology and methods can ensure delivery of robust, secure, cross-platform solutions.

Does the DBMS Scale Up to Manage Very Large Amounts of Data in a Secure Environment?

In the Fortune 2000 marketspace, a DBMS should scale to multiple terabytes to hold the massive amounts of detailed current and historical data used in daily operations, business-to-business (b2b) transactions, and for global strategic decision support. A CAFM solution must manage a large corporation's complete asset portfolio in a single, secure, well-structured database.

Many CAFM vendors downplay the sheer volume of data that will eventually reside in an enterprise-wide information system and therefore ignore the importance of providing industry standard databases. Too often, important records for valuable assets have been relegated to spreadsheets or file cabinets, or even the heads of key personnel.

All current enterprise data, as well as historical records used for determining trends and forecasts, should reside in a single, secure, well-structured database that can be easily integrated with other corporate, enterprise resource planning (ERP), CAD, and GIS applications. Beware of systems that cannot support all FM and real estate data in a single database.

Does the System Provide Options for Secure Integration with Other Corporate or Vendor Applications?

Inside large organizations, land, buildings, and other structures, plus assets such as furniture and equipment, are all being closely scrutinized for opportunities to increase enterprise prof-

its—especially by using automation to improve decision-making processes. Traditionally, data that are needed to describe and clarify the real estate and FM information are scattered in various manual and automated legacy systems across the corporation.

Today, corporate initiatives require much higher levels of integration and many more data delivery options than ever before, including delivering content to the Web. Work flow and business process automation are standard requirements and features expected in off-the-shelf, enterprise-level applications. E-commerce initiatives and strategies drive organizational goals, including new areas that have not traditionally been considered crucial to a company's success in the marketplace.

The FM and real estate systems that are used to manage and deploy a corporation's physical assets must easily integrate with all corporate, CAD, GIS, ERP, and other vendor systems in real time. They must also support multiple data access options, including serving data to portals and laptops, as well as wireless and hand-held devices—all while providing the appropriate levels of security.

Integration with GIS Products

Geographic information system functionality extends from inside the building to related land and infrastructures outside the building. For example, travel time may be computed starting at any office within a building and terminating inside a building across the street, across town, or across the country. Real estate managers may query the database for available parcels of land based on parameters that specify the desired demographics of the surrounding area (available labor force, distance from major transportation and appropriate housing, the quality of the education system, etc.). Cable lines and connections may be tracked both inside and outside the building. The CAFM vendor must meet the need for large organizations to be able to create, access, and update data securely in real time from anywhere at any time.

Can the System Be Deployed in the Web Environment and on Multiple Client/Server Operating Systems? Is the Entire Set of Features and Functionality Provided in Both Environments?

Too often, excessive manual verification of data for strategic planning causes delays of many months. Delays in getting the data required for making important decisions result in high labor costs, erroneous reporting, and the inability to deploy human, real property, and other assets appropriately and cost-effectively. These delays can cause real harm to an organization.

Oracle remains the leader in scalable, Web-deployable data management. Only those CAFM vendors employing 100 percent current technology and methods can ensure delivery of robust, secure, cross-platform solutions.

Are Reports Provided by the CAFM System Easily Generated? Do They Satisfy the Needs of All Organizational Levels of Planning, Management, and Operation?

Real estate and FM organizations are increasingly the focus of corporate reengineering efforts. Often, data in these areas are not readily available for informed decision making related to process improvements. Outsource vendors often provide deceptively simple, financially attractive alternatives to eliminate in-house FM operations. Many CAFM vendors offer solutions that appear attractive on the surface but that cannot deliver the scalable, corporate-level reporting capabilities that distinguish more robust systems.

A CAFM solution must reliably provide all of the information that executive management needs to evaluate the options and to make fully informed decisions. The information must be distributed to the right people, at the right time, using secure delivery methods.

Checklist of CAFM System Features

A complete best-of-breed CAFM system should provide the following features and functionality:

- Integrate all FM, real estate, and corporate databases with CAD and GIS drawings.
- Capitalize on Oracle 8i object relational database functionality to link database records with the enterprise's tabular data in CAD drawings and GIS maps.
- Work seamlessly with Oracle security, integrity, data manipulation, transaction support, data storage, distributed processing, and performance tuning.
- Provide built-in routines for auditing drawing versus database square footage totals.
- Depict cables and connections in a drawing using GIS network analysis techniques.
- Provide the ability to drill between various levels of regional maps to building and related floor drawings.
- Support relocation planning and move operations.
- Provide parcel maps for properties recorded in the database.
- Support client/server and Web-based publication and distribution of graphic queries of enterprise data on CAD drawings.
- Permit client/server, as well as Web-based, deployment.
- Generate complete floor plan layouts that include organizational adjacency and travel time requirements established by enterprise planners.
- Support the generation and publication of thematic maps used in spatial analysis processes.
- Exploit other GIS functionality for specific niche requirements inside the walls of the buildings.
- Expand the facility adjacency relationships through topology inside the walls of the building.

In summary, the view from the top is that corporate infrastructure resource management without current location data is just a budget total without line items. The Internet changes everything because mission-critical information can be distributed anywhere at any time *and* can be received anywhere at any time.

ARTICLE 3.3.11
HUMAN RESOURCES

Matthew C. Adams, P.E., APPA
Adams Consulting Group, Atlanta, Georgia

The range of functions fulfilled by human resources (HR) professionals is a key component in successfully managing any organization. New concepts are expanding the HR role from that of administration to a source of administrative expertise for the overall functioning of the organization.

Traditional roles met by HR departments include policy and regulatory enforcement, processing hiring and firing procedures, managing the paperwork aspects of benefits programs, and administering compensation decisions. Particularly empowered and proactive departments also may manage recruiting, training, and employee development programs, as well as design workplace diversity initiatives and the like.

Most of these procedures are disconnected from the real work of the organization. However, as the perceived ability of the HR function to positively affect actual operations increases, HR professionals are becoming more involved in processes that affect outcomes, such as creating economic value for owners, creating product or service value for clients, or creating workplace value for employees. New areas for participation include partnering with senior managers and line managers to execute strategy, to organize work more efficiently to reduce costs while maintaining quality, to champion employee concerns and increase employee contribution, and to serve as agents of continuous transformation to improve the organization's ability to change in a rapidly changing world.

In a world that is continually transforming itself at increasing speeds, HR can provide a key competitive advantage by contributing to organizational strength. Qualities such as speed, responsiveness, learning ability, agility, and employee skills will make the difference between success and failure.

STRATEGIC VALUE

By defining organizational architecture, HR can identify the organization's underlying way of doing business, compare it with models of the way things should be accomplished, and work to bridge any gaps that appear. By enabling the organization to clearly see how it functions in terms of strategy, structure, systems, style, skills, and shared values, HR can play a partnership role in ensuring the attainment of strategic goals.

To remedy perceived deficiencies in organizational architecture, HR can propose and create models for best practices to implement programs for culture change that will bring state-of-the-art approaches into play to create more effective structures.

Human resources should be able to assess its traditional activities, including employee initiatives such as pay-for-performance and action-learning experiences, to determine which contribute most to strategic accomplishment. This approach will enable HR to add value to the overall organization by becoming a strategic partner in a business sense.

ADMINISTRATIVE EXPERTISE

Rather than serving merely as rule enforcement police, HR professionals can move from an administrative role to a new capacity as administrative experts in which they help improve the efficiency of both their own departments and that of the entire organization. Processes should be identified that can be accomplished better, faster, and less expensively. Technology can be used in unexpected ways for scanning resumes of applicants and creating databanks of prospective personnel or for developing electronic bulletin boards that enable employees to communicate with senior managers. Human resource professionals throughout the organization can make the same contributions. Systems can be developed to create interdepartmental communication or to enable sharing of services, for example. A center of expertise can coordinate and share important information regarding organizational processes. Such achievements will cut costs and improve efficiency.

EMPLOYEE CHAMPIONS

Traditionally, HR people have attempted to ensure the loyalty and engagement of employees by meeting their social needs and improving family benefit programs. New techniques for creating value for employees include orienting and training staff about the value of high morale, serving as the employees' voice in management discussions, creating opportunities for personal and professional growth, and enabling employees to meet increased demands that may be placed on them.

By proactively identifying causes of low employee morale, for example, HR can help management develop and implement programs to counteract negative trends in productivity. By clarifying goals and providing enabling tools, HR can play a critical role in improving morale problems.

AGENTS OF CHANGE

An organization's ability to adapt, learn, and act quickly can make all the difference in a changing world. Human resources can play a strong role in contributing to an organization's ability to embrace and benefit from change.

By focusing on initiatives such as creating high-performance teams, reducing cycle time for altering procedures, and implementing new techniques, HR can facilitate change. The new HR could also ensure that mission statements are clear and reflect new realities and help to transform those missions into specific workplace behavior that contributes to their attainment.

Human resources can even take the initiative to create a change model, a managerial tool that enables the organization to identify key success factors for change and then assess strengths and weaknesses in meeting each factor. With this information, management can design programs to increase success, which can be monitored by HR to assess their effectiveness.

To facilitate change in culture, HR has four processes at its command that will facilitate success. Initially, the concept of the culture change itself must be defined. Second, the reasons for the necessity for the change must be made clear to all managers and employees. Third, HR should establish ways to assess current and desired cultures to measure the gap. Finally, creative approaches should be developed to close the gap to create the desired culture change.

HUMAN RESOURCES' MANDATE

Increasingly, HR professionals are being required to concentrate on the deliverables rather than on the traditional processes of their work. By focusing on value created, the HR function will develop and implement mechanisms that produce measurable effectiveness in terms of organizational strengths and cultural transformation.

These increased demands can be met if management makes the corresponding investment in the HR function. It must be understood by all that such "soft issues" do matter and that structure and operating paradigms contain value. Without this recognition, strategies become mere hopes rather than realities, and concepts outweigh results.

Management must also hold HR accountable for results in measurable terms. By tracking, measuring, and rewarding performance, management can expect substantially greater value from the HR function.

Investment in innovative HR practices is becoming the norm. Increased communication facilitates awareness of successful practices that can be implemented with appropriate adaptations to an organization's unique structure and mission. The tools, information, and processes are available. They need only be acquired and used.

The professionalism of HR personnel can be upgraded as necessary through continued training and by hiring experts in particular fields. Human resources professionals should understand their organization's purpose, the theory and practice of the HR function, have credibility, and be able to contribute to organizational change. Administrative expertise for facilitating change requires some knowledge of reengineering. With all of these skills, HR professionals will be in a position to effect real and meaningful change that will significantly contribute to an organization's success.

ARTICLE 3.3.12

USING CUSTOMER SURVEYS TO IMPROVE FACILITIES COMMUNICATIONS AND PERFORMANCE

William C. Ronco, Ph.D.
Gathering Pace, Inc., Bedford, Massachusetts

Sheila Sheridan, C.F.M., C.P.M.
Harvard University John F. Kennedy School of Government, Cambridge, Massachusetts

"Why survey customers?" many facility managers challenge.

"We already know what they think," many contend.

"And if we don't, we're not so sure we want to find out," others worry.

Actually, customer satisfaction surveys provide facility managers with an inexpensive, effective tool to improve communications and performance.

However, not all surveys provide reliable data. If amateur survey users are not careful, it is all too possible to invest more meaning into survey results than the tool warrants. Worse, it

is easy to misinterpret and misuse survey data. Several key steps ensure that surveys provide facility managers with useful data.

COMMUNICATIONS MISTAKES

Understanding the mistakes facility managers make in communications provides a foundation for understanding the most important communications tools and the need to use them. In addition to the passivity described before, facility managers make three other recurring mistakes when it comes to communications:

1. *Thinking you know what most customers think.* Facility managers explain, "My phone is ringing all the time. Believe me, I know what my customers want." Responding to a ringing phone can tell you what some customers want, but these are usually just a vocal minority, and they often do not represent the sentiments of the quieter majority.
2. *Thinking customers understand what you do.* "How can customers not understand what we do?" facility managers wonder. "We've been here longer than they have." Yet, time after time, facility managers discover that their customers have different expectations, goals, and methods than they do.
3. *Thinking customers understand how best to work with you to add value.* "It's their business," facility managers complain. "How can we tell them how to run it?" Yet, nearly every facility manager knows that customers use the department in reactive, last-minute ways that limit long-term effectiveness and productivity.

These recurring mistakes define the needs that facility communications tools must address. The tools include the following:

- Customer satisfaction surveys
- Internal marketing materials
- Written work plans
- E-mail
- Groupware
- Facility manager

Customer Satisfaction Surveys

Customer satisfaction surveys improve communications coming into the facilities department by providing an accurate picture of the way the overall customer base feels. Survey data are important because they are more accurate, more complete, and more objective than the occasional unsolicited praise or complaint letters that come in. Surveys also provide more specificity, more clarity for action improvements, and clear benchmarks for improvement and charting progress. Figure 3.3.12-1 is an example of a facility management customer survey identifying issues and a means to rate customers' satisfaction.

Not all surveys are useful, however, so it is important to distinguish what constitutes a valid survey:

- *A response of 100 percent or a valid sample.* Basing action conclusions on a 50, 60, or even a 70 percent response rate is misleading. A 100 percent response on a smaller but representative sample provides a more accurate picture of overall sentiment.
- *A tool that distinguishes different levels of sentiment.* "Yes" and "No" responses do not provide the information necessary to take action. The difference between a "Strongly Agree"

The Facility Department:	Strongly Agree	Agree	Slightly Sgree	Slightly Disagree	Disagree	Strongly	Not Applicable	*Priority* High		Medium		Low
Technical												
1. Has strong technical skills.												
2. Provides innovative solutions.												
3. Solves problems effectively.												
4. Provides a high level of technical service.												
Business value												
5. Tries to understand customer priorities.												
6. Responds to customer business priorities.												
7. Understands what adds value.												
8. Provides solutions that add value.												
Communications												
9. Provides adequate information about what they do and how they work.												
10. Works effectively with customer input.												
11. Provide adequate information while working on projects.												
12. Provides adequate opportunities for customer input during projects.												
13. Listens effectively.												
14. Treats customer interests with respect.												
15. Overall partners effectively.												
16. Things the Facility Department does well	Could improve											
17. Things I would like to see the Facility Department do:

and "Agree" response is a difference that facility managers need to know about and respond to.

- *A one-page form.* Response rates dive after the first page.
- *Both closed- and open-ended questions.* Both kinds of questions provide useful data.

ARTICLE 3.3.13
TOTAL COST OF OWNERSHIP

Stephen K. Lowe
Art Center College of Design, Pasadena, California, and Facility Information Systems, Inc., Camarillo, California

Any facility planner will tell you that the initial design and construction investment in a building is just the tip of the iceberg. During the life cycle of a large enterprise, expenditures for operations, space renovation, occupant relocation, and an abundance of ongoing asset resource budget items quickly eclipse initial construction costs. Facility life cycle economics starts with early planning tasks, continues through all operations, and ultimately ends with disposal issues.

For many of the largest, best-run organizations, facility management (FM) and infrastructure management (IM) are helping to ensure that the capital value of facility information is sustained over time. Moreover, it is critical that enterprise organizations continue to raise the level of understanding and use of financial impact as a key component for infrastructure decision models. Return-on-investment (ROI) evaluation for potential structure, infrastructure, and localized space investments all require real-world tools for measuring cost and estimating value.

The analysis of life cycle cost, which had its roots in the energy crisis of the early 1970s, represents a paradigm shift away from first-costs analysis. For example, before life cycle costing, a facility manager might have considered only the up-front costs of a backup diesel generator, while ignoring the ongoing costs of fuel, maintenance, and other associated infrastructure costs—such as local availability of trained repair personnel.

Today, there is still much discussion about quantifying *all* costs of procurement, operation, maintenance, and even disposal of systems for comparison. Only since the convergence of fast computer hardware and truly scalable database engines have we experienced the horsepower required to calculate the realistic costs of systems ownership for entire enterprises (Figure 3.3.13-1).

- *Distant past.* Workspace was "just another fixed cost."
- *Recent.* Space control reduced costs.
- *Current.* Proactive space management is mission-critical.

The basic principles underlying life cycle cost calculations are the same in all instances, but costs must always be calculated separately for each specific case. The actual comparison values are ideally drawn from current organizational data across the entire enterprise, chosen for relevance to the life cycle of the facility and its subsystems.

In general, costs are calculated at the discounted present value of the cost of components and services, measured in constant dollars for a selected time period, such as 15 to 20 years.

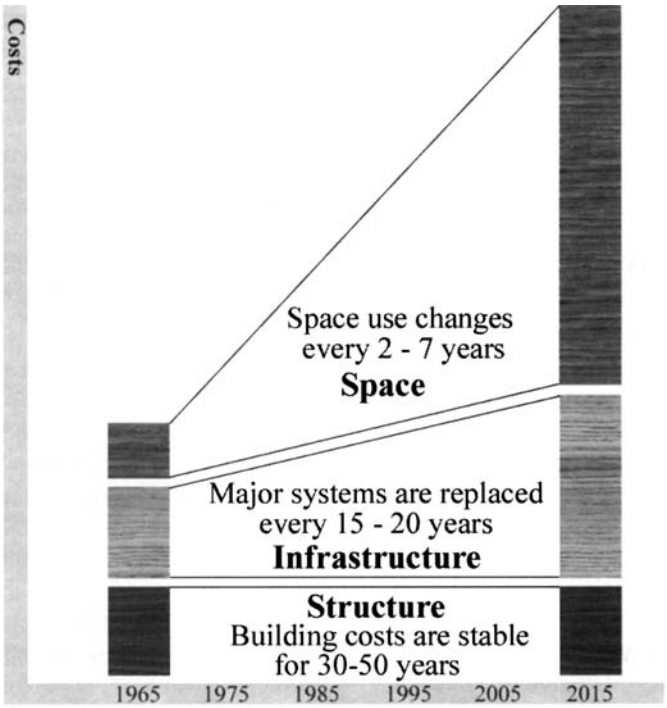

FIGURE 3.3.13-1 The life cycle costs of a facility.

For example, such time horizon and discount rates are commonly used in planning for the supply of electricity.

For simplicity, a linear depreciation schedule is often assumed, so that the residual value at the end of 15, 30, or 50 years is based on the fractional remaining life of the buildings and equipment, and so on. For very large footprint enterprises and federal government organizations, tens to hundreds of millions of dollars are at stake annually and the real cost of asset ownership soars well above initial acquisition costs.

Life cycle facility costing emphasizes ongoing operational and maintenance costs for all organizational systems, purposefully including items such as infrastructure expenditures that may be required for training maintenance and repair crews, and the like, which are often neglected in planning analyses. Costs in this category might be based on the wages and travel costs of contractors or agents who visit the organization, the costs of outside system operators and maintenance personnel, as well as the associated costs of hardware/software upgrades and other equipment. On a 15- to 20-year basis, future costs come into play, and it is often mistakenly assumed that these costs will remain unchanged in constant dollars over time.

Today's highly scalable database engines make the review of the entire facility life cycle—for equipment procurement, operational and maintenance costs, as well as diverse and disparate infrastructural requirements—reasonable now. Everything from installation of special elevators for delivering maintenance equipment, training for operations and maintenance personnel, and much more can now be included in the life cycle analysis for high-level strategic planning to be meaningful to various divisions across the enterprise.

Executives in strategic planning, real estate finance, program and property management, as well as human resources (HR), may gain numerous significant advantages from centralized, scalable software that molds and manages infrastructure delivery.

For large-footprint implementations, software and especially database scaling issues are probably going to be among the top FM technology issues as organizations merge and acquire each other in the years to come. Life cycle cost analyses will tend to require accounting for costs associated with failed pilot FM projects, which are often—especially at very large footprint organizations—directly associated with scaling issues. Facility planners, CIOs, CFOs, VPs of real estate development, and strategic planning executives should embrace scaling as clearly as possible before embarking on pilot implementations. Pilot projects should incorporate real-world growth estimates based on the future expectations of the organization.

Enterprise-wide software solutions may significantly extend traditional areas of FM to include real estate and property management, HR, call center systems, asset management, and computerized maintenance management systems (CMMS). Therefore, the long-term volume of information and ongoing demands on the consolidated data warehouse should be calculated to ensure consistent operation over the full life cycle of the automation system.

The following are examples of scaling-related details to consider for large-footprint FM data consolidation pilot projects:

- How many square feet will be cataloged in the pilot implementation?
- How many square feet are envisioned for the enterprise-wide implementation, assuming a successful pilot project?
- At what rate will additional facility drawings and data be added to the pilot project to complete the enterprise-wide implementation?
- How many people will be cataloged in the pilot versus enterprise-wide implementation?
- Will component technologies or methods of implementation used in the pilot project limit cataloging or differ in any way when cataloging resources are in full-scale implementation?

For planning at the Fortune 500 or federal government levels, planners should assume that virtually unlimited amounts of enterprise component data will be fed into a single database. Measuring costs to maintain, repair, support, upgrade, and manage enterprise properties—and associated buildings, floors, and spaces—is just the start. End uses of the facility by its workers and all ongoing operations to deliver products and services to customers must be considered. For large organizations, this will significantly increase loads on the database engine, and pilot projects should be based on full-load assumptions.

Additionally, at large-footprint organizations, commercial off-the-shelf technology (COTS) that integrates best-of-breed applications and all data sources for shared needs within disparate client organizations is often the specified solution. Life cycle economics requires that we calculate the ongoing costs associated with scaling, maintenance, training, and the like, along with first costs associated with implementation of these systems.

Enterprise resource planning (ERP) is evolving to include the interplay of physical assets, by location, to enable their effective use by the workforce because control of asset deployment to people in workspaces connects planning to productivity. Life cycle costing requires that planners embrace the long view, which will ultimately require unbreakably secure and scalable database engines, fully integrated with industry standard spatial data [computer-aided design (CAD) drawings and geographic information system (GIS) mapping] engines, for client/server, as well as fully Web-enabled implementation.

Facility management executives at many of the largest and best-run organizations are already fully immersed in effective life cycle decision making based on ongoing, long-term strategies for process improvement. Many strategic planners already expect access to mission-critical information at any time and from any location and the ability to view reports the way they want to see them, drawn from common data available across disparate departments, regions, and even time zones.

As the role of facility manager evolves to include meeting the demands of strategic planners adapting to rapid market changes, reliable methodologies for evaluation and review may

be the only compass in a sea of organizational turmoil. The ability to view current data in real time—and to display barriers, obstacles, and relationships over time—may be the difference between short-term success and long-term failure of a project, or even an entire organization.

Whether the task is determining the number of light bulbs required to illuminate the executive washroom or analyzing FM process and performance gaps, life cycle cost analysis will be a useful tool to help enhance and integrate business process improvements.

SECTION 3.4
NEW DEVELOPMENTS IN OPERATIONS MANAGEMENT

Kristin Hill, Cindy Aiguier, John Morganti, and Bonnie Seaberg
International Facility Management Association (IFMA), Boston, Massachusetts

Norm Faucher
Association for Facilities Engineering (AFE), Boston, Massachusetts

A well-managed facility can be likened to a well-oiled machine. If properly maintained, it will provide years of faithful service. Facility management becomes a natural operating mechanism for the facility. However, this is not enough. To simply "maintain" the facility is a stale formula for facilities management. A maintaining mind-set carries the risk of obsolescence. One cannot simply adopt an "if it is not broken, don't fix it," mentality.

The following articles on operations management will help you to understand all of the processes that occur within a facility. We begin by defining the processes that are conducted in the facility and seeing how to improve their effectiveness and efficiency. Next we look at identifying one process that shows that processes begin with understanding customer needs and wants and end with delivering products or services to the customer. The remaining articles identify several ways to improve the operations of the processes within the facility.

The new dictum for facility managers in the twenty-first century is that they must be visionaries. Facility managers must have the ability to foresee what is going to or likely to happen. Without vision, facility managers are living only for today. With vision, they are ready for change and are also actively making and directing it. Therefore, they will avoid having to perform costly damage control by playing catch-up with the future (now the past) after having invested time, money, and resources in maintaining a facility with old practices.

ARTICLE 3.4.1
OVERVIEW OF PROCESS DESIGN IN FACILITIES MANAGEMENT

Charles R. Harrell
ProModel Corporation, Orem, Utah

A facility houses the equipment and personnel that carry out the business processes of an enterprise. It only makes sense that the facility should be designed with the processes in mind. The layout of the facility can have a significant impact on the ability of the enterprise to execute its business processes effectively. This article discusses the role of process design in facilities planning. First, principles and concepts of process design are presented. Second, the relationship between process design and facility design is discussed. Finally, evaluation techniques, particularly computer simulation, are presented that are used to assess the effectiveness of a process design.

WHAT IS A PROCESS?

Before discussing the role of process design in facilities planning, it is helpful to have a clear understanding of the term *process.* A process is defined as a sequence of activities that converts inputs into outputs.[1] A process might be a sequence of production activities that convert raw materials into finished products. In the service sector, a process might be a set of activities required to treat patients in a health care facility.

An integral aspect of a process is the *system* used to carry out the process. A system is defined as a collection of elements that function together to achieve a common goal.[2] Thus, systems encompass processes but also include the resources and controls for carrying out processes. In the initial phase of process design, the focus is often on *what* activities need to be performed. In the final phases of process design, focus is turned toward the system details defining *how, when, where,* and *who.* Ultimately, any implementation of a process is an implementation of the system for carrying out the process. In manufacturing processes, the focus turns toward the machines, operators, and handling equipment used to convert raw parts into finished products. In a service system, such as an emergency room of a hospital, the processing system consists of the nurses, doctors, and equipment used to treat incoming patients.

PROCESS DESIGN

Process design considers the activities that are performed in the facility as well as the system elements that are needed to execute the process. Process design in this larger context is sometimes referred to as *systems engineering,* which can be defined as:

> The effective application of scientific and engineering efforts to transform an operational need into a defined system configuration through the top-down iterative process of requirements definition, functional analysis, synthesis, optimization, design, test and evaluation.[3]

Process design is essentially an iterative process of defining objectives, identifying requirements to meet those objectives, specifying a solution that fulfills the requirements and then evaluating the effectiveness of the solution in meeting overall objectives (see Fig. 3.4.1-1).

In some situations a specific process cannot be completely determined in advance. Job shops, for example, utilize general-purpose equipment that is capable of processing a broad range of products. In this situation, detailed process plans are not generated until an order for a product is actually received. In the case of job shops, the general range of processes anticipated is considered when selecting equipment.

For situations in which processing requirements are known in advance, the basic procedure for coming up with the best specification includes the following steps:

1. Define the overall process.
2. Select applicable processing methods and equipment.
3. Develop a detailed process plan.
4. Evaluate the effectiveness of the plan.

Although these steps are more easily applied when designing a new process for a "green field" facility, they are applicable in principle for improving processes in existing "brown field" facilities. Each of these steps in process design is discussed briefly.

Defining the Overall Process

The first step in process design is to determine the overall process that is best suited for meeting the processing requirements. Processing requirements are driven primarily by (1) the number of different types of products to manufacture or customers to service, (2) product specifications for manufacturing or, in the case of service industries, customer needs, and (3) production or service volumes. In examining the specifications for the finished output, planners should look at the product specifications, standard practices, and any other related documented specifications. Production forecasts showing anticipated production volumes over time also impact the process.

A flowchart is often used in the initial stages of process design to document the required processing steps as dictated by the processing requirements (see Fig. 3.4.1-2). At this stage, the focus is only on *what* activities should be performed and the appropriate sequence.

A flowchart is a visual way to illustrate processing logic and provides a general overview of the process. In its simplest form, it consists of boxes representing the activities and connecting arrows showing their sequential relationship. Symbols can also be used that more specifically characterize the nature of each activity. For example, a set of flowcharting symbols has been defined by the American Society of Mechanical Engineers (ASME) as shown in Table 3.4.1-1

Once a flowchart is constructed, analysis of the process can begin. For simple process improvements, traditional work analysis methods long prescribed by industrial engineering are useful. The most basic approach is to ask the following questions:

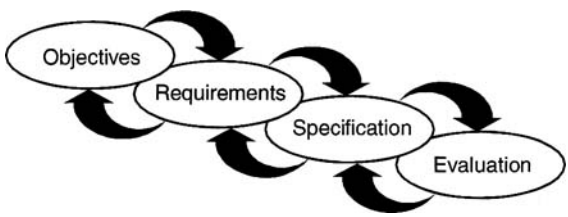

FIGURE 3.4.1-1 Four-phase iterative approach to process design.[4]

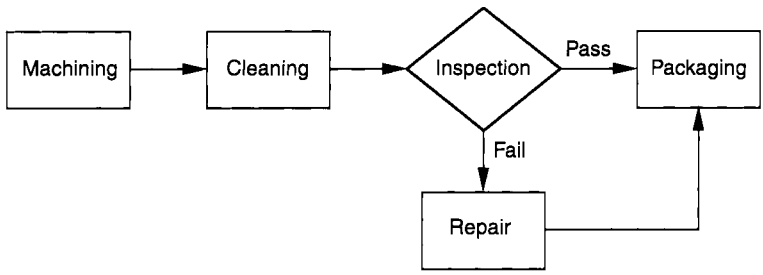

FIGURE 3.4.1-2 Sample process flowchart.

- Can any activity be simplified?
- Can any activity be eliminated?
- Can any activities be combined?

One approach used in process improvement initiatives is called *process value analysis.* This method is basically a systematic way of analyzing the costs and value associated with each step. Process steps or activities that add little or no value to the product (in the eyes of the customer) become candidates for elimination. Process value analysis includes the following steps:

1. Identify possible methods for meeting processing requirements.
2. Evaluate the effectiveness of alternative methods in meeting requirements.
3. Select the methods that meet the requirements at the least cost.

In conducting a process value analysis, the focus should be on essential or value-added activities, those for which the customer is willing to pay. Any activity related to inspection, revision, or rework should be evaluated for possible elimination. It is also useful to look at activities that are optional or occur only occasionally to determine whether there is a way to combine them with other activities so that a common, single flow can occur. The result of doing a process value analysis might be a list of processes needed and perhaps a rough process flow depicting the sequence of activities performed.

To ensure that the resulting process that is defined meets stated objectives and needs, it is recommended that the process flow be reviewed with appropriate managers, stakeholders, customers, and users. Often, more goes on inside a process than a single individual can assess. It always helps to get feedback and suggestions from others.

TABLE 3.4.1-1 Standard Process Flow Symbols

Method and Equipment Selection

Once the overall process flow has been determined, appropriate methods and equipment are selected to carry out the process. This step in process planning requires knowledge of work practices and available relevant technologies. Method and equipment selection should follow sound engineering practices and may even utilize computer-aided process planning (CAPP) software.

Not only should the appropriate resources be selected for performing each job or activity, but the number of resources needs to be estimated. The capacity of a resource is a measure of the number of items or customers it can process in a given period of time, taking into account factors such as availability, efficiency, and so forth. This adjusted capacity is known as the *effective capacity* of the resource. The number of resources required is determined by dividing the required processing volume by the effective capacity of the resource. The required processing volume is typically determined by the *maximum* number of items or customers that must be produced in any given time period.

When only a single type of product is produced or customer serviced, capacity analysis is straightforward. If 20,000 units of a product are required per year and the effective capacity of the resource is 8,000 units, then the number of resources required is 20,000/8000, or 2.5 resources. Because a half resource is usually not possible, three resources are required (unless, of course, overtime is planned to handle excess requirements).

Sometimes capacity planning must be based on a mix of products or customers. Resource sizing in this scenario is based on the combined processing requirements. Suppose, for example, that a machine has the capacity to produce 20,000 units of product A per year and 25,000 units of product B. If the required annual production is 8000 units of product A and 10,000 units of product B, then the load on the machine is (8000/20,000 + 10,000/25,000) × 100 percent, or 80 percent.

When analyzing capacity requirements, it is important to recognize that basing the number of resources on effective capacity does not take into account the interaction of the resource with other resources in the system. This interaction often makes the actual capacity less than the effective capacity. Elements in a system are interdependent, so nothing happens without affecting everything else in the system—like a domino effect. A machine failure at one workstation starves downstream operations and may even create a backup or logjam that halts upstream operations. Another type of interdependency in systems is due to shared resources. Resources are frequently limited and must respond to competing demands for their services. An operator loading one machine in a cell, for example, may be unable to respond immediately to another part waiting to be unloaded from some other machine in the cell.

System interdependency may be tight or loose, depending on how tightly linked the elements are. Elements that are tightly coupled have a greater impact on system operation and performance than elements that are only loosely linked. When an element such as a worker or machine is delayed in a tightly coupled system, the impact is immediately felt by other elements in the system. In a loosely coupled system, any disruption of an activity would have only a minor, delayed impact on other elements in the system. Several methods are used to decouple system elements, including provision for buffer inventories, designing in redundancies, and dedicating resources to single tasks. Unfortunately, these solutions often lead to excessive inventories and underutilized resources. Interdependencies in mixed-product manufacturing are particularly difficult to anticipate because bottlenecks may shift, depending on the current lot being run. For these and other reasons, the need for simulation to predict system performance accurately becomes important.

Developing a Detailed Process Plan

In manufacturing industries, a process plan is often documented in the form of a *route sheet, process chart, operation list, manufacturing data sheet,* and so forth. This process document

specifies the sequence of operations for a part, and alternative operations and routings are given wherever feasible. Other processing specifications that can be included on a route sheet are material requirements, machine tolerances, tools, jigs and fixtures required, setup time, and time allowances for each operation.[5]

A detailed process describes how the system will operate (who, what, where, when, and how) in terms of work schedules, processing quantities, resource usage, decision rules, and so forth. The operational specification is best defined from the perspective of the entity flow and should ultimately be extended to include movement in and out of queues, the time and resource requirements for each activity, and so forth. For a complete definition of a process, the following information should be specified for each part or customer at each stop or workstation:

- What activity is performed at the station?
- In what quantities is the activity performed?
- What resources are used to perform the activity?
- Where is the material drawn from and where is it placed afterward?
- To which station is the material sent next?
- In what quantities is the material moved?
- How is the material moved?
- What triggers the move (e.g., schedule, kanban, etc.)?

Process Evaluation

With a complete definition of the way the process is going to be executed, a realistic evaluation can be made of the plan's effectiveness. It isn't enough just to plan the system. What is important to know before the system is implemented is how well the system is going to work. We want to ensure that the system is capable of performing as expected. With the interdependencies and variability inherent in the system, this is not a trivial task. The questions to be answered include the following:

- Where are the bottlenecks?
- What is the expected resource utilization?
- What is the processing capacity of the system?
- How much waiting time can be expected?

Evaluating the effectiveness of a system is where tools such as simulation come into play. Simulation takes into account system interdependencies and variability and therefore accurately predicts how a particular system will operate in actual practice. It can help eliminate problems of overdesign, underdesign, and poor design.

PROCESS DESIGN AND FACILITY LAYOUT

If at all possible, the facility layout should not be done until the process design has been completed. The facility layout should support the flow of material and avoid unnecessary backtracking. The flow of material should be driven by the process design and be a primary consideration in arranging equipment within a facility.

Achieving good material and people flow in a facility is important—yet often neglected. Most facilities are designed with little thought to how objects will move about and whether

Next Page

there is backtracking, congestion points, or even collision points. As organizations and business grow, the impact of poor workflow planning magnifies and, if uncorrected, can become a source of problems in an operation. According to one manufacturing consultant, "Many U.S. plants have horrendous work flow patterns that have grown up over the years, over-laden with a cascade of traditional rules and procedures and systems that create more problems than they solve."[6] This observation is corroborated in an assessment made by a research group from Purdue University that states, "Despite years of effort at both the theoretical and applied levels, we still do not know how to manage the overall flow of work in factories."[7]

In planning the layout of a facility it is important first to have an overall system perspective of material flow. The overall part flow within a manufacturing facility, sometimes referred to as the *material flow system,* begins from the reception of material at the receiving dock and extends to shipping material from the facility (see Fig. 3.4.1-3).

Material flow is largely determined by the layout structure chosen for the system. Manufacturing systems are generally classified as one of the following six types (most of these categories also apply to service systems):

1. *Project shop.* Product produced one at a time remains stationary while equipment is brought to the product. Examples are aircraft manufacturing and patient surgery.
2. *Job shop.* Equipment is arranged by function so that different products produced in low volumes have different routings. Examples include sheet metal fabrication and medical laboratories.
3. *Cellular flow.* Equipment is arranged by process sequence that is common for a family of products produced in small volumes, so that flexible, one-piece flow is supported. Examples are small appliance manufacturing and circuit board assembly.
4. *Batch flow.* Equipment is arranged by process sequence that is common for a set of products produced in medium volumes. Examples include book printing, textile manufacturing, and loan application processing.
5. *Line flow.* Equipment is arranged by process sequence for a product with single-piece flow. Examples are automotive assembly lines and bank drive-thru services.
6. *Continuous flow.* Equipment is arranged by process sequence for continuous product flow. Examples include petrochemical manufacturing and paper mills.

This classification of processing systems does not imply that all systems fall neatly into one of these six categories. On the contrary, many systems have characteristics of more than one type. For example, mixed shops combine both functional and linear equipment structures at different stages in the manufacturing process. The two principal factors that dictate the type of production structure are *product volume* and *product variety.* Figure 3.4.1-4 shows the general applicable ranges of product volume and variety for each structure.

The implementation of the system structure is based largely on material flow. In job shops, machines are arranged according to function (i.e., machines that perform like processes are grouped together) because there is no single flow sequence. Different parts are assigned individual routings that often include backtracking. This type of layout is referred to as a *process layout.* In continuous flow, line flow, and batch flow systems, equipment is arranged according

FIGURE 3.4.1-3 The material flow system.

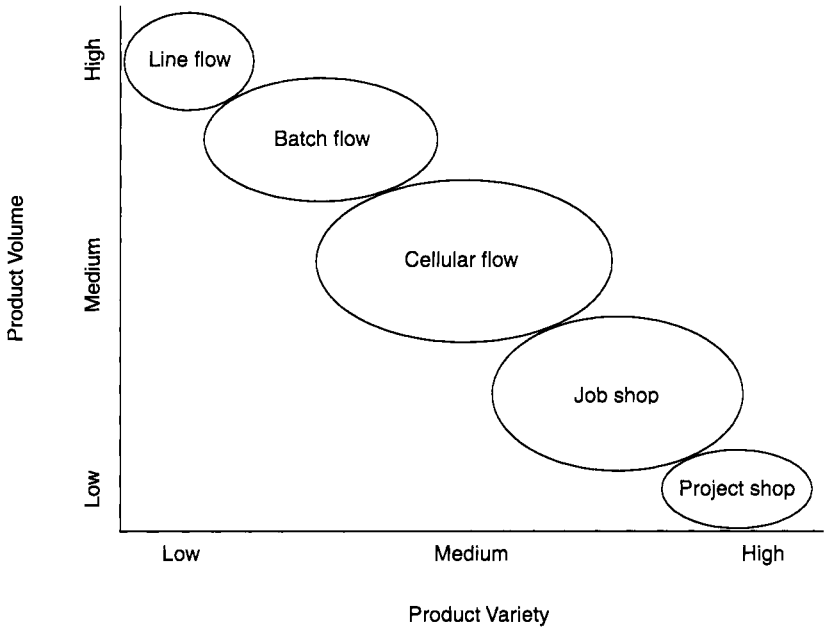

FIGURE 3.4.1-4 Range of application for different types of production systems.

to the processing sequence of a product. Therefore all flow follows essentially the same path. This type of layout is termed a *product layout.* In cellular manufacturing, machines are arranged to process parts of the same family. In cellular manufacturing, a cell usually consisting of less than 10 stations is arranged in the shape of a "U" to provide a common input/output point and enables a single worker to operate the cell. Figure 3.4.1-5 illustrates these three different types of arrangements and their implications for material flow.

PROCESS SIMULATION

Computer simulation is a technique that is frequently used to evaluate the effectiveness of a process design before it is implemented. Simulation itself does not *solve* problems, but it does clearly identify problems and quantitatively evaluate alternative solutions. As a tool for doing what-if analysis, simulation can provide a quantitative assessment of any number of proposed solutions to quickly home in on the best solution. Simulation also provides graphical animation to show the dynamic operation for the system (see Fig. 3.4.1-6).

By using a computer to model a system before it is built or to test operating policies before they are actually implemented, many of the pitfalls that are often encountered in the start-up of a new system can be avoided. Improvements that previously took months and even years of fine-tuning to achieve can be attained through computer simulation in a matter of days or only hours. Modern simulation tools even provide automatic optimization capability that iteratively runs models and changes model parameter settings until the best possible solution is found.

Simulation during the design phase of a system results in cost savings by identifying and eliminating unforeseen problems and inefficiencies. Cost is also reduced by eliminating overdesign and removing excessive safety factors that are added when performance projections are uncertain. It is not uncommon for companies to report hundreds of thousands of dollars in savings on a single project through the use of simulation. One Fortune 500 company

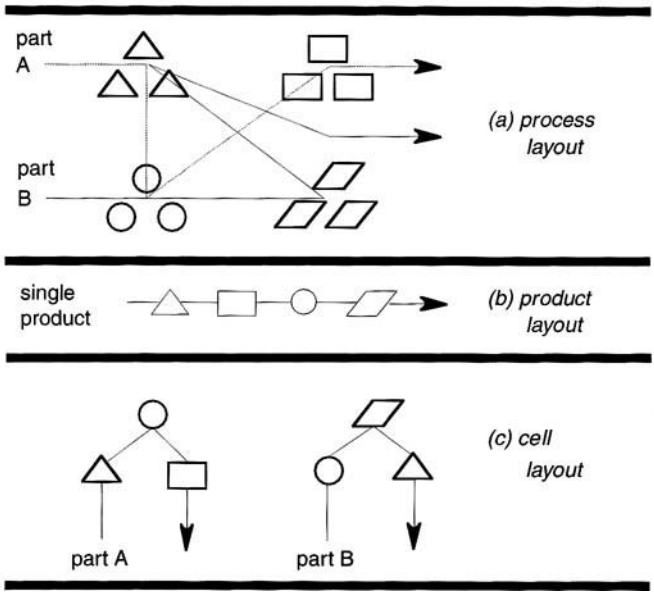

FIGURE 3.4.1-5 Comparison of (*a*) process layout, (*b*) product layout, and (*c*) cell layout.

was designing a facility for producing and storing subassemblies in preparation for the final assembly of a number of different metal products. One of the decisions involved determining the number of containers required for holding the subassemblies. It was initially felt that 3000 containers were needed to handle the activity. However, after a simulation study it was evident that throughput did not significantly change when the number of containers varied between 2250 and 3000. By purchasing 2500 containers instead of 3000, a saving of $528,375 was expected in the first year, with annual savings thereafter of more than $200,000 due to the savings in floor space from having 750 fewer containers.[6]

Even if dramatic savings or improvements are not realized each time a model is built, simulation at least inspires confidence that a particular system design is capable of meeting required performance objectives, and thus minimizes the risk often associated with new start-ups. The economic benefits from gaining others' confidence was evidenced when an entrepreneur, who was attempting to secure bank financing to start a blanket factory, used a simulation model to show the feasibility of the proposed factory. Based on the processing times and equipment lists supplied by industry experts, the model showed that the output projections in the business plan were well within the capability of the proposed facility. Although unfamiliar with the blanket business, bank officials felt more secure in agreeing to support the venture.[7]

Often, simulation can help to achieve productivity improvements without the need to invest heavily in new technologies or facility expansions. By looking at the overall operation of the system in compressed time, long-standing problems such as bottlenecks, redundancies, and inefficiencies that previously went unnoticed start to become more apparent. Consider the following actual examples:

- GE Nuclear Energy was able to increase its output of highly specialized reactor parts by 80 percent. The cycle time required for producing each part was reduced by an average of 50 percent. These results were obtained by running a series of models, with each one solving production problems highlighted by the previous model.[8]

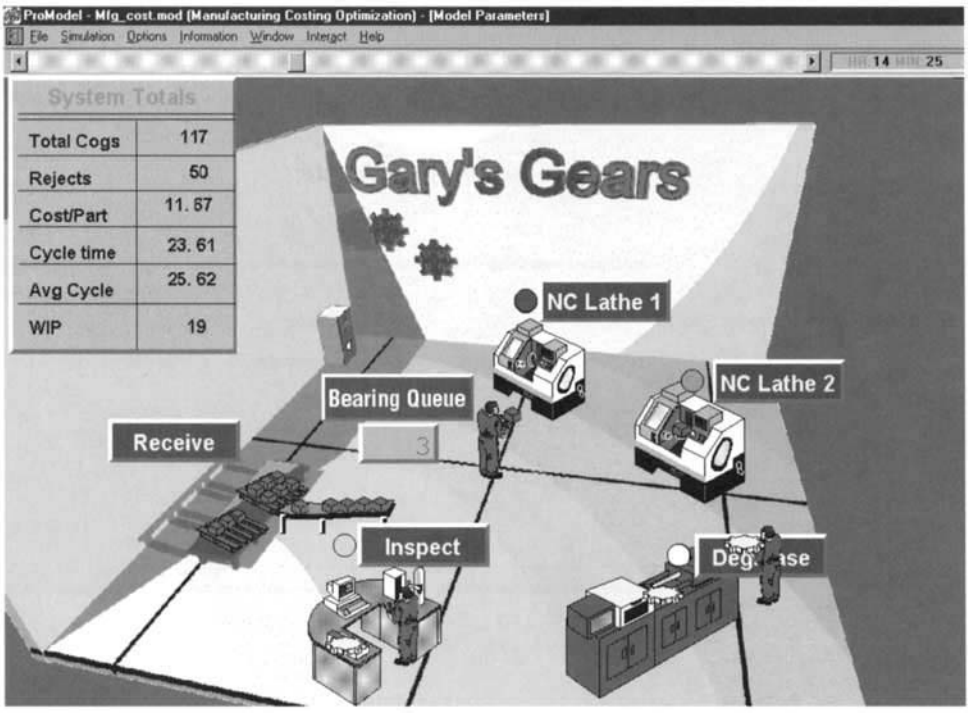

FIGURE 3.4.1-6 Simulation provides animation and performance statistics. (*Courtesy of PROMODEL Corporation.*)

- A large manufacturing company with stamping plants located throughout the world produced stamped aluminum and brass parts on order according to customer specifications. Each plant had from 20 to 50 stamping presses that were utilized at anywhere from 20 to 85 percent of capacity. A simulation study was conducted to experiment with possible ways of increasing capacity utilization. As a result of the study, machine utilization improved from an average of 37 percent to 60 percent.[9]
- A diagnostic radiology department in a community hospital was modeled to evaluate patient and staff scheduling and to assist in expansion planning over the next five years. Analysis using the simulation model enabled improvements in operating procedures that precluded the necessity for any major expansions in department size.[10]

The impact that simulation had on facilities management was significant in each of these examples because it completely eliminated the need for facility expansion by showing how increased capacity could be achieved using the existing facility.

Some of the specific questions that simulation can help address when designing or modifying a facility include the following:

1. What type and quantity of machines or workstations should be used?
2. What type and quantity of auxiliary equipment and operators are needed?
3. How much tooling and fixturing is required?
4. What is the production capability (throughput rate) of a given system?
5. What type and size of material handling system should be used?

6. What are the optimum number and size of storage areas and buffers?
7. What is the best layout of workstations?
8. What is the most effective control logic?
9. What is the optimum unit load size?
10. How effectively are resources being utilized?
11. What effect does a process or method change have on overall production?
12. How balanced is the work flow?
13. Where are the bottlenecks?
14. What is the impact of machine downtime on production (reliability analysis)?
15. What is the effect of setup time on production?
16. What is the effect of centralized versus localized storage?
17. What is the effect of vehicle or conveyor speed on part flow?
18. How many repair personnel are needed?
19. What is the overall effect of automating an operation?

Figure 3.4.1-7 illustrates the use of simulation to compare four conveyor system configurations simultaneously. After running the simulation, performance metrics such as throughput and cycle time were compared to determine the best configuration.

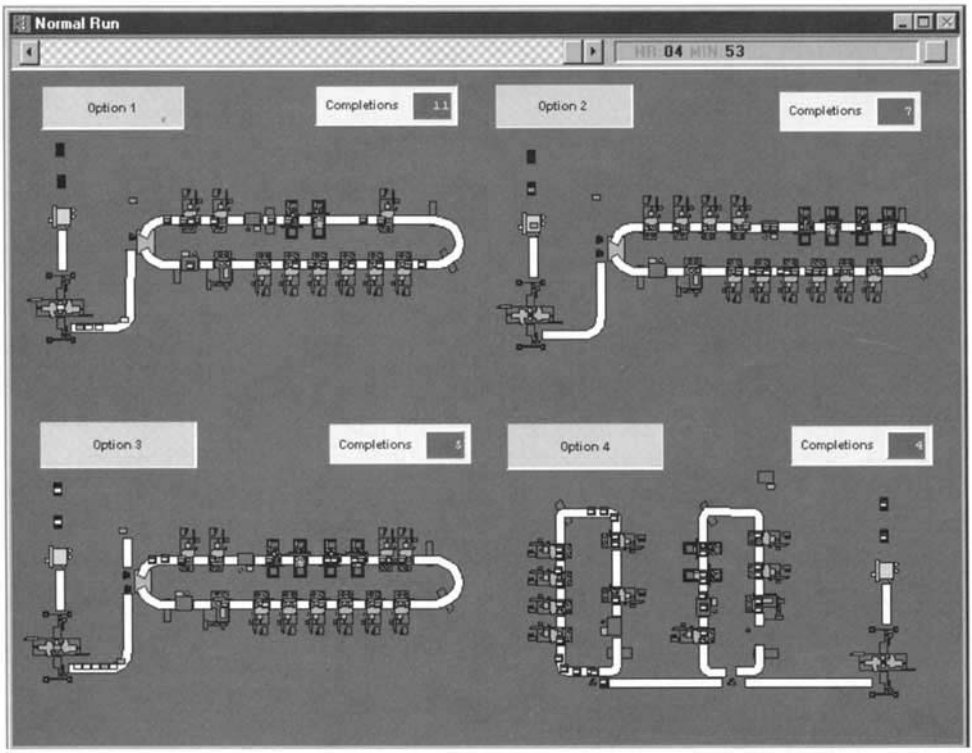

FIGURE 3.4.1-7 Simulating alternative configurations for comparison. (*Courtesy of PROMODEL Corporation.*)

Simulation is finding widespread application in manufacturing and also in service industries. Insurance agencies, health care facilities, airports, restaurants, and numerous other service facilities have all benefited from using dynamic simulation. Figure 3.4.1-8, for example, shows a radiology lab simulation where processing capacity and costs were evaluated to see if facilities were adequate to provide the best level of health care. The visualization of patient flow and staff movement provided an effective way to evaluate the layout for congestion in the waiting area and paths of travel for movement efficiency.

Even before a simulation run is made, the exercise of developing a simulation model alone is beneficial in ensuring that all of the operational issues of the system have been addressed. The philosopher Alfred North Whitehead observed, "We think in generalities, we live detail." This human tendency to overlook detail can lead to poor decisions that go undetected until implementation. Simulation forces one to think through the operational details of a system so they are not left to chance (simulation can work with bad information, but it can't work with insufficient information). The increased discipline that simulation brings to the design process is sometimes a sufficient reason itself for employing simulation. Often improvements present themselves solely as a result of going through the model building exercise—before any simulation run is made.

The benefits of simulation can be summarized as follows:

- Captures system interdependencies
- Accounts for variability in the system
- Is versatile enough to model any system
- Shows performance changes over time

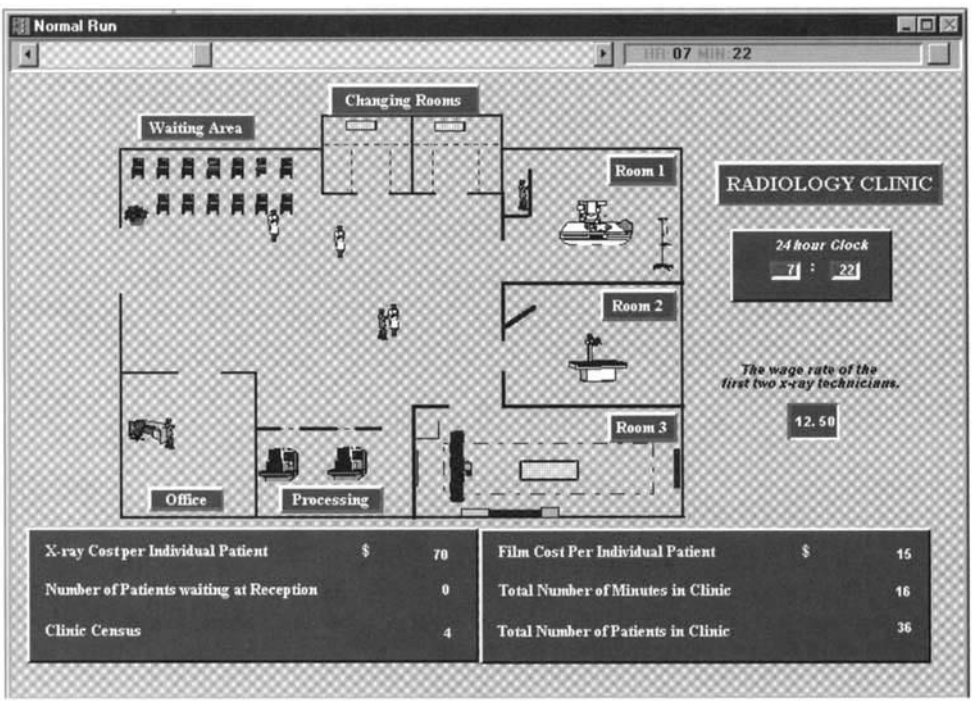

FIGURE 3.4.1-8 Simulating a radiology clinic reduces cost and improves performance. (*Courtesy of PRO-MODEL Corporation.*)

- Is less costly, less time-consuming, and less disruptive than experimenting on the actual system
- Provides information on multiple performance measures
- Is visually appealing and easy to understand
- Is easy to communicate results
- Runs in compressed, real, or even delayed time
- Stimulates interest and participation through animation
- Forces attention to detail in a design

SIMULATION TECHNOLOGY TRENDS

Simulation products have evolved to provide more than simply stand-alone simulation capability. Modern simulation products have open architectures based on component technology and standard data access methods (SQL, etc.) to provide interfacing capability with other applications such as CAD programs and enterprise planning tools. Surveys of the most popular simulation products show that most of them have the following features:

- Input data analysis for distribution fitting
- Point-and-click graphical user interface
- Reusable components and templates
- 2-D or 3-D animation
- Online help and tutorials
- Interactive debugging
- Automatic model generation
- Output analysis tools
- Optimization
- Open architecture and database connectivity

Simulation is a technology that will continue to evolve as related technologies improve and more time is devoted to developing the software. Products will become easier to use, and more intelligence will be incorporated into the software itself. Evidence of this trend can already be seen by optimization and other time-saving utilities that are appearing in simulation products. Animation and other graphical visualization techniques will continue to play an important role in simulation. As 3-D and other graphic technologies advance, these features will also be incorporated into simulation products.

Perhaps the most dramatic change in simulation will be in the area of software interoperability and technology integration. Historically, simulation has been viewed as a stand-alone, project-based technology. Simulation models were built to support an analysis project, to predict the performance of complex systems, and to select the best alternative from a few, well-defined alternatives. Typically these projects were time-consuming and expensive and relied heavily on the expertise of a simulation analyst or consultant. The models produced were generally "single-use" models that were discarded after the project. Now simulation is being integrated with other technologies such as facility layout software.

The trend to integrate simulation as an embedded component in enterprise applications is part of a larger development of software components that can be distributed over the Internet. This movement is being fueled by three emerging information technologies: (1) component technology that delivers true object orientation; (2) the Internet or World Wide Web (WWW), which connects business communities and industries; and (3) distributed computing standards

such as Common Object Request Broker Architecture (CORBA) and Distributed Component Object Model (DCOM). These technologies promise to enable parallel and distributed model execution and provide a mechanism for maintaining distributed model repositories that can be shared by many modelers.[11] The interest in Web-based simulation appears likely to continue.

Dedicated simulation products for addressing specific types of industries continue to grow and become easier to use. This is the main factor driving the increase in the use of simulation. PROMODEL Corporation, for example, has products specifically dedicated to modeling manufacturing facilities (ProModel), health care organizations (MedModel), and general service industries such as banking and transporation (ServiceModel).

SUMMARY

Process design in facilities planning is crucial to having a well-running facility. Process design requires a clear understanding of the objectives of the operation in providing goods and services. Process value analysis can help ensure that the best process is designed for delivering value to the customer. This design must then be expanded to specify the methods and technologies that are to be used to execute the process. Finally, consideration can be given to the facility that houses the process. The design of the facility should support the goals of the process. Because of the complexity of processing systems, it becomes challenging to accurately assess the expected performance of a given process design. Process simulation is a technique used to evaluate process designs and improvement ideas. The power of simulation is its ability to account for interdependencies and to show graphical animation of the process or system model. Simulation turns a static facility plan into a dynamic true-to-life model that is a virtual representation of the way the facility will actually function.

ARTICLE 3.4.2
SUPPLY CHAIN MANAGEMENT

James B. Rice, Jr.
Massachusetts Institute of Technology, Cambridge, Massachusetts

Jason Slibeck
Organic Inc., Cambridge, Massachusetts

The purpose of this article is to provide a basic understanding of the key concepts of supply chain management. Supply chain management is a popular topic, and it has a broad and growing impact on business.

This article also identifies relevant issues in applying supply chain management from the perspective of a facilities manager. In particular, the relevant supply chain management issues are primarily those within the four walls of the facility and in the execution of the business, supply chain, and operational strategies.

The parts of the supply chain that are outside the domain of the facility manager are integrating with external partners (customers and suppliers), developing new products, and designing the supply chain. These are important processes and tasks for the supply chain, although outside the scope of the facility manager. The facility manager cannot be entirely insular, however, in that any facility will need to receive materials; manufacturing facilities will also be shipping products. The facility manager will have to coordinate with suppliers and customers, although the company-wide relationship is typically managed by a central entity within the company.

Finally, this article suggests processes and potential solutions for pertinent supply chain issues and in some cases will suggest resources for developing solutions.

SUPPLY CHAIN MANAGEMENT IN DEFINED FACILITY PROCESSES

Supply chain management cuts across most of the nine other facility processes defined in this article and makes the distinction among these critical processes difficult to discern. By its very nature, supply chain management is cross-functional. Contrast this with the traditionally functional nature of business organizations and the overlap becomes clear. "Integrated Workplace Planning" represents concepts that are consistent with forward-thinking supply chain management and takes an enterprise-wide systemic approach to supply chain management to replace the traditional functional optimization that dominates most companies today.

As the reader will see in subsequent sections, our definition of the supply chain includes the manufacturing process. Accordingly, then, this will also include the quality management process. Although this is a critical deliverable of the supply chain, quality management and shop-floor management are best addressed by the organizations traditionally responsible for leading those efforts, the manufacturing organization.

Information management is addressed elsewhere and may have some redundancies with the information technology (IT) issues raised in this section. Although IT issues are addressed, the technical aspects of IT and supply chain management are not detailed.

FOUNDATION OF SUPPLY CHAIN MANAGEMENT AND ELEMENTS

In 1985, John Houlihan introduced the term *supply chain management* in an article in the *International Journal of Physical Distribution & Materials Management.*[1] Supply chain management has been an important concept for nearly 15 years, and the definition and understanding of it have evolved, but a consensus definition is still lacking. The supply chain has evolved from *physical distribution management* to *logistics,* and more recently, *demand chain* and *value chain.* Each has some distinction, but for the purposes of this writing, we focus on *logistics* and *supply chain.*

Definitions

The Council for Logistics Management (CLM) defines *logistics* as follows:

> Logistics is that part of the supply chain process that plans, implements, and controls the efficient, effective flow and storage of goods, services, and related information from the point of origin to the point of consumption in order to meet customers' requirements.[2]

This view of logistics accompanied by an understanding of the manufacturing process leads to an understanding of the broad scope that a supply chain approach can have.

Professor Bernard LaLonde of Ohio State University defines supply chain management as follows:

> The delivery of enhanced customer and economic value through synchronized management of the flow of physical goods and associated information from sourcing to consumption.[3]

Of particular note are the emphasis on enhancing value, synchronized flows, and the broad scope of the supply chain. Other definitions go further by including return processes (disposal, recycling), often called *reverse logistics.*

Using LaLonde's terminology, synchronizing flows creates economic value by coordinating and integrating the separate elements of the supply chain. Traditionally, companies delivered results through their various elements that "focused" on optimizing their respective functions. These are commonly called *silos* or *stovepipes.* Recognizing that this behavior results in suboptimal performance, many companies now place greater emphasis and resources on integrating the separate elements of their supply chain, internally and externally.

Scope of the Supply Chain—The Extended Enterprise™[4]

As suggested in LaLonde's definition, the scope of the supply chain is broad, from "dirt to dirt," as the saying goes. The supply chain scope is best understood by starting with the supply chain internal to the company.

Each company has its own internal supply chain that consists of planning, procurement, receiving, manufacturing, distribution, transportation, and customer service. (Some may also include engineering and product development.) These operations entail contact with suppliers and customers, but the main challenge is coordinating the flows across these different functions to respond to the external customers' demand. How this might look with the various linear flows along the processes is shown in Fig. 3.4.2-1.

Each company also has an external supply chain that consists of its suppliers and customers. In this case, however, the customers and suppliers equate to more than one supply chain. The notion of a single chain is misleading because modern organizations are more

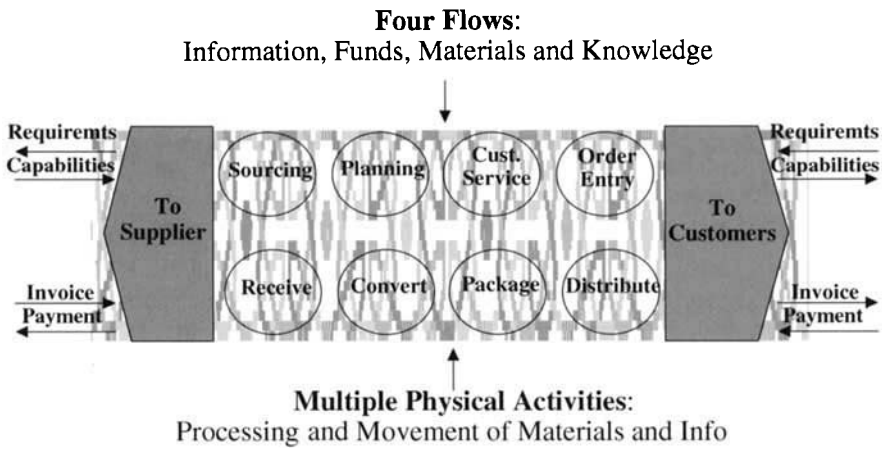

FIGURE 3.4.2-1 Process flow of supply chain management.

often a network of suppliers and customers, or processing nodes; the analogy of a chain directly highlights the dependency of each link on every other link. Companies are reaching out to their supplier's supplier, and to their customer's customer, extending their understanding and interaction further out into the supply chain in search of supply chain performance improvement and elimination of waste. The "supply chain" looks more like a "network" (see external supply chain in Fig. 3.4.2-2). This extended network captures the scope of the supply chain—from the base raw material supplier through all of the converting stages to the end consumer's use and disposal or recycling. Each company in the supply chain has its own internal supply chain not too dissimilar to that shown in the Fig. 3.4.2-1 (internal supply chain).

The definition and understanding of the supply chain will continue to evolve as more companies recognize the need to move beyond functional excellence and toward a process-oriented system-optimized business approach. Collectively, we define the supply chain as the set of processes that plan, source, produce, and deliver value in products or services to customers by managing four flows: physical goods, information, knowledge, and funds. The term

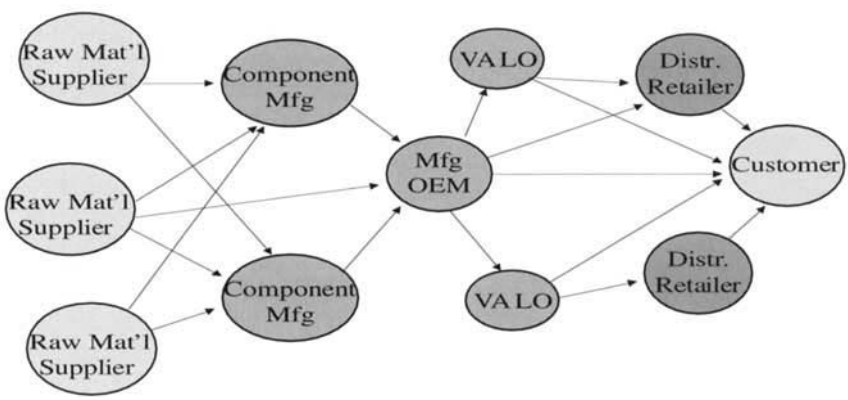

FIGURE 3.4.2-2 External supply chain flows across network and back through reverse logistics.

supply chain is likely to remain as the accepted term, but in the future most companies will be addressing issues of their *network* rather than their singular *chain.*

Background and History—Evolution to Corporate Silos and Independent Systems

Corporate silos and independent systems are the greatest achievements of the industrial revolution. This should not be a surprising statement if one remembers that dinosaurs were ideally adapted to the Jurassic period. In *Wealth of Nations,* Adam Smith analyzed the workings of a pin factory and introduced the world to the principle of division of labor.[5] This division was possible because the pin-making process could be deconstructed into specialized tasks. Advances in industrial technology facilitated labor and allowed one worker to do the work of many. Henry Ford refined the concept even further, and the modern industrial age was nearly complete. However, it was not until Alfred Sloan carried the division of labor concept from the factory floor to management bureaucracy that the subdivision of a process into functionally efficient units was complete. The creation of this industrial management system made the expansion of General Motors possible and ushered in an era of management by financial accounting goals and marketing objectives for functional business units with unique goals and performance measures.[6]

The era of unprecedented growth that fueled this migration to easily scalable hierarchical organizational pyramids was not able to withstand the information age and the three forces of the modern economy: customers, competition, and change.[7] The national mass markets of the 1950s, 1960s, and 1970s have been replaced by an empowered set of business and individual customers. These customers know what they want, what they want to pay, and which service level will accommodate their needs. This strategic shift in power is in part a result of easier access to an enormous amount of information for price comparison, quality judgment, and producer reliability.

Now, the national market forces also face stiff competition, as global trade has become a reality. International differences in factor costs such as labor rates have created enormous sociological changes. Competition has also come from entrepreneurial innovators. Entire sectors of the freight forwarding and distribution industry are now trying to expand the scope of their operations to justify continued existence as more nimble logistics providers force the question, "How do you add value for the customer?"

Finally, change has become a constant state of existence, and it is accelerating. To keep up with nimble global competitors and to react effectively to global market inputs, companies have accelerated the product development life cycle from years down to months. Having only a limited time frame within which to react, demand sensing and highly responsive, flawless execution systems have become critically important. Supply chain integration requires a reexamination of the assumptions of the industrial revolution and a move beyond functional excellence.

Before moving on, it is important to understand that silos have evolved to become detriments to optimal business performance. Internal to the company, the functional "silos" optimize functional performance at the expense of the broader enterprise. External to the company, the "company-focused" behavior of each of the companies in a supply chain results in excessive and redundant inventories carried by each company to protect its respective position, at the expense of higher overall supply chain costs for all.

Relevance of Supply Chain Management

One may ask, "What is the relevance of supply chain management to a facility manager?" Supply chain management has a significant and broad impact on the business. Managing the functions of a business as a customer-serving process—a supply chain—can impact business performance in the following ways:

- Creates a source of competitive advantage
- Satisfies a basic competitive necessity
- Augments financial performance

The importance of supply chain management stems from growing recognition that the supply chain may provide a source of competitive advantage (Dell, Chrysler, and Wal-Mart are good examples). Many others find that supply chain management has become a basic competitive requirement.

Financial Impact of the Supply Chain—Return on Assets

Measuring the financial impact of the supply chain on a business remains a fundamental method of determining the relevance of the supply chain. The financial impact of the supply chain can be understood and illustrated using the Du Pont model devised by F. Donaldson Brown around 1914, at the apex of the industrial revolution.[8] The Du Pont model in Fig. 3.4.2-3 shows the impact of a supply chain order-to-cash process and links with key financial indicators from the corporate balance sheet and income statement.

The model can also be used to show, for example, that a focus on electronic commerce enabled supply chains to impact return on assets (ROA) directly. The focus can be on increasing sales through personalization and customer loyalty, reducing fixed expense and fixed assets by moving from traditional bricks and mortar distribution to electronic storefronts, or reducing inventory and the cost of goods sold by focusing on improved forecast reliability and integrated purchasing systems.

When using the Du Pont model to measure the financial impact of the supply chain, consider the impacts across the scope of the entire supply chain, including all of the operations of the company. Increasingly, companies are finding that product development, process design, and engineering should also be included in the scope of the supply chain because these groups impact the ability of the organization to carry out the fulfillment process.

The use of the Du Pont model is primarily in measuring supply chain impact on costs, not revenues. When the supply chain provides a competitive advantage, it is legitimate to measure the increase in revenues through market share gains or price premiums. This remains an opportunity for many companies, especially when the company is considering making an investment in supply chain capabilities. Most companies must prepare a "business case for supply chain" to win the financial and personal support of the business leadership, yet these analyses often fall short because the true potential has not been adequately captured.

Issues and Solutions

To achieve the potential of the supply chain, several obstacles need to be overcome, including the following:

- Functional silo mentality and measures
- Mismatched incentives
- Requirement for new business capabilities
- Recognition of the requirement for fundamental change

These obstacles can be overcome by emphasizing the following key drivers and enablers of successful supply chain management.

Infrastructure and Organization Design

Too often companies look to the organization structure as the main way to "restructure" the supply chain. This falls far short of the need. According to recent studies, it is the most visible but perhaps not the most important element of organizational design.[9] These elements of organizational infrastructure—performance measures, compensation and incentive systems, communication systems, career development systems, training and education processes, tran-

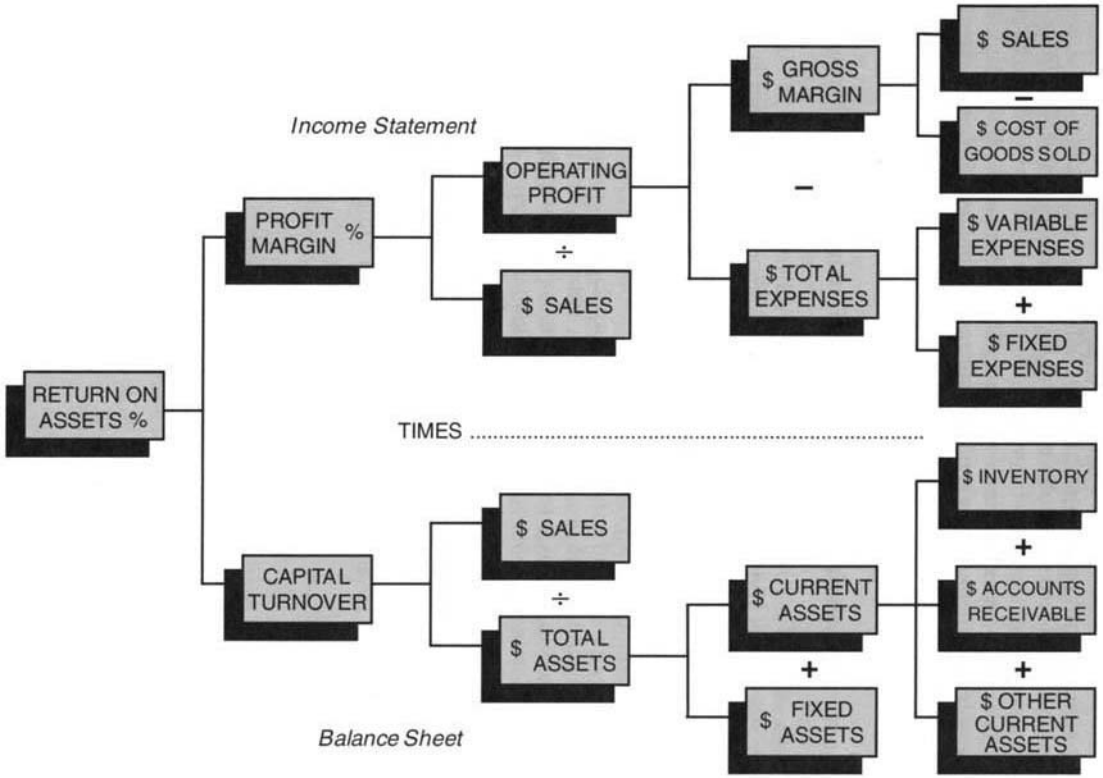

FIGURE 3.4.2-3 The Du Pont model.

sition planning, and performance appraisal systems—represent important design choices for delivering high-impact supply chain performance. Each of these gives the organization some leverage and control in establishing the business that has a strong "systems" orientation, instead of the traditional functional orientation. Unfortunately, many companies' performance measures and compensation systems provide incentive for individuals to optimize their function (department) at the expense of the overall business performance. Best approaches include designing each of these elements to support the overall system performance (of the business), not individual functional optimization (of a department).

Organizational structure should not be the primary and driving effort of a transition to process management. Many companies mistakenly depend on organizational structure as the cornerstone for their change efforts. There is a risk that organizational structure will become an obstacle, an end-all, or a focus for the organization, drawing it away from the real focus of the work. "Reorganization is insufficient to produce true integration and should be undertaken only as a natural result of redesigned business processes, and after individuals have internalized the new process objectives."[10]

Importantly, the supply chain infrastructure needs to support the supply chain strategy of the business. In turn, the supply chain strategy must equally align and support the corporate strategy. Corporate and supply chain strategies are not typically within the domain of the facility manager, but it is important to understand them.

Supply Chain Performance Measuring Systems

As the saying goes, "you won't get what you don't measure." To manage the supply chain processes, end-to-end measures must be developed—and actively used by the organization.

Congruent goals are required to align the different elements of the four aforementioned flows or horizontal processes. Congruent goals lead to measures that should be rewarded with incentives when attained. Measurement, goals, and incentives should be integrated when designing new systems. This should include the use of team-based measures for those on cross-functional supply chain teams.

Operational performance measures should change significantly when managing your company as a supply chain. They will shift from purely functional to a mix of functional and system performance that emphasize customer needs. System performance should be optimized, balancing efficient individual operations against system-wide performance measures such as capital deployed and overall service level. Some typical changes are offered as a reference for the facility manager:

- Measures such as "unit cost" and "labor cost per unit" should be augmented with measures such as "delivered on-time" or should be replaced by a balanced set of measures. Using "unit cost" and/or "labor cost per unit" as key measures often results in overproduction of finished product, additional warehousing and logistics costs, and increased product obsolescence. Often the inventory produced bears little or no relation to actual demand.
- The "volume produced, handled, delivered" measure should be replaced with more customer-specific performance measures such as "percent of orders delivered as promised, in proper condition, proper paperwork and as ordered" (perfect order). Using "volume produced" as a key measure often results in the production of products independent of customer needs. Such a production approach results in high markdown costs, high storage costs, and obsolete inventories.
- Equipment utilization measures are balanced against capital and asset productivity. Using equipment utilization as a key measure often results in the production of products and materials without demand or foreseeable demand, incurring additional handling and storage costs and burying quality problems Additionally, atypical performance measures should be considered to capture the impact of the supply chain. These might include inven-

tory productivity, asset productivity, service-delivery performance, product cycle time, cash-to-cash cycle time, customer satisfaction measures, and responsiveness to demand fluctuation (system capability), among others.

Incentive Systems

As noted earlier, incentive systems should be part of an integrated system that involves the goals and measures of the organization. As such, the most important decision regarding incentives is to design them to be consistent with the organization's goals and measures. This includes compensating individuals and teams for team performance, both in functional and process performance, as well as compensating them for optimizing overall system (business) performance at the expense of individual function (department) optimization. This serves to achieve needed balance between the functional and process requirements for employees (at all levels).

Incentives play a key role in aligning the authority and the responsibility for the supply chain. Often, a central staff is assigned the responsibility of the supply chain, yet without any authority to exercise control or change. This "authority/responsibility" predicament is a common obstacle to optimizing business performance for the entire (internal) supply chain. Incentives would be provided for the cross-functional team that has the "shared authority" spanning the horizontal supply chain process.

IMPLEMENTATION/CHANGE MANAGEMENT

Implementing supply chain management takes many forms, from changing organizational infrastructure to implementing software for supply chain optimization. A central staff group often supports and coordinates implementation in a variety of roles, ranging from single-point leader to cross-functional leadership team facilitator.

Many companies use cross-functional teams as a structural element of the supply chain organization. The degree of formality of the team structure, ranging from ad hoc to informal to formal structured leadership team, depends upon the level of coordination and the company situation. No single design works for each situation.[11]

The process of change can take the form of an "evolution" or a "revolution." Evidence exists to support both approaches, although there is a growing belief that change from a revolution will come about only through a revolution due to a crisis. Alternatively, changing through evolution—or over an extended period of time—would require the development of organizational learning capabilities and system thinking.[12]

Information Systems

Information technology has revolutionized the world and the capabilities of the supply chain, but it is not the sole answer to implementing supply chain management. A company needs advanced supply chain management information systems that, preferably, integrate operations with demand and supply in a seamless system. This is a challenge for any business and entails a dedication of significant resources. Enterprise resource planning (ERP) systems promise this capability, although this is a relatively recent development. Individual supply chain software solutions offer best-of-class software capabilities in contrast with a single ERP solution for the entire business. Whichever the choice, these solutions should be selected on the basis of realistic goals and should also be part of an overall supply chain initiative that is integrated with infrastructure changes.

In practice, progressive companies use information systems to facilitate broad information availability and to place more emphasis on real-time information. As with the infrastructure

choices that the facility manager makes, information systems should be designed to be consistent with overall desired level of communication and coordination, consistent with the supply chain strategy. Ford CIO James Yost underscores the role of technology in a recent quote: "My view is that technology is not the solution, but an enabler for changing business practices."[13]

SUPPLY CHAIN INTEGRATION

Supply chain integration seeks to achieve optimal performance of the supply chain as a whole by finding the appropriate balance of "focused" excellence and process coordination.[14] Successful supply chain integration requires connecting and coordinating the various flows (information, knowledge, materials, funds) and aligning incentives, measures, organizations, and goals across the internal supply chain and the external network.

Supply chain integration also requires that the coordinating and aligning change as a function of the product life cycle. Depending on the stage of the product life cycle, an integrated supply chain needs to deliver different capabilities to its partners. Early life-cycle supply chains have very uncertain demand profiles and therefore need flexibility (volume). Later life-cycle supply chains have more predictable volume demand but need lower cost and some product mix flexibility that comes with predictable product proliferation at the later stages of the product life cycle.[15]

Again, as suggested previously, to coordinate and align, no single solution works to integrate the supply chain in every case. The challenge is to take learnings from previous successes and reapply them *as appropriate* for your business situation. You still have to do the work.

Outsourcing to Restructuring the Supply Chain

The facility manager will not be tasked with supply chain design choices, but it is likely that the facility manager may wish to outsource some of the facility's needs. Outsourcing falls within the definition of supply chain design, but it is not always a centrally coordinated effort. Outsourcing has become an important aspect for many businesses because, in principle, it enables a company to focus its resources on the limited activities by which the company adds maximum value. It is a redistribution of the value-added tasks to the most efficient and most effective entities. Outsourcing has been widely used by large OEMs such as aircraft manufacturers, automobile manufacturers, and computer manufacturers.

Outsourcing can offer benefits in the following areas, depending on the situation: quality improvements, manufacturing cost reductions, faster cycle times, and rapid access to additional technology and capacity. At the same time, companies choose not to outsource to retain proprietary process and product technology or capabilities or to retain skills and capabilities that differentiate the company and its products in the marketplace.

In assessing whether to outsource tasks, processes, or functions, it is imperative to consider the long-term capabilities and technological impact of those decisions. Professor Charlie Fine of MIT highlighted the potential risk associated with outsourcing with his analysis of IBM's decisions to use outsourcing in the 1980s. While outsourcing operating system development (to Microsoft) and chip development (to Intel) seemed to make sense at time for IBM, it later became apparent that IBM had outsourced its future—resulting in a dramatic loss of market share, profits, and a relinquishing of its market dominance. The operating system and microprocessor later became more important than the hardware and system integration. Applying this learning suggests that it is worthwhile and important to consider the future implications of today's outsourcing decisions.[16]

The increase in the use of outsourcing is making it difficult to distinguish the lines that separate a company from its suppliers and customers, and the lines often change with some frequency. The nature of the buy-sell transaction is evolving from an "exchange" of value between parties into "the blur of fulfillment."[17] Examples of blurred distinction include cases

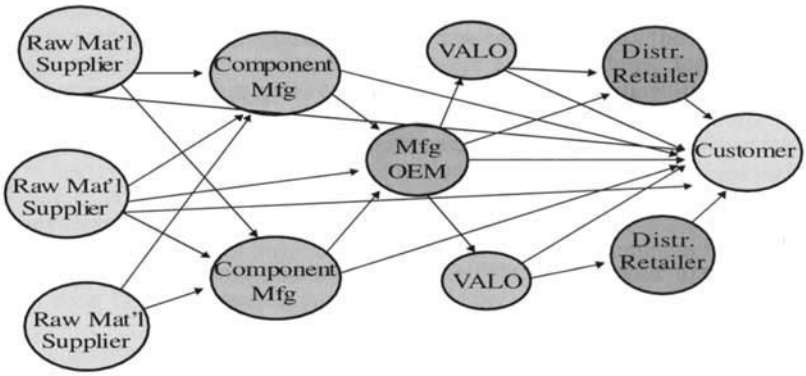

FIGURE 3.4.2-4 Future networked supply chain customer sourcing options increase. More buying options, electronically enabled.

where a manufacturer may have a third-party operator on company premises performing an 'outsourced' task, cases where the third party owns and operates their own equipment on company premises, cases where a third-party operator may take full responsibility for the entire customer service operation in a way that is transparent to the end customer, and cases where an entire facility and assets are outsourced to a third party. These practices are not uncommon even today, where customer service agents for airlines, manufacturers, and retailers are often employees of third-party service providers, unbeknown to the customer.

The capabilities of the Internet, the availability of real-time information, and the increasing potential of information systems integration have extended the potential of the outsourcing concept to actual restructure of the supply chain. These capabilities have enabled Dell Computer to sell directly to its customers, Chrysler to integrate and collaborate with module and component suppliers, and Cisco to integrate both customer and supplier in the product design process. "Disintermediation" (the process of eliminating existing intermediaries in the channel to the customer) represents at its core the redeployment of work, resources, and decision-making along the supply chain towards optimizing the entire extended supply chain "system" rather than the department or even company. In the future, the facility manager can expect to see an increasing application of these concepts, and should consider their potential application (benefits and risks) in day-to-day operations as well as planning for the future of the facility (see Fig. 3.4.2-4). Despite the potential created by technology advances, these are enablers and the success of potential restructuring will depend on careful application of outsourcing and restructuring, and the capabilities of the organization to implement and leverage the potential. This emphasizes all the more the importance of building a systems-oriented organization through organization infrastructure.[18]

ARTICLE 3.4.3
QUALITY ASSURANCE PRACTICES

Paul R. Smith, P.E., M.B.A., P.M.P.
Peak Leadership Group, Boston, Massachusetts

To move toward achieving superior quality, it is necessary to have a strong, unified, and consistent application of process control practices. This information is a foundation upon which all process control systems should be built for quality to standardize process control practices in each area.

NATURE OF THE MANUFACTURING PROCESS

Ideally, every manufacturing process attempts to reproduce parts that are identical to each other in every characteristic. However, there are uncontrollable variations in conditions, materials, equipment, operators, and so forth that make each unit slightly different from the design target and from each other. These unit-to-unit differences usually follow a normal distribution, represented by a bell-shaped curve. The standard deviation of the distribution—sigma—is a measuring unit of the amount of variation. The value of sigma decreases as variations are reduced, resulting in a narrower distribution (see Fig. 3.4.3-1).

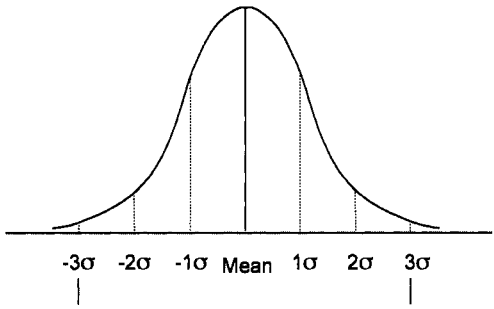

FIGURE 3.4.3-1 Normal distribution of process variation is represented by a bell-shaped curve. (*Courtesy of Peak Leadership Group, Boston, MA.*)

Traditional Process Capability

Traditionally, a process was judged satisfactory with a ±3-sigma capability. This means that if the process specification limits were placed on the process distribution curve, the upper specification limit would be at three sigmas to the right of the process average. The lower specification, likewise, would be at three sigmas to the left of the process average. The area under the curve between the two specification limits–99.73 percent of the total area—represents the products that conform to specifications. The area outside the specification limits—only 0.27 percent of the total area—represents nonconforming or out-of-specification products (see Fig. 3.4.3-2).

At first glance, a three-sigma process may look very good, but it is not good enough by today's standards. The seemingly low defect rate of 0.27 percent means that there will be at least 2,700 defective units for each million units produced. To put this in term's closer to the heart, the three-sigma capability would translate into more than 70,000 incorrect surgical operations each year in the United States. When it comes to health and safety, that rate of defects is obviously unacceptable. Moreover, process shift is an additional factor to be considered. Studied have shown that a process may shift up to 1.5 sigma from the usual process average. When it does, only 93.32 percent of the area under the curve is inside the specification limits. This equals a defect rate of more than 66,000 ppm. Now it is becoming clearer why the traditional three-sigma capability is not acceptable in today's marketplace (see Fig. 3.4.3-3).

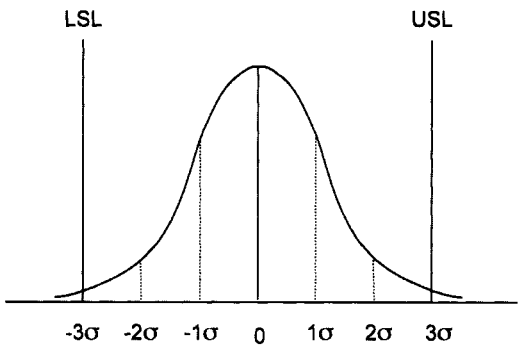

FIGURE 3.4.3-2 Traditional 3-sigma capability. (*Courtesy of Peak Leadership Group, Boston, MA.*)

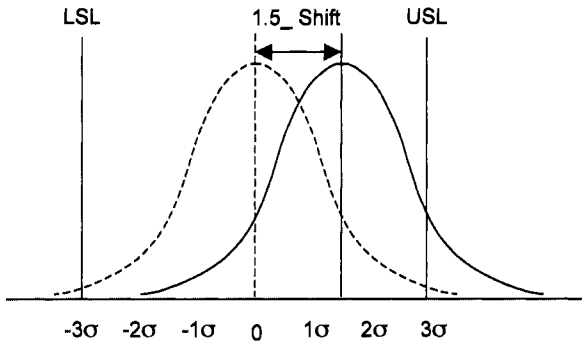

FIGURE 3.4.3-3 Three-sigma capability process with a typical shift. (*Courtesy of Peak Leadership Group, Boston, MA.*)

In reality, very few processes are perfectly centered and remain that way. Process shifts of up to 1.5 sigma are typical in many industries. When factoring in the typical 1.5 sigma shift in a Six-Sigma process, the result would be only 3.4 defects in every million units produced. This is a Six-Sigma goal (see Fig. 3.4.3-4).

AND BEYOND

Measurement Systems Capability

The capability of a measurement system must be ensured before the system is used for process control or for measurements used in capability studies. This prerequisite must be satisfied because the capability of the measurement system contributes significantly to the overall results. Too much variation in a measurement system may mask important variation in the manufacturing process. In addition, the goal of high process capability, as reflected by the C_{pk}

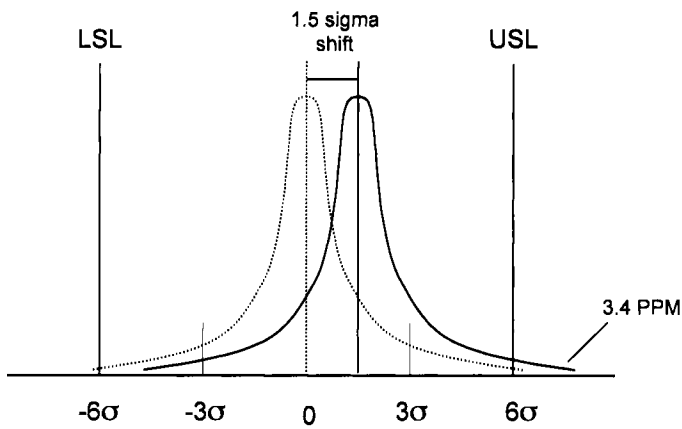

FIGURE 3.4.3-4 A 6-sigma process with a typical 1.5-sigma shift. (*Courtesy of Peak Leadership Group, Boston, MA.*)

index, can never be achieved with a measuring system that has high variability, no matter how much the process is improved.

The capability of a measurement system must be assessed by using appropriate statistical studies of accuracy, repeatability, reproducibility, stability, and linearity. The studies should be repeated periodically. Local organizations should establish time guidelines for repeating these studies.

To understand why a measurement error can make an arbitrary quality goal impossible, imagine a process that has a specification of ±10; the process is centered and has a standard deviation of sigma_p. The measurement error of sigma_m is 2.5. A goal of $C_{pk} = 1.5$ is set for the process.

The total observed variation sigma_t is

$$\text{Sigma}_t^2 = \text{sigma}_p^2 + \text{sigma}_m^2$$

Even when the process variation sigma_p is reduced to zero (an impossibility), C_{pk} of this process will never exceed 1.33.

$$\text{Sigma}_t^2 = 0 + \text{sigma}_m^2 = 2.52$$

Because the process is centered,

$$C_{pk} = C_p = \text{specification width}/6\ \text{sigma}_t$$

$$C_{pk} = 20 = 1.33/6\ \text{sigma}_t$$

The capability goal for this process will never be achieved because the measurement system has low capability. Without that realization, valuable resources might be wasted in trying to improve C_{pk} by reducing the process variation, which is not the root cause in this case.

A measurement system consists of a gauge, the people who use it, and the techniques, procedures, software, and so forth, for measuring. A good measurement system has the following characteristics:

- The system is in statistical control. The variation in the system is due only to "common causes," not special causes.
- The total variability of the measurement system must be small compared with both the manufacturing process variability and the specification limits.
- The scale increments of the measuring device must not be larger than one-tenth of the process variability or the specification limits, whichever is smaller.

Gauge Repeatability and Reproducibility (R&R) Studies. The most frequent gauge studies performed by engineers and manufacturing personnel are gauge R&R studies. Gauge R&R studies are statistical studies to investigate a gauge's ability to repeat a measurement on the same part (repeatability) and to give the same reading on the same part when used by different people (reproducibility). These studies generally use three operators to make the same measurements on the same set of 10 parts. The result of the study is one single number to represent the combined gauge repeatability and reproducibility errors. This combined gauge error is then compared with the process variability (process spread) to compute the *gauge percentage R&R*. The gauge percentage R&R is the basis for judging whether the gauge is good enough to be used for the process.

Gauge R&R Acceptance Guidelines. Several factors must be considered when determining the acceptance of gauge repeatability and reproducibility values. The gauge percentage R&R must be judged against the criticality of the measurement being made, the cost of retraining people in using the gauge, the available resources, the customer requirements, and so forth. In most cases the gauge percentage R&R should be compared with the following guidelines to make a decision:

- *Less than 10 percent.* The present gauge system is acceptable.
- *10 to 30 percent.* The gauge system may be acceptable depending on the importance of the application and various economic factors. Efforts should be made to improve the gauge capability, if possible. The gauge should be considered unacceptable for critical measurements.
- *More than 30 percent.* The gauge is not suitable. Efforts must be made to reduce the operator and/or equipment variation. A temporary method for reducing the percentage R&R by using the average of multiple readings is acceptable while permanent improvements are being investigated. In such cases, the required number of multiple readings should be statistically determined.

Traditionally, the gauge error was compared with the part's tolerance to estimate the percentage R&R, resulting in the P/T ratio (precision-to-tolerance ratio). However, this practice is no longer recommended, because our interest is to find out whether a gauge can measure a particular process characteristic that has its own unique variability. Because the process variability is totally independent of the part's tolerance, the gauge's error should be compared with the variability. This concept is very similar to the practice of using statistical control limits (variability), not specification limits (part's tolerance), to control a process.

This concept is especially important to any quality program in companies striving for best practice. With a high-capability process reaching and exceeding the Six-Sigma goal, the process spread is very small compared with the specification tolerance. An otherwise capable gauge, as determined by a P/T ratio (the gauge error is small when compared with the specification limits) may not be suitable for a process with a small process variability (the gauge error is too large compared with the process variability). Such a gauge is not precise enough for effective decision making within the normal process window. Over time, its inability to detect process shifts may mask the deterioration of the process capability and thus inhibit the effectiveness of continuous improvement programs.

To calculate the gauge's percentage R&R, the process variability is defined as 5.15 sigmas (representing 99.7 percent of the area under the normal curve).

Determination of Gauge Calibration Interval. Traditionally, the calibration intervals of a gauge are established either arbitrarily or loosely based on prior experiences or manufacturer's recommendations. Because no scientific method is used, the calibration intervals may not be frequent enough for the gauge in its real working environment. Then, the risk of using an inaccurate gauge could be significant. On the other hand, the calibration intervals may be too frequent, and resources can be wasted on unnecessary activities.

For these reasons, gauge calibration intervals should be carefully determined. Either an algorithmic method or a statistical method should be employed to establish and adjust the gauge calibration intervals, so as to minimize the risk and optimize resources.

Comparing Two Measuring Instruments. Occasionally, one measuring instrument must be compared with another similar device to determine whether the two are performing equivalently. In such cases, correlative study is not the best approach. Two measuring instruments often correlate with each other, even if the differences in measuring means are statistically significant.

Instead of correlative study, hypothesis testing should be used, which compares the paired differences in measurements of the same parts on two instruments. These differences should first be tested for normality. If the data are normal, a "t-test" may be used. If the data are not normal, a nonparametric test such as the Wilcoxon matched-pair, signed-rank test should be employed.

Quality Problem-Solving, Diagnostic Tools

Pareto Analysis, Pareto's Law. Pareto analysis is a very simple way of determining which problem to try to solve first. The problems that seem biggest or most urgent are those that attract

our attention. To be an effective problem solver, you must be able to sort out the "vital few" important problems from the "trivial many" other problems. Pareto analysis will help you do this. Pareto analysis was developed by Italian economist Vilfredo Pareto. He determined that approximately 80 percent of the wealth is held by approximately 20 percent of the population. This concept is also known as "Pareto's law." This same principle was adapted by other quality control people and can be used in a manufacturing or administrative process; that is, 80 percent of your problems are due to 20 percent of the causes. Or to put it simply, 80 percent of your headaches are due to only a few problems. So it pays to work on the first few problems and ignore the others until those first few are solved. Problems tend to sort themselves out. When you do some investigating, you usually find that of the many problems that you have, only one or two account for the largest dollar loss, happen most frequently, or account for the most failures.

Procedure. Figure 3.4.3-5 shows a list of failures taken from a soldering operation after one week's production by an automated soldering machine. Later a cumulative or percentage defective curve can be added.

Brainstorming, Fishbone (Ishikawa) Diagrams, Cause-and-Effect Diagrams. You might have heard some or all of these terms used when trying to problem-solve. In the problem-solving process, you need to identify problems, as well as determine their causes. Brainstorming helps you to do both. Kaoru Ishikawa in Japan created the fishbone or Ishikawa diagram in the 1940s. Ishikawa used this method for displaying and organizing the relationship between a problem and the possible root causes of the problem. Brainstorming is an outpouring of ideas. Have a team facilitator run the brainstorming session; this person will keep the team on track and will be unbiased in viewing the problem. The group should meet in a common meeting room. The room should have the facilities to record all of the ideas stated by the team. Use an overhead projector, chalkboard, computer, or anything else that will enable the group to view the results.

Prerequisites. Choose the subject for the brainstorming. Make sure that everyone has a clear idea of what the real problem is. This is a critical first step and may take some time. Discuss this until everyone agrees.

Form the team. This is also an important step; you must have a group of people who are willing to work together as a team. You should gather together all people from various disciplines of the job at hand. For instance, if this is a manufacturing problem, you may want to include maintenance, manufacturing, engineering, quality assurance, inspection, and so forth. Or for administrative problems, you may want to involve administrative assistance, service centers, the

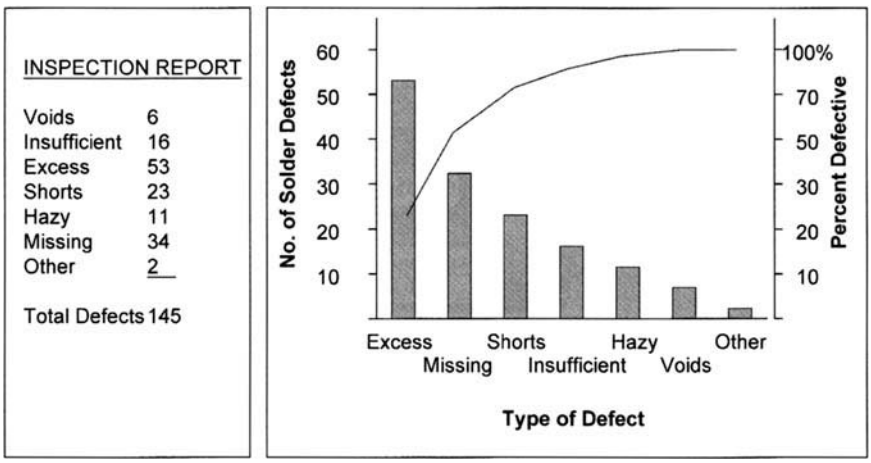

FIGURE 3.4.3-5 Pareto chart. (*Courtesy of Peak Leadership Group, Boston, MA.*)

manager of that operation, and so forth. Involve everyone who is concerned with the problem; this will facilitate more causes, and people will feel more ownership toward solving the problem.

Now you are ready to brainstorm. This can be done in different ways. Some groups find it helpful to go around the room and give each person a turn to express one idea. If people cannot think of ideas, they may "pass" until the next time around. Other groups decide that it is fine to throw out ideas randomly. If you have an idea, just say it, and it will be recorded.

Facilitators are responsible for recording all of the ideas expressed during the brainstorming session. Facilitators should be completely unbiased. Their job is to facilitate the group, to encourage discussion, and to be the timekeeper and mediator.

As a facilitator, your job is to extract *all* of the ideas your group has. The concept that "no idea is a bad idea" should be conveyed to the group. Any and all comments should be tabled until all ideas are exhausted. Do not criticize the ideas of others. If ideas are criticized, this will have the effect of shutting down the ideas of people who are less vocal in the first place. The facilitator also must maintain direction and should write down all ideas stated. Encouraging wild ideas may trigger someone else's thinking.

Procedure. On your overhead, chalkboard, or computer, draw a line from the left to the right. This will be the main bone of your fishbone diagram. Draw a rectangle to the right of the line, and place the stated "problem" in this area. Draw four additional lines from the main bone. These will act as the general categories of the potential causes of the problem. Typically, we use the four Ms, which are *manpower, machines, methods,* and *materials.* Other general categories may be *Mother Nature* and *measurements.* The team can select whatever categories may be needed for that situation.

Begin your brainstorming. If an idea or possible cause arises that involves a machine, place the idea in the machine category. This can be depicted with the idea and an arrow drawn to the machine category. If ideas or causes of that first idea spawn deeper ideas or causes, place those ideas with arrows pointing toward the original idea. Continue until all ideas are exhausted. This process can last for half an hour to several hours, depending on the complexity of the problem (see Fig. 3.4.3-6).

Process Performance Metrics

Three valuable metrics are used to measure the performance of all significant processes. The potential process capability index (C_p) and the process capability index (C_{pk}) are used to assess process capability. The instability index (S_t) is used to determine the stability of a process.

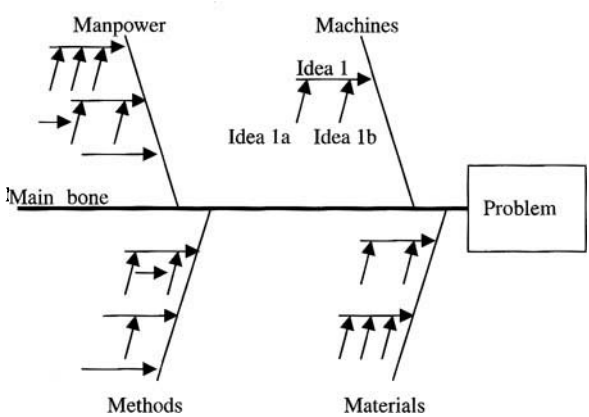

FIGURE 3.4.3-6 Fishbone/Ishikawa diagram. (*Courtesy of Peak Leadership Group, Boston, MA.*)

Potential Process Capability Index (C_p). C_p is defined as the ratio of specification width over the process spread. The specification width is predefined and fixed. The process spread (or process width) is the sole influence on the C_p index. When the spread is wide (more variation), the C_p value is small and indicates low process capability. When the spread is narrow (less variation), the C_p value becomes larger, indicating better process capability (see Fig. 3.4.3-7).

Process Capability Index (C_{pk}). In real life, very few processes are on their desirable target. An off-target process should be "penalized" for shifting from where it should be. C_{pk} is the index to measure this real capability when the off-target penalty is taken into consideration. The penalty, or correction factor, k is defined as

$$k = \frac{\text{target} - \text{process mean}}{\frac{1}{2}\text{ specification width}}$$

and the process capability index is defined as

$$C_{pk} = C_p (1 - k)$$

When the process is perfectly on target (see Fig. 3.4.3-8),

$$k = 0$$

and

$$C_{pk} = C_p$$

Design of Experiments

Poor quality in any arena can be traced to variation in parts, materials, people, and processes. The larger the variation, the poorer the quality. It has been observed that all work can be bro-

$$C_p = \frac{\text{spec width}}{\text{process width}} = \frac{\text{USL} - \text{LSL}}{6\text{ Sigma}}$$

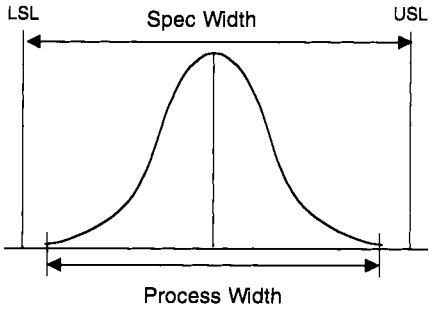

FIGURE 3.4.3-7 Process potential. (*Courtesy of Peak Leadership Group, Boston, MA.*)

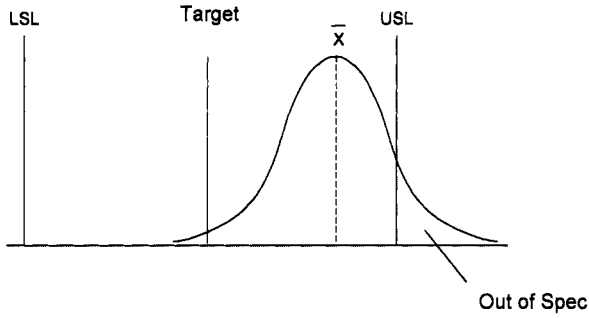

FIGURE 3.4.3-8 Capability index C_{pk}. (*Courtesy of Peak Leadership Group, Boston, MA.*)

ken down into processes. All processes, whether manufacturing or administrative, have inherent variability that affect their qualities.

Basic statistical process control (SPC) techniques such as Pareto analysis, cause and effect diagrams, graphical data presentation and analysis, and control charts have been widely incorporated in many businesses. These SPC tools are useful in identifying variation and keeping the process from deteriorating in quality. These tools do little, however, to make dramatic improvements in quality, and they are used primarily for maintenance and monitoring.

Immediate and continuous process improvements require additional tools beyond basic SPC. These techniques are generally classed as *design of experiments* (DOE). DOE encompasses a broad spectrum of approaches and tools. A large number of "quality gurus" have been active in the field of DOE. The most well-known approaches are the "classical," such as full factorials and fractional factorials. Next are the Taguchi and Shainin techniques. The classical approach is the most thorough and the most mathematically complex technique. The Taguchi approach is similarly mathematically complex, but allows shortcuts to the classical approach and thus is simpler and less expensive to perform. Although statistically well-founded, the Shainin approach is the least mathematically complex of these common techniques.

Cross-Functional Process Mapping

Mapping is a tool that can be used in a manufacturing or an administrative area. The concept of mapping out a process or system is simple. A cross-functional team is formed to challenge a problem or business issue. The team concentrates its initial efforts on how they do things presently (for example, how does billing flow from start to finish, or, how does this product flow through my production line?). The group will write down in detail how their process/system currently operates. This will give the team a very good idea of how the process works and what all the current problems/issues may be. A process map results in a list of all of the problems/issues.

The process proceeds to examine the following three steps of the total cycle time implementation process:

1. Identify key customer issues that impact cycle-time reduction through customer and organizational analysis.
2. Apply concepts and tools to reduce cycle time for a clearly defined customer or critical business issue.
3. Develop and implement an action plan to reduce cycle time based on a clearly defined customer or critical business issue.

As a cross-functional group, a team of individuals moves through each step. The team will practice applying the concepts and tools and developing their skills in using organizational

and process mapping techniques and mathematical formulas to determine "as-is" and "should-be" cycle times. The APQC best practices discussed in Chap. 2 are excellent sources of potential should-be processes maps. The maps identify a customer issue or critical business issue relevant to their work environment, which is used as the basis for the application activities of the implementation process. After going through this process, a group will be able to describe the total cycle-time implementation process, draw an as-is and should-be process map, establish as-is and should-be cycle times, and develop an action plan to support should-be process and cycle time. The plan usually determines and prioritizes the enhancements and changes needed to transition from the as-is to the should-be process. A gap analysis may help decide what to do and how to do it.

Why Create a Process Map? A process map (see Fig. 3.4.3-9) can be helpful to:

- Identify areas for cycle-time improvement
- Identify bottlenecks, rework, and non-value-added steps for elimination
- Provide documentation of how the process is conducted
- Demonstrate sufficient detail to make improvement recommendations
- Identify opportunities for simplification by comparing with best practices
- Visualize upstream controls

Establishing a Process Control System

An effective process control system requires careful research in the planning phase. The potential failure modes of each process and product characteristic must be explored and understood. The knowledge gained in this investigation is then used to plan the control system, such as determining the important process characteristics to be controlled, how to control them, how to react when the process is unstable, and so forth.

Generally, the *failure mode and effects analysis* (FMEA) for each process should be generated first to assess potential problems. The knowledge gained in developing the process FMEA is invaluable in developing the *control plan,* which is a detailed plan to control all pro-

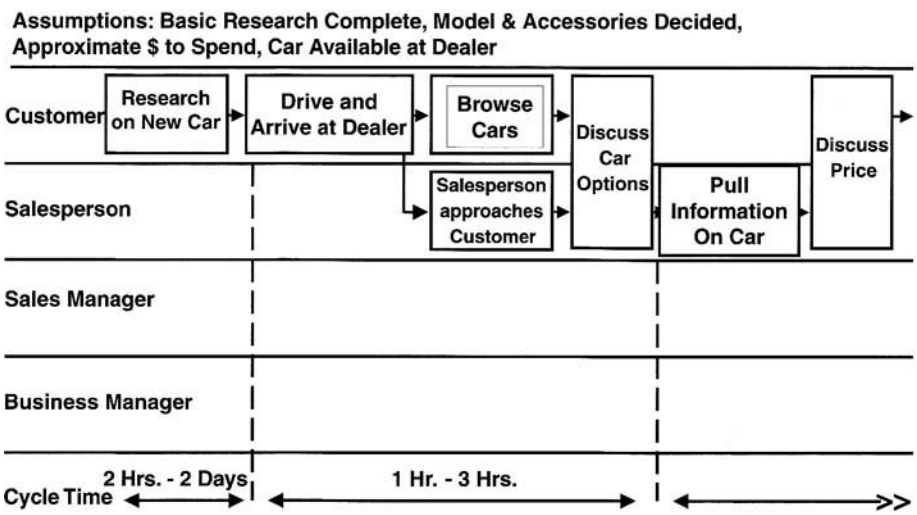

FIGURE 3.4.3-9 Process mapping (purchasing a car). (*Courtesy of Peak Leadership Group, Boston, MA.*)

cesses for a family of products. The process FMEA is equally important in driving the development of the total control methodology, which is designed to give complete and simple instructions to control each process at the production level.

Process Failure Mode and Effects Analysis (FMEA). A process FMEA is an analytical technique, which must be used for all significant processes to ensure that potential failure modes have been considered and addressed. An FMEA should be a summary of an engineer's analysis of what could go wrong with the process, the potential impact of such a failure, and how to deal with or correct the problem. A process FMEA should be developed for all new changed processes. The FMEA should also be reviewed periodically and revised when more knowledge is gained about the process. Normally, an FMEA will serve the following purposes:

- Identifies known or potential process failure modes
- Assesses the potential risk effects of the failures to the customer
- Identifies the potential manufacturing or assembly process causes and control actions
- Identifies significant process variables to focus controls for detecting and reducing similar failures

An FMEA will have a list of potential failure modes ranked according to their effect on the customer, thus establishing a priority system for corrective action. In a process FMEA, a "customer" may also mean a downstream process or operation, as well as the end user. When a FMEA is properly developed, it is a good tool for several purposes. An FMEA can help in developing new machines and processes, as well as troubleshooting old processes that perform below expectation. From a process control viewpoint, an FMEA is also important in the development of several components of the control plan and total control methodology (see Fig. 3.4.3-10).

Control Plan The development of a control plan is a key phase in establishing a process control system. A control plan is a summary description of the procedures for controlling all significant characteristics of the processes used to manufacture a family of similar products. It identifies the important processes used to produce a product, the significant characteristics of each process, and the way to control each of those significant characteristics.

A suitable control plan must be generated to successfully control a manufacturing line. Typical elements of a control plan include the following information:

- *Process.* Identifies the manufacturing process to be controlled.
- *Equipment.* Types of equipment or machines used in the process, either generic or specific.
- *Significant characteristics.* A list of all significant characteristics to be controlled. These should be input variables, but may also be output variables.
- *Measurement techniques and/or equipment used.* For measuring and/or method for obtaining the data.
- *Minimum.* The minimum acceptable number of units or readings for each sample size and monitor and the minimum acceptable frequency of monitoring.
- *Frequency analysis method.* Techniques to analyze the data collected. These can be statistical techniques such as X-bar and R charts, attribute charts, or nonstatistical techniques, such as Positrol logs.

Total Control Methodology. Several separate processes usually exist within each product line. Each one of these processes should have an individual plan to control significant machine, process, and product characteristics. The plan must be complete enough to cover all

periodic process control requirements. But the plan must also be simple and should be considered as the operator's complete and easy instructions and reference for controlling each specific process. Such a system is called a *total control methodology,* or TCM.

A TCM must be developed and implemented at each process within a product line. A cross-functional team approach should be used to develop and implement the TCMs. The design and contents of a TCM should be flexible enough to adapt to different environments, and contain the following major elements:

Positrol plan. A Positrol plan is one element of a TCM, and it is usually the first section of the package. A Positrol plan is a matrix in which different aspects of the control system are characterized.

The *rows* of the Positrol plan matrix define:

1. *What.* The process variable or characteristic to be controlled and related criteria.
2. *How.* How to perform the required control on the characteristic specified. Additional instructions such as procedures for measurements may be needed.
3. *Who.* The person responsible for performing specified actions.
4. *When.* The frequency of monitoring.
5. *Types of control techniques.* X-bar and R charts, P or N_p charts, Positrol plans/logs, and so forth.

The *columns* of the Positrol plan matrix define:

1. *Setup requirements.* Procedures to set up a machine/process and all necessary buy-off requirements before actual production run.
2. *Input characteristics.* All important input variables to be controlled; input variables often associated with the machine/process.
3. *Output characteristics.* All important output variables to be controlled; output variables often associated with the product, such as product measurement.
4. *Preventive maintenance (PM).* All PM requirements done by the operators.

Positrol Log. Control charts may not be necessary for some characteristics. However, these characteristics may still need to be validated periodically to make sure they are within control and/or specification limits., A log sheet known as a *Positrol log* is used to record the reading of those characteristics. A Positrol log generally contains:

- Characteristics to be monitored
- Frequency of monitoring for each characteristic
- Control limits or specification limits used as control limits
- Reactions when reading excess limits
- Other information such as date, time, initials, and so forth

Control Charts. A control chart is a common form of control required by a Positrol plan. The charts must be appropriately selected and used. See the separate section for control chart usage guidelines. The reverse sides of the control charts contain corrective action logs. These logs are required to record actions taken when a control chart shows an out-of-control condition. The action taken should conform to the *out-of-control action plan* (OCAP).

Out-of-Control Action Plan (OCAP). Sometimes called a *decision tree,* an OCAP (see Fig. 3.4.3-11) is a plan to help production personnel react to each specified type of out-of-control situation. It gives instructions for both product and process on what specific actions are needed to dispose of products and restore control when there is an indication of out-of-control conditions. An OCAP is a powerful tool to capture the engineer's knowledge and make it available for the operators. With an OCAP, many correct engineering decisions can

Out of Control Action Plan

Date
Time
Operator

To be used in the event of an Out-of-Control Condition on the Porting Control Chart or the Positrol Plan/Log

___ Yes	1.	Is the calculation and point plotted on the control chart correct? Continue with PCL.
___ No		Correct the calculation and/or point plotted, and have Cell Leader sign CAL and continue to run.
___ Yes	2.	Was The Out-Of-Control Condition; A Single Point Above The UCL; 2 Out Of 3 In Zone A Or Above; 4 Out Of 5 In Zone B Or Above; 8 In Zone C Or Above; Six Points In A Row Steadily Increasing? Adjust Adhesive Reservoir Pressure, down within specified limits. After adjusting the pressure perform a half dozen dispenses in order for the pressure to equalize. Check adhesive weight twice in a row and plot both points on the control chart. Continue to run.
___ No		Continue with PCL.
___ Yes	3.	Was The Out-Of-Control Condition; A Single Point Below The LCL; 2 Out Of 3 In Zone A Or Below; 4 Out Of 5 In Zone B Or Below; 8 In Zone C Or Below; Six Points In A Row Steadily Decreasing? Adjust Adhesive Reservoir Pressure, up within specified limits. After adjusting the pressure perform a half dozen dispenses in order for the pressure to equalize. Check adhesive weight twice in a row and plot both points on the control chart.
___ No		Continue with PCL.
___ Yes	4.	Was the System Air Pressure within specified limits? Continue with PCL.
___ No		Adjust System Air Pressure, up or down within specified limits. Check adhesive weight again, and plot on control chart.
___ Yes	5.	Was the Tower Air Pressure within specified limits? Continue with PCL.
___ No		Adjust Tower Air Pressure, up or down within specified limits. Check adhesive weight again, and plot on control chart.
___ Yes	6.	Was the Pedestal Rotation Speed within specified limits? Continue with PCL.
___ No		Adjust Pedestal Rotation Speed to left or right within specified limits. Check adhesive weight again, and plot on control chart.
___ Yes	7.	Was the Chuck Alignment within specified limits? Continue with PCL.
___ No		Adjust Chuck Alignment, align hole on chuck with hole on base of machine. Use small alignment hole for all other ports. Use large alignment hole for axial ports. Check adhesive weight again, and plot on control chart.
___ Yes	8.	Is the Weight Scale (Gauge) in calibration? Continue with PCL.
___ No		Check calibration sticker date, if OK Check adhesive weight again, and plot on control chart. If not, call Maintenance.
	9.	If all of the above has been tried and the dispensing is still not correct place "machine down" sign on, and call Maintenance.

FIGURE 3.4.3-11 Out-of-control action plan (OCAP). (*Courtesy of Peak Leadership Group, Boston, MA.*)

be made instantly by the operators. Generally an OCAP may have one of the three following formats:

- Decision tree in flow chart or simple box diagrams, showing diagnostic journey, with remedies.
- Narrative explaining the diagnostic, containment, and corrective actions.
- Interactive computer dialogue that appears when an out-of-control situation occurs, providing the necessary information to lead the operator through the diagnostics and remedies.

- *Setup checklist.* Summary of all important machine setup items that must be checked on a regular basis to make sure that the machine is operating at the baseline requirements.
- *PM schedule.* Schedule that specifies when equipment components are to be validated and checked for conformance, maintained, overhauled, or replaced.
- *PM checklist.* Assists validation that all components due for PM have been completed and are correctly set up to ensure that the machine can perform up to its inherent capability.
- *PM procedures.* General instructions and criteria detailing how equipment is to be maintained; usually includes brief acceptance/checkout procedures to be performed before release back to production.
- *Reference/backup.* A TCM should include supporting documents such as detailed PM procedures, machine setup procedures, process specs, and so forth. If the material is too extensive to be included conveniently, the name, document number, and location of the material should be referenced in the list of the TCM.

Quality Function Deployment (QFD)

Objectives:

- Highlight inviolate customer principles
- Translate the "voice of the customer" into product specifications
- Further deploy product specifications into part specifications, part specifications into process specifications, and process specifications into production/quality control
- Outline a variety of techniques that can capture the "voice of the customer":
  1. Value research : simple, effective
  2. Sensitivity analysis : a fine-tuning
  3. Multiattribute evaluation : systematic, effective
  4. Quality function deployment : comprehensive, effective
- Develop QFD as an umbrella technique, covering several disciplines in new product development

Benefits:

- New design in half the time with half the manpower, half the defects, and half the cost of previous designs
- Moving from customer satisfaction to *customer delight*
- Leapfrogging competition
- Quick transfer of knowledge to new engineers
- Making good engineers into excellent engineers

Continuous Improvement. A well-designed, well-executed process control system will keep a process under control at an existing level. The control charts will identify and even predict when a process is unstable. The OCAP will specify which actions are to be taken under which circumstances to bring an out-of-control process back under control and to dispose of the product. The control plan and TCM will specify in detail how to control a whole product line or any single process.

However, there is one thing a process control system cannot do: It cannot directly improve the capability of a process. A process can be improved only if we understand the significant characteristics that influence the final output, know how to optimize those characteristics, and keep them at the optimum level.

In the total picture of continuous improvement, process control is only one component among a number of other equally important components. These continuous-improvement components should be performed in a general sequence. The flow chart shown in Fig. 3.4.3-12 describes the main components and the logical sequence for making continuous improvements in a process. In reality, some flexibility to add other components and/or slight modification of the logical sequence may be needed to adapt to individual situations.

ARTICLE 3.4.4
INFORMATION-DRIVEN PROJECT MANAGEMENT FOR DESIGN AND DEVELOPMENT

Michael Stowe
The Boeing Corporation

Stephen Denker
GTE Internetworking

In today's business environment, many organizations have multiple design projects running simultaneously. Our inability to see the full impact of our own work and that of others or to quickly assess the changes we all can expect during a project is a significant contributor to schedule creep, uncontrolled resource usage, and cost overruns. Complicating matters further, projects as a whole often extend beyond their own business boundaries to external suppliers and customers.

Information-driven project management (IDPM)[1] shows how changes made during a project affect people individually and as a team. Everyone can see clearly how their individual information needs and responsibilities affect the entire project's desired deliverable, cost, and schedule goals. This added situational visibility opens the way to more ideas and innovations.

More than schedule and resource analysis, we need to design our projects. Definition and organization of the project steps to be performed are critical to project success. Designing an outstanding project is itself a creative, iterative project management process. Information-driven project management encourages using behaviors conducive to holistic project optimizations.

DESIGN AND ANALYZE PROJECT PLANS

Projects are sequences of dependent process steps that produce products or services. Over time, project complexity generally increases and changes. To cope, we need increased situational visibility. An integrated set of project visualization techniques and associated software tools, IDPM provides situational visibility by enabling project team members to design and analyze all of the significant information and resource relationships among a project's process steps that are necessary to meet specific goals. This visibility is available to project team members throughout both project planning and execution.

Information-driven project management takes us from a logistics view (managing tasks and deliverables) to a dependency view (managing arrays of dependent entities). Information-

driven project management provides project management with a clearer view of all intertask dependencies and an ability to resolve them. Information-driven project management surfaces project information dependencies and project resource constraints. Information-driven project management then deals with them—identifies opportunities. Information-driven project management combines the best of existing project planning methods with two new management capabilities—the Dependency Structure Matrices (DSMs; information dependency structure) and the Critical Chains (resource constraint structures). The DSMs lay out information dependencies in an easily understood spreadsheet-like format and also provide a topology-based foundation to manage dependency structures. Critical Chains differ from Critical Paths by including resource constraints. The Critical Chain, as the critical sequence of resource-constrained project steps, determines when a project is done, that all of its deliverables are delivered. Combined with DSMs, Critical Chains improve project plans by ensuring that they are feasible. The two conditions are interdependent—information dependencies determine the Critical Chain as much as do resource constraints.

IDPM PATHWAY

Within IDPM, projects are viewed as information processing systems. Systems require inputs and produce outputs. Inputs transformed by process steps use resources to produce outputs. We view these inputs and outputs as information. This insight led directly to creation of the IDPM systems approach. The IDPM system has six components just as the cube has six faces. Our overall goal is increased visualization of all of a project's perspectives. Figure 3.4.4-1 represents the complete six-step IDPM pathway.

Although there is only one entry point into the IDPM pathway portrayed in Figure 3.4.4-1, side trails adjacent to the main path permit flexible access to all steps within the IDPM system. The IDPM information processing approach can be repeated as necessary throughout a project's life. The path we actually take depends on how well we can understand and document our work processes and project goals. During the life of a project, process steps or their sequence may need to change because some information or resource is not actually ready when required.

IDPM STEPS

Step 1: Prepare Initial Goals

Right from the start, the better we can describe our project's development and performance goals, the better our chances for creating successful project plans. In many cases, however, the description of a new project and its goals only becomes clearer later, as the project proceeds. This is especially the case where we have little prior experience or timely access to information about similar projects. A project team should start a project goal's document by describing their final goals first and then working backward through each significant project phase to describe their corresponding goals. Be sure you understand all of the project requirements; if they are fuzzy, put in an early step to clarify them with your customer. For every significant project phase, three goals should be documented:

1. Deliverables (for each scope of work)
2. Time
3. Cost

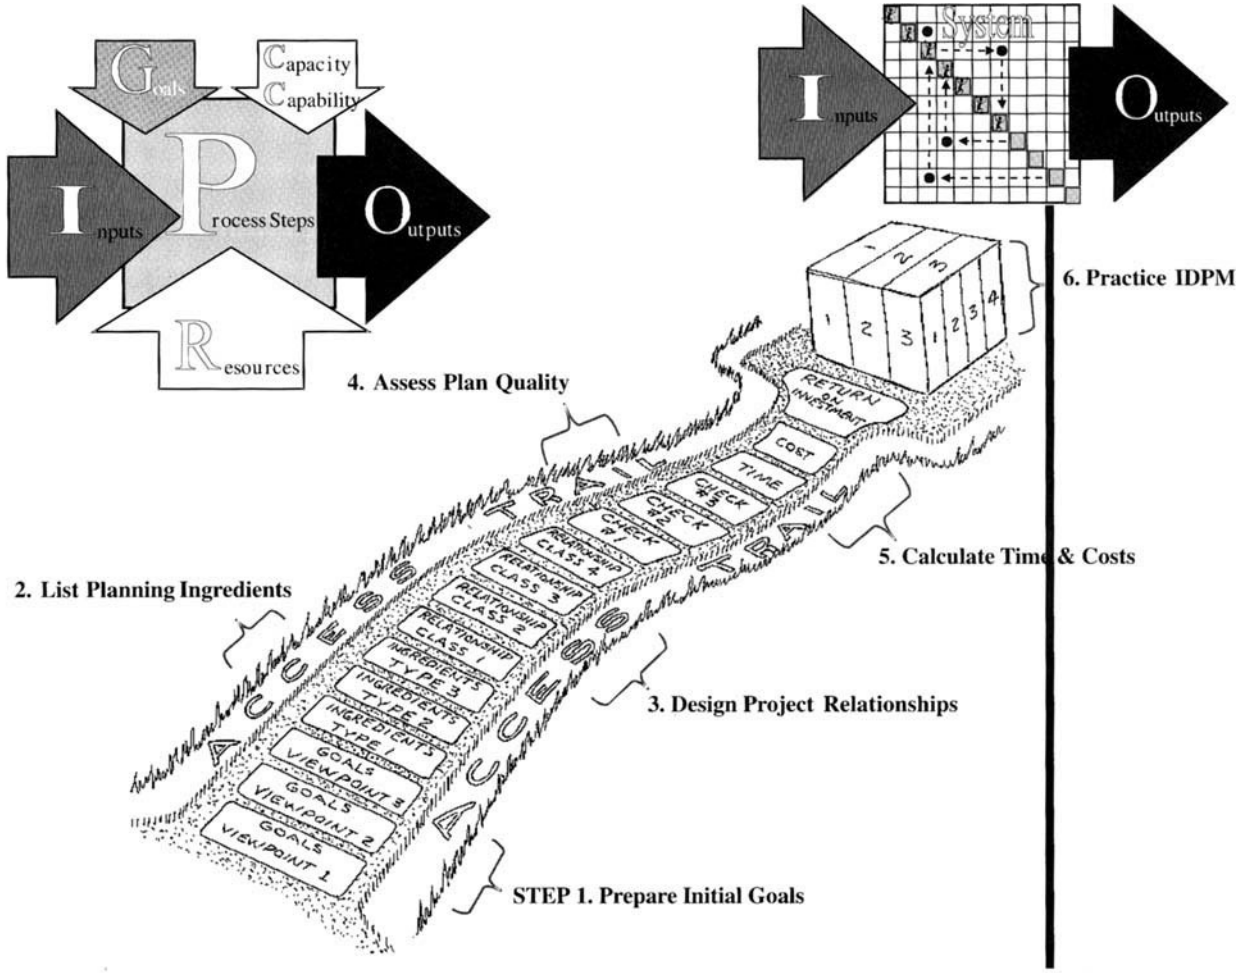

FIGURE 3.4.4-1 Six-step IDPM pathway.

Step 2: List Ingredients

Every project has information dependencies and resource constraints. Interview all team members to obtain this information. Knowing what questions to ask and how to arrange their answers for use is absolutely critical. We list descriptions of the project deliverables, schedules, and cost goals. We also list each team member's individual information dependencies, resource constraints, associated project step lists, and their durations. We update, as necessary, throughout the life of the project. During interviews, managers and project team staff must constantly ask themselves, What is the essential information that I need to make this decision? What do I need to start, update, or complete my work? Project ingredients identified in this step and designed in the next step are analyzed in Step 4 to confirm that the project's goals (specified in Step 1) are met. The three information lists include:

1. Resources
2. Process steps
3. Inputs and outputs

Resources are all those things that energize projects. People, tools, and facilities used within a project system are resources. Each resource has unique capabilities and availability. At this point, simply create lists of resources in any order, along with the associated quantities needed.

Some of the inputs-to and outputs-from process steps are external to the project. Project team members are responsible for bringing external information into the project (external inputs). Some or all of the information they create is considered internal outputs to be shared with project team members. Some of these internal outputs created by the project team are likely to serve as external outputs needed by others outside the project. It is extremely important to be able to identify internal and external inputs and outputs. When interviewing project team members about their respective project roles, we want to identify and list any input and output information both internal and external to the project. Clear definition of the input/output information that each team member provides ensures that the necessary interfaces between their roles match. One technique, a data dictionary, can be used to ensure that different words do not mean the same thing or that the same words do not mean different things.

Step 3: Design Project Relationships

This step makes all of the information dependencies among team members visible. The project team can see how information dependencies might create iterations and work out of sequence. Opportunities for concurrent project steps that increase throughput can be clearly identified. The project team can design a project that achieves its deliverable goals and also identifies key risks and the strategies for overcoming them. The project team uses the structured modeling (DSMs) to represent and optimize complex dependency relationships to arrive at the executable project step sequence before proceeding to resource constraint analysis (Critical Chains).

We build an initial project model based on information collected about person-specific and team-specific process steps. In IDPM, we choose to represent information dependencies using diagrams or matrices. To represent more complex relationships, we could use data flow diagrams. Some IDPM Working Group members use a hierarchical box and arrow language called IDEF0 to considerable advantage. Figure 3.4.4-2 illustrates the IDPM process using the IDEF0 language. Other IDPM Working Group members use DSMs to model their projects directly.

Dependency Structure Matrices offer an effective way to visualize the relationships among activities in a project. The DSMs were developed to solve problems based on the structure of the problem. The technique has been applied to many problem sets, including the design of project plans. The project's process steps have constraints and predecessors. In the design of the project plan, we want to organize process steps to provide the best plan. The DSMs map the dependencies between the project's process step inputs and outputs. We visualize and

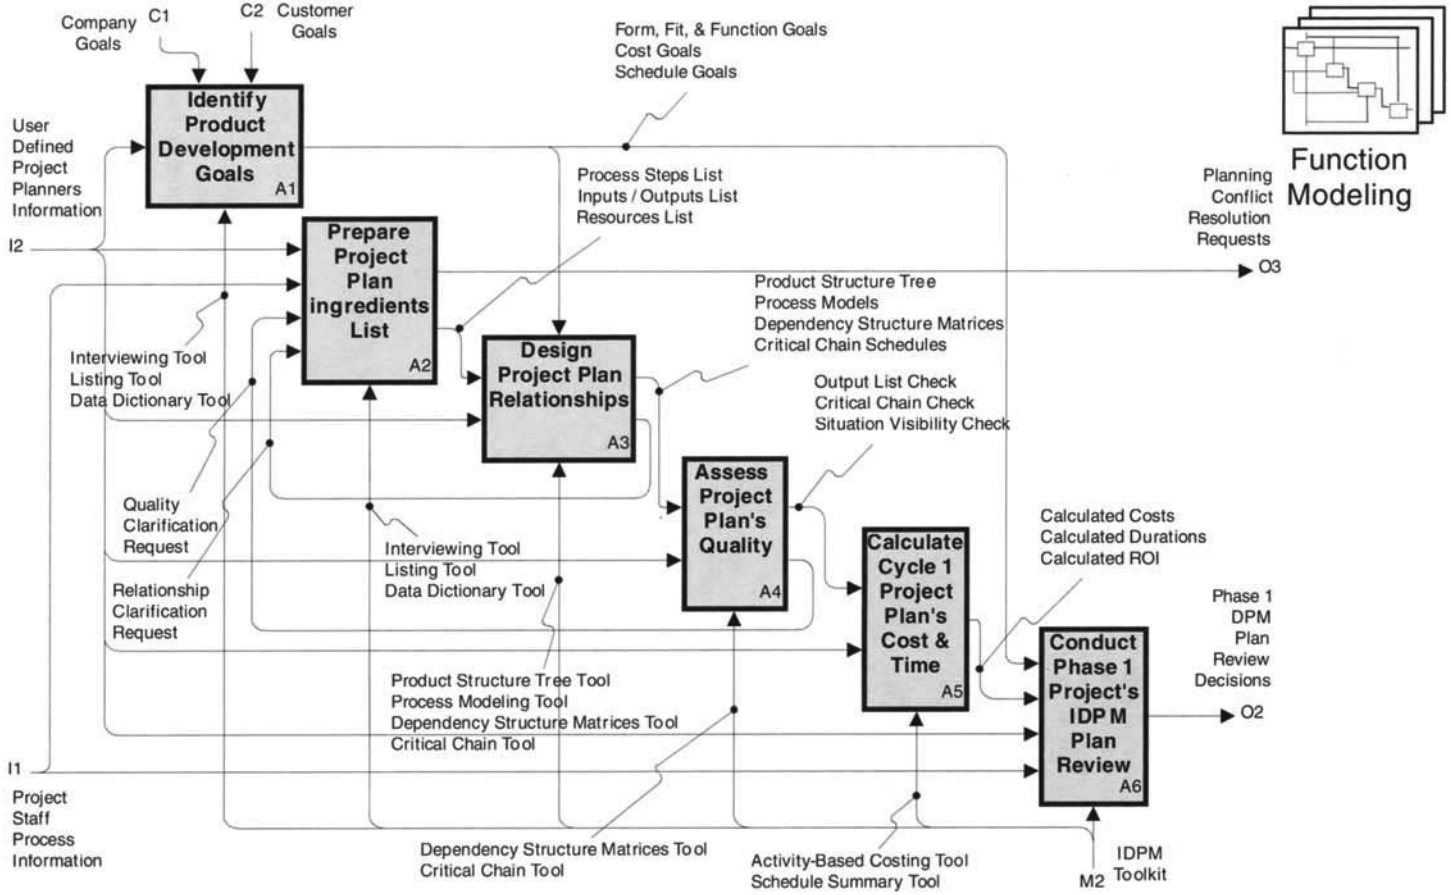

FIGURE 3.4.4-2 IDPM process description.

understand relationships between process steps by tracing information dependencies through a DSM to see all likely consequences. We can then visualize and understand relationships between process steps by tracing dependencies through a DSM to see all likely consequences. The approach presented in this subchapter follows that adapted by Boeing and NASA.

A DSM map can be used to transform the components (inputs, goals, capacity and capability, and resources) that enter process steps into external outputs. It visualizes the internal outputs created when the process steps transform any combination of external and internal inputs. The DSM map uses a square matrix as illustrated in Fig. 3.4.4-3. For simplicity, process step names in the initial matrices could be ordered alphabetically across the rows and columns.

A project plan that has N process steps determines the size of the square $N \times N$ DSM matrix. Two additional matrices that identify external inputs and external outputs are adjacent to the internal process step sequence matrix (the DSM) in the center. Some process steps produce both internal and external outputs. The external input matrix is above the DSM and the external output matrix is to the right of the DSM. These externals could determine the project team's success, and these external outputs are necessary to others outside the project. They depend on them.

A mark in each of the matrix cells in the DSM means that an input or an output relationship exists between the process steps. When the mark is above the diagonal, information is fed forward horizontally until it meets the vertical column of the process step that needs it. When the mark is below the diagonal, then information is fed backward horizontally until it meets the vertical column of the process step that needs it. Any backward flow means that an earlier process step might need to be repeated or that it is out of sequence.

Usually, we initially identify only input and output information exchanges between process steps internal to the project for our internal process step sequence matrix (the DSM). If any resource that performs one of these internal process steps cannot find its inputs in the DSM or if they are not visible, then they must be external inputs. Whatever outputs exit from the DSM to external destinations really determine when a process step is complete and presumably ready for another activity.

This matrix representation allows project team members to visualize a logical order necessary to create and manage its own project and identify all dependencies on external vendors and customers. It also quickly identifies all of the rework cycles that the project team's own internal sequence of process steps may be causing by identifying the backward feeds shown by marks in matrix cells below the diagonal of the center DSM matrix. Some of the backward feeds can be easily removed by simply changing their relative locations in the sequence matrix of internal process steps, so that they feed forward above the diagonal. For example, any necessary rework cycles can be planned now that they have been made visible. Also visible are the process steps that occur concurrently because there is no information dependency among them. This view of concurrence assumes that there are no resource conflicts among those process steps.

Because resource constraints are often significant, IDPM project planning always considers them. The Critical Chain includes the resource constraints that define the overall longest path (constraint) of the project. The method resolves all resource constraints while determining the project Critical Chain. For a project without resource constraints, the Critical Chain will be the same as the Critical Path.

The Critical Chain has the largest impact on any project's completion date and throughput. The Critical Path through a project's process steps represents the path of longest duration from the project's start to finish. Any changes made to the critical process steps have the most significant impact on the project's duration path. Goldratt[2] introduced the powerful viewpoint that a project is a set of chained process steps, one of which is the Critical Chain. Chains exist because there is some dependency between the adjoining chain links. To improve throughput and remove bottlenecks in the chain, special care must be taken when planning the capacity of each of the individual chain links. The DSM represents all of the chains formed by information dependency. The Critical Chain represents opportunities for significant improvement, if the project cannot meet its initial development time or cost goals. We must resolve the combined effects of information dependency and resource conflict within a proj-

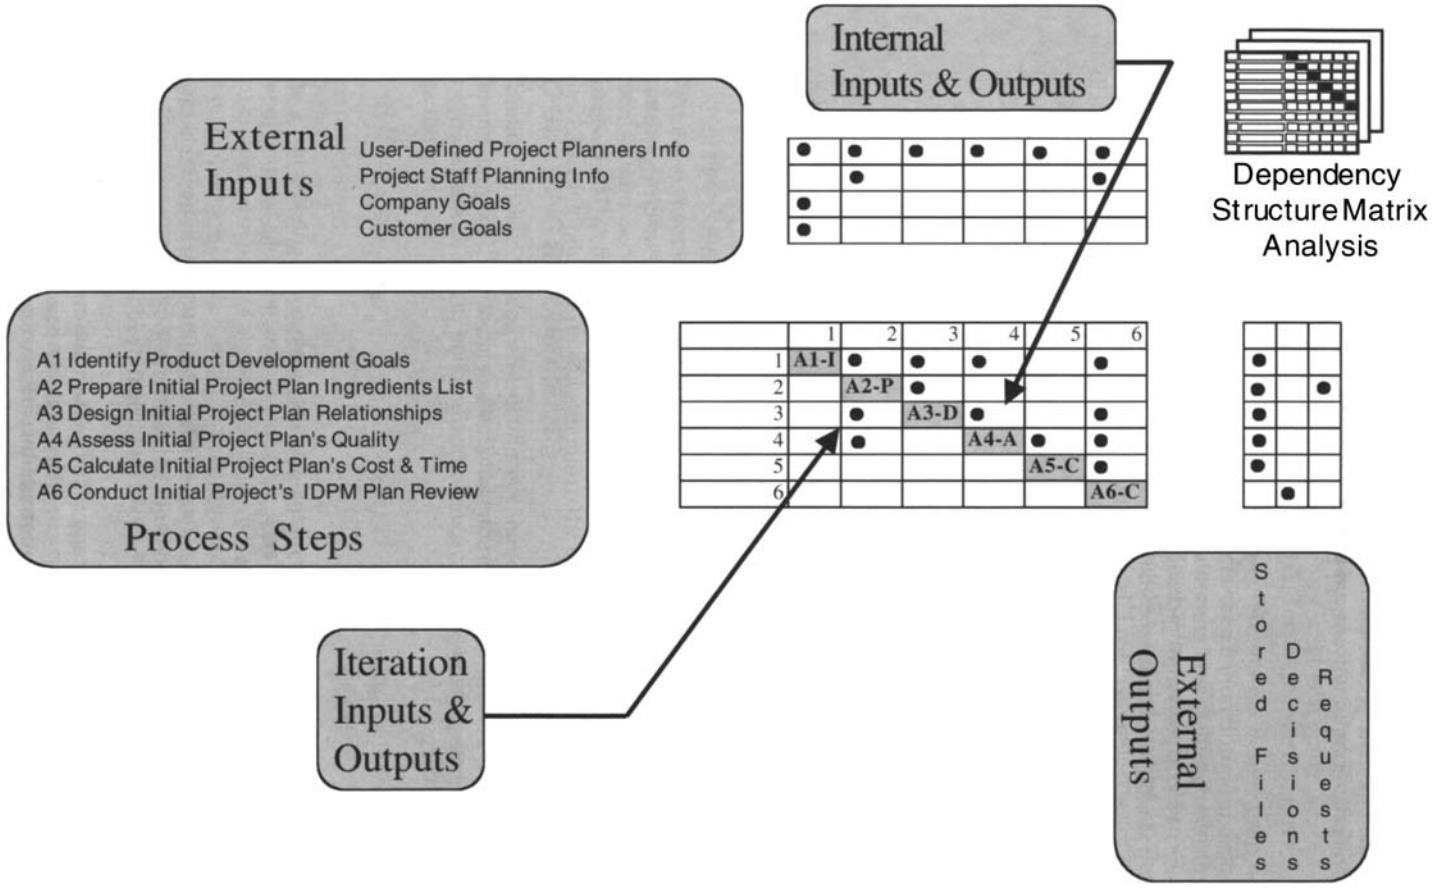

FIGURE 3.4.4-3 Dependency Structure Matrix (DSM) mapping.

ect and across multiple projects. We must manage our reserve of resources. Conflicts in resource usage could modify opportunities for concurrent project steps identified in Step 3. Another very important reason for resource identification on the chain is to prevent multitasking. When people experience resource conflicts due to multitasking on the Critical Chain, projects do not tend to meet their development time and cost goals.

Critical Path project planning often assumes that an acceptable way to account for potential resource constraints on the project is first to identify the critical path and then perform resource leveling. For most, application of resource leveling algorithms lengthens the overall schedule. For this reason, few projects use resource leveling tools. The essential change introduced by Critical Chain Project Management (relative to the current Critical Path practices) is development of the Critical Chain, using both process step information dependency logic and resource constraints.

There are four key IDPM planning relationships. As changes occur while designing the plan, these relationships can be updated in any manner convenient for the project teams. The four relationships include:

1. Product structure
2. Functions
3. Inputs and outputs
4. Resources

The process step functional relationships are a mapping of the inputs, outputs, controls, and resource relationships between process steps. Resource constraints form Critical Chains. Information-driven project management develops a Critical Chain, rather than a Critical Path, as the primary focus of a project manager. Carried out after DSM analysis, the Critical Chain includes both information dependence logic and resource constraints. We must resolve the combined effects of information dependency and resource conflict within a project and across multiple projects. Information-driven project management establishes the Critical Chain after removing resource contentions, rather than before. As for DSM analysis, Critical Chain analysis focuses on the whole project to provide focus and clear decision criteria for the project manager. Information-driven project management matches resource constraints (people, tools, and facilities) to the information-dependent process step sequences established in Step 3. We must manage our reserve of resources. Conflicts in resource usage could modify opportunities for concurrent project steps identified using DSMs.

Step 4: Assess Plan Quality

Now, the three primary quality checks of the project plan can be conducted. They result from the relationships designed in Step 3. They include:

1. Outputs
2. Resource identification
3. Critical Chain multitasking

We will not address the quality of the project produced when your plan is implemented. Good plans can and do produce bad products. Is your list of output names from the process steps complete? This check can be best accomplished by looking at internal and external outputs, represented by the cell marks in the DSM. Some process steps may require external inputs or produce outputs both consumed internally and externally. Project phase deliverables required for exiting that phase could be the creation of a set of external outputs. By reviewing the external outputs' list, we would then satisfy this planning quality check.

Have all the project resources (people, tools, and facilities) and their scheduled durations been identified and reviewed? This quality check ensures that all of the resources (people,

tools, and facilities) are available when indicated by the plan. All members of the project team should be able to find their names, associated process steps, inputs and outputs, and durations. All must have situation visibility as to the impact of their activities on the completion of the project. Other resources such as tools and facilities needed by project team members whose project steps are on the Critical Chain of the project must be reserved.

Are any of the resources along the Critical Chain (people, tools, and facilities) multitasking? This quality check reviews the Critical Chain relationship. For the project team resources identified as on the Critical Chain, it is important to ensure they are not scheduled to do any other work during their own Critical Chain process steps. Otherwise, people would be multitasking within or across projects. That would result in lengthening the time of all of the project steps for which they are responsible, and project(s) would be completed later than planned. Multitasking is performing multiple project activities at the same time. Most people think of multitasking project activities as a good way to improve efficiency. It ensures that everyone is busy all of the time. Often, we have to wait for inputs or for someone to call back before we can get on with our work. Multitasking makes good use of this time. But focus on local efficiency could damage the overall performance of a project. If this is a Critical Chain process step, this practice directly extends the duration of the project. Information-driven project management seeks to eliminate this type of multitasking by eliciting 100 percent focus on the process step at hand by considering all resources that support the project. Thus, eliminating "fractional head counts" is a primary Critical Chain consideration in planning a project.

Step 5: Calculate Time and Costs

If the project is interested in making a profit for the business, then the project team could determine a project market price at which to sell the project. The project's profit is equal to the difference between the combined materials and resource usage costs and the price the customer pays for the project. The return-on-investment (ROI) calculation is equal to the profit divided by the investment (total project costs). In Step 1, an initial list of the time and cost goals of the project was collected. The duration and costs of the associated process step can now be calculated. All of the resources (people, tools, and facilities) required by the project, as listed in Step 2, and the durations required by these resources and their usages, as designed in Step 3, form the basis for these calculations. The input and output lists may include some external inputs as bought materials and some external outputs as products sold for a price. We calculate the project's duration by summing up the durations from all of the unbundled process steps along the Critical Chain. The project team resources working these process steps determine how long it takes your entire project team to handle its work. The Critical Chain relationship designed in Step 3 gives the capacity answer. Adding the duration estimates performs the duration calculation for the full project. As soon as a process step is completed, the Critical Chain resource has capacity to handle more work. The calculation of the project cost is simply project step durations multiplied by the cost of using each of the resources required (people, tools, and facilities), added to any cost of any purchased input materials. As a project executes, a graph of the cost as a function of time can be depicted.

Step 6: Practice IDPM

For decades, great athletic teams have harbored one simple secret only a few select business teams have discovered, and it is this: To play and win together, you must practice together. A project team has now completed only Steps 1 to 5 make up the IDPM thinking process. To successfully deploy IDPM, we must motivate all team members to want to apply and practice IDPM as often as possible. So IDPM Step 6 is practice. Before project teams apply IDPM generally to their projects, they must practice together. As experience is gained, the time and cost that are associated with IDPM use diminishes significantly. This occurs for a competitive

champion sports team. Practicing and using IDPM often enough should enable everyone to think through effective plans more intuitively.

ARTICLE 3.4.5
ACHIEVING ISO 9000 CERTIFICATION

Graham K. Hill
Tomlin, Inc., Falmouth, Massachusetts

We look at a high-gain, high-speed approach that builds on client relationship, business planning, process analysis, and the acquisition of best practices in project management. For most firms, the step to ISO 9000 registration can be much smaller than they may realize. If the concepts of good business practice as laid out elsewhere in this book (strong relationship with customers, plans for growth, process analysis, continuous improvement, and the best practices in project management and design control) are already in place, then each firm has the necessary ingredients for simple ISO 9000 achievement. The myths of 2-year long ISO 9000 programs at M$1 of cost can be shattered.

This article will explain how existing pieces of a business can simply be brought together for ISO 9000 registration with reduced cost and documentation, and within an accelerated timeline. This approach has already successfully provided for engineering and design consultant firms[1]

- Eighty percent less documentation
- Thirty-five percent less resource demand (cost)
- Six months or less to full compliance (for a practice with up to 250 employees)

We will also show how to easily translate a manufacturing-based standard into a design and construction service firm environment. It will also show how ISO 9000 can directly benefit bottom-line performance, ensure project schedule and budget attainment, raise customer satisfaction, and stimulate growth for the business. The approach is based upon an electronic, paperless system easily compiled into an intranet environment through the use of standard Microsoft® tools.

This article is written for management considering or already committed to ISO 9000 implementation. It does not discuss the justification or merits of ISO 9000 for a design firm nor describe what ISO 9000 is. Resources to guide a firm and provide specialist assistance are listed in the appendix. *Note:* We will focus on successful management of an ISO 9000 implementation project. As such, it will not go into detailed explanation of the content of ISO 9000

and its separate elements, nor touch on the history and justification for ISO 9000. The reader may find numerous alternate reference articles and books on these subjects.

BACKGROUND

Engineering design and consultant firms have demanded a greatly simplified approach to ISO 9000 that acknowledge both their inherent history of good practices and the elevated educational and professional standing of their employees.

Manufacturing industry experiences with ISO 9000, born out of defense standards, regulated industry requirements (nuclear and drug), and a working environment of repetitive and highly prescriptive tasks have little place in a creative, project-centered business such as design and construction. The attempt to directly transfer those experiences into design and construction has justifiably created great skepticism and resistance within the design community. The history of bureaucracy, paperwork, and procedural overload associated with the defense, nuclear, and drug environments is equally out of place within a dynamic engineering practice.

What is repeatedly requested is an approach that:

- Fits the business, naturally
- Acknowledges the skills of personnel readily
- Uses the language of the industry
- Merges with (not replaces) existing processes
- Is attainable with an efficient use of time

CASE STUDY—HOW CAN IMPLEMENTATION BE SIMPLIFIED?

The following example is based on an engineering design firm with five regional offices and approximately 250 employees. They served primarily industrial and commercial clients. Although the company had practiced quality improvement, there was no previous experience with ISO 9000.

Many myths and fallacies around ISO 9000 taken from implementation in manufacturing industries had conspired to make management in the firm believe that ISO 9000 in design firms is unnecessarily difficult. The first step was to discard those ideas and begin afresh. Let's look at the challenges and questions posed by management.

Myth 1: Do We Have to Document Everything?

The standard requires that procedures be written ". . . where their absence would adversely affect quality . . ." Within regulated manufacturing industries, the quality experts insisted on writing each and every instruction. Paralysis by paperwork.

Solution. With personnel extensively trained in professional techniques, given guidance in project management, and expected to routinely exercise judgment and creativity, there existed a simple need just for compact guidance procedures: documents that indicate major steps—not detailed tasks. Samples and boilerplates from prior projects provided a simple library of good practices and eliminated the need for detailed work instructions. Preparing documents that recognize these factors reduced by 50 percent the level of documentation needed.

Myth 2: Does Implementation Have to Take 15 to 24 Months?

Implementation has traditionally been taken as an opportunity for a firm to discover their business processes, rewrite their operating procedures, and seek improvements and best practices as they go. The debate and wrestling with ISO 9001 interpretation and language extends project duration as personnel, in ignorance, pitch for a safe position of the highest expectations. The habits and practices that are commonplace in a firm are often assumed to be invalid for ISO 900 needs. Only cash-rich firms can afford this cost-loaded approach.

Solution. Well-led, focused, high-energy compact teams, using simple proven templates that fit their industry and working on high-level management procedures, completed all of the charts and supporting procedures and forms within 3 to 5 months. Some other firms have achieved ISO 9001 compliance within 4 months.

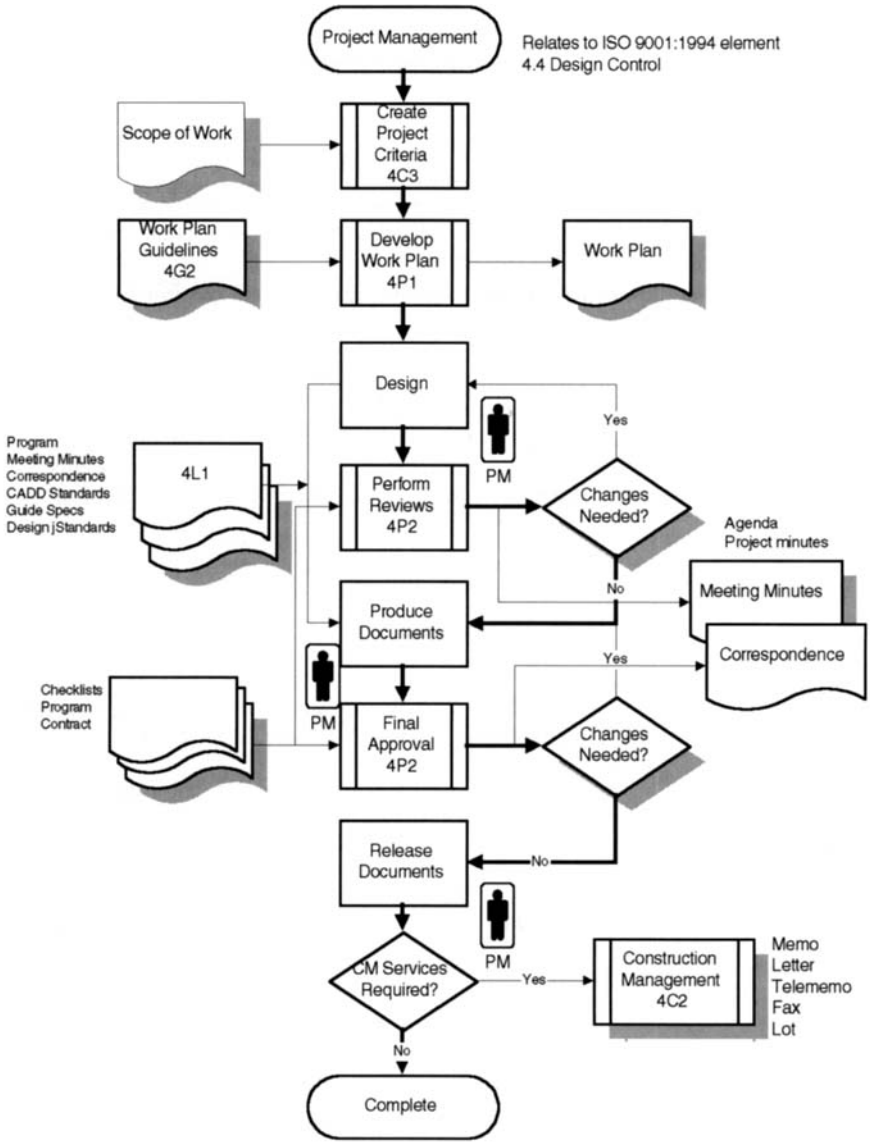
Myth 3: Must Documents Be Written in Governmental, Textual Style?

Examples often contain highly structured formats—Policy, Purpose, Responsibilities, Reference documents, and the like. Engineers, in particular, and the majority of the working population prefer to use diagrams, sketches, graphics, or maps to express ideas. They abhor the use of long, text-based procedures.

Solution. The use of charts to express ideas greatly simplified information communication and the amount of paperwork required. Charts were found to rapidly communicate each of the major process steps. Ideal charts were based on the business process and ignored any departmental or territorial ownership. As such, they clearly showed how different parts of the business link together. Charts were set at high level for management of the business. Graphics and clip art reduced the need for text definitions. They also aided orientation and training of personnel.

Charts, like those shown later, will meet the criteria of acceptable ISO 9001 procedures and can save over 40 percent in the actual use of paperwork. Figure 3.4.5-1 shows a sample success chart.

Myth 4: Does the Approach Require Many Teams and Resources?



Traditional implementation projects have allocated 20 separate teams—one for each element of ISO 9001, plus teams for ancillary activities. Is this necessary and expensive high demand on resources?

Solution. A resource-efficient approach was to create just a few, compact teams that reflect how the firm actually does business. It was not necessary to rigorously adhere to the ISO 9000 sequence of 20 elements. The firm chose to rearrange those elements to fit their current practices and habits. The release of first-draft procedures from each team, for immediate use by employees, accelerated acceptance for use within the firm.

Teams were formed around natural business groupings of the firm—not around the 20 ISO 9000 elements. Each process team was resourced by:

- *Process owner.* This was the team leader. The firm's best mentor for that topic and with ideal qualities in motivating and developing personnel. The process owner was responsible for best practices in a key business area for the firm.
- *Team members.* Personnel with *direct* content knowledge on that topic. Personnel with indirect knowledge attended team sessions as ad hoc members.

As with any significant company project, management formed part of the leadership group. See the project structure that follows. *Note:* ISO 9001 elements 4.9 Process Control, 4.10

FIGURE 3.4.5-1 Sample Success Chart® of an approved ISO 9001 procedure (shown 75 percent of full size).

Inspection & Test, 4.11 Measurement & Test Equipment (Calibration), and 4.12 Inspection & Test Status do not directly apply to an engineering design firm. These can be omitted from the action items in an ISO 9001 project.

Team 1: Management. 4.1 Management Responsibility; 4.2 Quality System; 4.14 Corrective & Preventive Action; 4.17 Internal Quality Audits; 4.19 Statistics

Team 2: Design Project Control. 4.3 Contract Review; 4.4 Design Control (Design Project Management); 4.8 Product ID & Traceability (Project Numbers); 4.13 Nonconforming Product (Design Reviews); 4.15 Storage, Labeling, Handling, & Delivery (Drawing, Document Storage, & Delivery)

Team 3: Documentation / Administration. 4.5 Document & Data Control; 4.16 Quality Records (Archiving)

Team 4: Purchasing. 4.6 Purchasing; 4.7 Customer Supplied Product

Team 5: Training. 4.18 Training

It was recommended that internal projects be organized and established in the same way as any client project: scope, criteria defined, Project Manager, teams, budgets, timelines and review, and reporting mechanisms. The project organization structure is shown in Fig. 3.4.5-2.

Myth 5: What Do We Do? Won't This Be Complicated?

Stories indicate a need for external help, major efforts, and complicated tasks, each disrupting the normal flow of work.

Solution. An ISO 9000 project is very similar to a design project. Clarify scope and elements, gather the best talent in teams, produce documents, have these reviewed and then released for implementation.

Experiences with continuous improvement and process analysis described in this book fitted perfectly with the desired approach to implementation. The four primary steps—plan, do,

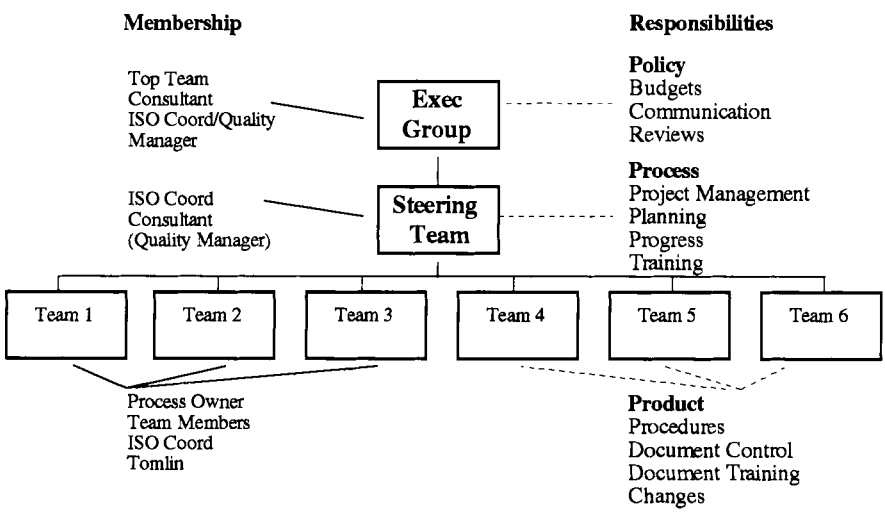

FIGURE 3.4.5-2 Project organization structure chart.

check, act—applied equally well for this firm. Figure 3.4.5-3 shows what a typical implementation project road map can look like.

Myth 6: Won't This Take a Long Time?

Early attempts at understanding and implementing ISO 9000 climbed up a long and slow learning curve. This no longer applies. Well-structured solutions exist for rapid deployment of solutions.

Solution. Management set aggressive expectations for the project and for their employees. Particular attention was given to the creation of high-energy teams and focused workshops. Teams met monthly for not more than 2 hours and were led by an external facilitator. Deliverables were clearly set for each team. Meeting 1: core processes; meeting 2: inputs and outputs; meeting 3: supporting forms and training of employees, release for use. Six hours of team meetings for standard components. Eight to ten hours for complex components.

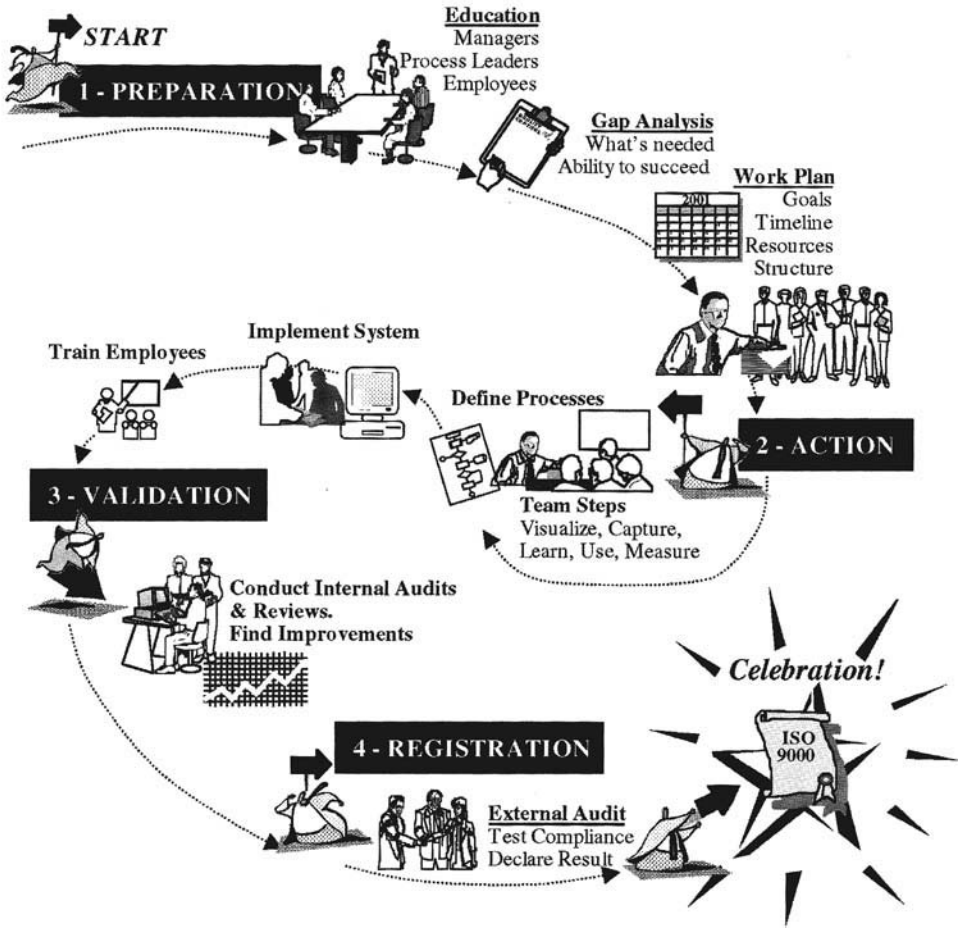

FIGURE 3.4.5-3 Typical implementation project road map.

The timeline ensured rapid orientation and training to the teams during the preparation phase. Go from kickoff to action fast. Each team was scheduled over the next 3 to 4 months for meetings and assignments, and deliverables were locked to dates. Testing effectiveness through audits included opportunities for improvement and fine-tuning. Registrar dates were locked in. Final preparation allowed for history and correction if needed. Figure 3.4.5-4 shows pages 1 (Fig. 3.4.5-4*a*) and 2 (Fig. 3.4.5-4*b*) of the actual timeline plan for the company.

Myth 7: What Are the Key Steps or Actions Once We Decide to Proceed?

Many firms gain an insight into the benefits of ISO 900 or even decide to proceed, but they are not sure what the first or significant steps should be.

Solution. First things first. The firm had reached consensus among the top management team for ISO 9000. Clarification of scope; setting project criteria; and discussing options, timelines, and budgets followed. The steps included the following preparation decisions:

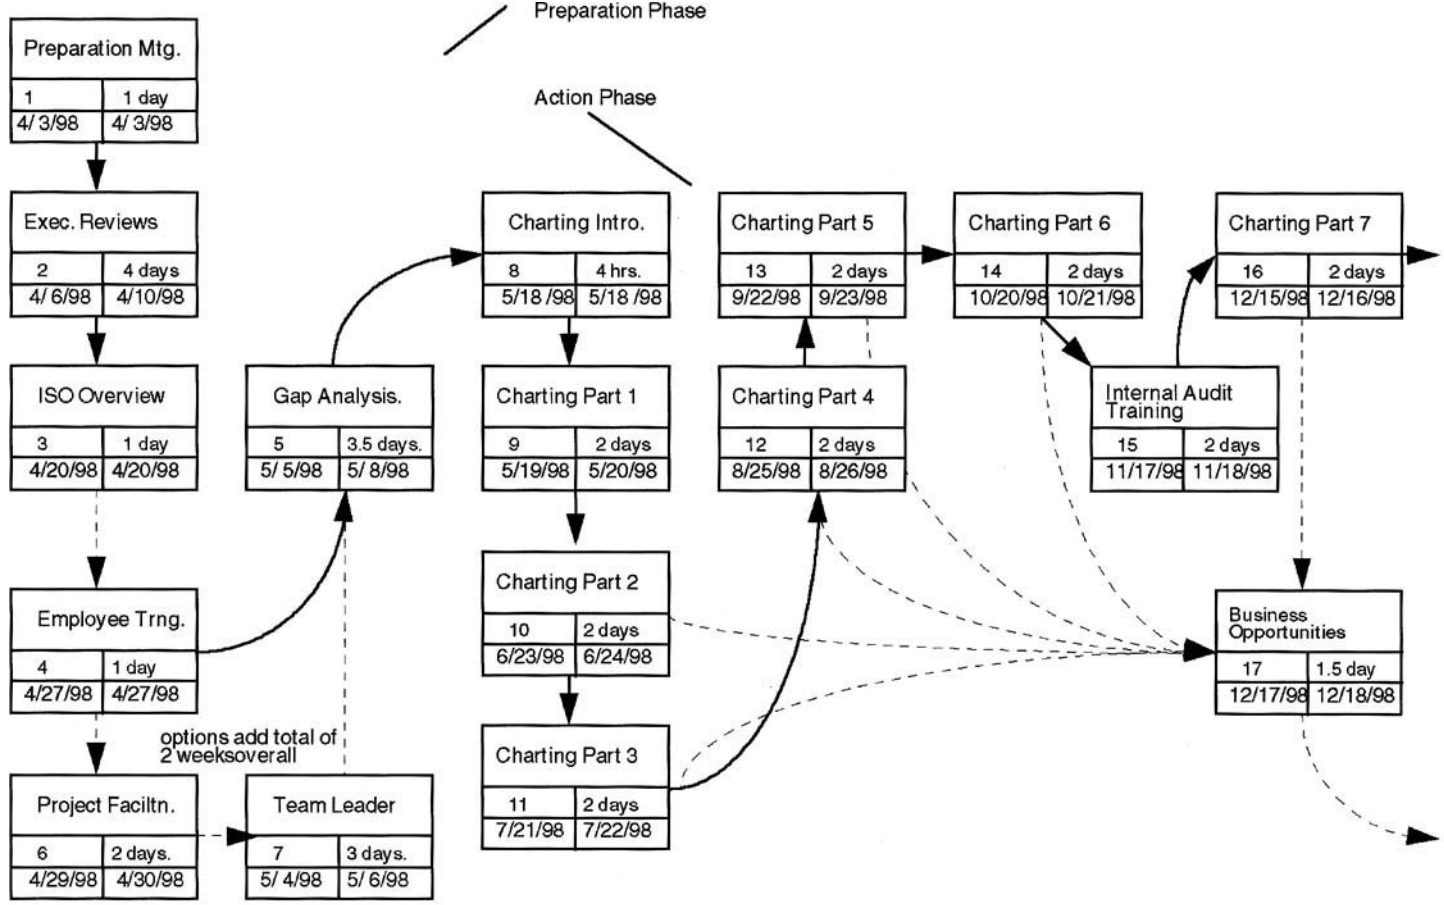
1. Choosing the appropriate ISO 9000 Standard that fits the business
The proper designation for ISO 9000 is the *ISO 9000 Series.* The family of standards includes:

- *ISO 9000.* The guidelines to help select the appropriate standard
- *ISO 9001.* The standard applicable to design firms
- *ISO 9002.* The standard applicable to manufacturing companies
- *ISO 9003.* The standard applicable to inspection-only firms (e.g., distributors)
- *ISO 9004.* The guidelines for best practice in the application of the standard

As will be seen from this, any engineering design firm will make use of the ISO 9001 Standard. For the rest of this article, ISO 9001 will be used.

There are other associated standards to the ISO 9000 series regarding quality manuals, audits, calibration, and so on that are not needed for this article. These are not discussed.

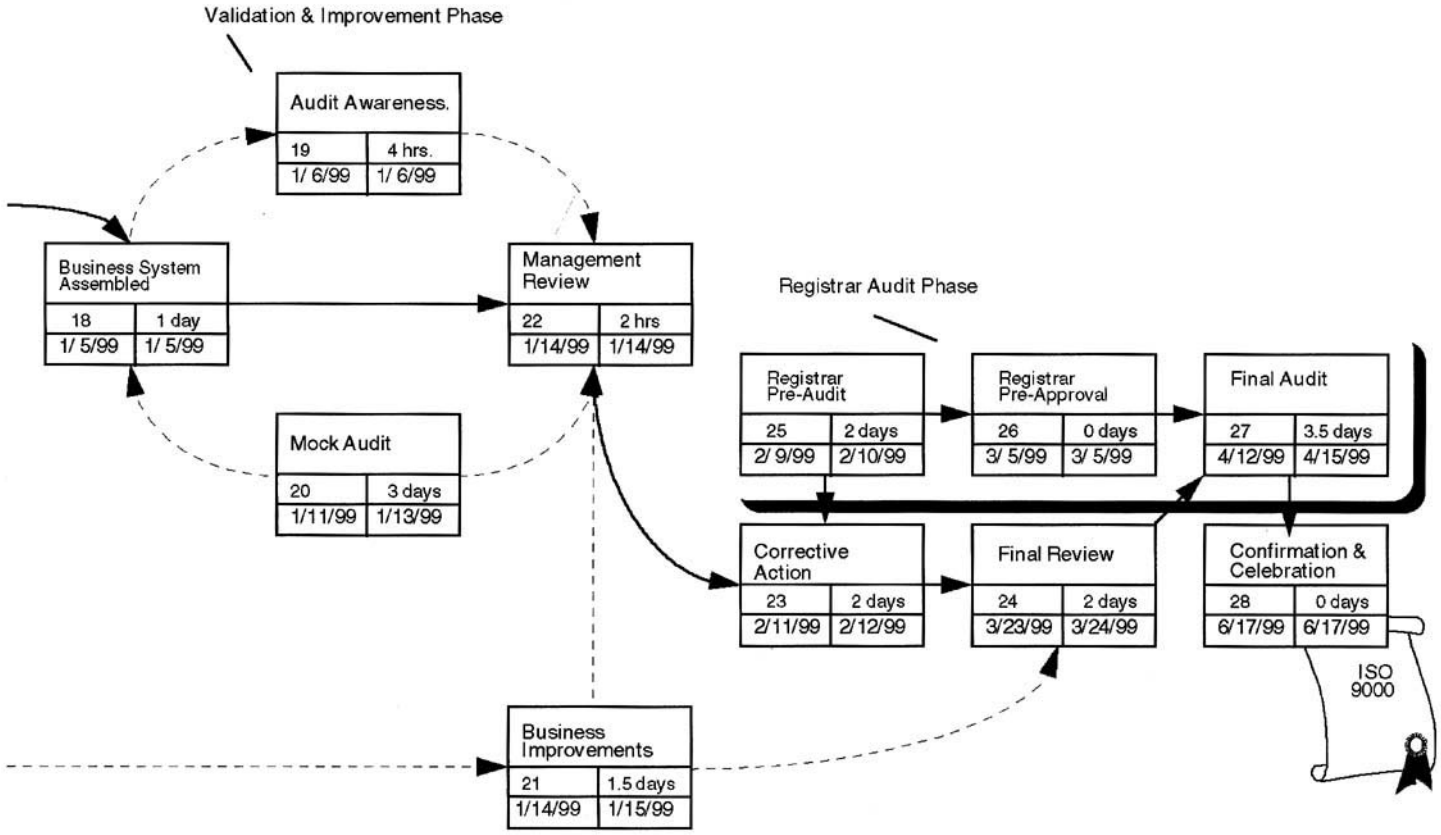
2. Define scope of coverage
ISO 9001 requires that project-based operations or processes *directly* affecting client deliverables be covered. That is, those activities covered by a contract with a client and payable as direct fee or expense work, are to be included.



Indirect activities not covered in a contract with a client are excused from ISO 9001 coverage. These may include such activities as management accounting, personnel recruitment, pay and benefits, general marketing and promotions activities (not project-specific), some general administrative activities, and some management activities. A considerable amount of unnecessary procedural work can be saved through this segmentation.

A first question for an engineering design firm is to clearly define the nature of the work performed by the business. This will determine the full scope of interface with ISO 9001: Will this be a total or partial overlap? Two assumptions are made here:

1. The firm performs purely a design and/or construction contract administration service (construction is actually performed by a contractor to the owner).
2. The firm performs a design/build service.



In situation 1, by focusing just on design as their core business, the firm has only partial overlap with all 20 of the required elements in ISO 9001. As a consequence, four elements of ISO 9001 (4.10 Process Control, 4.11 Measurement & Test Equipment, 4.12 Inspection & Test Status, and 4.13 Nonconforming Product) do not apply and need not be described in detail. A saving of approximately 20 percent on the extent of paperwork or procedures needed for compliance.

This scenario will apply to the majority of engineering design practices. The role of a firm in administering a construction contract on behalf of an owner places the direct responsibility

(a)

FIGURE 3.4.5-4 Timeline plan for the company. (*a*) Page 1 of the plan.

(b)

FIGURE 3.4.5-4 Timeline plan for the company. (*b*) Page 2 of the plan.

for construction with that owner—not with the firm. The design firm acts merely as an administrative interface. As such, the firm falls outside of the ISO 9001 requirements for documentation on construction.

In situation 2, if the firm has direct responsibility for design and uses a direct subcontract process to perform the build operation, then the subcontractors will be given the responsibility, by contract, to validate quality. As such, the role of subcontractors is regulated under element 4.6 Purchasing and does not require additional quality control procedures. However, if the firm employs their own direct labor and equipment to perform the build stage, then all 20 elements of ISO 9001 will apply. This firm will need to cover all aspects of ISO 9001 in their procedures.

3. Confirm number of business locations

A firm with a single-site location for its offices will apply ISO 9001 to their direct project activities.

A firm with operations at separate locations has basically two options:

1. Engage in one implementation project involving all locations simultaneously.
2. Have each location implement ISO 9001 independently.

Where a firm presents to its clients a unified position and shares project work among locations, the decision should be to engage in one implementation project across all locations—one firm, one ISO 9001 certificate. The advantage of a unified approach is consistency in practices and lower costs through integrated and shared implementation activities. The potential risk is in ensuring uniformity in pace and quality. Failure at a single location to pass the ISO 9001 certification audit can mean a delay for all locations.

Where a firm offers distinctly separate services at each location, operating autonomously, a decision may be made to engage in independent implementation projects—separate firms, separate ISO 9001 certificates. The advantage of an independent approach is the ability to respond to market needs in a planned and staged way and to customize the certification location by location to match different customer and business focus. Each certification will stand for itself. The potential downside is the cost of certification paid for each separate location ($10,000 to $20,000 each time) and the inability (a regulated restriction) of other locations to claim certification through a sister location. Likewise, the corporation cannot claim total coverage on ISO 9001 until each and every location has its ISO 9001 certificate.

Historically, it was possible for firms to segment out separate portions of their business and thereby gain ISO 9001 more easily and quickly by working on just a portion of their business. This is now frowned on by ISO 9001 regulators and not advised.

4. A/E/C operation and the fit with ISO 9001

Many firms follow the ISO 9001 20-element sequence when writing their quality manual. This is not required. It would be better that the ISO 9001 elements be rearranged to reflect the normal way of doing business. No firm need be "bent out of shape" to suit this external standard.

The different elements (or requirements) of ISO 9001 and their fit with a design practice may be shown through the following diagrams.

THE BASIC WORK PROCESSES (See Fig. 3.4.5-5.)

The events include the following:

1. Contract stage (proposal and contract setting)
2. Project control (design) activity
3. Transmittal of contract documents (drawings)
4. Construction administration (C/A)

At each stage, A/E/C activities will be indicated first, followed by the relevant ISO 9001 requirement.

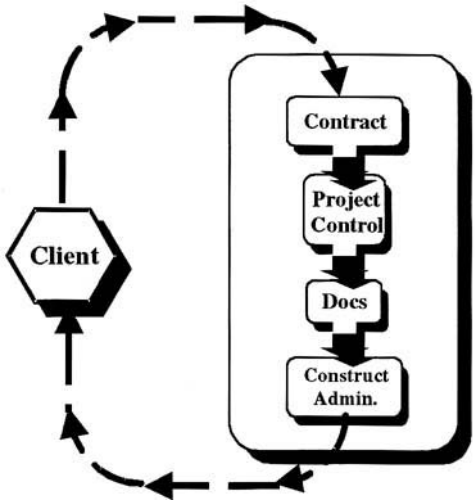


FIGURE 3.4.5-5 Basic work process.

To comply with ISO 9001, each of these requirements *must* be addressed.

Typically, an initial survey of readiness (gap analysis audit) of a firm shows that good activities are performed but often poorly documented.

As you proceed, you may wish to perform a mental assessment of the extent to which your firm already has these requirements in place—and as a result make an early and broad estimate about how much work may be involved in achieving ISO 9001 compliance.

THE 20 ELEMENTS OF ISO 9001

4.1 Management Responsibility
4.2 Quality System
4.3 Contract Review
4.4 Design Control
4.5 Document and Data Control
4.6 Purchasing
4.7 Customer-Supplied Product
4.8 Product ID and Traceability
4.9 Process Control
4.10 Inspection and Testing
4.11 Control of Inspection, Measuring, and Test Equipment
4.12 Inspection and Test Status
4.13 Control of Nonconforming Product
4.14 Corrective and Preventive Action
4.15 Handling, Storage, Packaging, Preservation, and Delivery
4.16 Control of Quality Records
4.17 Internal Quality Audits
4.18 Training
4.19 Servicing
4.20 Statistical Techniques

Note: For an A/E/C firm, five elements can be excused from full documentation (a reduction of 20 percent). The elements 4.9, 4.10, 4.12, and 4.13 apply to manufacturing. These can be "folded into" element 4.4 Design Control. Element 4.19 often does not apply and can equally be excused from full documentation.

STAGE 1: BASIC BUSINESS MODEL (See Fig. 3.4.5-6.)

A/E/C descriptors are shown in **bold upright font.**

The ISO 9001–associated elements are shown in *italic regular font.*

Each of these needs to be defined in documents (procedures) available to all personnel.

Documents can be in the form of traditional text-based procedures, flow charts, drawings, forms, videotapes, or any combination of the above.

Any media can be used to capture and document the designated process.

Simplification of these procedures, both in terms of content and structure, will greatly reduce complexity for implementation, training, and maintenance.

STAGE 2: ADMINISTRATIVE PROCEDURES AND SUBCONTRACTING ADDED (See Fig. 3.4.5-7.)

Clear descriptions are needed of the firm's policies and procedures for:

- Guiding work
- Providing training to employees
- Archiving project records

Additionally, subcontractor quality and how the purchases of materials or goods are handled needs to be described.

There is also a need to show how owner-supplied information (data, prior drawings, etc.) is protected and made secure while in the firm's care.

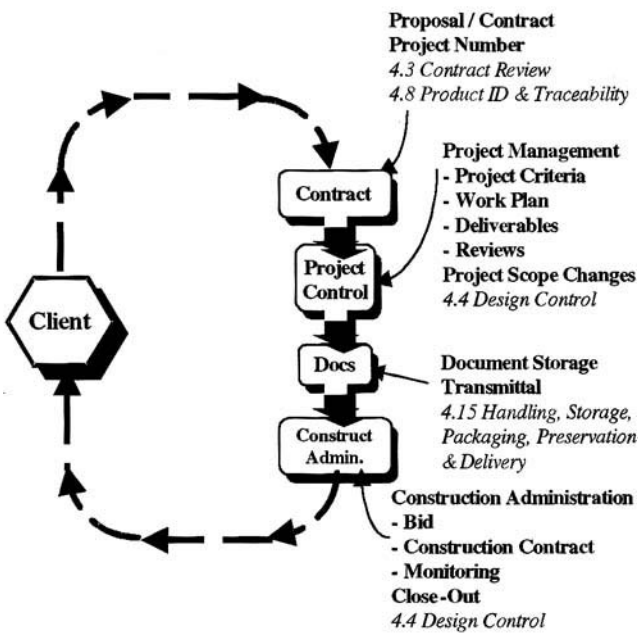

FIGURE 3.4.5-6 Basic business model.

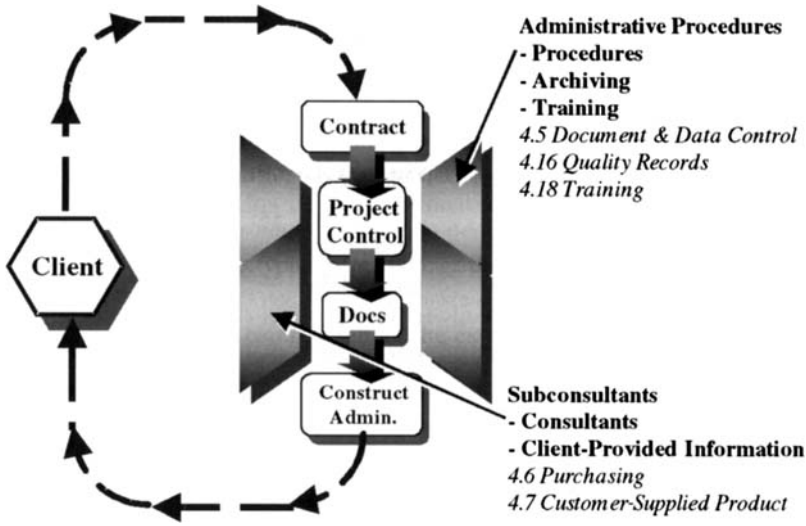

FIGURE 3.4.5-7 Administration and contractors.

STAGE 3: ADDING THE MANAGEMENT COMPONENTS (See Fig. 3.4.5-8.)

A clear organizational structure, stated company policies with objectives and plans, and someone responsible for quality need to be defined.

The management team should perform routine reviews of the business to test its effectiveness.

Additionally, management should have established measures for the key components of the business and for customer satisfaction.

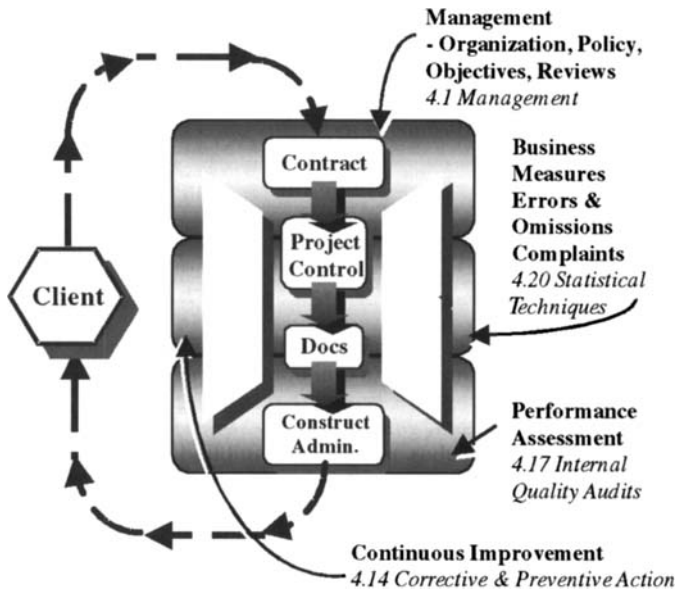

FIGURE 3.4.5-8 Management components.

To collect data for these reviews, there should be planned internal audits of effectiveness.

Finally, a formal process to identify and take action on problems and opportunities for improvement should be in place.

This corrective action and improvement process should be accessible to employees and include subcontractor performance and customer complaints.

ISO 9001 FOR ARCHITECTURE AND DESIGN FIRMS: AN EXPLANATORY SYNOPSIS

What or Who Is ISO?

ISO comes from a Greek word that means *equal*—as in *iso*sceles triangle, *iso*bars, and so on. The word *ISO,* when linked to ISO 9000, is used to signify equal acceptance of standards around the world—the creation of a level playing field.

The organization that publishes these International standards is known as the *Organization for International Standards,* or OIS, a confusing similarity.

The OIS is made up of representatives from each member country (currently over 130 member countries) who attempt to eliminate national quirks in the application of standards by harmonizing understanding and use in a large number of areas, such as safety, measurement, materials, food, testing, and quality. The OIS is a kind of United Nations forum of quality and technical experts from each country. The aim is to permit freer, more cost-effective trade among nations and companies by avoiding disputes of interpretation on technical grounds—an attempt to work at the logical level and avoid the political.

Each member country agrees to apply and uphold the standards it has approved at this international forum—both for their international trade and within their country. The United States has a strong voice within this group and is a principal sponsor (author) of many standards.

Standards are designated identification numbers in the same way that ASME, ASPF, ASTM, BOCA, CABO, or ASHRAE will designate numbers to their codes or standards.

ISO 9000 is the identifier for a series of standards related to quality systems and quality assurance. There are many other standards published by OIS under the ISO designation with different numbers. Many of these have nothing directly to do with quality.

Why was the ISO 9000 Series written? The standards were written because too many businesses did not sufficiently care about *how* they were working. Customers were unhappy about quality and needed a benchmark standard upon which to demand reliability and improvement in service. Hence, the ISO 9000 standard.

Customers also wanted a standard that placed the responsibility for quality directly with the supplier, eliminating the costly need for the customer to check (or recheck) supplied work.

A principal goal of ISO 9000 is to regulate the contractual relationship between the customer and the supplier regarding quality of service. This provides the customer with a process to select or reject potential suppliers based not just upon their technical and professional expertise, but also particularly upon their ability to deliver superb quality.

This results in a standard that requires management to consciously design business systems in a way such that quality, reliability, consistency, and improvement are natural parts of the business, a process that provides assurance around proactive management techniques—not reactive ones. ISO 9000 is about *how* the business is planned and run—not just *what* it does. This condition provides customers with greater confidence in their selection of a particular supplier.

The ISO 9000 standard covers a wide range of business activities affecting the customer relationship—not just the production of the service, and not just quality. The ISO 9000 standard covers the goals, plans, organization, operational performance, administration, employee training, measurement, and corrective and improvement processes of the business.

What Does ISO 9000 Require?

Customers (through the authors of ISO 9000) defined their expectations of a good supplier as being the company or firm where the following requirements are vigorously practiced.

Management. Objectives, goals, and approaches to quality within the business are clearly expressed. Responsibilities are clear. Company plans are clearly understood at all levels within the firm and are effectively implemented, well tracked, reported, and reviewed. Plans are aligned with customer needs. There is a common structured process for fixing problems and making improvements. The company relies on factual, objective data and trends regarding its business.

Operations. Best practices and expectations are clearly defined for all personnel—across the complete customer relationship cycle. These include initial contact, proposal, contract stage, project/scope definitions, project control, project reviews and release, delivery, project closeout, support, performance evaluation, customer satisfaction, and so on.

Administration. Support structures for administrative processes are equally well designed. These cover document and data management, purchasing, archiving/records, and the training/professional development of employees

What Is the Relevance to A&E Design Firms?

The External Pressures. Industrial customers have developed a strong history of quality. They have learned how to run their own businesses more effectively and what to expect from other businesses that work with them. Their visions of mutual and peer-based relationships have made them highly selective about whom they chose to work and grow with.

Industry has increasing demands about what constitutes good service, based upon their own experience and ability to change the norms of performance.

They want to work and grow only with others who share the same values for constantly learning and being the best. They were the leading edge in ISO 9000 application. They do not want to partner with those closed to the notion of change or improvement. They do not want to partner with those that say ISO 9000 or quality is only a manufacturing issue.

Industrial companies see that now is the time to move their expectations to second-level suppliers: the professional service firms.

State authorities have also seen the benefit of demanding ISO 9000–style performance from supplier firms when it comes to managing tax dollars. Pennsylvania DOT (PennDOT), Maryland DOT, New Jersey DOT, New York DOT, California DOT, and Massachusetts DOT are among those demanding or giving notice of ISO 9000 requirements from their design consultants.

Government departments, such as GSA Building Division, use ISO 9000 themselves and expect similar performance from their design consultants.

Global activity now makes ISO 9000 a minimum requirement for RFP's in Europe, Australia, and the Southeast Asian communities. Canada, Mexico, and other Latin American countries are also leaders in ISO 9000 application for design consultants. The United States lags many of these nations in the use of ISO 9000.

Commercial marketplace customers are becoming savvier about quality and the specific benefits of ISO 9000, but lag behind the industrial marketplace. Few individual commercial clients have embraced ISO 9000 as a model. Their time will come.

Health, education, and local government groups have not, as of yet, adopted ISO 9000 as an operational need—primarily from a lack of resources, rather than a lack of knowledge or desire.

Because of the risk of being accused of trade restriction, no customer will actually *mandate* ISO 9000 as a requirement for continued business. Most requests from customers are expressed as a preference for the supplier to have a quality program or to be ISO 9000–registered. The lack of a clear mandate can be misunderstood as the lack of customer need or interest. However stated, the implication is still there—listen to your customers' needs.

Benefits. As a strategic goal, the design consultant firm should decide if it wishes to anticipate and support customer requests regarding quality and be among the leading group. Or the design consultant firm can resist until actual client losses and competitor gains become all too clear.

The implementation of ISO 9000 *may* gain a firm some new clients or market activity. However, the lack of ISO 9000 or a strong quality program will eventually lead to the loss of clients and contracts. In this context, ISO 9000 is similar to the implementation of CADD or EDI technologies during the late 1980s and early 1990s.

Liability insurance organizations provide discounts to professional design consulting firms registered to ISO 9000. Some design consultant membership organizations provide funds directly to firms to aid ISO 9000 registration.

The Internal Pressures. Many design consultant firms face a dilemma. Customers demand higher quality, higher functionality, and faster production and lower cost (fees). They also expect higher levels of service, innovation, and special treatment.

- When it comes to managing their assets, the customer demands discipline, control, and faultless delivery—*no surprises, please!*
- When it comes to solutions, they want imagination, creativity, and verve—*surprise me, please!*

A design consultant firm sells time combined with a unique professional skill. Therefore, the effective use of time and the application of that skill determine success or failure, profit or loss. Anything that robs a project of time or the wise use of skill diminishes the chance to succeed.

Benefits. ISO 9000 can manage the allocation of time and skill in a planned, structured approach during production and operations. This is how time and budgets are maintained, and it is how efficiency is achieved.

ISO 9000 can deliver significant improvements in the use of time and how work is managed (productivity) through significant changes in habits. This is how effectiveness is achieved.

ISO 9000 does not hamper creativity. It can help to reduce wasteful time. Improvements in the management of time can mean less time on production and more time for creativity.

Systematic methods implemented through ISO 9000 can be used to create larger margins in the cost/profit profile. Consistency and speed are among the keys, plus a "right first time" mentality (accuracy). This is project management par excellence.

Scope drift is an enemy to the design consulting firm. ISO 9000 processes can be used to clarify, define, and control client demands. Nurturing the client includes proactively managing scope definition. ISO 9000 can reduce scope drift through poor management of the client at the start of the project and poor control during project design phases. This is customer service par excellence.

ISO 9000 methods ensure that all employees work from a common model of efficiency and effectiveness in project management. New employees are brought "on stream" more quickly.

Overall benefits to ISO 9000 include the following:

To Marketing

Customer relations improved

Clearer agreements about expectations (fewer changes?)

Increased reliability (in budget, on time)

Recognition (firm "benchmarked")

To Operations

Commonly understood best practices

Focus on project management effectiveness

Reduction in project design rework

Enlarged resource capacity (throughput)
Data based management
Less variability in techniques
Reduced project overruns (time and cost)

ISO 9000 is about

Developing "best practices" in the business
Leadership and energy
Simplicity and guidance
Quality management by everyone
Staying with what you do best
Improving the business
Shaping ISO 9000 to suit your business

ISO 9000 is not about

Controlling innovation or creativity
Abandoning individuality
Regimentation or repetitiveness
Paperwork, paperwork, paperwork
Quality engineering
Changing the business to suit ISO 9000

SECTION 3.5
CLOSURE

Kristin Hill, Cindy Aiguier, John Morganti, and Bonnie Seaberg
International Facility Management Association (IFMA), Boston, Massachusetts

Norman E. Faucher
Association for Facilities Engineering (AFE), Boston, Massachusetts

Is there closure for a facility's life cycle? At any time, it may appear as though the facility's life cycle is ended. But the truth may be that it is beginning another phase of the cycle. The life cycle is a continuum. Even upon demolition of a facility, the land is likely to be reused. Possibly a new facility will be built that meets the needs of another plan. The facility's life cycle, like that of the facility manager's role, is continual and evolutionary. Facility management is the art and science of reinventing facility management as changes take place in business, technology, and processes to achieve the original goals.

It is important along the way to take time to assess the process that the facility has been through. The relationships of those involved from the initial plan through the cycle of management should be evaluated. Question whether the process supported the progress. Has a particular project improved the facility so that the company is better positioned for the future?

A facility and its management team will constantly be presented with new opportunities by the constantly changing business environment. These opportunities may include new tools, technologies, or methods of conducting business. The key is for the initial facility to be adaptable to meet these opportunities. The importance of planning for the future and not to catch up with the past is ever present. The initial goals must include the adaptability of the facility for the unknown future.

FACILITIES ENGINEERING

Paul R. Smith, P.M.P., P.E., M.B.A., Chapter Editor
Peak Leadership Group, Boston, Massachusetts

Mark Neitlich, M.B.A., Chapter Editor
Massachusetts Institute of Technology, Cambridge, Massachusetts

William L. Porter, Ph.D., F.A.I.A., Chapter Editor
Massachusetts Institute of Technology, Cambridge, Massachusetts

Anand K. Seth, P.E., C.E.M., Chapter Editor
Partners HealthCare System, Inc., Boston, Massachusetts

David L. Stymiest, P.E., SASHE, C.E.M., Chapter Editor
Smith Seckman Reid, Inc., New Orleans, Louisiana

Roger P. Wessel, P.E., Chapter Editor
RPW Technologies, Inc., West Newton, Massachusetts

The organization of this part was a source of numerous discussions. We wanted to provide a single repository for common information pertaining to the most traditional types of buildings and facilities. Thus, Part 2 of this handbook contains information pertaining to facilities engineering for most types of buildings, including commercial buildings. The unique added engineering features required for special types of buildings such as industrial or institutional buildings are addressed in Part 3. Thus, the facilities engineer for an industrial building should refer to Part 2 for normal engineering topics and to Part 3 for the unique issues of specific building types.

Part 2 introduces the planning and programming process in Chap. 4 as a natural precursor to the engineering and design process in Chap. 5. Chapter 6, following in the most common sequence for creating a facility, covers construction-related issues. Then, Chap. 7 addresses facility operations, maintenance, and assessments. Finally, Chap. 8 rounds out our treatment of facilities engineering issues of common building types with a discussion of codes and standards.

CHAPTER 4
PLANNING AND PROGRAMMING PROCESS

William L. Porter, Ph.D., F.A.I.A., Chapter Editor
Massachusetts Institute of Technology, Cambridge, Massachusetts

A good program may not guarantee a good building, but it is a very good head start. And it can spare the facility manager countless headaches later in the process. As Sims and Becker (the leading experts in the field and the authors of this chapter) point out, without programming "facilities opportunities are missed and the likelihood of mistakes or simply poor value for money is high." "Correcting mistakes, or simply making changes, becomes more expensive at each successive stage of facility development." Therefore, it is the programming phase that offers the least expensive opportunity for satisfying complex needs and for cost savings. Good programs have other extraordinary benefits that include detailed understanding of the requirements that the building must satisfy and the forging of consensus among those who will use the facility and among those whose decisions are critical to its realization. This chapter describes the processes that comprise programming. These include forming the project team, determining the kinds of data that must be collected, choosing methods of data collection and analysis, and developing specific requirements for proposed buildings. It also discusses how programming can contribute to the evaluation of existing buildings. This chapter does not suggest a formula for programming in every circumstance. Instead, it offers resources that are essential for inventing a programming process uniquely suited to each specific situation.

SECTION 4.1
WHAT IS PROGRAMMING?[1]

William Sims, Ph.D., C.F.M., IMFA Fellow, Professor, and Franklin D. Becker
Cornell University, Ithaca, New York

Programming is the front end of the planning/design process. William Peña,[2] recognized widely as the grandfather of architectural programming, defines *programming* as problem seeking and *design* as problem solving. Duerk[3] describes it as "the problem definition phase of the design

process. It is done by gathering and analyzing information about the context within which the design must be done and by stating the qualities that the project design must have to be successful." It is a process of collecting, analyzing, and organizing the information needed to guide the search for an architectural solution. In turn, it is useful for evaluating proposed solutions.

INTRODUCTION

Why Is It Important?

All organizations need to prepare a design program at some point. A renovation, a move to a new space, or construction of a new facility all require that the organization determine what it is trying to accomplish with the project before it seeks solutions. Unfortunately, many client organizations and their designers immediately jump to solutions based on assumptions, conventional wisdom, or fashion, be it hoteling, a new headquarters in a greenfield site, or an intelligent building. When this happens, facilities decisions are made in a way that no manager would ever envision when dealing with the other resources of the organization. When done in this way, facilities opportunities are missed and the likelihood of mistakes or simply poor value for money is high. The program focuses the design efforts on the important issues and makes the design process more effective, resourceful, and perhaps most important, accountable. It enables the designer and client to understand why certain issues were selected, the priorities and trade-offs among the project requirements, and the context and constraints within which the project must operate.

A facility program and the process used to produce it are critically important to the designer and the client/user organization of a building project. Buildings are incredibly complex things, and they must satisfy many diverse needs. The needs must be identified, organized, prioritized, and ratified by decision makers in order to design properly. Thus, to design a building responsibly requires analytical tools and the skills to use them—a programming process, a skilled programmer, and a creative designer.

The information required for decisions at various stages in the planning and design process varies in amount, type, and source. But inevitably the information is of an amount and complexity to require some form of systematic process to ensure that all of the relevant issues and needs are uncovered and evaluated and to develop and manage the information during the process. Similarly, a process is needed to ensure that decisions are made by the appropriate individuals and are based on objective and factual evidence to the fullest extent possible.

What Are the Benefits?

A programming process requires the participation of all stakeholders at the critical early stages of decision making when most of the resources are committed to a project and when most of the decisions that affect the cost and direction of the project are made. Most important, it is at this stage in the project that redesigning work processes or organizational structures should be done before the building is designed.

By providing objective information and priorities regarding the goals, constraints, and other factors influencing a project, a programming process can actually increase the designer's ability to solve the problem in a creative and cost-effective way. It ensures that the client's needs are addressed comprehensively, that important issues are not overlooked, and that the design does not become too focused on a few fashionable issues at the expense of others. Having a good program actually decreases the search time (and cost) involved in arriving at a solution by enabling the designer to focus on "problem solving" rather than "problem seeking."

Being able to correct mistakes early in the process is one of the benefits of good programming. Correcting mistakes, or simply making changes, becomes more expensive at each successive stage of facility development, and the ability to impact or reduce the total cost of the project is lessened. (See Fig. 4.1-1.)

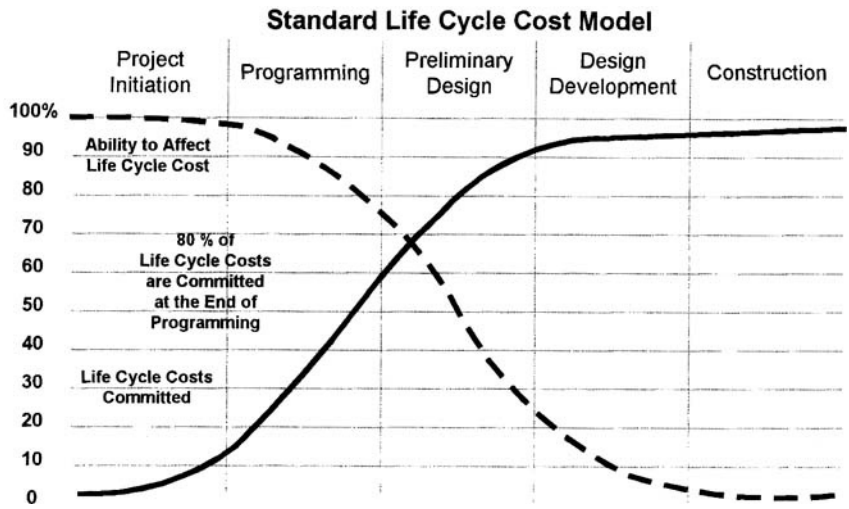

FIGURE 4.1-1 Impact on cost of decisions compared with expenditure of funds at different stages. (*Courtesy of William Sims and Frank Becker.*)

LEVELS OF PLANNING AND DESIGN

Decisions about building projects are made at a variety of levels. Each of these requires some form of problem identification and analysis or programming. Each addresses particular kinds of issues and requires different types of information. The decisions made in subsequent stages build on those of the previous. These levels include:

- Strategic planning
- Master planning
- Site selection and design
- Building design
- Interior design
- Postoccupancy evaluation (POE)

Strategic Planning

Programming can engage the fundamental strategies of the organization. Good programming goes beyond simply collecting information about the current area, equipment, and adjacency requirements. *It can also act as a powerful mechanism for organizational development.* It can frame a better understanding of the way the organization works and lead to insights for better organizing and carrying out its mission.

If employee involvement is included in this process, it can also lead to better understanding of organizational, and improvements in employee, goals and programs. By involving staff in meaningful ways, programming can go beyond generating accurate information toward strengthening staff commitment to the decisions and to the organization generally. These are issues that senior management understands and appreciates. Viewing the programming process as a form of organizational development shifts facility planning and design to concern for the ways in which planning and designing facilities can contribute to employee motivation and commitment, to clarifying and attaining corporate

goals and objectives, to rethinking roles and relationships, and to reformulating and clarifying strategy and tactics.

Master Planning

Master planning looks at the long-range needs of the organization. It is based on the current conditions and anticipated future needs. It should provide strategic direction about the moves, construction, and real estate activities of the organization. It provides a context for making coordinated decisions about building projects. It answers questions such as: How much and what types of space will we need in the future? What are our space requirements and our space availability over the next 5 years? Where should departments be located to maximize performance and minimize cost?

The master plan must take into account the strategic business objectives of the organization, real estate costs, markets, taxation, growth trends, regulatory environment, and so on. The time horizon and planning cycle should coincide with those of the business plan. The value of the master plan is not in its precision or accuracy in anticipating future needs, but rather it is in its ability to quickly model or assess alternative futures. "If we grow faster than anticipated, how will we handle it? Is it better to retain some of the additional space freed up after a consolidation or to sublease it?" (See Fig. 4.1-2.)

Site Selection and Design

Feasibility studies are used to evaluate options such as the suitability of a particular building or site for relocating a business unit. Does the zoning permit the proposed use? Is it large

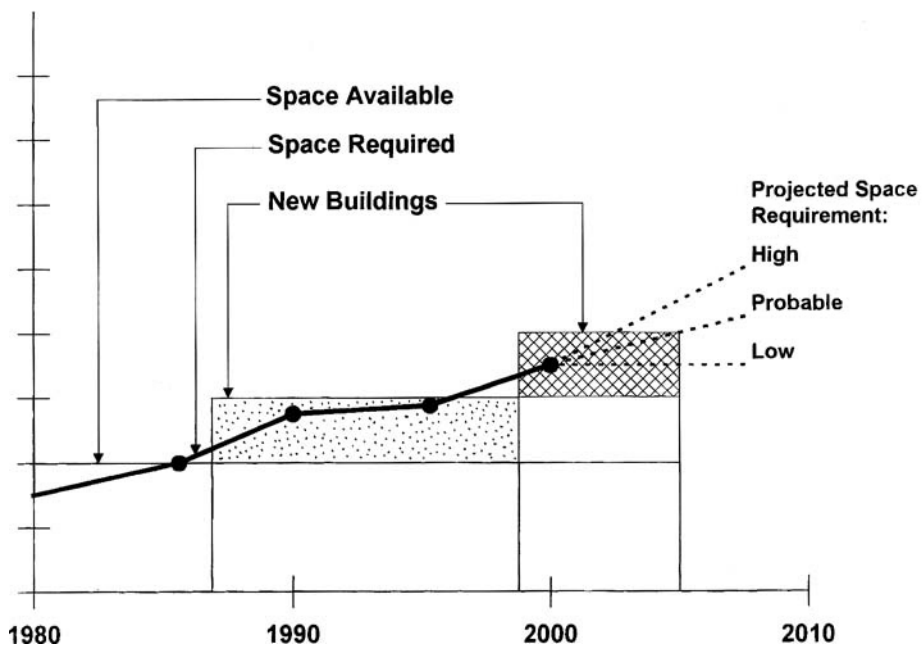

FIGURE 4.1-2 Space projection versus space availability. (*Courtesy of William Sims and Frank Becker.*)

enough? Will it permit future expansion? Will it lay out efficiently? Is accessibility adequate for employees, customers, suppliers, and so forth? (See Fig. 4.1-3.)

Building Design

Many organizations such as government agencies, hospitals, and universities are required to conduct a basic needs assessment study as a part of the initial justification for a project. This involves a careful analysis of needs. For example, a request for an additional building would require a utilization study of the existing facility coupled with projections of future use to document the need for additional space.

Architectural programs are required for renovations or new building projects. They define floor and building sizes; height requirements; structural, mechanical, and other shell, core, and service requirements. This program usually also includes the site requirements as well. Parking, landscaping, pedestrian and service circulation, lighting, security, and signing issues are among the items typically included. The key to architectural programming is identifying the clients' requirements in enough detail to ensure that their needs are understood while generalizing the fixed elements of the building so that it will be flexible enough to adjust to future needs of this client and to other occupants and uses. Buildings tend to last much longer than the initial occupant's requirements. Because buildings typically outlast their occupants, flexibility or adaptability to other occupants and uses should be considered not only as a programmatic requirement, but also as adding to the building's future economic value.

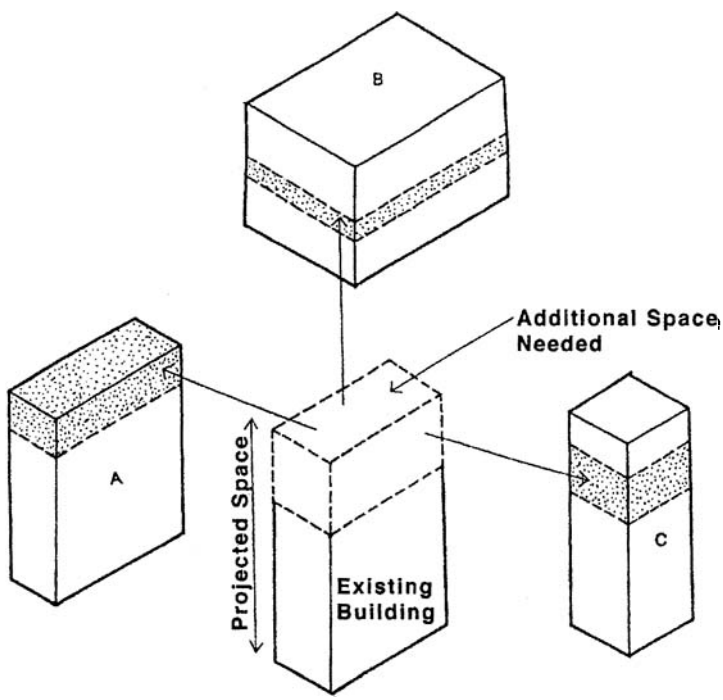

FIGURE 4.1-3 Relocation options. (*Courtesy of William Sims and Frank Becker.*)

Interior Design

Interior Design Programs. Interior design programs are the most detailed and must deal with all of the elements that make up the interior environment of a building and the relationships among them. This includes rooms, circulation, finishes, furnishings, equipment, signing, acoustics, lighting, adjacencies, image, and the like. For offices, the space and equipment requirements of the different types and numbers of employees (current and projected), along with the necessary auxiliary and support spaces, are the primary drivers of the space requirements. For certain types of facilities such as hospitals, laboratories, or manufacturing, equipment and special spaces may be the primary elements that drive the need for space. Although most interiors last for shorter periods than buildings, the issue of flexibility to deal with future changes needs to be considered.

Postoccupancy Evaluation

Evaluation throughout the construction process and after completion is also very important. A POE should be done to compare the finished project with the objectives agreed to in the Statement of Needs and the Strategic Program. When used by clients, who build serially, such evaluations can help to shape the management, procedures, and content of future construction projects and thus cumulatively improve performance. But even for clients with smaller, one-off projects, a POE can identify changes needed to make the building perform better.

BRITISH PRACTICE

Francis Duffy[4] describes standard programming and design practice in the United Kingdom as one involving regular feedback throughout a project among clients, advisers, and the design or project team. He notes that, because projects involve and integrate so many people and interests, even the simplest requires a series of documents, each taking the preceding one to a greater level of detail.

To get the maximum benefit from a project, a client must regularly and systematically ensure that relevant options for design solutions are evaluated, that appropriate decisions are made, and that there are sufficient resources for programming throughout the project to manage and take ownership of the series of programming documents that will be developed.[5] There are four initial stages:

1. *Statement of Needs.* A document prepared for board approval at the outset of a project, which defines the objectives and needs of the client organization in relation to a specific property or construction opportunity.
2. *Options Appraisal.* A formal review of the relative value of the chief options available to the client, including the possible use of existing resources rather than constructing, moving to a new building, or acquiring more space, and the calculation of the benefits, drawbacks, and risks associated with any such option.
3. *Strategic Program.* The setting out of the broad scope and purpose of the project and its key parameters, including the overall budget and timetable; it should include an outline specification that explains in clear terms what is expected of the project.
4. *Project Execution Plan.* An explanation of the way the project will be implemented, including details of the procurement system that will be used and the appointments to be made by the project team.

The design and construction phase of a project should develop in three further steps:

5. *Project Program.* This converts the strategic program into construction terms, establishing initial sizes and quantities for each element of the project and giving each of them an outline budget.
6. *Concept Design.* Once the project sponsor establishes the project program, the project team can begin to test the design options that will contribute toward the eventual concept design. The tests should include the cost and schedule of the construction program and should also examine whether the concept design is likely to meet the criteria expressed in the client's business case for the project. Duffy warns that it is wise to beware of the bias toward supply-side criteria that is characteristic of the thinking of most in the construction and property industries.
7. *Detailed Design.* When the concept design is agreed to and signed off, the project team can begin the development of detailed design, specifying the performance requirements for all of the elements of the new project. The detailed design should freeze as much of the design as possible, defining and detailing every component of the construction.

WHERE DOES PROGRAMMING FIT IN THE BUILDING DESIGN PROCESS?

A typical version of the design process consists of a series of steps or phases of activity usually with feedback loops and decision points between each phase. The phases are as follows:

1. Programming
   - Intelligence
   - Design requirements
2. Design
   - Schematic design
   - Evaluation of alternative proposals
   - Selection of preliminary design
   - Design development
   - Construction documents
3. Construction
   - Construction
   - Commissioning
4. Occupancy
   - Move-in
   - Operation and maintenance
   - POE

The feedback loops often relate back to the programming phase as decisions become more specific and as questions arise that require more information. Most variations on this model involve further disaggregation of the phases into more specific steps or collapsing them into more general ones.

Programming Phases

There are two basic phases during programming. The first, the intelligence phase, is concerned with identifying the potential goals for the project, the assumptions or givens upon which it must be based, and the constraints within which it must operate. The second, the requirements phase, is about reaching agreement on the specific requirements, assumptions, givens, or constraints within which the project must operate.

Intelligence Phase: Establishing the Context. In the intelligence phase for a renovation project, one of the concerns is determining the existing conditions of the facility that may affect the design. These include the conditions of the building and furnishings, personnel and job functions, and such things as ownership versus lease tenure in the building, as well as the conditions in the area surrounding the building such as the other uses, availability of parking, building maintenance, and access to amenities. These may have a bearing on the nature of the design, how long it will remain appropriate, and on the quality and character of the space. It is important to collect information from a variety of sources and confirm it with site visits and interviews. Because the design will be in effect for a number of years, it is important to anticipate the changes that are likely to occur in these existing conditions.

What are the constraints within which the project must operate? Budget and public regulations such as building codes and zoning ordinances significantly determine what can and cannot be done. It is important to know both the formal and informal internal policies of the organization. These conditions are not "cast in stone" but rather are constraints, which must either be accepted or steps must be taken to alter them. It is important to have formal and explicit agreement on them from the relevant decision makers.

Intelligence Phase: Establishing Potential Project Goal. The second major concern of the intelligence phase is to identify a list of goals that the project might pursue. These potential goals are identified with only cursory attention to resource and time constraints, but all must have implications for design. It is from this list of potential goals that the actual project requirements will be selected. The four basic types of potential goal statements are (1) *problems* posed by the existing or projected conditions that should be eliminated or corrected, (2) *assets* that should be preserved, (3) *opportunities* that should be seized, and (4) *goals* that should be pursued.

Requirements Phase. In the requirements phase, the concern is with choosing the subset from all of the potential objectives that the design will try to achieve. This is a winnowing activity, and it is critical to remember that this important decision phase must involve those persons empowered to make such choices.

Another key aspect of this phase is operationalizing the selected goals and converting them into measurable objectives and into design or project requirements. Ease of operationalization alone should not determine what is included in the program. Some characteristics (lighting) are easily converted into operational statements because the underpinning science is well developed, whereas others equally important (aesthetics) are not because the knowledge base is less developed. The list also needs to be prioritized. It is important to get a formal sign-off by the relevant decision makers on the program at this stage even though it will change as the process moves forward.

Design

Schematic Design. The previous phases have been primarily analytical or political. The design phase involves problem solving and is one of synthesis, involving activities of imagining or creating solutions. It is holistic and integrative. As each solution is generated, it is con-

tinuously and informally evaluated against the program requirements and assumptions. When a design "feels" as though it satisfies these conditions, it can be put aside for more formal and careful evaluation in the next phase. Other possible solutions should be generated if time and resources permit.

Evaluation and Selection. When two or three alternative design proposals have been developed that appear to satisfy the requirements, then a more formal and careful process of evaluation is in order. This involves carefully assessing how well each satisfies the program requirements and determining whether there are any other impacts or consequences that need to be considered. Following approval of the recommendation, the selected alternative will be refined.

Design Development. In this phase, the selected alternative is refined and developed. The program should be used to guide this process. Using a matrix, weak areas can be pinpointed and improved (see Fig. 4.3-3 on page 4.75). Once this process is complete, final approval is sought to proceed with construction documents.

Construction Documents. Once the decision is made to proceed, it is still necessary to devise the measures that will make a reality from what is still a paper proposal. This involves developing the construction documents—working drawings and specifications. This is often as creative an activity as the initial imagining of the design. The design goes through a lot of change as the difficulties of making it into a reality are encountered.

Construction

Next is the process of selecting a contractor and constructing the building. The processes of value engineering—of seeking more cost-effective ways to achieve the same level of design intent—often occurs during this phase, and the design again goes through considerable change. Finally, change orders inevitably occur as difficulties, errors, omissions, and changes in needs result in yet more adjustments to the design.

Commissioning. Once construction is completed, the building should be commissioned. During this phase, the facility is accepted and readied for use. The operator's staff is trained, and performance of the building and all its systems is verified under normal and extreme operating conditions.

Occupancy

Once construction is completed and the building is commissioned, then the users move in and the operations and maintenance and general facility management (FM) process begins. Often the building is in need of immediate change because the design must be frozen during the construction process to get it built. Yet the organization has not been frozen during this period and continues to change and evolve. Changes occur that could not have been anticipated during the programming process. Departments may have been merged or eliminated, work processes may have changed, or new equipment purchased.

Postoccupancy Evaluation. After the occupancy phase has been completed and users have had a chance to settle in and adapt to the new facility, it is a good idea to conduct a POE to see how the design is working. This information can identify needed changes and can feed forward both successes and failures to future projects.

PROGRAMMING MODELS

Relay Model of Programming

There are numerous versions of the planning and design process, but one critical difference centers around the role and position of programming. The first is what we have termed the *Relay Model.* In this case, a staff separate from the designers develops the program, and the program is handed off to the designers who then go about designing the building. Peña[2] argues forcefully for the clear separation of programming from design as a means of maintaining the integrity of each. This is also the policy of Public Works Canada, the Canadian equivalent of the U.S. General Services Administration, the government landlord. In standard American Institute of Architects (AIA) documents, the design process is similarly divided into predesign (programming, feasibility, master planning, prototype development), schematic design, design development, construction documents, construction administration, and postdesign (POE, users' manuals, evaluation research). In the AIA model, the program document becomes the legally binding agreement between the architect and the client as to the scope, focus, and direction of the design project.

The relay model has many problems. First, it assumes that all of the major decisions can be made at the front end of the process and that all of the requirements identified and contained in a document can be handed off to the designers. Most likely this is not the case. If the program is based on one set of assumptions about the problem that must be changed as later information comes to light, then the program document often becomes irrelevant and is ignored.

Rugby Model

The *Rugby Model* envisions that the programmer and designer participate in a cross-functional project team with other expert professionals and user stakeholders who work together from the project's inception to completion. The process is iterative and cyclical. The roles shift with the programmer in the lead during the early stages of problem definition, and with the designer assuming the lead in later stages of problem solving, at each of the levels of the process, such as master planning, architectural design, and interior design. As new possibilities emerge during design, clients and users are critical participants in this process by helping to think through new ways of accomplishing the mission and functions that the building is to accommodate and foster. Designers and programmers can be catalysts in the process by offering insights into organizing the building and the particular process in a new way. Often, this is achieved by showing examples of ways other organizations have solved the same or similar problems.

This cross-functional approach, where designers participate during the problem definition stages, enables them to understand the rich background of information, deliberations, and decisions that went into the definition of the problem, which can never be fully captured in a report. Similarly, it enables the designers to ask questions about assumptions, to offer suggestions and insights based on their experience in solving similar problems, or simply to offer creative insights into new ways to define or solve the problem. The designer can challenge the programmer to be more explicit or to clarify particular requirements.

Similarly, when the designer assumes the lead role during the problem-solving phases, the programmer can be on hand to ask questions. "How does this design solve the problem, that we identified in the program phase, of enabling teams to have rapid and spontaneous collaboration and at the same time offer individuals the opportunity to carry out tasks requiring high levels of concentrated activity?" Also, this enables the programmer to offer insights into ways of fine-tuning the design to better achieve an objective.

This continuous involvement does not mean that there are no decision points, where formal agreement is reached on the program, at key points in the process. It simply recognizes that there will be changes as more is learned about the problem and as alternative approaches

to solutions are examined and rejected. In this cross-functional rugby model there is a continuous process of programming and evaluation of proposals based on the program. Similarly, the need for more information to make subsequent decisions requires more programming.

GATHERING INFORMATION

Guiding the search for and evaluating design solutions requires information about the organization, the operating environment, job functions and work styles, space furniture and equipment, building systems and equipment, and the site and surrounding context. Information about the number and type of employees, adjacencies and existing space, furniture and equipment standards—the typical approach to programming—is necessary but not sufficient. Information should be collected about individuals, groups, and departments and their current and projected interaction, current and expected technical requirements, professional identities and work styles, and implicit and explicit organizational goals and values. Good design is based on what works well (and should be preserved) and what needs to be improved (and should be changed). This means understanding the overall operating environment and organizational culture and goals and identifying factors that constrain design options, as well as those that might stimulate change and innovation.

This information must be collected for the current situation and for at least 3 to 5 years into the future. In general, it is sensible to opt to be approximately right rather than precisely wrong. In other words, there is little benefit from spending enormous efforts to be extremely precise about figures that can be only approximations. But for space forecasting purposes, in particular, approximations can be useful in setting basic boundaries and identifying the magnitude of a problem. Things change, and the lesson to be learned is not to abandon efforts to understand future directions but to keep monitoring and updating information and the planning based on it.

Use Multiple Methods

There is no single best data collection method. All have benefits and drawbacks. Every method can be done in an elaborate or large-scale fashion or quite simply, while still retaining the basic characteristics of the approach. It is better to use a variety of techniques in a "quick and dirty" way than it is to use one very sophisticated technique that relies on only one type or source of data—this is called *triangulation.* Data from a variety of sources and users can be obtained without chaos within a brief time frame and with limited resources. These are outlined later. It is usually necessary to derive or extract goals and objectives from the data through a judgmental process of analysis and inference. How elaborate the method is depends on the time frame, budget, and complexity of the problem and the amount of familiarity or existing knowledge. Even the smallest programming processes can, and should, use multiple methods. This may mean interviewing 20 people rather than 200, or distributing a single-page machine-readable survey rather than a detailed 10-page questionnaire, running 2 focus groups rather than 10, or conducting observations over 1 rather than 10 days. The overall picture of the organization's and its departments' and employees' requirements is likely to be more accurate and better understood using a range of these techniques, on any scale, rather than concentrating on a single technique used exclusively and extensively.

Dynamic Process

Organizations' goals, priorities, and constraints will change over the course of the project, and so mechanisms to anticipate such changes must be embedded in the process. The tendency is

to blame the occupant groups for any changes or just to ignore them. A plan for accommodating information technology (IT) is made obsolete by new developments in the technology and the decision of the user department to purchase it to improve its operation. The project team must regularly communicate with informants and structure the planning process to reflect the totally predictable fact that there will be changes during a long-term building project. The old model of the programming process as a discrete (and terminal) step before design development is simply obsolete.

Types of Information Needed

Good programming requires a broad range of different types of information about the organization, the operating environment, job functions and work styles, and the physical environment. In all cases, information should be collected about the current situation and about the best guesses of various players in the process as to how things will look in the future.

About the Organization

Goals. What are the organization's strategic goals? This kind of information can be learned in part from annual reports, but corporate strategic business plans and interviews with influential senior managers are likely to be more accurate and realistic.

Managers will not divulge this kind of information unless they know exactly why it is needed and are also confident that in doing so their trust will not be abused. There are no shortcuts to building trust. It takes time and is based on a track record. A good starting point is to take the time to explain why the facilities group needs to know about confidential business plans. Explanations and illustrations of the way facilities decisions can impact business plans, or the way facilities can be a critical factor in helping to achieve business goals, are the keys to helping managers understand this need. If the project is important enough, directives from the highest levels can help. Often, this strategic direction can be achieved by putting a building committee of senior executives in charge of the project. A workshop of senior executives to outline future strategic directions that have an impact on and can be supported by facility designs is a powerful way of discovering this information and building commitment at the highest level for the project. It can also serve as a useful organizational development tool.

Plans. What initiatives are already in place or about to start? Why waste time designing better facilities for a group that top management has decided to spin off in 6 months? The project team needs to be kept appraised of plans regarding such business objectives so they can see how their facility plans mesh with them and also determine whether they need to collect different or additional information to answer questions that arise as these plans are implemented.

Constraints and Givens. What are the fixed and controllable constraints and are they expected to change (or could they be changed)? Will all of the old furniture be reused? Will there be open planning? How many people will be allowed to occupy the building? Is the project time frame cast in stone? Can a height limit or parking requirement be changed? Answers to these questions can help in allocating scarce programming resources (the time and money to collect information) by targeting data collection efforts at those areas that are most open to influence and are under the control of the organization itself.

Corporate Culture. Understanding the corporate culture is critical to effective programming. Goals and philosophy proclaimed in annual reports, posters, and other corporate communication programs should be viewed skeptically. Instead, the corporate culture is better

reflected in the daily actions and activities of management and staff: how people interact with one another and management, how they dress, how they use time and space, the ways in which decisions are made, who makes what kinds of decisions, and the kind of information or evidence considered in decision making.

Asking different staff and managers to describe what the company considers a "good" manager or staff person, persuasive evidence or an effective presentation is a simple way to elicit lots of information about "the right way to do things around here." Observing how and where people interact, how presentations are made, how people are introduced to one another, how space and time are used, and so on provide invaluable clues to the validity of the archival and interview data. It also can stimulate questions to ask, "Why is it done that way?" "Why couldn't it be done this way?" "What would happen if . . . ?"

Understanding the corporate culture also helps structure the type of information to collect (interview data and anecdotes may be useful in one company, whereas quantitative survey data may be considered good evidence in another), as well as helping to identify the best people to whom to present the findings and the best way to do it. If a group makes decisions, why waste time presenting the information to a single individual (unless the objective is to test the idea with a "friend of the court" before making the official presentation)?

Many organizations are pursuing purposeful cultural change processes to improve effectiveness, agility, and their ability to attract and retain the best employees. Often, a new building or a major renovation project is seen as an integral part of this process. The process of planning and designing the new facility and the new facility itself are seen as major elements in this process.

Organizational Structure. Organizational structure influences adjacencies and determines, at least formally, reporting relationships and decision hierarchies. The project team needs to know how decisions are made formally and whether the existing organizational structure is likely to remain stable or change. This kind of information can determine from whom to collect information and about what. If, for example, two departments are to be merged, it will be useful to know how the new manager views the situation, because the views of the new manager will drive the facility decisions.

Staff and Space. Head-count projections for a 5-year period and their relation to space requirements are probably the most basic information collected in any programming process. But the issue is not just how many people, but also what kind of people: What kind of work do they do? What are their expectations, their work styles, and their communication patterns? What tools and equipment do they use? Are they professionals for whom demand exceeds supply (and, therefore, have a strong bargaining position)? Are they the same kinds of people who have been hired in the past, or are they different, better educated, more professional, or from different racial or ethnic backgrounds, that may affect their work styles and expectations or their ergonomic requirements?

About the Operating Environment

Business Conditions. What are the market forces? Where is the competition coming from now and where is it likely to come from in the future? Is money tight or easily available? Answers to these kinds of questions affect the organization's attitudes about the nature, amount, and quality of space that it needs. If more international firms will be competing in the same city, for example, then information about these firms' facilities should be obtained. Some U.S. companies consciously design their facilities in Asia to a higher standard than is customary there to differentiate themselves from their competitors and attract more qualified staff. Office standards in London have improved dramatically in large part because of the influx of large American financial companies that imported higher American office stan-

dards. All of them have raised expectations among the workforce as to what constitutes an acceptable working environment.

Laws and Regulations. Codes, standards, laws, and regulations can be seen as the "given" program. These include zoning ordinances, building codes, subdivision regulations, special districts, covenants and deed restrictions, and easements. What uses does the zoning permit? How much parking is required? What are the height limit and setback requirements? It is important to do a search for applicable regulations because they can vary with location. What are the tax laws, and how will they affect building form, the decision to renovate an old building, or to build a new one? In the United States, one of the driving forces behind the success of systems furniture and open planning was the tax code, which treated panels as furniture, thereby allowing them to be depreciated at a much faster rate than conventional drywall construction. The provision of plazas (in name if not in ambience) in New York City is directly related to variances in zoning-dictated height restriction if such amenities are provided at street level.

New Technologies. From computers to automated building systems, information must be collected about the nature, extent, and use patterns of existing IT, as well as expectations about the way it may change in the future. Union Carbide's headquarters building in Danbury, Connecticut, for example, was wired with fiber-optic cable long before it could actually be used, based on the much lower cost of installing it during the original construction. Everything from workstation size to the size and location of electrical closets, risers, and wire management systems will be affected by expectations regarding technology. For many organizations today, the best approach is hedging the bet by putting in more than less. At the least, the decisions should be deliberate, based on the best information available and without believing that it comes with a guarantee.

Labor Force Patterns. Labor force patterns should be predicted with some accuracy. Will there be more women, dual-wage earners, older workers, or Spanish-speaking employees? Workers' expectations are rising with respect to pay and also to air quality, comfort and safety, time and spatial freedom, and the extent to which the environment supports their sense of personal and professional identity, their human dignity, and their sense of competence. These are not trivial issues in areas and industries in which the demand for well-educated, professional employees exceeds the supply.

Given demographic trends that show that there will be fewer qualified workers over the next 2 to 3 decades, understanding how shifts in the workforce affect facilities decisions is essential. Information about these workforce patterns has direct and immediate effects on both design requirements and design solutions. For example, families that have two wage earners put increased pressures on transportation systems, day care, and access to shops and services; more women employees work at all times of the day and night and increase demands for safety and security both inside and surrounding the workplace; age shifts in the workforce lead to more concerns about health, fitness, lighting, air temperature, and air quality.

Competitor Actions, Plans, and Experience. We all measure our own situations by comparing them with others' situations, and so competitors' facilities can become a benchmark. The project team can also learn from its competitors' experience: How did they handle space planning or churn, and how did it work? What have been the benefits and drawbacks of a new automated building system?

About Job Function and Work Style

Task Analysis. What exactly do different employees do? How do they work? Both written job descriptions and interviews are useful for understanding what different people actually do and how they relate to different jobs and parts of the organization.

Environmental Satisfaction. How satisfied are staff with their current environment, and how do they believe it affects their ability to work effectively and productively? Just because they have survived in their current surroundings should not imply that their current situation is satisfactory or should be continued. Interviews are effective for discovering how employees see that their work environment affects their performance. Surveys are an easy, cost-effective method for quickly obtaining large amounts of quantitative information. These data can be analyzed by department, discipline, age, previous job experience, and sex to find out how widespread opinions are and to target areas that have special problems.

Communication Patterns. Who communicates, where, when, and how often now? Is that considered acceptable? Desirable? What are some of the problems within or among departments? Before changing the environment to support a new communication pattern, it is useful to see whether the problem is perceived or real and to distinguish among different types of communication.

Adjacency Requirements. Adjacency requirements are related to communication and range from seating location and even orientation of workers within a team or group area to the relationship of departments, buildings, and whole sites to one another. Most of the computerized adjacency software packages are based on the premise that people who have strong organizational relationships should be physically close to one another. It is more important, however, to know who should be communicating and who is likely to communicate. Then, adjacencies can be designed to support groups that should communicate but are unlikely to do so without close proximity. In other words, spatial bonds can be used to overcome organizational barriers.

Space, Furniture, and Equipment Requirements. How do people work, what equipment do they use, and how do they use it (in what way, sequence, combination with other equipment, other materials and resources, alone, together, etc.)? What kinds of furniture and equipment do they believe reflect their personal and professional identity or job status? Functional analysis rooted in ergonomics and human factors are important, but function goes beyond lumbar support, glare, and keyboard height, and it should include desired images of a functional and effective workstation.

Information Needed for the Internal Physical Environment. Information must be collected that describes clearly both what is and what is anticipated (to whatever degree of precision that makes sense). Many organizations have no accurate inventory of the type or amount of equipment they have or its special environmental requirements. Many have not thought through what kind of electronic networking they want or expect and in what time frame. Although the accuracy of such information is often questionable, simply seeking it forces organizational players to share their (possibly conflicting) visions of the future. It is impossible to plan realistically or effectively without such information.

An inventory should be made of existing furniture, equipment, and support spaces like cafeterias and break areas, libraries, conference rooms, computer center, and project rooms that determines their condition, location, availability, ability to support technology, and flexibility and adaptability. The principal questions are what is available (or will be by the time it is needed) and whether what is available is suitable for its intended purposes (now or in the foreseeable future). This information is invaluable for determining whether new furniture or equipment will be needed, whether what exists can be used as is, and what might be usable if it were refurbished or renovated.

Information Needed for the External Physical Environment. Information about the external physical environment will determine what services and amenities are provided on-site and at what level. Again, it is important to understand how a site or neighborhood will be changing, and it also is important to use caution in basing amenities, such as dining or parking, on

comparable services available off-site. Knowing that something will be available can, however, justify a smaller investment and modest plans during the interim period.

Collect information that will be used, and use the information that is collected. Collecting and making sense of all these data can be a frightening prospect. But remember: The objective is not to collect every conceivable bit of information but to collect that needed to make an informed decision. Often, so much effort, time, and resources are devoted to collecting information that no resources are left for data analysis or use in the decision process.

SECTION 4.2
PROGRAMMING ACTIVITIES AND TOOLS

William Sims, Ph.D., C.F.M., IMFA Fellow, Professor, and Franklin D. Becker, Professor
Cornell University, Ithaca, New York

Regardless of the exact description of the programming product you will have to make, there are activities that are common to all. In this section, we suggest tools that can help you to accomplish these activities. Some will be quite familiar; others may not be even thought of as programming tools. The less familiar will probably be those that delve more deeply into the strategies of the organization and attempt to link programming to the organizational mission and those that dig into the way facilities are used and into the preferences and knowledge of the users. The order in which we describe the tools is not necessarily the order in which they should be employed in every case. For example, we indicate that evaluative tools can be used as programming tools, yet we list them next to last, because customarily they are employed after a project is completed and often before a new one is underway. The first, structuring the process, is often omitted from programming and, if so, it is much to the disadvantage of the organization. Without this step, programming may run off in an incorrect direction or receive too little commitment from its top management or from the other stakeholders.

In this section we describe the following:

- Structuring the process
- Forming the project team
- Linking programming to organizational strategies
- Gathering information about the context
- Gathering information about the organizational subunit
- Analyzing the individual user
- Determining building requirements
- Using evaluative methods as programming tools
- Developing concepts for the future

In each programming project, not all of these activities must be carried out in the depth that may be implied by our descriptions. Nevertheless, they do comprise a range that every

facilities project requires. The tools can be selected and modified as appropriate and combined into a programming process to meet the particular programming task. They should be taken only as suggestions because each programming task is unique, and the specific techniques must be custom designed to meet the particular situation based on the resources available, the complexity of the problem, and so on.

STRUCTURING THE PROCESS

Project Mission

What is this project about? What is it intended to accomplish? What is the overall purpose? The *project mission* is a statement that clearly and concisely expresses the reason that the client is undertaking the project. It defines the special purpose of the building and the needs that it must satisfy. Top management must establish the project mission. It is an opportunity for them to clarify their purpose in undertaking the project. A clear mission is helpful for management and others to communicate what the project is to achieve and to build support for it.

Top Management Support

The project team should make sure that top management understands, agrees with, and is willing to visibly support the basic programming approach and the project requirements that it produces. Top management should establish and maintain strategic direction for the project but should not get involved in day-to-day operational decisions. From a senior management perspective, the main concern should be with the way the decisions made help the organization to achieve its strategic and operational goals and plans. Management needs to know the implications of alternatives in terms of time, cost, personnel, flexibility, image, and so forth. They should review and sign off on the decisions periodically.

Clear Roles, Authority, Responsibility, and Accountability

To avoid wasted time, energy, and frustration, the project team responsible for organizing the programming process needs to identify the classes of decisions to be made by different individuals and groups. The team should not second-guess delegated authority or tolerate second-guessing of its own decisions. It should have a good sense of what it needs to do a good job and then request the resources (time, money, expertise) needed to fulfill the team's responsibilities. If these are denied, it is the team's responsibility to inform management of the likely consequences. It should also be held accountable, that is, to measure the extent to which it has achieved its goals in light of the resources and authority at its disposal.

Design Participation Matrix

Create a design participation matrix to clarify who are the key stakeholders in the process and what role each will play. This matrix identifies the different players in the process from CEO to janitor and indicates the nature of the participation of each stakeholder or group in decisions at each stage in the process. In short, it outlines who decides what. This does not mean that all employees should be involved in all decisions, but it does mean that from the outset a clear conceptual structure should identify which decisions different groups in the organizations should share. It suggests what kinds of decisions different levels should be involved in, ranging from workstations to the site as a whole. It is a good idea that all employees be given

the opportunity to influence some aspects of their physical surroundings, but not that every employee be involved in every kind of decision. Some are best left to technical experts, and some are the responsibility of management.

A decision matrix serves several purposes. First, it separates tactical from strategic or operational decisions. Clearly, senior management should be responsible for and more involved in the broader, strategic decisions than in details about workstation design, furniture, and finish selection. Should we have a new building? What form should it take? Where should it be located? Where does it fit into the overall corporate strategy? Second, the decision matrix helps to set realistic expectations that give employees a sense of what kinds of decisions they will and will not be able to influence. It also helps remind senior management what kinds of decisions they should not be making.

Clear Philosophy

The project team should have a *big-picture* view of the overall project and process. The team needs to think about the implications of its philosophy; for example, "doing it right the first time" may delay the project to make it better, it may require unexpected resources, or it may suggest the need to restructure old relationships or typical work patterns. Senior management must understand these kinds of organizational implications if their support of the big-picture approach is not to be empty rhetoric.

Calculated and Controlled Risk Taking

Good projects often break the mold. The project team needs to be willing to take risks, but it should help others to understand the benefits of risk relative to cost. Top management must buy into risk with the project team. Regular reviews and sign-offs, in which the organizational implications of different choices are presented (e.g., the effect of a cutback of amenities on the ability to attract and retain staff, the impact of fewer common areas on informal communication processes and subsequent innovation, the improved response time and lowered cost and disruption of relocations if raised-access floors are installed), is one way of doing this.

Tracking and Monitoring

The team should keep track of decisions made and stress the importance of these decisions on other actions, players, and outcomes. Team members should also identify the kinds of information they need to make good decisions in a timely manner and to sell the decisions to top management and users. Finally, they should anticipate the consequences by team brainstorming, contacting others with similar experience and special expertise, and continuing contact with a wide range of users and others involved in the process.

Procedures

Checklists and procedural guides help users and others provide programming information and review program materials, proposed designs, and working drawings. Too often, the project team assumes that the representatives of occupancy groups or their managers know how to effectively solicit feedback from their staff or to explain proposed plans; often, however, they do not. Some simple tools, which may be no more sophisticated than a checklist of questions that should be asked of staff, can ensure better feedback and better-informed decisions. Procedural guides and training, to ensure that this critical input is sought and received in a credible and thorough manner, are a good idea. Also, a member of the project team should provide

Next Page

technical support to the project team representative, in the form of asking and answering questions and probing responses, to ensure that all needed information is obtained.

Recording Forms

The information obtained in each of the tasks must be recorded in a standard way so that it can be analyzed and communicated to designers and clients. Use cards or sheets of card-stock paper to record the information. These cards can be arranged in categories on a wall so that the programming team can interact with the client/user representatives. These cards are used graphically and with simple text to indicate the space needs that have been derived from the project goals, the strategic visioning, the unit, and user analyses. These can be taped or pinned to the wall, rearranged by category or priority, discarded, or corrected in the course of developing understanding of the program needs.

Involvement of Employees

Employees at all levels should be involved in the project in some way by completing surveys and participating in interviews, helping to identify design requirements, and reviewing preliminary design proposals and policies for allocating and using space.

The appropriateness of particular techniques for involving users and collecting data depends very much on the availability and accessibility of the users or clients. Lynch[6] developed a typology that summarizes these client conditions very nicely.

The client or user is

Present

Absent but reachable		Homogeneous		Vocal
or is	**and is**	or	**and**	or
Not reachable but known		Diverse		Silent

Unknown

In the most direct and simple programming situation the client is the user, is present on the site, and is homogeneous and vocal. In this case, if there are multiple users, then they are homogeneous in terms of their roles, functions, values, and so forth. They can be interviewed, observed, respond to simulations, or be involved in the programming process. The users/clients have concrete experience with the site, and their assessment of its adequacy for their present and future purposes is as direct and straightforward as it possibly can be. In this situation, data collection or a participatory programming process can be quite effective.

The task becomes more complicated if the clients/users are complex in terms of their roles, values, uses, and intentions. Then, each client type must be identified, and some way must be established to ensure participation either by every client of each type or representatives of each type. The process becomes much more political, and the programmer's role becomes one of mediator and catalyst.

The process is still further complicated when certain users have no choice in the process. This can arise out of the political or institutional structure of the situation or out of the cultural tradition of the users themselves. In many institutions, certain actors traditionally have no voice in deciding their surroundings. Students, for example, typically have little say in the design of classrooms in a university. Upper-level employees of a company involved in a major renovation effort are experienced and effective advocates for their points of view in a situation that involves attending meetings, lobbying, discussing, voting, and the like. Lower-level employees, on the other hand, often have no experience in such situations, and their attitudes regarding such participation may be negative. Consequently, they will not participate at all or

Previous Page

Copyright © 2001 Knovel Retrieved from www.knovel.com

will do so passively with the expectation that it is futile in any case. Such attitudes are very difficult to overcome, especially when they often reflect the political realities of the situation.

The problem becomes still more complex when the users/clients are removed from the site, as in the case of a move to a new facility, because they do not have immediate concrete experience to guide their assessments. This removal can be further exacerbated if there is a major organizational redesign or change process underway. But in any case, they can be assembled, interviewed, observed, and so on, and can directly participate in the process. Techniques such as envisioning or simulations can help in this situation.

The most complex situation is when the clients/users are neither assembled nor reachable, even though the type of client/user may be well known. Unfortunately, this is a very typical programming situation. It is a speculative office building, where the occupants will not be assembled until after the building is completed and the tenant organizations have made their leasing decisions. In this case, the programmer is forced to fall back on surrogates, similar to the prospective buyers/clients/users in terms of organization type, basic work processes, and for individual user needs on job type, stage in life cycle, or other relevant dimensions. Programming is made especially difficult because one is never quite sure what the relevant "dimensions" are, and it is difficult to assemble the surrogate users. Finally, given the unreality of the situation, the seriousness and reliability of the surrogate clients regarding the process is questionable.

Time and Resources

The organization must make available the time and resources that employees need to make informed judgments and decisions. It is unfair and a waste of time and goodwill to create committees and focus groups and then not give the participants access to the resources necessary to do a good job. Such resources may include access to informed experts such as consultants, site visits to broaden one's experience and image bank of alternatives, and time to do one's homework.

Timely Involvement

Employee, consultant, and staff involvement should be timely. The greatest gains are likely to be realized when people are involved at the beginning rather than at the end of any stage in the process. Also, nothing is more irritating than to find that the information that one has worked hard to provide is too late to influence the decision.

FORMING THE PROJECT TEAM

The project team composition and the way it is organized depends, to a large extent, on the size of the organization and the importance of the building in its overall operations. In large organizations, it is unlikely that the entire senior management group will be available regularly to participate in workshops and to review and approve project team proposals. A good solution is to appoint a building committee that comprises knowledgeable senior executives who are charged with overall responsibility for the project. It is important that they and the rest of the senior management understand the time commitment and importance of the responsibility—and that it cannot be delegated to their administrative assistants. The project team reports to this management committee.

The project team leader should probably be a member of the facilities department of the organization. There should also be user representatives from each of the affected organizational units. These should be members who are knowledgeable about the current and future needs of the organizational unit and who have good communication and people skills. Their role will be both to represent the needs of the unit to the project team and also to communi-

cate the results of the project team's work to their unit. There should be a group of internal and external advisers who are experts or especially knowledgeable about some aspect of the project. Other stakeholders (e.g., customers, visitors, maintenance and operations staff, service providers, mail, delivery, food service, emergency, and security personnel) should be identified and their roles in the process determined.

Variety of Expertise

It is helpful to have a core project team that spans the kinds of expertise most central to the project. Almost all building projects today are sufficiently complex to make it impossible for a generalist programmer to have the knowledge and experience needed to make good decisions about all aspects of facility planning and design. To get the right information and to make good choices, many types of experts will be needed at different stages in the design process. Such experts include architects; interior designers; landscape architects; mechanical, structural, and electrical engineers; lighting and acoustical designers; ergonomics experts; organizational ecologists; facility managers, operations and maintenance staff; value engineers; and construction managers. When hiring or selecting consultants, it is advisable to consider not only their expertise and experience but also their approach to the process and its compatibility with that of the project team.

The *design participation matrix* (Fig. 4.2-1) is a technique that uses a simple matrix to structure a group discussion about the role of different players in a project. Its purpose is to identify the stakeholders, the kinds of decisions that need to be made, and the nature of the participation of each stakeholder group in each type of decision. This process helps to identify different views within the organization about which individuals or groups should make which kinds of decisions. The design participation matrix can help reduce the conflict and wasted effort when confusion arises over which individual or group should be making which decisions or participating in a particular way. It also forces the organization to think of all of the relevant stakeholders and to consciously consider their roles in the process.

The core project team should develop the design participation matrix. Senior management should review both the stakeholders identified and the type of participation that the core project team has assigned to different stakeholders. The objective is to increase the likelihood that no significant group is overlooked and to ensure that top management understands the role of each participant, including its own. This minimizes later second-guessing and end-runs in the project. Other key functional areas such as human resources (HR) and management information system (MIS) should also review the design participation matrix to ensure that no key parties to the project have been overlooked and that there is agreement across functional lines on the roles and the nature of the involvement of all participants.

Logistics

The time required to complete the design participation matrix may vary. At least 1 or 2 hours should be planned to allow initially for full discussion; at least 1 hour is required for top management and other groups to review the matrix. It requires group facilitation skills, knowledge of the company, and the ability to synthesize information. It also requires a clear sense of who ought to be involved and the different kinds of involvement that may be appropriate for different stakeholders.

LINKING PROGRAMMING TO ORGANIZATIONAL STRATEGIES

Increasingly, new buildings and renovations are being used to facilitate cultural change in organizations. These changes typically involve reengineering the work processes and organi-

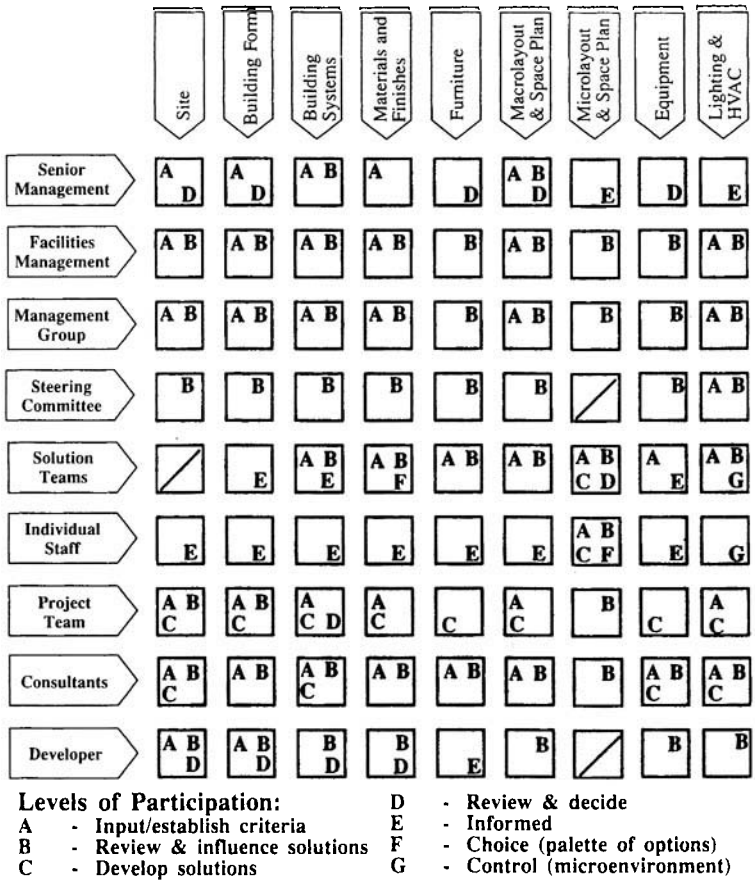

FIGURE 4.2-1 Design participation matrix. (*Courtesy of William Sims and Frank Becker.*)

zational structure and culture. Often, this leads to creating new ways of working and much more dynamic use of space.

Strategic organizational plans can and should have important links to facility planning. In fact, many building projects grow out of an organization's plans for transforming the way they operate or for acquiring or developing a new line of business. These are two central questions:

1. What are the implications of the strategic plans of the organization for the facilities?
2. How can the facilities help to achieve the organization's strategic vision?

Plans to start a new line of business, to grow or shrink one dramatically, or to acquire or merge with another organization all have substantial and obvious implications for facilities that must be considered as a part of the organizational strategic planning process. Where should the new plant be located? How big should it be? How long will it take to bring it on line? How much will it cost? What is our exit strategy for the facility in the event that the new product does not work out as planned?

Visions of where the organization is going, how it is trying to get there, and the best paths for success all have a strategic vision. If the organization is planning a cultural and work pro-

cess change, the question of how the facility is planned, designed, managed, and used can play a central role in that process. Thus, programming establishes facility goals and performance requirements from the strategic vision and, in turn, uses both the process and the design of the new building to help achieve that strategic vision.

Management Interviews

Management interviews include a set of questions for conducting a focused interview with key management people.[7] These questions are constructed to uncover aspects of the organizational unit, such as the mission, the major activities, the nature of organizational challenges, the different aspects of organizational culture, the attitudes and aspirations around innovation and change, the nature of the business and marketplace, and how all of them are changing, that will affect the nature of the design and the overall success of the project.

Management interviews are common and their value obvious, but we provide a sample of them because they are critical to the success of any design. Furthermore, at least some of the questions one should ask may not be obvious. Understanding some of the key aspects of the culture, for instance, may influence not just which solutions are put in place, but how they are implemented and sold to the organization.

Management interviews are helpful at the beginning of a project in trying to understand the context for the new design and the factors that may both drive the change and also impede it. They are especially important in identifying business challenges that the organization is facing, so that those developing the design can frame their solutions around helping the organization meet these fundamental business objectives.

Depending on the type of information sought, interviews may involve key management in all areas of an organization. Of particular relevance are managers in information systems, HR, and the business units themselves. Executive leaders should also be interviewed to get an understanding of the vision of the corporation at the highest levels. Any managers involved in reengineering, strategic planning, technology, or TQM projects are also good candidates for interviews.

Individual management interviews usually do not require more than from 1 to 1.5 hours per manager. Having a well-thought-out and organized set of questions ready for each interview will pay huge dividends. However, the time necessary to analyze, tabulate, and/or synthesize the data collected may eat up a much larger chunk of time. Allocating time for analysis and interpretation is critical because the data by themselves have little value.

Sample: Management Interview Questions In the following list are examples of the types of questions that should be included in management interviews directed at setting the goals of the project:

- Describe your company's business.
- Do you have a formal mission statement? What is it? Can you give some examples of the way it is reflected in what your organization (and the people in it) does/has done?
- Do you have a formal statement of organizational values and philosophy (e.g., corporate culture)? What are its major tenets? Can you give some examples of the way this philosophy and these values reflect what the organization (and the people in it) does/has done?
- How do you characterize your firm's management style or philosophy?
- Is this an unusual management style or philosophy in your field?
- Can you describe the incentive system? What are people rewarded for doing? Are there any differences between the way the formal and informal incentive systems work?
- What are the key organizational challenges that your organization is facing? Are there internal and external challenges (e.g., reducing costs, attracting and retaining staff, building teamwork, increasing market share)?

- What has your organization been doing (or considering doing) to meet these challenges?
- How do you characterize your firm's philosophy about change and innovation in the way it conducts its business? Can you give an example that reflects this character?
- Can you describe the decision-making process? Who makes what kinds of decisions? Can you give an example of a major decision that was made in your firm and how it came about?
- What is the role of rank-and-file staff in the decision process (e.g., What input do they provide in making decisions? How do they provide it? What sorts of decisions?)? Can you give some examples of decisions made by different people/levels in the organization?
- On what basis are decisions typically made (e.g., data, tradition, authority)?
- How are decisions typically made (e.g., by consensus or fiat)?
- Generally, what degree of certainty about the expected outcome is required before decisions are made?
- How do you characterize your firm's attitude about risk taking in its core business? Can you give an example that reflects this character?
- Describe the type of people who work for (or that you might want to work for) your company.
- How difficult is it for you to attract the kind of employees you want (supply versus demand of desired workforce, competitive pressures)? Is it more difficult for you to attract employees at different levels within the organization?
- What helps you to attract the kind of staff you want? Are there differences between job levels?
- How are differences in status and rank conveyed in your firm, if at all? Can you give some examples to illustrate (e.g., offices for upper management, parking spaces, executive lounges, airport club membership, etc.)?
- How important is the communication of differences in status and rank? Is it changing or has it changed recently?
- Is turnover viewed by management as healthy and natural, something to be avoided, or just not a major issue?
- What is your current client base? Where are these firms located in relation to your office (distance and time)?
- Is cost containment a significant concern in your organization?
- Is real estate cost a significant concern in your organization?
- How much is spent on real estate annually now (e.g., rental costs annually per square foot, number of square feet being paid for currently)?

Workshop to Develop the Facility Implications of the Strategic Vision

What is the process for uncovering and then translating strategic ideas for changing the culture and work processes of an organization into a program to guide the design of a facility to support that change? One approach is to use a series of workshops with the project team and the senior corporate executives involved in planning and implementing the new direction. The starting point is not the building design, cost reduction, detailed work processes, or detailed descriptions of particular spaces, their sizes, and related equipment. Rather, it is an analysis of the challenges that face the organization and the strategic ideas the organization has for meeting those challenges. Once these are identified and agreed upon by the team, they become the driving forces for the project. The next step is to derive the implications for the design of the facility. This task focuses on developing a few good rules or principles to guide

the overall design of the building, so that it will build commitment to the values and new ways of working that senior management is trying to promote.

Very often, it is difficult for senior managers of the organization to comprehend the implications of some of the design principles that come out of this process. It is important that they do understand them and that they are committed to them if they involve significant changes from current practice. Nothing is worse than a sudden realization that the proposal is not what management had envisioned and that it is too radical for the culture. Second, senior managers often reject concepts out of hand that are in fact appropriate for their strategic vision because they have a negative image of the idea. Nonterritorial offices, open plans, or universal workstations all have strong negative stereotypes in the minds of many. It becomes important to enrich the image bank, so that decisions are made with a good and realistic understanding of the possibilities and drawbacks of the choices. One good way of doing this is to show real examples of the way other organizations have translated similar issues and concerns into new facilities. These presentations may include actual site visits and discussions with relevant counterpart executives where possible. When this is not possible, a photographic slide show or video of other places, combined with data illustrating how well the solutions have worked to meet the organizational challenges previously identified, can be employed. The goal is not to reach decisions about the proposed building. It is rather to stimulate a lively discussion about what the organizational challenges are and how these and the organization's strategic vision, values, and philosophy might be expressed in the building project. Following this workshop (or series of workshops if necessary), the project team would produce a set of recommendations for discussion and approval by the senior executives.

For example, a common strategic goal for many organizations these days is a flatter and more integrated organizational structure. Flatter organizations imply reductions in hierarchy to achieve quicker decisions through fewer levels of management. Commonly associated with this is a move to a more egalitarian culture, empowering employees, and getting them more engaged in and connected to the values and goals of the organization. Increased integration implies more communication and interaction and a shift from individually oriented to a more collaborative workstyle—teamwork. All of these values have significant implications for facilities:

- A horizontal building with few gate functions to indicate status.
- Workspaces sized, designed, and furnished for function rather than as status indicators.
- Work consists of movement between multiple work settings designed to support particular tasks at a high level of performance rather than at a single setting designed to support all tasks.
- Workspaces designed to support spontaneous collaborative teamwork and concentrated individual work.
- A redistribution of space—reduced individual workspaces designed to support only concentrated tasks to provide for dedicated collaborative team spaces.
- Provision for individual employees and groups to personalize their workspaces.
- Workspaces designed for quick and easy adaptation by individuals and groups to improve work processes.
- Circulation systems designed to concentrate, rather than disperse, pedestrian traffic to foster increased chance encounters.
- Clustering communication magnets, break areas, and settings for informal meetings along the major circulation path.
- Settings and places designed to accommodate displayed thinking where projects and accomplishments can be displayed for comment and information sharing.

These are just a few examples of the types of design implications that can be derived from a strategic vision for transforming the organization.

GATHERING INFORMATION ABOUT THE CONTEXT

One of the main concerns in programming is determining the existing and projected internal and external conditions that might affect the design of the building. Peña[2] describes this step as establishing the facts about the project. It is also about uncovering the list of potential goals and objectives that should be considered for the project. Use a checklist to ensure that the important conditions are considered.

Existing Conditions

Internal or endogenous conditions include the type and conditions of the existing building and its furnishings and equipment, personnel and job functions, and such things as ownership versus lease tenure in the building. It is also important to consider the external or exogenous conditions in the area surrounding the building such as the availability of parking, building maintenance, access to amenities and services for employees, and access for customers and suppliers. The quality of the surrounding buildings and uses and their appropriateness for the intended building or renovation may have a bearing on the nature of the building and its continued viability. Collect information from a variety of sources, and confirm it with site visits and interviews. Some of the information can be obtained from a simple walk-through. Others may require on-site measurements and archival searches.

Future Conditions

Because the design will be in effect for a number of years, it is important to anticipate as many as possible of the changes in the building that are likely to occur during that period. An already approved but not yet constructed addition to the existing facility, organizational changes that have been approved but not yet implemented, the effects of an emerging technology, the effects of wear and tear, the life expectancy of systems, and lease expirations are just some examples.

Identify what will be happening in the surrounding area during the planning period. Whether the area is projected to decline or improve may influence the decision of the company to stay or relocate and consequently will affect willingness to invest in improvements. A projected public action such as a freeway requiring your building site for right-of-way may nullify or make imprudent any planned improvements. Not knowing about an adjacent property owner's plans to construct a building that will block a desirable view could make a design that capitalized on that view and the project team that produced it look very foolish. Even the potential that such a building could be constructed should be evaluated. The decision of an adjacent property owner to develop a center containing shops, dining, and other services would affect the desirability or need for such services on-site.

Determine the real status of such plans before hard decisions are based on them. Often, such projects are only desires rather than real projects with a strong probability of being implemented. The status of such projects and plans and the probabilities of their being implemented should be explored and nailed down with the relevant planning officials and with knowledgeable real estate professionals.

Use the following checklists as guides to developing the information on the existing and future conditions or the context within which the design must be developed.

Local Area Checklist

- The character of surrounding environs (the status and image of the area, the reputation of organizations in the area, etc.)
- The character and quality of adjacent structures

- Civic services (fire, police, health care, libraries, schools)
- Access (air, rail, bus, etc.)
- Traffic volumes and patterns
- Climate
- Sewerage
- Electric power
- Water
- Storm drainage
- Energy sources
- Telecommunications
- Solid-waste disposal
- Land costs
- Taxes
- Development costs
- Incentives

Site Checklist

- Acreage—adequate for buildings, parking, expansion, and the like
- Shape
- Topography
- Soil and subsurface
- Vegetation
- Views
- Drainage
- Microclimate (precipitation, prevailing winds, extremes, solar orientation, etc.)
- Accessibility by cars and trucks (relation to and capacity of roads and streets; parking capacity and quality)
- Accessibility by pedestrians (routes, crossings, and distances)
- Accessibility to public transportation (bus, trains, distance to stop or station, frequency of service, etc.)
- Accessibility to airport (frequency of service, etc.)
- Accessibility for emergency vehicles (distance to fire and police stations)
- Safety and security (law enforcement, social climate)
- Amenities (shops, stores, restaurants, banks, post office)

Existing Building Checklist. Also see the Serviceability Scales and Orbit 2.1 systems described later.

- Functionality of layout
- Building efficiency (assignable-to-rentable ratio or assignable-to-gross)
- Entrance (attractive, ADA-accessible)
- Access to common facilities, entrance, and service
- Structural and building modules
- Floor loading

- Flexibility
- Ease of subdivision
- Expansion capability
- Way-finding aids (signing, clarity of circulation system)
- Vertical transportation (elevators, stairs, service, etc.)
- Electrical capacity
- Telecommunications
- Restrooms
- Indoor air quality (temperature, smells, pollutants, air movement, humidity, control, etc.)
- Light (artificial, daylighting)
- Finishes
- Energy efficiency
- Views (from inside)
- Acoustics
- Safety and security (access control, parking, lighting, etc.)
- Maintenance and maintainability (roof, exterior walls, interior finishes, etc.)
- Waste disposal (separate room, access to loading dock, etc.)

Constraints or Givens

What are the constraints within which the project must operate? Budget and public regulations such as building codes, zoning ordinances, and the host of other laws and regulations significantly determine what can and cannot be done as do certain company policies or decisions. These conditions are not necessarily "cast in stone," but they must either be accepted, or active steps must be taken to alter them. Such changes require time and resources and often have uncertain outcomes. It is important to have an explicit agreement on these givens.

The following is a list of codes, regulations, and standards that may apply to a project. Check to see if they are required and which edition is in effect. It is important to remember that the applicability and specific provisions vary by political jurisdiction. For example, does one of the model codes apply or has the state or local government adopted a combination or written their own?

Checklist of Codes, Regulations, and Other Constraints

- Building code (BOCA National Building Code, Standard Building Code, Uniform Building Code)
- Plumbing code (BOCA National Plumbing Code, Standard Plumbing Code, Uniform Plumbing Code)
- Mechanical code (BOCA National Mechanical Code, Standard Mechanical Code, Uniform Mechanical Code)
- Electrical code (National Electrical Code)
- Life safety code (National Fire Protection Association NFPA 101)
- Americans with Disabilities Act (ADA) Guidelines
- One- and two-family dwelling code
- Model energy code
- Zoning ordinances

- Special ordinances
- Subdivision regulations
- Health codes
- Historic preservation
- Covenants and deed restrictions
- Easements
- Environmental Protection Agency (EPA) Act
- Fair Housing Act (FHA)
- Occupational Safety and Health Administration (OSHA) Act
- National Fire Protection Association (NFPA) Standards
- American Society for Testing and Materials (ASTM)
- Underwriters Laboratories (UL)
- American Society of Heating, Refrigeration and Air Conditioning Engineers (ASHRAE)

Steps in a Code Search Process. A search process would involve the following types of steps:

- First, determine which code applies.
- Then, determine the occupancy classifications, calculate the occupancy loads, and review any specific occupancy requirements.
- Determine the construction type along with the ratings for structural elements and the maximum floor area and building height allowed.
- Next, determine the requirements for egress, in terms of quantity and type, travel distances, minimum widths, and signage.
- Next, determine the requirements for fire and smoke barriers, fire and smoke detection, and fire suppression systems. Determine the types and numbers of plumbing fixtures required.
- Similar reviews for the electrical, mechanical, and other codes are needed along with a review of the special requirements for types, tests, and ratings for finishes and furniture.

GATHERING INFORMATION ABOUT THE ORGANIZATIONAL SUBUNIT

Once the strategic overall directions of the project and the context have been established, the next task is to begin the detailed programming for each of the organizational subunits, divisions, departments, and work groups. The first step in this part of the programming process is to have the unit representatives define the missions of their organizational units followed by the functions and operations that are used to accomplish it. Critical to this step is to ensure that the question of how can we best accomplish the mission, as opposed to how we currently do it, is addressed in the light of the overall strategic directions established earlier.

The next step is to create a statement that describes the mission of each of the organizational units. A mission statement explains why an organizational unit exists and what its main purpose is within the overall organization. It should explain what the organizational unit is about. This mission statement needs to be as clearly and simply stated as possible. Next, it is necessary to describe the functions that are used to accomplish the mission, and then, finally, to describe the activities that are carried out to accomplish a function.

Management Interviews[7]

As in the case of management interviews at the organizational level, management interviews at the unit level (division, department, work group) conduct a focused interview with key management people of each of the units. The questions should be similar and constructed to uncover aspects of the organizational unit, such as the mission, the major functions and activities, the nature of organizational challenges, the different aspects of organizational culture, the attitudes and aspirations around innovation and change, the nature of the business and marketplace, how all of them are changing, and how that will affect the nature of the design and the overall success of the project.

Work Process Analysis[7]

Work process analysis is a technique used to understand the nature of the work process. Patterns of work are analyzed to determine where and when different activities occur; how predictable these patterns are; and the human, technological, and printed resources involved in these activities.

Data to be collected from individuals include job title, description, and responsibilities, all work activities, and their sequence and regularity. This also includes where, how, and with whom the work is accomplished. Additionally, people are asked qualitative questions to determine what they like or dislike about their jobs, what they would preserve or change, and how could they do their jobs better. Suggestions for improvement might include changes in policies and procedures as well as physical and environmental changes.

Work process analysis should be used whenever a new workplace design is being considered. It is a major way of identifying whether modifications in an accepted workplace design need to be considered to account for variations in local conditions. For example, a field sales function that serves mostly large firms in a major metropolitan region may require a kind of office and technology support different from field sales that serves a large number of smaller clients over a wide geographical region.

Work process analysis can be used early in the programming process to find out how work is done presently and how people feel about their jobs. Any rumor of change will get employees' attention. Involving employees in a process connected with researching and planning for prospective changes will result in more employee cooperation and involvement when the actual changes are implemented.

Who to involve in a work process analysis depends on the scale of the project. However, at least one person, and preferably two to three people, from each functional group in the workplace should be involved. The analysis should also include someone from each management level, professional function, and support staff within a functional group.

Each interview will last about 45 to 60 minutes. The time needed to organize and compile the data will depend on the number of interviews conducted; it can be fairly substantial. Work process analysis is somewhat difficult. It requires a clear understanding of the issues, excellent communication, listening and interviewing skills, and the ability to synthesize information. The process will be somewhat easier if the interviewer is familiar with the activities of the work area.

The Five Why's: A Method for Analyzing the Workplace and Work Patterns

The Five *Why*'s is an exercise based on a Japanese quality technique that forces people to search for the root of a recurring problem, instead of accepting the first explanation they find. People using this technique ask *why* five times in either a group setting or individually. The premise is that the actual problem will not be uncovered until answering the fifth *why*. The first four times the question is asked, the user is simply uncovering symptoms of the problem without finding the cause. The answers to the questions should not try to lay blame on any individual or department but should attempt to find events or policies in the organization that can be changed to ensure that the problem does not recur.

The time to ask and answer the Five *Why*'s varies. Sometimes, the answers to the questions may be quite obvious. At other times, it may take several days to actually trace the root of the problem.

The Five *Why*'s method is very easy to use. Users need to be able to sift through the many random answers they may receive to trace the original problem.

***Sample: The Five* Why's.** In conducting the work process analysis at Burdell, Inc., facility managers found that it took quite a long time for customers to receive their orders for Whickywacks, a very valuable business tool in today's global market. Facility managers hoped that the design they were proposing would improve the work processes within the organization, thus making it easier for them to push the design through. After talking to several people, however, they were not exactly sure why it was taking so long for the orders to be delivered, so they could not determine how the new design could help.

Janet, who had been working for facility management for only a year, had heard of the Five *Why*'s technique in college. She decided to try the technique to trace inefficiencies in the order process. She started with the customers' first contact with the company: field sales representatives. Her day went something like this:

As soon as Jim, one of the field sales reps who had been working for the company for 10 years, arrived at the office, Janet grabbed him and said, "I've heard that it takes several months for orders to be filled for Whickywacks. That sure seems like a long time."

Jim: "Yes, it is. I've heard from customer relations that we receive a lot of complaints about it and that we sometimes lose return business."

Janet: "*Why* do you think it takes so long?"

Jim: "I think it has to do with the people we use to deliver the Whickywacks. They are constantly losing the orders or filling them inaccurately."

Janet: "*Why* do they lose the orders?"

Jim: "The orders are sent to them in hard copy form by the finance department. I guess maybe the orders sometimes get hung up in the finance department or don't get entered correctly into the system."

Janet: "*Why* would they get hung up or entered incorrectly?"

Jim: "Well, I guess it's because the fulfillment people are supposed to verify the order with the sales administration before they enter the order into their system. That sometimes takes a while to do because sales administration then has to track down either the customer or the sales rep to confirm."

Janet: "*Why* do they have to go through sales administration? Why don't they go directly to the sales rep?"

Jim: "The orders don't have the sales rep information on them. Once we call in an order to sales administration, it becomes their order. The orders will have one of their names on it."

Janet: "*Why* does the order have to go through sales administration? Why can't you send the order directly to finance?"

Jim: "We don't actually enter the orders into the system. We just call the order in on the telephone or bring in a completed order form. Sales administration then enters the order into the computer for us."

From this brief conversation, Janet was able to uncover the following: What was one of the problems? The sales reps did not have responsibility for the orders. They did not have the means to enter the orders themselves, so they therefore had to turn over the orders to sales administration, at which point they lost control. Giving the sales reps the technology they need to do this while they are sitting with the customers would give them direct control over the orders, in addition to reducing the chance that the orders would be entered incorrectly.

Further Analysis of the User Group

Following are some of the different data collection techniques that may be useful in probing groups that comprise organizational units and discussions about their advantages and disad-

vantages. Detailed descriptions of these are beyond the scope of this chapter but can be found in various sources.[9-12] In general, a wide range of users and experts should be involved, but in different ways.

When the project team wants a representative viewpoint (generally a good idea) across user groups or types of employees, some form of random selection is appropriate. If it wants to gain insight into a particular problem or to explore future developments, then it makes sense to use people who are especially knowledgeable or experienced in the area. The project team can ask managers to select representatives for committees and focus groups to act as liaisons between the department or group and the project team. If the group is sufficiently small, then the whole group may be consulted.

The type of data to look for depends on the situation. If the program is for a new or existing facility for an existing staff, then most of the techniques can be used to study that staff in their current setting. If the program is for a new facility for employees yet to be hired, then surrogates must be used who are similar to the new employees. It is essential to sample a full range of users.

Communication with Users. The most commonly used data source involves communication with users. The questionnaire or survey is the most widely used technique. Questionnaires require knowing in advance the dimensions or attributes about which information is desired. Interviewing in a more informal style is useful in developing design requirements. Who to interview is at least as important as how it is done. Informal interviews with a representative range of users is often more useful than elaborate questionnaires. A good technique is to "walk people through a typical day in their work," asking them what causes problems, what they would like to keep, and what they would like to have. Direct communication allows access to feelings, plans, desires, and so on, as well as memories of past behaviors. It is reactive, however, and people do not always remember correctly or tell the truth. Consequently, interviews should be done in combination with behavioral observations. It is necessary to go through a process of deriving requirements from this data.

Interviews and Focus Groups: Pros and Cons. These are good for:

- Probing responses
- Following new directions
- Creating goodwill
- Understanding complex relationships

Interviews and focus groups are not good for:

- Developing quantitative data
- Tapping a broad sample of employees quickly

Interviews and the focus group provide a gut feeling about what people are thinking, feeling, and concerned, excited, or skeptical about. They are a good way of collecting anecdotes, which can be a persuasive source of evidence in some organizations. Because of their hands-on, face-to-face character, interviews also tend to be highly visible and liked by employees. Especially when employees are skeptical about whether management or the project team really cares about their views, interviews are a better medium than surveys, which are remote and impersonal. Pulse-taking interviews, 3- to 10-minute random discussions with staff conducted in their own workspace, are especially effective in getting a sense of a place and generating goodwill.

The interview's greatest drawback is that it is time-consuming (in terms of the number of people who can be reached in a given period of time) and expensive (in terms of the time needed to conduct a large number of interviews and to analyze the resulting data). And although it is possible to obtain quantitative data from interviews, it is more difficult than

from surveys. The focus group, in which 5 to 10 people are brought together to respond to a specific proposal or charge, and group interviews, which may be more wide ranging, are quick ways of eliciting responses from many people. In efficiency, both fall somewhere between individual interviews and the survey. The group interview's main drawback is that one or two people can dominate the discussion, and if there are strong status differences among the participants, lower-level staff may choose to remain silent or mute their responses. The main benefit is that a range of opinions and views becomes apparent, and group members may stimulate one another, leading to new insights.

In conducting an interview, remember to

- Explain the purpose of the interview and who will see the results.
- Allow time for someone to answer. Do not rush the respondent.
- Find a comfortable location with reasonable privacy.
- Explain how long the interview will take.
- Watch for confusion and repeat explanations if necessary.
- Write down key words and phrases; elaborate right after the interview ends.
- Probe answers; ask for more explanation.
- Do not suggest the right answer or become defensive.

Done properly, the interview is enormously versatile and becomes even more powerful when combined with survey methods.

Surveys. Surveys are good for:

- Generating quantitative data
- Tapping a broad cross section of employees quickly
- Enabling a statistical analysis of subgroups
- Obtaining data cost-effectively

Surveys are not good for:

- Probing responses
- Understanding complex nonstatistical relationships
- Generating goodwill and confidence in the process

The survey's strength is the interview's weakness, which is why a combination of the two is so useful. In organizations that value quantitative analysis or whose top management is skeptical of interviews as a technique, surveys, with their charts, tables, and graphs (numbers!) can be a more persuasive form of data analysis and presentation than interviews. The interview's contribution, used in conjunction with a survey, is the anecdotes that bring to life the numbers and charts, giving them a human face that helps fix in memory a particular point that may slip away if presented only in a chart or table. "A good story is worth a thousand charts."

Structured Observation. These are good for:

- Raising questions to include in surveys and interviews
- Checking information given in surveys and interviews
- Generating visual evidence to support interviews and surveys
- Generating quantitative data, if systematic
- Getting at issues that employees may have difficulty verbalizing

Structured observations are not good for:

- Understanding why something is occurring
- Understanding how employees feel about a situation
- Getting at "what could be"
- Generating goodwill (unless coupled with interviews)
- Getting a representative view of the situation, if only short-term

One of the best and most objective types of data is observing what the users of a facility actually do. It is important because often people are not consciously aware of what they do each day and consequently will not mention it in an interview.

Structured observation can take many forms. One systematic and quantitative technique is called *behavioral mapping,* which uses predetermined codes to indicate where and when certain behaviors occur in a setting. This can involve observing selected individuals through a typical day or task or can focus on an area and record all the behaviors that occur in it. Mapped over several times of day and several days or months, such behavior records build a picture of which areas in a building are being used by what kinds of people, in what ways, and at what times. This information can then be analyzed to identify the physical characteristics associated with different use patterns. For example, lounges at the ends of corridors tend to be used less than those near major circulation paths and activity nodes like mailrooms and coffee areas. Or it may reveal that conference rooms designed to accommodate meetings of 30 people host meetings of 3 to 4 participants almost exclusively.

Less structured and quantitative, but quicker and still useful, are focused observations in which the programmer and another team member, who can then share their observations and check their interpretations, walk around the facility and observe certain behaviors and their residue (e.g., jury-rigged storage or lights brought in from home). Most behaviors leave traces behind which can be used to understand behavioral patterns. Wear and tear is an *erosion trace* that can also be used to infer past behaviors. Objects left behind are *accretion traces,* which may allow one to identify the behavior. Like direct observation, erosion or accretion traces usually do not tell much about the inner feelings or desires of the user. There are also problems of selective survival and deposit. Things to observe, each of which offers clues to environmental dysfunctions and actual (as opposed to expected or desired) behavior, include attempts to solve problems, typical and atypical uses, and inventive ways of using standard furniture or equipment. Heavy wear patterns, or the opposite, indicate use patterns.

In addition to noting observations on a recording sheet in predetermined categories, a photographic record of these findings is helpful for representation in which this hard evidence can be shared with people who were not present on the observation tour. Again, the value of such data can be enhanced by combining them with information from interviews and surveys to explain why certain things are occurring, how these affect the way people work, and so on. Observational data has limits—always consider before collecting data if it will offer useful insight. Often, it is a good idea to ask the users to interpret observations.

Simulation. This is good for:

- Exploring "what if" possibilities
- Enriching the image bank of possibilities
- Eliciting responses to new designs or plans
- Removing skepticism that something will happen
- Avoiding costly mistakes
- Stimulating the imagination
- Generating enthusiasm and excitement

Simulation is not good for:

- Getting a completely realistic response

Simulations allow people to see and experience new possibilities. It is important that the search for a new design not be totally limited to the past experiences of the users. Simulations allow the programmer to obtain people's response to solutions that have been successful elsewhere or that have been envisioned but not yet built.

Simulations take many forms, including photographs, models, drawings, full-scale mock-ups, games, computer and video animation, and even site visits. They are good for getting a sense of the way people who are unfamiliar with a particular design or furniture arrangement might actually respond to it. Although the state of the technology is rapidly improving in its ability to make simulations more realistic, simulations are always just representations of reality and not the reality itself. The amount of time and the circumstances under which the simulated environment is experienced inevitably fall short of the real thing.

Yet, by having intact work groups visit and carry out typical tasks in a full-scale mock-up of a work area equipped with different furniture systems, lighting, seating, and a working computer system, quite realistic feedback can be obtained. Despite the limitations inherent in any form of simulation, the feedback is far superior to blind guessing about the way people will respond. When coupled with systematic evaluations (observations, interviews, focus groups, and surveys), they can also be used for incremental improvement of prototypes, and when the results of the user assessments and suggestions are communicated back to users, they can be very effective in generating goodwill and acceptance of designs.

Simulations do not have to be expensive. Simple working models with few details can be used for exploring different layout issues, and the cost of very realistic computer animations is reducing rapidly. The cost of a simulation should be considered in relation to the cost of making a major mistake. Buying a million dollars' worth of new workstations that do not accommodate technology, that have inadequate storage, that do not meet employees' expectations for acoustic privacy, or that are much harder to assemble or disassemble than expected can make a 50 thousand dollar mock-up study (which identifies the dysfunction before the design is implemented) look like a very good value for the money. In this context, even the costs of full-scale mock-ups are by no means unrealistic.

Archival Records. These are good for:

- Nonreactive information
- Inexpensive data collection
- A check on other sources of information

Archival records are not good for:

- Understanding the dynamics of a situation
- Understanding why something is happening
- Looking at an issue in a detailed manner
- Interpreting data accurately
- Predicting new needs

The final technique of data collection is archival records. This information, collected by the organization as a part of its ongoing record keeping, is often a good source of readily available information. Grievance reports or annual employee satisfaction surveys may offer insights into facility-related problems that need to be addressed in the program. Records of exit interviews of people who have decided to leave the organization (did the facility contribute in any way to their decision to leave?), of job recruitment interviews (did the facility influence their decision in any way to accept or decline the job?), medical and insurance records (complaints,

visits to the doctor), of absenteeism, and of turnover are all sources of data that can be used to gain insights into the design of a new facility or the redesign of an existing one. Such data can be related to parts of the building (does an area with old, large-zone HVAC have more medical complaints or higher levels of absenteeism?) and to planning processes (do projects in which employees are more involved have fewer change orders and higher levels of satisfaction with the workplace?).

Analyzing the Data. A common difficulty in programming is that there is never enough information in exactly the right form to answer all the questions rigorously. There is never enough time or resources. Yet, to paraphrase Abraham Kaplan, we are in a taxi and the meter is running—we must decide. That is the difference between the art of programming and science. The task is to collect sufficient information to answer the main questions.

Real skill comes in collecting as few data as are needed and in analyzing them as much as possible. Unfortunately, the reverse is often the practice. Collecting data is easy (although collecting accurate and valid information is more difficult). Analyzing information and interpreting its implications for facility decisions often feels more like art than science. But they are skills that can be learned.

Simply counting instances of a given response can be very enlightening. How many staff reported (in interviews or a survey) poor air quality or lighting? Relating it to environmental characteristics is equally as important as accuracy in tabulating the responses. Did conference rooms with windows get more usage? Looking for patterns is also useful. Surveys revealed that people complained about the lack of conference room space. Observations revealed that all the conference rooms were designed to accommodate meetings of 30 people (of which there were few) but were used almost exclusively for meetings of 3 or 4 people (of which there were many). Deriving conclusions that lead to design requirements is the difference between research and programming. There is adequate space devoted to conferencing, but it is not distributed so that it matches the number and size of meetings. There is a need for more small four- to six-person conference rooms with only one or two sized for large meetings—even those should be divisible into smaller rooms if needed.

If the responses in samples of up to a few hundred are very simple (a checked box on a survey, for example), this kind of analysis can be done very quickly by hand. Many simple computer statistical or spreadsheet packages are available to summarize, display, and analyze the data quickly. These are useful for larger samples, particularly if the project team wants to do more sophisticated statistical analyses. In either case, quantitative analyses can be done quickly, accurately, and cheaply—often with impressive results in the form of computer-generated graphs and charts.

For qualitative data such as interviews or focus groups, do a thematic analysis. Read the transcripts and look for themes (poor air quality, way-finding problems, distracting noise, lack of privacy or a beautiful view, etc.).

When interpreting results from interviews, surveys, observations, or archival data, try to do the following:

Look for patterns of agreement:

- Across data sources
- By mediating variables
- With literature
- With experience

Look for contradictions:

- Across data sources
- By mediating variables

- With literature
- With experience

Try to understand contradictions:

- Through alternative plausible explanations for a finding
- By reexamining the data
- By collecting specific data to test alternative hypotheses

Identify the most important findings:

- By organizing and prioritizing them

Present the findings simply:

- Charts, tables, and diagrams
- Selected photos or videos to illustrate an important point

ANALYZING THE INDIVIDUAL USER

This section describes five approaches to the problem of developing design requirements that are oriented to the needs of individual users: the user characteristics, social/psychological functions, behavior circuits, behavior settings, and user participation approaches. These approaches complement and can be combined with those described in the section that focuses on analyzing the users in an organization by standard social science tools of observation, interview, survey, and the like. They are also complementary with each other and can be used in combination. For example, the behavior circuit approach can be used to enhance a participatory approach by having the user participants describe their typical circuits, even act them out, and then suggest design requirements. It is also possible to envision typical behavior circuits and their related design requirements as part of a user profile in the user characteristics approach. A specific methodology suited to the problem or resource conditions needs to be developed. Each of the approaches is described along with an abbreviated example to illustrate the approach and the types of information each requires and generates.

The User Profiles Approach

Most environments are used by different types of people who are likely to differ in their basic needs. Environmental needs are basically homogeneous within the user types, however. Typical types of groupings are stage in the life cycle, stage in the development process, ethnicity, social class, role, job function, and so on.

Build a detailed picture or profile that catalogs the special behavioral patterns, preferences, environmental needs, and vulnerabilities, such as mobility status, agility, dexterity, sensory acuity, and the like, that are associated with each of the particular types of users of the site. From this profile derive design requirements.[9]

Basic Steps

- Identify user types.
- Construct user profiles of each group.
- Derive design requirements for each.

For example, one of the types of users of a public pedestrian system is the elderly. Among the characteristics of this group identified in the user profile is an increasing opacity of the eye lens that makes it difficult to locate and isolate critical edge conditions in the visual field. This condition is exacerbated by declines in balance, response time, general agility, and by much greater risks of serious injury in falls, and the like. From these characteristics, it is possible to derive a number of design requirements, for example, for a pedestrian system:

- Public signs should have a contrasting border to facilitate isolating the sign from its background.
- Steps should have their leading edges marked by a 2-inch stripe that contrasts sharply with the background tread and riser color.

The major strength of this approach is that it deals holistically with all of the characteristics of a particular type of user (e.g., behavior patterns, physiological, psychological, social, economic, etc.), which might have an effect on environmental needs. Beyond simply serving as a source of programmatic material or design requirements, the material contained in the profile should also enhance the designer's understanding of the users for whom the design is intended. This should enhance the ability to go beyond simply satisfying the requirements of the program in searching for and evaluating solutions.

The major weakness is that it is dependent on a good archival system with relevant information organized so that it is accessible to a programmer/designer. Constructing a profile can be time-consuming, but this is counterbalanced by the fact that once constructed, the profile can be used for other problems and by other programmers.

The Social Psychological Functions Approach

This approach to developing design requirements involves focusing on particular processes or functions that are affected by the environment. The procedure is to identify the particular process (e.g., social interaction, way finding, crime, stress, etc.), that the design should support (or in certain instances prevent). Then, based upon knowledge of the way the environment affects that process, derive the design requirements.

Basic Steps

- Identify the function (e.g., social, psychological, physiological, etc.) to be supported or suppressed (e.g., image formation, burglary, stress, etc.).
- Identify the characteristics in the environment that affect this process.
- Derive performance statements or design requirements.

For example, the goal is to facilitate rapid, accurate, and comprehensive mental map formation for newcomers to a college campus. Recall of elements such as landmarks is directly affected by their visual exposure. From this relationship, it is possible to derive design requirements for making a college campus imageable. For example,

- Organize the pedestrian path system so that new students would be visually exposed to the major facilities, settings, and so on, of the campus during their normal daily routine.

Similarly, if one wanted to facilitate friendship formation in campus housing, a number of design requirements could be derived from the extensive work done on the relationship between physical setting and interpersonal interaction.[10] These requirements might deal with the organization of doorways and pedestrian systems, the clustering of units around courtyards, and shared facilities such as laundries, mailboxes, car wash areas, tot lots, and the like. The work of Oscar Newman[11] has resulted in a wealth of design requirements for a variety of environmental settings and population types that are aimed at reducing criminal behaviors and vulnerability to crimes of various sorts.

One of the strengths of this method is that it enables the programmer to deal with environmental needs of which the user may be unaware. On the other hand, it relies on having theory that explains how the environment affects a particular social or psychological process.

The Behavior Circuit Approach

Design requirements can be developed by focusing on the behavior of typical individual users of the environment. The stream of behavior of an individual can be broken into coherent segments or sequences that are related to particular environmental settings.[12] Because of the habitual nature of much of behavior, it is possible to describe a very significant portion of a person's stream of behavior by a relatively few recurring behavior circuits. The routines of going to work, going shopping, going to school, and so forth are relatively stable in both their spatial and temporal patterning. They tend to be similar for different individuals.[13]

In the behavior circuit approach, one identifies the major sequences of behavior of a particular user type. These sequences can be broken down into discrete behavioral units and the environmental characteristics can be specified that are required to support, prevent, or discourage them at a particular level of adequacy.[14]

Basic Steps

- Identify predominant behavior sequences for each user type (going to work, going shopping, etc.).
- Break each of the circuits into discrete behavioral units (walk to bus stop, wait for bus, etc.)
- Specify the level(s) at which the behavior is to be supported.

  Safety/survival

  Task efficiency

  Comfort

  Pleasure/enjoyment

- Using a checklist of environmental attributes, derive the design requirements for the setting(s) in which that behavior is to occur.

  Spatial form. Such things as the size, shape, and character of bounding surfaces; internal organization of objects; connection to other settings, and so forth

  Communications. Both implicit and explicit signs, symbols, and such communicating information needed to carry out the behavior in question

  Activities. The type, pattern, intensity, and scheduling of the other behaviors potentially occurring in the same space at the same time, which might act to support or constrain the behavior in question

  Ambience. Light, sound, smell, microclimate, and so forth

- Repeat for each behavior in the circuit and for each user type.

This approach is systematic and concrete. It focuses on behavior so that design implications become obvious. It provides comprehensive and detailed programmatic information. It tends to focus on overt physical behavior, not on internal processes such as environment perception/cognition or user satisfaction.

The Behavior Setting Approach

This approach focuses on areas or settings within which there are relatively stable patterns of recurring behaviors. So, instead of building up a program by looking at the sequences of

behavior of typical individuals, this approach identifies the patterns of behavior within a particular setting or area. Most action settings or behavior settings have a particularly enduring form in space and schedule in time. Usually, a particular physical and social form supports a particular set of behaviors and coerces or constrains the behavior of people within it. The people, objects, and events inside the settings are ordered in a bounded pattern that takes its form in response to the recognized needs of the activity going on in it. Most such settings exist as a part of a larger structure of settings (e.g., a classroom within a university), they exist independently of particular actors and their actions, and the pattern endures over time.

To generate design requirements by using this approach, one must identify the predominant recurring patterns of behavior in the setting. Then, by breaking the patterns of behavior into discrete units, it becomes possible to derive the setting characteristics that are required to support each behavioral unit at a particular level of adequacy. The process is basically the same as that for the behavior circuit approach. As in the previous case, this approach is highly systematic and is focused on overt, concrete behaviors. This approach focuses the programmer on relatively stationary patterns of behavior and on groups, as opposed to the typical circuits of an individual.

The User Participation Approach

The approaches previously described for generating design requirements rely for the most part on experts to develop the information. User participation in the process is usually relatively passive. It takes the form of responding to questions posed by the researcher/programmer. The user's needs are developed through the programmer expert. User participation enables the user to participate much more directly in the process of developing design requirements. Professional expert programmers and designers are still a part of the process, but the professional skills that they use most are those dealing with the facilitation of group processes.

A number of specific user participation programming methods have been developed. Each method involves variants of the following approach. First, the users, their representatives, or surrogates must be assembled and their role in the process decided. Next, they begin an intelligence phase. As individuals or small groups, they systematically examine their environment and try to identify assets or strengths—those aspects that currently function well and warrant preservation in the probable future—and problems or weaknesses—those aspects that do not function well or are not anticipated to do so in the future and consequently need modification. Often, this process is done using simple disposable cameras. Each user participant is issued a camera and asked to photograph the elements they see as problems and assets. These photographs are then used to communicate with the group and with the programming team and designers. This phase of individual analysis is usually followed by a group process in which the whole group agrees upon and prioritizes a list of problems and assets. This phase is followed by an exercise wherein individuals or small groups are assigned the task of envisioning possibilities and thinking about what qualities an ideal setting might have. The group then comes together to formulate group ideals. Then follows a period wherein all three sets of programmatic conceptions, problems, assets, and ideals are combined into an agreed-upon program.

Basic Steps

- Client assemblage
- Individual assessment of problems and assets
- Group agreement on a prioritization of problems and assets
- Individual identification of ideal qualities
- Group agreement on ideals
- Group agreement on problems, assets, and ideals, or "the program"

The primary factor that most distinguishes this approach from the others is the involvement of the users in an active role. The characteristics and availability of the clients/users determine the type of participatory approach, or even whether one can be used at all.

Visual Programming

Most users have difficulty articulating their preferences and dislikes for the visual character of places, even though this character is of considerable importance to them. One way of overcoming this limitation is by using a technique called visual programming. The approach can be done in several ways, but the following is typical. First, assemble a set of 100 photographs that represent the full range of appearance types for the type of building or facility being programmed. Select a sample of the different types of users. Ask each to sort the photographs into 10 equal piles, ranging from the ones they like best to the ones they like least. Then, have them sort the least and most preferred piles in order from those least liked to those most liked. Then, have them describe what it is about the environments shown in each that causes them to like or dislike it. Keep track of the preferences for all the participants and look for patterns of likes and dislikes. Use these images to convey directly to the designers and others the preference patterns that emerge.

Basic Steps

- Assemble photographs.
- Individuals sort according to preferences.
- Individuals describe features or characteristics they like and dislike.
- Programmer analyzes all responses for patterns of likes and dislikes.
- Photographs are used to communicate preferences directly to designers and decision makers.

DETERMINING BUILDING REQUIREMENTS

Once the mission, functions, and activities of each of the units are described (and redesigned if needed), it is necessary to describe the space, equipment, and infrastructure needed to carry out the activities.

Space Requirements

There are several approaches to forecasting the amounts of space required. Because any method of forecasting the future is potentially fraught with error, it is a good idea to use multiple methods, especially if they go about the task in very different ways and use different information as the basis for the projection. Following are the descriptions of three basic methods, ideally used in combination with one another. The trend projection and the gross area method are used as checks on the total area estimate produced by the method of detailed requirements. None is very precise, and each relies heavily on informed judgment.

Detailed Requirements Approaches. Because this approach is based on detailed descriptions of the space required for each activity or employee type, it is often seen as the most accurate. However, we must remember that small errors multiplied many times can yield large mistakes. There are several variations of this approach. The description of one version follows, and then variations are suggested. The basic process involves determining the footprint

or area required for each of the different types of shared or unshared spaces such as workstations, laboratories, and conference rooms.

Project any changes in area or footprint that might be likely or planned for these space types. These may be driven by technology or work practice changes or by policies regarding space use. For example, when distributed computing using personal computers was first used, there was a net increase in the amount of space required for office workstations to accommodate the desktop personal computers and additional peripheral equipment such as printers, scanners, and modems. Policy changes may reduce the area required. This was common in the cost-driven 1990s, during which companies had consciously reduced real estate costs by reducing the sizes of workstations. Once the future area requirements for individual space types are determined, then the required numbers of such spaces that will be required in the future must be determined. For spaces assigned to individuals, this requires projecting the future number of employees of that type, which is usually done by the managers or heads of each functional unit. Shared spaces such as conference rooms also need to be projected. Often, these are based on a ratio of support spaces per number of employees or individual workstations.

Use patterns can also affect the amount of space required. The practice of *hoteling,* or unassigned nonterritorial workstations where there are more employees than workstations, is an example. In this case, it would be necessary to determine the ratio of employees per workstation to project the total. A change in work practice such as a shift to teamwork could involve a shifting of space by reducing the size of individual workstations to allocate space for team rooms for collaborative group work.

Determining the Footprint. There are several ways to go about this process.

Space Standards. As noted before, many organizations have adopted standards for space types. These often include the footprint enclosure type such as panels or partitions, furniture, and equipment. These standards prescribe the space, furniture, and equipment provided for each type of employee. They also often spell out the sizes, furnishings, and equipment of shared facilities such as conference rooms and a formula for determining how many should be provided. These standards are usually published as a policy guide and are available from the facilities manager.

Standard Practice. There are also many standard architectural references that describe the typical size, layout, equipment, and other special requirements for a wide range of spaces for many different building types.[15] The standards are good guides. They are based on conventions of practice gained from wide experience over many years. They need to be examined by the user representative for their appropriateness to the particular case. They may also not reflect the latest developments in technology or practice.

Estimating the Size of Spaces. Estimating the size of spaces for which there is no standard is one of the most difficult and important tasks in programming. The project team should work on this task with a knowledgeable representative from each of the organizational units. That person may in turn have to involve particular employees who have special knowledge about a particular space, operation, or piece of equipment. The project team should also recognize the need to assist in the task of determining the space requirements. This assistance may take the form of having a member of the programming staff simply ask good questions. Often, a checklist is a good idea to ensure that the user representatives think through all of the possible requirements and visualize and estimate the space required for equipment, access, and so forth. There is a general tendency for everyone to overestimate the amount of space they need. One good way of getting users to think more conservatively about this is to make them aware of the costs of space. For example, knowing that each additional square foot of space will cost $175 to construct with an added 10 percent of that every year thereafter for maintenance and operating costs will get most users to think much more carefully about their space needs.

GRAPHIC METHOD: Work with the user representative to lay out the space at a scale of ¼ or ⅛ inch to the foot on standard graph paper. On a separate sheet, lay out to scale the

footprints of all equipment and furniture needed for the space, and cut out these pieces. These dimensions may have to be obtained from the manufacturer's specifications or product brochures. Have the user representative consider any necessary clearances, such as door swings for cabinets or refrigerators, and the like. It may also be necessary to do a cutout for typical circulation spaces. Then, work out a basic layout of the space, taking into account the circulation and access to other spaces or corridors, and their work process. This first layout may be overly generous or too small. The project team representative should work with the user representative to ensure that it is a workable and efficient layout. Discuss and explore options that might improve the layout. It is possible to do this in a group workshop with user representatives. This can shorten the time required by the project team representative. The interaction among the user representatives can stimulate useful insights and ideas for improving the layout and prevent oversights. Finally, confirm the layout with the user representative.

EXISTING EXAMPLES AND PROTOTYPES: Many spaces are simply relocations to a new facility or a new location. In these instances, the amount of space, the layout, and special requirements can be derived from an existing example. The user representative and the project representative (and the actual user if the use is highly specialized) should meet in the space. If there are several variations, then they should all be examined. Discuss the pros and cons of the existing arrangement and ways it might be improved. It is useful to work this out on graph paper, as described earlier. Visiting other facilities that have innovative and successful examples of the types of spaces being proposed is also useful.

Determining the Total Net Building Area. After all of the individual areas or footprints for each space type are determined, the next step is to calculate the net building area. This involves totaling up the areas for the different types of spaces identified previously:

- For assigned spaces where each space, such as an office or workstation, is dedicated to one employee's sole use, it is necessary to project the number of employees who will be assigned to that type of workstation (e.g., managers, technical, clerical, etc.).
- Multiply the projected number of employees for each assigned space type by the footprint to obtain the net area required. Repeat this calculation for each assigned space type.
- Many spaces such as conference rooms and mailrooms are shared by users. Determine the number of employees per shared space type (e.g., one conference room for each 100 employees).
- Divide the total number of employees by this ratio to determine the number of shared spaces required. Multiply this figure by the footprint area required for shared spaces. This will yield the net area required for shared spaces.

Adding the assigned and shared space totals still yields only the net assignable area.[16] It does not include the area required for the building walls, circulation, core, and other building services. (See Fig. 4.2-2.)

Calculating Total (Gross) Building Area Required. A final factor is needed to convert the net assignable area to the total or gross building area required. *Failure to include this factor can lead to a serious underestimate of the space needed for the building.* The conversion factor varies considerably with the type of building. This factor may be obtained in two ways. Derive it for current facilities by subtracting the net workstation and shared spaces identified earlier and determining the ratio. Or standard conversion factors can be used. See Table 4.2-1 for some examples.

Checking the Gross Area Estimate. The total or gross area derived from the detailed requirements method is subject to the error produced by adding together many small errors or miscalculations. It is useful to check this against other benchmarks. There are several ways of doing this.

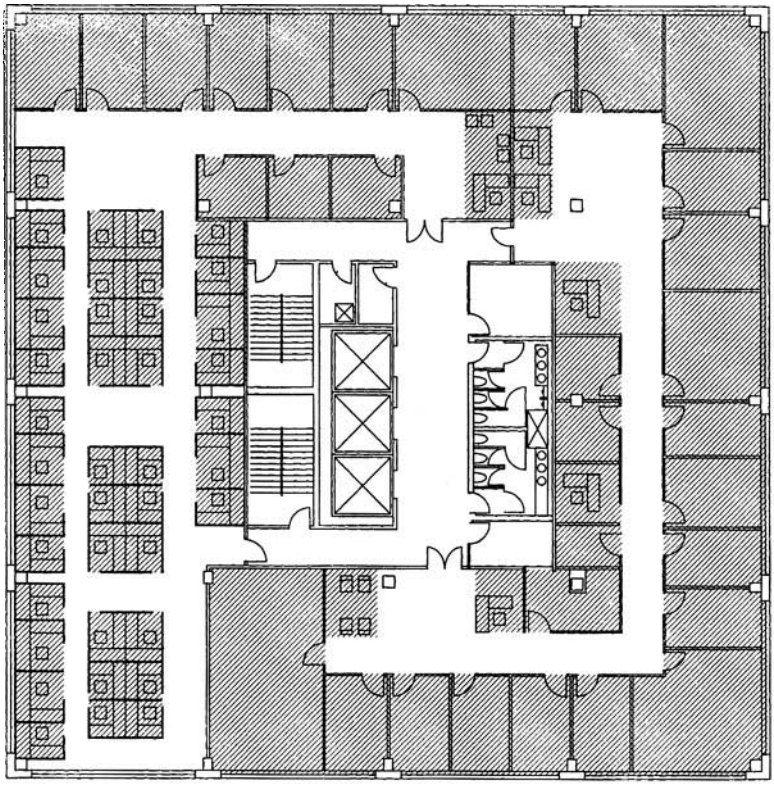

FIGURE 4.2-2 Net assignable area. (*Courtesy of William Sims and Frank Becker.*)

Trend Projection. The simplest method (and because of that simplicity, often the best method) is to project a historical trend. In certain industries, such as the high-technology area where growth has been so explosive and the actual specifics of the requirements are so unpredictable because of the rapid creation of entirely new technologies, this has been the only way that the industry could ensure that they had the needed space on hand when it was needed. Uncertainties or probabilities can be added to the trend projections to produce a range of possible outcomes.

TABLE 4.2-1 Calculation of Gross Square Footage

Building type	Net-to-gross conversion factor	
Office	1.35	1,000 nsf = 1,350 gsf
Laboratory	1.71	1,000 nsf = 1,710 gsf
Bank	1.40	1,000 nsf = 1,400 gsf
Warehouse	1.08	1,000 nsf = 1,008 gsf
Apartment	1.56	1,000 nsf = 1,560 gsf
Hospital	1.83	1,000 nsf = 1,830 gsf

Source: Means Assemblies Cost Data, 1989.

Gross Area Factor Approach. This is also a very simple approach to space projection. The first step is to determine the current space usage for some factor that can be projected, typically employees (e.g., divide the gross area by the total number of employees), but it could be sales, product output, and so on. This current area factor can then be modified for future changes based on changing technology, work practices, or policy changes (e.g., a decision to decrease the amount of space per person by reducing the average size of workstations to some benchmark derived from industry best practices, the decision to use hoteling, or to move to a paperless office). The next step is to project the future number of employees. This may be done by asking department heads to project their future employment needs over the planning period and adding this to a total for the organization. The number of future employees may also be estimated by using a trend projection. Finally, the modified area factor is multiplied by the projected number of future employees to obtain the required gross building area.

Benchmark Data. Finally, a number of organizations such as BOMA and IFMA maintain benchmark databases that contain data on the average space, per person, per unit of sales, and so forth, for various industries and building types. Many companies also benchmark their space use against their competitors'.

Utilization Studies[7]

Utilization studies are used to build a picture of the way the spaces are being used. The purpose is to build a picture showing who, when, and how people are using a particular workplace and associated equipment. Several times a day over a period of weeks, someone trained to work from precoded floor plans records the use pattern for the workplace. This provides data on the way spaces are being used, where people are working at different times of the day, and depending on the detail collected, what they are doing, and their pattern of movement in and out of their workstations.

Understanding how the workspace is currently being used is the indispensable starting point for determining whether a new workplace is needed. These studies provide decision makers with the basic data needed to develop recommendations for new designs and for strategies to make more efficient use of existing facilities. Utilization studies can also be helpful to support information collected through other means such as surveys and interviews. Typically, observed use patterns provide a much more accurate and valid view of work patterns than surveys or interviews. Conversely, information collected through utilization studies can be used to suggest questions to include in surveys and interviews.

For most time/space observations, only a recorder is necessary. This person can be anyone who is in the office on a regular basis and can spare a few minutes each hour to make a brief tour of the floor or area being observed. In many cases, a secretary or administrative staff person who has been given some training is a good candidate to conduct the observations.

The time required depends on the size of the operation. Typically, from less than 5 to 15 minutes is required for each data collection cycle with approximately 50 people or fewer per general location observed. For larger areas with large numbers of people, a single data collection could take an hour or more. Over a period of 3 weeks, this technique may require a total of several person hours. It is also necessary to train the recorder and to test that the forms are being filled out as expected. The only equipment needed is the observer recording form.

- Record over enough days of the week and over several weeks, months, or seasons, so that a representative sample of periods is included.
- Do not record during atypical periods (e.g., vacation season, right before Christmas).
- If there are predictable seasonable variations (e.g., the busy season for auditors), try to conduct observations that reflect these different seasonal patterns.
- Missing one or two observations periods is not a fatal flaw; the goal is to build up a credible picture of use patterns that most reasonable people within the firm will believe.

Basic Steps. Obtain a floor plan of the office where the group is currently working. If workstations and offices are not represented, manually add these components to the floor plan. Make a copy of the floor plan for each observation period. The person recording the information should indicate on the floor plan if

- Each workstation, office, conference room is permanently vacant [the workstation shows no signs of having been occupied (no code)], temporarily vacant [the workstation shows signs of being occupied—briefcase, papers, etc.—but is unoccupied at the moment (code = V)] or occupied (see the following).
- If occupied, the number of people using the workstation at the time.
- If occupied, the task being accomplished:

  Working on the computer (code = C)

  Reading materials (code = R)

  Talking on the telephone (code = T)

  Paperwork (code = P)

  Meeting (code = M)

  Other (code = O)

Leave appropriate space on the floor plan for the recorder to fill in information, or develop a coding system for the recorder.

Adjacency Analysis

Another important tool in the programmer's kit is *adjacency analysis* (or affinity analysis as it is sometimes called). This is a procedure that analyzes the communication patterns within an organization to determine desired spatial relationships or adjacencies among the individual spaces. Most computer-aided facility management and design programs use automated versions of this tool to carry out stack and block planning leading ultimately to the floor plan layouts of the facility. Typically, locational requirements are based on communications, joint tasks or projects, shared files, shared equipment, paper flows, task sequences, and on avoidances. In large organizations the analysis usually occurs at two levels—among units and within units. When determining desired adjacencies between organizational units, the analysis looks at group-to-group connections and group-to-ancillary facilities. Within-unit analyses focus on individual user-to-user connections and on such relationships as individual users to shared equipment and spaces.

Relationships
Within unit:

- User to user
- User to shared equipment spaces

Among units:

- Group to group
- Group to ancillary facilities

The basic process usually consists of a *communications survey* to determine the desired relationship patterns. This is summarized in an *adjacency matrix* that displays the adjacency requirements between units on a scale ranging from absolutely required, important, ordinary, and unimportant to undesired. This matrix is then transformed into a *bubble diagram* in

which bubbles represent units and the lines that connect them represent the relationships. By manipulating the bubble diagram, it is possible to optimize the relationships into patterns. If the building is multistoried, then the bubble diagram can be used to produce a *stack diagram.* This is a diagram in which the vertical scale represents the floors of the building and the horizontal scale represents the area on the floor. This diagram is a very fast way to allocate units to floors on the basis of their adjacency requirements. Once the units are allocated to floors, the next step in the process is the *block diagram.* In this diagram, the bubbles are replaced by rectangles sized to represent the areas of the units. These rectangles are arranged within the basic outline of the floor plate of the building if the task is space planning an existing building. If a new building is being designed, then the basic block diagram or block plan can be used to inform the overall layout of the building.

Once the blocks are established, then the within-unit adjacency analysis can be used to guide the layout of the unit in much the same way as the overall process. (See Fig. 4.2-3.)

The Communications Survey. The communications survey may be based on direct employee ratings or on expert ratings based on a formal communications analysis. Typically considered are the means of communication such as face-to-face, by mail, or electronically by phone, e-mail, videoconferencing, and the like. Other factors such as the frequency, urgency, and necessity of the communication may also be considered. This survey should also identify other factors that affect the need for adjacency between organizational units or between individuals such as joint tasks or projects, shared files or equipment, or work process sequences. Equally important is the need to identify avoidances such as reception or a high-security R&D area.

The Adjacency Matrix. Analysis of the results of the communications survey will yield the information needed to construct the adjacency matrix. This is a simple two-way matrix that identifies the adjacency requirements between any two organizational units (or the spaces they occupy). The adjacency requirement is a judgment rating based on the information from the communication survey. It is a simple rating usually on a four- or five-point scale:

1. Absolutely required (immediately adjacent)
2. Important (on the same floor)
3. Ordinary (in the same building)
4. Unimportant (unimportant)
5. Not desired (located as far away as possible)

The Bubble Diagram. The bubble diagram is a simple graphic tool for analyzing and communicating the desired spatial relationships among units. It can be simple, showing only the importance of the relationships among units, or it can contain a range of information about the relative size of units and other information about the nature of the spatial connections among them. The required adjacency relationship can be shown as a number or letter or can be represented by the thickness of the line connecting the units.

The bubble diagram can also be used to determine groupings of units. The relative spatial area of the units can be represented by the size of the bubble. The next step is to arrange the bubbles so that the lengths of the heaviest lines representing the most important connections are minimized. This may take several iterations to achieve an easily comprehended diagram that shows the relationships and identifies important groupings. In a new building design, these groupings and the relationships among them can be used to determine which units need to be immediately adjacent, near each other, or just on the same floor or whether a multifloor building is even desirable. When allocating units to an existing building, the diagram can be used to determine which units should be grouped together on the same floor and which should be on adjacent floors. Many CAD/CAFM programs have automated this process.

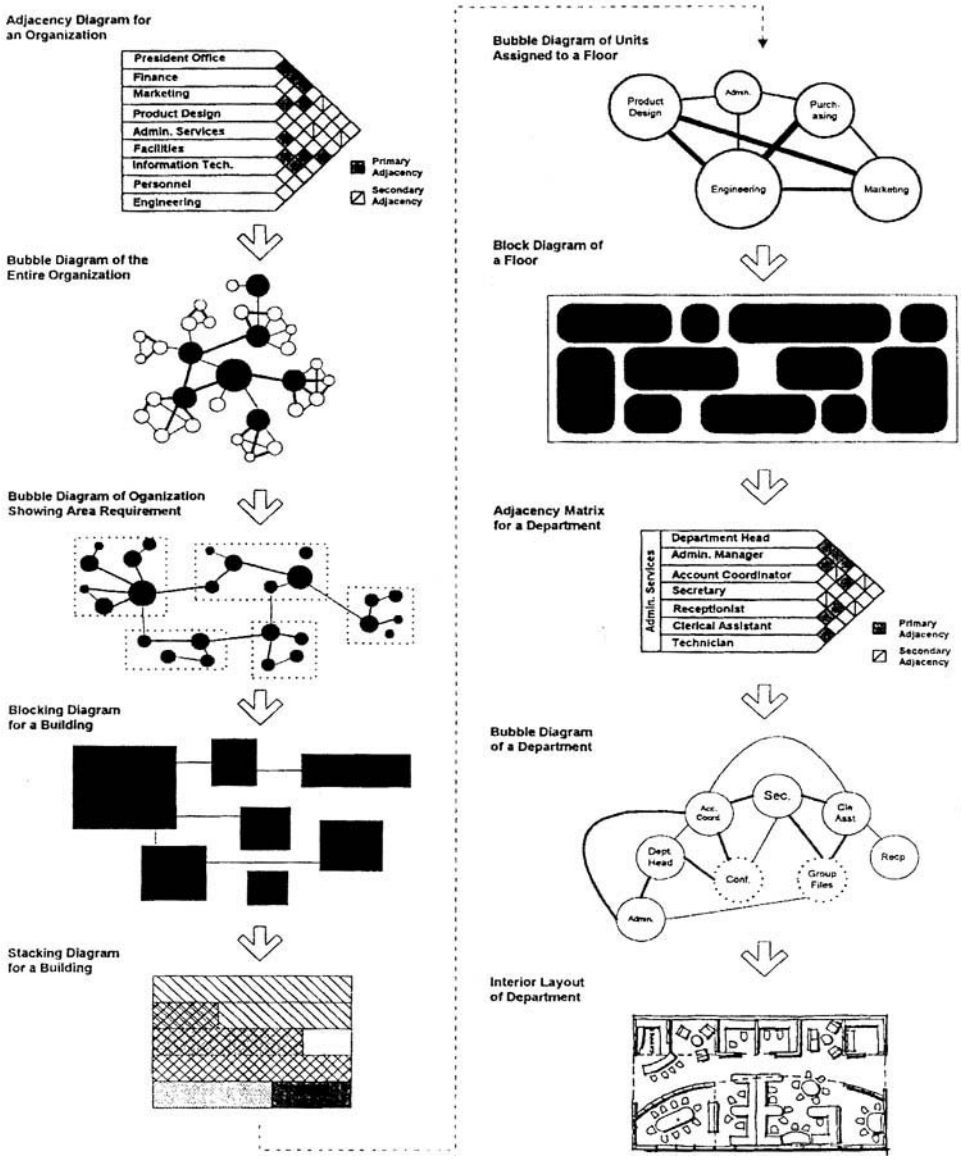

FIGURE 4.2-3 Adjacency analysis. (*Courtesy of William Sims and Frank Becker.*)

Stacking and Blocking Diagrams. These two tools verge more on the planning and initial design of the building, but it is useful to show how they relate to the previous two phases.

If the building is multistoried, stacking diagrams are the first step in allocating units to floors in the building. The stacking diagram is an efficient way of determining this pattern because it focuses solely on fitting units with high adjacencies on the same or adjacent floors. It is a simple graphic tool resembling a bar graph. The vertical units of the stacking diagram represent the floor levels of the building. The horizontal dimension represents the area of the floor to some scale. The process of stack planning is to allocate units that have high affinities

Next Page

to the same floor. A bar representing each unit is then placed on the desired floor with other units to scale until all of the floor area is consumed. If floors are too small to accommodate all units that have high affinities, then some units may have to be placed on adjacent floors or in the case of a new building, the floor plate may be increased in size. Often, several trials may be necessary to arrive at the best grouping that most closely uses the areas available on the floors and achieves the best adjacency pattern.

Once the units have been allocated to floors in the building, then the process of block planning can occur. In block planning, rectangles representing the areas of each unit are arranged within a diagram of the floor to which they were allocated. This diagram also shows the main core(s) and major circulation of the floor. As in stack planning, it may be necessary to rearrange the location and configuration of the areas representing each unit several times to reach an optimal block plan.

Within-Unit Adjacency Analysis. Once the overall block planning for the building has been completed, the next step is to repeat the process within each of the units. The basic procedure is the same, except that now the focus shifts from unit-to-unit adjacency to individual-to-individual users. Thus, the communication survey focuses on interactions between individuals within the unit and with shared equipment and spaces. It may also be necessary to include connections with individuals from other adjacent units. Similarly, a within-unit adjacency matrix is constructed, followed by a bubble diagram and a block diagram for the unit.

Equipment and Support

Factors often left out of programming exercises or given short shrift include many of those necessary to guarantee a well-functioning facility. Many of these are listed here:

Shipping and Receiving

- Loading and dock space
- Temporary storage
- Secure storage
- Berthing space
- Access to dumpster
- Centrality
- Proximity to freight elevators
- Proximity to primary users

Security

- Operations center location
- Guard posts
- Personnel access system
- Vehicular access system
- Executive access system
- Access by visitors and nonsecure personnel

Mail and Distribution

- Access to national mail system
- Distribution/collection schema
- Secure storage
- Access by external messengers

Motor Vehicle Pool

- Overnight storage
- Daytime parking
- Pickup/drop-off points

Previous Page
Copyrighted Materials
Copyright © 2001 Knovel Retrieved from www.knovel.com

Shops

- Access to materials
- Sizing
- Access to freight elevators
- Locker room
- Security

Food Service

- Layout
- Access to staff
- Centralized or decentralized coffee bar
- Access for foodstuffs
- Egress for garbage
- Locker room
- Vending locations

Conference Services

- Stage
- Audiovisual requirements
- Acoustics
- Lighting and lighting controls
- Recording capability
- Seating—fixed or movable

Vertical and Horizontal Transportation

- Personnel elevators
- Freight or service elevators
- Escalators
- People movers
- Robots
- Location
- Access by people and goods
- Access to garages and roofs
- Security

Miscellaneous

- On-site furniture storage
- Custodial closets

Communications

- Closets
- Duct systems
- Location of file servers and network command elements

USING EVALUATIVE METHODS AS PROGRAMMING TOOLS

An evaluation of the current facility is a useful source of programming information. It is also a good idea to review other projects of similar type. Postoccupancy evaluations are especially useful because they will identify what has worked and not worked on those projects. Visits to projects that are considered especially good examples are also a good way of learning what to do and what not to do. Walk-throughs followed by meetings with informed users are an excellent way of learning about building types.

In recent years, building-evaluative tools have emerged that have important uses in programming. They were originally conceived as tools for evaluating buildings, but it soon became evident that they were equally useful for programming. One such tool, the Serviceability Tools process, provides a useful conceptual model that illustrates especially clearly how a performance appraisal system can be used for programming. The Serviceability Tools process is an ASTM standard process.

Postoccupancy Evaluation

The basic purpose of postimplementation or postoccupancy evaluations is to provide programmatic information to designers. This form of evaluative research involves systematic examination of a design once it has been completed and occupied for a reasonable length of time. This evaluation might range from a simple return visit by the designer to formal research, but its primary purpose is to identify what might be termed "the problems and assets of the design." Problems are those features of the design that through oversight or error do not meet the needs of its users and, consequently, should be modified both in the example evaluated and in future examples. Assets are those features of the design that work well and are valued by users. Assets should be preserved in renovation projects and incorporated into new designs. "Do what works, change what doesn't."

Designers can use the results of POEs as programmatic inputs. This will enable them to systematically improve the design of the overwhelming majority of projects that are repeated as slight variations on a theme: schools, prisons, parking lots, office buildings, and apartment condominiums. As Marcus has noted, this provides the designer with a way to link isolated building projects into a single design activity, aimed at discovering the optimal solutions to typical problems.[17] Robert Sommer described this process of incremental improvement of prototypes in his "Volkswagen Model."[18] He contrasts the activities of the producers of the Volkswagen Beetle, which consisted at that time of annual refinements of the basic Beetle design, with that of the Detroit designers who pursued a course aimed at producing a novel design each year with little reference to the functional successes or failures of preceding models. His analogy very nicely serves to illustrate the power of POE research in giving the designer the possibility of progressive design improvement, as opposed to purposeless variation.[19]

Using POE as programmatic input obviously requires that the designers have access to relevant evaluations or be able to conduct their own.

Basic Steps

Do a literature search for POEs that deal with:

- Similar settings (e.g., elementary school) or elements that make up the setting (classrooms, playground)
- Similar populations

Translate the findings to the specific problem.

Conduct a POE of the current setting.

Collect data that describe employee satisfaction with various elements of the current environment, the process used to plan and design it, and various aspects of behavior and performance. This may take the form of a survey, but a POE can also include other data-gathering methods, such as the use of focus groups, individual interviews, and workplace observations. A POE should be conducted of the existing environment, and then again after the initial completion of a pilot project (if possible) to provide benchmark data. Evaluation should continue at planned intervals, such as 6 months and 1 year, to allow for adjustment and to incorporate changes that are deemed appropriate.

In a pilot project, it is important to include as many participants as possible in all POE activities. The use of a survey makes it possible to collect information efficiently from a very large number of people. If users are sampled, be sure to include at least a few people from each functional area. Interview people responsible for managing, supporting, and maintaining the new workplace strategy, not just those working in it.

Some Tips for POE

- Consider adapting an existing survey to fit your specific situation rather than trying to develop a new survey from scratch.
- Closed-end questions (rating something or checking an item) are much easier to code and analyze than open-ended questions (calling for comments or opinions). A survey can be composed mainly of closed-end questions, but also provide the opportunity for comments. These help explain why people have answered as they have.
- Do not rely on a single method (e.g., a survey). Use a combination of methods that include observations of the way the space is used (which areas are not used and which are used differently than anticipated or have been modified by the users to make them more suitable), focused interviews, focus groups, and (if there are 50 or more people) surveys.
- Comparisons of the new workplace with the old are very helpful.
- Many aspects of the organization typically change at the same time there are changes in the workplace (e.g., management policies and practices, information technology, etc.) Identify all of these changes on a chart, and structure a discussion within the firm about the way these factors may influence what you are hearing and seeing about the workplace itself. Note that some changes affecting the organization may be external, relating to the economy or political situation.

Logistics. Postoccupancy evaluations can vary enormously in complexity and scope. They may involve a few focus groups and interviews with key informants during a few days, surveys sent to all participants, as well as observations and walk-throughs, and interviews and focus groups. Analysis of the information collected is likely to require several days, depending on the size of the project and the scope of the POE techniques used. Open electronic forums or databases can also be used for continuous feedback. Survey forms, focus group questions, and the like are used, as appropriate. Statistical software, including spreadsheet analyses and graphing (e.g., Excel) will also be needed to analyze quantitative data. Postoccupancy evaluations require knowledge of conducting simple statistical analyses (if surveys are done) and developing charts and graphs that accurately summarize data and the ability to synthesize information.

Sample: POE Survey. Excerpts from a survey (shown in Figure 4.2-4) designed to look at an office workplace are examples of how POE surveys can provide feedback on issues such as work effectiveness and employee satisfaction with the office design and planning process.

The major strength of a POE as a source of programmatic information is that it is based on an assessment of the performance of a real setting rather than on predictions derived from theory. Even in those rare instances where we have good theory, it is very limited in its relevance to the entire range of concerns that the designer of an environmental setting must consider. Looking at the overall performance of a real setting, on the other hand, provides one with a comprehensive and concrete list of attributes that work and do not work for particular client groups in particular situations. Given the limited state of environment/behavior theory, this holistic nontheoretical stance is probably the major strength of this approach. It does not work well for nonprototypical environments.

The Serviceability Tools.[20] The Serviceability Tools were developed for the American Society for Testing and Materials (ASTM) Subcommittee Eo6.25, part of Committee E6 on

Cornell Workspace Survey

PART 1: Background Questions

PART 2: Workspace Ratings

PART 3: Additional Questions

This survey typically takes 15 to 20 minutes to complete.

PURPOSE:
The purpose of this survey is to identify aspects of the workplace which work well or could be improved from the employees' perspective. No data will be associated with any specific individual.

COMPANY NAME _____

Building Name or Address _____

FIGURE 4.2-4 Sample postoccupancy evaluation (POE) survey. (*Courtesy of William Sims and Frank Becker.*)

PART 1. Workspace Environmental Checklist

Please rate your workspace on each of the characteristics below. First indicate your SATISFACTION with each item by circling the number that reflects your level of satisfaction. Then rate how IMPORTANT each of the characteristics is to you in the same way (circle the correct number).

If some factor is particularly excellent or needs major improvement, please record your thoughts in the last column. Otherwise you may leave the area blank. Space is provided at the end of the questionnaire for you to elaborate upon these points.

WORKSPACE ISSUES (Please rate SATISFACTION and IMPORTANCE)	Very satisfied	Satisfied	Neutral	Dissatisfied	Very dissatisfied	Does Not Apply
1. Size of your own assigned work area	1	2	3	4	5	N/A
2. Amount of surface area for work at desk or workstation	1	2	3	4	5	N/A
3. Space for individual file storage at desk or workstation	1	2	3	4	5	N/A
4. Space for storing binders and books at desk or workstation	1	2	3	4	5	N/A
5. Space to accommodate computer/typewriter/ telephone at the desk or workstation	1	2	3	4	5	N/A
6. Comfort of desk chair	1	2	3	4	5	N/A
7. Task lighting at workstation or desk (e.g. amount, color, glare, etc.)	1	2	3	4	5	N/A
8. Adjustability of task lighting at workstation or desk	1	2	3	4	5	N/A
9. Auditory privacy (e.g. not being distracted by office noise, other conversations)	1	2	3	4	5	N/A
10. Conversational privacy (e.g. not being overheard by others)	1	2	3	4	5	N/A
11. Visual privacy (e.g. not being distracted by others working or passing by)	1	2	3	4	5	N/A
12. Number of electrical outlets	1	2	3	4	5	N/A
13. Location of electrical outlets	1	2	3	4	5	N/A
14. Adjustability of temperature at workstation or desk	1	2	3	4	5	N/A
15. Opportunity to rearrange furniture and equipment at workstation or desk	1	2	3	4	5	N/A
16. Amount of individual display space for work-related items at workstation or desk	1	2	3	4	5	N/A
17. Amount of storage space for personal items at workstation or desk (e.g. coat, purse, etc.)	1	2	3	4	5	N/A
18. Accommodations for small (2-3 person) meetings at workstation or desk	1	2	3	4	5	N/A
19. Opportunity to display personal photos, art, mementos, etc. at workstation or desk	1	2	3	4	5	N/A

GROUP AREA ISSUES (Please rate SATISFACTION and IMPORTANCE)	Very satisfied	Satisfied	Neutral	Dissatisfied	Very dissatisfied	Does Not Apply
20. Access to other people with whom you need to work	1	2	3	4	5	N/A
21. Amount of group display space for work-related items within group area	1	2	3	4	5	N/A
22. Space for group file storage (near or within department area)	1	2	3	4	5	N/A
23. Artificial lighting in group area or floor (e.g. amount, color, glare, etc.)	1	2	3	4	5	N/A
24. Accommodations for small (2-5 person) meetings in group or department area	1	2	3	4	5	N/A

PART 2. Background Information

Please circle the letter next to the appropriate response, except where blanks are provided for responses.

1. What is your sex?
   a. male
   b. female

2. What is your age?
   a. under 21
   b. 21-25
   c. 26-30
   d. 31-35
   e. 36-40
   f. 41-45
   g. 46-50
   h. 51-55
   i. 56-60
   j. over 60

3. What is your position title? _____

4. What is your department or division? _____

5. On the average, how much time do you spend AT YOUR DESK per week?
   a. less than 8 hours
   b. 8-16 hours
   c. 17-24 hours
   d. 25-32 hours
   e. more than 32 hours

6. On the average, how much time do you spend IN OTHER AREAS WITHIN YOUR DEPARTMENT (e.g. working in a conference area, with a coworker at his or her desk, etc.) per week?
   a. less than 8 hours
   b. 8-16 hours
   c. 17-24 hours
   d. 25-32 hours
   e. more than 32 hours

7. On the average, how much time do you spend in parts of the building OUTSIDE YOUR DEPARTMENT per week?
   a. less than 8 hours
   b. 8-16 hours
   c. 17-24 hours
   d. 25-32 hours
   e. more than 32 hours

8. Please circle the letter which best describes your current individual workstation:
   a. Individual enclosed office (floor to ceiling walls)
   b. Individually assigned desk or workstation surrounded by high panels on at least two sides (i.e. cannot see over the panel when seated)
   c. Individually assigned desk or workstation surrounded by low panels on at least two sides (i.e. can see over the panel when seated) separating each desk or workstation in open plan office
   d. Individually assigned desk in a large shared group space (no panels around each desk or workstation)
   e. Shared enclosed (floor to ceiling walls) office for 2-4 persons in which each person has an assigned desk
   f. Shared group office (there are no individually assigned desks)
   g. Other (please describe briefly)

      _____
      _____

Part 3: Additional Questions

Please give your comments regarding the questions below:

1. What do you like most about your office workspace?

   _____
   _____

2. What do you like least about your office workspace?

   _____
   _____

FIGURE 4.2-4 (*Continued*)

Performance of Buildings. These tools were designed to enable organizations to rate the functionality of a building for office work. The scales are also useful as programming tools.

There are more than 100 scales in three groups (see the list in the appendix that is also useful as a checklist for programming topics). The scales in Group A, which cover the primary concerns of occupants, focus on requirements for group and individual effectiveness. The scales in Group B are about the property and its management. The scales in Group C provide a scan for issues involving laws, codes, and regulations. For example, under the category "Change and Churn by Occupants," potential occupants would rate the amount of disruption due to physical changes such as minor changes to layout and partition wall relocations that are tolerable.

"Over the years, buildings have been evaluated in many ways," says Gerald Davis, chairman of ASTM Subcommittee Eo6.25 on Whole Buildings. "Often, the evaluators simply reinvented the wheel, treating each project as a one-of-a-kind event and getting lost in the technical details. For building evaluations to be useful they must relate directly to the needs of the organization on issues that managers and users see as important for their organization and its employees to succeed." These same issues pertain equally to programming. Many programming issues are common among projects of similar building type, making it possible for statements of program requirements to be standardized, thus eliminating the necessity for time-consuming one-off drafting of the statements, as well as the resulting variability in quality. The task simply becomes one of picking the relevant requirements from the standard list and adapting them to the particular context, if necessary.

USING THE SERVICEABILITY TOOLS FOR PROGRAMMING

One group of Serviceability Tools, the *Occupant Requirement Scales,* are used to ascertain what functionality and quality are required. A questionnaire is used to identify the needs of the group that will occupy the proposed office building, as well as those of visitors, facility owners, and managers. The Occupant Requirement Scales, written in the language of office users, helps them to describe how their facilities should support operations. For each topic, such as meeting and conference rooms, shipping and receiving, or electrical power at the workplace, several options are provided, ranging from a very low level of requirements to the most demanding.

Each of these statements has a matching statement in the Facility Rating Scales, written in the technical language of facility managers, engineers, and architects. These more technical statements describe the generic features that are found in a typical office building in North America that meet the requirements of an occupant group with those operations.

The Serviceability Scales: Both for Setting Requirements and for Rating Buildings

Figure 4.2-5 is an example of one of the Serviceability Scales. Both the Occupant Requirement Scale (left column) and the Facility Rating Scale (right column) are printed on the same page. The left column gives occupant requirements, or the "demand side." The right column gives the "supply side"—a description of the building design strategy that will provide the required level of performance on the issue.

The scales function as a multiple-choice questionnaire. When setting the required level of serviceability, the client/user representative has only to choose which of the five paragraphs in the left column best describes what is needed. Each defines one level of serviceability, either 9, 7, 5, 3, or 1. If the actual requirement is partly described by one paragraph and partly described by the paragraph above or below it, then the requirement level would be an in-between number (i.e., an 8, 6, 4, or 2).

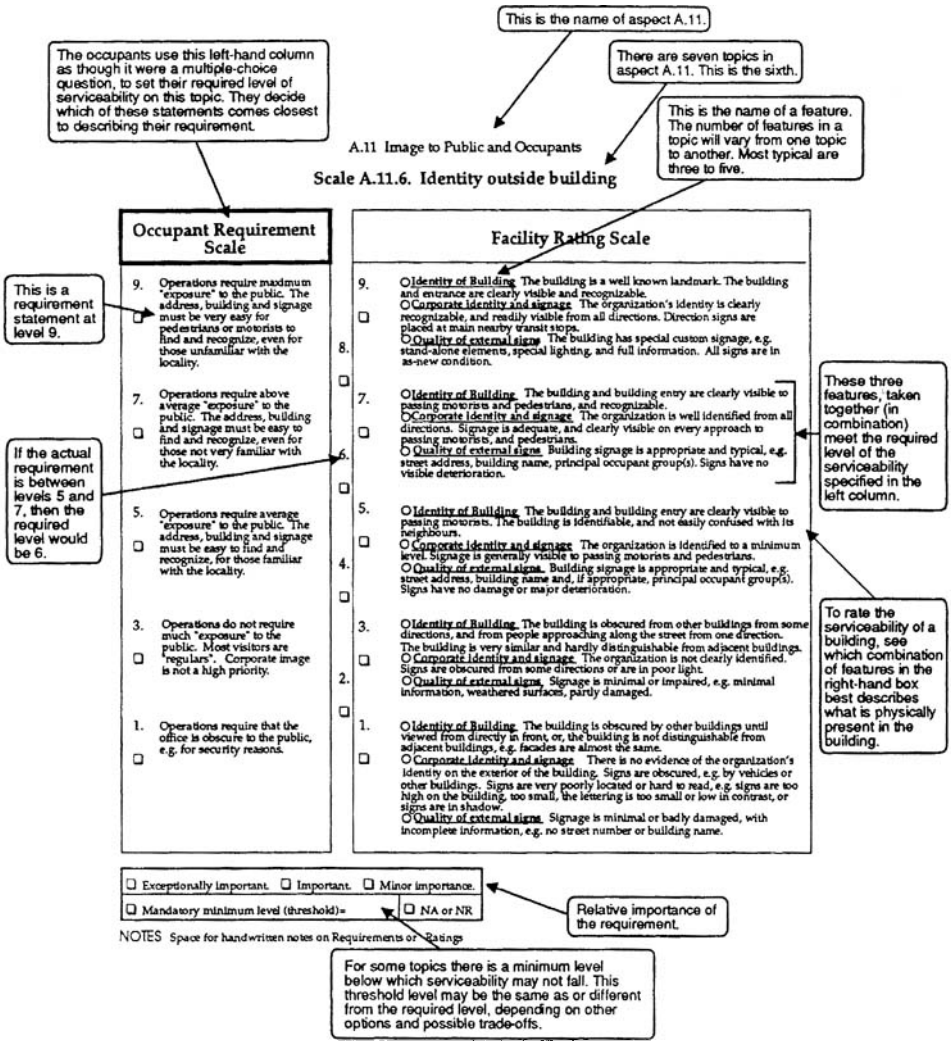

FIGURE 4.2-5 Example of a pair of Serviceability Scales. (*Courtesy of William Sims and Frank Becker.*)

Some requirements are more important than others. This relative importance differs from one organization unit to another, depending on their work and functions. At the bottom of the Occupant Requirement Scale is a place to indicate this relative importance. If trade-offs have to be made when setting a budget or selecting a place to lease, this can be vital information.

Many people who set requirements do not know whether a particular requirement would be more or less costly to meet. An additional Serviceability Tool deals with cost sensitivity.

In the Serviceability Rating Scale on the right side of the figure, the title of each feature is underlined. This listing at each level of serviceability makes explicit the range of features that are needed to deliver the required functionality and quality on that topic and how those features should change when higher or lower levels are required.

Using the Serviceability Scales to Program a New Facility or a Renovation

The Serviceability Tools can be used as programming instruments to set the requirements for a new building or to identify the changes needed in an existing one to meet occupant requirements.

New Facility. In the case of a new facility, all that is necessary is for the client/occupants to identify the performance levels required on the requirement scales. The designers can then compare those performance levels with the Building Scales to identify the design strategies that will provide that performance. They will then need to adapt those strategies to the special context and other specific circumstances of the project.

Renovation. For a renovation project, the task is similar. The Occupant Requirement Scales are used to identify the required performance levels for each feature. The Building Scales are then used to evaluate the performance of the building by comparing the descriptions of each of the design strategies with those in the building and selecting the closest match. This determines the performance level of the building for that feature. When there is a difference between the closest description, there is a process for modifying the performance score. These building performance profiles are then matched against the demand profile obtained from the Occupant Requirement Scales. When the two match, no renovation is required. When there is a mismatch, the building design strategy that matches the occupant requirement level identifies the renovation that is needed.

Using the Serviceability Scales to Evaluate a Proposed Design

When rating the serviceability of a proposed design, one looks on the Serviceability Scale for the description of the combination of features that best matches what is described in the proposal. As in renovation, a mismatch between the requirement scales and the building rating the requirement scales will identify the changes needed in the proposal. (See Fig. 4.2-6.)

Using the Serviceability Tools in Master Planning

For corporations and governments, for occupants and for building owners, the bottom line is better value for money. For building owners and custodians of real property who can more easily compare buildings in inventory and identify which are most likely to offer high functionality to the occupants or be easier to lease in future years, the bottom line is less vacancy, better fit, and higher returns.

The serviceability ratings can be used to identify those facilities that most closely match the particular requirements of an occupant organization. This would indicate which occupants could move in with the lowest fit-up cost and the highest expectation that their requirements have been met. The scales also provide an efficient and economical way of comparing properties offered for lease or purchase.

The manager or custodian of a portfolio of real property can use them to get an objective scan of the quality and functionality of properties in the portfolio. It will also identify any facilities in inventory that should be investigated in depth or that require special remedial attention, and it will call attention to any functional anomalies where the cost to cure might be significant.

Leasing agents can use this approach to scan available properties and short-list the best options for review by a prospective occupant or owner. Any professional and any occupant can use this procedure to learn how building subsystems and materials interact to provide an overall level of serviceability and how various serviceability requirements interact to determine building or facility serviceability. The process provides tangible benefits in enhanced understanding between people with different roles and particular mind-sets.

resentative may be able to ask questions or offer insights that trigger realizations of impacts that would have gone undiscovered if each representative were to work in isolation. Checklists of typical impacts of changes are also useful. Will this change affect the space needed, the electrical requirements, the HVAC loads, lighting, access, personnel, adjacencies, and so on?

PROJECTION TECHNIQUES

Delphi Technique[21]

The Delphi Technique can be used to arrive at consensus decisions, solve problems, or forecast future developments. It is helpful in forecasting the future needs of a group by bringing together the knowledge of all parties. After defining the issue, problem, or outcome, concerned parties are asked to provide written input on probable future outcomes based on their expertise or knowledge area. This input is made available to the entire group in full or summarized form. The group then provides written input on the results of the first round. These rounds continue until consensus is reached. The process allows participants to understand the positions of the group throughout the steps, resulting in a buyin to the final future projection.

The Delphi Technique allows people whose input is valued but are reluctant to participate in normal meetings to express their views anonymously. People from many locations may be involved because input is written rather than verbal. Experts who have specific knowledge relevant to the project should be involved. Their input may be enhanced as they synthesize the information from the rest of the group.

The Delphi Technique may be fairly time-consuming. This depends on how quickly rounds of input can be summarized and returned to the group for the next step. Also, some participants may take longer than others to complete each round in the process. The technique can be done more quickly by using automated communications systems such as e-mail or groupware software.

In its simplest form, no equipment is required to use the Delphi Technique. However, for the best results, particularly with remote participants, a computer system with e-mail capabilities or groupware can reduce turnaround time. Some organizations have even equipped conference rooms with networked personal computers especially for this type of idea sharing. The Delphi Technique can be somewhat difficult to use. It requires analytical skills and the ability to synthesize, edit, and summarize ideas succinctly. Without an automated communication system, using this tool with remote participants can be time-consuming.

Basic Steps

- Define the issue or problem.
- Have the team provide individual, written input.
- Summarize the team's input, and redistribute it.
- Have the team provide a second round of individual, written input.
- Summarize the second round, and redistribute it.
- If necessary, have the team provide a third round of individual, written input.
- Summarize the third round.

Brainstorming[21]

Brainstorming is a planning and consensus-building tool used to encourage suggestions from team members. One or two participants are specifically assigned the task of recording all

comments, but brainstorming essentially involves a group of people suggesting imaginable solutions to a particular problem, issue, or situation. It can be used in small groups to seek solutions to problems such as anticipating future changes, as well as to draw out nontraditional approaches to situations. Brainstorming is an effective way of generating new ideas. The premise behind brainstorming is that no idea is too outlandish or without merit. People are encouraged to suggest ideas as they come to them.

The entire planning team should be involved in any brainstorming sessions that focus on projecting the future context of the project. Teams of more than 12 are likely to be less effective than smaller teams. Because the goal is to generate innovative solutions, people should also be invited to participate who are known to have a creative way of defining problems, who come from other fields or disciplines, and who may be from inside or outside the company. If a brainstorming session is held to tackle a specific problem, make sure that all persons who have a stake in the problem are encouraged to participate.

Brainstorming sessions varying in duration from one-half hour to several hours can be quite productive. The session should be focused and have a clear end point. A congenial setting and food and drink may facilitate the free flow of ideas. Brainstorming sessions require minimal special equipment. A flip chart or overhead projector and markers are necessary for recording ideas and suggestions so that they may be seen easily by all participants. It is also helpful to provide a closed room for any brainstorming session to encourage participation and enthusiasm without disturbing others.

A successful brainstorming session requires a leader who has the ability to persuade others to participate in the process. One of the keys to productive brainstorming is an atmosphere in which no idea is considered too outrageous and all suggestions are recorded for later evaluation. Therefore, first, it is important to appoint a person to act as the session recorder who can capture many ideas quickly in a concise, legible manner. Next, set a time limit, and stick to it. If your participants discover that a productive 20-minute brainstorming session really takes only 20 minutes, they will be much more likely to participate again, enthusiastically.

Basic Steps

- Brainstorming begins with the first idea offered. It is useful to have a few thoughts before the session starts to "prime the well."
- Monitor the flow of information as others start to voice ideas and suggestions.
- Record ideas on a flip chart, and tape the sheets to a wall.
- If only some people are participating or if the ideas are flowing much faster than the recorder can capture them, switch to a round-robin method in which each person offers one idea at a time.

The following ground rules are helpful to encourage a productive brainstorming session:

- *Do not* edit someone else's contribution.
- *Do* build on the ideas that spark other suggestions.
- *Do not* criticize each other.
- *Do* contribute wild and crazy ideas—creativity is the goal.

GENERATING DESIGN REQUIREMENTS FROM THE DATA

In addition to planning the building to meet those needs that can be reasonably anticipated, programming also needs to address the issue of uncertainty. In spite of our best efforts and our predictive tools, it is still difficult to anticipate with any precision what the future may bring. All organizations are operating in an environment of change, but many fast-growth

companies are growing as fast as basic facilities and infrastructure can be provided. Lack of the right kind of space can inhibit the growth that otherwise would be possible. However, anticipating the right kind of space and the quantity needed is a virtually impossible task. The pace of change driven by global competition, changing markets, and technological innovation adds another requirement to this task of planning buildings that should last for 40 or 50 years. That is planning for unanticipated change. This is sometimes referred to as an exit strategy, but the concept is far broader than that. It involves thinking through how the building might be designed to accommodate a broader range of uses than that being planned for. There are many strategies that can be used to make buildings more receptive to changes:

- Planning the building to match needs of the broader market in the immediate area
- Providing for expansion
- Providing for internal subdivision of the building so that additional tenants can be accommodated
- Selecting structural modules, bays, and floor heights that can accommodate several different types of uses
- Providing multiple service entrances and risers that are generous in size and well distributed to accommodate a variety of service providers and increased levels of service

Several basic types of requirements become part of the program. First are those that derive from the overarching strategic vision or goals of the organization. These provide an overall direction and also help to provide for the overall organization of the project. Second are the requirements that derive from the mission, functions, and activities of each of the organizational subunits (divisions, departments, workgroups, etc.). These are followed by individual user requirements. There are also technical requirements relating to such things as the electrical power required to operate an elevator, the turning radius necessary for a semitrailer to maneuver into a loading dock, or the operational requirements of equipment. Another set relates to legal and regulatory requirements such as codes, ordinances, and standards designed to protect the public health, safety, and welfare or to implement governmental policy.

Now the task is to use the information that has been collected and analyzed to generate design requirements. Generating these requirements is an art that uses some of the tools of science. These requirement statements will be used to guide the search for solutions and to evaluate design proposals. The task is to make them

- Specific enough that it is possible to tell when a design satisfies the requirements
- Specific enough that they enable discrimination among alternative proposals
- General enough that they do not specify a particular solution

What does a good design requirement look like? Here are some examples.

Privacy

Management offices and conference rooms should enable full conversational privacy. Conversations at a normal speech level should not be discernible by someone in an adjacent space or passing by in a corridor.

Lighting

General ambient lighting should not create veiling reflections on computer screens or create direct-source glare for occupants.

Informal Communication

Selection and placement of circulation, stairs, activity generators (e.g., coffee, copy, mail) should maximize the potential for unexpected face-to-face contact in which spontaneous conversations can occur without visually or auditorily disturbing people in their workstations or offices.

These requirements do not specify how privacy, lighting, or informal communication are to be achieved. They do not say to use a 6-foot-high panel or uplighting or create small lounge areas. The design solution can reflect the designer's creativity and inventiveness. Second, they are not technical (although STC or NIC sound ratings could be specified). Rather, the intent is to state what is to be achieved, in terms that designers, the project team, and users can understand. Third, the requirements are specific enough to enable either the designer or the client to ascertain whether a design proposal satisfies them. Fourth, they are specific enough to be used to compare and choose between two design alternatives or perhaps to reject both and hence to continue the search.

Requirements can take several different forms that derive from different types of measurement and the state of the underpinning science related to a phenomenon.

Nominal. This is a simple categorical or binary measurement. Gender and job type are examples of nominal variables. "Provide a conference room" is an example of a design requirement using a nominal measure. Assessing the design is a simple yes or no question. Is there a conference room or not?

Ordinal. This is a ranking measure. Qualities can be ranked as in relative heights of people, but there is no way to determine the amount of difference. "Maximize the natural light in the classrooms" is an example of a design requirement using ordinal measurement. It does not specify by how much. In evaluating alternatives for this requirement, one would select the one that provided the most natural light.

Interval. In this case, there is a scale comprising equal intervals. But the zero point is arbitrary and does not indicate an absence of the quality being measured. The Fahrenheit temperature scale is an example. The scales used in the Serviceability Tools are examples. The requirement would specify that privacy at a level of 5 should be provided using the scales supplied.

Ratio or Metric. A scale of equal intervals exists, and the zero point is nonarbitrary. The metric system of measurement is an example. In this case, the requirement could specify that the main hallway should be a minimum of 8 feet wide or that lighting levels on the floor surface should be 30 foot-candles.

In certain highly critical areas such as acoustics or lighting, it may be useful to seek advice from human factors or acoustical experts who have a deeper understanding of the available research and more experience in assessing the adequacy of the requirements and proposed solutions.

ORGANIZING PROJECT GOALS, REQUIREMENTS, AND ASSUMPTIONS

Requirements need to be organized and displayed. A good method for this is the one developed by Peña in the "Problem Seeking Process."[2] Each statement is written on an 5-in by 8-in index card. These cards are purposely kept small so that only one idea or concept can be expressed on them. The cards are then pinned or taped to a wall where they can then be easily organized and reorganized. A card can be easily replaced as the idea it expresses is clarified or reformulated. This format allows easy reordering for editing and prioritizing.

Prioritizing the Requirements

The next step in the process is to prioritize or rank the goals and requirements that will guide the search for a solution. This is obviously a phase that must confront the fact that the project probably cannot accomplish all of the needs identified. The card system just described works well for this. The project team should rank-order the cards by using the data obtained. In the process of doing this, it is often possible to reformulate the concepts so that they can combine or consolidate requirements. Two other techniques for prioritizing are described later.

Instant Priorities[7, 22]

Instant priorities is a technique for reaching group consensus. It assists teams in establishing which requirements the group feels are most important. The process involves listing all requirements and having each group member complete an individual grid of preferences in which each requirement is paired with one other. Then individual totals are combined to produce a group total for each requirement. The group totals indicate which requirement received the greatest number of votes and how wide the gaps are between requirements, an additional piece of information that may help the group decide which requirements to consider. Instant priorities can also be used at the beginning of the project to help prioritize the goals and objectives of the project and simplify the number. Any employees who are instrumental in developing the design such as facility managers, MIS, HR managers, user representatives, senior managers, and others should participate in the instant priorities exercise. (See Fig. 4.2-7 for an example of an instant priorities chart.)

Logistics. Depending on the size of the group involved, instant priorities can be completed in a period of between 10 min to about 1 h.

Basic Steps

1. Agree on 10 or fewer requirements, and write them on the requirements form (on the next page) so that each one is numbered.
2. Give every member of the team a photocopy of the form with the statements written on it.
3. As individuals, work your way through the chart. In every gray square, circle the number of the requirement you prefer. For instance, the top box gives you a choice between requirements No. 1 and No. 2.
4. When you are finished choosing, enter the number of times you voted for each requirement in tally col. A.
5. Then, in col. B, identify your priorities by ranking the requirements—1 for the requirement for which you voted most (the highest number in col. A) and 10 for the statement for which you voted least (the lowest number in col. A). If there are tie votes in col. A, pick one or the other as the higher ranked item in col. B.
6. When all team members are finished, add their tallies (from col. A) together to get a group total. Column C is provided here to contain the group tally.
7. Once again, identify priorities by ranking the requirements, but this time as a group. Put the group rankings (1 for the group's favorite, 10 for its least favorite) in col. D.

Note: Column D gives you the group's decision. Column C, however, tells you how wide the gaps were between the top-ranked and bottom-ranked requirements—a vital bit of information. It may show you, for instance, that the top three requirements are the only ones really worth considering over the long run.

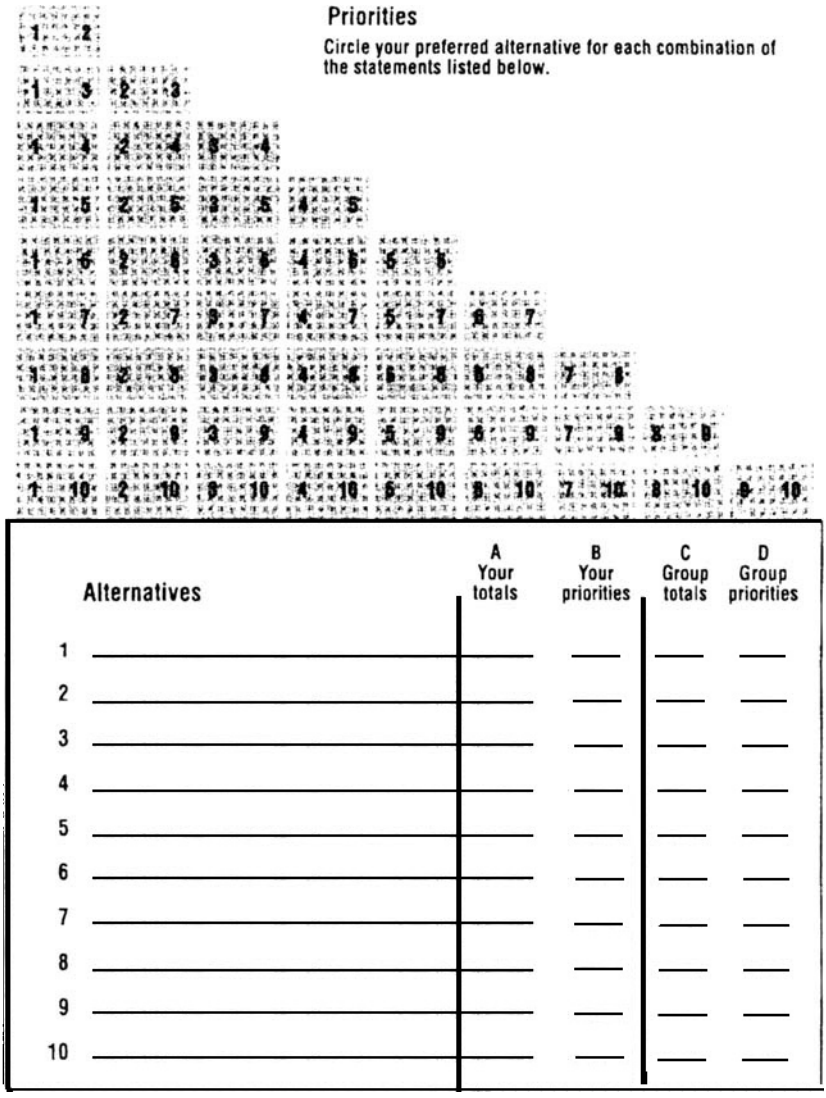

FIGURE 4.2-7 Sample instant priorities chart. (*Courtesy of William Sims and Frank Becker.*)

Nominal Group Technique[21]

The nominal group technique (NGT) helps teams select and prioritize requirements. Through silent voting and limited discussion, an NGT provides a way to give everyone in the group an equal voice in requirement selection. This is particularly helpful when the problem is sensitive or controversial. An NGT allows the whole team to participate in the prioritization process. An NGT produces team decisions with a minimum of conflict, yet allows discussion of the pros and cons of the alternatives. It can also be very useful in helping a group explore innovative solutions to the inevitable problems associated with a new design. All members of a

team, task force, or group involved in the decision-making process should take part. This may include planning team members, management, end users, MIS, HR planners, and so on.

Logistics. This depends on the number and complexity of the problems. Two to three hours should probably be scheduled. No special equipment is necessary.

Getting a Sign-Off on the Project Program

Once the prioritizing has been completed, the project team should arrange a meeting with the decision-making body. The purpose is to present the information and seek their approval for the project program.

SECTION 4.3
USING THE PROGRAM

William Sims, Ph.D., C.F.M., IMFA Fellow, Professor, and Franklin D. Becker, Professor
Cornell University, Ithaca, New York

Whether using a structured tool such as the Serviceability Scales or a more customized programming effort, it is critical that the information actually be used in the design process. Research has shown that even in cases where a good program document exists, it was not used by the designers to generate the design and, even more surprising, it was not used by the clients to evaluate the proposals offered.[23] In part, this can be attributed to the inadequacies of the relay model process in which changes at later stages rule earlier decisions and information irrelevant. At the same time, there is a powerful inclination among designers to follow their own ideas about what is needed and what constitutes good design. These may not relate to the client's interests. What can be done to change this?

Using the Program to Guide the Search for Solutions

In the rugby model of programming, in which programming and design are seen as a continuous and interwoven process, the program is always a part of the decision-making process. It is important to have an explicit process of referencing the program during the design process. The program requirements can be reordered in priority and changed or refined as the team learns more about the problem during the design process.

Something as simple as a periodic review in which the program is used systematically as a guide can be critical to keeping the design and the program related. This simple process will go a long way toward ensuring a design that complies with the requirements of the program.

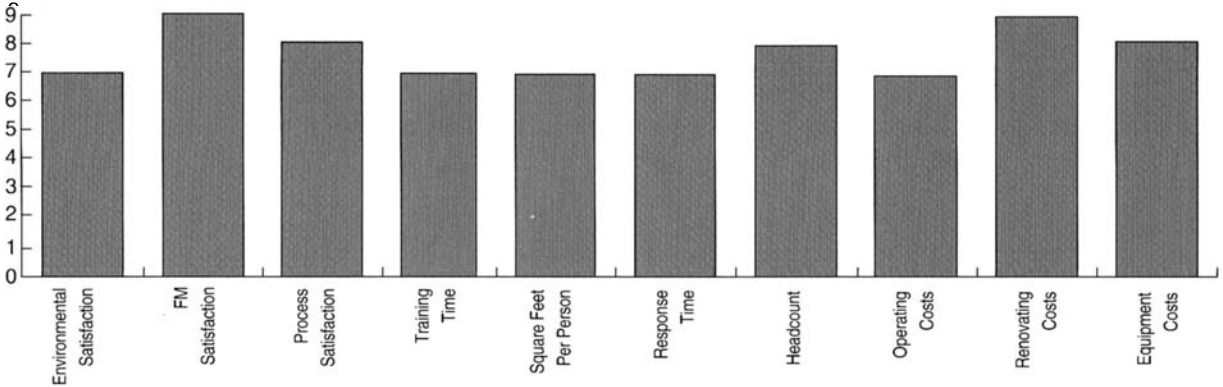
More formal procedures could involve developing a checklist with weights for priorities. Then, the design could be rated subjectively by members of the project team on a scale and the scores displayed in a matrix. It is also possible to have an organizational ecologist or environmental psychologist assess the effects of the design on things like way finding or informal com-

munication. In other cases, there may be formal models that can be used to calculate or estimate the effects of the design. Acoustic and lighting calculations are examples. These typically occur in areas where the science is relatively well developed and, as in the case of lighting and acoustics, there are computer programs that predict the performance of a design with a high degree of accuracy. It is important to not allow these tools, as convincing as they may be, to overshadow the process and compromise a holistic and balanced assessment of the design on the other requirements that may be more important but less easily or precisely assessed.

Using the Program to Evaluate Proposals

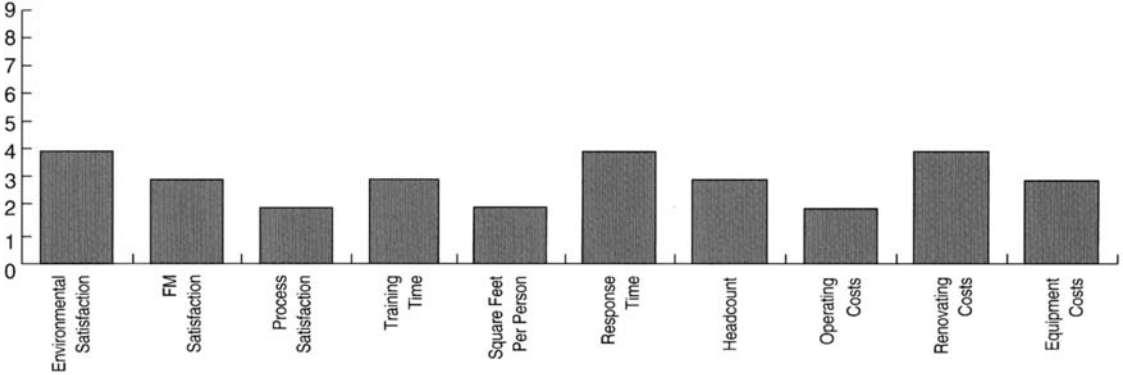
When two or three alternative design proposals have been generated that informally seem to "satisfice,"[24] then a more careful and formal process of evaluation and refinement is in order. Two procedures are useful for this process. They are (1) the performance profile and (2) the weighted matrix.

The Performance Profile.[25] The performance profile is a way of evaluating proposed design alternatives using a systems perspective. It stresses the overall pattern of outcomes. Performance profiles can be used to show the level at which the proposal performs in achieving the design requirements versus what was targeted. Employees and managers who will work in the proposed design and other people who are instrumental in the implementation should agree on a core set of measures to be depicted in the performance profile.



The time required to develop the performance profile varies significantly. If the measures are already in place and will be applied before and after the implementation, the profile requires only that the results be graphically displayed. The Serviceability Tools are an example of a performance profile tool that is available for use with no preparation required. The development of new performance measures and methods of collecting information will add a considerable amount of time to the task. Many software packages are available to graph the performance profile. Performance profiles are fairly easy to use. Again, the most resource-intensive task is developing the measures to display. (See Fig. 4.3-1 for a comparison of two performance profiles.)

Weighted Matrix. The weighted matrix is another way to compare alternatives for the program by using a systems perspective. First, construct a matrix for each solution, and in a careful way using a simple rating scale (+3 to −3), rate the degree to which it satisfies the program requirements. Also note whether any assumptions or givens were violated. Then, determine whether there are major impacts or consequences of the design that were not included as program requirements and need to be considered. Remember that the same issue may impact or affect different users in different ways. Also note that the impacts may differ in different regions or areas of the design. (See Fig. 4.3-2.)



Once the impacts are identified, it is necessary to place values on them. At the simplest level, are they good or bad? As in the case of the requirements, use a simple rating scale (−3 to +3). It is important to remember that different groups may value the same result differently. It may be necessary to recognize that certain groups weigh more heavily in the decision than others, and therefore it may be necessary to assign weights in the matrix. Similarly, different requirements may be more important than others and can be weighted. It is a good idea to leave room in the matrix for notes describing particular issues or factors about each of the evaluations.

Selecting a Preliminary Design

Now, all of the information is in the matrix that is needed to rank the alternatives. Sum the rows and columns, and determine the total score for each alternative. Remember that this is not a precise process, and it must be viewed in that way. Alternatives with relatively close scores are probably not really very different. Also, be sure to look at the pattern of scores

Alternative One

Alternative Two

because a solution with a slightly lower overall score may simply be weak in one area that can easily be modified to raise its score substantially. This information should be presented to management for a decision. (See Fig. 4.3-3.)

Design Development

The matrix can be used to improve and refine the selected design. Look at the patterns of scores. Is one user group treated poorly by the design (alternative 3 in the Fig. 4.3-3)? How can the design be changed to improve the score for that group? In the case of a single low score (alternative 2 in Fig. 4.3-3), think of ways to change the design to improve that score. Be sure that the changes do not negatively affect other scores, however. Finally, when no further improvements can be identified, a decision is needed to proceed to the development of contract documents.

CONCLUSION

The program gives the organization, architects, designers, and project managers a constant reference point for keeping the project's goals in focus. It also helps guide the development, evaluation, and eventually the selection of a design that will meet the organization's needs, not only at the moment, but for the next few years.

Programming is a process involving many different techniques and tools for collecting, analyzing, prioritizing, and communicating the requirements of a project. It requires that pro-

13. Constance Perin is one of the originators of this idea.
14. The particular degree of disaggregation depends upon the type of environment being designed and is a judgmental act. For example, behavior described as recreation or work is clearly much too aggregated to be of use for most environmental design problems because work or recreation comprised many discrete behaviors. Similarly, one could go to the other extreme and describe every muscle twitch involved in walking to the bus stop. Therefore, behavior described at the level of muscle twitches is irrelevant to an urban designer designing a downtown mall but might be highly relevant to an industrial designer who is designing a new typewriter.

CHAPTER 5
ENGINEERING AND DESIGN PROCESS

Paul R. Smith, P.M.P., P.E., M.B.A., Chapter Editor
Peak Leadership Group, Boston, Massachusetts

Anand K. Seth, P.E., C.E.M., C.P.E., Chapter Editor
Partners HealthCare System, Inc., Boston, Massachusetts

David L. Stymiest, P.E., SASHE, C.E.M., Chapter Editor
Smith Seckman Reid, Inc., New Orleans, Louisiana

Roger P. Wessel, P.E., Chapter Editor
RPW Technologies, Inc., West Newton, Massachusetts

The organization of this chapter was a source of numerous discussions. Many books serving the facilities engineering industries are written on a *component* basis, such as boilers for providing heating and chillers for providing air conditioning. We believe the new way of thinking in facilities engineering is to look at a *systems approach* instead. We have divided the major engineered systems into one of five engineering and design categories. These five categories are as follows:

1. Architectural and structural systems
2. Electrical systems
3. Lighting systems
4. Mechanical systems
5. Instrumentation and control systems

Each of the five major engineering and design categories is further divided into the major engineered *systems* within that category. By providing information on all systems, which taken together form the facility infrastructure, we believe that the reader will have an opportunity to understand the relative merits and importance of every system. One can not have human comfort without an HVAC system, which is not possible without a robust electrical system and a well-lit, controlled, structurally capable, and architecturally pleasing environment. This is the basis of our first edition.

Our goals in this chapter are to provide sufficient information for each of the engineered systems categories so that facility managers can effectively manage new construction, addi-

tions, and renovation projects at their facilities while operating and maintaining their facilities reliably, economically, and safely. We also want facilities managers to understand the challenges at hand and to be able to communicate effectively with their engineering and construction counterparts in all phases of projects. Finally, we aim to provide a document that those facility managers will find user-friendly.

SECTION 5.1
ARCHITECTURAL AND STRUCTURAL SYSTEMS

Roger Wessel, P.E., Principal, Section Editor
RPW Technologies, Inc., West Newton, Massachusetts

INTRODUCTION

In the editor's opinion, architectural and structural systems establish the foundation, framework, form, and appearance of a building and facility for the life of the structure. Before the civil engineering work for a building or facility can begin, a geotechnical evaluation of the site is required to support the design of the building's foundations. Article 5.1.1 covers the geotechnical considerations needed to support the civil design and engineering described in Art. 5.1.2. The structural aspects, skins and facades, and roofs are addressed in Arts. 5.1.3, 5.1.4, and 5.1.5, respectively. An integral part of the architectural and structural aspects of any contemporary facility includes the design of elevators, escalators, and moving walks, which is addressed in Art. 5.1.6.

ARTICLE 5.1.1
GEOTECHNICAL CONSIDERATIONS

J. Lyndon Rosenblad, Ph.D., P.E.
Consulting Engineer, Westwood, Massachusetts

INTRODUCTION AND OBJECTIVES

This article provides information on the geotechnical issues that must be considered and addressed when siting a facility. Whether the location is in an urban or in a rural environment, the facility is totally new, or an existing facility is being expanded, many issues are the same. Some issues, however, take on a greater degree of importance in an urban area or require

information in more detail than in an undeveloped rural area. The same is true for the development of a totally new facility versus adding to an existing one. Information about a totally new facility has to be developed from scratch, whereas information is already available for an existing facility, in most cases, and must be updated, enhanced, or verified. The type of facility to be built, the weight of the structures, the overall plan area, the access required, the utilities required, and the discharges emitted from the facility, however, will be unique to the facility. State and local regulations and laws can also cause variations in the number of issues that need to be addressed or the degree to which each must be addressed. For major projects, significant consideration in the planning, design, and construction must be granted to communities and citizens through community participation.

The objectives of this article are to present and discuss critical geotechnical issues to assist an owner, an engineer, a nonengineer agency inspector, or a concerned citizen in the planning process for a facility.

The approach presented focuses on the issues that must be considered in all cases. For each topic, a brief discussion is presented highlighting the most important items in that area. The first topic covers the type and number of investigations and testing that are required to obtain information on a regional basis, as well as at the site. A discussion follows that identifies hazards that could be an issue and those that need to be factored into the design with proper contingencies. Interferences can become costly, time-consuming, and a safety issue, especially in an urban area. Examples of such interferences are presented. Development of the design criteria from the exploration and testing that have been done is the ultimate purpose of the program so that the designer has the necessary parameters. The selection of foundation types for the structures is an important item in determining the cost of the facility and its performance. Some excavation is required for most facilities. Putting a hole in the ground requires planning, engineering, and good design to ensure that the desired goals are obtained, as well as to ensure that the safety of the workers and the integrity of surrounding structures are not jeopardized. The last discussion centers on construction liaison. All of the best planning, engineering, design, and specification preparations are for nothing if the construction is not done properly. Liaison during construction is extremely important and should not be ignored or eliminated.

INVESTIGATIONS AND TESTING

Regional Investigations and Testing

Investigations and testing are a necessary part of the geotechnical work that must be done in obtaining information for a new facility or in expanding an existing facility. On a regional scale, the investigations usually consist of research into work that has been done by others in the geographic region where the facility is to be constructed. The purpose is to gain information on the regional geologic picture using U.S. Geological Survey geologic and topographic maps, U.S. Soil Conservation Service soil maps, aerial photos, satellite photos, and state and county soil maps. From these sources and others, one can develop the general subsurface profile beneath the area. Unusual conditions are often highlighted or evident from these maps and photos. Topographic maps often show landslide areas or drainage patterns that may need to be addressed. Topographic highs might indicate resistant rock outcrops or deposits of unconsolidated material such as a terminal moraine left by receding glaciers. Topographic lows might indicate areas that are in a flood plain and would be subject to flooding. Local sources such as county or town maps yield important information about land usage. County maps might show land that is in agricultural production or heavily forested. City maps show developed areas and current utilization. Aerial photos may provide the most comprehensive readily available information. If the proposed site region has been flown over recently and photos are available in stereographic pairs, then one can learn about current land usage and look at the region in three dimensions.

Other sources of information that are available and should be used are rainfall records, flood records, and earthquake records in certain parts of the United States. From these records, one can ascertain whether there is a tendency for flooding or if the area has been subjected to earthquake activity in the past. The potential for flooding or earthquake activity can sometimes render an area unsuitable for a facility or can add significantly to the cost of the facility.

Depending on the development and the types of facilities in the area, another valuable source of information is from the private sector. Engineering and geologic data and design information that were collected, analyzed, and used by owners in constructing their facilities can be most helpful. Boring logs, test pit logs, soils and geologic maps, geophysical records, construction records, and data from instrumentation all have value.

If rainfall data and flood records are not available from the literature or governmental agencies, this information must also be obtained. Usually at least a year is required to obtain these records, so planning and executing this program should be done early in the process.

In addition to learning as much as possible from records and information in the public and private domain, one should also visit the area to confirm what has been written and to see what changes have occurred since the written material was prepared. The visit to the area will also point out the type of facilities that are in the area now and how each one is performing. The facilities that should be looked at are buildings and also other structures such as roadways and pavements, bridges, culverts, embankments, and geologic features such as road cuts and outcrops of natural material. Conversations with people who live in the area can sometimes be very revealing. Information that does not enter into the written record can be obtained by talking with those who experience the area every day.

Site-Specific Investigations and Testing

Once a specific site has been tentatively selected for the facility, additional specific information is needed about the site. At this time the geotechnical engineer has general knowledge of the area based upon his or her regional study and also has obtained information from the structural engineer about the type of facility, loadings, plan area, and land required. Now the geotechnical engineer is ready to determine whether the site is technically feasible, is unacceptable, or will have significant cost penalties to solve some deficiencies.

Soil Site

If the site is believed to be a soil site based upon the understanding of the regional work, the program will focus on obtaining soil foundation design information. For lightly loaded structures, the program should consist of a series of shallow borings and/or test pits that will yield information on the properties of the soils in the upper few feet beneath the structure. These could be auger borings, rotary wash borings, or borings using a sonic or air-driven rig. The depth of at least one or two borings should be a minimum of 2 times the least dimension of the building or structure that will be built above it. The number of borings should be spaced to cover the building area and extend outside of it. As the borings are being made, the geotechnical engineer or geologist must be present to log the materials as they are removed from the boring and will also determine the sampling and testing to be done in the boring. If the type of rig allows for split-spoon samples, a sample should be taken every 5 ft. At a minimum, blow counts should be recorded as split-spoon samples are taken. Blow counts are a key indicator of the integrity and physical properties of the material. Correlation from the literature is used to indicate the strength and other properties of the material. As the material is removed from the split-spoon sampler, logged, and placed into sealed jars, the engineer may also obtain more information by doing pocket penetrometer tests or vane shear tests on the samples.

For facilities that will produce heavy loads, that cannot tolerate very little or differential settlement, and will rest on thick soil deposits, a more extensive exploration program is required. The program should be planned to yield information about the soils, so that deep foundations can be designed. As such, more of the borings will be deep, and some will probably extend to or into the top of rock. These borings will require casing or the use of drilling mud and are usually rotary wash borings. If in-the-hole permeability tests are planned, drilling mud should not be used. As before, split-spoon samples should be taken every 5 ft in the boring. If soft cohesive material is encountered, undisturbed tube samples should be taken of that material. The tubes used to obtain these samples are thin-walled (to minimize disturbance) and are pushed into the soft cohesive material. Each tube should be sealed to prevent moisture loss; care should be taken in handling, storing, and transporting the tubes to the laboratory. After samples have been taken, logged, and put in sealed containers, they should be moved to an environment that does not subject them to extreme cold, extreme heat, or vibrations.

The depth to the water table is an important piece of information that must be logged by the field engineer. This reading should be made when the water level has stabilized after the hole has been completed. A 24-h period is usually long enough.

Additional in-hole testing is sometimes warranted. These tests may consist of vane shear tests, cone penetrometer tests, pressure meter tests, and standing-head or falling-head flow tests. Strength, modulus, and permeability values of the in situ material are obtained in this way.

Sometimes it is advantageous to incorporate geophysical exploration, in conjunction with borings, into the program. Geophysical techniques such as crosshole or downhole testing, along with seismic refraction or seismic reflection, can provide information on the materials between borings. This usually requires fewer borings and may result in some efficiencies in the exploration program. These geophysical techniques require a small energy source to produce waves that pass through the subsurface material and a geophone or geophones to receive the waves. The time that it takes these waves to pass through the subsurface materials is an indicator of the properties of the materials. The energy source will produce more than one type of wave, for example, primary or shear waves. Geophysicists interpret the results of the tests such as the time for travel, the shape of the curve, and the relative position of peaks and valleys to yield information on boundaries of the layers, thickness, relative strength, moisture content, and relative density of the subsurface materials.

The laboratory tests performed on the soil samples obtained from the field exploration program should yield pertinent information about the site and the type of foundation that is anticipated. These tests at a minimum will consist of Atterberg limits, moisture contents, grain size analyses, and a definitive soil classification. If undisturbed tube samples of soft cohesive material are obtained, consolidation and strength tests should be performed. The strength tests may be triaxial compression, uniaxial compression, or direct shear tests. For samples of noncohesive material, tests may consist of triaxial compression tests, permeability tests, or dynamic tests. Laboratory tests should be performed in accordance with standards and procedures established by the American Society for Testing and Materials (ASTM). The number of tests should be based on the size of the site, the variability of the materials, the thickness and number of soil deposits, and a statistically satisfactory number of values.

Rock Site

If the depth to rock is believed to be shallow, the foundation exploration program should focus on obtaining the necessary information about the rock. Core borings are the best means of obtaining these data. Drill rigs with the capacity and capabilities to core rock are required. These borings should continue at least 10 ft into sound rock. The amount of rock recovered and the amount of rock that exceeds 4 in in length are important indicators of the rock quality. The Rock Quality Designation (RQD) is the percentage number obtained by adding up

the total length of the number of pieces of cored rock that are 4 in or longer divided by the total length of cored hole and multiplying by 100. The higher the percentage of core recovery and the higher the percent RQD, the better the in-situ rock quality. The recovered rock core should be placed into wooden or cardboard boxes after it has been logged and kept indoors until it is transported to the laboratory.

Additional in-hole testing may also be a part of the program. Information about the in-situ permeability of the rock formations can be obtained by performing pressure tests, falling-head tests, or other similar tests to determine the flow of water into or out of the formation. Borehole cameras are also used to get a look at the fractures in the wall of the boring and the locations where water is entering the hole. The borehole camera can be a video camera or one that provides still pictures.

The borings should be spaced so that the plan area of the entire facility is investigated and a top-of-rock contour map can ultimately be prepared. In areas where the bedrock is limestone or dolomite, other precautions need to be taken. Under certain conditions in the geologic past, a soluble limestone or dolomite formation may have been eroded by running water that left voids in the bedrock. These voids or *solution channels* are commonly filled with air, water, soft clays, or saturated silts. This is known as a *karst* condition. These caverns can be just beneath the top of rock surface or at depth as shown in Fig. 5.1.1-1.[1] If heavily loaded structures or facilities are built over these caverns, they might collapse into the void. For facilities overlying anticipated karst conditions, more borings might be required. Sufficient borings into sound rock should be made to assure the engineers and owners that voids do not exist at that location or that their presence will be incorporated into the design.

Empirical relationships have been developed that show relationships between the RQD and the in situ rock mass strength and the in situ rock mass modulus. Geophysical exploration can also be an effective tool in evaluating rock sites. Empirical relationships have also been developed that correlate the ratio of the primary velocity obtained by sonic or seismic techniques in the field to the velocity measured in the laboratory squared (called the *velocity index*) and the in-situ rock mass strength and in-situ rock mass modulus. The ratio of the field and laboratory velocities is a measure of the degree of fracturing and weathering of the rock mass. These relationships can be very helpful to the designer in gaining a better understanding of the rock mass properties, not just the intact rock core properties. Table 5.1.1-1 shows an engineering classification of in-situ rock developed by Merritt.[2]

The rock obtained from the field boring program should be sent to a laboratory with rock-testing capabilities. The laboratory tests on the rock core should be done in accordance with ASTM or International Society of Rock Mechanics (ISRM) standards. These tests are usually velocity tests and uniaxial and triaxial compression tests that yield strength and modulus values for the intact rock. Other index-type tests, such as Schmidt hammer readings, Brazilian tests, and tensile tests, are also used as indicators of strength values.

HAZARDS EVALUATION

Natural hazards must be considered in planning and designing a facility or expanding an existing facility. The designer must examine each part of the proposed facility and decide on the appropriate criteria for different hazards, the likelihood of combined loadings, and the consequences if an extreme loading situation does occur. A systematic examination of these potential loadings will identify the most critical situation. It will also identify the situations where it is not rational or economically justifiable to provide for the combined effects. Examples of items to be examined are the foundation type; structural parameters governing behavior such as stress, strain, and deformation; the materials in the facility and their resistance; and the quality of construction. Some of the natural hazards that must be considered are floods, earthquakes, faults, liquefaction, collapsible soils, shrinking and swelling soils, and slope failures.

TABLE 5.1.1-1 Engineering Classification of in-Situ Rock

RQD, %	Velocity index	Description
0–25	0–0.20	Very poor
25–50	0.20–0.40	Poor
50–75	0.40–0.60	Fair
75–90	0.60–0.80	Good
90–100	0.80–1.00	Excellent

Floods

The hydrologist must establish whether the site is susceptible to flooding from a nearby river or stream, or just from inadequate drainage and runoff. The problems associated with floods are those associated with unexpected buoyant effects on the facility, foundation damage and subsequent loss of support, high-velocity water loads on equipment and buildings, and submergence of the facility. The hydrologist should perform analyses using historical flood records.

Earthquakes

It is necessary that the designer establish the probability that an earthquake will occur in the area of the proposed facility. The basis for making such a determination involves judgments about degrees of acceptable risk, consideration of the life and safety of the surrounding population, the effects on the environment, and the consequences of interruption of service in the event of severe damage to the facility. The selection of the earthquake intensity by the designer is one of the important elements in the decision process. Because aboveground and belowground structures move and respond differently to earthquakes, the design criteria for the two situations may be quite different.

Faults

Surface faulting is a dangerous source of differential movement in a facility. Surface faulting, however, is a relatively rare occurrence. Care should be taken not to place a facility over a known fault where there has been movement. The engineer and geologist must prove without a doubt that the fault is not active and that there will be no movement along the fault during the life of the facility and for years beyond. If it is absolutely imperative that the facility rest on the fault or cross the fault and movement is anticipated, the design should take this into account and allow for such a contingency. Piping, conduits, utilities, and even tunnels that cross an active fault must be able to accommodate the displacement.

Liquefaction

One of the major seismic hazards for facilities built on saturated cohesionless soil deposits is liquefaction and the potential for ground movements and foundation failures. For major structures such as dams, nuclear power plants, oil storage tanks, and other structures susceptible to movement, it is imperative that the subsurface be thoroughly investigated to ascertain whether there is the potential for liquefaction. Liquefaction may result from vibrations from natural sources such as earthquakes or from construction activities such as blasting or pile driving.

One of the basic soil parameters used in liquefaction analyses is *relative density.* Various subsurface investigative techniques, such as standard penetration tests, Dutch cone soundings, and undisturbed sampling with subsequent laboratory testing, may be utilized to yield relative density data.

Where a site is believed to be prone to liquefaction, it may have to be abandoned and not used. In many cases, however, the subsurface properties can be improved or strengthened by using one or more ground improvement techniques, such as dynamic compaction, vibrocompaction, compaction grouting, blast densification, or drainage by installation of wick drains.

Collapsible Soil

Soil displacements caused by collapsible soils are a more common occurrence than surface faulting and are comparable in magnitude. Many types of deformation may result, including flow failures, lateral spreads, subsidence, loss of bearing, and buoyancy effects. Collapsible soils are soils placed in an environment that results in a loose configuration and a highly compressible material. These can be materials placed in a natural environment or in a human-made environment, such as reclaimed mined land. Collapsible soils are often cohesionless materials that have a uniform particle size. When subjected to shaking such as in an earthquake (liquefaction), to submergence, or when a load is applied, these soils may collapse. An experienced geotechnical engineer can detect soils that are susceptible to collapse. Further laboratory testing will confirm if there is such a problem. Many techniques or construction methods are used today to improve such soils. The nature, severity, and real extent of the problem, as well as the limitations imposed by the surroundings, will help determine the most suitable method. Methods commonly in use today fall into three categories: soil improvement, soil reinforcement, and soil treatment. *Soil improvement* methods include deep dynamic compaction, drainage and surcharge, electro-osmosis, compaction grouting, blasting, and surface compaction. Examples of *soil reinforcement* are stone columns, soil nails, micropiles, jet grouting, soil mixing, fiber reinforcement, mechanically stabilized earth, and lime columns. *Soil treatment* examples are soil cement, lime admixtures, fly-ash admixtures, dewatering, and freezing.

Shrinking and Swelling

Certain fine-grained cohesive deposits such as clays, silts, and organic material are other potential sources of differential settlement beneath a structure. Claystones and mudstones may contain bentonitic clay minerals that swell upon exposure to water, causing heave and subsequent shrinkage during dry periods. They may also exhibit characteristics of dispersive, erodible clays when immersed in running water, resulting in piping and erosion. These conditions are most pronounced in semiarid environments.

Slope Failures

Slope instability has the potential for damaging ground movement under either static or seismic loading conditions. This instability can occur in natural slopes or in cut slopes. The greatest seismic risks are associated with those slopes that show signs of instability under static conditions. If instability involves slumps and relatively shallow slides, slope stabilization or installation of drains may be effective in correcting difficulties. Landslides, however, involve downslope movements of large masses of soil and rock that may occur under static or seismic conditions. The principal forms of movement include rock falls, sliding of soil, and deep translation and rotation of soil and rock. Field and analytical studies should be done to assess the potential and risk for a slope failure or landslide if a facility is to be built on or at the toe of a

potentially unstable slope. The costs for stabilizing and maintaining a slope can be sizable and should be factored into siting a facility.

INTERFERENCES

Siting a facility in an urban environment has interferences that are not as prevalent as in an undeveloped or relatively unpopulated area. Interferences can be existing utilities, previous structures, buried structures, and historical artifacts. The locations of existing utilities such as water lines, gas lines, sewer lines, or buried electrical lines need to be identified before any exploration or excavation is begun. Utility companies and communities have formal programs, such as *Digsafe,* which provide this service. As-built records of the existing utilities should also be utilized. In areas where there has been filling, buried foundations of previous structures may also be present. Buried structures such as seawalls and revetments can also cause major problems during exploration and excavation and can add significantly to the cost of a facility. When historical artifacts are located at a site, additional issues are involved. Not only is there an effect on the time schedule and cost because of the care that must be taken in preserving these artifacts, it may be that the site cannot be used at all.

ENVIRONMENTAL AND OTHER CONSIDERATIONS

In addition to sound technical and procedural practice, other major factors must be considered in siting and developing a facility. These include environmental and socially related issues, public health and safety, regulatory requirements, political considerations, reliability, and economic factors, to name a few.

As an example, the Environmental Impact Statement is one of the vehicles used to evaluate and present the environmental issues for a facility. Potential environmental damage or impact might include loss of an amenity as a result of noise, vibration, visual intrusion, dust, dirt, odor, traffic, or site drainage. Refer to Art. 3.2.9, "Environmental Compliance and Issues Management," for a detailed discussion of environmental issues. Each of these issues and others that might affect neighbors or landowners need to be studied. Impacts must be assessed. Where possible, the facility design should try to preclude or minimize the impact. Where that is not feasible, measures need to be taken to mitigate the impact.

Similar studies are needed for the remaining issues as well. These issues are addressed in more detail in other sections of this book.

DEVELOPMENT OF DESIGN CRITERIA

Using the data that have been obtained for the site, the geotechnical engineer should now prepare the design criteria for inclusion in the contract documents and for use by the structural engineer. These data include the information obtained from the literature, from construction of nearby structures, from road cuts, from the exploration program, from the field and laboratory testing program, and from the analyses that have been done on the data. These design criteria include values for all of the soil and rock parameters that the structural engineer will need in the design, such as soil unit weight, soil modulus of subgrade reaction, soil compressive strength, rock unit weight, orientation and strength along rock discontinuities, and rock mass modulus, among many others.

SELECTION OF FOUNDATION TYPE

Selection of the foundation type for a facility is based on several factors. These factors include the sensitivity of the structure to total and differential settlements, the properties and depth of soil, the depth to bedrock, the orientation and properties of discontinuities, the loads to be supported, the presence or absence of water and/or hazardous materials, the type of foundation and performance of nearby structures, the proximity of other structures, and the relative cost. Shallow spread footings are generally acceptable for supporting lightly loaded structures with good soil and water conditions. Foundation design considerations include bearing capacity, seismic response and liquefaction potential, settlement, and swelling. For poorer soil conditions and heavy structures, deep foundations such as piles or caissons are required. The subsurface conditions at the site are an important part of the selection process for caissons or piles. Geotechnical design considerations include the presence of a good bearing layer at a reasonable depth, skin friction, potential negative skin friction (downdrag), bearing capacity for end-bearing designs, obstructions, the location of the groundwater table, the ability of a hole to stand open, the drivability of piles, swelling soils, collapsing soils, the availability of foundation materials and installation equipment, the effect of vibrations on the subsurface and adjacent structures, and cost. If piles are selected, the right pile for the site must be selected. There are several types of piles to choose from, including timber, concrete, and steel piles. For each of these materials, there are several types from which to choose. Issues such as weathering, corrosion, drivability, displacement, noise, vibration, length, availability, and cost must all be considered.

For sites where the rock is shallow, high strength, unweathered, and massive, the foundation design is straightforward. Footings constructed on the rock can support both light and heavy loads of the proposed facility. For rock sites with weathered rock, weak rock, swelling rock, soluble rock, or limestone sites with karst conditions, additional precautions may be required in construction.

EXCAVATIONS

The construction of most facilities, whether large or small, requires some excavation of the site. For small, lightly loaded facilities, the excavation might consist of site grading and shallow excavation for footings. Larger excavations may be required for other structures where a portion of the facility is to be built underground. Geologic and groundwater conditions are a primary consideration for excavation stability, as well as for temporary and permanent ground-stabilization systems. The more complex these conditions, the greater are their influences on the various elements of construction. Some of the excavation conditions that must be addressed are dewatering, blast monitoring, support instrumentation and monitoring, and materials handling and disposal.

Dewatering

Water encountered in an excavation is almost always considered a nuisance, if not a real threat to the progress of the project. Water in this sense includes either surface water or groundwater. Predicting the location and volume of water is one of the harder tasks of the geotechnical exploration team. The prediction should come from exploration observations and measurements and evaluation of general geotechnical conditions. Methods of handling the water vary and can depend upon the contractor's preference. At other times, the method of handling the water is dictated by the need to preserve the strength of the surrounding

material or to reduce or eliminate the water load on excavation support systems. If the surrounding material is not eroded by the water, as the excavation progresses and the contractor's excavation techniques can accommodate it, the least expensive and usual method is to "sump and pump." In this method, a hole is made in the lowest part of the excavation, and a pump or pumps are placed in the hole. Then water is lifted to the ground surface and carried away from the excavation. For deeper excavations where water under high pressure may be confined beneath the excavation bottom, care must be taken that the bottom does not blow. This water pressure must be relieved before the lifting force of the water exceeds the weight of the overlying material. For excavations that must be dry during the excavation process, a more elaborate dewatering system is required. This could consist of dewatering wells or well points that are placed outside of the proposed excavation and drilled to a depth well below the proposed excavation bottom. Using a system of piping and headers, water is pumped from the wells or well points and collected and carried away from the proposed excavation. This system is installed and put into operation before excavating begins. A monitoring well should be drilled at the center of the proposed excavation and readings taken before and throughout the excavation process to ensure that the water level remains well below the excavation bottom. Depending upon the quality of the water being removed, it may be necessary to collect and treat it before it can be discharged.

It is important to note that in all dewatering operations, the dewatering system must operate continuously 24 h per day, 7 days per week, while the excavation remains open. The cost for this continuous operation as well as the need for a backup power supply should be factored into the project planning process.

Blast Monitoring

For sites where the top of rock is near the ground surface and excavations are required, it is usually necessary to use explosives to break up the rock so that it can be removed. Using explosives to break rock generates air- and groundborne vibrations that could have detrimental effects on nearby structures and cause irritation to or complaints by nearby residents. A variety of complaints attributable to vibrations have always been received when blasting is done. Human response levels to ground vibrations are considerably below those levels necessary to induce damage to residential structures. To ensure that structures are not damaged, that complaints are minimized, and that actual blast data are recorded, it is imperative that each blast be monitored using a seismograph. The monitoring should be done by the contractor and also by the owner or owner's engineer.

A safe blasting limit of 2.0 in/s peak particle velocity measured from any of three mutually perpendicular directions on the ground adjacent to a structure should not be exceeded if the probability of damage to the structure is to be small. Complaints can be further reduced if a lower vibration level is imposed. Air blast does not usually contribute to the damage problem in most blasting operations. Millisecond-delay blasting should be used to decrease the vibration level from blasting because the maximum charge weight per delay interval rather than the total charge determines the resultant amplitude. Data in the literature or from other blasting jobs should be used initially to determine a conservative and safe charge weight per delay, or a test program should be done. These data are presented showing a relationship between peak particle velocity and scaled distance. *Scaled distance* is obtained by dividing the distance from the blast to the seismograph by the square root or cube root of the charge weight per delay interval. Knowing the distance to the structure in question and the safe blasting limit, the charge weight per delay can be calculated. After each blast, the measured peak particle velocity should be plotted versus the scaled distance, and appropriate changes should be made to the blast envelope, if necessary, for the design of the next blast. A safe blasting job requires good communications and cooperation between the blasting contractor and the geotechnical engineer.

Support

Excavations in soil and rock are usually made with the steepest faces possible to minimize the amount of material to be removed, the backfilling required, and the land area disrupted. These steep excavated faces are usually unstable and require support. The type of support depends upon the type of materials to be excavated, the height of the excavation, the presence or absence of water, and the size of the excavation, among many other factors. For excavations in soil, support is provided by soldier piles and lagging, sheet piles, or slurry walls. These vertical or near-vertical walls hold back the soil material as the excavation proceeds downward. High-strength tension rods anchored deep in the soil behind the walls help carry some of the load imposed by the soil and water. More than one row of anchors is required for deeper excavations. Other newer techniques may also be used, such as soil nailing and soil mixed walls (SMWs), as shown in Fig. 5.1.1-2.[3] For narrower excavations, cross excavation bracing may be used instead of soil anchors. The design of these support systems is complex and must be done by a geotechnical engineer experienced in this area.

If the excavation is to be in rock and blasting is to be used to break the rock, care must be taken to ensure that the rock surrounding the excavation is left in the best possible condition and that overbreak is minimized or eliminated. Controlled blasting techniques such as line drilling, presplitting, cushion blasting, smooth-wall blasting, or preshearing should be used. Sometimes vertical rock bolts are installed just outside the excavation line before any blasting begins to assist in holding together the rock that is to be left in place. The production blasts should be planned to minimize the amount of energy that is sent back into the remaining rock. These blasts should be directed as much as possible to a free face. Controlled blasting techniques are not a cure-all, however. Overbreak control is still primarily a function of the geology, and slopes should be designed to accommodate the geology. As the excavation proceeds downward, rock bolts or other support should be installed to help support the exposed rock face. Rock bolts should be designed with the geologic discontinuities in mind. The orientation, length, spacing, and type of bolts and anchorage should be designed to accommodate the site conditions. Timing to provide the support is important. Support should be installed as soon as possible after the face is exposed. Depending on the site conditions and availability of materials, the rock bolts used are usually solid steel bars anchored and encapsulated by either cement or resin grout. Mechanical anchored bolts also have their applications. The design of these bolts should also include the need and benefit of prestressing them. Ancillary materials such as steel straps or wire mesh may be used to minimize and collect any small pieces of rock that could fall from the slope. Shotcrete is another form of support that is sometimes used. This is cement and small aggregate that is sprayed onto the rock face as it is exposed. The shotcrete, in conjunction with wire mesh, provides support to the rock face. The shotcrete is usually 3 to 4 in thick. It is important that drainage be provided through the shotcrete so that water pressure does not build up behind the shotcrete and dislodge it.

Instrumentation and Monitoring

In an urban environment or at an existing facility where structures may be close to a proposed excavation, it is imperative that protection of adjacent structures be included in the design and planning process. The potential impacts of the proposed excavation on the existing nearby structures include lowering the groundwater table during excavation, movements of the proposed earth or rock support system, damaging or removing the foundations of the structures, or shaking the structures during blasting operations. To reduce the possibility of damage to the existing structures, an instrumentation and monitoring program should be designed and installed before the excavation begins. In addition to the instrumentation that is to be selected and installed, a preconstruction survey of the structures including extensive use of photographs should be made to document the conditions before the nearby excavation

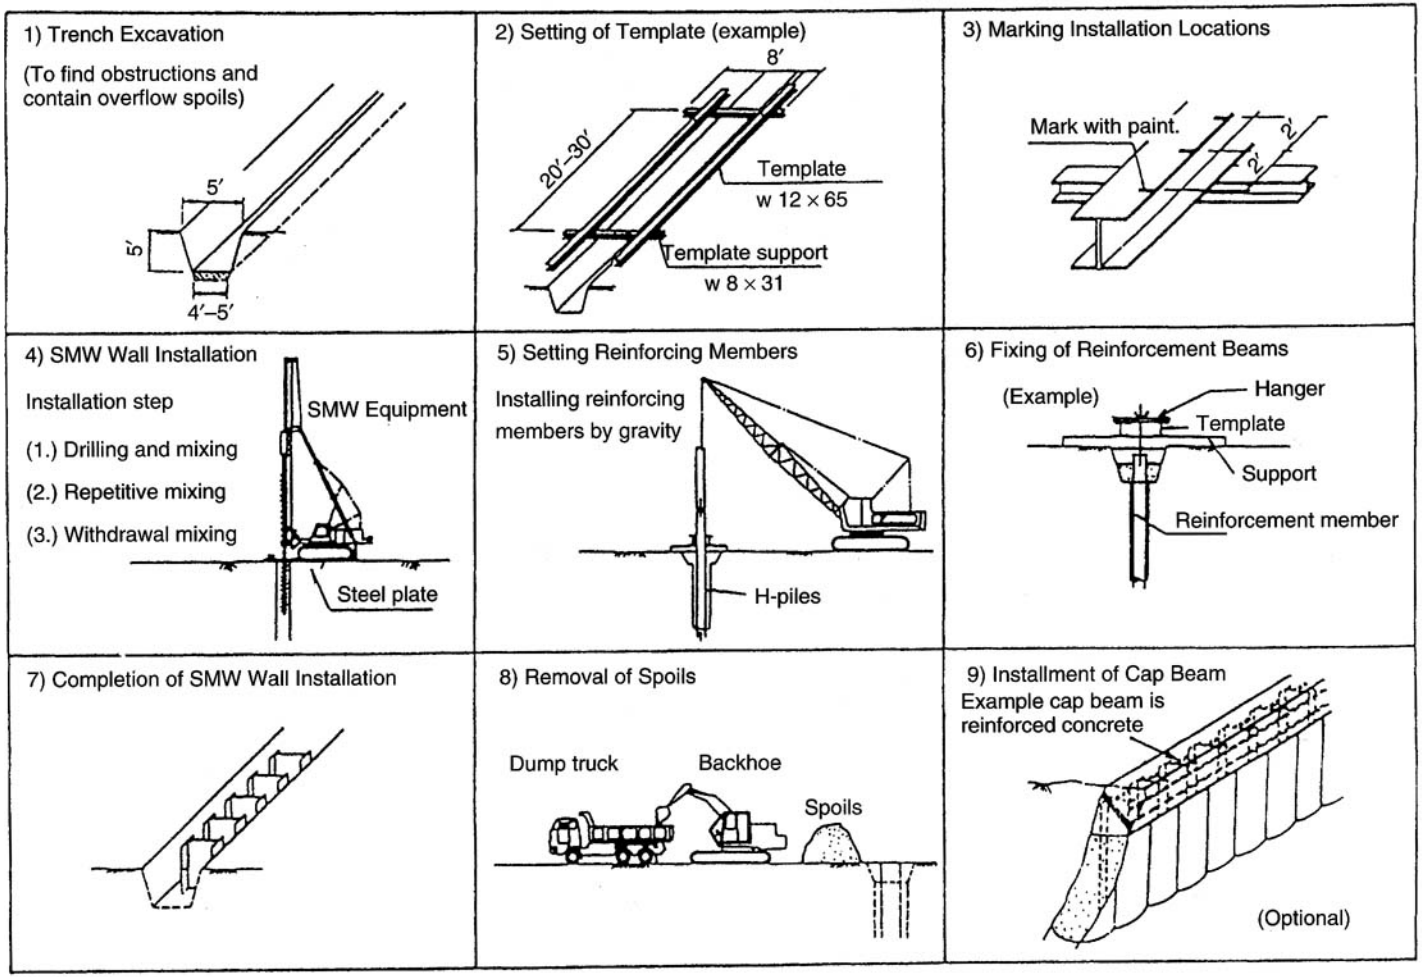

FIGURE 5.1.1-2 Soil mixed wall (SMW) installation procedure. (*Courtesy of S. L. Pearlman and D. E. Himick.*).

starts. This program allows the geotechnical engineer to monitor the behavior of the excavation and the adjacent structure as the excavation proceeds and to adjust the excavation program as needed. It also provides a record for any future questions that may be raised. The geotechnical engineer should establish acceptable limits of movement of the excavation walls and the adjacent buildings. Contingency plans must be in place for implementation if the movements reach these levels. The owners and residents of the nearby structures should be included in the planning process. Their comments and concerns should be addressed before beginning the excavation. Good communication and cooperation are advantageous in this process. After completion of the excavation and construction of the new facility, a postconstruction survey of the adjacent structures should be made and documented. The monitoring process should also continue until well after the new facility is completed and all concerns have been addressed.

Materials Handling and Disposal

The nonhazardous material excavated at the site should be used as fill material at the site if possible. Unless it is processed, it is not likely that it could be used as structural fill, but it may be quite suitable for raising the grade of portions of the site that will not bear heavy structures. After obtaining the necessary permits, the contractor should transport any hazardous materials and materials that cannot be used at the site to an off-site area that has been permitted to receive such materials.

LIAISON DURING CONSTRUCTION

It is imperative that a geotechnical engineer be on-site during foundation construction to ensure that the foundation is constructed as it was designed. The geotechnical engineer acting as on-site liaison during construction represents the owner at the site, ensures that the specifications are followed, makes on-site decisions and analyses where adjustments are required, provides communication with the engineer and designer in the office, and facilitates communication with the contractor.

ARTICLE 5.1.2
CIVIL ENGINEERING

Ronald P. O'Brien, P.E., Steven L. Bernstein, P.E., and Robert F. Daylor, P.E.
Daylor Consulting Group, Inc., Braintree, Massachusetts

This article discusses strategies for managing the civil engineering aspects of facility planning, design, and construction. Civil engineering encompasses disciplines such as geotechnical, structural, environmental, wastewater, water, fire protection, traffic, and site development engineering. Although all of these disciplines are important facets of facilities engineering, this article will guide the reader through the most critical civil engineering site development components.

The civil engineering aspects of a design define the physical constraints of a project. Civil engineers focus on the planning, design, and construction of works in or on the ground and are called upon in design teams to provide primary expertise in regulations dealing with the land, such as zoning, land development codes, wetland protection, and water quality management. Project constraints often consist of one or more of the following: zoning, access, water supply, sanitary sewage and sewerage availability, storm water discharges, existing utility infrastructural capacities, environmental resources, and subsurface conditions.

ZONING

Zoning requirements are regulated locally and are not uniform from state to state or within a specific state. Performing a thorough zoning review is a critical first step when planning a new site development or facility upgrade. The zoning district dictates allowed uses, dimensional requirements, and some of the permitting processes for all site developments. Although it is possible to have a zoning district changed or to apply for variances from certain zoning requirements, this process can be lengthy; its outcome is uncertain; and it is expensive. A facility manager should meet with the local zoning enforcement officer to discuss the proposed project, current zoning, and specific permitting requirements for the development. Selecting sites or designing new facilities in locations that are zoned to accommodate the proposed project pose the least risk to the schedule.

At a minimum, the dimensional requirements in most zoning regulations dictate the requirements for lot area, frontage, property line setbacks, building coverage, building height, number of structures, and impervious lot coverage. Other regulated items that may be in the zoning regulations include but are not limited to the following: the number of parking spaces, parking area dimensions, off-street loading, landscaping, floor-to-area ratio, outdoor lighting, and exterior signs. Other constraints found in zoning regulations or other local bylaws may relate to sensitive environmental or municipal resources such as wetland districts or aquifer protection districts. These resource-based overlay districts are drawn on top of other zoning categories. Overlay districts are more restrictive than their respective underlying zoning districts.

It may be necessary to create a lot or subdivide an existing lot for the proposed development. If the parcel to be created abuts an existing road or right-of-way (ROW), then it can be created in accordance with the local zoning requirements of the district. If the parcel does not

have adequate frontage, then it may be necessary to create a new ROW to provide frontage for the lot. If the project requires creating a ROW, then additional local permits are required. The new road design must conform to local standards, as must the utilities within it.

PERMITTING

This article discusses potential time constraints, permitting issues, and costs that may be encountered during the permitting process. Permitting costs vary greatly from region to region. In some areas of the country where infrastructure is at or near capacity, regulatory agencies typically require significant contributions from potential developments. In other areas of the country, the local or state government may make the infrastructural improvements or provide tax benefits to encourage development.

There are many permits in addition to those required by local zoning. They may be more restrictive to the development than the local zoning requirements. For example, the site may be constrained by wetlands, may be designated as an environmentally sensitive habitat, or may have historic significance. The site may be upstream of an environmentally sensitive area or near a historic landmark. It is impossible to list every permit that may be required for a specific project because every site is unique, and every state, county, and municipality has unique permitting requirements. The intent of this article is to make the reader aware that many permitting agencies at many levels administer regulations that can significantly constrain or prevent a proposed development. A facility manager should retain a land development engineering company and/or land-use real estate attorney to perform a feasibility study to determine required permits and estimated permit schedules before designing a new facility or upgrade. Also, refer to Art. 3.2.9, "Environmental Compliance and Issues Management," for a detailed discussion of these and other related issues.

Permits can be administered at one or more of the following levels: federal, state, regional, county, and municipal/local. The following list of frequently encountered permits is typical but not exhaustive: wetland protection, flood-plain protection, connection to municipal sewers, subsurface sewage disposal, discharge to surface waters, connection to municipal water, groundwater discharge, groundwater withdrawal, coastal development, railroad right-of-way, and access to federal, state, or county highways.

EXTERNAL AND INTERNAL TRAFFIC AND ACCESSIBILITY

When siting a new facility, the capacities (maximum vehicle trips per day and peak-hour vehicle trips) of existing roads and intersections should be considered. The distances from major highways, airports, or rail facilities and the availability of public transportation should also be considered. The new facility will generate additional traffic that will impact existing streets and intersections. The permitting process may require a comprehensive traffic analysis and may result in some form of traffic mitigation if the proposed development generates significant traffic. Traffic mitigation can be significant and must be included in the project's budget and schedule. In high-traffic corridors, some traffic demand management, such as staggered work hours, ride sharing, shuttle buses, or subsidies to public transportation, may be required. Permit thresholds may be based upon specific traffic estimates. The standard for traffic generation estimates is the Institute of Transportation Engineers (ITE) *Trip Generation* manual. A traffic engineer should be consulted to determine if the proposed facility will generate a significant number of vehicle trips or if existing roads or intersections are at or near their respective capacities.

Internal site circulation should accommodate the following traffic types: personal vehicles, emergency response vehicles, maintenance vehicles, delivery trucks, and pedestrians. Other traffic types, such as public transit or bicycles, may be encountered. Personal vehicle and pedestrian traffic are closely tied to the parking configuration for internal site circulation. Parking areas should be located within a convenient distance to the buildings that they serve. The maximum distance from building entrances to the furthest parking space may be regulated by zoning. Parking may not be allowed directly adjacent to a building because of fire lane requirements. A facility manager should check with the zoning and/or the local fire department.

Parking areas with perpendicular parking and two-way travel aisles usually provide more parking spaces than angled parking with one-way aisles. However, angled parking is more efficient than perpendicular alignments in some instances. Locating parking spaces on the perimeter of a parking area maximizes the total number of parking spaces. However, this causes significant traffic conflicts if the perimeter travel way is a primary access for the facility. Primary access routes should be designed to be similar to public streets and should minimize traffic conflicts. Angle parking should be used where one-way traffic is desirable or where width limitations preclude right-angle parking layouts. Figure 5.2.1-1 shows a recommended 90° layout. Figure 5.2.1-2 compares 90° parking to angle parking. Figure 5.2.1-3 lists typical dimensions for parking spaces and aisles. Zoning generally dictates a minimum number of parking spaces for specific uses, as well as minimum space and aisle dimensions.

After satisfying the parking requirements in zoning and any additional owner needs, handicapped requirements conforming to Americans with Disabilities Act (ADA) Accessibility Guidelines for Buildings and Facilities must be incorporated into the design. Handicapped accessible routes must be provided to facilities with sufficient handicapped parking as close as possible to the facility that they serve. Handicapped ramps that comply with ADA must be provided whenever an accessible route crosses a curb. Figure 5.1.2-4 presents ADA handicapped parking requirements and parking space dimensional requirements. The ADA guidelines are minimum federal requirements, and the facility must also adhere to all state and local handicapped-accessibility regulations.

There are many options for pedestrian circulation. In general, pedestrian traffic in the parking area is routed along the edges of the aisles. If pedestrian traffic travels along a road or high-traffic aisle, then a sidewalk must be provided. It is important to provide well-marked pedestrian crosswalks at crossings that have significant volumes of pedestrian traffic. Visual obstructions should be avoided at intersections or other areas with vehicle and pedestrian conflicts. The facility manager should determine what level of pedestrian accessibility is necessary for internal operations and access to the site. Pedestrian routes should be vertically separated from vehicle traffic by a 6-in curb. Sidewalks should be a minimum of 4 ft wide, well lit, and handicap accessible. Sidewalks should not be used for bicycle traffic. If desired, separate lanes can be located along the shoulders of travel lanes and delineated for bicycle traffic. Many types of curbing can be used at the edges of travel ways and within parking areas. Zoning may dictate the type of curbing required for specific applications. Bituminous concrete (asphalt) curbing is the least expensive and least durable material. Vertical bituminous curbing is vulnerable to snowplow damage. Concrete curbing can be approximately 3 times more expensive than bituminous concrete curbing but is much more durable. Concrete curbing can also be damaged in cold climates by snowplows and road salt. In warmer climates, concrete curbing and gutter is the standard road edge. Granite curbing is the most durable but is not readily available in all regions and is approximately twice as expensive as concrete curbing.

Local ordinances and local fire departments dictate the portion of a building or facility to be accessible to emergency vehicles. Their decision will be based upon the intended use of a building, the level of internal fire protection, and the proximity to other structures. The design must provide room for parking fire trucks near the building while allowing other vehicles to pass. Landscape areas can accommodate heavy-duty emergency vehicles such as fire trucks if

they are reinforced with lawn pavers and are at a suitable grade and alignment. Common lawn pavers are made from concrete or high-strength plastic and allow grass to grow through, rendering them virtually invisible. Fire trucks must have access to the fire hydrants serving the parking areas. Well-marked fire lanes must be provided and maintained by the facility. Access routes for fire trucks should be designed on the basis of the criteria of the local municipality. Access should be designed for a standard ITE WB-60 truck at a minimum, unless local regulations differ. Other emergency vehicles, such as ambulances, must have unobstructed access to buildings and be able to park without blocking traffic flow.

Delivery trucks need adequate access routes. In general, it is good practice to segregate employee automobile traffic from truck routes. A route designed to accommodate a WB-60 truck should be adequate for truck access. However, a bus design vehicle has the most restrictive inner turning radius. Figure 5.2.1-5 presents scale drawings of the turning requirements for a large vehicle.

Loading areas or loading bays for delivery trucks can be accommodated in many ways. The most common loading-bay layout is perpendicular to a building face. In this scenario, a truck can approach the bay parallel to the building and back into the loading dock. It is important not to block travel ways when a truck is parked in a loading bay. Angled loading bays require less maneuvering space beyond the building face. Parallel loading bays require the least maneuvering space beyond a building face. Parallel loading bays would not be a good choice for high-volume, multiple-bay loading or transfer facilities, but would be an excellent choice for a facility with limited space beyond the building and minimal loading activity.

Loading bays can slope toward or away from the dock at the building face. If the bay slopes down toward the building, then care must be taken to prevent the top of the truck from striking the door mechanism or the building above the doorway. This can be accomplished by extending the loading bay, providing bumpers, or increasing the height of the door. High-traffic loading bays should have dock shelters to provide weathertight seals between the truck and dock. Dock shelters should accommodate the loading-bay slope and be perpendicular to the back of the truck. They should also have adjustable skirts on top to accommodate different truck heights. The slope of the loading bay should be as flat as possible (0.5 to 1 percent is recommended). Although delivery trucks can negotiate a slope of 5 percent or more, it is important to consider the safety of the fork truck operators during loading or emptying of the trailer. Dock levelers may be installed at loading docks to accommodate trucks with different bed heights.

It is advisable to use trench drains to capture water from loading bays that slope toward the building. The use of catch basins in those areas would require cross slopes that may misalign a truck at the dock. Ideally, the loading-bay slope, toward or away from the building, will be a continuous plane, perpendicular to the building without cross slopes parallel to the building.

WATER

An adequate water supply is critical to facilities for many reasons. It is used for drinking, sanitation, fire protection, process applications, cooling, irrigation, and conveying sanitary and process wastes. Water may be obtained from a municipal service, surface water, or groundwater source. If water is supplied by a municipal system, it is critical to determine how much is available, at what pressure, and at what cost. Generally, the cost of a municipal supply includes an initial hookup fee and construction costs for the connection and meter, followed by subsequent water bills based upon use. The initial connection fee could be significant depending upon the flow requirements of the new facility and the municipality's total available capacity.

Water systems from different sources cannot be cross-connected. Most municipalities have control ordinances that describe connection types for specific uses. Municipal water cannot be directly connected to fire sprinkler systems, process systems, boilers, wastewater treatment

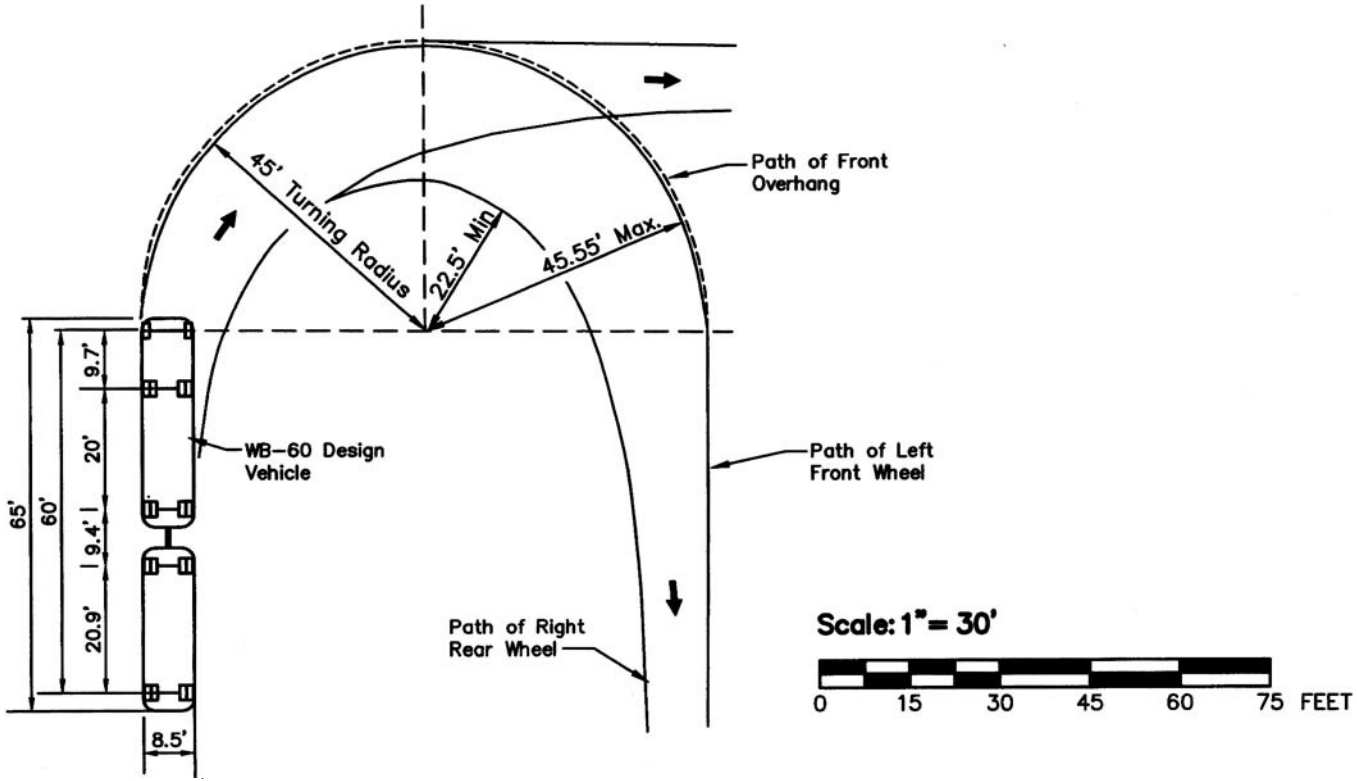

FIGURE 5.2.1-5 Minimum turning path for WB-60 design vehicle. (*Courtesy of Daylor Consulting Group, Inc.*)

facilities, or other nonpotable uses without a backflow preventer. These valves require at least annual inspection and testing to assure that no backflow will occur.

Before constructing a new facility, a facility manager should check with the water supplier to determine the closest adequate water service. If a water main with adequate flow and pressure is distant, then a cost analysis should be performed to decide between extending the water main versus developing an on-site source and constructing a storage reservoir. This cost analysis should be based upon long-term planning for the facility. It should consider fire protection, fire insurance costs, water quality, water treatment costs, maintenance, and staff requirements for an on-site system. If the pressure in the existing water main is not adequate but the supply is adequate, then a booster pump may be required for domestic demand and/or fire protection. If the existing water system does not have an adequate supply for fire protection, an independent fire protection supply and distribution system must be designed and constructed.

If municipal water service is not available or the cost to connect to it is prohibitive, an alternative source is required. In most areas of the country, the alternative source is groundwater. However, in riverfront or lakefront areas, it may be surface water. Federal regulations require treatment of water taken from a surface reservoir for potable use.

Groundwater may also require treatment if it is used as a potable source. Raw water for use as a potable source must conform to federal, state, and local standards. A treatment plant permit may even require a licensed operator to operate and maintain it. Care should also be taken to properly analyze and/or pretreat raw water used for process, cooling, or even landscape irrigation. Raw water can inhibit chemical processes, cause mineral deposits in piping, corrode pipes, and stain sidewalks and buildings.

The water distribution grid should be well planned because it delivers the most critical resource to a facility. A registered professional engineer should perform the distribution design. Water mains should be looped and furnished with gate valves at each leg of major water main intersections to allow isolating segments without impacting other sections if a break occurs. Looping water mains increase the overall pressure of the system, increase the total capacity of the system, and provide needed flexibility. Dead-end pipes should be avoided because they cause water-quality problems. Gate valves should also be installed at 500-ft intervals to isolate water mains. The municipality or fire department will most likely specify the location and type of valves.

A fire protection engineer should perform the fire protection design. The associated water main should be sized to accommodate future facility expansion. Fire flow demands are determined by zoning, fire insurance underwriters, and/or by building codes and vary with the type of occupancy and the value of stored materials. Municipal water systems normally have available hydrant test data that include the static pressures, residual pressures, and fire flow in gallons per minute. If this information is not readily available, the municipality will usually conduct these tests for a fee. Pressures required in water mains for fire fighting depend upon the type of fire apparatus.

Newer water mains are typically made from cement lined ductile iron (CLDI), polyvinyl chloride (PVC)–coated steel, or concrete. Ductile iron is a type of cast iron that has ductile properties. References to cast iron and ductile iron relate primarily to their ductility. Other materials that were used for distribution mains in the past included cast-iron, asbestos-cement, and wood pipelines. Water services are typically copper or PVC, but lead, zinc, galvanized steel, brass, and bronze piping have been used in the past. CLDI piping is the most common material for city water mains. Standard sizes range from 4 to 24 in in diameter. Iron tubercles may form in unlined cast-iron pipes and seriously affect flow capacity. Lining with cement or epoxy can prevent tuberculation. Asbestos-cement pipe, although no longer available, can be easily broken by unevenly distributed external loads, such as pipe crossings, or by nearby excavation activities.

Local regulations specify the maximum allowable distance between fire hydrants. Fire hydrants should be located at high points of the water main alignment to allow the relief of air from the line. Hydrants should be the same model and from the same manufacturer as the

municipal system even if they are on a separate system. If possible, hydrants should not be located too close to buildings or structures in order to allow firefighters safe access to hydrants when the facility is on fire. A fire hydrant should be located near every outside sprinkler connection on buildings in order to allow a pumper truck to pump water from the fire hydrant to the sprinkler system. The placement of the hydrants and external connections should be coordinated with the municipal fire department and the facility fire insurance underwriter.

Another issue regarding water mains is that facilities frequently upgrade and/or add new structures. Excavating to construct new utilities is inevitable; therefore, water-main fittings and elbows must be constructed with mechanical joint restraints and/or concrete thrust blocks. Constructing new buried utilities invariably disturbs soils and bedding material surrounding existing utilities. Sometimes the existing water mains fail during the new construction, sometimes they fail during the next winter or thaw, and sometimes they fail when they are stressed under extreme conditions such as during a fire. Water-main failures are never convenient, never budgeted for, and are never inexpensive. Functioning water mains are critical during fire emergencies. Water is the lifeblood of a facility and will cost the facility if it is interrupted.

WASTEWATER

Wastewater collection and disposal are also critical planning components for a new or expanding facility. Wastewater is generally classified into three categories: domestic, industrial, and infiltration and inflow. If a municipal sewer with adequate capacity is available within the immediate area, then the facility should connect to it. If a municipal sewer is not available, wastewater must be treated on-site and disposed into subsurface soils or nearby surface water. Treatment standards and allowable discharge methods vary from state to state.

The level and complexity of the required permits and treatment generally depend upon the estimated daily flows, wastewater category, and discharge location. Domestic wastewater and industrial wastewater require different levels of treatment. Generally, larger flows also require more extensive treatment if the wastewater is to be discharged on-site.

Estimates of daily wastewater flow rates for specific uses are usually established by state permitting agencies. These numbers enable a designer to determine if existing municipal sewer facilities are adequate. If the new flows exceed the capacity of the existing system and/or wastewater treatment plant, it may be possible to detain the wastewater in on-site tanks and to discharge it to the municipal system during off-peak hours. The daily flow estimates will also allow an engineer to properly design an on-site treatment and disposal system, if it is required.

The size of a sewer should be based upon peak flows and not daily average flows, because sewer flow rates vary daily and possibly seasonally depending upon the use. The ratio of peak flows to average daily flows for residential use ranges from 2 to 6.0. Peaking factors for industrial wastewater should be estimated on the basis of water use, the number of shifts worked, and pertinent details of plant operations (Metcalf & Eddy, 1989).

In some communities, industrial and commercial users must purchase capacity because many wastewater treatment plants are limited by flow. Therefore, once the wastewater volume is known, the facility should check its agreement with the municipality to determine if additional capacity is available or can be purchased. Other factors that may limit a facility's daily wastewater flows are the size of the existing sewers and pump station capacities. Purchasing capacity may be expensive and should be budgeted into the project cost.

Connecting to a municipal sewer system requires a facility to adhere to the local or state sewer use ordinance. This ordinance may restrict certain pollutants to minute quantities. If a facility discharges process water, the ordinance could require pretreatment. Common sewer ordinance restrictions apply to mercury, copper, zinc, high temperatures, high and low pH,

high total suspended solids (TSS), and high biological oxygen demand (BOD). Domestic sewage does not usually require pretreatment before discharge to a municipal sewer.

Normally, a flow meter such as a parshall flume is installed in a manhole at the facility outfall to measure the sewage volume discharged to the municipal sewer system. The metering manhole is used to collect samples for analysis to determine conformance with the sewer permit or ordinance. Transmittal of the recorded data to a central facility may be required.

The sanitary sewer should be designed by a registered professional engineer and should conform to state and local standards. The following design guidelines were excerpted from New England Interstate Water Pollution Control Commission (1998):

1. Minimum slope of an 8-in gravity sewer is 0.004 ft/ft.
2. Minimum full flow velocity should not be less than 2 ft/s.
3. Velocity of 12 ft/s should not be exceeded under any flow conditions.
4. Sewers should be no closer than 10 ft to water mains.
5. Sewers closer than 10 ft may be allowed on a case-by-case basis if the crown of the sewer is at least 18 in below the invert of the water main.
6. Manholes should be installed at the end of each line; at all changes in grade, size, or alignment; and at all intersections.
7. Manholes should not be spaced greater than 300 ft for sewers with diameters of 15 in or less and spaced no greater than 400 ft for sewers 18 to 30 in in diameter.
8. Provide a drop pipe for sewers entering a manhole more than 24 in above the invert.

A facility manager should check with local regulations for sewer design criteria that may be more stringent.

The minimum size for building sewer connections is 6 in. The minimum size for sewer mains is 8 in. Service connections should be no larger than the sewer main to which they are connected. Downstream sewers should be larger than all of the upstream sewers to enable them to pass the solids contributed by the upstream sewers. When joining different sized small-diameter sewers, it is standard practice to match the inverts of the pipe to enhance free flow of sewage.

Smaller-diameter pressure or vacuum sewers (1½ to 2 in) can be used in lieu of gravity sewers but only if solids are properly handled. Solids can be handled by grinder pumps, settled out, and/or screened out in a comminutor before discharge to small-diameter pipes. Small pressure or vacuum sewers can save significant construction costs when difficult subsurface conditions are encountered because the trench depth can be kept to a minimum. Small-diameter sewers are more expensive to operate because they require solids control and sewage pump stations that need power, maintenance, and backup power.

Larger sewage pump stations or ejector stations are required when the receiving sewer is at a higher elevation than the facility's sewer system. There are several types of sewage pump stations. The sanitary district, municipal engineering department, or state regulators may specify the type of station. Common types of sewage pump stations include wet well/dry pit, submersible pumps, suction lift pumps, and ejector pots.

Generally, the preferred type of pump station depends upon the region of the country in which the system is located. Pump stations have stringent design criteria for determining the capacity of the pump, the size and shape of the wet well, alarm protocols, flow meters, control methodologies, and ventilation. At a minimum, two alternating pumps should be provided in the pump station. As with the smaller pressure and vacuum sewers, solids handling is critical. Larger pumps should be able to pass 3-in solids, at a minimum, but depending upon the specific application, it may be necessary to provide a comminutor upstream of the pumps to capture larger solids. The sewage pump station should be designed by a mechanical and/or a civil engineer assisted by an electrical engineer. The cost of sewage pump stations for individual facilities depends on the capacity, subsurface conditions, type of drives, emergency standby

power, gas detection equipment, screens, comminutor, flow meters, chemical feeders for odor control, and controls.

Velocity criteria for force mains are derived from observations that solids do not settle out at a velocity of 2.0 ft/s or greater. Solids do settle at lower velocities or when the pump is stopped, and a velocity of 3.5 ft/s or greater is required to resuspend the deposited solids. For small-sized or medium-sized pumping stations where flow may be pumped intermittently at any rate up to the maximum, the desirable force main velocities range from 3.5 to 5 ft/s. Blow-offs are normally not required on force mains. However, when the force main contains a long depressed section between high points, a blow-off is desirable to allow it to be drained and pumped out. A suitable blow-off might consist of a valved connection in a manhole at the low points, discharging to a manhole or vault that would serve as a wet well for a portable pump. The size of the blow-off should not be less than 6 in. It should, if possible, be large enough to provide flushing velocities in the force main (Metcalf & Eddy, 1989).

If possible, force mains should be designed without high points, and the top of the force main should be below the hydraulic grade line at the minimum pumping rate, so that air-relief valves are not needed. If the elimination of high points is not feasible, an automatic air-release valve should be installed at each significant high point where air could become trapped. A high point maybe considered significant if it is 2 ft or more above the minimum hydraulic grade line or, when pumping is intermittent, above the static headline. An air-release valve may discharge to a sewer manhole, a vented dry well, or other suitable place (Metcalf & Eddy, 1989).

On-site wastewater treatment is regulated by the local health department, county agencies, and/or state environmental agency. Once the average daily flow is determined, site suitability for the disposal of effluent is determined. Discharge to subsurface soils is the most common method for disposing of effluent from small on-site systems. Discharge to groundwater and surface waters is permitted in some areas if the on-site system is capable of meeting proper effluent discharge standards.

For most areas, the Natural Resources Conservation Service has delineated soil types for the top 60 in of the soil. The soil maps provide a general overview of the site and are, of course, not exact. The only accurate method for determining the soil type, depth to groundwater, and soil permeability is to perform in-situ test pits and permeability tests. Most states require trained, qualified engineers to perform these tests and to prepare soil reports. Leaching systems generally require large tracts of land for disposal of treated effluent. Leaching areas must be well ventilated to allow oxygen into the subsurface biomat so that continued aerobic biological processes occur.

Septic tanks remove about 40 percent of the BOD and TSS. They also have tees or baffles to prevent scum (floatables) from leaving the tank. Septic tanks require annual inspection of the amounts of sludge and scum. If the sludge is more than one-third the depth of the tank, then the sludge should be pumped out by a licensed septic hauler and disposed of properly. It is critical to prevent the septic tank solids from discharging into the disposal field. Therefore, it is important to have a licensed septic hauler on a regular pumping schedule. A leaching field can cost tens of thousands of dollars, or in larger systems, hundreds of thousands of dollars to replace.

If the disposal site is within a sensitive environmental area, aquifer protection district, and/or nitrogen sensitive area, then additional treatment may be warranted. Several devices on the market today can be added after the septic tank and before discharge that enhance treatment and remove additional quantities of BOD and TSS, as well as nitrogen.

Large on-site systems may require comprehensive hydrogeological studies to determine the impact of treated effluent on the local receptors. These studies include a comprehensive soil-boring program that includes soil sampling and water testing.

Flows that exceed 50,000 gal per day require more conventional wastewater treatment, similar to municipal types. If the project site has inadequate receiving soil and/or is limited in area, it is not uncommon for the facility to purchase suitable off-site land for disposal purposes. Process wastewater discharged to the ground normally requires pretreatment, similar

to the requirements for discharging sewage into municipal sewers. These discharges usually require groundwater discharge permits that set effluent standards and require periodic confirmatory sampling and reporting.

To reduce the amount of treated wastewater to be discharged into the ground, graywater reuse is possible. Greywater is discharge from sinks, showers, and bathtubs. In some instances, it can be used for irrigation, toilet flushing, process water, and/or cooling water. At a minimum, the treated wastewater must be disinfected before reuse.

STORM DRAINAGE

Managing stormwater involves many issues. From the standpoint of site development, it is desirable to limit the amount of stormwater flowing from off-site sources onto the developed areas of a facility. It is also important to design positive drainage patterns to direct stormwater away from facilities and to convey it efficiently from paved and landscaped areas into the storm-drain network via catch basins or other stormwater collection structures. Once in the storm-drain piping, the stormwater should be efficiently routed to discharge locations.

Increases in impervious area, altered drainage patterns, channeling of flow, and reduction of vegetation shorten the time of stormwater concentration on the site, decrease the infiltration of rainfall, and increase the flow rate and volume of runoff leaving the site. In addition, sediment, silt, and urban pollutants from paved surfaces are carried in the runoff. Stormwater is recognized now as a non–point source of pollution that can degrade downstream water quality. As such, many states regulate stormwater and require some form of treatment before discharge to the environment. Treatment may consist of one or more of the following: vegetated swales; constructed wetlands; stormwater detention facilities; stormwater retention facilities, such as swirl concentrators; or engineered facilities.

Most local regulations mandate that site improvements cannot increase the rate of stormwater runoff from a facility. This can be achieved by detaining stormwater in a detention pond or retention pond and allowing it to discharge at a low flow rate off-site (detention) or infiltrate into the ground (retention). If regulations dictate that the volume of stormwater runoff cannot be increased by a development, then stormwater infiltration into the ground is necessary. Mitigating stormwater runoff requires as much as 5 to 10 percent of the total buildable area, so it is important to account for it in the early planning stages.

Storm drainage systems are designed to convey specific storm events (10-, 25-, 50-, or 100-year). The storm designation describes the statistical likelihood that a particular design storm will occur in any given year. For example, a 10-year storm has a 10 percent chance of occurring in any given year or once every 10 years. A 100-year storm has a 1 percent chance of occurring in any given year or once every 100 years. This does not mean that once a 100-year event has occurred that it will not occur again for 100 years. Storm data have been statistically analyzed to forecast the likelihood of specific rainfall events.

Storm-drainage systems are usually designed for 10-year storm events. Culverts under roads are generally designed to convey flows from a 100-year event. Local and state regulations dictate the required design storm for specific drainage structures. Storm-drain systems are made up of a series of components that convey stormwater to downstream structures. Storm-drain systems are only as effective as the lowest capacity structure in the series. For example, if drainage piping is large enough to convey a 25-year storm but the catch basins can pass only a 10-year event, then the catch basins are the controlling factor in the system. Local and state regulations generally require that the runoff from a developed site be no larger than it was in its undeveloped condition for storms up to a 100-year event. Detention and retention ponds are designed to mitigate the maximum required storm. However, storm sewers and catch basins are not usually designed to convey a 100-year event efficiently. Catch basins will puddle if they are at a low spot in a road or parking area or will be bypassed by 100-year storm flows if they are on slopes. Storm piping will generally overcharge during large storms. There-

fore, some means must be provided for a large storm to discharge into detention or retention facilities even when the drainage system is beyond its capacity. It is critical to provide surface routes for stormwater to flow safely without flooding buildings, roads, or parking lots. For example, if a low spot with a catch basin is next to a building, the rim of the low area must be lower than the finish floor of the building. The surrounding topography must be designed to allow stormwater overflows to drain away from the building to protect it in extreme storms.

The storm drainage system should be designed by a registered professional engineer and should conform to state and local standards. If no local criteria exist, the following design parameters should be adhered to:

1. To size the storm sewer mains, assume that the facility is at the maximum allowable build-out (impervious surfaces) for areas that will be developed in the future.
2. Minimum pipe size should be 12 in, and minimum full flow velocity should be 2.5 to 3 ft/s.
3. Manhole spacing and design should conform to the criteria in items 6 and 7 in the subsection on wastewater.
4. Catch basin spacing should be no greater than 300 ft. Spacing depends upon gutter flow widths for highways and other critical roads and may result in closer spacing intervals for catch basins.
5. Use a minimum of 2 ft of cover over pipes.
6. Catch basins should be located upstream of intersections and crosswalks, if possible.

SUBSURFACE CONDITIONS

It is important to investigate the subsurface conditions under a proposed facility to determine the soil characteristics (bearing capacity, permeability, soil classification, and other engineering properties). It is also prudent to determine if contaminated soils or groundwater underlie the site. In addition to contaminated material, there may be construction debris or other landfill materials beneath the site. The depth to bedrock and groundwater should also be determined. These issues impact foundation costs for the new facility, as well as construction costs for utilities and any other subsurface structure.

Groundwater may limit the depth of foundations and utilities or may require underdrain systems. High groundwater may also cause pavement frost heaves in cold regions if pavement is not properly underdrained and constructed on frost-susceptible fill. Lowering the groundwater may impact adjacent existing facilities. For example, if the site is underlain by saturated clay, lowering groundwater will cause existing facilities to settle. If the adjacent facilities are on wooden piles, then lowering the groundwater may degrade the piles.

Underdrains should be used to lower groundwater in the vicinity of utilities, roads, or subsurface building structures. For underdrains to lower groundwater effectively below utilities and/or pavement, they must discharge by gravity to open channels or drainage ditches. To lower groundwater under subsurface buildings, a system of perimeter drains and underdrains should be used to convey groundwater to either a gravity discharge or sump pump. In addition, waterproofing methods such as impermeable membranes should be installed between the drainage system and the structure. Waterproofing is critical at construction joints and seams. Waterproofing alone will not prevent groundwater from seeping into a building. Waterproofing measures decrease the rate of infiltration, but the water level inside a building tends to equilibrate to the level of the groundwater outside of the building. If the subsurface soils are very permeable and/or a structure is to be constructed deep below the groundwater (subsurface parking garage), then it may be best to construct a waterproof system outside of the underdrains in order to minimize the size of the sump pumps and pumping costs. In this scenario, the underdrain system would discharge only water that leaks through the imperme-

able membrane or other impervious barriers, such as clay. Any buildings that use sump pumps to lower groundwater should have a backup power supply for the pumps.

Excavation dewatering during construction requires a permit in most areas of the country. Dewatering varies dramatically depending upon the following factors: depth of excavation, depth to groundwater, soil permeability, proximity of surface water, and length of an open trench or area of an excavation. All excavations must be performed in accordance with Occupational Safety and Health Administration (OSHA) standards and regulations contained in Title 29: Subpart P—Excavations, Trenching, and Shoring. In general, all excavations deeper than 5 ft require specified side slopes or trench protection, as mandated by OSHA to protect the safety of personnel. Excavations must have proper side slopes and/or trench boxes, sheet piles, or other excavation support. Precautions must be taken to protect existing utilities and aboveground structures when excavating.

Underground utilities for a proposed or existing development can consist of any or all of the following: natural gas, electrical, cable, telephone, potable water, storm sewer, sanitary sewer, force mains, fire protection, steam, or other industry-specific utilities. Subsurface utility networks can be complicated and require careful planning to minimize conflicts (horizontal and vertical). The sanitary sewer and storm sewer are generally the most complicated to design and construct because they flow by gravity. Most of the other utilities can be redirected during construction to avoid existing utilities or other obstructions. It is recommended that the storm sewer and sanitary sewer systems be designed first and other utilities be designed to accommodate them.

As-built drawings are invaluable when constructing close to existing utilities. Construction as-built drawings are sometimes omitted or not requested by an owner. As-built drawings may also be forgotten because they are prepared at the end of the construction project when the deadline is most pressing and are therefore skipped to save some time. Buried utilities are difficult to locate in the field, and facility managers cannot rely upon their memories or even the memory of the most skilled construction manager. The need to know where a utility is buried in order to avoid it or connect to it may not occur for years or even decades. If reliable as-built drawings are not available, it will likely be necessary to dig test pits at key locations before designing utilities.

ARTICLE 5.1.3
STRUCTURAL SYSTEMS

Michael L. Brainerd, P.E., and James C. Parker, P.E.
Simpson Gumpertz & Heger, Inc., Arlington, Massachusetts

UNDERSTANDING THE STRUCTURAL SYSTEM FOR FACILITY MANAGEMENT

Many engineers and facility managers believe that the structural system of a facility is built to last and that, if properly designed and constructed, the structural system will not need much of their attention throughout the facility's life. Relative to other building technologies, such as HVAC systems, electrical systems, and elevators, this perception is quite true. There are situations, however, when the facility manager must understand the behavior and limitations of the structural system. The structural system may be an important factor in managing significant changes to the other building systems and changes in the facility's use. With older buildings, the facility manager should be aware of any deficiencies in the original structural design criteria with respect to current practices and code requirements. And although the structural system usually requires less maintenance than other systems in the building, there are certain structures, such as parking garages, where diligent and continual maintenance of the structure is vital to the facility's economic life.

This article is intended to help the facility engineer and/or manager understand the behavior and limitations of the structural system. The approach to this task is twofold: first, we provide a brief primer on structural materials, design loads, structural elements and behavior, and structural system types; second, we explore some of the important structural aspects of new building design, building renovation, and building maintenance.

DESIGN LOADS

The aspects of the structural system most frequently evaluated over the facility's life are its strength and ability to safely support the intended use and to stand up to natural hazards such as snow, wind, and earthquakes. The weight that the structure is to support and the potential pressures and forces from windstorms and earthquakes influence the design loads. Structures must be safely designed with due consideration given to their service and imposed loads. Loads imposed on structures fall into two broad categories: gravity loads and lateral loads. *Gravity loads* result from gravity acting on a mass. Gravity loads, which act vertically downward on a structure, include dead loads, live loads, and snow loads. *Lateral loads,* which act horizontally on the structure, are forces generated by wind, earthquakes, and earth or fluid pressure.

Dead Loads

Dead loads include the structure's own weight and the weight of any permanent stationary components, including but not limited to roofing; floor finishes; ceilings; mechanical, electrical, and plumbing (MEP) components, such as pipes, ducts, conduits, and equipment; heavy

partitions; and exterior cladding. The dead loads used for design are computed on the basis of the actual weights of the building materials and components.

Live Loads

Live loads on floors include the weights of building occupants and temporary nonstationary components such as light partitions, furnishings, light movable equipment, and stored items. Live loads on roofs include minor accumulations of water and building occupants to varying degrees, depending on intended roof access. Live loads are typically prescribed by building codes. Codes prescribe loads both in terms of a uniform load in pounds per square foot (lb/ft^2) to be applied over the entire floor or roof area and a concentrated load in pounds (lb) to be applied separately over a small area anywhere on the floor or roof. Typical code-prescribed live loads for floors range from 50 lb/ft^2 for office use to 250 lb/ft^2 for heavy manufacturing and heavy storage use.

The 50-lb/ft^2 live load for office use assumes that items included in the live load are reasonably well distributed. In office layouts involving heavy concentrations of tall file cabinets, the floor loading of the cabinets alone often exceeds 50 lb/ft^2. Judicious positioning of banks of file cabinets relative to the structural framing (near columns and over girders) may be necessary to accommodate certain layouts on office floors designed for the code minimum live load of 50 lb/ft^2. Office floors are often designed for a live load of 100 lb/ft^2, including an allowance of 20 lb/ft^2 for partitions. This approach provides flexibility in space planning by not constraining the location of localized heavy loads, lobbies, and corridors.

Typical code-prescribed live loads for roofs range from about 20 lb/ft^2 for limited access roofs to well over 100 lb/ft^2 for roof-level plazas accessible to large numbers of occupants.

Snow Loads

Roofs in cold climates are exposed to accumulations of snow. Building codes prescribe design snow loads as uniform loads in pounds per square foot to be applied over the entire roof. Where roofs of differing elevation either adjoin or are in close proximity, snow will accumulate due either to drifting or sliding from a nearby sloped roof. Drifting also occurs at projections of large mechanical units, screen walls, and parapets. Current building codes include provisions for computing localized additional snow load to account for drifting and sliding snow. Note that codes before the 1970s did not prescribe drifting snow loads, and many older roofs do not have safe capacity for drifting snow.

Rain Loads

Rain can accumulate on roofs due to deflection of the roof structure and blockage of the drainage system. Building codes address rain loading to differing degrees, but generally they require designing roofs for the maximum amount of water that will accumulate if the primary drainage system becomes blocked. The depth of water is based on the deflection of the roof framing and the height of overflow at scuppers or roof edges. Roof framing should be designed with strength adequate to carry rain loads and stiffness adequate to preclude unabated progressive deflection.

Lateral Loads to Account for Potential Windstorms

Wind blowing against and around a structure exerts lateral loads as pressure on the windward face and suction on the leeward face. The magnitude of the wind pressure is proportional to

the square of the wind speed. Globally, wind speed and, therefore, wind pressure varies from region to region. The design wind speed in most of the central United States is typically about 70 mph. The design wind speed can be 100 mph and higher near the coastlines. Wind speeds throughout the life of the structure are highly variable. Therefore, U.S. codes generally require designing structures for a wind speed that has a .02 annual probability of being exceeded—in other words, for a windstorm that, on average, occurs every 50 years.

The engineer must estimate the wind pressures on the building on the basis of the wind speed. Wind speed increases with the height above ground and is influenced by the shape of the structure, the number and shape of nearby structures and obstructions, and the surrounding topography. Localized wind effects, such as vortex shedding, increase wind pressure near building corners. Building codes prescribe very detailed methods for computing wind loads on structures as a whole and on components of structures, considering all of the effects described.

Lateral Loads to Account for Potential Earthquakes

Ground motions due to earthquakes are sudden, usually caused by sudden ruptures along faults in the earth's crust. The center of the earthquake is called the *focus,* and the spot on the earth's surface directly above the focus is the *epicenter.* Complex vibrations in the form of ground waves emanate from the rupture. When the ground waves reach a structure, the base of the structure is subjected to a complex motion. As the base of a structure moves, the inertia of the upper portions of the structure resists this movement, and forces are generated within the structure. The magnitudes of these seismic forces are highly variable with time during the earthquake. Given a recording of actual earthquake records, engineers can estimate resulting forces in a particular building if the building's construction is relatively well documented. Because the exact location and magnitude of, and ground motions resulting from, future earthquakes are unpredictable, it is very difficult to predict the actual forces that a structure may experience. Therefore, current practice incorporates a probabilistic approach in designing buildings for earthquake loads. Most current codes prescribe designing for ground motions that have about .002 annual probability of being exceeded. Codes often express this ground motion as that which has a 10 percent chance of being exceeded in 50 years or that has an average recurrence interval of 475 years. (This is about 10 times less likely than the typical design wind speed.) If a building is near a known fault (a known location of weakness in the earth's crust where earthquakes have occurred in the past), then some codes require a deterministic approach to design. In this case, the design ground motions are based on the maximum expected earthquake on the given fault, the type of geology between the fault and the building, and the distance of the building from the fault.

For most common buildings, current codes do not require designing for actual ground motions from past earthquakes or ground motions predicted to occur in the future. Instead, codes prescribe a highly simplified approach of designing for horizontal static forces on the building by using prescriptive structural details. This approach does, however, account for the building's use, the building's fundamental frequency, and the site's soil conditions. The current codes, which are minimum requirements, aim to protect life, not necessarily to prevent damage to the building and its contents. Codes recognize levels of protections. Fire stations, hospitals, and communications centers require a higher degree of design. Because of the simplified and empirical nature of the code approach, the goals are only implicit and are not explicitly defined. Generally, damage from the design level ground motion is expected, but the damage should have a low probability of causing hazard to life. For ground motion 50 percent greater than the design level, damage is expected to result in hazard to life, but the probability of total collapse is still small. Future earthquake codes are likely to adopt more elaborate procedures that allow designing for a given level of performance, such as immediate safe occupancy after the earthquake or various degrees of protection from damage to the building and/or contents.

The first earthquake design rules were adopted for portions of the West Coast after the 1933 Long Beach, California, earthquake. Adoption of earthquake design rules spread along the West Coast and have been evolving as new data are collected from the responses of buildings to earthquakes and from earthquake research. Adoption of earthquake design regulations for other parts of the United States lagged far behind those adopted on the West Coast despite knowledge of the potential for earthquakes elsewhere in the country. For example, a significant historical earthquake occurred in New England in 1755, and the largest known earthquake in the continental United States occurred in Missouri in 1811. The first earthquake regulations east of the Rocky Mountains were adopted in Massachusetts in 1975. Therefore, the original designs of many buildings currently in use in the United States did not account for seismic ground motion, and these buildings present a real risk should an earthquake occur. Although many of these buildings are "grandfathered" into existing codes, exempting them from retroactive requirements for strengthening, many new codes now include triggers, such as change of use, additions, or restorations, that require seismic strengthening of older buildings.

Vibratory Loads on Structures

Human rhythmic activity, such as marching, dancing, and aerobics, can cause vibration of floor systems. Long-span structures supporting open spaces that are free of damping elements such as full-height partitions are most susceptible to vibratory loads. Vibrations can be perceptible to the point where they alarm occupants and can, in the extreme, damage the structure. Occupied spaces over convention center exhibition halls and cantilevered seating areas of stadiums and auditoriums have been known to vibrate perceptibly due to human rhythmic activity. Moderate-span light-steel structures may vibrate perceptibly if used for dancing or aerobics. Building codes are often silent on the issue of vibratory loads, although some require considering such loads in the design but do not prescribe how to do so.

Reciprocating machinery and mechanical equipment can also cause perceptible and possibly damaging vibrations. The supports for these components should be designed to minimize transmission of vibrations to the structure.

Load Combinations

Structures should be designed for the credible combination of loads that produces the most unfavorable magnitude of the structural effect being examined. In some cases this may occur when one or more loads are not acting. The least credible load combination, dead load alone or some fraction thereof, may produce the largest magnitude of some structural effects. Some loads are unlikely to occur at the same time. The design need not consider that wind and earthquake loads will act simultaneously. The chance of simultaneous occurrence of dead load, full live load, and lateral load (seismic or wind) is small. Therefore, the combined effects of these loads are typically reduced. Building codes prescribe the load combinations that must be considered in most usual situations.

BASIC STRUCTURAL ELEMENTS AND BEHAVIOR

Foundation Elements

Building foundations can be broadly classified as either shallow or deep foundation systems. The most common *shallow foundation* element is the spread footing. *Spread footings* are individual rectangular concrete elements that support one or more building columns. The spread footing transfers the load from the column to the soil. The size of the footing in plan is a func-

tion of the column load and the allowable soil-bearing pressure. When the allowable soil-bearing pressure is very low or the soils are prone to settlement, buildings are founded on mat foundations that are essentially a single spread footing covering the entire footprint of the building. The bottoms of shallow foundations that extend beyond the perimeter of the building must be located below the frost line, which can be several feet or more below grade.

When suitable bearing soils are not reasonably close to the surface, *deep foundations* are used. Deep foundations include *piles* and *drilled piers.* Unlike spread footings, which are constructed in a general excavation extended to the bearing strata, piles and drilled piers are constructed by driving or drilling through unsuitable material into the load-bearing soils. Piles and drilled piers transfer the column load to the soil by friction and/or end bearing. Many types of piles are commercially available, including steel H piles, round steel-pipe piles, and cast-in-place and precast concrete piles. Groups of closely spaced piles are installed at each column location and are covered by a single concrete cap, upon which the building columns bear. Drilled piers are relatively large diameter, round, concrete foundation elements that are constructed by casting concrete in predrilled holes. Drilled piers, also known as *caissons,* have straight shafts or are widened (belled) at the bottom. Typically, an individual drilled pier is installed at each column location and is covered with a rectangular concrete cap, upon which the column bears.

Superstructure Elements

Superstructure elements include vertical elements such as columns and load-bearing walls, and horizontal elements such as slabs, beams, and girders. The basic horizontal superstructure element is the slab. All superimposed vertical dead and live loads are carried by the slab, which spans either one way between beams or bearing walls or two ways between columns in the case of two-way slab systems. In structures with one-way slab systems and beams, the slabs are supported on the beams, which are in turn supported either directly by the building columns or by girders that span between building columns. Columns and bearing walls carry the loads from the various floors down through the building to the foundations.

Lateral Load-Resisting Systems

The lateral (wind and seismic) loads on a building are carried by the lateral load-resisting system. There are two basic types of lateral load-resisting systems: braced-frame/shear-wall systems and moment-resisting frame systems. *Shear walls* are vertical walls of concrete, masonry, or wood, depending on the structural system type. *Braced frames* comprise one or more building columns interconnected by diagonal members to create a stiff wall-like lateral load-resisting element. Braced frames are usually steel but can also be constructed of concrete. In braced-frame/shear-wall buildings, the lateral loads on the floors and roof are resisted by a series of braced frames or shear walls, two or more in each direction, that cantilever from the foundations.

Moment-resisting frames are comprised of columns and beams or girders in a plane rigidly connected to one another. Because the beams and columns are rigidly connected at the joints, the lateral loads are resisted by the bending strength of the columns and beams or girders.

COMMON STRUCTURAL SYSTEM TYPES

Concrete Systems

Concrete is a composite of cement, stone, sand, water, and chemical admixtures. Concrete is fluid when first mixed, and chemical reactions between the cement and water cause the mass

to harden into a rocklike solid that is very strong in compression, but weak in tension. As a result, tensile loads are carried by reinforcing bars embedded in the concrete. Because concrete is transformed from a fluid to a solid, it can be formed into virtually any shape either on-site or in a precasting plant. Because it is versatile, concrete can be used to varying degrees in all building structures.

Concrete structural systems fall into two general categories: cast-in-place and precast systems. *Cast-in-place* concrete systems are constructed by erecting forms and casting the concrete on the project site. The components for *precast* concrete structures are cast at a precast plant, then shipped to the site, and set in place with cranes. Common cast-in-place concrete systems include one-way slab, joist, and beam systems (Fig. 5.1.3-1); one-way slab, beam, and girder systems (Fig. 5.1.3-2); and two-way flat slab and waffle slab systems (Figs. 5.1.3-3 and Fig. 5.1.3-4). Common precast systems include hollow-core plank and inverted tee-beam systems; precast, prestressed hollow-core plank and inverted tee-beam systems (Fig. 5.1.3-5); and precast, prestressed, double-tee and inverted tee-beam systems (Fig. 5.1.3-6). Precast systems usually include a cast-in-place concrete topping to provide a level floor and increase load-carrying capacity.

Concrete systems typically weigh more than other structural systems, such as steel. Because of the higher gravity loads and seismic loads, concrete superstructures require stronger and more costly foundations and seismic load-resisting systems than comparable steel superstructures. The higher mass of concrete structures makes them less susceptible to transmission of vibrations due to human activity and machinery.

Concrete is generally considered fire resistant as long as sufficient concrete cover is provided over the reinforcement. For usual fire ratings, no special fire protection is required on concrete elements.

Concrete is generally considered a very durable building material. Under certain exposures, however, concrete must be specially formulated to withstand premature deterioration. The most common exposures that deteriorate concrete include exposure to weather, particularly freeze/thaw cycling and deicing salts, and exposure to salt and sulfate in seawater and certain soils. Exposure to weather in cold climates can result in disintegration (scaling) of the exposed concrete surface due to freezing while saturated with moisture. Resistance to freeze/thaw damage is achieved by incorporating a system of small bubbles (entrained air) in

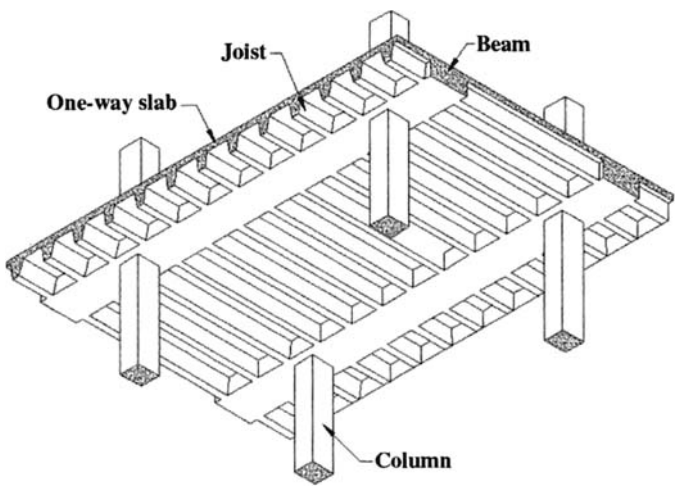

FIGURE 5.1.3-1 One-way slab, joist, and beam system. (*Courtesy of Simpson Gumpertz & Heger, Inc.*)

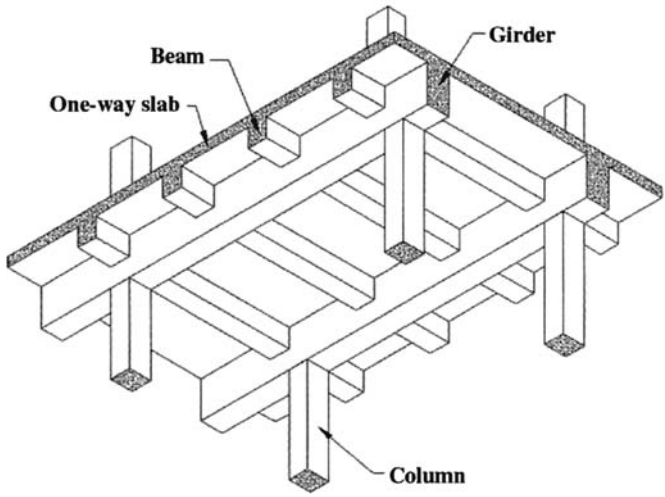

FIGURE 5.1.3-2 One-way slab, beam, and girder system. (*Courtesy of Simpson Gumpertz & Heger, Inc.*)

the concrete by adding air-entraining admixtures. Exposure to deicing salts and salt in seawater can cause corrosion of the steel reinforcement. Resistance to corrosion damage is achieved by using low permeability concrete and by increasing the distance (cover) between the exposed concrete surface and the reinforcement. Corrosion-inhibiting admixtures and coated reinforcement are also available to combat corrosion damage. Exposure to sulfate in seawater and soil can cause general disintegration of the concrete. Resistance to sulfate attack is achieved by using low-permeability concrete and special cements.

Steel Systems

Steel is an alloy predominantly composed of iron and carbon. Modern structural steel for buildings falls into two broad categories: carbon steel (ASTM A36) and high-strength, low-alloy steel (ASTM A572), with minimum yield strengths of 36,000 and 50,000 lb/in^2, respectively.

Structural steel systems fall into two general categories: steel beam systems (Fig. 5.1.3-7) and steel joist systems (Fig. 5.1.3-8). Steel beam systems are comprised of concrete slabs sup-

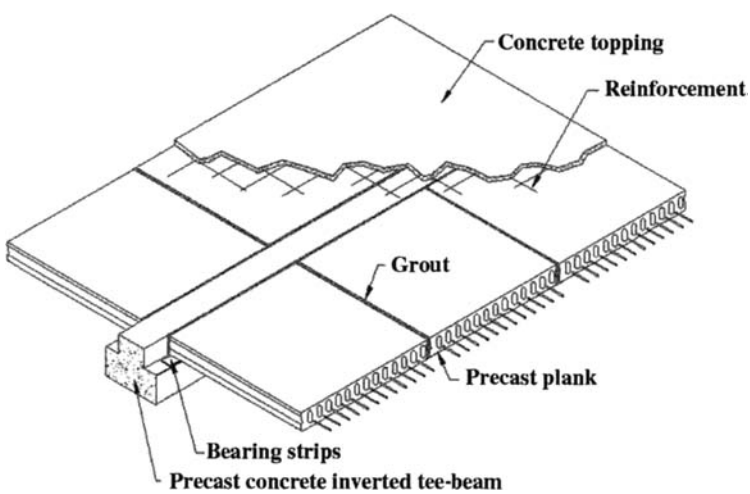

FIGURE 5.1.3-5 Precast, prestressed hollow-core plank and inverted tee-beam system. (*Courtesy of Simpson Gumpertz & Heger, Inc.*)

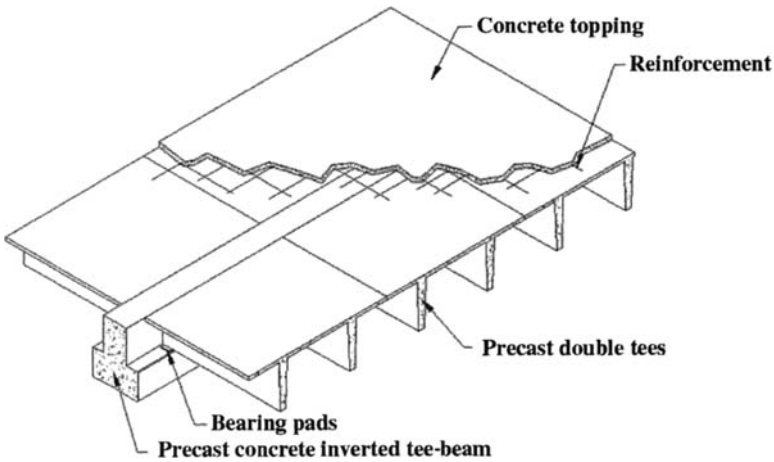

FIGURE 5.1.3-6 Precast, prestressed double-tee and inverted tee-beam system. (*Courtesy of Simpson Gumpertz & Heger, Inc.*)

ported by steel beams, girders, and columns. Common slab systems used with steel beam framing include cast-in-place concrete on metal deck, formed cast-in-place concrete, and precast hollow-core plank with a cast-in-place topping. Slabs on steel joists are usually cast-in-place concrete, either formed or on a metal deck.

Many prefabricated structural steel shapes are readily available. The most widely used are wide-flange sections (W shapes), American standard channels (C shapes), and angles (L shapes). Except for angles, structural shapes are generally designated by a letter that indicates the shape and is followed by two numbers. The first number indicates the nominal depth, and the second indicates the weight of the section in pounds per foot. For example, W14 × 22 identifies a 14-in-deep wide-flange section that weighs 22 lb/ft. It is important to realize that the depth designation is nominal only and that the actual depth may vary significantly within the nominal depth category, particularly for the heavier sections within a grouping. The designations and properties for design and detailing of commonly produced structural shapes are tabulated in the *Manual of Steel Construction* published by the American Institute of Steel Construction (AISC).

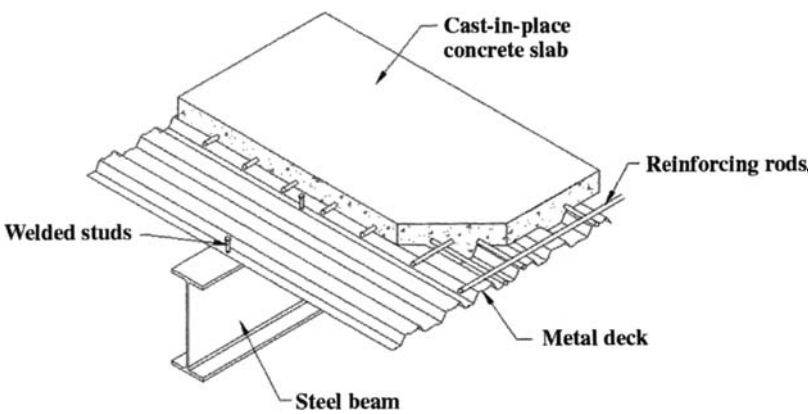

FIGURE 5.1.3-7 Steel beam system. (*Courtesy of Simpson Gumpertz & Heger, Inc.*)

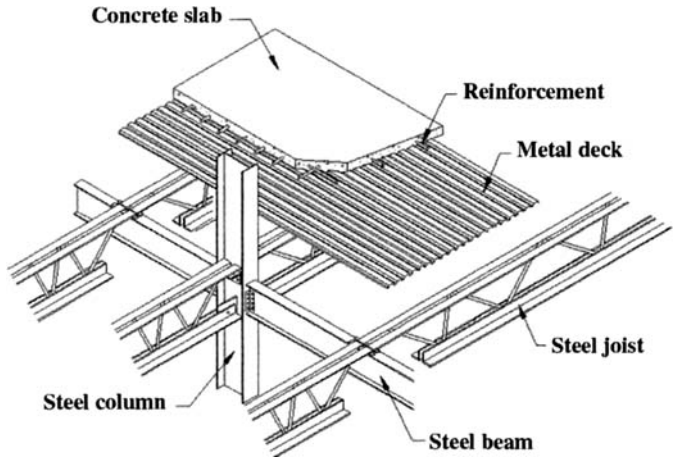

FIGURE 5.1.3-8 Steel joist system. (*Courtesy of Simpson Gumpertz & Heger, Inc.*)

Prefabricated truss-type steel components, typically referred to as open-web steel joists, are also readily available commercially. These members are often fabricated from angle shapes and round bars. Open-web steel joists, which often are comprised of double-angle top and bottom chords and a continuous round bar bent to form the web members, are produced in standard depths from 8 to 30 in. Each depth class contains many joists of varying capacity and weight. Safe load capacities of joists are contained in load tables published by the Steel Joist Institute.

Unlike concrete, steel is susceptible to fire damage and often requires additional fire protection, such as spray-on fireproofing or fire-resistant enclosures.

Masonry Systems

Modern masonry structures typically are comprised of reinforced masonry-bearing walls supporting slab systems of cast-in-place concrete or precast hollow-core plank with a cast-in-place topping. Older masonry structures may have wood floor framing systems. The masonry-bearing walls typically carry both the gravity and lateral loads. A masonry wall, by itself, does not have significant lateral load-carrying ability.

Masonry components most commonly used in modern building construction include stone, clay brick, and concrete brick and block. Clay and concrete units may be either hollow or solid. Masonry is used for exterior cladding (veneer), non-load-bearing walls, load-bearing walls, columns, and beams. Masonry walls may be either reinforced or unreinforced, although most current building codes require constructing exterior walls, walls around stairwells, and load-bearing walls of reinforced masonry. Masonry components are constructed by placing masonry units by hand with mortar in the joints between adjoining units. Horizontal reinforcement consists of truss or ladder-type constructions made from small-diameter wire and laid in the horizontal mortar joints. Vertical reinforcement usually consists of deformed reinforcing bars grouted solid in the collar (vertical) joints between multiple widths of masonry or in the hollow cores of individual widths.

The strength of masonry assemblages is a function of the compressive strength of the individual units and of the type of mortar. Clay brick is classified as NW (no exposure), MW (moderate weathering), or SW (severe weathering), and the minimum compressive strength

for each grade is 1500, 2500, and 3000 lb/in^2, respectively. Concrete masonry (brick or block) is classified as either N (high strength and resistance to moisture penetration and severe frost) or S (moderate strength and resistance to moisture penetration and frost). The minimum strengths of Grade N and S concrete brick are 2500 and 3500 lb/in^2, respectively. The minimum strengths of Grade N and S hollow load-bearing block are 700 and 1000 psi, respectively. Mortars are classified as Type M, S, N, or O and have minimum compressive strengths of 2500, 1800, 750, and 350 lb/in^2, respectively. Structural masonry is generally constructed with Type M or S mortar.

Wood Systems

Wood structures typically are comprised of plywood flooring on wood joists supported by wood beams and bearing walls. The wood joists are either sawn lumber or any of a variety of proprietary prefabricated joist elements. Beams are either ganged pieces of sawn lumber or any of a variety of proprietary prefabricated beam members, including glulam beams and microlam beams.

The strength of wood is highly variable because of many factors, including moisture content and defects such as knots, splits, and checks. The strength of wood also varies with the load duration and the direction of the load relative to the grain of the wood. All of these factors are considered in designing wood components by using load factors for loading duration and allowable stresses based on the type, quality, and moisture content of the wood and on the type and orientation of the stress.

Common modern wood members include sawn lumber, glulam beams, and microlam beams. Glulam beams are members comprised of smaller wood members laid flat and affixed together with adhesive. Microlam beams are members comprised of wood veneers, oriented vertically and laminated together. The flexural strength and modulus values of common lumber, such as spruce, pine, and fir, are 1000 and 1,200,000 lb/in^2, respectively. By comparison, the flexural strength and modulus values of microlam members are 2,800 and 2,000,000 lb/in^2, respectively. There are also numerous proprietary wood joists and truss type components available comprised of combinations of sawn lumber chords and web members of sawn lumber, plywood, particleboard, and light-gauge metal.

NEW BUILDING DESIGN

Design Criteria

One of the first tasks of the engineer-of-record in the structural design of a new building is preparing the structural design criteria. This document lays out all of the criteria that will be the basis for the structural design. As a minimum, the design criteria should contain the following information:

- Identification of the governing building codes. Some jurisdictions publish complete building codes based on one of the national model codes, and others adopt one of the national model codes and publish supplements with jurisdiction-specific modifications.
- Identification of the report of the geotechnical investigations for the project and a summary of the foundation design recommendations contained therein.
- Design loads assumed in the design, including computations and a summary of the dead loads, a summary of the live loads, and computations and a summary of the wind and seismic lateral loads.
- Limits on deflection for floor and roof framing.

- Limits on drift for the lateral load-resisting system.
- Special loading, deflection, and vibration requirements and limitations.
- Description of the structural systems employed in the project.
- Description of the lateral load-resisting system and load paths.

Although preparing the design criteria is one of the first tasks, the criteria will evolve through the schematic design phase and into design development.

Structural Configuration

The configuration of the structure is determined by the available space, the functional requirements, and local codes. In the schematic design phase, the structural engineer and architect work closely to identify bay sizes (column spacing) that fit within the space planning constraints and are both feasible and economical. If unconstrained, story heights are selected to accommodate the desired ceiling height and structural system depth and to provide adequate space between the ceiling and structure to accommodate MEP components. However, story heights are often constrained either to match nearby or adjoining buildings or to maximize the number of stories within code-imposed building-height limitations.

Structural System Type

Once bay sizes and story heights are established, the structural engineer identifies one or more structural system types that can accommodate the desired configuration and develops schematic-level designs for cost comparison. The structural engineer identifies the advantages and disadvantages of structural system alternatives in terms of important characteristics such as cost, constructability, availability of materials and qualified contractors, future maintenance, and flexibility of structural modifications associated with future space changes. This information provides a rational basis for the owner, with the assistance of the structural engineer and architect, to select the most suitable structural system type.

STRUCTURAL IMPLICATIONS OF BUILDING RENOVATION

Interior Remodeling

Interior remodeling projects can impact the building structure to varying degrees, depending on the nature and scope of the project. Changes to layouts of interior walls often have little impact, if any, on the structure, as long as the walls are non-load-bearing and as long as the weight and/or concentration of walls are not significantly increased. Whether a wall is load bearing is not always obvious. If there is any doubt about a wall's function, it is prudent to review the original structural drawings and records of subsequent building modifications to identify load-bearing walls. In the absence of such information, inspection by a structural engineer may be necessary.

Interior remodeling projects often involve closing and/or adding door openings in load-bearing walls. Adding and closing openings affects the path of loads down through the wall and also affects the wall's ability to carry lateral (wind and seismic) loads. The structural effects of such modifications must be carefully evaluated to confirm that they do not impair the wall's ability to carry design loads safely. The level of effort required to complete such an evaluation can be substantial, depending on the number, size, and locations of openings. Record drawings of bearing-wall modifications should be maintained for use in evaluating

future wall modifications. The lack of such records can lead to costly field investigations of existing conditions and errors in evaluating future wall modifications. Figure 5.1.3-9 shows an elevation of a story-high, posttensioned concrete beam taken from the structural design drawings for a building. This wall is actually a transfer girder that carries several stories of the building above it while creating a large column-free space below. An uneducated eye could easily view this wall in place and mistake it for an ordinary bearing wall which could readily accommodate a new door opening without significantly affecting the support for the floor immediately above. Depending on its location, however, such an opening could completely destroy the wall's ability to act as a transfer girder.

The addition of stairways and elevators requires large floor openings. The impact of such openings on the structure and the need for strengthening and additional structural supports depends on the size and location of the opening and the type of structural system. Generally, one-way slab systems with steel beam and girder framing can often accommodate large openings with little structural modification, particularly when the opening fits between adjacent beams or girders. Two-way flat slab systems, on the other hand, often require significant strengthening to accommodate large openings.

MEP Modifications

Modification of MEP systems often involves removing, replacing, and adding ducts, pipes, conduits, and equipment. Such changes can impact the structure by adding weight and requiring openings in slabs, beams, and walls. Openings for ducts, pipes, and conduits are usually small and easily accommodated unless they are numerous and closely spaced. As a general rule of thumb, small horizontal openings through beams can be accommodated (without impairing the load-carrying capacity of the member) if they are not numerous and closely spaced and are located within the middle third of both the depth and span of the beam. Openings through slabs are usually readily accommodated, particularly in one-way slab systems, but may require some minor supplemental framing around large duct openings or banks of pipe and conduit openings. In two-way cast-in-place concrete slabs, openings near columns must be avoided or at least limited, because they can greatly diminish the transfer of the floor load from the slab to the column. Large duct openings and numerous closely spaced pipe and conduit openings impact walls in much the same way as door openings, as discussed in the previous subsection on interior modifications.

MEP modifications that involve adding duct work and small-diameter pipes and conduits usually do not significantly affect the loads on structures that have been designed with a reasonable allowance for suspended MEP components, usually about 10 to 15 lb/ft^2 for most commercial and institutional structures. Manufactured metal buildings, on the other hand, are usually designed for ancillary loads of only several pounds per square foot and therefore require careful evaluation for even minor additional loads.

Mechanical rooms are typically designed for large live loads in order to account for miscellaneous light- to medium-weight equipment and servicing activities. In both new design and design for MEP modifications, the impact of heavy MEP components, such as cooling towers, generators, large heating units, and large-diameter liquid-filled pipes, is evaluated on the basis of the specific size, weight, and location of each component. Replacing existing units with larger units and adding units and large-diameter pipes, particularly outside of mechanical rooms, usually requires strengthening the structure.

Changes in Use

Changes in use from one of lower live loading to one of higher live loading may require structural strengthening. As an example, changing from office use to heavy storage would require that the structure be capable of carrying an additional 200 lb/in^2 of live load. Changes in use

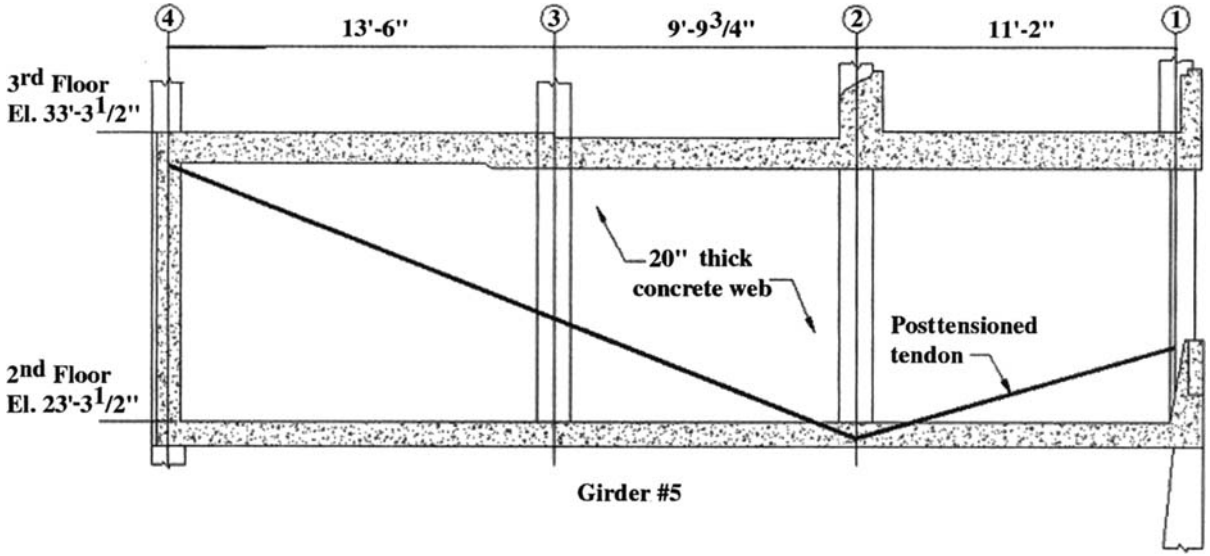

FIGURE 5.1.3-9 Posttensioned story-high concrete beam. (*Courtesy of Simpson Gumpertz & Heger, Inc.*)

from one involving minor human rhythmic activity, such as normal office use, to one involving significant rhythmic activity, such as dancing, aerobics, or reciprocating machinery, will usually require modification of the dynamic characteristics of the floor structure in order to minimize annoying vibrations and preclude damage to the structure.

Seismic Hazard Mitigation

As previously discussed, many older buildings in many jurisdictions were constructed before code-prescribed seismic design requirements were introduced. More recent buildings in many jurisdictions were designed and constructed in accordance with seismic design requirements that were less stringent than today's requirements. Most current building codes contain provisions for mitigating seismic hazard that require that existing buildings undergoing significant repair or modification be evaluated and upgraded to ensure at least some minimum level of seismic resistance; under certain circumstances, full compliance with the seismic requirements for new buildings must be met. Project teams must plan for seismic hazard mitigation early in the conceptual development of the project because it can have a wide-ranging impact on scope and cost.

Seismic hazard mitigation has two components: ensuring that the risk of life-threatening structural damage is acceptable; ensuring that the risk of life-threatening damage from nonstructural components such as walls, MEP equipment, ceilings, lights, and tall, heavy furniture is acceptable. Sophisticated owners of large numbers of buildings that are vital to their business operations have seismic hazard mitigation programs that include identifying and upgrading seismically deficient buildings. In general terms, seismic upgrading includes strengthening or augmenting the existing lateral-load-resisting system of the building and anchoring nonstructural components.

STRUCTURAL MAINTENANCE

Most building structures are enclosed and are thereby shielded from the deteriorating effects of weather. The interior conditioning of most buildings is benign. Under these circumstances, building structures require little maintenance. There are, however, some notable exceptions. Unenclosed structures, such as parking structures and outdoor sports facilities, and exposed building components, such as balconies and uncovered exterior slab edges, beams, and columns of otherwise enclosed buildings, are all exposed to the damaging effects of weather and the atmosphere. Buildings with special interior conditioning or exposure, such as natatoriums and certain industrial and food-processing facilities, are exposed to the damaging effects of humidity, high temperature, and chemicals.

Structures with deleterious exposures must be designed to include durability features above and beyond those of usual building structures. Concrete components may require specially formulated concrete, reinforcement with protective coatings, or topical treatments. Steel components may need to be fabricated from special steel or galvanized steel, or be provided with protective coatings. Most deteriorative mechanisms involve an incubation period during which the conditions necessary for initiating deterioration develop. Once deterioration begins, in most cases, it will continue at an ever-increasing rate. In many situations, maintenance and repair will generally slow but will not stop ongoing deterioration. The choice of durability measures depends on the type and severity of exposure, the cost, and the tolerance of the structure for maintenance.

The condition of the building structure should be audited periodically to identify structural conditions requiring repair or maintenance. Inspect exposed structural elements and building finishes to identify readily visible signs of deflection, cracking, movement, and deterioration

Next Page

(crumbling concrete, rotted wood, corroded steel, and debonding and wear of protective coatings). Also inspect structural components that are exposed in unfinished spaces or are readily accessible behind finishes which can be easily removed and reinstalled, such as acoustic tile ceilings. Pay particular attention to locations of potential water infiltration and associated deterioration, such as below roofs and plazas and where structural components adjoin exterior walls. Conditions of deflection, cracking, movement, and deterioration will require evaluation by a qualified engineer to determine the cause and seriousness of the damage and to design repairs. Facility managers can commission a general, overall assessment of the condition of a facility, or of a campus, by a qualified engineer. Effective condition assessments require blending diligent inspection, engineering judgment, and experience.

ARTICLE 5.1.4
SKINS AND FACADES

Michael J. Kearns, C.C.S., R.C.I.
CID Associates Inc., Boston, Massachusetts

This article addresses the general architectural and engineering design criteria of external wall systems that are typically used in today's industrial and institutional facilities. This discussion will enable facility engineers and building owners to better understand the intended purpose of various design elements and to anticipate the intricacies of the design process as they relate to the facades of their facilities. Our scope is limited to the exterior walls and does not include the roofing system, which is discussed in Art. 5.1.5, "Roofs."

The building facade provides the facility with a controlled environment. The primary function, therefore, is to keep the interior of the facility free of the elements. We typically consider rain and snow when referring to "the elements." However, the building facade controls additional weather-related anomalies from intruding upon the controlled interior environment. The facade keeps wind from blowing through the workspace and provides a barrier to the flow of temperature and humidity. The facade must provide this protective environment while working with the facility structural systems and, in some cases, also acting concurrently as a significant structural element. Here are the typical performance requirements of the building facade as we have identified them thus far:

- A shield from precipitation
- A wind and airflow barrier
- A vapor retarder
- An insulating element
- A structural element
- A defining element of the building aesthetics

These are some of the basic design requirements that engineers and architects expect from the building facade. In addition to performing the basic system requirements that provide the facility with the proper controlled working environment, the facade is also the most obvious and immediately noticeable architectural feature of any building. Today the choices of facade building materials are quite extensive. The choices of materials to be used are often driven by the desire to make an architectural statement and by budgetary constraints. Facility engineers should be acquainted with the design elements of their particular facilities. This article examines the basic construction techniques and maintenance requirements for some of the typical exterior wall systems and materials.

The oldest and most common type of building facade is some form of masonry construction. This category can include natural stone, concrete block, brick, structural clay tile, and precast concrete, as well as combinations of each. Typical masonry construction from the turn of the century through the 1960s and into the present entailed a design of low-rise load-bearing exterior walls. Earlier designs consisted of 3- or, in some cases, 4-wythe-thick solid brick walls. The mass of brick and mortar was normally sufficient to keep out moisture and wind. In-wall flashing when detailed was limited to wall openings such as small windows and doors. The solid walls were typically tied together using soldier courses of brick at regular intervals and patterns. A brick placed in a soldier position is one that is turned so that the length of the brick spans 2-wythe wall sections.

Over time, masonry construction developed from the solid wall configuration to the cavity wall, shown in Fig. 5.1.4-1, that is more common today. Masonry cavity walls are still typically load bearing but use less material to achieve the same or better performance. Cavity walls also typically combine both brick and concrete block in their matrix. The use of concrete block provides construction cost savings over a solid brick wall. Thus, greater structural capacity can be obtained at lower cost by employing this construction method. However, cavity wall design and construction requires that additional techniques be employed to ensure that the facade will provide the five basic requirements listed before.

Structural integrity is maintained by the placement of wall ties that join the outer face brick to the concrete backup wall. The placement of wall ties is critical to the stability of the wall system. If an insufficient number of ties is used along with either improper placement or type of ties, the outer facade can be left in an improperly supported condition. Because the backup wall typically assumes the load-bearing components of the roof and floor framing systems, the use of inadequate ties can leave the facade in a cantilevered state. Again, depending on the wall height and slenderness ratio, an inadequately supported wall can be very unstable.

Moisture is deterred from penetrating through the wall system by placing dampproofing materials and systems within the wall cavity. Typical materials used for through-wall flashing are lead-coated copper, asphalt membranes with copper fabric backing, and other synthetic membranes. Weep holes placed at the base of the through-wall flashing materials within the cavity are necessary to convey the moisture from within the wall. These accessory items must be incorporated into the cavity wall system at specific locations in order to control and manage the flow of water through the wall without enabling penetration into the building interior.

The outer brick face provides a barrier from wind, and the structure of the wall and building system is designed to accommodate extreme wind loading. Insulating value can be added to the facade by placing insulation within the core of the concrete block or on the back of the wall system. Vapor barrier requirements are determined by geographic location and use of the facility. Vapor barriers are placed on the *warm* side of the facade, which is normally the building interior. Exceptions to this standard are controlled, chilled environments, such as freezer storage or humidity-controlled environments in hot, humid climates, in which case vapor barriers are located closer to the facade exterior. To be effective, particularly in buildings with tight humidity-control requirements such as museums, it is critical that vapor barriers be continuous. This requires close attention to detailing, especially at lap joints and penetrations. Retrofitting vapor barriers to existing masonry facades (a popular wish in museums and galleries) involves issues that are very difficult to achieve. The continuity of the vapor barrier and risks associated with a failing vapor barrier present problems. Generally, altering the vapor profile through any existing wall is risky. A dew-point analysis should be carried out to determine the risk of interstitial condensation for any humidity-controlled environment, especially if it is being added to an existing facility.

Current masonry construction includes the use of brick facades on high-rise structural steel frame buildings in which the masonry skin is primarily an architectural design element. In this use, the masonry does not contribute to the structural load-bearing capacity of the wall and must be carried by the structural framing elements. However, in this type of construction, the outer brick still serves as the primary protective barrier to the penetration of wind and precipitation into the facility, and the same cavity wall design elements must be included in the system for the desired environmental protection. This construction type is used for speed of construction (the steel contractor doesn't wait for the masonry contractor) and interior finishes can be added later.

Another current masonry construction technique that has been developed is the use of single-wythe, load-bearing masonry facades. These facades typically use a single concrete-block wall with split-face exterior block, hollow-block or cast-masonry units (CMUs), and bond beams. The interior finish wall is mounted directly to the exterior wall with light-gauge studs. Insulation is placed on the interior concrete-block surface because the cavities of the block need to be grouted and reinforced with steel bars for structural capacity. This type of construction is economical but also more difficult to make watertight. In-wall flash-

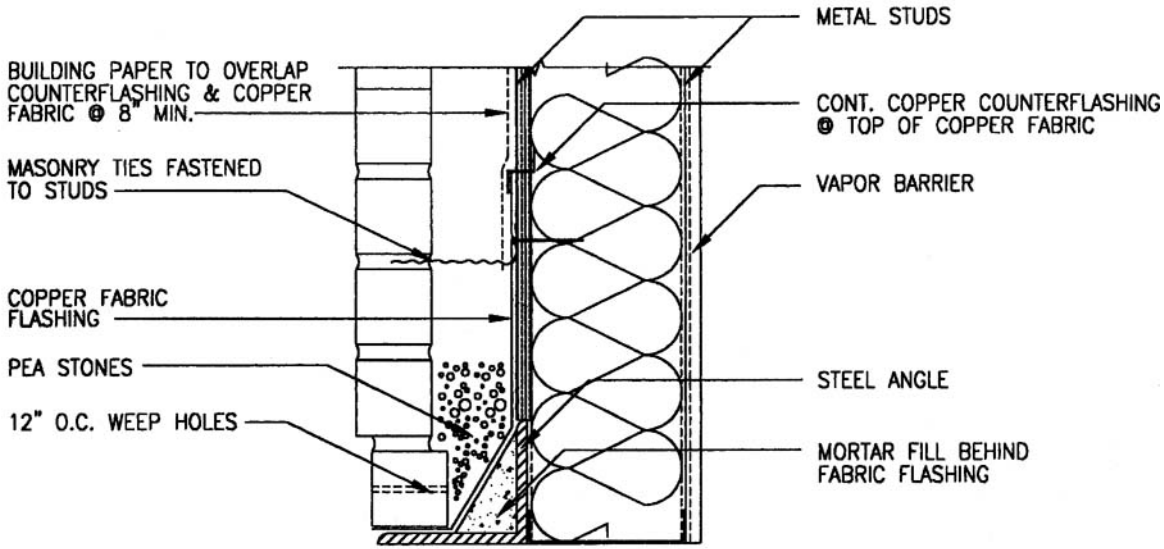

FIGURE 5.1.4-1 Typical cavity wall. (*Courtesy CID Associates, Inc. Boston.*)

ing detailing must include the use of split block and placement of flashing at all wall penetrations (Fig. 5.4.1-2).

Sealant is another element that is used in all current facade types. Sealant is used for a variety of purposes but primarily to form a weatherproofing seal for some aspect of the facade. In masonry wall construction, sealant may be used at locations of wall-penetrating elements, such as windows, louvers, and doors, and at expansion and control joints. Sealant in this case is in the form of what is generically referred to as *caulk* and is applied at joints. Facade expansion joints need to be properly aligned with building structural expansion joints. In addition to true structural expansion joints, the materials may require additional control joints to accommodate thermal expansion and contraction. Control-joint placement must be determined and installed to prevent splitting of the wall facade.

Liquid-applied masonry sealers are used to enhance the water repellency of outer masonry or concrete surfaces. These materials form a protective barrier either at the surface of the materials or within the matrix of the block, brick, and mortar. Sealant of this type is sometime viewed as a way to repair wall leaks. When using this type of sealant in conjunction with masonry, it is important to investigate the vapor transmission properties of the product. As mentioned earlier, vapor barriers should be placed on the warm side of the facade surface. Some liquid-applied sealants form a vapor barrier on the outer face of the masonry that restricts transmission of vapor out of the building. In cool weather, the trapped vapor condenses, and in freezing conditions, this liquid moisture changes to ice. Water expands in freezing, which places the surface of the masonry in tension. Masonry is a weak material in tension, and the end result is often spalling of the face of the affected unit. In most cases, it is advisable to use a penetrating sealant that allows vapor transmission while restricting the flow of liquid moisture. These materials are also very helpful when used with the previously mentioned single-wythe block wall systems. The architectural feature of a split face on the exterior is typically more absorbent and therefore more prone to allow water into the wall system. As noted, single-wythe construction does not allow a proper cavity to conduct drainage, which makes the system much more susceptible to moisture penetration.

When properly designed and constructed, masonry walls are extremely durable and have exceedingly long life spans with low maintenance requirements. Masonry pointing is one common maintenance need that is eventually required. The facility engineer needs to monitor the depth of the mortar joints and note the development of cracks between the mortar and brick or block. If cracks develop that are 1/16 in or greater in width and the depth of the mortar joint erodes by 1/4 in or more, it is time to consider pointing. This repair method requires that the joints be prepared by saw-cutting the existing mortar to a depth of 1/2 to 3/4 in beyond the outer face of the brick or block. The surface must also be surface saturated as with new work before applying and tooling new mortar. This process is an extensive undertaking and should include replacement of soft sealant joints. Monitoring of sealant joints is also necessary because these materials require replacement at shorter intervals than masonry pointing. The design of sealant joints is also critical to the long-term performance of the sealant material. The facility engineer should check the design limitations with the manufacturer of the particular sealant being used. In most instances, however, the width of the joint should not exceed twice the depth, and a bond-breaker tape or backer rod should be employed to prevent three-sided bonding of the sealant.

The metal wall panel is another common type of facade material construction that is prevalent today. Wall panels may be manufactured with insulated cores and light-gauge skins on either side. In common industrial buildings, this type of manufactured wall system may serve alone, or the panels may be combined with glass units to form a more complex curtain-wall system. In either instance, the metal wall panels are not structural and are mounted to the framing with a series of cleats and fasteners. These systems are optimized for weathertight integrity when the fasteners are concealed and not exposed to the weather directly. Metal-panel and curtain-wall systems depend on facade materials to provide protection from precipitation, airflow and vapor and thermal transmission. Curtain-wall systems typically employ the design of internal gutter and drainage channels to conduct water from the facade. Lock

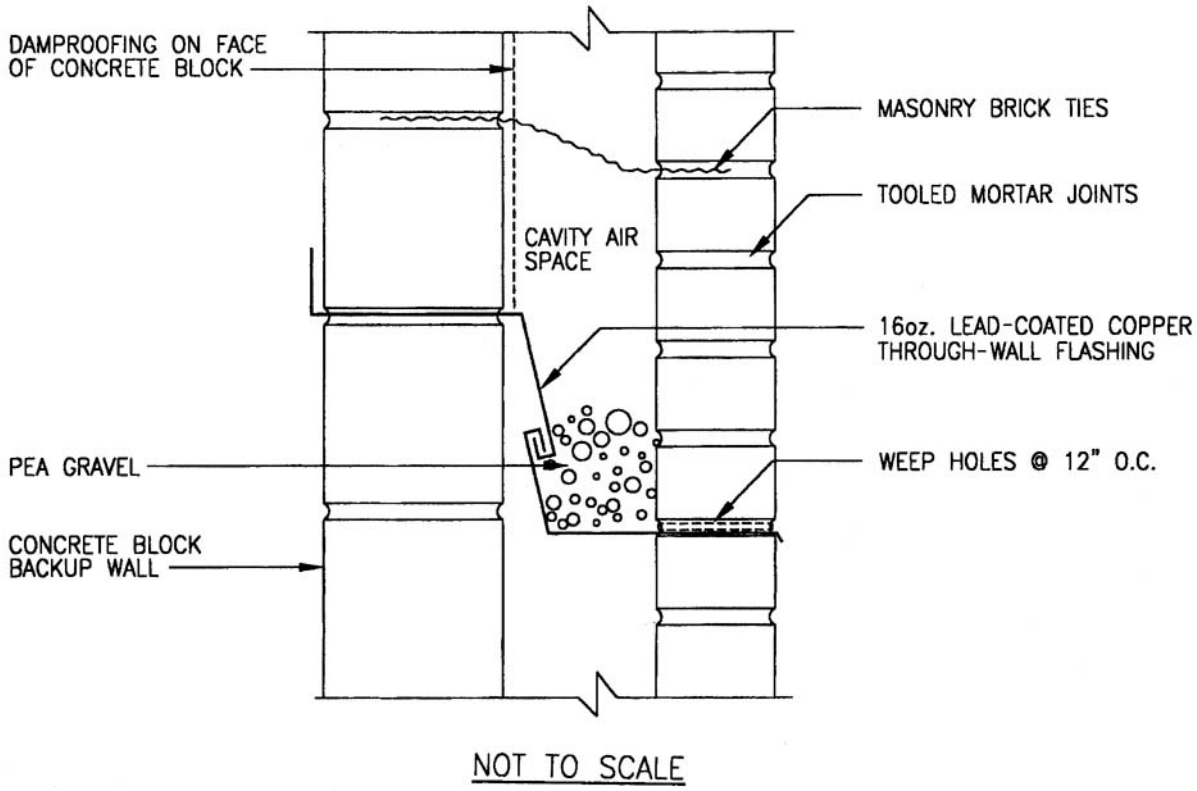

FIGURE 5.4.1-2 Typical through-wall flashing. (*Courtesy CID Associates, Inc., Boston.*)

joints and seals use nonskinning sealant that is placed within the joints in a permanently compressed state, rather than the exterior sealant joint design mentioned in the discussion of masonry facades. External sealant joints should not be used as the primary protection for a metal-panel or curtain-wall facade.

Metal wall panels come prefinished with anodized color or in mill-finish aluminum. Maintenance is typically limited to cleaning and the replacement of the sealant in exterior joints. Oxidized aluminum can be cleaned with specialty products that are compliant with volatile organic compound (VOC) regulations and are nonhazardous to the environment. Anodized panel, cleaning, if required, should be carefully considered and tested on an area of low visibility to ensure acceptable results before initiating a large-scale project.

These systems must also be designed to accommodate structural building expansion joints, movements due to wind loading, and thermal expansion and contraction. High-rise buildings experience significant deflection when subjected to wind loads, and curtain-wall systems have been designed to accept these conditions.

The exterior insulation finish system (EIFS) is another type of facade that is becoming more prevalent in construction. These systems are relatively new and do not have the proven track record of the systems discussed previously. EIFS systems are being used in retrofitting or refurbishing older existing buildings and also in new construction. When used in a refurbishment project, an EIFS facade system consists of placing expanded or extruded polystyrene insulation board over an existing exterior facade. The insulation boards are either mechanically attached to the existing facade substrate or bonded to the substrate with adhesives. As with the outer brick facade component of a masonry cavity-wall system, the EIFS face is not structural. Unlike masonry cavity walls and even metal and glass curtain-wall systems, the coatings and sealants placed on the outer surface of the expanded or extruded polystyrene insulation board comprises the primary means of weatherproofing. No internal backup drainage systems are included in the design of these facade walls.

After the new insulation substrate has been placed, it is finished with exterior stucco-like material and embedded reinforcement mesh. The finish material may be latex modified and applied in several coats, depending on the particular manufacturer's requirements. The reinforcing mesh can generally be specified to provide varying impact protection. A stronger reinforcing layer used in unison with a high-density extruded polystyrene insulation board will prove to be more durable than the standard EIFS system. Carefully evaluate the local environment to which your facade will be exposed when considering an EIFS facade refurbishment project.

The new EIFS facade must be made to accommodate the existing expansion and control joints, as well as all fenestration design elements (see Fig. 5.1.4-3). Failure to mirror the existing facade design elements will result in a breach and in ultimate failure of the EIFS facade. When considering this type of system to refurbish an existing facility, an in-depth evaluation of the performance implications of the system should be undertaken. Particular attention should be directed to the impact of the external insulation in determining the location of the dew-point temperature for a particular facility during winter conditions. Improperly applied EIFS systems that were not given full design consideration have been cited as the cause of structural wall failures. Relocation of the dew point has resulted in condensation within the existing wall systems that the EIFS facades were intended to refurbish. This condition is often undetected until failure of the wall is imminent. In addition, this condition has resulted in fungal and bacterial growth within wall systems, which has caused unhealthy interior environments. Design detail considerations should ensure proper backwrapping of the reinforcement materials at all perimeter and exposed locations. If not properly protected, the insulation substrate is also subject to attack by common insects.

These systems have been popular with facility owners and their engineers in recent years due to the relatively low cost and the initially dramatic face-lift effect upon completion. However, these systems do not have a long and proven history and are being viewed critically as they enter their second decade of popularity. If your facility currently has an EIFS facade, close visual inspection of the entire facade is encouraged twice a year. It is also advisable to

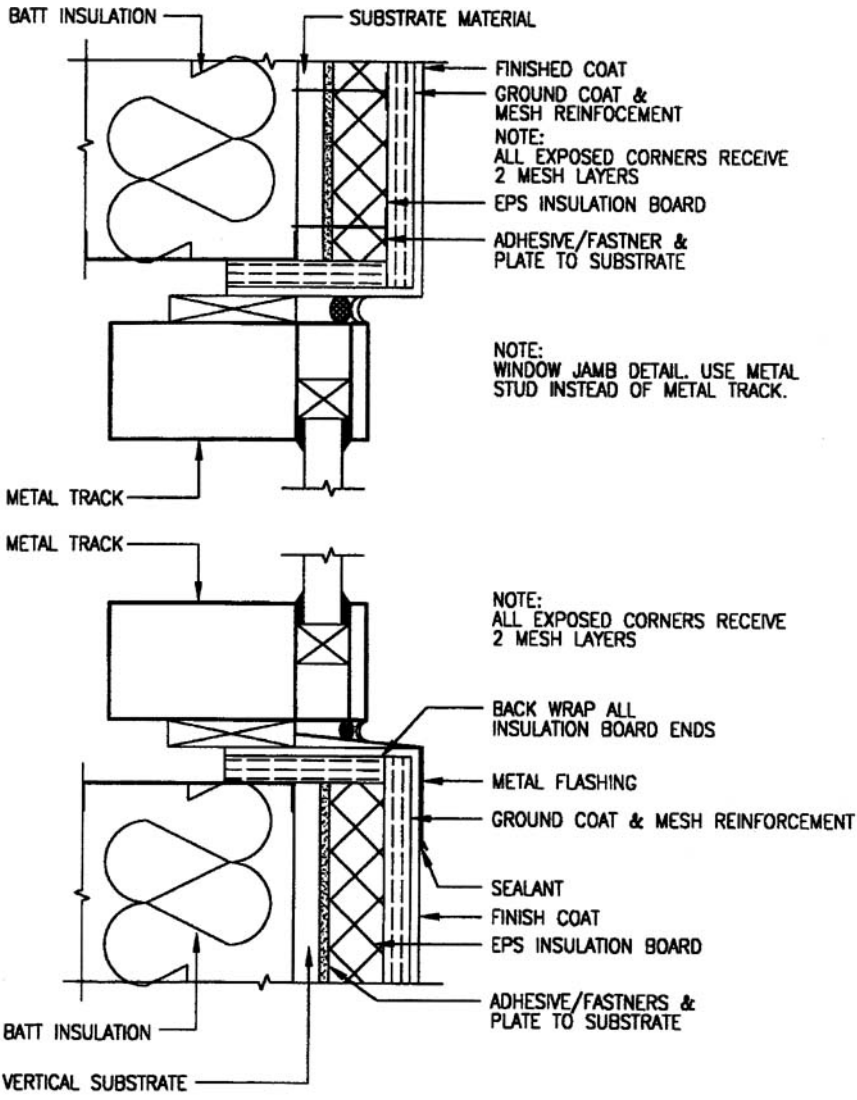

FIGURE 5.1.4-3 Typical exterior insulation finish system (EIFS) window sill and head. (*Courtesy CID Associates, Inc., Boston.*)

conduct wall cuts through the interior to check the condition of the wall structure and insulation. If considering an EIFS facade as a retrofit of your facility or for new construction, be sure to have all design considerations reviewed before bidding and awarding a contract.

ARTICLE 5.1.5
ROOFS

Harrison McCampbell, AIA
McCampbell & Associates, Brentwood, Tennessee

This article provides a mind-set to assist facility managers in the proper care and maintenance of their roofing systems, whether aging roofs or ones recently installed on new facilities. A cognitive perception and definition of the building's roofing needs is necessary when attempting to control the long-term costs related not only to the installation of the roofing system, but to its upkeep as the primary source of protection for the building's operations and occupants. Initially, analytical information about the facility should be gathered and discussed with as many of the involved parties as possible (operations, maintenance, accounting, etc.), followed by a review of the upkeep procedures currently in place and the necessary revisions to the structure of the same.

For the next phase, this article presents a general primer on roofing systems and associated terminology. This is provided as a foundation of a methodology for best applying particular roofing knowledge to a particular facility's requirements. As with any other type of operation, the degree of consistency, the quality of intent and knowledge, and the depth of persistence and tenacity determine the long-term value of participation in such a program. Once a structured line of command is created and implemented, subsequent managers will be able to more clearly understand their place on the team. This clearly defines areas of responsibility that reiterate what successful team efforts can accomplish. Roofing issues are usually one of the least desirable items to deal with when taking care of buildings. Most people do not know one roofing system from another, nor one roofing contractor from another. Too many building maintenance agendas are fixated on issues that demand and receive far more attention than roofing, yet cost much less. Roofing dollars, if spent on catastrophic conditions instead of their prevention, only increase with time. Proper analysis of problems and application of remedies provide dependable costing cycles.

ATTITUDE OF MANAGEMENT AND PLANNING

There are two primary factors that affect the efficiency of the roofing envelope, one of which begets the other. The definition of management's focus is paramount. Is this facility being cared for with profit-oriented, short-term goals in mind, or is the owner's primary outlook

more toward a long-term continuity of maintenance? Certainly there is room for both views, but the primary intent of management has to be defined—is management's concern for time periods measured in 3-month quarters or in 5-year periods? Another consideration is the length of time the owner plans to keep the building.

Second is the issue of money. Once the pace and quality of care for the roofing system is defined, the financial decisions about how to sustain that particular course of action are much easier. Most costs related to roofing are derived from the direct costs of labor and materials needed to install and maintain a roofing system. But there are other costs brought about by the failure of the roofing system to keep water out. They are the indirect costs for ceiling tile, carpet cleaning or replacement, paint, computers, telephone switching equipment, and the like that may cost someone something, but are not listed under "roofing" at the end of the year.

There are a few other issues that could have an effect on the long-term care of a roof. One is whether the building is owned or leased. Find out who is responsible for its maintenance and also for its eventual replacement. Make a list of the scope of work performed and the types of materials used as an extra source of information tracking. If possible, ask that a water test be performed, following a contractor's repair attempt and prior to payment, to save further finger pointing if the work is not effective.

A roofing file should be kept to record all items of the project related to the maintenance of the roof. This file should be available to all through one source for control and monitoring. Warranties should be included in order to dictate how to handle leak calls. With the assistance of computers, automatic periodic notices should also be provided so that regular preventive maintenance can be implemented. This way the roof can function properly and the warranties can be kept intact. Any work done on any roof should be recorded on the roof plan, listed in some kind of report, and filed. Whether the entity responsible for roofing issues is in-house or not, it is imperative that files be updated on both existing conditions and available products used for repair. Knowledge of the installed system's maintenance requirements is necessary to keep the warranty intact. Not unlike insurance policies, many owners do not find out what their particular warranties cover until trouble arises and they attempt to enforce them.

EXISTING FACILITY CONDITIONS

It is important that you know what kind of roofing system you have, what you require of it, what your building's insurance carrier may require, and how best to take care of your system when considering the long-term aspects of what you want. While gathering the proper knowledge for the care of the roof itself, remember that the roof is part of a system, as are the insulation and structural deck. All are elements of the exterior building envelope that demand and deserve consideration.

One of the first courses of action is to document the existing roof conditions on all of the buildings within the company's operation. In general, you need to create a drawing or plan of each building that shows each separate roof area. This should include all fan curbs, vent pipes, roof drains, pitch pockets, dimensions, and slopes, with their locations on a key plan, if necessary. Any and all penetrations through the roof should be documented and located on the plan as close as possible to their actual positions on the roof. Along with the drawing, there should be a list of pertinent information, including the type and number of roofing systems, insulation, vapor retarder, structural deck, date of installation, information on both contractor and materials manufacturer, and any warranty information.

If a building owner has multiple buildings in different locations, is it imperative that care of the roofs be consistent. Having the technical ability to handle roofing problems is only part of the requirements for handling roofing issues of long-term concern. Education is necessary to understand and appreciate what is required for proper care of roofing. Knowing more than just roofing can only help provide the best care for a roof. Outside forces can act on a roofing system and, unless the source of the problem is addressed, it may be a waste of time and

money to pursue a cure. For instance, many roof leaks have been attributed to negative air pressure in roof-mounted mechanical units—rain is literally sucked into the unit housing. The poor roofing contractor usually tires of coming out on calls to repair the roof, loses patience with the owner, and feels that compensation is in order. The owner, on the other hand, has paid for a roofing system, still has leaks, and now feels abandoned by the roofing contractor. Without proper analysis, this scenario can lead to ill will at best and lawsuits at worst.

A condition that is rarely thought about, but probably occurs on a daily basis, is that when roof insulation becomes wet from previous leaks, it slowly changes from an insulator (something that provides dead air spaces that slow down the rate of heat transfer) to a conductor of heat. This condition diminishes the heating and cooling efficiency of the building's mechanical systems.

HISTORY OF ROOFING

Roofing came about as shelters were built by early humans from overlapping leaves, bark, palms, and various natural objects. The shingle effect was found most effective and led to steeper slopes as a method of getting rid of water more efficiently. But as the need for bigger buildings grew, so did concern with building up height just to provide the shingle effect. As early as 1607, larger buildings requiring flatter roofs started using a combination of parchment paper and pine tar as an early version of what is known today as *built-up roofing.* In essence, the built-up roof is accomplished by multiple layering of a waterproofing substance (asphalt, coal tar, pine tar, etc.) with some type of reinforcing material. These are, or have been, materials made from asbestos, wood pulp, cotton rags, polyester, and fiberglass, among others. The waterproofing agent in built-up roofing is known generically as *bitumen,* and it comes in two similar forms from two different sources.

Asphalt, the most widely used type of bitumen, is composed of high-molecular-weight hydrocarbons, found in nature or obtained through petroleum processing. It is produced as a byproduct somewhat near the end of the process of manufacturing gasoline and heating oils. Sir Walter Raleigh discovered natural asphalt lakes in Trinidad and brought the substance back to England because it was effective for sealing boats against leakage.

Coal-tar pitch is obtained by the destructive distillation of coal. In nineteenth-century London, Samuel Warren began to use coal-tar pitch in built-up roofing and started roof contracting as a viable business. Pitch is a noncrystalline material, whose flow properties can "self-heal" small fissures that form during the service life of a roof. Coal-tar pitch is designated for slopes that do not exceed 2 percent. Coal tar can be bothersome, even caustic, to anyone in contact with it or its fumes, but coal tar tends to age better than asphalt because there are no oils to escape upon exposure to the elements.

Built-up roofing was the most widely used type of roofing for decades, but outside forces brought about changes that led to the multiple choices available today. By the early to mid-1970s, roofing selection was a matter of choosing from among 10 to 15 systems, ranging from gravel surfacing to a granular-surfaced cap sheet to a coated smooth-surface finish. The *1998 Roofing Materials Guide* published by the National Roofing Contractors Association listed around 170 manufacturers and more than 500 systems. So the choices of roofing systems and accessories have exploded during the last two decades, confusing even the most seasoned specifier.

The Middle East crisis in the 1970s led to still other changes in the roofing industry. One factor was the increase in the price of crude oil, which trickled down to higher asphalt prices, making asphalt-based built-up roofing more costly. The second factor was the higher cost of fuel oil and gasoline as energy concerns led to the creation of more thermally efficient buildings, which in turn led to a more competitive market in roof insulation. Politics also joined the fray, demanding that new buildings and remodeled old buildings meet certain standards of thermal efficiency. A new concern for the amounts and rates of air flow in buildings created

new awareness of wall, window, and ceiling construction. Traditional insulating board, usually made from cane fiber, cork, or perlitic ore, was originally used more for a substrate under roofing material than for its insulating qualities. But after the oil crisis, roof insulation became more integral in the selection and eventual fate of most roofing systems.

As a general observation, it appears that a number of roofing problems began to rise with the increased use of roof insulation. The more the roof could work as an integral part of the building, the better it seemed to perform. But as the roofing membrane began to move further and further away from the roof deck, disparate factors began working against, instead of with, one another. Ancillary items such as fasteners, along with the use and positioning of vapor retarders, brought subtle complex concerns with their contributions to roofing systems.

For years, asbestos was used to manufacture roofing felts that provided both coal-tar pitch and asphalt-based built-up roofing with qualities of dimensional stability and resistance to ultraviolet rays, fire, and rot. However, health concerns regarding the mining and manufacturing of asbestos products overwhelmed the economic and performance advantages and virtually eliminated asbestos-related materials from the construction industry.

Changing trends in the textile industry also brought about changes in the roofing industry. As cotton and wool fibers were replaced in the 1970s with double-knit polyester, the resultant shrinking sales of cotton fabrics led to reduced availability of cotton rags, and the use of rag felts diminished, requiring an alternative for reinforcement plies. Until that time, cotton had been blended with wood fibers and waste paper—it absorbed asphalt well, provided good tensile and tear strength, and was a relatively stable material. Consequently, wood and waste were substituted for rag felts. Problems with moisture, stability, and fire and rot resistance forced the market to keep looking for a better product. Presently, fiberglass is the most widely used built-up roofing felt, and organic felt (asphalt-saturated No. 15) continues to be used as a shingle underlayment.

As the costs of built-up roofing rose in the 1970s, marketers of a relatively new generation of roofing systems began to concentrate on the American markets. Single-ply roofing had been used throughout Europe for decades, but because of higher costs of manufacturing and shipping to the United States, it could not compete with the U.S. built-up roofing market. The increasing cost of petroleum-dependent products, coupled with the demand for more thermally efficient roof systems, made built-up roofing a prime target for the rubber and plastic industries.

Single-ply manufacturers found an ally in expanded bead polystyrene (EPS) roof insulation. On the basis of dollars-per-*R*-value costing, EPS is probably still the most cost-effective roof insulation. Its use in a loose-laid, single-ply system allowed an attractive cost saving if the *R* value exceeded 12. A synthetic rubber of thermoelastic origin, ethylene propylenediene monomer (EPDM), was promoted to represent single-ply roofing, and a 0.045-in membrane was the thickness of choice.

Originally, a number of manufacturers made their own EPDM sheet goods, but because of economies of scale and mergers, now there are only two, Firestone Building Products and Carlisle SynTec Systems. The remaining suppliers rebrand the EPDM but may have their own accessories, such as adhesives, seam tapes, fasteners, roof vents, boots, and rubber flashing. Do not assume, nor fall prey to seemingly knowledgeable salespeople in believing, that accessories and components from one EPDM system are successfully interchangeable with another.

Thermoplastic roofing membranes, such as polyvinyl chloride (PVC), were introduced in the United States in the mid-1970s as competitors to EPDM. Neither sheet at that time generally used any type of reinforcement. The general idea of loose-laid, single-ply roofing was to provide a more flexible cover that could take incremental building movement considerably more easily than the typical built-up roof.

Ultimately, this proved to be a major factor in the demise of many loose-laid, single-ply roofing systems. Shrinkage at the perimeter of a considerable number of PVC roofs was the first sign that the unreinforced sheets were not as represented. The phenomenon was blamed on the migration of the plasticizers within the chemical structure of PVC that allow it to be flexible. Plasticizer migration also resulted from direct contact with EPS roof insulation.

Later on, slip sheets were introduced to minimize this problem. Currently, only reinforced PVC sheets are offered, and their plasticizer stability is greatly improved.

Built-up roofing sales began a decline in the early 1980s that persisted until the mid-1990s. This was mitigated somewhat when the desirable properties of both built-up roofing and single-ply roofing were provided in a type of roofing called *modified bitumen.* Modified bitumen also traces its early roots to Europe, where it originated in the late 1960s. Essentially, modified bitumen is the same type of waterproofing medium (recently made available with both asphalt and coal-tar pitch) that offers more durability and flexibility by the addition of polymers. Presently, modified bitumen comes in various premanufactured thicknesses, with a choice of reinforcements (usually polyester and/or fiberglass mats and scrim sheets) and surfacings.

So, as the latest market trends have oscillated back and forth between asphalt and non-asphalt roofing during the last two decades, the market is now generally divided into the three sectors of built-up, single-ply, and modified bitumen, which together comprise approximately 90 percent of the roofing market. Metal roofing and sprayed-on polyurethane foam comprise the remaining 10 percent. Metal roofing is probably the fastest-growing segment of roofing at this time, due in part to a small market share and an increase in the number of manufacturers, systems, and available applications, as well as its tie-in to the metal building industry. Depending upon the area of the country, each type of roofing may have a greater market share than another, but market shares are always changing.

ROOFING SYSTEMS

Built-up Asphalt Roofing

As discussed, built-up roofing is mainly an asphalt-oriented market, and coal-tar pitch is used as a secondary material The asphalt-based built-up roofing market can also be categorized into hot and cold applications. Hot, of course, is the most widely known and used. Asphalt comes from the processor in a solid form known as *kegs* or in heated tankers. Propane-fired kettles heat the bitumen to temperatures from 400 to 500°F. The asphalt is applied by hand mopping or mechanical spreaders onto the roof deck and/or roof insulation and between the roofing felts. The covering layer is a flood coat of asphalt and small gravel evenly distributed across the roof, with a mopped-on granular-surfaced cap sheet or a coating of some type that is usually finished in aluminum or a light color to reflect the sun's rays. All of them act in the same capacity, to protect the asphalt from the effects of the elements. Heat and the direct rays of the sun tend to bake the oils out of asphalt and render it brittle and hard.

Another form of asphalt-based built-up roofing is called *cold-process* roofing. An application of an emulsion (a dispersion of asphalt in water) is reinforced with polyester fabric or a solvent-based carrier. The bitumen is usually modified with fibers and fillers, resulting in a somewhat flexible asphalt covering that is easy to monitor for maintenance and repair.

Built-up Coal-Tar Pitch Roofing

Coal-tar pitch provides excellent water-repellent elements that are used for low-slope roofs. The self-healing characteristics of pitch make it unique and desirable, but many people object to the noxious fumes when applying it hot. Because it flows so readily, many issues must be addressed when using coal-tar pitch, such as pitch guards around roof drains and raised gravel guards (to keep pitch out of the drainage system and off building facades), installing a vapor barrier (to keep pitch from dripping down onto building occupants through the roof deck), and making proper repairs and tie-ins (pitch and asphalt are not compatible when mixed). Coal-tar pitch roof systems are surfaced with gravel or slag.

Modified Bitumen Roofing

Modified bitumen is a type of roofing that provides some of the desired elements of both single-ply roofing (premanufactured thicknesses) and built-up roofing (layers of asphalt and reinforcement). It is, essentially, a redundant system, and some of the flaws attributable to labor are diminished, if not removed. The roofing industry's goal is to finally provide a foolproof system that can be installed without problems or that never needs maintenance, or both. Some of the concerns with modified bitumen roofs, as with any other new product on the market, are such issues as who makes the modifier, and how much is enough; how one knows which products are equivalent when going out for bids; and what standards, if any, for determining product integrity are available.

Some designers and contractors bring two worlds together and call for *hybrid* systems that use layers of built-up roofing in which the top surface is a modified cap sheet with granular surfacing instead of the usual flood coat and gravel. Modified caps have a more uniform surface, have an extra layer in the reinforcement, and offer more flexibility with polymer-modified versus straight-run asphalt.

The type of reinforcement used in the modified sheet depends on factors such as whether the system is heat-applied or mopped on (sheet stability), whether there is heavy pedestrian rooftop traffic (puncture resistance), or whether certain insurance requirements have to be met (fire ratings) (see Fig. 5.1.5-1).

Styrene-Butadiene-Styrene. Styrene-butadiene-styrene (SBS) is an elastomeric polymer additive. This roofing membrane is usually installed in an application of solid-mopped asphalt. Some cities are starting to refuse to allow open kettles of asphalt or their residual fumes, so that cold-adhesive applications are becoming more popular in the larger metropoli-

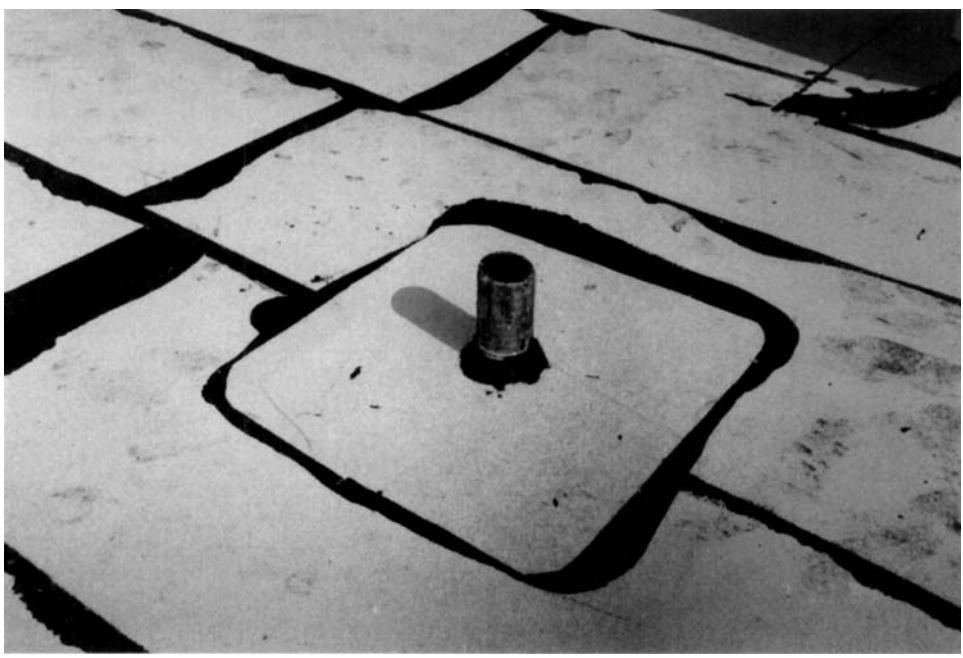

FIGURE 5.1.5-1 Vent pipe properly flashed with modified bitumen roofing. (*Courtesy of McCampbell & Associates, AIA.*)

tan areas. Heat-applied methods using open-flame torches have been used in Europe for years, but torching SBS requires a trained and certified torch operator. The melt point of SBS is considerably lower than that of atactic polypropylene, and one can burn through to the reinforcement quite easily if not diligent in using the open-flame method.

Atactic Polypropylene. Atactic polypropylene (APP) is a thermoplastic polymer that is used to modify asphalt. APP is somewhat stiffer than SBS and can tolerate higher temperatures. Hot mopping with asphalt is not possible because of the high melt point required by APP. Open-flame torching is the most popular method of application, although APP systems are now used in cold-adhesive applications where seaming is done with hot-air guns for safety.

Cold-Process Roofing

Cold-process roofing can mean different types of roofing in different parts of the country. In the middle and western United States, it may refer to multiple layers of emulsion and polyester fabric, finished with a coating that provides a smooth surface. In the southern and eastern regions, *cold process* may simply refer to the contrast with hot or asphalt-based roofing. Cold process here probably means using cold adhesives to secure the roof instead of mopping with hot asphalt or coal-tar pitch. More and more insurance companies are offering lower rates to contractors who do not use propane-fired kettles and open-flame torching methods. Workers' lost-day claims and the resultant cost to the construction market are certainly an important concern nationwide. Insurance companies are constantly looking for ways to diminish payments for injuries and property loss.

Sprayed-On Foam Roofing

Known generically as sprayed-on polyurethane foam (SPF), this type of roofing is mixed on the job site right at the point of application and is applied directly over either an existing roofing system or a new deck. Its sales niche is primarily in the reroofing market. SPF has been used for years in industrial, commercial, and institutional installations, and residential sales are generally centered in the Sun Belt states. It offers ease of application with little preparation, high insulating values, light weight, and various color finishes. There are, however, critical issues that have to be attended to when analyzing the construction conditions and application methods for SPF roofing.

As an example, improper analysis by an overly energetic SPF salesperson, as with any other system, could lead an owner to believe that an SPF system can be successfully installed directly over a water-saturated built-up roof by installing roof vents to release any trapped moisture. The deleterious effects of this scenario would probably go unnoticed for some time but eventually could cost the owner many times the amount "saved" by not removing the original roof. And the generally warm, fuzzy feeling that comes with the warranty would probably vanish as soon as a close reading reveals that the terms and conditions disclaim any incorrect technical information—even when given by an authorized representative or applicator.

Metal Roofing

For decades, metal roofing has enjoyed a small share of the American roofing market. Improved seaming techniques and coating technologies have driven some companies to offer long-term warranties on what were previously thought to be inadequate slopes. Nowadays, one can obtain a 20-year warranty on a metal building installation, either a new building or a reroofing project, that provides slopes as shallow as ¼ in/ft. This, again, calls for increased knowledge and concern when making decisions based on economic parameters. Short-term

installation costs may be overshadowed by bothersome long-term maintenance and performance results. The same warning has to be applied for an installation over an existing low-slope roofing system that contains moisture. Gambling that the moisture can escape before any resultant damage is done can be costly to the owner who is not fully aware of the downside of such a decision. And the failure to design for conditions such as the possible change in the dew-point temperature and provide proper ventilation between the metal roof and the existing roof can lead to untold problems in a few years.

Metal roofing certainly has its place in building construction. Low maintenance, various styles and colors, light-weight construction, and excellent fire and wind ratings are all positive factors to consider when selecting a roofing system for a new building or providing a solution for the leaks of an older one.

ROOFING COMPONENTS

The many integral parts of a roofing system must work in concert with one another if a roof is expected to work as a full system. No one component is more important than another, although one component's failure could possibly allow more water entry than that of another of its counterparts. The vast majority of leaks in a building are found at the edges and penetrations. The edge conditions usually include gravel stops and parapet walls around a building's perimeter. Penetrations may be considered base flashings on curbs and penthouse walls, vent pipes, roof drains, pitch pockets, lightning rods, and/or window-washing stanchions.

If a contractor is not directed as to how an edge or penetration is to be flashed (sealed properly), the success of the flashing installation may rest in the hands of an unskilled laborer who is not knowledgeable in the specific requirements of a particular roofing system. Good-quality roofing documents (both specifications and drawings) are a critical ingredient in the success of any building's first line of defense against the entry of water.

Metal Edging

The two most popular elements for terminating perimeter metals are a gravel stop and a drip edge. The difference between the two is simple. The gravel-stop metal has a slight rise (usually ¼ to ½ in in height) that restricts the gravel from falling over the edge of the building. It also provides a clean line along the top edge of the building when viewed from the ground. Drip-edge metal is usually found with single-ply, modified, or built-up smooth-surfaced systems.

A drip, or hem, should be provided along the bottom face of the metal edging no matter how deep the face. Keeping the exposed metal edge fascia's profile down will lessen the chance of "oil-canning" or undulations in the planar surface. Cleats should be used on almost any metal edging. Intermittent clips, preferably made of a heavier gauge, can be installed to provide some uplift protection. Fascias on buildings located in areas of high winds should have continuous cleats to afford maximum protection. Continuous caulking along the interface of the drip edge and the exterior wall may help prevent sudden gusts from getting under the face of the metal and causing bowing or blow-offs.

Parapet Walls

Walls that encompass a building's roof areas are called *parapet walls.* There are usually two ways to seal a parapet wall. One is to extend the base flashing up the wall to a counter flashing or to take the material up and over the wall, finishing with a coping. Parapet walls must remain open on one side so that they can "breathe." Sealing in both sides of a parapet wall could seal in moisture if water somehow gets in along the top and causes hidden moisture problems.

Coping

A cap that sits atop a parapet wall is called a *coping* and is usually made of metal or stone. Some of the older buildings had terra cotta tile, but its use is practically obsolete. Coping is all too often installed with poor workmanship and little planning. The most common conditions for failure are installing the coping on a dead-level wall fastening through the top. This results in ponding water conditions around the lowest level of the coping (where the hammer impacts the metal), and bowing of the metal prevents any positive flow over either of the edges. Laps are rarely more than 1 in, and sealing is paltry at best. Most caulking is pulled apart as the metal expands and contracts.

Ideally, coping should be installed with the wall flashing continued from below and turned down at least 1 in over the outside face of the wall (Fig. 5.1.5-2). All coping should be sloped at least ½ in toward the inside to drain back onto the roof and diminish staining the outside of the building. Cleats, either intermittent or continuous depending upon wind requirements, should secure the outer face, and the inside face should be fastened through slotted holes on approximately 2-ft centers using hex-head fasteners with rubber washers. This allows for future removal for ease of wall flashing maintenance and replacement. Seam or lap techniques in the coping are almost cosmetic if the wall flashing is continuous below the coping. Otherwise, the laps are the weak link in the chain and must be designed and installed properly. Various methods are lap and caulk, flat-lock seam, and standing seam, among others.

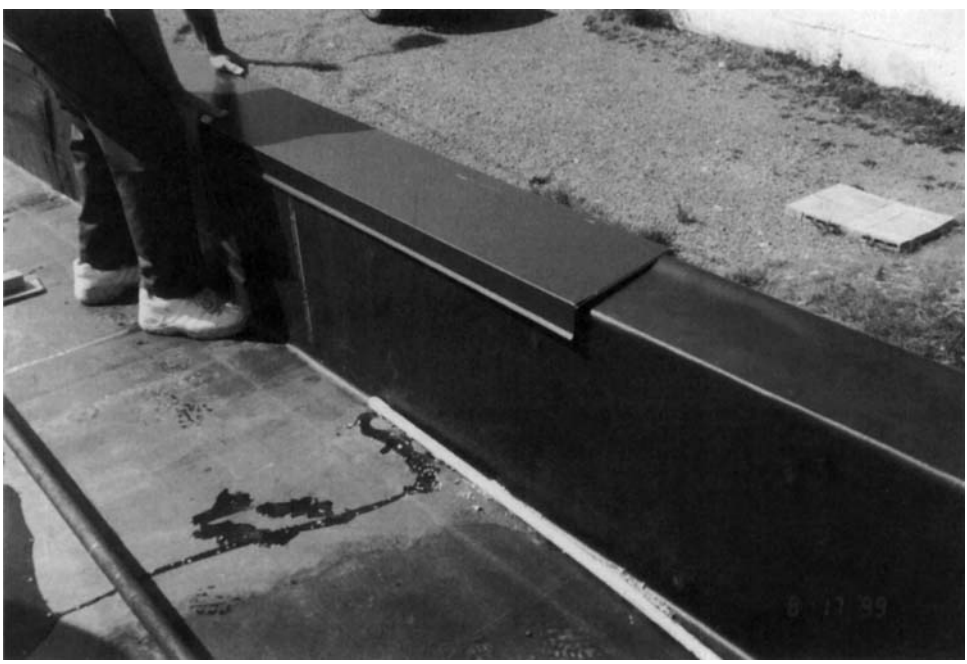

FIGURE 5.1.5-2 Sheet-metal coping being installed atop a parapet wall with a single-ply rubber roofing membrane extending up and over the top of the wall for added protection. (*Courtesy of McCampbell & Associates, AIA.*)

Flashing

Any time a penetration is made through the roofing membrane or system, the opening in the roof must be able to afford protection against water entry, and the seal also must be able to withstand movement between the rooftop element to which it is attached and the roofing system itself. Movement is caused by the differential rates of expansion and contraction between various materials and also by the cyclical movement from hourly, daily, and seasonal changes brought about by exposure to the elements.

When considering what kind of roofing system belongs on a particular building, one must take into account the factors both below and above the roof. Manufacturing, for instance, may involve heavy vibration from machinery in the building as well as from some of the equipment installed on the roof. Air conditioning units are renowned for their cyclical vibratory demands on roofing systems. Compressors emit oils occasionally. Kitchen exhaust fans are known as one of the biggest enemies of roofing because they emit various types of animal fats and greases. When coupled with a lack of proper drainage and poor maintenance, the useful average life cycle of kitchen roofs is probably one of the shortest in the roofing industry.

Mixing flashing between systems is probably a sizable gamble unless considerable attention is paid to all of the appropriate elements of the particular building's demands. The issue is how the flashing is held in place—how the flashing is adhered to the curb and how the top of the flashing is mechanically fastened to secure it against sliding. Proper overlapping of the flashing onto the roof and onto the adjoining sheet is imperative.

Flashing generally must be somewhat heavier than the type of membrane it is sealing. This requires installation techniques specific to a particular manufacturer's sheet flashing membrane. The proper installation and maintenance of all flashing has to be done in strict accordance with the individual manufacturer's instructions. Unskilled laborers with buckets of roofing cement may do more long-term damage to the roof than the original problem.

Counterflashing

Counterflashing is as its name implies. You seal a rooftop element with flashing, and then you seal the top of the flashing with counterflashing. Most likely, the top of the flashing cannot remain sealed day in and day out. Galvanized sheet metal is probably the most widely used, but other materials, such as copper, lead-coated copper, and aluminum, are used for various reasons, including cost, compatibility, ease of installation, warranty requirements, longevity, and availability, among others. Counterflashing is usually surface-mounted, saw-cut into masonry or brick, or installed with the original masonry in a through-wall condition.

Some may try to save money by making all of their counterflashing materials in one piece. If the flashing is bent up to work on it or to remove the existing flashing for replacement, it almost never bends back down to its original position. And installing a fastener through the face is not recommended because it increases chance of leakage. Along with that, the metal is most likely now seriously bowed and looks as if it had been beaten with a hammer. (Actually, it probably was!)

The ideal remedy is to provide and install a two-piece counterflashing that allows removing the main counterflashing and reinstalling it. The initial incremental cost is far outweighed by the cost savings for fully replacing or jeopardizing the integrity of a one-piece counterflashing by turning it up and down again.

One of the worst mistakes that can occur in reroofing a building is terminating the new roofing system's edge flashing somewhere over the line of the original through-wall counterflashing. Many times extra insulation is added with tapered board to provide a more positive slope. But if this is done and the existing through-wall flashing in a higher wall, especially one

with weep holes, tries to exit water encased in the wall by absorption, it will send the water out of the wall underneath the flashing of the new system.

Crickets and Saddles

Providing positive slope for rooftop drainage is one of the primary rules of good roofing practice. Many times this is ignored behind certain roofing penetrations. Mechanical units, fan curbs, skylights, and other elements wider than 18 in too often block proper water flow. This allows water to stand on the base flashing and can cause premature aging of some types of roofing materials. A *cricket* is a triangular raised area of the roof that provides positive slope in a reverse direction for the flow going toward the drain. Roof drains should be installed away from walls, and crickets are used between them and the walls to kick the water back from the walls toward the drain. A *saddle* is simply two crickets installed side by side as one unit that is centered in a valley between drains.

Expansion Joints

These are required in most roofing conditions, but many factors must be considered in proper design, placement, and installation. One of the most important places for an expansion joint is at a change in the direction of metal decking. The flutes of a metal deck expand and contract in a single axial direction. When different roof areas come together, there is most likely a need for a break in the decking system. This break has to be continued up through a relatively fixed-in-place roofing system unless it is a loose-laid or a mechanically fastened single-ply roof. Only these systems provide ample movement capabilities in their composition.

Most expansion joints are built up of vertical wood members with a bellows-type expansion joint sitting atop the nailers. Frequently, the rubber membrane that surfaces the bellows comes only in 10-ft lengths, and end laps may require periodic repair. Often the failure of expansion joints is the result of either poor installation or maintenance of the laps in this rubber membrane. Unreinforced asphalt-based roofing cement will not last more than a few weeks. And most of the caulking found on the market, especially the inexpensive types, will not properly adhere to the finished rubber bellows material.

Drains and Scuppers

Positive drainage is certainly the most critical aspect of good roofing (Fig. 5.1.5-3). At a minimum, drains must meet certain sizing requirements matched to the area of the country, the size of the immediate roof area being drained, and the design intensity of the rainfall, for anywhere from 10- to 100-year rains. Overflow requirements must also be met to prevent overloading the structure. If 4 or more inches of water are allowed to collect, the added weight could exceed the live load capacity of the structural system.

One of the most popular methods of auxiliary drainage is to provide through-wall scuppers near the primary drains. These must almost always be installed no more than 2 in above the roof drainage level so that no more than 10 lb/ft^2 of water ever builds up in a worst-case scenario. The corners of the scupper, especially on the low side, are suspect to possible water entry due to the x-y-z direction of the pulling forces that compose a boxlike element. Unreinforced asphalt-based roofing materials are probably the most liable to fail. Some of the modified bitumen systems, along with most of the single-ply systems, may allow more differential movement, but all of these still rely on proper installation techniques and maintenance.

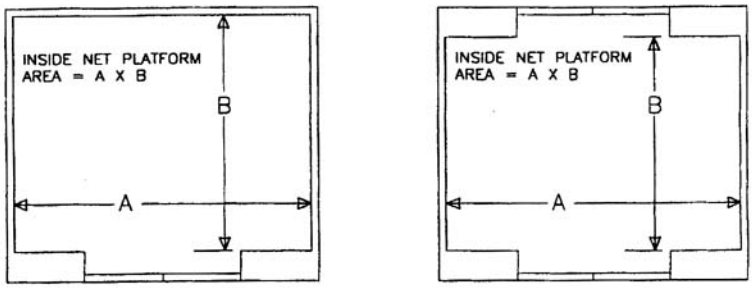
ARTICLE 5.1.6
ELEVATORS, ESCALATORS, AND MOVING WALKS

James W. Fortune, M.B.A.
Lerch, Bates & Associates, Inc., Littleton, Colorado



Elevators are commonly classified by their functions and the types of people and goods that they transport. Passenger elevators, the most commonly encountered, are used to transport ambulatory and handicapped (wheelchair-bound) people (passengers) vertically between floors. Service elevators and freight elevators are generally used to transport specialized support people, goods deliveries, and bulk freight items and their handlers (Fig. 5.1.6-1). Most elevator codes do not differentiate between passenger elevators and service elevators because they are commonly equipped with sliding side doors (generally center-opening on passenger elevators and side-opening on service elevators), and the same net inside platform area requirements are used to determine their capacities (about 90 to 100 lb/ft^2). Passenger and service elevators in the United States have suspension components and platforms that are rated for 125 percent of load (capacity), so it is virtually impossible to overload them with people (Fig. 5.1.6-2). Passenger elevator platforms are typically shaped as wide, shallow units (a three-person depth is ideal) in order to move passengers rapidly in and out. Service elevator platforms are typically provided as narrow, deep units in order to accommodate carts, dollies, construction materials, furniture, ambulance stretchers, patient gurneys, and patient beds. Service elevators are often called *hospital shaped* because their inside platform depths and the maximum length items they can accommodate are often their critical design components.

Freight elevators are usually equipped with biparting doors and lift-up car gates and can have platform sizes that are designed to accommodate everything from palletized freight on hand trucks to items transported on fork lifts, and even full-size semitrailer trucks. The inside areas, capacities, and loading types of freight elevators are typically set by the type of goods or freight loadings that are to be moved on the platform. Typical freight capacities start at 4000 lb and can go up to 10,000-, 15,000-, 20,000-, or even 60,000-lb capacities. The use of freight elevators is restricted by code to an operator and a freight handler in most cases. Under certain conditions, local jurisdictions may waive this rule and permit freight elevators to transport employees.

Since the adoption of the Americans with Disabilities Act (ADA) in 1988, the most commonly used passenger elevator platform sizes that permit the mandated three-point turn for a wheelchair, when equipped with center-opening doors, are 3000, 3500, and 4000 lb. A 2100 to 2500 lb passenger elevator platform meets the ADA requirements with side-opening doors. However, in most cases where groups of passenger elevators are provided, rapid passenger

movement in and out of the elevator cars is crucial, so they are almost always equipped with center-opening doors.

A high-rise building (typically 4 or more stories with heights above 75 ft) usually must be equipped with one or more elevators that can accommodate an ambulance stretcher in the horizontal position (across the car threshold). The stretcher sizes vary by the building code requirements but are generally about 24 in wide by 76 in deep. Some jurisdictions require an "ambulance stretcher" elevator in buildings of three or more floors.

ELEVATOR MOTIVE MEANS

Two motive means are used to move elevators that run vertically in their own guide rails within a hoistway: traction and hydraulics (Fig. 5.1.6-3). *Traction elevators* use hoist ropes (wire cables) that go over a reversible electric drive motor sheave (pulley) and are connected to the elevator car and a counterweight that runs alongside or behind the car in its own set of guide rails. The elevator's direction of travel, speed, and acceleration are controlled by the drive motor.

Hydraulic elevators use pressurized oil obtained from a self-contained pump unit as a force medium to move a hydraulic cylinder (ram) in a linear motion. The elevator car is directly or indirectly coupled to the hydraulic cylinder plunger, which moves the elevator up and down in the hoistway.

TRACTION ELEVATORS

When the electric hoist motor turns the drive sheave (pulley), it converts the rotary motion of the drive motor to linear motion through the hoist ropes to move the elevator and counterweight vertically in the hoistway. When a traction elevator car is at its lowest terminal floor, the counterweight is positioned near the very top of the hoistway. The counterweight is the same weight as the empty car plus 40 percent of the capacity load. The counterweights move in opposite directions as they travel through the hoistway. The use of a counterweight makes traction elevators very efficient (above 90 percent) because the hoist motor need be only large enough to overcome system friction and move (lift) the maximum rated car load.

Modern traction elevators are available with two types of hoist machines: geared traction units and gearless traction units. *Geared traction hoist machines* use an electric drive motor coupled to a worm and gearbox (can also be helical or planetary gears) to impart rotary motion to the drive sheave. Geared elevators are used in medium-height buildings with up to 15 stories and typically have speeds that range from 200 to 500 ft/min. The drive sheave for a *gearless traction hoist machine* is mounted directly to the machine motor armature. Thus the term *gearless* is used. Gearless elevators are generally used in high-rise buildings (15 to 125 stories) and employ speeds of 500 ft/min. The world's fastest units travel at 3280 ft/min. Gearless traction elevators require relatively slow-speed, high-torque drive motors that can be very precisely controlled for rapid runs between floors, express travel at up to the elevator contract speed, and accurate floor stops. Elevator speed is used to partially overcome travel distance established and express run requirements. For instance, a building of 12 to 15 stories might require elevator speeds of 350 to 500 ft/min; a 30-story building might use 500 to 800 ft/min; a 45-story building might have elevators at 1000 to 1200 ft/min; and a 60-story building might employ speeds of 1400 to 1800 ft/min. Very high speed elevators from 1800 to more than 3000 ft/min might be used as sky lobby shuttles and to service upper-level observation decks and restaurants. Virtually all geared and gearless elevators accelerate and decelerate at the same rate (about 3.0 to 4.0 ft/s^2), so it simply takes longer for the faster elevators to get up

to and slow down from their contract speeds. On a typical one-floor run, traction elevators might achieve a speed of only about 350 ft/min, regardless of their contract speeds. Passenger elevator stops in high-rise office buildings are typically divided into multiple elevator groups and zoned so that there are no more than 6 to 8 elevators per group and no more than 12 to 15 stops per zone.

HYDRAULIC ELEVATORS

Hydraulic elevators employ ac induction motors to drive positive displacement pumps. The pressurized oil is used to actuate the hydraulic cylinder that is connected to the elevator car. The elevator acceleration/deceleration values and travel direction are controlled by a series of solenoid-operated mechanical valves. Moving the elevator in the up direction requires activating the pump motor to drive the elevator cylinder plunger. The elevator is lowered by the controlled application of gravity when the lowering valve opens to permit the elevator to travel down while the oil returns to the pump unit reservoir. Hydraulic cylinders can be located directly under the elevator (direct plunger), alongside the elevator and directly coupled to the elevator (direct offset application, also called *holeless*), or alongside the elevator and coupled to it by a series of ropes (1:2 or 2:4 roped hydraulic). Hydraulic elevators typically employ speeds of 100, 125, 150, 175, or 200 ft/min and take about one-third more time than a traction elevator to travel between floors. Hydraulic direct offset applications (single or double cylinders) are generally limited in capacity and speeds and to travels of about 25 to 30 ft and 3 stops. Direct plunger applications have travel limits up to 50 to 60 ft in 5 to 6 stops and are generally limited to 150 ft/min. Roped hydraulics can have up to 10 stops and about 100 ft of travel and can travel at speeds up to 200 ft/min. Because hydraulic elevators normally do not have counterweights, they are not nearly as efficient as comparable traction units and generally require 45- to 75-hp motors to move a given load. However, hydraulic units are relatively inexpensive to purchase, install, and maintain. They become a logical choice for specialized applications such as in suburban office buildings of 3 to 5 stories, many automobile parking applications, retail mall environments, low-rise hotels, low-rise scenic glass-cab designs, and for very large, heavy-duty freight elevators.

Because of environmental concerns about ground pollution that can be caused by leaking direct-plunger cylinders, many states have now passed very stringent buried jack cylinder protection requirements that require auxiliary casings and leakage monitoring requirements. In the future, direct-plunger buried jack cylinders might be severely restricted, and the use of roped hydraulic applications will probably increase in the United States because of their flexibility and extended duty capabilities.

ELEVATOR DOOR TYPES

Virtually all passenger and service elevators are equipped with door panels that open to the side (Fig. 5.1.6-4). Because their platforms are wide and shallow, most passenger elevators are equipped with center-opening (CO) doors, each of whose panels has to travel only one-half of the clear opening width. Center-opening doors speed up the elevator trip because they open and close very rapidly and allow for efficient passenger loading. Service elevators are typically equipped with side-opening (SO) doors because the elevator platforms are usually narrow and deep to accommodate long objects and wheeled carts and dollies. In this case, the major concern is to equip them with wide openings to facilitate the transport of large objects, palletized materials, and carts. For wider openings, both center-opening and side-opening doors can be provided as two-speed units (2SCO or 2SSO).

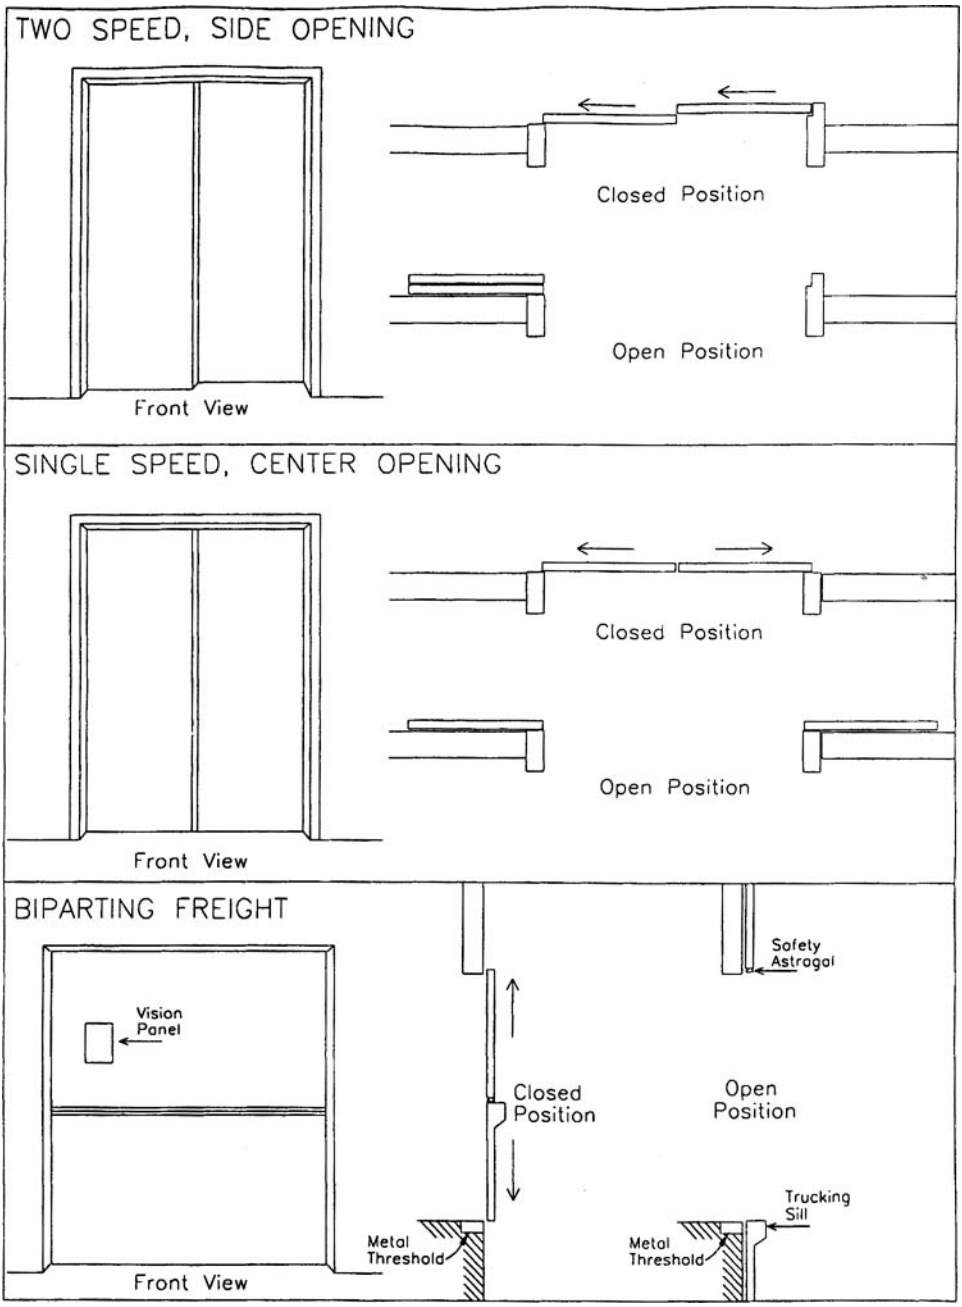

FIGURE 5.1.6-4 Elevator door types. (*Courtesy of Lerch, Bates & Associates, Inc.*)

Passenger and service elevators are equipped with master door operators that are located on top of the elevator cab. When the elevator is approaching a landing, the motion of the master door operator opens the car doors and unlocks the hoistway door interlock (an electromechanical locking device). At the landing, the car doors are physically coupled to the hoistway doors through a mechanical vane and drive-block system. This master door operator arrangement permits very smooth, rapid car and hoistway door openings with quick reversals and quiet checking.

Master elevator door operators are rated by their application and opening speed:

Operator designation	Opening speed, ft/s	Typical applications
Slow speed, light duty	1.0–1.5	Hydraulic elevators
Medium speed, medium duty	2.0–2.5	Geared elevators
High speed, heavy duty	2.5–3.0	Gearless elevators

Automatic elevator door closing speed is limited by the ASME A17.1 Elevator Code to the kinetic energy of the total door system (7 ft · lbf with a reopening device), which typically limits the door closing speed to no more than 1.0 ft/s. Table 5.1.6-1 lists some of the standard-width door times with 7-ft-high panels.

Freight elevators are typically equipped with manually operated (usually no more than 6 ft wide) or power operated vertically sliding, biparting hoistway doors and lift-up car gates. The upper and lower hoistway door widths and heights are determined by the sizes of the openings required, and the freight elevator car side panels are connected with chains or cables, so that they counterbalance one another when opening and closing. When open, the hoistway doors provide unobstructed access to the complete car width and height and can easily accommodate forklifts for moving palletized materials on and off the elevator. When the door is open, the bottom of the lower door panel acts as a trucking sill, filling the gap between the floor threshold and the elevator car sill. For power operation, each biparting door unit is equipped with an individual door operator located inside the elevator hoistway. Similarly, each vertically sliding car gate is equipped with a car-top-mounted gate operator. The ASME A17.1 Elevator Code limits the average hoistway door closing speed to 1.0 ft/s and the gate closing speed to 2.0 ft/s.

Power-operated biparting doors and lift-up car gate closings are normally controlled by constant-pressure pushbuttons located in the car and at each hoistway entrance. Automatic power closing of the doors and gates is permitted only if preceded by a 5-s audible warning signal and sequential closing of the car gate and hoistway doors. With automatic power-operated sequential operation, the hoistway doors must be at least two-thirds open before the car gate starts to open. In closing, the car gate must be two-thirds closed before the hoistway doors can start to close.

TABLE 5.1.6-1 Standard-Width Door Times with 7-ft Panels

		Door times, s			
		Opening speed, ft/s			
Door width	Door type	1.0	2.0	3.0	Closing speed 1.0 ft/s
3.5 ft	CO or 2SCO	2.4	1.6	1.4	2.4
	SO or 2SSO	4.0	2.4	1.9	4.0
4 ft	CO or 2SCO	2.7	1.8	1.5	2.7
	SO or 2SSO	4.5	2.7	2.1	4.6

ELEVATOR APPLICATIONS—THE PLANNING AND PROGRAMMING PROCESS

The suggested elevator design criteria and required vertical transportation equipment applications vary by the type of facility, the expected building population, and the on-site passenger arrival and departure process. The primary elevator design terms are calculated for peak periods and are expressed as: (1) the frequency of departures of elevators from a main loading terminal, called *average interval;* and (2) the number of persons transported on the elevators during the same peak period, termed *group handling capacity.* To be meaningful, the average interval, expressed in seconds, and the group handling capacity, expressed as the number of persons or as a percentage of the zone population moved, must be measured over the same time period (usually 5 min of peak traffic). Residential, hotel, office building, and medical building traffic differ greatly from each other and must be evaluated accordingly. Vertical and horizontal transportation devices are installed in many different types of facilities. These are some of the major applications, along with the types of vertical and horizontal transportation equipment typically found in them:

Vertical and Horizontal Transportation Equipment

1. Passenger elevators
2. Service (firefighting) elevators
3. Freight elevators
4. Escalators
5. Moving walks
6. Dumbwaiters or inject/eject cart lifts

Facility Type

- Office building: 1, 2, 3, 4
- Hotel: 1, 2, 3, 4
- Hospital: 1, 2, 3, 4, 6
- Residential apartment/condominium: 1, 2
- Judicial/courts/jail: 1, 2, 3, 4
- Retail/shopping mall: 1, 3, 4
- School/university: 1, 3
- Concert auditorium/stadium/sports arena: 1, 2, 4
- Parking garage: 1, 4
- Airport: 1, 2, 3, 4, 5

Each of the facility types listed has different elevator/escalator design criteria that depend on the number of people in the facility and their arrival and departure process. For instance, in a sports facility, it may take about an hour or longer for all of the fans to arrive and be seated. At the conclusion of the game, there is usually a mass exiting queue when everyone wants to depart at once, generally within a 20- to 30-min period. The peak vertical transportation equipment design criteria are therefore selected for the exiting peak. The number of units required to satisfy the selected design criteria and their duty is determined through a statistical mathematical process called *traffic analysis.*

Office building passenger elevators are designed for a 5-min morning up-peak traffic period, when the bulk of the building tenants arrive at the main floor lobby and require vertical transport up to their office floors. If the theoretical morning up-peak elevator calcula-

tions can meet or exceed the selected design criteria, then the number of elevators provided should give an acceptable level of service at other traffic peaks (such as the lunchtime two-way-peak and the evening down-peak) during different periods of the day.

Average waiting time is the time in seconds it takes for an elevator to answer a hall call after registration. Average waiting time standards are not generally used to design elevator systems. However, they can be derived from average interval calculations (about a 65 to 70 percent ratio for office buildings) or from a computer traffic simulation. Actual average waiting times and the number of hall calls answered within certain time parameters can be physically counted and tabulated for existing elevator groups. These measurements assist in evaluating the quality level of the elevator dispatching process. They can also be used to prove the specified performance parameters for a new elevator system, to evaluate the performance of an existing elevator system, or to document the performance characteristics before and after elevator modernization.

Escalators and moving-walk waiting times are normally zero because a passenger can board immediately without a wait, unless a passenger queue has formed at the boarding area. Escalator and moving-walk designs are selected on the basis of the number of persons they can transport during a peak 5-min or hourly period. Nominal escalator people loads are determined from a maximum load (1.0, 1.5, or 2.0 persons/step) by using a normal occupancy ratio (about 70 percent of the maximum). Escalators and moving walks are rated by the width of the tread and the moving (contract) speed selected.

SERVICE ELEVATORS

Service elevators are generally designed for specific facility applications and for the amount of goods, materials, and carts that they must handle. Their motive means can be hydraulic, geared traction, or gearless traction, depending upon the building height, application, and frequency of service desired. In high-rise office buildings, the service elevators often serve separate lobbies and enclosed vestibules, so that they would be used for building emergencies such as medical assistance, firefighting, and handicapped evacuations. Because the ASME A17.1 Elevator Code generally classifies them as *passenger* units, they must also meet the ADA handicapped accessibility requirements for a three-point turn in a wheel chair. The minimum ADA-mandated service elevator platform inside width is 5 ft 8 in (a 6-ft-wide platform), and the minimum inside car depth must accommodate at least a 6-ft 4-in ambulance-type stretcher. So, typical capacity ratings are 3500, 4000, 4500, and 5000 lb. Hospital applications for moving patients in wheelchairs or gurneys might require a capacity of 5000 to 6500 lb. Some hospital trauma service (inpatient) elevator applications can be 8000 to 10,000 lb. to accommodate full-size motorized beds and the accompanying patient life support systems. A jail or courthouse prisoner transfer service elevator is typically provided with inmate handcuff restraints or even very elaborate prisoner transport cages.

The number of service elevators required in an office building is typically selected by the amount of net rentable square feet planned for the facility. The general standards shown in Table 5.1.6-2 apply. Hotel and hospital service elevator applications can be selected from a ratio of one unit for so many guest (patient) beds or as a percentage of the number of passenger (ambulatory) elevators provided. The selections vary by the type of hotel and hospital and the requirements of the facility operator. For instance, a convention facility with lots of room service might require more service elevators than a conventional businesspersons' hotel.

FREIGHT ELEVATORS

Freight elevators are classified by the loads that they are expected to carry and the type of equipment that is used to load and unload the car (Fig. 5.1.6-5). Because the elevator plat-

TABLE 5.1.6-2 General Standards for Number of Elevators

Service elevators		
Number	Type	Net rentable area, ft^2
1	Combination passenger/service	≤250,000
1	Service	≥300,000–375,000
1–2	Service	≥375,000–600,000
2	Service	≥600,000–800,000
2–3	Service	≥800,000–1,200,000
4	Service	≥1,200,000–1,500,000

forms are typically narrow and deep and are often equipped with front and rear powered, biparting hoistway doors and car gates, they lend themselves more to large bulky items, palletized cargo, and automobiles.

Freight elevators can be manually loaded and unloaded using wheeled dollies, hand trucks, forklifts, or powered "mules." Freight elevators are found in manufacturing plants, warehouses, materials distribution areas, parking garages, and at restricted building loading docks.

The use of freight elevators is typically restricted to handling freight and the freight handlers. Passengers are normally not permitted to ride on freight elevators because the platforms are not constructed to meet the code-mandated 125 percent of load passenger-loading requirements. Freight elevators are exempt from ADA compliance requirements.

Freight elevator selections are based upon the amount and type of materials to be moved and the frequency of turnover. The amount of material that can be moved is paramount in the selection process, and little thought is given to the "waiting times" for service. Freight elevator motive means can be either hydraulic or traction (normally geared units), and the type of equipment is selected by the number of stops, the height of the facility, and the car speeds required.

MATERIAL-HANDLING EQUIPMENT

Automated and manual material-handling equipment is typically found in banking, data processing, mail sorting, and medical facilities. Dumbwaiters are the most common type of material-handling equipment employed. They can be manual or automatic, floor or counter loading, and can use hydraulic or geared traction motive means. Dumbwaiter car platforms are limited by code to a maximum 500-lb capacity, 9 ft^2 of inside platform area, and a 4-ft clear car height. These restrictions are to minimize the possibility of a person riding in the dumbwaiter car. Counter-loading dumbwaiters are typically equipped with vertical, biparting doors and car gates, whereas floor-loading units usually have lift-up doors and car gates. Dumbwaiters can be equipped with automated inject/eject devices that can automatically transport plastic totes (counter loading) or specially equipped carts (floor loading).

Material lifts are special floor-loading units that can have capacities of up to 1500 lb and maximum inside heights of about 6 ft. They must also be equipped with automatic cart-loading and -unloading devices as an integral part of the platform in order to minimize the possibility of persons riding on them.

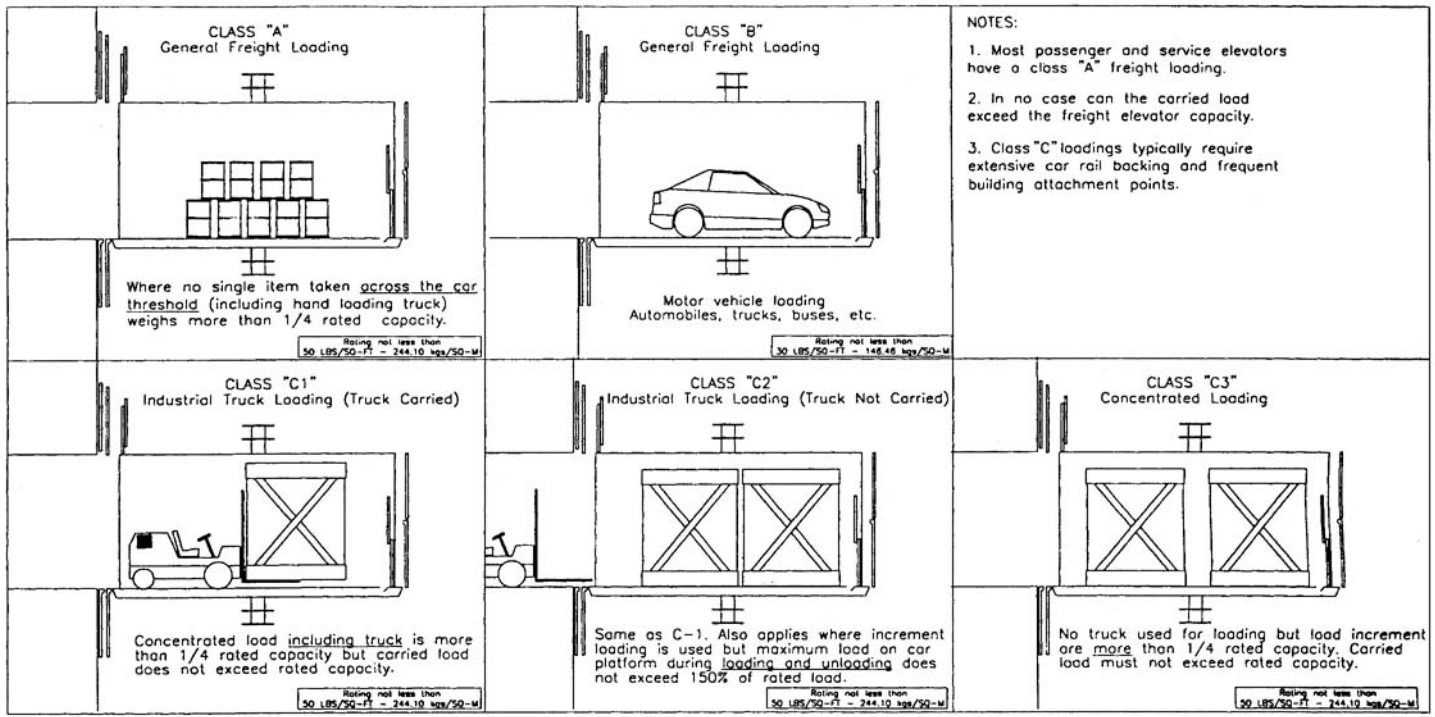

FIGURE 5.1.6-5 Freight elevator classes. (*Courtesy of Lerch, Bates & Associates, Inc.*)

ESCALATORS

Escalators are designed to facilitate the rapid movement of a high number of people, based on the escalator speed and the number of people carried on each escalator step. Maximum escalator capacities range from 1 to 2 persons per step, depending on the step width and the escalator speed (90, 100, or 120 ft/min).

The mechanics of design for escalator usage are quite well developed. Once the requirements for moving a desired number of people from one floor to the next are known, it is a relatively simple matter to select the number, speed, and width of the units necessary to handle this load.

Table 5.1.6-3 shows escalator capacities expressed in terms of maximum and nominal capacity loads.

We never utilize the maximum passenger movement capacities for escalator selection because the calculations are based upon each step being fully loaded. This is an almost impos-

TABLE 5.1.6-3 Escalator Capacities

Width	Speed, ft/min	Maximum capacity, persons	Nominal capacity, 75%
32 in (28-in step tread; 1 person/step)	90	338/5 min 4056/h	254/5 min 3042/h
	100	376/5 min 4512/h	282/5 min 3384/h
	120	451/5 min 5412/h	338/5 min 4059/h
32 in (28-in step tread; 1.25 persons/step)*	90	423/5 min 5076/h	317/5 min 3807/h
	100	470/5 min 5640/h	353/5 min 4230/h
	120	564/5 min 6768/h	423/5 min 5076/h
40 in (32-in step tread; 1.5 persons/step)	90	507/5 min 6084/h	380/5 min 4563/h
	100	564/5 min 6768/h	423/5 min 5076/h
	120	677/5 min 8124/h	508/5 min 6093/h
40 in (32-in step tread; 1.75 persons/step)*	90	592/5 min 7104/h	444/5 min 5328/h
	100	658/5 min 7896/h	494/5 min 5922/h
	120	789/5 min 9468/h	592/5 min 7101/h
48 in (40-in step tread; 2 persons/step)	90	676/5 min 8112/h	507/5 min 6084/h
	100	752/5 min 9024/h	564/5 min 6768/h
	120	902/5 min 10,824/hour	677/5 min 8118/h

Note: The ADA guidelines for transit facilities [10.3.1(16), 10.3.1(17)] require that all escalators have clear widths of at least 32 in, at least two flat steps at the top and bottom entry/egress points, and 2-in-wide, colored, nonslip demarcation strips on the nose of each step.

* Most elevator companies use 1.25 or 1.75 persons per step on these widths to allow for an adult with a child.

sible occurrence, even in the heaviest traffic situations when people depart from a rapid-transit station or a sports complex. Numerous surveys of escalator use have indicated that escalator peak nominal loads are about 75 percent of the maximum theoretical capacity, or about 1 to 2 persons on every other step.

MOVING-WALK APPLICATIONS

Moving walks were developed to provide pedestrians with an assist when they have to traverse long horizontal distances. People who board a moving walk usually have a choice of either standing in place on the unit until they arrive at their destination and then stepping off, or walking on the moving-walk treads to speed up their trip even further. It is an almost universal convention that people stand on the right and walk on the left. A traffic conflict and an impediment to passenger flow occurs when the walk treads (pallets) are not wide enough to permit some persons to walk and pass while others ride. The latest airport moving-walk applications employ double-lane pallet treads that are up to 5 ft wide. These wide units easily permit walkers to pass riders even if they are carrying bags or packages or pushing baggage carts, trolleys, or strollers.

Each moving walk is an independent, self-contained device that has its own individual drive unit, support pallets or moving belt, truss, balustrades, handrails, landing plates, and safety circuits. Moving walks are often installed in pairs so that one unit is running in the departure (outbound) direction and a parallel, adjacent unit is running in the arrival (inbound) direction. Moving walks are classified by length, tread or pallet width (single or double lane), inclination, speed (0 to 4 ft/min for a flat moving walk; 4 to 12 ft/min for a moving ramp), and reversibility.

There are two basic types of moving walks; the metal (die-cast aluminum) pallet type, which is similar to a flattened out escalator, and the rubber-belt type, which is similar to a conveyor belt. Most elevator and escalator manufacturers make only the pallet-type moving walk.

Pallet-type moving walks are provided with full support trusses (similar to escalators) that must be supported on the drive and turnaround ends and at about every 35 ft of lineal length. The truss-type units require about a 4-ft-deep truss depth (pit) that runs the entire width and length of the unit. A second pallet type of moving walk uses stanchion-mounted supports located on about 3-ft centers along the full length of the center walk. These types of units require continuous poured-concrete beds about 18 in deep between the drive and turnaround truss sections.

Moving-walk applications in airport terminals and concourses are primarily used to speed up transit passenger trips between concourses. They are also used to feed departing and arriving passengers to and from the outlying airplane loading gates. Individual moving-walk airport applications are normally installed between airplane loading gates, usually with a maximum length of about 250 to 300 ft, and are spaced along a transit axis adjacent to walking corridors, with 25- to 30-ft loading/unloading breaks between walks spaced along the travel path.

Much like escalators, moving walks are rated by the number of people that they transport within certain time segments. The smallest time period that gives a reliable average is 5 min. Moving-walk capacities also vary in whether they can accommodate single-lane (28-, 32-, or 40-in-wide treads) or double-lane (48-, 54-, 56-, or 60-in-wide treads) passenger movement. Contrary to popular belief, moving-walk capacities do not increase when passengers walk on the moving treads. The area (headway) between the passengers increases to accommodate an average adult's faster walking speed of about 250 ft/min, which is about twice the moving-walk speed. Even though passengers walking on the moving-walk treads do not increase the unit's capacity, passengers should still be encouraged to walk on the units because their relative speed is about 3 times as fast as the moving-walk tread speed, which reduces their own trip times to their destinations. Table 5.1.6-4 indicates moving-walk capacities and nominal loads.

TABLE 5.1.6-4 Moving Walk Capacities

	Nominal loads, persons moved*					
	Single lane†			Double lane†		
Moving-walk speed, ft/min	1 min	5 min	1 h	1 min	5 min	1 h
90	45	225	2700	90	450	5,400
100	50	250	3000	100	500	6,000
120	60	300	3600	120	600	7,200
125	62.5	313	3756	125	626	7,512
140	70	350	4200	140	700	8,400
150	75	375	4500	150‡	750‡	9,000‡
180	90	450	5400	180‡	900‡	10,800‡

* Capacities are figured at a 250-ft/min average pedestrian horizontal walking speed and a 24-in headway between persons with a 0.5 s/person boarding rate (see J. J. Fruin, *Pedestrian Planning and Design*, pp. 40, 108, and 110). Nominal loads are the 5-min rates.

† Per ASME A17.1, Rule 902.7: single lane—28-, 32-, or 40-in tread width (maximum speed 180 ft/min); double lane—48-, 54-, 56-, or 60-in tread width (maximum speed 140 ft/min). *Note:* 0 to 4 ft/min flat walk unrestricted tread width; 4 to 12 ft/min inclined walk—maximum tread width 40 in; minimum tread width is 22 in.

‡ Not permitted by ASME A17.1 code.

SECTION 5.2
ELECTRICAL SYSTEMS

David L. Stymiest, P.E., SASHE, C.E.M., Senior Consultant, Section Editor
Smith Seckman Reid, Inc., New Orleans, Louisiana

This section of Chap. 5 presents nine detailed treatments of the major aspects of electrical systems for all types of buildings and facilities. The first two articles (Arts. 5.2.1 and 5.2.2) on service entrances and electrical distribution systems cover the gamut of building electrical power distribution issues from the electrical utility to the basic panelboard. Then, in Art. 5.2.3,

Previous Page

we supplement this comprehensive treatment of electrical distribution issues with a detailed presentation on emergency power supply systems, including emergency electrical generators. Following that, we focus on specific electrical components of buildings and facilities; raceway and cable systems (Art. 5.2.4), wiring devices (Art. 5.2.5), and grounding systems (Art. 5.2.6). The next two articles (Arts. 5.2.7 and 5.2.8) present engineered systems that are often not given enough attention in many buildings and facilities—cathodic protection systems for corrosion control and heat tracing systems for both freeze protection and process heating. Finally, in Art. 5.2.9, our treatment of electrical systems concludes with an important article on power quality.

ARTICLE 5.2.1
SERVICE ENTRANCES

Jack W. Dean, P.E., Electrical Department Head
Novare Engineers, Inc., Providence, Rhode Island

RESTRUCTURED ELECTRIC UTILITY INDUSTRY

Under restructuring, the American electric utility industry is being split into three major components: (1) generation, (2) transmission, and (3) distribution. Electricity is generated in hydroelectric plants, other renewable energy plants, nuclear power plants, coal and oil-fired plants, and is transmitted through the electric utility grid to local distribution companies (LDCs), also sometimes called *wires companies.* Locally, utility-supplied electric power is sometimes supplemented with steam or gas-fired cogeneration systems or other locally generated renewable sources. In the United States, transmission systems are regulated by the Federal Energy Regulatory Commission, and the distribution of electricity within states is regulated by state public utility commissions or departments. Refer to Art. 7.1.6, "Fuel and Energy Procurement," for a more detailed discussion of issues related to the restructured electric utility industry, also sometimes referred to by the misnomer the *deregulated* electric utility industry.

Because most of the electric power is still generated in large power plants and must be transported over large distances, electricity is generated and transmitted at voltages that are much higher than utilization voltage to minimize distribution losses. Therefore, it must be transformed to a lower voltage when it reaches its point of use. Discussion of regional distribution networks, the effects of deregulation on purchasing decisions, and the reliability of delivering electric power to the site is beyond the scope of this section. We will concern ourselves solely with the point at which the LDC interfaces with the facility—the service entrance and the associated electrical equipment.

THE SERVICE ENTRANCE

The electric power furnished by the LDC is connected to a facility at the service entrance. The service entrance installation consists of various types of equipment (called *switchgear,* or simply *gear*), depending on the source of power and the reliability of service required. That gear is arranged in various configurations for distributing power. The types of loads and the required continuity of service, the system capacity, the voltage required, the voltage drop, the

installation conditions and restrictions, and the maintenance requirements are major considerations. The following six systems cover most basic arrangements of service entrance equipment that, in different combinations, address all reasonable service entrance schemes:

1. Simple radial system
2. Loop primary-radial secondary system
3. Primary selective-radial secondary system
4. Two-source primary, secondary selective system
5. Spot network system
6. Medium-voltage distribution system

Common Elements

After a general discussion of the common elements of these schemes, each scheme is presented in detail, along with the elements of each service entrance scheme that will be a major concern of facility managers. This section centers on the elements of ownership, cost, space considerations, reliability, and power quality and efficiency.

Service entrance equipment consists of overcurrent/disconnecting means (switches, circuit breakers, and relays); transformers (indoor, outdoor, dry, and liquid); and switchgear, switchboards, and substations—this equipment is arranged to distribute power effectively to the overall facility. Because equipment required for service entrances and that required for distribution systems overlap, this article limits detailed discussion to equipment rated for medium voltage (600 to 65,000 V). Refer to Art. 5.2.2, "Electrical Distribution Systems," which describes components such as switchgear, switchboards, and step-down transformers for low-voltage operation (600 V and below).

Metering

Metering is the means by which a supplier of electrical energy measures the amount used by a customer, and this is the amount upon which billing is based. Metering is performed at the user's site and may be measured on the primary (high-voltage or medium-voltage) side of the service entrance equipment or on the secondary (low-voltage) side. Primary and secondary metering reflect different utility rates based on the generalization that the owner provides (and owns) all equipment downstream of the meter. Although primary metering may reflect a lower rate, the owner must incur the cost of purchasing and maintaining the primary disconnects and transformers, as well as the risk of their failure. In secondary metered installations, this equipment is normally furnished and maintained by the serving utility.

Obtaining the metering information may be by direct reading (i.e., visually recording the data) or remotely via the Internet or via a modem. Remote reading may become required rather than optional due to the industry restructuring. Also of consideration is the use of analog or digital (solid-state) read-out. From a utility's standpoint, the time of peak demand of power usage is very important relative to how much generating capacity must be provided. Because of this, cogeneration and/or load peak shaving has gained increasing prominence in recent years as both owners and utilities strive to keep costs in check.

Cogeneration

Cogeneration is the production of electrical power concurrently with the production of steam, hot water, and similar energy uses. Electric power can be the main product, and steam or hot

water is the by-product, or the steam or hot water can be the primary product, and electric power a by-product. Refer to Art. 5.4.5, "Cogeneration," for a detailed discussion of this strategy.

Where a cogeneration system is being considered, the electrical distribution system becomes more complex. The interface with the utility company is critical and requires careful relaying to protect both the utility and the cogeneration system. Many utilities have stringent requirements that must be incorporated into the system. Proper generator control and protection is necessary, as well. Utilities require that when the protective device at their substation opens, the device also opens that connects a cogenerator to the utility. One reason is that most cogenerators are connected to feeders that serve other customers. Utilities desire to reclose the feeder after a transient fault is cleared. In most cases, reclosing will damage the cogenerator if it remains connected to their system.

Islanding is another reason why the utility insists on disconnecting the cogenerator. Islanding is the event that occurs after a fault in the utility's system is cleared by the operation of the protective devices, when a part of the system may continue to be supplied by cogeneration. Such a condition can be dangerous to the utility's operation during restoration work. Major cogenerators are connected to the subtransmission or the transmission system of a utility. Major cogenerators have buy-sell agreements, in which case, utilities use a trip transfer scheme to trip the cogenerator's tie breaker.

Peak Shaving

Many installations now have emergency or standby generator sets. In the past, they were required for hospitals and similar facilities but were not common in office buildings or shopping centers. However, many costly and unfortunate experiences during utility blackouts in recent years have led to more frequent installation of generator sets in commercial and institutional systems for life safety and to supply other important loads. Industrial plants, especially in process industries, usually have some alternate power source to prevent extremely costly shutdowns. These standby generating systems are critical when needed, but they are needed only infrequently. They represent a large capital investment. To be sure that their power is available when required, they should be tested periodically under load.

Because of the rise in the cost of electricity in recent years and because utilities will bill on the basis of power consumed and also on the basis of peak demand over a small interval, a new use for in-house generating capacity has developed. Utilities typically measure demand charges on the basis of the maximum demand for electricity in any specified period (typically 15 or 30 min.) during a month. Some utilities have a demand "ratchet clause" that continues demand charges on a given peak demand for a full year, unless a higher peak results in even higher charges. In these cases, one large load coming on at a peak time can create higher electric demand charges for a year.

Reducing the peak demand can result in considerable savings in the cost of electrical energy. For those installations that have generator sets for emergency use, modern control systems (computers or programmable controllers) can monitor the peak demand and start the generator set to supply part of the demand as it approaches a preset peak value. The generator set must be selected to withstand the required duty cycle. The simplest of these schemes transfers specific loads to the generator. More complex schemes operate the generator in parallel with the normal utility supply. The savings in demand charges can reduce the cost of owning emergency generator equipment. In some instances, utilities with little reserve capacity have helped finance the cost of some larger customer-owned generating equipment. In return, the customers agree to take some or all of their load off the utility system and onto their own generators at the request of the utility (with varying limitations) when the utility's load approaches capacity. In some cases, the customer's generator is paralleled with the utility's to help supply the peak utility loads, and the utility buys the supplied power. Some utilities have been able to delay large capital expenditures for additional generating capacity by such arrangements. Air quality regulations and site-restricted emissions permits in certain

regions may prohibit or curtail this strategy. Refer to Art. 3.2.9, "Environmental Compliance and Issues Management," for a discussion of these types of restrictions.

Utility Service Voltage

Whether the utility service is at primary or secondary voltage depends upon many factors such as type of building, total load, class of user, and the utility rate structure and standard practice. In most downtown metropolitan areas, the utility serves a single commercial or institutional building only at secondary voltage. In more open areas, especially for large buildings or multiple-building installations such as shopping centers, educational institutions, and hospitals, the utility may offer a choice of primary or secondary service.

Where a choice is available, the decision is essentially economic. Utility rate structures provide higher cost for a given load served at secondary voltage than for the same load served at primary voltage because the utility must provide and maintain the substations and pay for substation losses on the secondary service. The lower cost of primary service to the customer must be weighed against the cost of the primary distribution equipment and substations required, the space they occupy, the cost and availability of qualified maintenance for the primary distribution equipment and substations, the reliability of service, the cost of substation (mostly transformer) losses, and similar factors. It is common for industrial plants that have large loads, available room for electrical equipment, and well-qualified maintenance to take advantage of primary service. It is also usual for commercial buildings to use secondary service. Institutional services vary, depending upon the size of the institution, the number and arrangement of buildings, the continuity of service required, and the quality of maintenance available.

Designing for Maintenance

A major consideration in designing or upgrading a facility's service entrance equipment and connection to the service entrance conductors should be how the equipment will be maintained. Designs that allow isolating faults (electrical short circuits) without interrupting power to major portions of the facility are desirable. Regular maintenance to prevent faults from occurring requires isolating portions of the service entrance equipment. Designs that enable such activities easily and without undue hardship on the facility's operation should be part of the design philosophy.

Ease of maintenance can be achieved by using the following strategies:

- Using main breakers in lieu of multiple disconnecting means; up to six are allowed [per paragraph 230-71 of the National Electrical Code (NEC)][1]
- Using transformer primary and secondary tie breakers
- Using backup tie feeders between main centers of load distribution
- Including a separate bypass/isolation switch in an automatic transfer switch enclosure
- Using draw-out circuit breakers rather than bolt-in circuit breakers in main switchgear
- Using hinged covers and three-point locking systems on electrical switchgear enclosures and distribution panels
- Using double-ended unit substations rather than larger single bus substations

Primary Disconnecting Means

If the transformer is located outdoors and furnished by the utility company, the transformer will have an internal primary fused or a nonload break-type switch to offer transformer over-

current protection and/or means of disconnecting the service. For primary metering, however, the primary switch(es) and transformer(s) will be the property of the owner and must be owner-furnished. The means of disconnecting service is located before the service transformer and must be suitable for interrupting the electric company's distribution voltage and available short-circuit current. This equipment is generally fusible or circuit-breaker type.

Fusible-Type Primary Switchgear. Fusible-type switches are less expensive than circuit breakers. They are normally furnished in what is known as metal-enclosed (ME) load-interrupter switchgear. This gear includes interrupter switches, power fuses (current-limiting or non-current-limiting), bare bus and connections, instrument transformers, and control wiring and accessory devices. This gear generally houses one or more fused or nonfused switches in a metal lineup without barriers (Fig. 5.2.1-1).

Circuit-Breaker-Type Primary Switchgear. Circuit breakers are normally provided in what is known as metal-clad (MC) switchgear and can be vacuum type (Fig. 5.2.1-2) or sulfur hexafluoride (SF_6) insulated type. This switchgear has the following four features:

1. Removable- (draw-out) type switching and interrupting devices move between a connected and disconnected position with self-alignment and self-coupling
2. Major parts of the switchgear are completely enclosed by grounded metal barriers for compartmentalization
3. Automatic shutters cover primary stabs or studs when the removable element is in the disconnected, test, or removed position
4. All primary bus conductors and connections are covered with insulation throughout

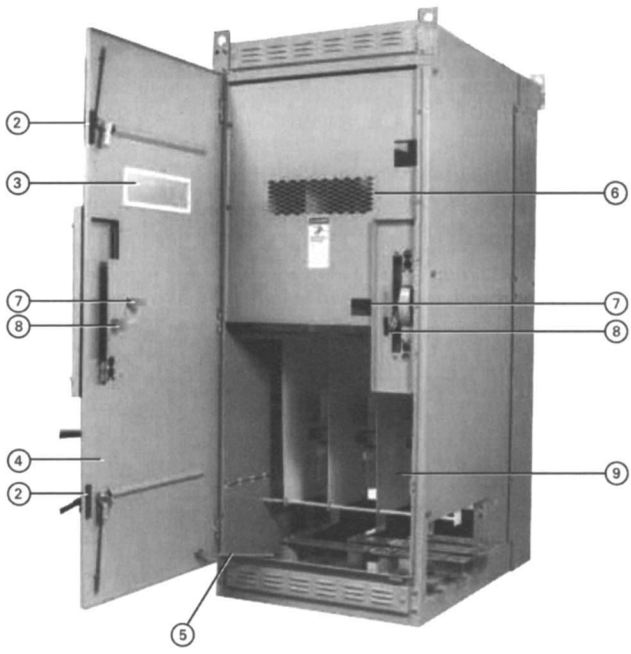

FIGURE 5.2.1-1 Example of load-interrupter fusible switchgear. (*Courtesy of Cutler-Hammer.*)

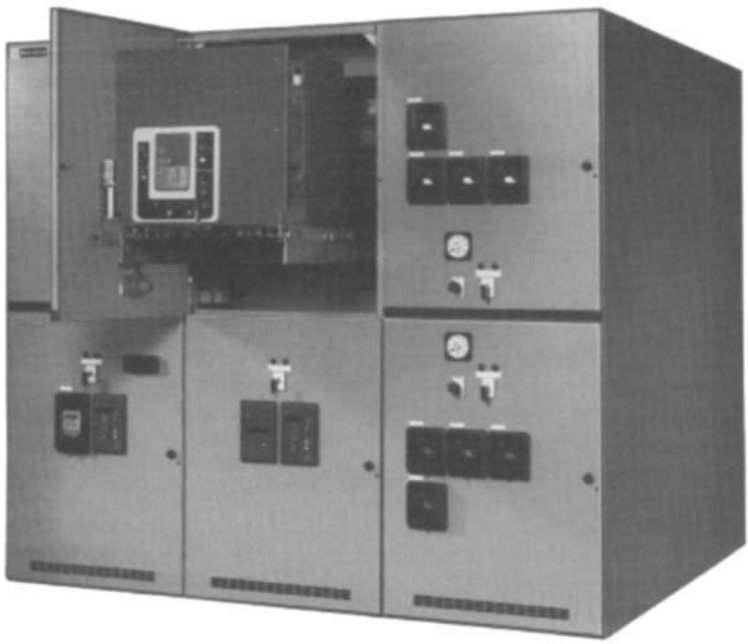

FIGURE 5.2.1-2 Example of MC vacuum breaker switchgear. (*Courtesy of Cutler-Hammer.*)

From Table 5.2.1-1, it is quite clear there are significant differences (first cost included) to consider when selecting ME or MC switchgear. The following paragraphs explain some of these differences in terms of owner and engineering value.

Construction. The first selection factor, construction, is related to the continuity of electric service and the negative financial impact of an extended shutdown. For lineups of switchgear, MC construction offers superior short-circuit (fault) isolation from compartment to compartment because the grounded sheet-metal barriers surround all major components and devices. In ME construction, however, because of its more open and uncompartmentalized construction, an internal fault, while rare, could propagate throughout the switchgear. The probability and total cost of extended downtime, as well as the additional first cost for MC construction, need to be addressed in the selection process. (For single vertical-section application, barriering offers much less value.)

Metal-clad switchgear incorporates only insulated buses with sufficient air clearances in between-phase bussing. However, insulated bus joints are more difficult to check and maintain. Although some ME load-interrupter equipment may have insulated bus, standards permit open uncovered bussing. Insulation of the bus provides additional safety against faults due to unattached equipment or tools left on bus bars.

The draw-out feature in MC switchgear is very important, especially for lineups, for continuity of service because the entire lineup does not have to be shut down to remove a single element for maintenance and /or repair. Obviously, the draw-out feature does not offer as significant a benefit for a single load-interrupter switch on a secondary unit substation. In radial systems that have one primary upstream load interrupter feeding one or more unit substations with primary ME switches, unnecessary power outages, although unlikely, may occur if the feeder switch has to be removed from service. If the secondaries of these unit substations are fed from more than one source, the importance of this feature is considerably reduced in terms of continuity of service.

TABLE 5.2.1-1 Summary of Some Major Differences Between ME and MC Types of Equipment

Parameter*	ME-Type WLI			MC—Type VacClad-W		
Voltage Range	4.76–38 kV			4.76–38 kV		
BIL (Basic Impulse Level)	5 kV–60 kV BIL 15 kV–95 kV BIL 25.8 kV–125 kV BIL 38 kV–150 kV BIL			5 kV–60 kV BIL 8.25 kV–95 kV BIL 15 kV–95 kV BIL 27 kV–125 kV BIL 38 kV–170 kV BIL†		
Standards—switchgear Switch or breaker—device	C37.20.3—1987 C37.20.4 and C37.22			C37.20.2—1987 C37.04—.11		
Size/structure‡	Width	Depth	Height	Width	Depth	Height
inches	36.0	55.3–70.0	90.4	36.0	96.3	95.0
mm	914.4	1404.6–1778.0	2296.2	914.4	2446.0	2413.0
Weight	1800 lb—816.5 kg			2650 lb—1202.0 kg		
Cost/switch/breaker	$12,000–14,000			$22,000–25,000		
ANSI minimum§ electrical duty cycle	30			1,000		
Protective device	Power fuse			Protective relays/breaker		
Operation	Manual operation (electrical operation is optional)			Electrically operated only		
Compartmentalization	Open			Barriered		

* Some data is typical and represents close estimates.
† ANSI standards at 38 kV require 150 kV BIL.
‡ Data based on 5–15 kV class equipment. Feeder breakers may be stacked two high.
§ ME data is for 15 kV, 600-A switches. MC data is for 1200-A–2000-A breakers.
Source: Courtesy of Cutler-Hammer.

One additional advantage occurs when a spare vacuum breaker is available to minimize a particular feeder's downtime. In lineups of load-interrupter equipment, this would be impractical.

Again, estimates and analysis of the importance of continuity of service and prospective downtime need to be reviewed to make these evaluations.

Another construction feature concerns resettability, reenergizing primary circuits and/or transformers after an overload trip. In the case of ME fusible devices, fuses obviously must be replaced, whereas with protective relays, the protective relay may be reset and service can be resumed in a significantly shorter time. In addition, the protective sensing devices that use MC switchgear are typically protective relays such as induction disk or microprocessor-based protective relays, which can be tested and removed while the circuit remains energized.

Size. Table 5.2.1-1 shows size differences per structure. For lineups of primary protective devices, size advantage in length may reside with MC vacuum circuit breakers because feeder breakers can be stacked two high. In essence, this allows two 15-kV feeder devices in a single section. In terms of depth, load-interrupter switchgear provides significant size reduction for lineups.

For single devices in a unit substation configuration, the ME sizing offers a clear advantage. The nominal 8-ft minimum depth of MC draw-out vacuum circuit-breaker switchgear is more dimensionally constraining than the smaller load-interrupter switchgear. In addition, MC switchgear requires minimum aisles in front for circuit-breaker withdrawal and to enable lift trucks to remove these breaker elements from the lineup, along with rear accessibility and working space. Metal-enclosed switchgear is accessible from the front or rear, depending upon options and cable entry and exit requirements.

For primary selective applications (two sources of primary power), ME types offer two options: (1) a duplex configuration (see Fig. 5.2.1-3) and (2) a selector configuration (see Fig. 5.2.1-4). Costs are dramatically higher for MC duplex equivalent arrangements because two vacuum breakers are required. No equivalent exists in an MC type for the selector configuration.

Method of Operation. Most load-interrupter switchgear is manually operated, whereas all MC, vacuum circuit-breaker switchgear is inherently electrically operated either from a dc or an ac source. For single-section ME equipment, feeding a single transformer such as a unit substation, this presents no adverse problems; in fact, the simplicity of a manually operated switch may lend itself to many of these installations.

For lineups with automatic transfer (also called *throw-over*) using load-interrupter equipment, the mains and ties would have to be equipped with motor operators, which typically require auxiliary structures and are add-on devices at increased cost. (Some ME equipment is available with integral motor operators that require no additional space.) In MC construction, with automatic transfer schemes, the inherent motor operation of vacuum breakers can be more meaningful to the designer in addition to the obvious benefits of convenient operation. The speed required in a transfer also affects selection (breakers operate in several cycles; one cycle is ⅙₀ s, or 16.7 ms).

Duty Cycle. Table 5.2.1-2 depicts duty cycle differences, which in essence define their useful life. In this regard, there is a stark difference between ME load-interrupter switches and MC vacuum circuit breakers. Obviously, the application must take duty cycle into account when selecting different types of equipment such as automatic transfer schemes and especially those that are exercised on a scheduled basis.

Protection with Fuses versus Relaying. Protection is one of the major differences and reasons for selection between ME (fuse) and MC (relay) switchgear. Table 5.2.1-3 summarizes some of them. For further discussion, see Sec. 5.4 in the IEEE Gray Book.[2]

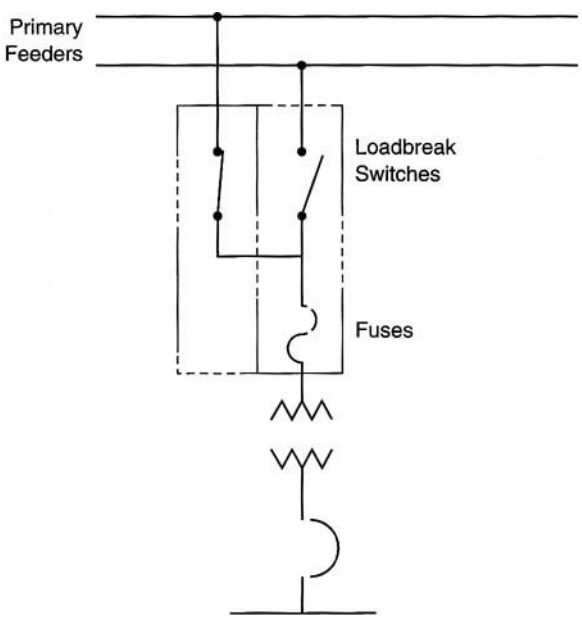

FIGURE 5.2.1-3 Duplex fused switch in two structures. (*Courtesy of Cutler-Hammer.*)

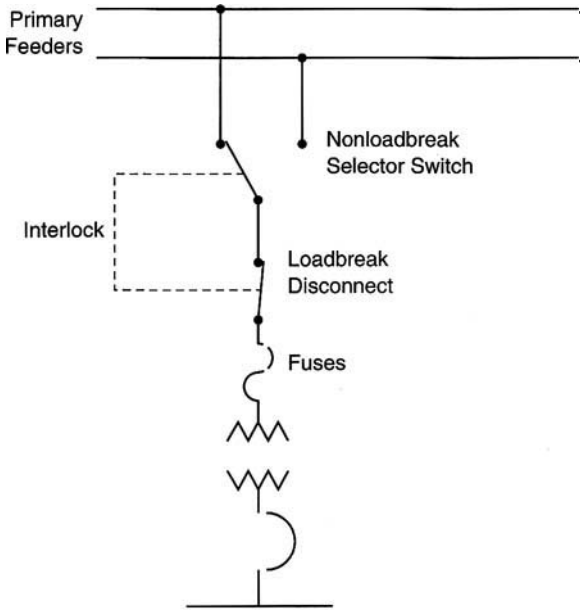

FIGURE 5.2.1-4 Fused selector switch in one structure. (*Courtesy of Cutler-Hammer.*)

Metal-enclosed switchgear typically relies on fuses for protection, which in general provide safe and cost-effective means for medium- and high-fault clearing. Several application comments are given here.

In some cases, switches have been specified on 5-kV low-resistance grounded systems where ground faults are limited to values below the switch rating, typically 600 A. Basically, external relays are called upon to signal the load interrupter to open. Because this occurs while a fault is in progress, it is possible for the fault to escalate into a higher phase-to-phase fault just as the switch is called on to open. Because of this, a vacuum circuit breaker should be used; it can interrupt up to 1000 MVA. A switch is not recommended for a ground-fault

TABLE 5.2.1-2 Duty Cycle Differences

Device*	Number of Load Current Switching Operations	Number of Mechanical Operations
ME interrupter switches (per ANSI)	30	500
MC breakers (per ANSI)	1000	10,000

application. Medium-voltage fuses provide poor ground-fault protection because the magnitude of the ground fault may be well below the current rating of the fuse.

Care should also be taken to prevent single-phasing of fusible load-interrupter ME equipment. (See Sec. 13.3.15 of the IEEE Buff Book.[3]) It can be shown that as little as a 3 percent of voltage unbalance can produce upward of 20 percent of overheating in induction motors. Single-phase and/or blown-fuse protection is optionally available for ME switchgear.

Possible voltage spikes/transients produced by fuses during significant current limitation should also be factored into the selection process and should be coordinated with surge protection.

References for medium-voltage fuses and load-interrupter equipment and their recommended usage can be found in Secs. 5.3, 9.2, and 9.3 of the IEEE Red Book,[4] and also in Secs. 5.12 through 5.17 of the IEEE Buff Book. These references indicate that load-interrupter fused switches are commonly used in many applications, especially for transformer protection.

Protective relays and associated current transformers, on the other hand, are for fault sensing in MC switchgear. Several application comments are given here.

Relays can provide very sensitive ground-fault protection under any condition because the vacuum breaker is a fully rated interrupting device and can be called upon to interrupt under those conditions. References for further discussion of relays include Secs. 5.5, 9.2, and 9.3 in the IEEE Red Book, 5.5 in the IEEE Gray Book, and Chap. 4 in the IEEE Buff Book.

Relays offer close overload protection. Standard power fuses do not provide overload protection and can rarely provide good backup protection for secondary main devices during overload conditions, but electronic fuses may overcome many of these imitations (see later).

Other types of protection such as differential protection can be provided by using protective relays.

Another important difference is curve shaping. Facilities likely to be expanded and /or to have changing loads may benefit from relays and MC switchgear.

Standard fuses cannot be tested, whereas protective relays can be calibrated and tested. For hospitals, waste treatment plants, and industrial plants, this may provide extended life and reduced downtime. For other types of buildings that emphasize maintenance less, the maintenance requirements of protective relays and MC switchgear may actually detract from selecting them.

Fair to good coordination is available with standard fuses, depending on the shape of the upstream and downstream overcurrent protection devices. Relays generally can be set to nest

better and provide shorter wait time in tripping. Because fault damage is proportional to I^2t, significantly more damage occurs for each additional cycle during which the fault flows. (See Chap. 7 on ground fault protection in the IEEE Buff Book. Also see Chaps. 9 and 10 on equipment selection in the IEEE Buff Book.)

The previous discussion compares relay capabilities with standard-type power fuses. However, a broad selection of time–current characteristic curves, plus high continuous current and fault-interrupting ratings, makes electronic power fuses a good selection for service entrance protection, medium-voltage transformer protection, underground subloop protection, and backup protection for overdutied devices such as power circuit breakers. The fast response provides a degree of protection superior to that provided by power circuit breakers and at continuous-current levels far exceeding those available with current-limiting fuses. Moreover, the special response characteristics available with certain electronic power fuses make selecting them a good option for application where traditional types of protective equipment have not been completely satisfactory.

Maintenance. Recommended maintenance information can be found in NFPA 70B,[5] as well as in the IEEE Buff Book maintenance section. Westinghouse Electric's *Westinghouse Maintenance Hints,* Chaps. 6, 7, and 40, provides good reference information.[6] Another reference source is Chap. 11 of the *Facility Manager's Operation and Maintenance Handbook.*[7] Also refer to Art. 7.2.3, "Electrical Testing and Maintenance," for a brief discussion of maintenance issues.

Summary. The selection process for medium-voltage switchgear should include evaluations of building life and reliability needs, maintenance, qualifications, of operating and maintenance personnel, first cost, size and room configurations, protection of circuits, continuity of service, available ratings, and single-unit or lineup arrangements. Refer to Art. 5.2.2, "Electrical Distribution Systems," for a discussion of the various types and operation of medium-voltage fuses, circuit breakers, and relays referred to previously.

Transformers. Most electric company–furnished transformers are oil filled for long life, lowest first cost, and quiet operation and are pad-mounted outdoors. If they are to be located indoors, a transformer vault built to utility company and building code requirements is required. If transformers are to be furnished by the facility and will be located indoors, nonflammable silicone or dry-type transformers are recommended to avoid the cost of vault construction required to minimize the potential damage from fire. Refer to Art. 450-B of the NEC for specific requirements for the different transformer categories. Although the NEC discusses the location requirements of Askarel™-filed transformers, they are no longer acceptable environmentally because of the Environmental Protection Administration and state environmental protection agency rulings against fluids containing PCBs. Refer to Art. 3.2.9, "Environmental Compliance and Issues Management," for a further discussion of related issues. It should also be noted that some states have adopted into law the efficiency levels of the National Electrical Manufacturers Association (NEMA) Standard TPI-1996[8] for distribution transformers (those designed for operation on electrical distribution systems at primary voltages of 34.5 kV and below and secondary voltages of 600 V and below).

Pad-Mounted (Compartmentalized) Transformers. A *pad-mounted (compartmentalized) substation transformer* usually denotes a power transformer with direct cable or overhead line termination facilities that distinguish it from a unit substation transformer designed for integral connection to primary or secondary switchgear, or both, through enclosed bus connections. The substation classification is further defined by the terms *primary* and *secondary.* The primary substation transformer has a secondary or load-side voltage rating of 1000 V or more, whereas the secondary substation transformer has a load-side voltage rating of less than 1000 V.

Secondary Unit Substation Transformers. Unit substation transformers, as distinguished from substation transformers, are designed for integral connection to primary and/or secondary switchgear via enclosed bus connections. Secondary unit substation transformers have

load-side voltage ratings of less than 1000 V and typical ratings of 300 to 2500 kVA. Primary ratings do not exceed 34.5 kV.

Liquid-Filled Transformers. Although NEMA TRI[9] and ANSI C57.12.00[10] differ to some extent on definitions of insulation class, the following is typical in the industry for unit substation transformers. Typical liquid transformers (Fig. 5.2.1-5) are designed with insulation systems to operate at a maximum temperature rise of 65°C, plus 40°C maximum ambient (average temperature of 30°C over a 24-hour period), plus a 15°C hot spot allowance for a total insulation rating of 120°C. Thus, 65°C is the standard specified for temperature rise. However, liquid-filled transformers can be specified with a 55°C rise, suitable for continuous operation up to a 65°C rise with an increase of 12 percent of the base kVA rating. For example, a 1500-kVA liquid-filled transformer designed for a 55°C temperature rise can operate continuously at 1500 kVA × 112%, or 1680 kVA. This optional 55°C temperature rise rating usually costs approximately 5 percent additional over the base price of the transformer. This extra 12 percent rating may be used for

- Unknown future load growth
- Obtaining kVA ratings slightly above standard ratings
- Double-ended unit substations to obtain increased kVA capacity when operating on only one transformer
- Operation at temperatures higher than the expected standard 40°C ambient conditions, but not exceeding 50°C

Essentially, the insulation systems of standard mineral oil, high-flash-point silicone or hydrocarbon, and nonflammable liquid-filled transformers are similar. However, some of the actual insulation materials, gaskets, and bushings may vary to ensure chemical compatibility with the fluid used.

Trade-offs between types of transformer insulation systems dramatically affect the safety performances and life cycle cost of the equipment. Both the NEC and the National Electrical Safety Code (which applies to electric utility distribution systems) allows transformers that are rated as *less flammable* with overcurrent and fault protection to be installed indoors without a 3-hour fire-resistant vault.

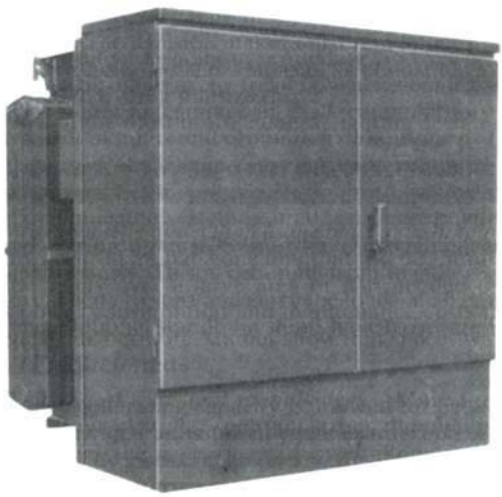

FIGURE 5.2.1-5 Typical liquid-filled transformer. (*Courtesy of Square D Company.*)

This can mean a lower installed cost for owners without additional protections, such as extinguishing systems, large separation distances, and barriers, both indoors and outdoors. In recent years, new dielectric liquids have emerged that meet less-flammable criteria. Although dry-type transformers are used quite widely, the insulating properties of "wet" designs are often superior.

The least expensive of the less flammable materials (those that have a fire point greater than 300°C and are self-extinguishing) are hydrocarbons such as Cooper Power System's R-Temp™ fluid. Most expensive are synthetic esters. In between in cost are silicones and natural esters (vegetable oils). ABB's Bio-Temp™ and Cooper Power Systems' Envirotemp™ (FR3) are two natural esters.

Voltage Regulation. Voltage regulation is the percent of voltage drop of a line relative to the receiving end voltage.

$$\text{Percent regulation} = \frac{100(|E_s| - |E_r|)}{|E_r|}$$

Where E_s is the sending end voltage and E_r is the receiving end voltage.

When a system load is relatively small compared with the capacity of the source (i.e., the on-site transformer kilovolt-amperes), the difference between the sending end voltage and the receiving end voltage is relatively small, and the percent of regulation is high. As load increases relative to the available transformation, the percentage regulation tends to fall off.

Oversizing a transformer beyond a reasonable limit, however, results in transformer losses that lead to inefficiencies. Sizing transformers too close to peak demand loads reduces transformer life and negatively impacts voltage regulation.

Other Considerations. Ordinary outdoor oil-filled pad-mounted transformers that serve an office building or factory are long-lived, have the lowest first cost, and operate quietly. In the rare instance of failure, they are easiest to obtain and replace. No hatchways in floors need to be removed, no walls chopped down; simply hire a crane. They are relatively mass-produced and are shipped most quickly.

An advantage of liquid-filled transformers is that oil (or silicone) keeps the insulating material soft, pliable, and in its original state. The liquid also dampens lamination noise, so that liquid transformers are quieter than the dry type.

Network transformers are often used on spot networks (see later). Network transformers are much more rugged, have a longer life, and a considerably higher ANSI damage point. On a true network system, they are quite desirable because they are reliable, can withstand overloads for greater periods of time, and are relatively maintenance-free.

Open Dry-Type Transformers. Typical types of nonliquid transformers are ventilated dry-type transformers or cast transformers that use Class B 80°C rise, Class F 115°C rise, or Class H 150°C rise insulation systems. Most dry-type, noncast transformers that are constructed today for unit substations are made of Class H materials suitable for a total temperature of 220°C. This is composed of 150°C rise, plus a 40°C maximum ambient (average temperature of 30°C over a 24-hour period), plus a 30°C hot spot allowance. The 30°C hot spot allowance allows for differences in temperature at various locations inside the windings, because of their uneven heating and cooling. Transformers can be specified with all Class H 220°C materials, but with an optional winding temperature rise of either 115°C or 80°C. This optional 115°C or 80°C rise will result in a larger core and coil assembly that has typically 115 and 135 percent continuous overload capability, respectively. These transformers with an optional 115°C or 80°C winding temperature rise typically have lower total losses and slightly higher no-load losses than standard 150°C rise units. Their *X/R* ratio (ratio of a transformer's reactance, *X*, reflected by its no-load losses to its resistance, *R*, reflected by its load losses) is slightly higher than standard units.

Previously, conventional ventilated dry-type Class H transformers utilized NOMEX™ paper and a dip-and-bake process. Due to the increasing demand for dry-type transformers in

moisture-laden or harsh service conditions and/or chemically polluted environments, vacuum pressure–impregnated (VPI) or vacuum pressure–encapsulated (VPE) transformers have become the standard of many manufacturers (Fig. 5.2.1-6).

VPI transformers are constructed with Class H 220°C materials and then are given additional environmental protection by vacuum pressure impregnation of polyester varnish suitable for a maximum of a 150°C rise. These VPI transformers have become the standard for normal applications indoors or outdoors.

VPE transformers are also constructed with Class H 220°C materials and then are given additional environmental protection by a vacuum pressure encapsulation of silicone resin suitable for a maximum of a 150°C rise. This premium VPE silicone insulation system is often specified for use in heavy moisture or outdoor locations and indoors in industrial locations, especially where harsh chemical atmospheres exist. In addition, the VPE silicone resin process is approved by the Navy for shipboard use and meets MIL-1-24092.

Both the VPI and the VPE insulation systems meet al ANSI, NEMA, and IEEE tests, including basic impulse level (BIL) tests before the environmental protection vacuum impregnation process. The VPI and VPE processes are not used for mechanical support. The glass polyester and silicone are compatible with the thermal expansion of copper and aluminum windings.

Dry-Type Design (Non-Liquid-Filled). Cast transformers can be supplied in full cast designs or partial cast designs (Fig. 5.2.1-7). The epoxy insulation systems are available for a 155°C total temperature rise and an optional maximum total temperature rise of 115°C, plus 40°C ambient, plus 30°C hot spot, which equals 185°C. Standard cast transformers would be specified with an 80°C rise and a 155°C total temperature insulation system. As an option, transformers can be specified with an 80°C rise and with the optional 185°C total temperature system, which would have a continuous overload capability of 17 percent. Another option would be to specify transformers with a 100°C rise and with the 185° total temperature system, which would have a continuous overload capacity of 6 percent. A transformer could also be specified with a 115°C rise and a system total temperature of 185°C that would not have

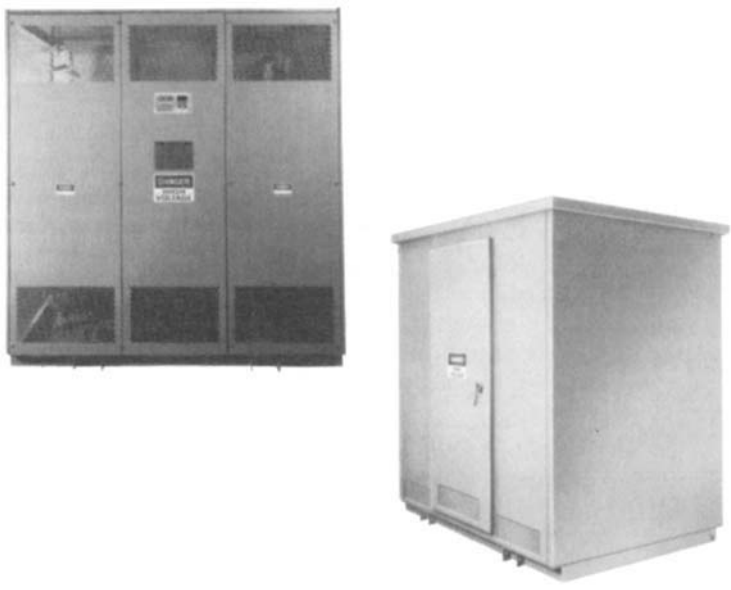

FIGURE 5.2.1-6 Typical dry-type transformer. (*Courtesy of Square D Company.*)

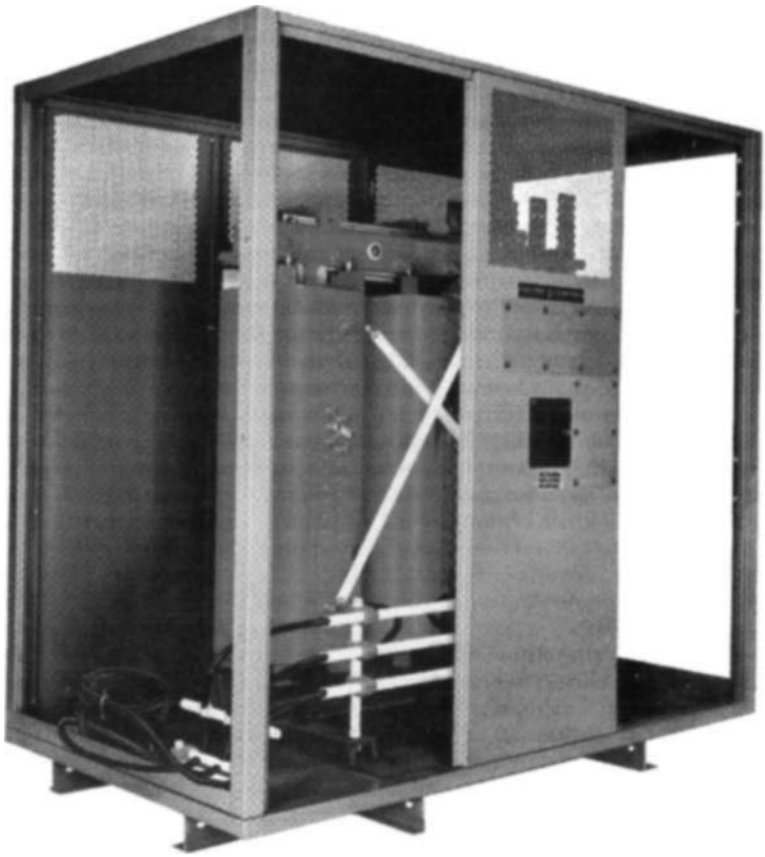

FIGURE 5.2.1-7 Typical cast-coil transformer. (*Courtesy of Square D Company.*)

any continuous overload capability. When fully loaded, it would be operating at the maximum allowed temperature rise.

Another alternative epoxy cast design dry-type transformer, known as Resibloc™, is available with a high-voltage winding reinforced with multidirectional glass fiber. This type of transformer offers lower first cost than full cast-coil transformers.

Because all cast transformer designs are of a solid epoxy cast material, they have greater inherent short-circuit strength than any other type of transformer. The cast must be uniform and without voids to prevent a corona from occurring. The dielectric quality of a solid cast transformer is related to the quality of the cast. When cast transformers are properly manufactured, they can be subjected to severe load cycles (cold start to maximum load) and exposed to harsh climates (freezing, heat, chemicals, and moisture).

Cast-coil designs originated in Europe where sheet-aluminum windings that withstand greater short-circuit stresses than copper were initially used. Others have used copper and a different low-voltage epoxy-casting method. Cast-coil transformers offer the high basic insulation level of liquid-filled transformers, but are free from liquid containment problems.

If transformers are idle for a period of time (e.g., medium-voltage transformers serving large chillers that are shut down during the winter months), the cast-coil type is often recommended to avoid the problem of moisture buildup in coils (from condensation or humid air)

that can cause serious damage to the windings when they are reenergized. The alternate to turning off the chiller transformers is to run them during the noncooling seasons at no load, which would waste energy.

General Discussion. The VPI, VPE, and cast transformers are highly resistant to humidity and are suitable for both indoor and outdoor service when located in an appropriate NEMA Type 3R enclosure. All information discussed previously is applicable from 0 to 3300 ft in altitude. Above 3300 ft, typically, a transformer's continuous kilovolt-ampere rating and, in some cases, its short-term overload rating must be derated. All three transformer types are resistant to most normal chemicals; in addition, VPE silicone and epoxy-cast transformers are resistant to caustic and very acidic chemicals. Of the three, VPI polyester is the lowest-cost transformer, VPE silicone is in the middle range, and cast transformers generally have a much higher first cost.

Other Considerations. This discussion of transformers divides secondary substation transformers (300 through 2500 kVA with 34.5 kV maximum primary voltage and 600 V and below secondary voltages) into two general categories:

1. *Liquid transformers.* Flammable mineral oil, less flammable liquid with 300°C flash point (silicone and hydrocarbon fluids), nonflammable liquids.
2. *Dry-type transformers.* Standard VPI polyester, premium VPE silicone, epoxy cast transformers

Transformer Initial Material Cost. The first cost of each type of transformer will vary significantly for a specific rating if nonstandard electrical ratings are specified, nonstandard physical dimensions are required, or special options are selected. Table 5.2.1-4 provides an approximate first-cost comparison of standard units built to ANSI standards, with a 15-kV class primary and 480Y/277-V secondary. Table 5.2.1-4 also indicates the standard temperature rise for each of these units. Besides the first cost for each unit, the table also indicates the relative costs of other types of transformers, compared with mineral oil transformers of the

same kVA, and the approximate cost per kVA for each unit. *Note:* The tables are based on standard typical BIL, sound levels, and 5.75 percent impedance (±7 percent tolerance). For these 15-kV primary transformers, the VPI and VPE transformers have a 60-kV BIL, and the cast and liquid transformers have a 95-kV BIL.

Direct and Indirect Transformer Installation Costs. Direct transformer installation costs vary, depending on the NEC and local code special requirements previously discussed. For example, typically, a flammable mineral oil transformer installed indoors requires a code-approved transformer vault. A vault can add 40 to 80 percent or more of the first cost of the transformer to the installation costs of mineral oil transformers. Less flammable fluid transformers, containing silicone and hydrocarbons, would require sprinkler systems and liquid confinement (curbing) adding approximately 20 to 40 percent or more of the first cost to the installation cost of these transformers. Dry-type transformers, on the other hand, do not have any of these extra installation costs (Table 5.2.1-4)

Indirect transformer installation costs include the labor to handle and install the transformers that vary with the weight and size of the transformer. Table 5.2.1-5 shows approximate dimensions, floor space in square feet, and the weights of the various types of standard designs. *Note:* The dimensions and weights can vary significantly from those shown if special electrical characteristics are specified or certain options are selected. For example, a standard 2000-kVA dry-type VPI or VPE transformer, designed with a 5-kV primary, a Class H insulation system, and a 150°C temperature rise, is 90 in high by 102 in wide by 66 in deep and weighs 9400 lb. The same transformer designed for an 80°C or 115°C rise is 102 in high by 112 in wide by 66 in deep and has an increased weight of 12,000 lb.

The area in square feet shown in Table 5.2.1-5, along with the addition of code-required clearances, has to be considered in relationship to building cost per square foot. In some cases, especially in modifications to existing facilities, existing openings, and elevator capacity could be evaluative criteria in transformer selection.

Operating Cost Considerations. Many specialized computer programs are available for transformer loss evaluations that can consider different utility rate structures, first costs as losses are varied, customer loading criteria, and economic evaluation of the customer's cost of money. This section considers only an abbreviated approximate method of loss valuation. Table 5.2.1-6 gives a relative comparison of standard approximate losses for the various types of transformers at different kilovolt-ampere ratings. The table is based on transformers that have 15-kV primaries and 480Y/277-V secondaries built to ANSI standards. Losses vary significantly, depending on types, grades, and quantities of materials utilized in the core and coil, and on manufacturing techniques for constructing the core and coil.

In addition, if special lower-than-standard temperature rises are specified (which normally result in higher first cost), no-load losses increase slightly and total losses decrease signifi-

Source: Courtesy of Cutler-Hammer.

cantly. Dry-type VPI and VPE transformers, designed with special higher-than-standard BIL to make them equivalent to liquid transformer BIL, have slightly higher no-load losses and slightly higher total losses. In most cases, it is more cost-effective to apply a special low spark-over distribution class surge arrester at the primary connections to the VPI or VPE transformer to obtain a BIL equivalent to that of liquid transformers.

Using some abbreviated formulas for cost analysis, the differences among the various types of transformers can be evaluated approximately. Following are the key formulas and a typical example:[11]

$$I^2R \text{ losses} = \text{total losses (TL)} - \text{no-load losses (NL)}$$

$$I^2R \text{ losses are proportional to the load factor squared } (L^2)$$

$$\text{load factor } (L) = \frac{\text{actual load (kVA)}}{\text{total rated load (kVA)}}$$

$$\text{operating losses} = \text{no-load losses} + I^2R \text{ loss at the appropriate } L$$

Thus, consider an example of a 1000- kVA transformer of the following three types: (1) liquid 65°C rise, (2) VPI dry-type transformer 150°C rise, and (3) cast dry-type 80°C rise, all under the following plant operating conditions:

- 5 days per week with one 8-hour shift
- Cost of electricity: $0.04 /kWH
- 800-kVA load during working hours and 100-kVA load at al other times

Thus, for working hours, L = 800 kVA/1000 kVA = 0.8. For nonworking hours, L = 100 kVA/1000 kVA = 0.1. Then, Table 5-2.1-7 can be derived by using the preceding formulas and the data of Table 5.2.1-6. Table 5.2.1-7 indicates the approximate yearly operating cost for the various units under the given conditions. Changing the loading factors, the amount of time the unit is loaded at the various load levels, and the cost of energy will change the relative analysis of savings. For this example, if we analyze first cost and operating loss expense between 65°C rise silicone liquid, 150°C rise dry-type VPI, and 80°C rise dry-type cast, we obtain the data shown in Table 5.2.1-8.

TABLE 5.2.1-7 Simplified Calculation for Loss Evaluation

Line Number	1000 kVA Transformer Description	Liquid 65°C Rise	Dry-Type VPI—150°C	Dry-Type Cast—80°C
1	Full load losses (W)	15,100	25,000	7,250
2	No-load losses (W)	1800	3400	4150
3	For $L = 1.0$ I^2R losses = (Line 1) − (Line 2) (W)	13,300	21,600	3100
4	For $L = 0.8$ I^2R losses = (Line 3) × 0.64	8512	13,824	1984
5	For $L = 0.8$ Total losses = (Line 2) + (Line 4)	10,312	17,224	6134
6	For $L = 0.1$ I^2R losses = (Line 3) × 0.01	133	216	31
7	For $L = 0.1$ Total losses = (Line 2) + (Line 6)	1933	3616	4181
8	Cost of losses for working hours = (Line 5)/1000 × 52 wk × 5 days/wk × 8 h/day × $0.04/kWh	$858	$1433	$510
9	Cost of losses for nonworking hours = (Line 7)/1000 × 52 wk × 128 h/wk × $0.04/kwhr	$515	$963	$1113
10	Total yearly operating costs = (Line 8) + (Line 9)	$1373	$2396	$1623

Source: Courtesy of Cutler-Hammer.

In this example, with the given first cost, load factor, and losses, if the liquid-filed transformer is located outdoors as part of a unit substation, it is the least expensive. Liquid confinement and spill control procedures would have to be considered in the evaluation. For indoor applications, the difference in the yearly operating costs between the VPI and the cast unit is $773.00/year, and the first-cost difference is $26,000.00. Based on this, it would take more than 33 years to pay back the additional cost of the cast unit.

Besides the specific facility requirements, a financial analysis (refer to Chap. 2) should be performed. The heat (BTUs) generated by the transformer, which varies directly in relationship to the total losses at a given load, must be considered. This heat and the possible cost of removing it must be considered for indoor applications (number of watt-hours of losses × 3.143 = number of BTUs).

Maintenance. The availability and cost of experienced qualified maintenance personnel within the owner's organization or the cost of purchasing outside maintenance services must be considered. Most dry-type transformers normally require very little maintenance other than cleaning accumulated dust and dirt from the core-and-coil assembly and any exposed bushings or bus work. In addition, bus bar joints should be checked for tightness. Most liquid-type transformers can be furnished with liquid level gauges, winding temperature gauges, and pressure vacuum gauges, which should be inspected periodically (normally once a month during the first year and once a year thereafter) to ensure that proper liquid level, temperature,

TABLE 5.2.1-8 First Cost and Operating Cost for 1000-kVA Example

Cost	Liquid Oil—65°C	Dry-Type VPI—150°C	Dry-Type Cast—80°C
First cost	$15,000	$20,000	$46,000
Yearly operating cost (losses)	$1373	$2396	$1623

Source: Courtesy of Cutler-Hammer.

and pressure are being maintained. Readings should be recorded at each inspection and saved for future comparison. Refer to Art. 7.2.3, "Electrical Testing and Maintenance," for a brief discussion of these issues and to Chap. 11 of the *Facility Manager's Operation and Maintenance Handbook* for a more comprehensive discussion.

Lower-Than-Standard Temperature Rise. Transformers can be specified with lower-than-standard temperature rises for a first-cost price increase. The lower temperature rise generally results in higher-than-standard no-load losses but significantly lower total losses. A lower temperature rise increases the size of the core and coil and therefore generally increases the outside dimensions and weight.

For example, a standard dry-type transformer using an insulation system composed of all Class H materials suitable for a 150°C temperature rise, 40°C ambient, and a 30°C hot spot for a 220°C total temperature system, could be specified with an optional 80°C rise. For a 1000-kVA transformer (VPI), the price would increase (see Table 5.2.1-4) approximately 20 percent from $20,000.00 to $24,000.00. The losses could be expected to decrease from the 150°C rise value of 3400 W no-load and 25,000 W total load to the 80°C rise losses of 4200 W no-load and 13,500 W total load (see Table 5.2.1-6). The size and weight would probably increase to the dimensions and weight of a standard 1500-kVA transformer.

In summary, consideration of the operating loss cost savings for a particular application (based on expected loading conditions versus the increased first cost and size), along with cost of capital, most be considered when deciding which type of unit to use. Refer to Sec. 2.7, "Financial Analysis," for further guidance.

Basic Impulse Level (BIL). If system requirements dictate the need to increase standard indoor dry-type VPI and VPE transformers to equivalent liquid or cast transformer BILs, this normally results in a price increase of approximately 10 to 15 percent over the standard unit base price for primaries rated 15 kV and below. In most cases, the addition of distribution or intermediate-class surge arresters to achieve a comparable overall BIL is more economical. When dry-type transformers are part of outdoor unit substations, station class arresters should be considered because of their higher surge current rating and lower spark-over values. When the transformer BIL is increased, normally the size and weight also increase, and both no-load and total losses increase slightly.

Sound Level. Per the NEMA standards, liquid-type transformers are about 5 to 6 dB quieter than comparable dry-type transformers. Both liquid and dry-type transformers can be built to operate more quietly than these NEMA standards. The approximate cost of reducing the sound level is 2 to 4 percent of the transformer price for every decibel below the NEMA standard in the range of 3 to 4 dB below standard. A sound level lower than 5 dB below NEMA standard requires much special design and increases costs. Adding fan cooling generally raises the sound level 3 to 7 dB above the self-cooled 60 to 68 dB rating of dry-type transformers and up to approximately 67 dB on all liquid ratings from a standard level of 56 to 63 dB for liquid-filed transformers.

These criteria should include consideration of NEC requirements regarding location and flammability, first cost, losses in relationship to operating load profile, and maintenance. Special transformer design requirements, temperature rise, BIL, sound level, impedance, and options such as fan cooling, must also be evaluated in terms of the cost and capital expenditure budget. This article discusses some of these considerations and points out that most of these factors are interrelated. Once specific project criteria are established, the manufacturer should be consulted for specific transformer technical data, sizes, and cost estimates.

Secondary Unit Substations. A secondary unit substation is a close-coupled assembly that consists of enclosed primary high-voltage equipment, three-phase power transformers, and enclosed secondary low-voltage equipment. By locating power transformers and their close-coupled secondary switchboards as close as possible to the areas of load concentration, the secondary distribution cables or busways are kept to minimum lengths. This concept has obvious advantages such as reduced power loss, improved voltage regulation, improved service continuity, reduced exposure to low-voltage faults, increased flexibility, minimum installed cost, and efficient space utilization (Fig. 5.2.1-8).

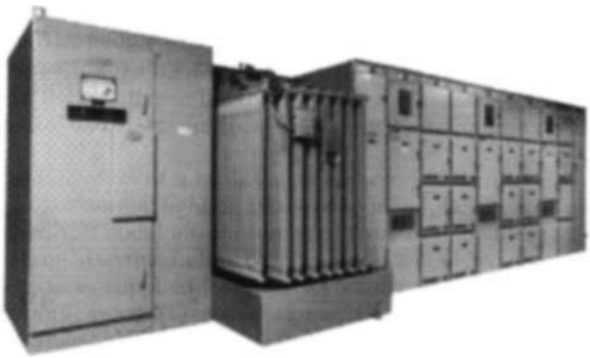

FIGURE 5.2.1-8 Secondary unit substation with primary switch, transformer, and switchgear. (*Courtesy of Cutler-Hammer.*)

The incoming line section provides for connection of the incoming primary circuit or circuits and may have line selector switches, disconnect switches, fuses, or (rarely) circuit breakers. The switching equipment required depends on whether the primary distribution system is radial, primary selective, or primary loop. Circuit breakers can be relayed more exactly than fuses to provide better transformer protection and more coordination with both upstream primary protective devices and secondary overcurrent protection, but fused switches are considerably less expensive. Occasionally, oil switches or oil-fused cutouts are used for primary disconnects. If the overcurrent protection and disconnecting means are at the supply side of the feeder, the substation incoming section may be simply an air chamber for cable connection.

The substation transformer can be almost any type of dry, liquid-cooled, or gas-filled unit. Sizes usually range from about 300 to 2500 kVA, although larger and smaller substations are available. The ventilated dry-type transformer is cabled or bussed to the primary disconnect and usually bussed to the secondary distribution equipment. Liquid-cooled transformers must have a throat connection between the transformer tank and the primary and secondary gear. Gas-filled transformers have primary and secondary bushings brought out of the sealed enclosure.

Transition sections are sometimes required between the transformer and the primary and secondary equipment to provide room to make the cable or bus connection between the transformer buses or bushings and the primary section output or the secondary section buses. It is important to isolate transformer vibration from the primary and secondary structures to keep noise levels down. This requires cable or flexible braids in primary and secondary connections and vibration-absorbing gaskets between transformer enclosures or tank throats and incoming and outgoing section structures. In addition, dry transformer core and coils must be vibration-isolated from their housings.

The secondary distribution section of a unit substation is essentially a low-voltage switchgear or switchboard, close-coupled to the transformer. This section can consist of fixed or draw-out air or molded-case circuit breakers, fusible switches, or a combination of several types of equipment.

Unitized Dry-Type Power Centers. Unitized dry-type power centers are self-contained, metal-enclosed unit substations especially designed to supply and distribute low-voltage power from medium-voltage lines in modern commercial and industrial systems (Fig. 5.2.1-9). They are ideal when equipment size, accessibility, maintainability, ease of installation, and overall economy are uppermost. Because unitized power centers are inherently compact, they are easily and conveniently applied in multiple throughout a distribution system at locations close to centers of load concentration. Thus, the distribution voltage is stepped down to

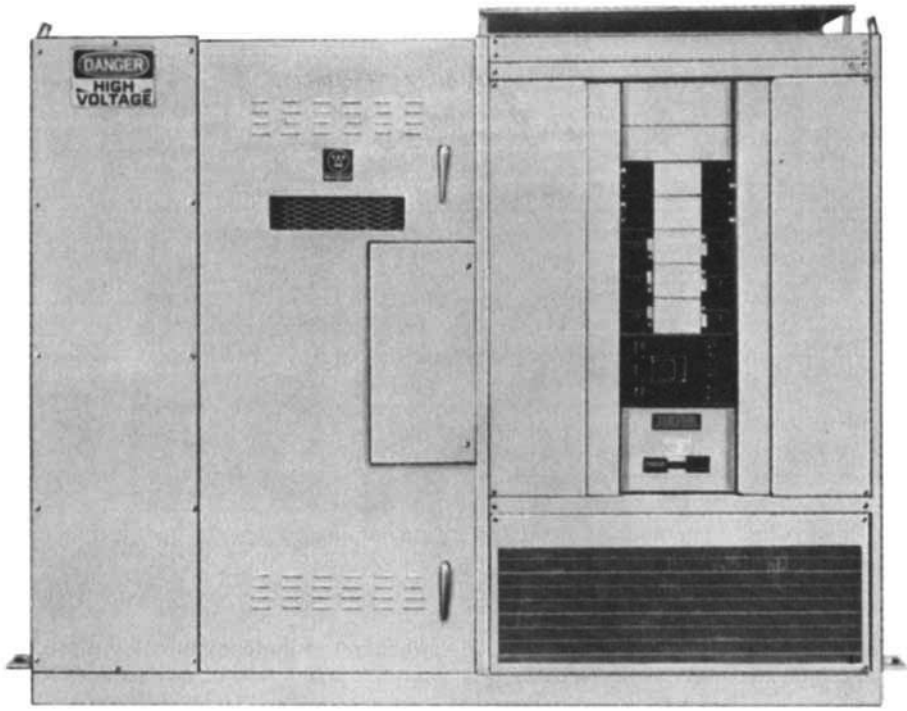

FIGURE 5.2.1-9 Unitized dry-type power center. (*Courtesy of Cutler-Hammer.*)

the utilization voltage only at or near the areas of demand, and kilovolt-amperes are allocated as required for new construction or renovation in existing buildings. Applying unitized power centers in this manner results in several advantages not available with conventional secondary unit substations. Future load growth is easily accommodated by adding unitized power centers to the system without affecting the units that serve the original load areas.

Each unitized power center is completely assembled and tested as a unit at the factory and arrives at the job site in one shipping unit. Rigging (moving) into place is facilitated by the rugged channel base construction and lifting eyes included with each assembly. Field installation consists merely of connecting the incoming and outgoing cables after rolling or lifting the unitized power center into place. All standard unitized power centers are especially designed to minimum dimensions consistent with safety and reliability. Standard unitized power centers that are accessible from the front make against-the-wall installations possible.

Lower losses in the medium-voltage portion of the distribution system result in continuous operating cost savings. Secondary output voltage may be adjusted at each unitized power center to compensate for unusual load conditions without affecting the voltage setting of other apparatuses in the system. Trouble is more quickly isolated with individual units located at or near their served loads. Primary power purchased from the utility at the lower primary power rates results in operational cost savings throughout the life of the equipment. Overall installed cost is lower because of the cost benefits of medium-voltage distribution cable compared with low-voltage cable. The apparent negative cost effect of multiple small unit substations versus a large unit substation is more than offset by the relatively low cost of secondary overcurrent devices that may be applied to each unitized power center.

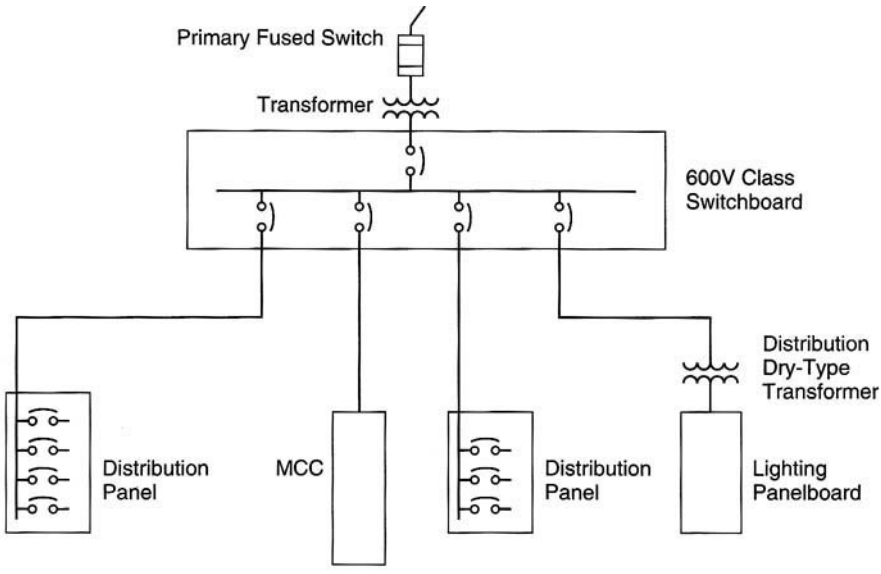
Simple Radial System

The most basic system for providing service to a facility is called *simple radial.* Service from the utility company enters underground (or overhead) at the utility's distribution voltage and meets utility- (or customer-) owned switch(es) and step-down transformer(s) to achieve the facility's utilization voltage (Fig. 5.2.1-10*a*).

Components. When the customer receives its supply of power from the primary system and owns the primary switch(es) and transformer(es) along with the secondary low-voltage switchboard or switchgear, the equipment may be a separate primary switch, a separate transformer, and a separate low-voltage switchgear or switchboard. Alternatively, this equipment may be combined as an outdoor pad-mounted transformer with an internal primary fused switch and secondary main breaker feeding an indoor switchboard. Another alternative is a secondary unit substation where the primary fused switch, transformer, and secondary switchgear and switchboard are designed and installed as a close-coupled secondary assembly.

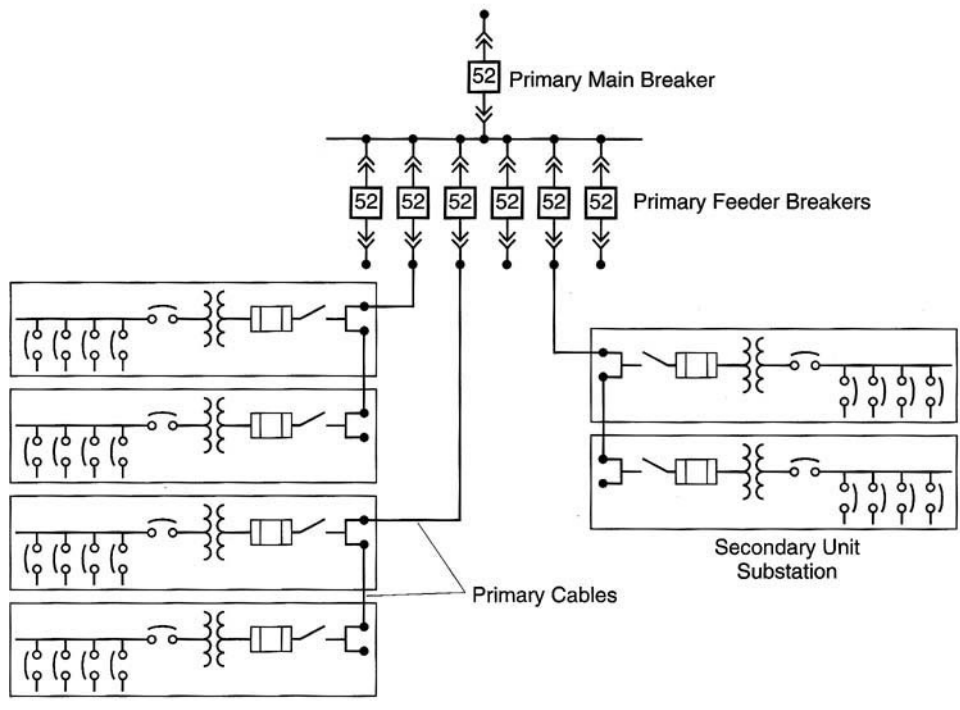
When the utility owns the primary equipment and transformer, the power is supplied to the customer at the utilization voltage, and then the service equipment becomes low-voltage main distribution switchgear or a switchboard.

A modern, improved form of the conventional simple radial system distributes power at a primary voltage. The voltage is stepped down to utilization level in the several load areas within the building, typically through secondary unit substation transformers. The transformers are usually connected to their associated load bus through a circuit breaker, as shown in Fig. 5.2.1-10*b.* Each secondary unit substation is an assembled unit that consists of a three-phase, liquid-filled or air-cooled transformer, an integrally connected primary fused switch, and low-voltage switchgear or a switchboard with circuit breakers or fused switches. Circuits are run to the loads from these low-voltage protective devices.



Discussion of Merits. The simple radial system is the simplest and least costly system, it is easy to coordinate, and it has no idle parts.

Ownership. If the utility company is willing to provide the transformer for the step-down to utilization voltage, the primary switch and transformer(s) usually are outdoors, pole-mounted or pad-mounted, and utility company–owned. The customer must furnish the primary underground duct bank, as well as the transformer pad, constructed in accordance with utility company standards. Primary conductors to the transformer are generally furnished and installed by the utility. Secondary conductors (and duct bank) are supplied by the customer. Metering, which requires current transformers (CTs), is provided by the utility in a CT-and-meter enclosure provided by the customer, or remotely at the transformer pad or building exterior. The CTs, as well as the meter itself, are furnished and installed by the utility company. These divisions of responsibility are the more common, but the local utility's rules must be reviewed closely for every facility.



If space is available for an indoor primary switch and transformer or a secondary unit substation, this equipment can be owner-furnished, with provisions for metering in the secondary switchgear or switchboard.

Cost. The initial investment in service equipment is lowest when the utility company provides the primary switch and transformation to utilization voltage. This would be the preferred arrangement if in-house maintenance capability were limited to utilization voltage experience. At a somewhat higher initial cost, but with no utility company leasing costs for the equipment they otherwise would provide, would be a secondary unit substation. Purchased as a closely coupled assembly, a secondary unit substation reduces the cost of interconnecting cabling, bus duct runs, and so forth.

Because the entire load is served from a single source, full advantage can be taken of the diversity among the loads. This makes it possible to minimize the installed transformer capacity and, hence, the overall cost.

(a)

(b)

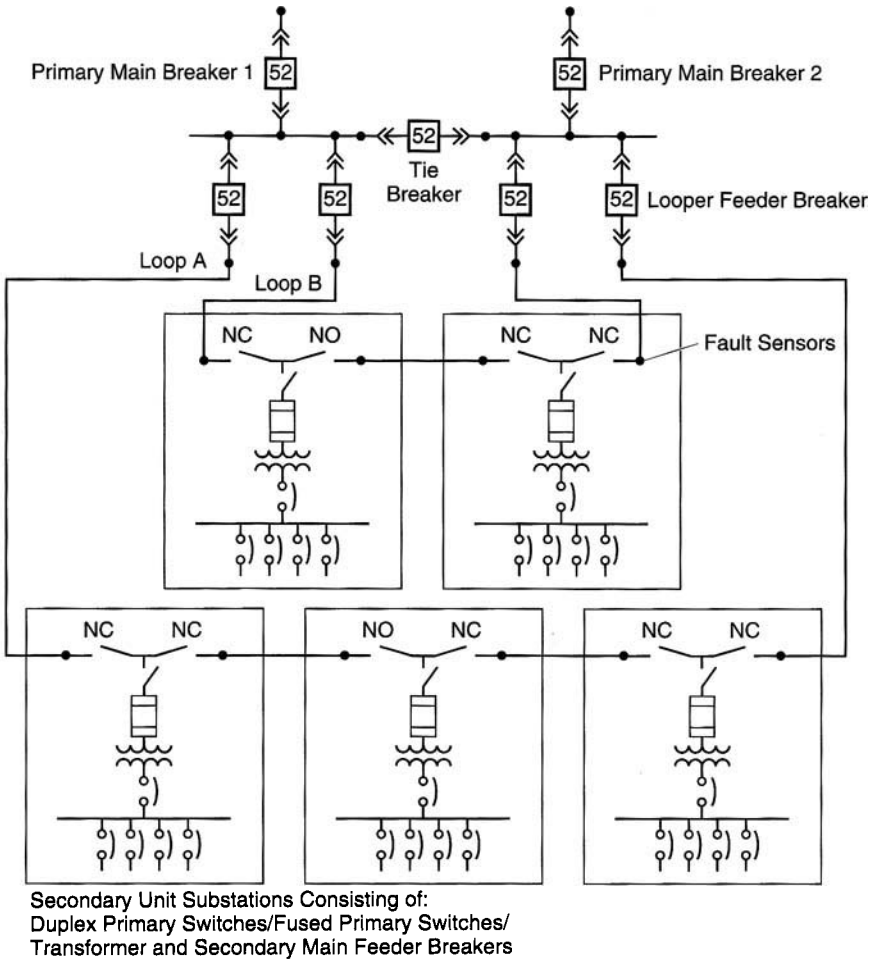
FIGURE 5.2.1-10 (*a*) Simple radial system. (*b*) Primary and secondary simple radial system. (*Courtesy of Cutler-Hammer.*)

This modern form of the simple radial system is usually lower in initial investment than most other types of primary distribution systems for buildings in which the peak load is above 1000 kVA.

Depending on the load kilovolt-amperes connected to each primary circuit and if no ground-fault protection is desired for either the primary feeder conductors and transformers or for the main bus, the primary main and/or feeder breakers may be changed to primary fused switches. This significantly reduces the first cost but also decreases the level of conductor and equipment protection. Thus, if a fault or overload condition occurs, downtime could increase significantly, and a higher cost of increased damage levels and the need for use replacement are typically encountered. In addition, if only one primary fuse on a circuit blows, the secondary loads could be single-phased, causing damage to low-voltage motors.

Another approach to reducing costs is to eliminate the primary feeder breakers completely and use just a single primary main breaker or fused switch to protect a single primary feeder circuit and supply all secondary unit substations from this circuit. Although this system would result in less initial equipment cost, system reliability would be reduced drastically because a single fault in any part of the primary conductor would cause an outage of all loads within the facility.

The costs of the low-voltage feeder circuits and their associated circuit breakers are high when the feeders are long and the peak demand is above 1000 kVA.



Reliability. One limitation of the simple radial system is that there is no redundancy. Continuity of service depends upon the integrity of the one utility feeder, upon the operability of the primary switch, and upon the durability of a single service transformer. Fortunately, these components are usually quite dependable, provided that they are properly serviced and maintained. A fault on the secondary low-voltage bus or in the source transformer will interrupt service to all loads. Service cannot be restored until all of the necessary repairs have been made. A low-voltage feeder circuit fault will interrupt service to all loads supplied over that feeder.

The improved form of the conventional simple radial system described earlier (Fig. 5.2.1-10*b*) distributes power at a primary voltage, and voltage is stepped down to the utilization level in each of the building's load areas. In this improved form, a fault on a primary feeder circuit or in one transformer will cause an outage to only those secondary loads served by that feeder or transformer. When a primary main bus fault or a utility service outage occurs, service is interrupted to all loads until the trouble is eliminated. Reducing the number of transformers per primary feeder by adding more primary feeder circuits will improve the flexibility and service continuity of this system; the ultimate is one secondary unit substation per primary feeder circuit. This, of course, increases the investment in the system but minimizes the extent of an outage resulting from a transformer or primary feeder fault.

Voltage Regulation. The voltage regulation and efficiency of the system portrayed in Fig. 5.2.1-10*a* may be poor because of the low-voltage feeders and single source. Because power is distributed to the load areas at a primary voltage in the Fig. 5.2.1-10*b* scheme, losses are reduced, voltage regulation is improved, feeder circuit costs are reduced substantially, and large low-voltage feeder circuit breakers are eliminated. In many cases, the interrupting duty imposed on the load circuit breakers is reduced.

Loop Primary System—Radial Secondary System

Description. This system consists of one or more primary loops with two or more transformers connected on the loop. This system is typically most effective when two services are available from the utility, as shown in Fig. 5.2.1-11*a*. Each primary loop is operated so that one of the loop-sectionalizing switches is kept open to prevent parallel operation of the sources.

(a)

FIGURE 5.2.1-11 (*a*) Loop primary-radial secondary system. (*Courtesy of Cutler-Hammer.*)

When secondary unit substations are used, each transformer has its own duplex (two load-break switches with load-side bus connection) sectionalizing switches and primary load-break fused switch, as shown in Fig. 5.2.1-11*b*. When pad-mounted compartmentalized transformers are used, they are furnished with loop-feed, oil-immersed, gang-operated, load-break sectionalizing switches and draw-out current-limiting fuses in dry wells, as shown in Fig. 5.2.1-11*c*. By operating the appropriate sectionalizing switches, it is possible to disconnect any section of the loop conductors from the rest of the system. In addition, by opening the transformer primary switch (or removing the load-break draw-out fuses in the pad-mounted transformer), it is possible to disconnect any transformer from the loop.

A key-interlocking scheme is normally recommended to prevent closing all sectionalizing devices in the loop. Each primary loop-sectionalizing switch and the feeder breakers to the loop are interlocked so that they require a key to be closed (which is held captive until the

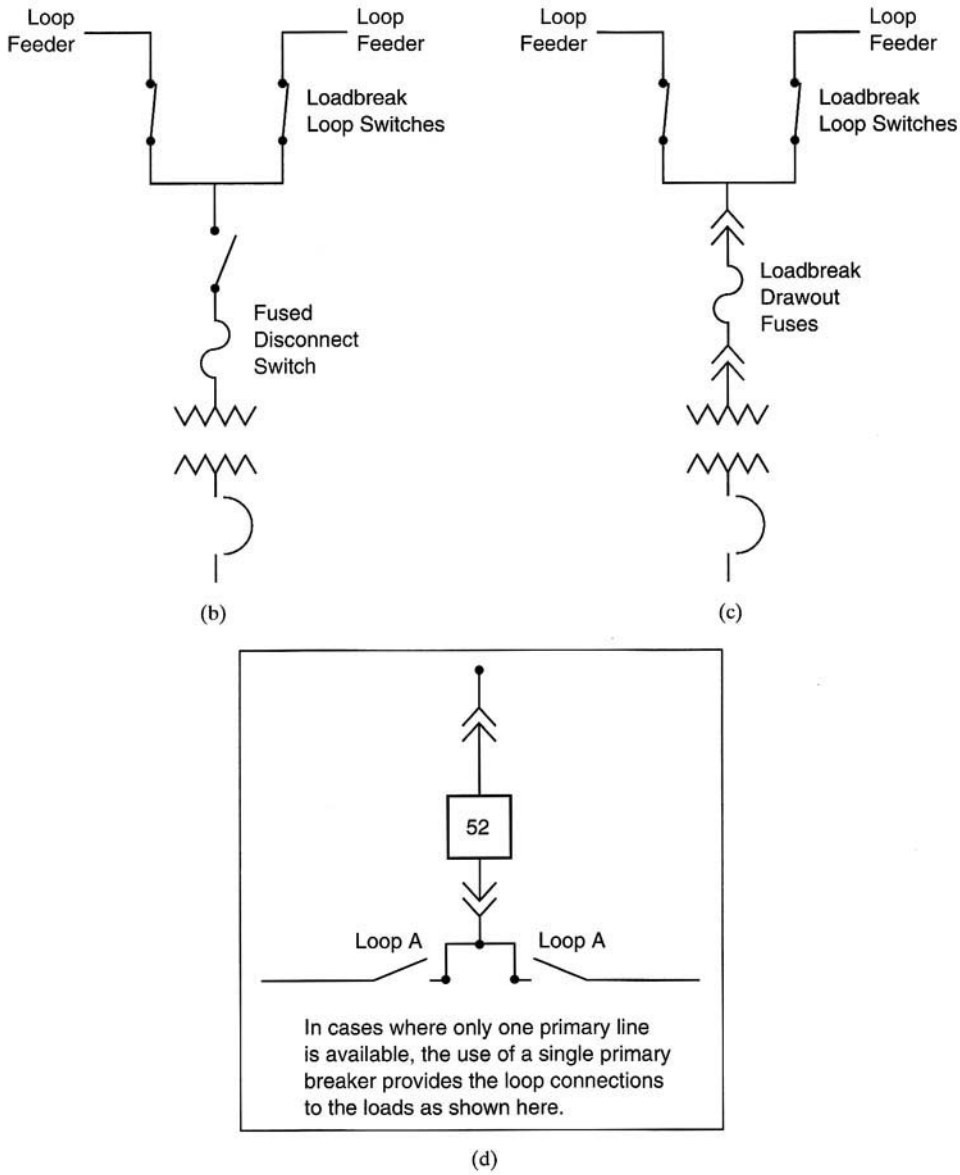


FIGURE 5.2.1-11 (*Continued*) (*b*) Secondary unit substation loop switching. (*c*) Pad-mounted transformer loop switching. (*d*) Single primary feeder loop system. (*Courtesy of Cutler-Hammer.*)

switch or breaker is opened), and one less key than the number of key interlock cylinders is furnished. An extra key is provided to defeat the interlock under qualified supervision. In addition, the two primary main breakers, which are normally closed, and the primary tie breaker, which is normally open, are either mechanically or electrically interlocked to prevent paralleling the incoming source lines. For slightly added cost, an automatic transfer (throw-over) scheme can be added between the two main breakers and the tie breaker. During the

more common event of a single utility line outage, the automatic transfer scheme provides significantly reduced power outage time.

The system shown in Fig. 5.2.1-11*a* costs more than that shown in Fig. 5.2.1-10*a* but offers increased reliability and quick restoration of service when (1) a utility outage occurs, (2) a primary feeder conductor fault occurs, or (3) a transformer fault or overload occurs. If a utility outage occurs on one of the incoming lines, the associated primary main breaker can be opened, and then the tie breaker is closed manually or through an automatic transfer scheme.

When a primary feeder conductor fault occurs, the associated loop feeder breaker opens and interrupts service to all loads up to the normally open primary loop load switch (typically half of the loads). Once the faulted section of primary cable has been found, then the loop-sectionalizing switches on each side of the faulted conductor can be opened. Then, the loop-sectionalizing switch, which had been previously left open, is closed, and service is restored to all secondary unit substations while the faulted conductor is replaced. If the fault occurs in the conductor directly on the load side of the one of the loop feeder breakers, the loop feeder breaker is kept open after tripping, and the next load-side loop-sectionalizing switch is manually opened, so that the faulted conductor can be sectionalized and replaced. Under this condition, all secondary unit substations are supplied through the other loop feeder circuit breaker, and thus all conductors around the loop should be sized to carry the entire load connected to the loop. Increasing the number of primary loops (two loops shown in Fig. 5.2.1-11*a*) reduces the extent of the outage from a conductor fault but also increases the system investment.

When a transformer fault or overload occurs, the transformer primary fuses blow (open), and then the transformer primary switch has to be manually opened, disconnecting the transformer from the loop and leaving all other secondary unit substation loads unaffected. A basic primary loop system that uses a single primary feeder breaker connected directly to two loop feeder switches that in turn feed the loop is shown in Fig. 5.2.1-11*d*. In this basic system, the loop may be normally operated with one of the loop-sectionalizing switches open, as described before, or with all loop-sectionalizing switches closed. If a fault occurs in the basic primary loop system, the single loop feeder breaker trips, and secondary loads are lost until the faulted conductor is found and eliminated from the loop by opening the appropriate loop-sectionalizing switches and then reclosing the breaker.

Primary Selective-Secondary Radial System

Description. The primary selective-secondary radial system, shown in Fig. 5.2.1-12*a*, differs from those described previously in that it employs at least two primary feeder circuits in each load area. It is designed so that when one primary circuit is out of service, the remaining feeder or feeders have sufficient capacity to carry the total load. Half of the transformers are normally connected to each of the two feeders. When a fault occurs on one of the primary feeders, only half of the load in the building is dropped.

Duplex fused switches, shown in Fig. 5.2.1-12*a* and detailed in Fig. 5.2.1-12*b*, are normally chosen for this type of system. Each duplex fused switch consists of two, load-break, three-pole switches, each in its own separate structure, connected together by bus bars on the load side. Typically, the load-break switch closest to the transformer includes a fuse assembly with fuses. Mechanical and/or key interlocking is furnished so that both switches cannot be closed at the same time (to prevent parallel operation) and are interlocked so that access to either switch or fuse assembly cannot be obtained unless both switches are opened.

As an alternative to the duplex switch arrangement, a non-load-break selector switch mechanically interlocked with a load-break fused switch can be used, as shown in Fig. 5.2.1-12*c*. The non-load-break selector switch is located at the rear of the load-break fused switch, thus requiring only one structure, and it reduces the cost and floor space compared with the duplex arrangement. The non-load-break switch is mechanically interlocked to prevent it

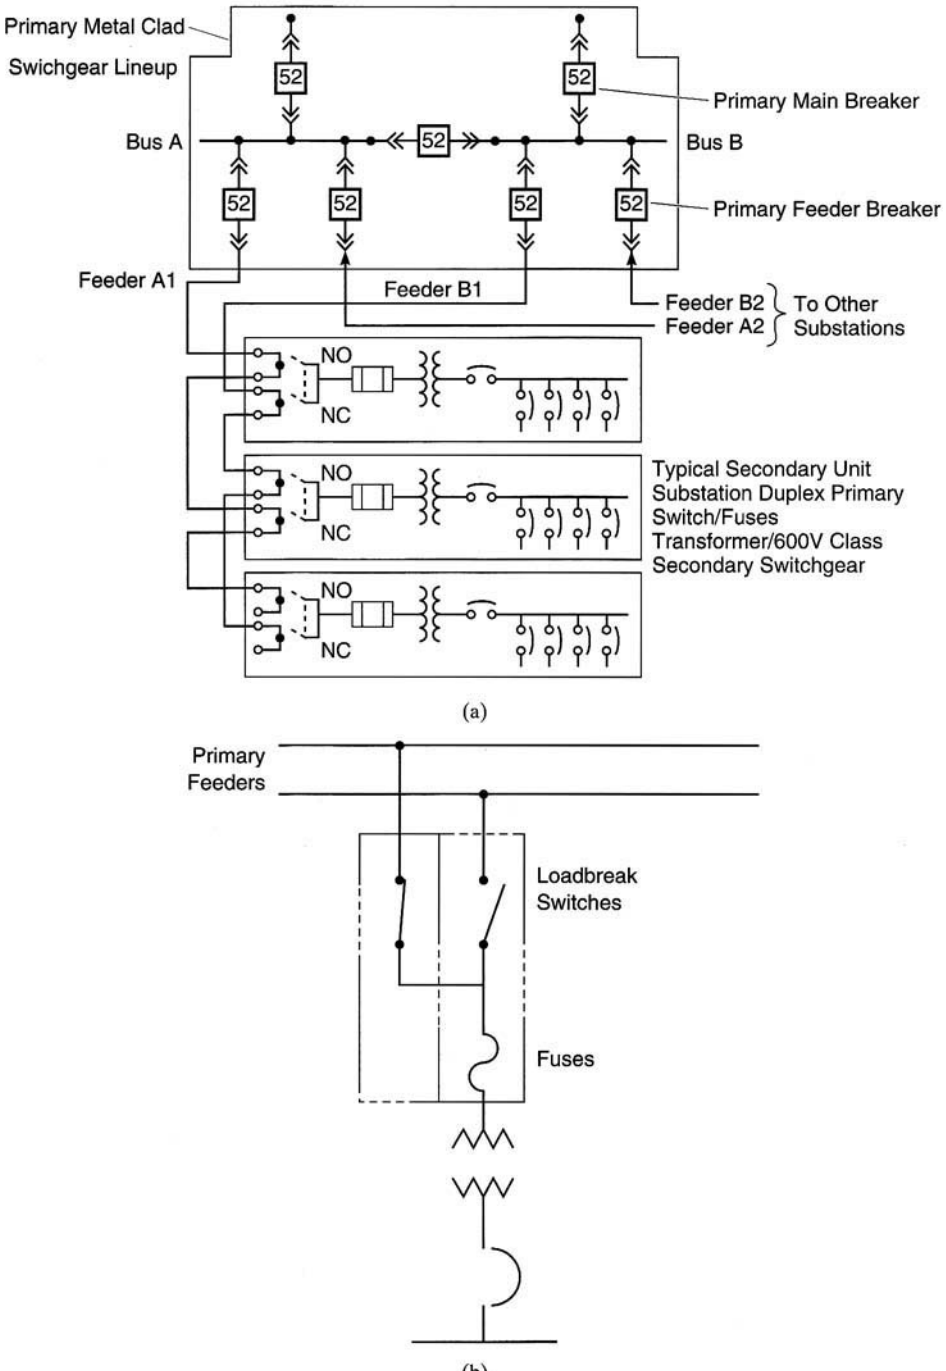

FIGURE 5.2.1-12 (*a*) Primary selective-secondary radial system. (*b*) Duplex fused switch in two structures. (*Courtesy of Cutler-Hammer.*)

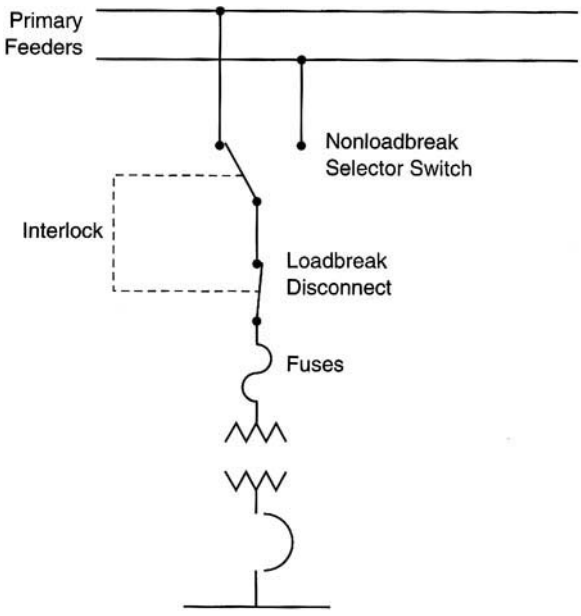

FIGURE 5.2.1-12 (*Continued*) (*c*) Fused selector switch in one structure. (*Courtesy of Cutler-Hammer.*)

from operating unless the load-break switch is opened. The main disadvantage of the selector switch is that conductors from both circuits are terminated in the same structure. This limits cable space, especially if double lugs are furnished for each line, as shown in Fig. 5.2.1-12*a* and if a faulted primary conductor has to be changed, both lines would have to be deenergized to change the faulted conductors safely.

In Fig. 5.2.1-12*a,* when a primary feeder fault occurs, the associated feeder breaker opens, and the transformers normally supplied from the faulted feeder are out of service. Each primary switch connected to the faulted line must be opened manually, and then the alternate-line primary switch can be closed, connecting the transformer to the live feeder and thus restoring service to all loads. Each of the primary circuit conductors for Feeder A1 and B1 must be sized to handle the sum of the loads normally connected to both A1 and B1. Similar sizing of Feeders A2 and B2, and so on, is required.

If a fault occurs in one transformer, the primary fuses blow and interrupt the service only to the load served by that transformer. Service cannot be restored to the loads normally served by the faulted transformer until the transformer is repaired or replaced.

The cost of the primary selective-secondary radial system is greater than that of the simple primary radial system, shown in Fig. 5.2.1-10*a,* because of the additional primary main breakers, the tie breaker, the two sources, the increased number of feeder breakers, the primary-duplex or selector switches, and the greater amount of primary feeder cable required. The benefits derived from reducing the amount of load dropped when a primary feeder is faulted, plus the quick restoration of service to all or most of the loads, may more than offset the greater cost. Having two sources allows for either manual or automatic transfer of the two primary main breakers and the tie breaker, if one of the sources becomes unavailable.

The primary selective-secondary radial system, however, may be less costly or more costly than the primary loop-secondary radial system of Fig. 5.2.1-11*a,* depending on the location of

the transformers, although it offers comparable downtime and reliability. The cost of conductors for the two types of systems may vary greatly, depending on the location of the transformers and loads within the facility, and may greatly override the differences between the two systems in the costs of the primary switching equipment.

Two-Source Primary, Secondary Selective System

Description. This system uses the same principle of duplicate sources from the power supply point using two, primary main breakers and a primary tie breaker. The two primary main breakers and the primary tie breaker are either manually or electrically interlocked to prevent closing all three at the same time and paralleling the sources. Upon loss of voltage from one source, a manual or automatic transfer to the alternate source line may be used to restore power to all primary loads.

Each transformer secondary is arranged in a typical double-ended unit substation, as shown in Fig. 5.2.1-13. Again, the two secondary main breakers and the secondary tie breaker of each unit substation are either mechanically or electrically interlocked to prevent parallel operation. Upon loss of the secondary source voltage on one side, manual or automatic transfer may be used to transfer the loads to the other side, thus restoring power to all secondary loads.

This arrangement permits quick restoration of service to all loads when a primary feeder or transformer fault occurs by opening the associated secondary main and closing the secondary tie breaker. If the secondary voltage is lost because of primary feeder fault and the associated

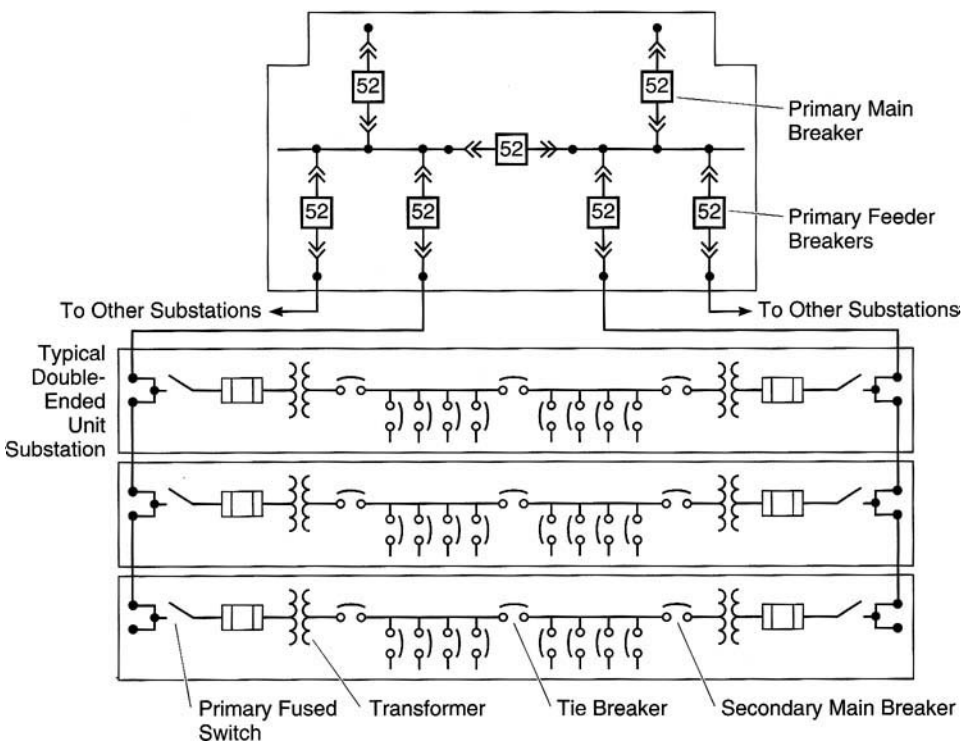

FIGURE 5.2.1-13 Two-source primary, secondary selective system. (*Courtesy of Cutler-Hammer.*)

primary feeder breaker has opened, then all secondary loads normally served by the faulted feeder have to be transferred to the opposite primary feeder. Therefore, each primary feeder conductor must be sized to carry the load on both sides of all of the secondary buses that it serves under secondary emergency transfer. If the voltage is lost because one of the transformers in the double-ended unit substation has failed, then the associated primary fuses blow and take only the failed transformer out of service. Then, only the secondary loads normally served by the faulted transformer have to be transferred to the opposite transformer.

In either of these emergency conditions, the in-service transformer of a double-ended unit substation must be able to serve the loads on both sides of the tie breaker. For this reason, transformers used in this application have equal kilovolt-ampere ratings on each side of the double-ended unit substation, and the normal operating maximum load on each transformer is typically about two-thirds of the base nameplate kilovolt-ampere rating. Typically, these transformers are furnished with fan cooling and/or a lower-than-normal temperature rise, so that under emergency conditions they can carry the maximum load continuously on both sides of the secondary tie breaker. Because of this spare transformer capacity, the voltage regulation that is provided by the double-ended unit substation system under normal conditions is better than that of the systems previously discussed.

The double-ended unit substation arrangement can be used in conjunction with any of the systems discussed that involve two primary sources. Although not recommended, if allowed by the utility, momentary retransfer of loads to the restored source may be made closed transition (antiparallel interlock schemes would have to be defeated) for either the primary or secondary systems. Under this condition, all interrupting equipment and momentary ratings should be suitable for the fault current available from both sources. Special consideration should be given to transformer neutral grounding and equipment operation for double-ended unit substations equipped with ground-fault systems. Where two single-ended unit substations are connected together by external tie conductors, a tie breaker is recommended at each end of the tie conductors.

Simple Spot Network Systems

Description. The secondary network system usually in the form of utility grids has been used for many years to distribute electric power in the high-density downtown area of cities. Modifications of this type of system make it applicable to loads within buildings.

The major advantage of the secondary network system is continuity of service. No single fault anywhere on the primary system interrupts service to any of the system's loads. Most faults are cleared without interrupting service to any load. Another outstanding advantage of the network system is its flexibility in meeting changing and growing load conditions at minimum cost and minimum interruption in service to other loads on the network. In addition to flexibility and service reliability, the secondary network system provides exceptionally uniform and good voltage regulation, and its high efficiency materially reduces the costs of system losses. The major disadvantages of the secondary network system are the relatively high levels of fault current that can be generated and the higher cost of distribution equipment necessitated by this system.

Three major differences between the network system and the simple radial system account for the outstanding advantages of the network. First, a network protector is connected to the secondary leads of each network transformer in place of, or in addition to, the secondary main breaker, as shown in Fig. 5.2.1-14. Second, the secondary windings of the transformers in a given location (spot) are connected together by a switchgear or ring bus from which the loads are served over short radial feeder circuits. Third, when any one primary feeder is out of service, the primary supply has sufficient capacity to carry the entire building load without overloading.

A network protector is a specially designed heavy-duty air-powered breaker, spring-closed with an electrical motor-charged mechanism or motor-operated mechanism, and has a net-

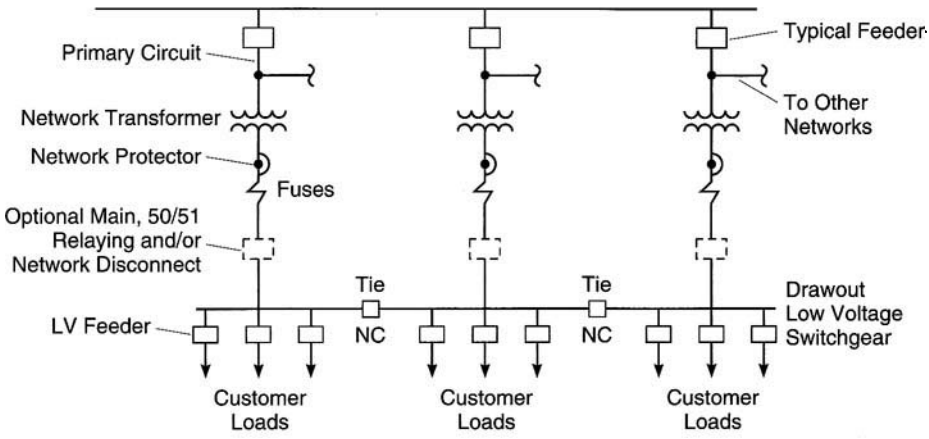

FIGURE 5.2.1-14 Three-source spot network. (*Courtesy of Cutler-Hammer.*)

work relay to control the status of the protector (tripped or closed). The network relay is usually a solid-state microprocessor-based component that is integrated into the protector enclosure. It closes the protector automatically only when the voltage-conditions are such that its associated transformer will supply power to the secondary network loads and opens the protector automatically when the power flows from the secondary to the network transformer. The purpose of the network protector is to protect the integrity of the network bus voltage and the loads served from it against transformer and primary feeder faults by quickly disconnecting the defective feeder-transformer pair from the network when backfeed occurs.

The simple spot network system resembles the secondary-selective radial system in that each load area is supplied over two or more primary feeders through two or more transformers. In network systems, the transformers are connected through network protectors to a common bus from which loads are served, as shown in Fig. 5.2.1-14. Because the transformers are connected in parallel, a primary feeder or transformer fault does not cause any service interruption to the loads. The paralleled transformers that supply each load bus normally carry equal load currents, whereas it is difficult to obtain equal loading of the two separate transformers that supply a substation in the secondary-selective radial system. The interrupting duty imposed on the outgoing feeder breakers in the network is greater with the spot network system because of fault contributions through more than one transformer.

The optimum size and number of primary feeders can be used in the spot network system because the loss of any primary feeder and its associated transformer does not result in the loss of any load, even for an instant. Despite the spare capacity usually supplied in network systems, the costs of primary switchgear and secondary switchgear are often lower compared with a radial system with similar spare capacity. This occurs in many radial systems because more and smaller feeders are often used to minimize the extent of any outage when a primary fault occurs.

When a fault occurs on a primary feeder or in a transformer in a spot network, the fault is isolated from the system through automatic tripping of the primary feeder circuit breaker and all of the network protectors associated with that feeder circuit. This operation does not interrupt service to any loads. After the necessary repairs have been made, the system can be restored to normal by closing the primary feeder breaker. All network protectors associated with that feeder close automatically.

The chief purpose of the normally closed ties of the network bus is to provide for sharing of loads and balancing of load currents for each primary service and transformer, regardless of the condition of the primary services. The ties also provide a means of isolating and sec-

tionalizing ground faults within the switchgear network bus, thereby saving a portion of the loads from service interruptions, yet isolating the faulted portion for corrective action.

Spot network systems provide users with several important advantages. First, they save transformer capacity. Spot networks permit equal loading of transformers under all conditions. Networks also have lower system losses and greatly improve voltage conditions. The voltage regulation of a network system is such that both lights and power can be fed from the same load bus. Much larger motors can be started across the line than in a simple radial system. This can result in simplified motor control and permits using relatively large low-voltage motors that have less expensive controls. Finally, network systems provide a greater degree of flexibility in adding future loads; they can be connected to the closest spot network bus.

Spot network systems are economical for buildings that have heavy concentrations of loads covering small areas, considerable distance between areas, and light loads within the distances that separate the concentrated loads. They are commonly used in hospitals, high-rise office buildings, and institutional buildings where a high degree of service reliability is required from the utility sources. Cogeneration equipment is not recommended for use in networks unless the protectors are manually opened and the utility source is completely disconnected and isolated from the temporary generator sources. Spot network systems are especially economical where three or more primary feeders are available, principally, because they supply each load bus through three or more transformers and less spare cable and transformer capacity are required. They are also economical compared with two-transformer double-ended substations with normally opened tie breakers.

Medium-Voltage Distribution System

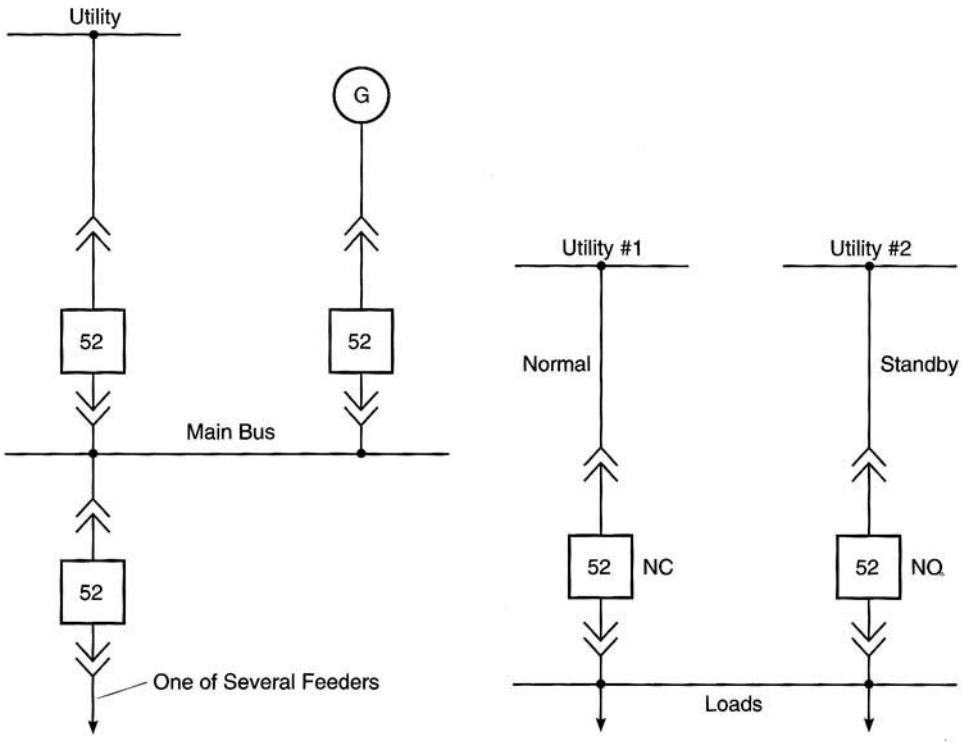
Single-Bus System. Figure 5.2.1-15*a* illustrates a single-bus system. The sources [utility and/or generators(s)] are connected to a single bus. All feeders are connected to the same bus. Generators are used where cogeneration is employed. This configuration is the simplest system; however, outage of the utility results in total outage.

Normally, the generator does not have adequate capacity for the entire load. A properly relayed system equipped with load shedding and automatic voltage and frequency control may be able to maintain partial system operation. Note that the addition of breakers to the bus requires shutting down the bus.

Single Bus with Two Sources from the Utility. Figure 5.2.1-15*b* illustrates a single-bus system that has two utility sources. It is the same as the single bus, except that two utility sources are available. This system is operated normally with the main breaker to one source open. Upon loss of the normal service, transfer to the standby normally open (NO) breaker can be automatic or manual. Automatic transfer is preferred to restore service rapidly, especially in unattended stations.

Retransfer to the normal can be closed transition, subject to the approval of the utility. Closed transition momentarily (5–10 cycles) parallels both utility sources. *Caution:* When both sources are paralleled, the fault current available on the load side of the main device is the sum of the available fault current from each source, plus the motor fault contribution. It is recommended that the short-circuit ratings of the bus, feeder breakers, and all load-side equipment are rated for the increased available fault current. If the utility requires open transfer, the disconnection of motors from the bus must be ensured by suitable time delay on reclosing, as well as supervision of the bus voltage and its phase with respect to the incoming source voltage.

This busing scheme does not preclude the use of cogeneration but requires sophisticated automatic synchronizing and synchronism-checking controls, in addition to the previously mentioned load shedding, automatic frequency, and voltage controls. When paralleling sources, reverse current, reverse power, and other appropriate relaying protection should be added as requested by the utility.



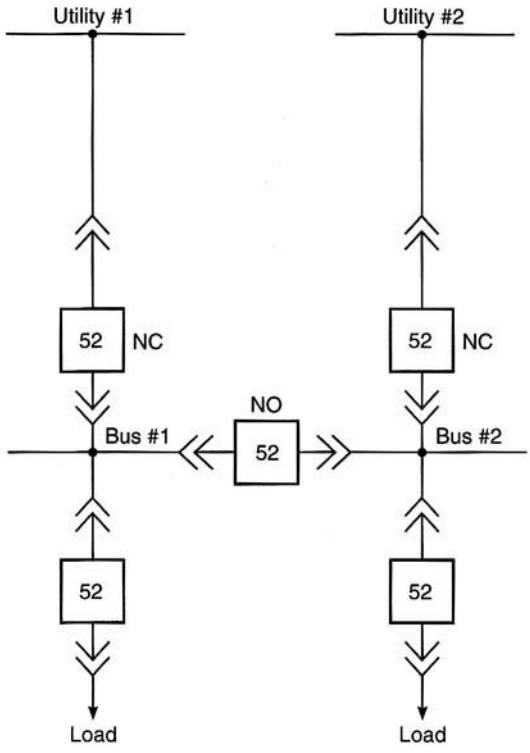


FIGURE 5.2.1-15 (*a*) Single bus. (*b*) Single bus with two sources. (*Courtesy of Cutler-Hammer.*)

This scheme is more expensive than the scheme shown in Fig. 5.2.1-15*a*, but service is restored more quickly. Again, a utility outage results in total outage to the load until transfer occurs. Extending the bus or adding breakers requires shutting down the bus.

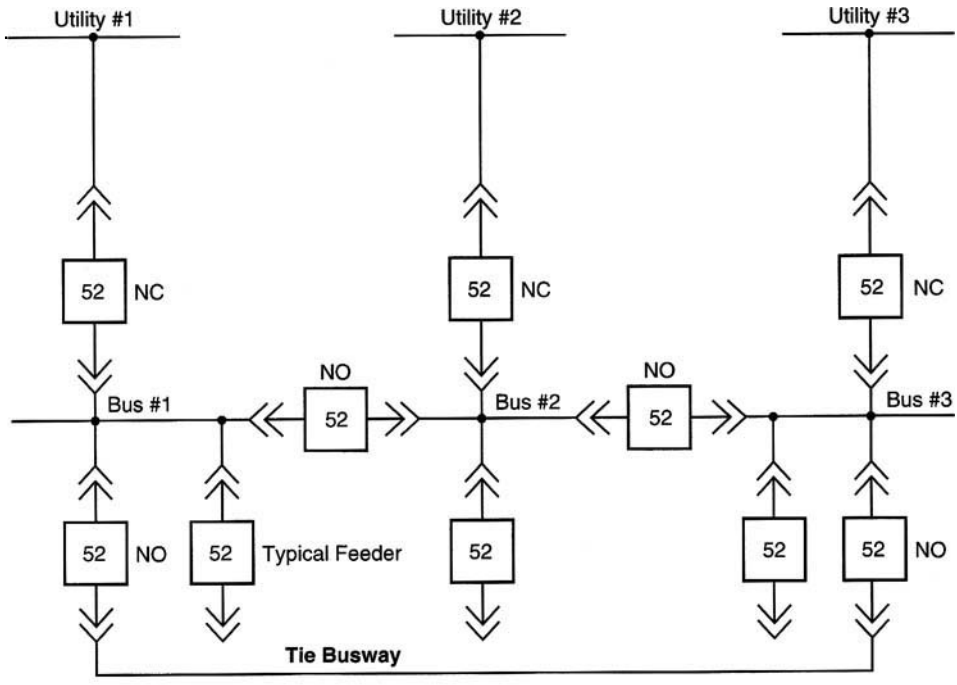
Multiple Sources with Tie Breaker(s). In Fig. 5.2.1-15*c*, the scheme shown is basically the same as in *b*, but the tie breaker is added. The outage to a system load for a utility outage is limited to half the system. Again, the tie breaker can be closed manually or automatically. The statements made for the retransfer of Fig. 5.2.1-15*b* apply also to this scheme. This system is more expensive than the one in Fig. 5.2.1-15*b*. The system is not limited only to two buses (see Fig. 5.2.1-15*d*). Another advantage is that if the buses are momentarily in parallel, no increase in the interrupting capacity of the circuit breakers is required as other buses are added, provided that only two buses are paralleled momentarily for switching. If a looped or primary selective distribution system for the loads is used, the buses can be extended without a shutdown by closing the tie breaker and transferring the loads to the other bus. The tie breaker can be closed manually or automatically after a main breaker is opened. However, because a bus can be fed through two tie breakers, the control scheme should be designed to make the selection.

Continuous Paralleling of Sources. If continuous paralleling of multiple sources is planned, reverse current, reverse power, and other appropriate relaying protection should be added. When both sources are paralleled, the fault current available on the load side of the main device is the sum of the available fault current from each source, plus the motor fault contri-

(c)

FIGURE 5.2.1-15 (*Continued*) (*c*) Two-source utility with tie breaker. (*Courtesy of Cutler-Hammer.*)

bution. Bus bracing, feeder breakers, and all load-side equipment are required to be rated for the increased available fault current.



Summary. The medium-voltage schemes described are based on using MC, medium-voltage, draw-out switchgear. The service continuity required from electrical systems makes single-source systems impractical.

In designing modern medium-voltage systems, the system should

- Be as simple as possible
- Limit an outage to as small a portion of the system as possible
- Provide means for expanding the system without major shutdowns
- Operate relays so that only the faulted part is removed from service and damage to it is minimized consistent with selectivity
- Apply all of its equipment within published ratings and meet national standards pertaining to the equipment and its installation.

System Selection

Where secondary service is delivered, most buildings will use simple radial distribution from the service. The utility will supply the load in various ways, ranging from a single pad-

(d)

FIGURE 5.2.1-15 (*Continued*) (*d*) Triple-ended arrangement. (*Courtesy of Cutler-Hammer.*)

mounted transformer, several transformers for a multibuilding installation, or spot networks for a high-rise office building.

Where the service is at primary voltage, the distribution can be from a single substation for smaller installations or from primary distribution to multiple load-center unit substations for larger systems. Primary distribution can be radial or have multiple feeders or one or more loops to single-ended or double-ended substations. Secondary distribution can be radial, loop, secondary-selective, or even secondary network. Any of the primary and secondary distribution methods described previously may be used. The choice will depend on the continuity of service required and the cost of the system. Generally, those systems that provide higher service reliability also cost more, and the initial and operating costs must be weighed against the cost of downtime. In industrial installations, especially in the process industries, the cost of an outage can be tremendous, and distribution systems with maximum reliability flexibility and redundant equipment can easily be justified.

There has been a large increase in high-rise buildings in recent years. This type of building has very large loads and often high available short-circuit fault currents. In most cases, the electric utility company serves these buildings at a secondary voltage of 480Y/277 V from one or more spot networks.

One example would be a typical block-square 60-story office building in New York City. The utility would have one spot network in a utility vault under the sidewalk that supplies services in the basement and another in a specially constructed fireproof utility vault on the 40th floor of the building that supplies additional services to reduce the length of secondary feeder runs. Each vault might have six 2500-kVA network transformers that supply four 4000-A, 480/277-V service takeoffs. The fault current at each service would be nearly 200,000 A. Many lower high-rise office buildings are served by a utility network system at 480/277 V and have a secondary radial distribution system within the building.

Large Vertical Buildings. A spot network system is particularly applicable to large vertical buildings such as office buildings, stores, apartments, hospitals, and hotels because it is often the most economical method of providing service reliability and good voltage characteristics (i.e., voltage regulation).

Large Horizontal Buildings. Large horizontal buildings such as shopping centers can use a number of different systems. Size and building configuration are the determining factors. Although somewhat dated, Table 5.2.1-9, obtained from Westinghouse Electric Corporation's *Power Distribution System Design,* dated December 1966, compares the relative merits of systems for several types of shopping centers.[11]

The ratings take into account initial investment, service continuity, flexibility to handle new or changing loads, operation and maintenance costs, voltage regulation, and efficiency. Each of these factors has been weighted in proportion to its relative importance for each load magnitude and type of shopping center. The "A" ratings indicate that analysis of the system rates it as the top of the 12 systems compared in each column. The other quality ratings are given in terms of a percentage of value of the "A" system: B: 81 to 90 percent; C: 71 to 80 percent; D: 61 to 70 percent; E: 51 to 60 percent; and F: 41 to 50 percent.

Groups of Small Buildings. The form of distribution system for a group of small buildings and the type of equipment in the distribution system depend on the number and sizes of the buildings, the spacing between them, the power requirements of the individual buildings, and the degree of continuity of service required.

The simple radial system is often used to serve groups of relatively small buildings such as the buildings on a university campus.

The likelihood of a primary feeder fault should be considered in designing the distribution system. A fault in an underground cable circuit usually requires several hours to locate and repair. Such a fault puts the feeder circuit out of service for a considerable period of time. Therefore, it becomes important to provide means of restoring service to the buildings within a reasonably short time after a primary feeder fault. This possibility is provided by the primary selective-radial secondary system.

The small additional cost of the extra primary feeder circuit and the selector switches is usually well justified for groups of smaller buildings. Although this system does not eliminate extended outages due to transformer failures, such failures are relatively rare compared with feeder failures, especially where primary feeder circuits are long.

The duration of an outage caused by a primary feeder fault is also reduced by using a secondary selective system. In addition, this type of system prevents a prolonged outage when a transformer failure occurs.

Industrial Plants. The variation in magnitude and characteristics of loads among industrial plants of the same size is greater than the variation among other types of buildings of the same size. Within a given industrial plant, the addition of new loads and the relocation of existing loads are more frequent than in other types of buildings. These factors indicate that estimating both initial and probable future load is more critical in determining the best system for an industrial plant than in system design for other types of buildings.

A careful comparison of the characteristics of the distribution systems described and identified by designations 1 through 7A in Tables 5.2.1-10 and 5.2.1-11 was made before the publication of these tables in Westinghouse's Specification Data 470 in December 1966 for industrial plant applications. The results are given in Tables 5.2.1-10 and 5.2.1-11 (formerly Tables IV and V in the original publication). Letters in the tables indicate the relative standing or grading as in the preceding discussion of large horizontal buildings.

Based on the general comparison of isolated characteristics given in Table 5.2.1-11, it is possible to assign weighting factors to six major system characteristics and determine the best system for any particular plant. To find the relative merit of the various distribution systems for the usual, or normal, plant, the following weighting factors were assigned to the six system

TABLE 5.2.1-9 Comparison of Distribution Systems for Several Types of Shopping Centers

characteristics: flexibility, 3; service continuity, 2; regulation, 1; efficiency, 1; operation and maintenance, 1; and initial investment, 6.

The results of this calculation are given in the first column of Table 5.2.1-11. It is recognized that there may be no such thing as a *normal* industrial plant. The term is used here to mean a plant whose load characteristics and requirements are closest to those of the majority of industrial plants. Eight of the 12 systems are about equally applicable in a normal plant. Actually, the loop primary-radial secondary system and the primary selective network system are somewhat better than the other systems that have a C grade. This is indicated by the grade C+, which equals 79 or 80 percent.

The load characteristics and requirements of most plants will depart somewhat from the so-called normal, and the weighting factors can be changed to fit the individual plant. The weighting factors used will depend upon the characteristics and requirements of the loads in the plant; however, they will seldom differ widely from those given for a normal plant, except possibly to increase the importance of one of the characteristics.

TABLE 5.2.1-11 Relative Merit of Characteristics, Where Characteristics Are Rated as Isolated Elements

Types of Systems	Flexibility	Service Continuity	Regulation	Efficiency	Operation and Maintenance Cost	Initial Investment

7A Primary-selective spot-network	C	A	B	A	D	D

Source: Courtesy of Westinghouse Electric Corporation.

From Table 5.2.1-11, each characteristic was taken in turn and considered of primary importance. Its weighting was increased until two of the systems emerged that are better than the others. Thus, the relative merits of the various systems applied to other than normal plants are given in Table 5.2.1-10.

For example, if flexibility is of greater importance in the plant than in an average plant, under *flexibility* in Table 5.2.1-11 it will be seen that either the banked secondary radial system or the primary selective network system should be used. The third best system for the plant would be the simple network system. Table 5.2.1-10 makes it possible to narrow the number of systems under consideration from 12 to 2 or 3, at most. Consideration of the second, and possibly third, most important characteristics usually makes it possible to eliminate all but the best system for the plant.

This comparison of systems on the basis of their major characteristics, together with the proper weighting of the characteristics, is helpful in selecting the best distribution for a plant without making a number of different system design and cost comparisons. This is possible because the comparisons given are based on a large number of such designs and studies.

ARTICLE 5.2.2
ELECTRICAL DISTRIBUTION SYSTEMS

Jack W. Dean, P.E., Electrical Department Head
Novare Engineers, Inc., Providence, Rhode Island

The type of electrical power distribution chosen for a facility can have a major impact on the overall usage of energy, on the ease or difficulty in expanding or modifying the existing plant, and on the general reliability of power throughout the facility. Article 5.2.1, "Service Entrances," discusses the elements required to get electricity to the service entrance and to the main distribution equipment. It also discusses the options for distribution system configurations that best meet the needs of the facility. This article discusses the elements involved in the distribution of that electricity and the relative merits of each element.

Certain common elements are required for distributing electricity once it is available at the service entrance. Among these elements are voltage, main service equipment, means of distribution, supplemental equipment, maintenance considerations, system reliability, and space requirements.

The rated voltage of an electrical distribution system varies as one moves downstream from the service entrance (the point at which electricity entering a facility is first controlled). Voltage changes are a function of several items, among them the size of the facility, the type of facility, and the availability of electricity from the serving utility. For any facility, a discussion of voltage must consider service voltage, distribution voltage, and utilization voltage.

Service voltage is the voltage of the electricity delivered to the facility by the serving utility or the generating source. It is the voltage fed to the service entrance equipment or equipment that constitutes the main control and means of cutting off the supply of electricity. For primary metered power, the voltage may be several thousand volts (i.e., 13,800 or 4160 V, etc.) because utility companies transmit power from their power plants at elevated voltages to min-

imize line energy losses and other expenses. The voltage is transformed at the user site (by a transformer) to a lower voltage by the owner in primary metered services or by the utility company for secondary metered services. In the case of primary metered power, the service voltage is transformed by the owner to distribution voltage, usually in the range of 277/480-V, three-phase, four-wire or, for small facilities, possibly 120/208-V, three-phase, four-wire service. In the case of secondary metered service, the voltage is transformed by the serving utility to the distribution voltage previously mentioned. For secondary metered (referring to the secondary or low-voltage side of the transformer) services, the service voltage and distribution voltage may be the same.

Distribution voltage is the voltage that a facility deems suitable for distributing electricity throughout the plant or building(s). For long distances, it is more efficient and cost-effective to distribute at a higher voltage and then transform to utilization voltage, if necessary, where the energy is needed. For example, in an office or on the factory floor, convenience receptacles require 120-V power for most plug-in equipment. Distribution at 277/480 V to the vicinity and transformation via small transformer(s) near the point of use to the utilization voltage of 120/208 V is often desirable.

Utilization voltage is the operating voltage that equipment in a plant requires. There often is more than one utilization voltage, depending on the equipment to be powered, and for that reason, the distribution voltage and the voltage required for a particular piece of equipment (utilization voltage) may be the same (i.e., 480 V).

The most prevalent secondary distribution voltage in American commercial and institutional buildings today is 480Y/277 V with a solidly grounded neutral. It is also a very common secondary voltage in industrial plants and even in some high-rise, centrally air-conditioned and electrically heated residential buildings because of the large electrical loads. Until the early 1950s, most commercial buildings, such as offices and stores, used 208Y/120-V distribution. About 1950, several simultaneous developments brought about changes. First, central air conditioning became standard practice, more than doubling the previous loads for similar non-air-conditioned buildings. Second, lighting levels were increased, and fluorescent lighting replaced most of the incandescent lighting. Third, the development of 277-V ballasts and 277-V wall switches made it possible to serve this fluorescent lighting load from a 480Y/277-V system. Finally, economical, mass-produced dry-type 480- to 208Y/120-V transformers became readily available to step down the voltage for 120-V incandescent lighting and receptacle loads.

With the increase in building electrical loads and their ability to serve air-conditioning and other motor loads at 480 V and increased lighting loads at 277 V, 480Y/277-V systems have become the most economical for distribution. This voltage allows smaller feeders or larger loads on each feeder and fewer branch circuits because powering loads at a higher voltage allows a corresponding reduction in the load current. In addition, the problem of excessive voltage drops from large loads on 208-V systems is greatly reduced with 480-V distribution. In very tall high-rise office buildings, it is nearly impossible and can be prohibitively expensive to use 208-V distribution and keep voltage drops within acceptable limits.

The choice between 208Y/120- and 480Y/277-V secondary distribution for commercial and institutional buildings depends on several factors. The most important of these are the sizes and types of loads (motors, fluorescent, or high-intensity discharge lighting, incandescent lighting, receptacles) and the lengths of feeders. In general, large motor and fluorescent or high-intensity discharge lighting loads and long feeders tend to make the higher voltages, such as 480Y/277-V, more economical. Very large loads and long runs tend to use medium-voltage distribution (4160 or 13,800 V) and make load center unit substations close to the loads more economical. Conversely, small loads, short runs, and a high percentage of incandescent lighting and receptacle loads tend to make lower utilization voltages such as 208Y/120 V more economical.

Industrial installations that have large motor loads are usually rated for 480- or 4160-V systems. These systems are often ungrounded delta, resistance-grounded delta, or wye systems. Because most commercial low-voltage distribution equipment is rated for up to 600 V and

conductors are insulated for 600 V, the installation of 480-V systems uses the same techniques and is essentially no more difficult, costly, or hazardous than for 208-V systems. The major difference is that an arc (also called a *fault* or *short circuit*) of 120 V to ground tends to be self-extinguishing, whereas an arc of 277 V to ground (also called a *ground fault*) is self-sustaining and is likely to cause severe damage. For this reason, the National Electrical Code (NEC) requires ground-fault protection of equipment on grounded wye services of more than 150 V to ground but not exceeding 600 V phase-to-phase (for practical purposes, 480Y/277-V services) for any service-disconnecting means rated at 1000 A or more. The NEC permits voltage up to 300 V to ground on circuits that supply permanently installed electric discharge lamp fixtures, provided that the luminaires (fixtures plus lamps) do not have integral manual switches and are mounted at least 8 ft above the floor. This permits a three-phase, four-wire, solidly grounded 480Y/277-V system to supply directly all of the fluorescent and high-intensity discharge (HID) lighting at 277 V as well as motors at 480 V. Refer to Section 5.3, "Lighting Systems," for a further discussion of these and other issues concerning light source selection.

The principal advantage of using higher secondary voltages in buildings is that for a given load, they use less current and thus require smaller conductors and have lower voltage drops. Also, when compared with a 208-V system, a given conductor size on a 480-V system can supply a large load at the same voltage drop in volts, but a lower percentage voltage drop because of the higher supply voltage. Fewer or smaller circuits can be used to transmit the power from the service entrance point to the final distribution points. Smaller conductors can be used in many branch circuits that supply power loads, and a reduction in the number of lighting branch circuits is usually possible.

It is easier to keep voltage drops within acceptable limits on 480-V circuits than on 208-V circuits. When a 480-V system supplies 120-V loads through step-down transformers, using primary tap adjustments on the transformer can compensate for a voltage drop in the 480-V supply conductors, resulting in full 120-V output. Because these transformers are usually located close to the 120-V loads, secondary voltage drop should not be a problem. If it is a problem, primary taps may be used to compensate by raising the secondary voltage at the transformer, as previously stated.

The principal loads in most buildings can use equipment rated for either 480- or 208-V systems. Three-phase motors and their controls can be obtained for either voltage and are less costly for a given horsepower at 480 V. Fluorescent and HID lamps can be used with either 277- or 120-V ballasts (refer to Art. 5.3.3, "Light Sources, Luminaires"). However, in almost all cases, the installed equipment will have a lower total cost at the higher voltage. The break-even point for these decisions can be determined, if necessary, although many facility designers do not go through detailed cost analyses for each facility.[1]

Incandescent lighting, small fractional-horsepower motors, wall receptacles, and plug-and-cord-connected appliances for receptacle loads require a 120-V supply. With a 480Y/277-V service, it is necessary to supply these loads through step-down transformers. If the 120-V load to be served is high, this can influence the choice of supply voltage or the relative cost of 480- and 208-V systems. Therefore, in addition to the obvious benefits of using more efficient light sources (refer to Art. 5.3.5, "Design Practices, Lighting Calculations & Economics"), it is also often economically advantageous to minimize the amount of 120-V load by using as little incandescent lighting as possible.

The higher secondary voltage system is usually more economical in office buildings, shopping centers, schools, hospitals, and similar commercial and institutional installations, as well as in industrial plants.

Grounding

Equipment grounding is essential to the safety of personnel. Its function is to ensure that all exposed non-current-carrying metallic parts of all structures and equipment in or near the electrical distribution system are at the same electric potential, and that this is the zero refer-

ence potential of the earth. Refer to Art. 5.2.6, "Grounding Systems," for a detailed discussion of this topic. Both the NEC (NEC Article 250)[2] and the National Electrical Safety Code[3] require grounding. Equipment grounding also provides a return path for ground-fault currents, permitting protective devices to operate. Accidental contact of an energized conductor of the system with an improperly grounded non-current-carrying metallic part of the system (such as a motor frame or panelboard enclosure) would raise the potential of the metal object above ground potential. Any person who comes in contact with such an object while grounded could be seriously injured or killed. In addition, current flow from the accidental grounding of an energized part of the system could generate sufficient heat (often with arcing) to start a fire. Two things must occur to prevent such an unsafe potential difference. First, the equipment-grounding conductor must provide a return path for ground-fault currents of sufficiently low impedance to prevent an unsafe voltage drop. Second, the equipment-grounding conductor must be large enough to carry the maximum ground-fault current, without burning off, for sufficient time to permit protective devices (ground-fault relays, circuit breakers, fuses) to operate and clear the fault. The grounded conductor of the system (usually the neutral conductor), although grounded at the source, must not be used for equipment grounding.

The equipment-grounding conductor may be the metallic conduit or raceway of the wiring system or a separate equipment-grounding conductor, run with the circuit conductors, as permitted by the NEC. If a separate equipment-grounding conductor is used, it may be bare or insulated; if insulated, the insulation must be green. Conductors with green insulation may not be used for any purpose other than for equipment grounding.

The equipment-grounding system must be bonded to the grounding electrode at the source or service; however, it may also be connected to ground at many other points. This will not cause problems with the safe operation of the electrical distribution system. Where computers, data processing, or microprocessor-based industrial process control systems are installed, the equipment-grounding system must be designed to minimize interference with their proper operation. Often, isolated grounding of this equipment or completely isolated electrical supply systems are required to protect microprocessors from power system noise that does not in any way affect motors or other electrical equipment.

System grounding connects the electrical supply from the utility, from transformer secondary windings, or from a generator to ground.

Ground-Fault Protection

A ground fault normally occurs by accidental contact of an energized conductor with normally grounded metal or as a result of an insulation failure of an energized conductor. When an insulation failure occurs, the energized conductor contacts normally non-current-carrying grounded metal, which is bonded to or part of the equipment-grounding conductor. In a solidly grounded system, the fault current returns to the source primarily along the equipment-grounding conductors, and a small part uses parallel paths such as building steel or piping. If the ground return impedance were as low as that of the circuit conductors, ground-fault currents would be high, and the normal-phase overcurrent protection would clear them with little damage.

Unfortunately, the impedance of the ground return path is usually higher, the fault itself is usually arcing, and the impedance of the arc further reduces the fault current. In a 480Y/277-V system, the voltage drop across the arc can be from 70 to 140 V. The resulting ground-fault current is rarely enough to cause the phase overcurrent protection device to open instantaneously and prevent damage. Sometimes, the ground fault is below the trip setting of the protective device, and it does not trip at all until the fault escalates and extensive damage occurs. For these reasons, low-level, ground-fault protection devices with minimum time delay settings are required to clear ground faults rapidly.

The NEC requires ground-fault protection only on the service-disconnecting means. This protection works so fast that for ground faults on feeders, or even branch circuits, it will often open the service disconnect before the feeder or branch circuit overcurrent device can oper-

ate. This is highly undesirable. A fine-print note (FPN) in the NEC (230-95) states that additional ground-fault protective equipment is needed on feeders and branch circuits where maximum continuity of electric service is necessary. Unless it is acceptable to disconnect the entire service on a ground fault almost anywhere in the system, such additional stages of ground-fault protection must be provided. As an example, at least two stages of protection are mandatory in health care facilities (NEC, Sec. 517-14).

Lightning and Surge Protection. Physical protection of buildings from direct damage by lightning is beyond the scope of this section. Requirements vary with geographic location, building type and environment, and many other factors (see the IEEE Green Book).[4]

Any lightning protection system must be grounded, and the lightning protection ground must be bonded to the electrical equipment-grounding system.[5] Where required, lightning protection systems should also be listed.[6]

Designing for Maintenance. Usually the simpler the electrical system design and the simpler the electrical equipment, the fewer the maintenance costs and operator errors. As electrical systems and equipment become more complicated (to provide greater service continuity or flexibility), the maintenance costs and chance for operator error increase. The systems should be designed with an alternate power circuit to take electrical equipment (requiring periodic maintenance) out of service without dropping essential loads. Ease of maintenance can be achieved by:

- Using draw-out-type protective devices such as breakers and combination starters to help minimize maintenance cost and out-of-service time (it is much easier, quicker, and safer to draw out a large device on a mechanism designed for the purpose than to unbolt it)
- Using more and smaller switchgear sections, served by main breakers and interconnected with tie breakers, rather than one large switchgear section
- Including transformer primary and secondary tie breakers in the service entrance switchgear
- Having backup tie feeders between main centers of load distribution
- Including a separate bypass/isolation switch in an automatic transfer switch enclosure
- Using hinged covers and three-point locking systems on electrical switchgear enclosures and distribution panels

Recommended maintenance information can be found in NFPA 70B,[7] as well as in the IEEE Buff Book[8] maintenance section. Westinghouse Electric's *Electrical Maintenance Hints,* Chaps. 6, 7, and 40, provide good reference information.[9] Another reference source is Chap. 11 of the *Facility Manager's Operation and Maintenance Handbook.*[10] Also refer to Art. 7.2.3, "Electrical Testing and Maintenance," for a brief discussion of maintenance.

Distribution Reliability. The degree of service continuity and reliability needed will vary, depending on the type and use of the facility, as well as on the loads or processes being supplied by the electrical distribution system. For example, a power outage of several hours may be acceptable for a smaller commercial office building, whereas only a few minutes may be acceptable in a larger commercial building or industrial plant. In other facilities such as hospitals, many critical loads permit a maximum of 10 s outage and certain loads, such as real-time computers, cannot tolerate a loss of power for even a few cycles. Refer to Sec. 9.6, "Electrical Systems (Health Care Facilities)," for a further discussion of design considerations that affect distribution reliability. Typically, service continuity and reliability can be increased by:

1. Utilizing multiple utility power sources or services
2. Providing multiple connection paths to the loads served

3. Providing alternate customer-owned power sources such as generators or batteries supplying uninterruptible power supplies
4. Selecting the highest quality of electrical equipment and conductors
5. Using the best installation methods

MAIN SERVICE EQUIPMENT

Service-Disconnecting Means

A service-disconnecting means is required in all buildings so that the electrical power serving that building or, if under one ownership, a cluster of buildings may be disconnected from one location, if necessary, in the event of a fire or other unusual circumstance. That service-disconnecting means, by code, must occur within 10 ft of the electric service entrance, where it penetrates the exterior wall of the basement slab if it enters from underground. The service-disconnecting means can be a fused switch, a circuit breaker, or a lineup of up to six such devices that may be grouped together. The switch(es) or circuit breaker(s) may be individually mounted or may be part of an assembly (a switchboard or distribution panel). Refer to Art. 5.2.1, "Service Entrances," for a discussion of the primary disconnecting means and other equipment for handling power at the point of service to the building or facility.

Overcurrent Protection and Switching Equipment

In specifying overcurrent protection and switching equipment, we must spell out both the protection and the switching requirements, whether performed by a single device or separate devices. Protection requirements include continuous current ratings, operating characteristics (time–current curves) of overcurrent, time delays and pickup values, instantaneous trip settings, ground-fault settings, special relaying such as undervoltage or reverse-current tripping, and for fuses, maximum fault-clearing and current-limiting ability. Switching requirements include voltage ratings; manual or electrical operation; ability to switch under no-load, full-load, or other load conditions; and the ability to interrupt and clear overcurrents and short-circuit currents. Each individual piece of equipment must be able to switch and protect at the available voltages and currents and in the desired manner, and all of the protective devices in the system must also be chosen to provide the desired selectivity and system coordination.

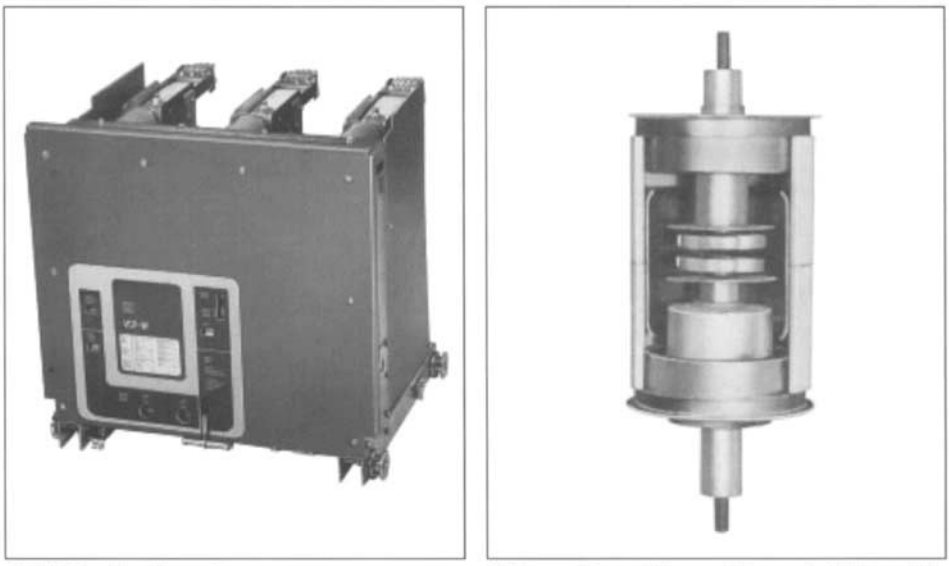
Medium-Voltage Switches and Fuses

Medium-voltage switches include many varieties, such as steel-structure-mounted air switches, vacuum breakers, oil-immersed fused or unfused cutouts, and single-pole, hook-stick cutouts. Switches can be mounted individually or as part of a switchgear lineup or unit substation.

Fuses for medium voltage can be oil-immersed types, but these are growing less common because oil-filled switches and fuses have limited fault-interrupting capabilities and present certain hazards. The fuses used most frequently are expulsion-type power fuses, usually boric acid–filled and current-limiting types. Expulsion-type fuses are available in a wide range of continuous ratings and interrupting capacities. They do not provide energy limiting and are usually used with mufflers to reduce the flame and force of the expelled gases. Because they do not interrupt until the first current-zero point, they are slow enough to provide fair coordination with secondary voltage protective equipment. Current-limiting fuses expel no hot gases, are quiet, limit the energy of the fault, and are faster than the expulsion type. They are available in a smaller range of continuous ratings, which has expanded in recent years with

increased demand. Their fast operation makes them more difficult to coordinate with secondary protective devices, however.

Medium-Voltage Circuit Breakers



Medium-voltage breakers include magnetic-air types, vacuum breakers, SF_6-insulated breakers, and oil-filled units. In the class of 15 kV and below, magnetic air equipment was formerly almost universal, but now vacuum breakers are becoming quite prevalent. Oil circuit breakers are rare, even outdoors. Above 15 kV and up to 34.5 kV, outdoor oil circuit breakers are usual, and some minimum-oil types, vacuum circuit breakers, and SF_6-insulated circuit breakers are also available for this application (Fig. 5.2.2-1).

All medium-voltage circuit breakers are actually switches. They open or close the circuit but cannot sense overloads, faults, or other abnormal conditions. Sensors (current and potential transformers, for example) that actuate relays external to the circuit breaker do such fault detection. The relay then signals the breaker to open or close as required. Many different types of relays are available for protection against almost any type of deviation from normal operation, as discussed later. Proper relay selection and setting can provide excellent protection (using suitable circuit breakers) and selective coordination for any distribution system.

The selection of appropriate medium-voltage equipment depends on the available voltage and short-circuit fault currents, the flexibility and features required, and the costs. New technology and higher voltages require careful specification for effective design.

Low-Voltage Air Circuit Breakers

This category includes both draw-out power air circuit breakers and insulated-case breakers. The air circuit breakers are described in the "Low-Voltage Switchgear" paragraph of this sec-

VCP-W Breaker Element

Cut-away View of Vacuum Interrupter (Enlarged to Show Detail)

FIGURE 5.2.2-1 Vacuum-type, medium-voltage circuit breaker. (*Courtesy of Cutler-Hammer.*)

tion. The insulated-case breaker is a draw-out, molded-case, solid-state trip (static) breaker with all of the major features of a draw-out switchgear power breaker except one. These breakers do *not* have a 30-cycle momentary rating equal to their instantaneous interrupting rating; therefore, they are all provided with instantaneous overrides for faults that exceed their short-time (momentary) ratings. True power air breakers can be fully selective because backup breakers can have a short time delay and no instantaneous trip (Fig. 5.2.2-2). Insulated-case breakers can be fully selective with a short time delay only up to the setting of the instantaneous override. For faults exceeding this level, the backup breaker, as well as the downstream breaker, will trip. The advantages of these breakers are that they can be installed in switchboards similar to draw-out switchgear and cost considerably less. The disadvantage of course is the lack of protective coordination above those fault levels.

Molded-Case Circuit Breakers

Lighting-panel breakers and some larger units are available for plug-in mounting, as well as for bolting to the panel bus. Molded-case breakers are available up to about 3000-A frame sizes, and the insulated-case type described earlier is available to 4000 A (Fig. 5.2.2-3). Thermal-magnetic trips are usual in the smaller frames, 400 A and less. Both thermal-magnetic and solid-state trips are common in the 400- to 1200-A range. Above 1200 A, thermal-magnetic trips have been almost completely phased out in favor of solid-state trips.

Molded-case breakers are available with a wide range of accessories (Fig. 5.2.2-4). Most require derating to 80 percent of their *trip,* not frame, ratings for continuous duty. Some of the larger frames, however, are now 100 percent rated for continuous duty, and so labeled, which can often be a distinct economic advantage if properly specified.

The fault-interrupting abilities and ratings of molded-case circuit breakers are substantially higher than in earlier years. In addition to standard ratings, high-interrupting capacity designs are available, and if these capacities are not adequate, molded-case breakers with integral and coordinated fusible current limiters extend the ratings to faults up to 200,000 A. Several designs of true current-limiting molded-case breakers without fuses are also available that not only interrupt faults of up to 200,000 A, but do so within the first half-cycle, limiting

FIGURE 5.2.2-2 Air magnetic draw-out power breaker. (*Courtesy of Cutler-Hammer.*)

FIGURE 5.2.2-4 Molded-case circuit breakers. (*Courtesy of Square D Company, with permission.*)

the current. This current limiting is sufficient, in many cases, to protect standard lighting-panel breakers downstream. It is important to follow all NEC rules for the use of current-limiting equipment to protect other equipment.

Low-Voltage Switches

Low-voltage switches include safety switches; panelboard and switchboard devices; and large, high-current power switches. They can be unfused, for switching duty only, or fused to provide both switching and overcurrent protection. Some can be electrically opened and closed, and some can be shunt-tripped for use with ground-fault protection or other relaying.

Safety switches range from 30 to 1200 A, rated for 250 or 600 V (some also have dc ratings). Switches can be horsepower-rated for motor use, and the UL label provides the motor sizes for which the switch has been tested to open locked-rotor current safely (which may vary with time-delay or non-time-delay fuses). All switches up to 600 A can safely open at least their full-load current at full voltage; switches rated 800 or 1200 A can also do so, unless labeled "For Isolating Use Only," in which case they must not be used to break current. Switches can be equipped with fuse rejection devices that prevent insertion of any but current-limiting fuses (Class R, J, or L), and such switches are labeled with the maximum short-circuit capacity of the system in which they may be applied—usually 200,000 A at rated voltage. The National Electrical Manufacturers Association (NEMA) classifies switches as heavy-duty [30 to 1200 A, 240 or 600 V ac (and sometimes dc), or general-duty (30 to 600 A, 240 V ac only). UL does not make this distinction but labels the switches with horsepower, short-circuit, and load-interrupting data, as well as voltage and current ratings. Safety switches are also available in double-throw designs and have NEMA-rated enclosures for various environments. Some NEMA enclosure standards are NEMA 1 (general purpose), 1A (semi-dust-tight), 3R (rainproof), 4 and 5 (watertight and dust-tight), 7 and 9 (various hazardous atmospheres), and 12 (industrial use).

Switches for panelboards and switchboards are similar to heavy-duty safety switches and have similar ratings. They are usually rated for horsepower and short-circuit application. Many manufacturers use the identical switch mechanisms, and the enclosure is designed for panelboard or switchboard mounting. At least one manufacturer can provide switches from 400 to 1200 A that can be shunt-tripped for ground-fault protection or other applications. For small fusible panels, such as the residential type, switches are sometimes simply molded pull-out heads with fuses mounted in the head.

Large switches, those from 1200 up to 6000 A, fall into two basic types. One is the bolted-pressure contact switch, the other the butt-contact switch. Originally, bolted-pressure switches (BPS) were manual, slow acting, and capable of breaking full-load current. In the closed position, the bolted-blade contact is the equivalent of a low-heat, low-resistance bus joint. These switches have been adapted for modern high-power systems, including the need for closing into possible faults and tripping open on ground faults. Stored-energy closing mechanisms enable the modern BPS, with proper current-limiting fuses, to close into faults of up to 200,000 A. Shunt-tripped opening mechanisms permit the switch to break up to 12 times the full-load current, as is required for ground-fault application.

Butt-contact switches, called *power protectors* (or fused power circuit devices by UL) are essentially circuit-breaker mechanisms without automatic tripping operation, used as switches in series with integrally mounted fuses. Most of these switches have power air breaker mechanisms, although one manufacturer uses the lighter-duty, lower-cost, molded-case breaker mechanism. Because the breaker mechanisms are high-speed, stored-energy devices originally designed for remote operation and shunt tripping, they can close in (with fuses) on faults of 200,000 A, and, more easily than the BPS, open currents of 12 times rating and often much more. On opening, their speed is somewhat greater than a BPS, and they have a maximum clearing time of about three cycles for currents within their ratings. This makes them especially useful for ground-fault protection. Both the BPS and the power protectors

are available with many variations and accessories, such as electrical operation (both close and trip), electrical trip, blown-fuse anti-single-phase prevention, and blown-fuse indication.

Low-Voltage Switchgear

Low-voltage switchgear is a specific class of equipment that consists of an assembly of draw-out power air circuit breakers (Fig. 5.2.2-5). All other types of low-voltage distribution equipment using molded-case circuit breakers, insulated-case circuit breakers, or fusible breakers, either fixed or draw-out-mounted (especially as a main disconnect), are *switchboards.*

Low-voltage switchgear is the top-of-the-line distribution equipment. It comes at a premium price and provides top-grade features, such as best-system selectivity and flexibility, easiest maintenance (and repair) with minimum downtime, and circuit breaker interchangeability. Switchgear consists of a structure with integrated bus work, circuit breakers in compartments or cells, and accessories. The structure is simply a housing and support for the other components, designed for indoor or outdoor application, and arranged for convenient accessibility, operation, and maintenance. Structures are often compartmentalized to isolate line-side bus from load-side bus and load cables.

Buses are usually aluminum, and copper is available as an extra-cost option, rarely justified except under atmospheric conditions harmful to aluminum. Bus joints are usually bolted.

FIGURE 5.2.2-5 Low-voltage, metal-enclosed, draw-out switchgear. (*Courtesy of Cutler-Hammer.*)

Bus plating method and thickness is important, especially on aluminum, where tin plating is preferable to silver because of the moderate joint pressures.

Circuit breakers are available in a wide range of continuous-current and fault-interrupting ratings. Interrupting ratings vary. Both the manually operated circuit breaker and the old solenoid-type electrically operated breaker have been replaced by the stored-energy, spring-operated breaker. The spring is either manually or electrically charged, but the breaker is always spring-operated. Stored-energy mechanisms are either *dependent* (the handle or motor compresses the spring for most of its travel, and then the spring is discharged to operate the breaker), or *independent* (the handle or motor compresses the spring and latches it, and in a separate action then or later the breaker is operated by releasing the spring with a pushbutton or solenoid).

All modern breakers have solid-state tripping, and an extremely accurate electronic relay gets its signal from current-transformer sensors and opens the breaker by a shunt trip coil. Solid-state relay tripping provides very close trip curve tolerances, excellent repeatable accuracy over the breaker's lifetime, and great flexibility in setting long-time and short-time delay pickup values and curves and instantaneous pickup points.

Circuit breaker compartments, called *cubicles* or *cells,* consist of the enclosure in which the breaker itself is mounted. Usually, the cell is ventilated and has a hinged front door. The movable breaker has two sets of contacts that engage fixed contacts in the cell. The main contacts are assemblies of heavy, spring-loaded contact fingers, two for each phase, line, and load, to slide onto the fixed power bus in the cell. The secondary contacts provide connections to the control power source for electrically charged breakers and to the shunt trip, auxiliary switch contacts, and other devices for interlocking, alarm, and control. The breaker can be racked or cranked into three positions—fully inserted (with all main and secondary contacts engaged), test position (main contacts disengaged, most auxiliary contacts engaged), and fully withdrawn (all contacts disengaged). The breaker is interlocked so that it cannot be moved from one position to another unless it is in the open position, and it is safely grounded in test and fully inserted positions. In most equipment, the cell doors can be closed with the breaker in any position, and some permit the breaker to be racked in and out with the door closed. Accessories are available on the breaker (various trip options, alarm contacts, auxiliary switches) or in the switchgear (metering transformers, ammeters, voltmeters, breaker hoist or lifting device, trip unit tester, and calibrator).

When the available fault current exceeds the interrupting rating of the breaker, current-limiting fuses are used with the breaker in a safe, coordinated combination. The NEC requires that such combinations be listed. In breakers in up to 1600- or 2000-A frames, the fuses are mounted integrally on the breaker. In larger 3000- or 4000-A frames, some manufacturers mount the fuses on the breaker and others mount them in a separate draw-out compartment, interlocked with the breaker compartment. As standard or as optional accessories, these fuses have indicators to locate a blown fuse and anti-single-phase protection to trip the three-pole breaker when any fuse has blown. The fuse/circuit-breaker combinations are usually good for available fault current up to 200,000 A (Fig. 5.2.2-6).

Low-Voltage Switchboards. Low-voltage switchboards are similar to low-voltage switchgear, but they are less standardized, have many more variations available, and usually cost less. In top-of-the-line switchboards that use power-type draw-out insulated-case circuit breakers, the switchboard is almost identical to the switchgear. At the other extreme, a switchboard can be merely a series of panelboards in floor-mounted enclosures, bolted, and bussed together—or even one section containing a floor-mounted panelboard. Because of the wide variations available in equipment and construction and an equally wide range in final cost, it is important to specify carefully exactly what is required.

Switchboard structures depend on the type of distribution equipment used and the location and accessibility of the switchboard (Fig. 5.2.2-7). A switchboard can be classified as *front-connected* or *rear-connected.* A front-connected board has all incoming and outgoing connections made from the front. It is often placed with its back against a wall, but this is not

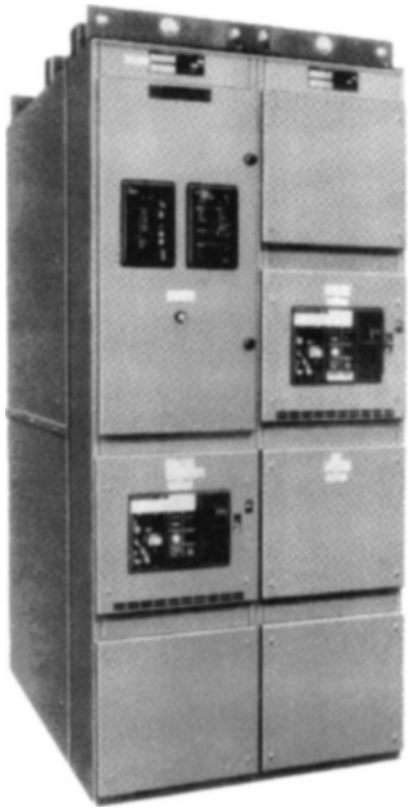

FIGURE 5.2.2-6 Low-voltage insulated-case circuit breaker switchboard. (*Courtesy of Cutler-Hammer.*)

advisable unless the equipment was specified, designed, and built for *complete* front accessibility, including all bus joints, connections, and devices that might require service or maintenance. A rear-connected board has incoming and outgoing connections in the rear. This class of construction cannot be placed against a wall because rear access is necessary, but it permits the maximum bus sizes and bracing, and there is no limitation on the size and type of feeder equipment and accessories.

Switchboards are also classified by the method of mounting the feeder-disconnecting devices. These can be individually mounted and connected and have separate line-side bus connections to each device, or they can be group-mounted. Individually mounted switches or circuit breakers can often be compartmentalized (have metal barriers) to any desired extent. This construction permits maximum flexibility, size, service, and maintenance. It also requires rear access and is more expensive than group-mounted construction. A group-mounted device consists of a distribution power panelboard chassis, mounted in a switchboard enclosure, and connected to the main switchboard bus. Group-mounted switchboards can often be designed to be completely front-accessible, if necessary. They permit somewhat less variation in layout and accessory devices. Switchboards are often a combination of both types, the main disconnect, and sometimes some large feeder devices are individually mounted and the smaller feeder devices are group-mounted. Many manufacturers can provide almost any equipment and layout desired in a switchboard. A switchboard bus is similar to a switchgear

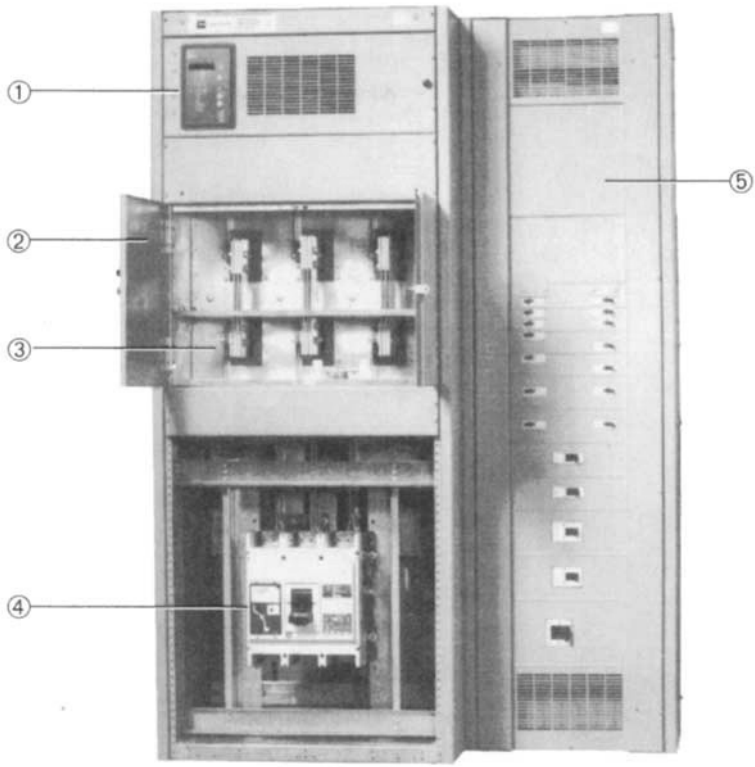

FIGURE 5.2.2-7 Low-voltage distribution switchboard, front-accessible, with group-mounted feeder devices. (1) Customer metering, (2) NEMA utility metering, (3) ground-fault panel, (4) main, (5) group-mounted distribution. (*Courtesy of Square D Company, with permission.*)

bus. Although more bus arrangements are necessary to accommodate the diversity in switchboard designs, the fundamental construction is the same.

Switchboard main and feeder devices can be any of the many switching and protective devices available, depending on the ratings required, the application, the cost, and personal preference. These include air power circuit breakers, fused or unfused, power insulated-case breakers, fused power protectors, bolted-pressure switches, molded-case breakers, fusible switches, and sometimes even motor starters. Larger equipment can be fixed or draw-out-mounted. Combinations of different units are frequent. It is not uncommon to see a large air power breaker as a main disconnect and molded-case breakers for the feeders or a bolted-pressure switch main and standard fusible switch feeders.

Accessories include devices mounted on the circuit breakers or switches; metering, relaying, ground-fault, and similar apparatus mounted in the switchboard.

Transformers

Purpose of Transformers. Whether located outdoors at the serving utility's generating station, in a vault at the owner's premises, in a lineup of switchgear within a building, in an electric closet on a floor, or in a small piece of equipment (i.e., a control panel), a transformer's

role is to change voltage from one level or value to another. Although normally used to transform voltage from a higher to a lower level (step-down), a transformer can also boost the voltage from a lower to a higher level. This occurs typically via electromagnetic induction and by using coils of wire or windings. A detailed discussion of how this occurs is beyond the scope of this book and is not necessary for the facility manager to know in detail, but it is, in simple terms, what actually occurs.

It is important for an informed facility manager to know the types of transformers and the relative merits of each. Type of transformer in this instance refers to the insulating means that is employed to keep the windings separated from each other so that voltage can be induced and so that short circuiting does not occur. The types most commonly encountered are oil-filled, non-flammable fluid, cast-resin, and dry-type.

Fluid-filled and *cast-resin transformers* are normally classified as power-type transformers, those with ratings above 500 kVA. Those classified as distribution type (from 3 to 500 kVA) are normally dry-type. Refer to Art. 5.2.1, "Service Entrances," for a detailed discussion of power-type transformers.

Dry-Type Transformers. Generally, for economy and distribution of power, it is desirable to locate dry-type distribution transformers as near as practicable to the load (Fig. 5.2.2-8). Typical loads for dry-type distribution transformers include lighting, heating, air conditioners, fans, and machine tools. Such loads are found in commercial, institutional, industrial, and residential structures. If frequencies other than 60 cycles/s are required, such transformers must be specifically designed. The discussion of this section will be limited to standard 60-Hz dry-type units. Industry standards classify insulation systems and rise as shown in Table 5.2.2-1. The rated lives of transformers that have different insulation systems are the same—the lower-temperature systems are designed for the same life as the higher-temperature systems.

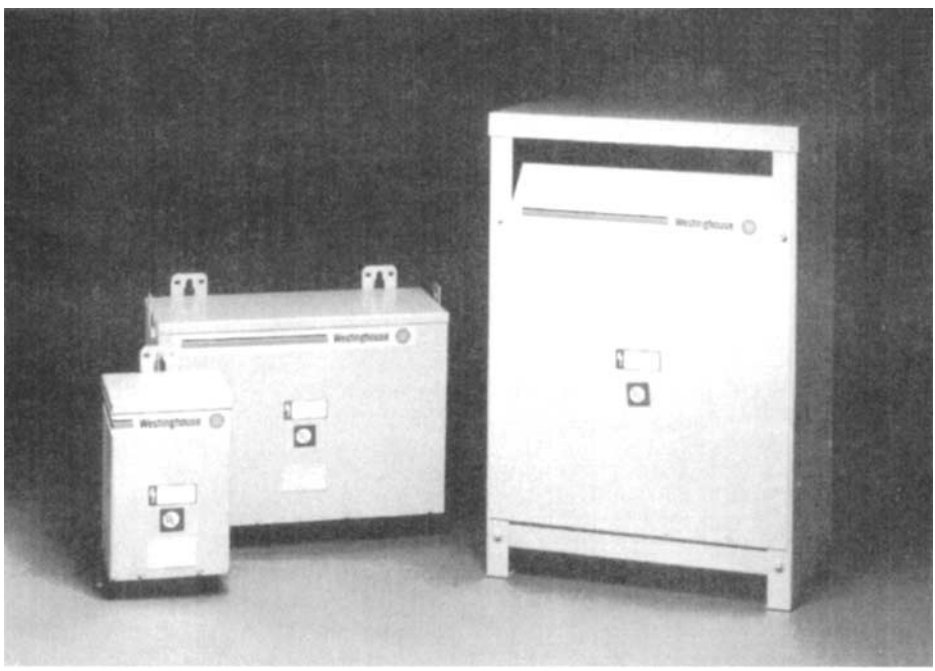

FIGURE 5.2.2-8 General purpose dry-type distribution transformers rated 1000 kVA and less. (*Courtesy of Cutler-Hammer.*)

TABLE 5.2.2-1 Dry-Type Transformer Insulation System Classification

Temperature Class	=	Ambient Temperature	+	Winding Temperature Rise	+	Hot Spot Allowance
150°C		40°C		80°C		30°C
185°C		40°C		115°C		30°C
220°C		40°C		150°C		30°C

Transformer Overload Capability. Short-term overload capacity is designed into transformers as required by ANSI and defined by IEEE Standard C57.12.01-1989.[11] Dry-type distribution transformers deliver 200 percent of nameplate load for ½ hour, 150 percent for 1 hour; and 125 percent load for 4 hours without being damaged, provided that a constant 50 percent load precedes and follows the overload. Continuous overload capacity is not deliberately designed into a transformer because the design objective is to be within the allowed winding temperature rise for the nameplate loading.

Transformer Taps. Primary taps are available in most ratings to allow compensation for source voltage variations. Common taps in most transformers are two 2.5 percent taps below normal and two 2.5 percent taps above normal. A primary voltage 2.5 percent below rated voltage can be compensated for by setting the primary taps at the first 2.5 percent below normal setting. This will cause the transformer secondary voltage to be at rated voltage for this condition.

Series-Multiple Windings. Series-multiple windings consist of two similar coils in each winding which can be connected in series or parallel (multiple). Transformers with series-multiple windings are designated with a × or / between the voltage ratings, such as primary voltage of 120/240 or 240×480. If the series-multiple winding is designated by a ×, the winding can be connected only for a series or parallel connection. With the / designation, a midpoint also becomes available in addition to the series or parallel connection. As an example, a 120×240 winding can be connected for either 120 (parallel) or 240 (series), but a 120/240 winding can be connected for 120 (parallel), or 240 (series), or 240 with a 120 midpoint.

Buck-Boost Autotransformers. An autotransformer has only one winding and therefore is smaller and more economical than the conventional two-winding transformer. In an autotransformer, the primary and secondary are electrically and mechanically connected together. The required secondary voltage is obtained by "tapping off" from the single winding.

Buck-boost autotransformers are insulated units with 120×240- or 240×480-V primaries and 12/24-, 16/32-, or 24/48-V secondaries and provide a very economical method for minor voltage adjustments where circuit isolation is not needed. Autotransformers can be used only where local electrical codes permit and where isolating the two circuits is not required.

In general, autotransformers are used when the transformation ratio is three or less and the electrical isolation of the two windings is not required. The usual application of autotransformers includes the following:

- Power distribution (lowering and raising voltage level)—buck-boost operation
- Induction motor starters on a selected basis
- Small variable-voltage power supply units

The advantages of autotransformers are that for the same input and output, the weight of the conductor, core material, and insulation of an autotransformer is less than that of a two-winding transformer. Refer to the IEEE Red Book,[12] pp. 504 and 505, for further discussion.

On-Site Power

Although virtually all facilities obtain power from a public utility and that power is distributed throughout the facility, consideration of alternate sources for code-mandated life safety needs, for the economics of cogeneration, or for peak shaving during heavy-usage periods frequently enters the picture. Depending on its intended use, complete separation of the alternate sources and their distribution may be required. Refer Art. to 5.2.3, "Emergency Power Supply Systems," for a discussion of these alternative sources.

Motor-Generator Sets. Power from motor-generator sets (also called M-G sets) can be primary power or standby power. In most facilities, standby generators are installed that run, outside of normally scheduled testing, only when the utility source of power is interrupted. These sources are moderately sized to power only those loads that are considered critical to operation of the facility and/or the safety of its occupants.

Standby units are usually fired with diesel oil or natural gas. Gas-fired units generally cost the same or less than diesel-fired units up to about 100 kW. Beyond this size, the cost of gas units comparable in capacity with diesel units becomes less and less favorable. Refer to the section on metering in Art. 5.2.1, "Service Entrances," for a discussion of cogeneration and peak load shaving using M-G sets. Also Art. 5.2.3, "Emergency Power Supply Systems," for a more detailed discussion of standby power systems.

Protecting the Distribution System

As noted in Art. 5.2.1, "Service Entrances," the main service equipment located at the service entrance is a disconnecting means and a point of separation between the serving utility and the use of electrical power by the owner. In addition, the service equipment protects the distribution system by limiting the amount of current that can flow from the service entrance to each use location. Achieving this protection requires using fuses, breakers, and relays that are sized and coordinated to protect the premises from distribution system overloads or utility voltage anomalies.

Protection of the distribution system takes place in many locations and takes various forms. There are several manufacturers' publications, including the IEEE Buff Book, that provide guidance on protective coordination and industry standards that deal with recommended practices. At the service entrance equipment, power system protective devices provide the intelligence and initiate the action that enables circuit-switching equipment to respond to abnormal or dangerous system conditions. Normally, relays control power circuit breakers rated above 600 V and current-responsive, self-contained elements operate multiple-pole, low-voltage circuit breakers to isolate circuits that experience overcurrents in any phase. Similarly, fuses function alone or in combination with other suitable means to isolate faulted or overloaded circuits. In other cases, special types of relays that respond to abnormal electric system conditions may activate circuit breakers or other switching devices to disconnect defective equipment from the remainder of the system.

In systems that employ circuit breakers, other than those with direct-acting devices that use fault current to power relaying and trip functions, there is always a risk that the system voltage can drop suddenly during a fault to a value too low for the protective devices to function. For this reason, station battery sets or capacitor trip devices are often employed to provide tripping energy. It is important to be able to test the circuit breaker and relay systems during planned or accidental power outages. The stored-energy system should be designed to provide these functions. Large battery sets are usually provided in large systems that have centralized switchgear. Capacitor trip devices are often used in small, low-voltage systems where manual charging of springs can supply the stored energy during prolonged power interruptions. Capacitor trips are often applied in small, remote, medium-voltage systems. In systems where direct-acting devices are used for overcurrent protection, functions such as

undervoltage protection, sensitive ground-fault protection, or other similar protection may require stored-energy tripping sources.

Relays. The overcurrent relay is the most common relay for short-circuit protection of an industrial power system. Overcurrent relays are typically of the electromagnetic attraction, induction, solid-state, or bimetallic element types. The solenoid type is the simplest overcurrent relay that uses the electromagnetic attraction principle. The basic elements of this relay are a solenoid wound around an iron core and a steel plunger or armature that moves inside the solenoid and supports the moving contacts. Other electromagnetic-attraction-type relays have hinged armatures or clappers of different shapes. These relays operate without any intentional time delay, usually within one-half cycle, and are called *instantaneous overcurrent relays.* The pickup or operating current for all overcurrent relays is adjustable. When the current through the relay coil exceeds the setting, the relay contacts close and initiate the circuit breaker–tripping operation. The relay operates on current from the secondary of a current transformer.

When the overcurrent is transient, such as that caused by starting a motor or some sudden overload of brief duration, the circuit breaker should not open. For this reason, induction disk overcurrent relays are used because they have an inherent time delay that permits a current several times in excess of the relay setting to persist for a limited period of time without closing the contacts. If a relay operates faster as current increases, it is said to have an inverse-time characteristic. Overcurrent relays are available with inverse, very inverse, and extremely inverse time characteristics to fit the requirements of the particular application. There are also definite minimum-time overcurrent relays that have an operating time that is practically independent of the magnitude of current after a certain current value is reached. Induction disk overcurrent relays provide for variation of the time adjustment and permit change of operating time for a given current. This adjustment is called the *time lever* or *time dial setting* of the relay. The previous brief discussion centered on overcurrent relays. There are a number of other types of relays, directional relays, differential relays, and ground-fault relays, each designed to provide protection from various circuit anomalies. Distribution equipment often has several of these different types. More in-depth discussion of these and other relays is beyond the scope of this section. For further information, refer to the bibliography.

Electromechanical Trip Devices. For many years, low-voltage power circuit breakers were equipped with electromechanical series trip devices as the basic form of protection. State-of-the-art technology that uses solid-state devices has replaced electromechanical trip devices on low-voltage breakers; however, these older devices may still be available in service and in replacement breakers. The moving armature-type electromechanical series trip uses heavy copper coils that carry the full-load current to provide the magnetizing force. A dashpot that restrains the movement of the armature provides overload protection. Short-circuit protection is provided when the magnetic force suddenly overcomes a separate restraint spring. A separate adjustable unit is required for each trip rating.

Several combinations of adjustable long-time, short-time, and instantaneous overcurrent trip characteristics are available (see Fig. 5.2.2-9). These units do have some inherent disadvantages. The trip point will vary depending upon age and severity of duty, the devices have a limited calibration shape with a broad tolerance band, and selective coordination of tripping with other devices is difficult.

Solid-State Trip Devices. In contrast to electromechanical devices, solid-state trip devices operate from a low-current signal generated by current sensors or current transformers in each phase. Signals from the sensors are fed into the solid-state trip unit that evaluates the magnitude of the incoming signal with respect to its calibration set points and trips the circuit breaker if preset values are exceeded. As with electromechanical trip devices, several overcurrent trip characteristics are available. In most instances, switch settings or ratings plugs determine the trip ratings of solid-state devices; thus, separate trip units are not required for

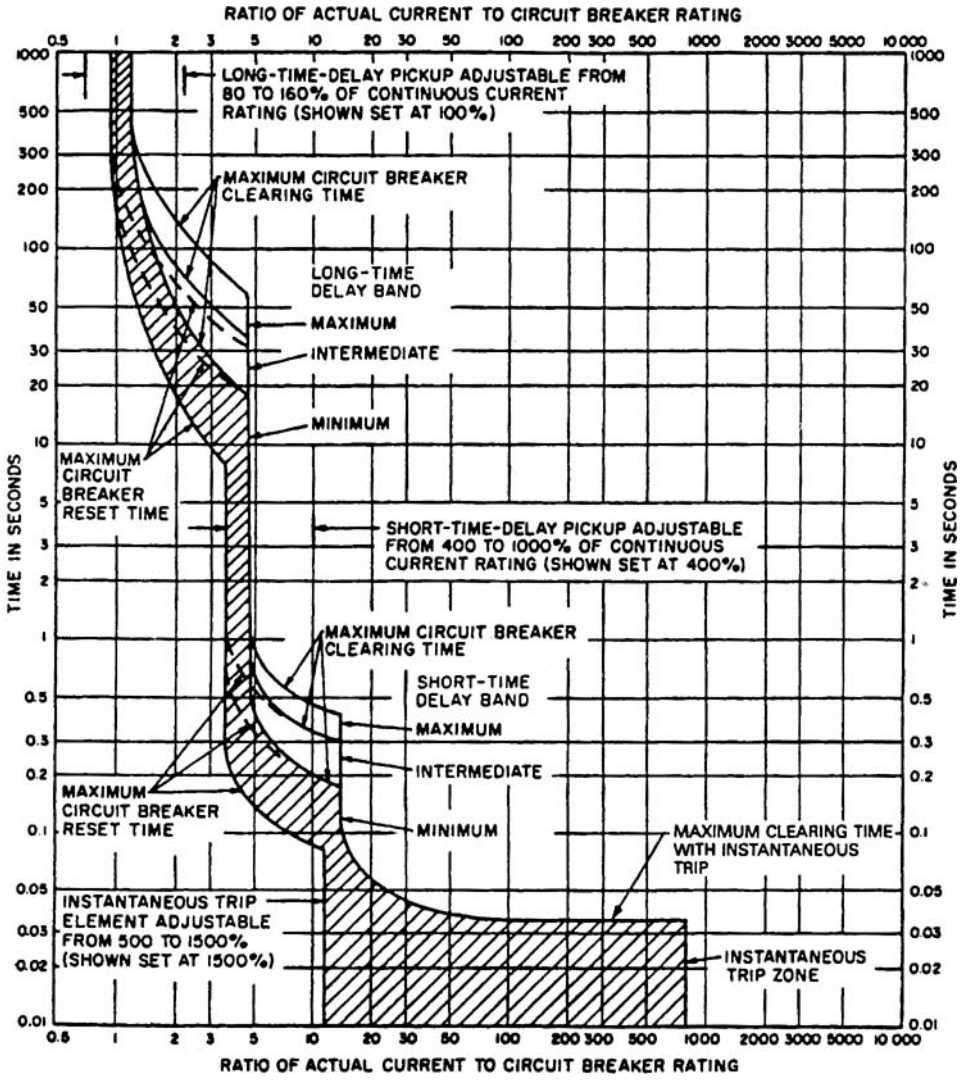

FIGURE 5.2.2-9 Typical time–current plot for electromechanical trip devices. (*Ref. 12, with permission.*)

each trip rating. In addition to phase protection, the solid-state trip device is available with integral ground-fault trip protection.

Solid-state trip devices are more accessible in the circuit breaker than trip devices and are much easier to calibrate because low-current values can be fed through the device to simulate the effect of an actual fault-current signal. Special care or provisions are sometimes necessary to guarantee predictable operation when applying solid-state trip devices to loads that have other than pure sinusoidal current wave shapes. Vibration, temperature, altitude, and duty cycle have virtually no effect on the calibration of solid-state trip devices; thus, excellent reliability is generally possible. The most important advantage of solid-state trip devices is the shape of the trip characteristic curve, which is essentially a straight line throughout its work-

ing portion (see Fig. 5.2.2-10). These devices have a very narrow and predictable tolerance, which enables several such devices to be selectively coordinated.

Continuous Current. Standard molded-case circuit breakers are calibrated to carry 100 percent of their current rating in open air at a given ambient temperature (usually 25° or 40°C). In accordance with the NEC, these breakers, as installed in their enclosures, should not be continuously loaded over 80 percent of their current rating.

Low-voltage power circuit breakers and insulated-case circuit breakers are specifically approved for 100 percent continuous duty. These breakers can be continuously loaded to 100 percent of their current rating at 40°C ambient, when installed in proper enclosures.

Interrupting Rating. The interrupting rating (or short-circuit current rating, as it is referred to for a low-voltage power circuit breaker) is commonly expressed in root-mean-square (rms) symmetrical amperes. It may vary with the applied voltage and is established by testing per UL or ANSI standards.

Short-Time Rating. The short-time current rating specifies the maximum capability of a circuit breaker to withstand the effects of short-circuit current flow for a stated period, typically 30 cycles or less, without opening. This provides time for downstream protective devices closer to the fault to operate and isolate the circuit.

LIVE GRAPH

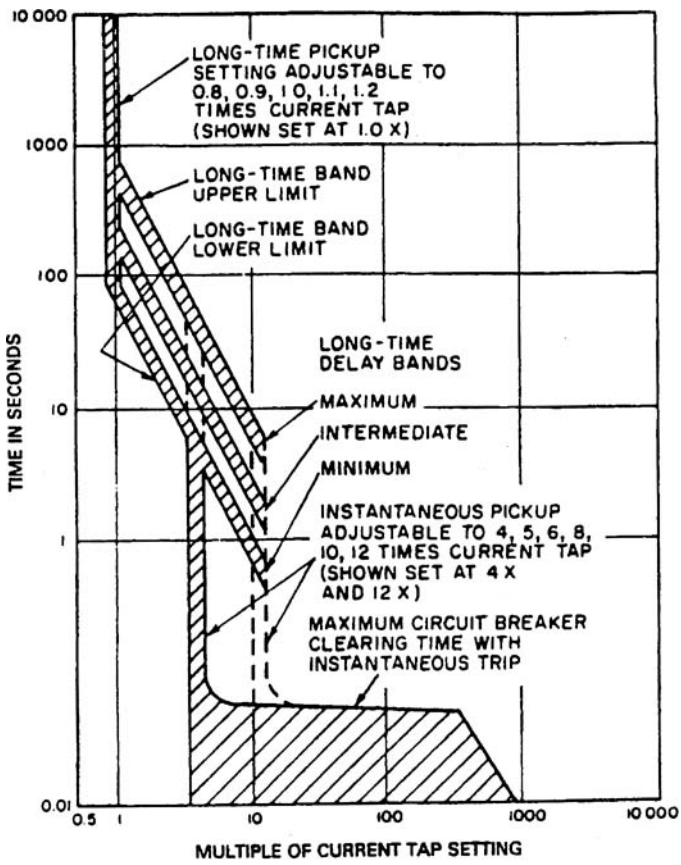

FIGURE 5.2.2-10 Typical time–current plot for solid-state trip devices. (*From Ref. 12, with permission.*)

The short-time current rating of a low-voltage power circuit breaker without instantaneous trip characteristics is equal to the breaker's short-circuit interrupting rating. Most molded-case circuit breakers are not provided with a short-time current rating; however, some higher-ampere-rated molded-case circuit breakers are provided with a short-time current rating in addition to the short-circuit interrupting rating.

A circuit breaker that has an instantaneous trip function should not be used where continuity of service requires only long-time and short-time delay functions.

Control Voltage. This is the ac or dc voltage to be applied to control devices that are intended to open or close a circuit breaker. These devices are normally supplied with a voltage rating needed for a particular control system.

Where the interrupting ratings of conventional molded-case circuit breakers or low-voltage power circuit breakers are not sufficient for a particular system application, other options are available, including current-limiting circuit breakers, integrally fused circuit breakers, and fuse/breaker coordination combinations.

Trip Unit. The trip unit is an integral part of the circuit breaker. It may be electromechanical (thermal-magnetic, mechanical dashpot) or solid-state electronic. It senses abnormal current conditions by continually monitoring the current flowing through the circuit breaker. Depending on the magnitude of the current, the trip unit will initiate an inverse-time response or an instantaneous response. This action will cause a direct-acting operating mechanism to open the circuit breaker contacts and interrupt current flow. The following discussion covers those trip unit characteristics commonly available in low-voltage circuit breakers:

- Continuous-current rating
- Long-time current
- Long-time time delay
- Short-time current
- Short-time time delay
- Instantaneous current response

The continuous-current rating may be fixed or adjustable. Some constructions may require replacing all or part of the trip unit to change the continuous rating. Overcurrent trip characteristics are a multiple or percentage function or the continuous-current rating.

Most molded-case circuit breakers are not provided with a long-time adjustment or short-time function. The inverse-time response characteristic is strictly related to how long a particular level of current has been flowing. Molded-case circuit breakers that have electronic trip units and low-voltage circuit breakers usually have long-time and short-time current adjustments. These adjustments are used to set the current level (pickup point) at which the circuit breaker trip unit begins timing to initiate tripping action. A low-voltage power circuit breaker may also be provided with or without an instantaneous trip function.

Power Fuses (over 600 V). There are four types of power fuses rated over 600 V: (1) the distribution fuse-cutout type, (2) the current-limiting type, (3) the sold-material type, and (4) the electronic type. Most fuses are available in designs that comply with ANSI E rating, R rating, or K rating requirements. Electronic fuses are very versatile power fuses that operate at a specific minimum pickup fault current, which is selectable based on coordination requirements, rather than within E or K rating requirements. Expulsion fuses can also be E-, K- and T-rated, and also meet ANSI standards. The K and T ratings refer, respectively, to relatively fast and slow melting expulsion fuses. The following is a guide to the ANSI designations:

- *E designation.* Fuses rated 100E or less melt in 300 s at a current value between 2.0 and 2.4 times the E number. Fuses rated above 100E melt in 600 s at a current value between 2.2 and 2.64 times the E number. If the current is higher than 2.0 to 2.4, or 2.64 times the E number, the user must consult the time–current curves for that particular fuse.

- *R designation.* The fuse melts in 15 to 35 s when the current equals 100 times the R number. If the current is higher than 100 times the R number, the user must consult the time–current curves for that fuse.
- *C designation.* The fuse melts in 1000 s at a current value between 1.7 and 2.4 times the C number. If the current is higher than 2.4 times the C number, the user must consult the time–current curves for that particular fuse.

Distribution Fuse Cutouts. This type of fuse is generally used in distribution system cutouts or disconnect switches. An arc-confining tube with a deionizing fiber liner and fusible element is used to interrupt a fault current. The arc is interrupted by the rapid production of pressurized gases within the fuse tube, which extinguish the arc by expulsion from the open end or ends of the fuse.

Enclosed, open, and open-link types of expulsion fuses are available for use as cutouts. Enclosed cutouts have terminals, fuse clips, and fuse holders mounted completely within an insulating enclosure. Open cutouts have these parts completely exposed. Open-link cutouts have no integral fuse holders; the arc-confining tube is incorporated as part of the fuse link (Fig. 5.2.2-11). Because gases are released rapidly during the interruption process, the operation of expulsion-type fuses is comparatively noisy. They are rarely, if ever, applied in an enclosure because of the special care required to vent any ionized gases that might be released and would cause a flashover between internal live parts. Fuse cutouts and disconnect switches are used indoors to protect industrial plant distribution systems and to provide fault and overload protection for distribution feeder circuits, transformers, and capacitor-bank fault protection. They have an inverse time–current characteristic that is compatible with that of standard overcurrent relays.

Current-Limiting Power Fuses. This type of fuse is designed so that melting of the fuse element introduces a high arc resistance into the circuit in advance of the prospective peak current of the first half-cycle. If the fault-current magnitude is sufficiently high, the arc voltage that rapidly escalates forcibly limits the current to a peak value that is lower than the prospective peak. This reduced peak value, referred to as the peak let-through current, may be a small

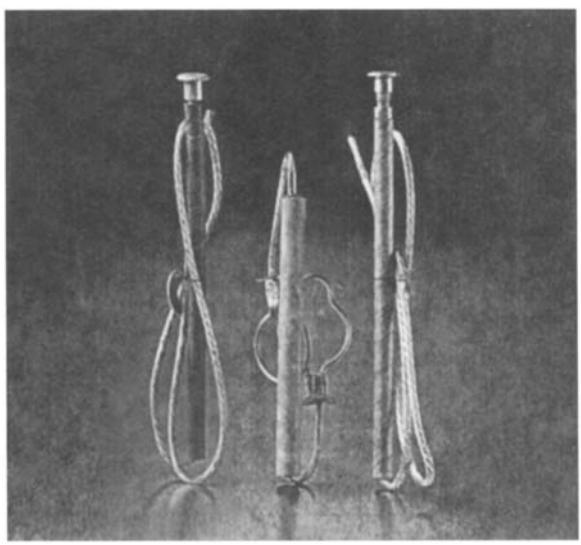

FIGURE 5.2.2-11 Medium-voltage fuse links. (*Courtesy of Bussmann Company, with permission.*)

fraction of the peak current that would flow without the current-limiting action of the fuse. If the fault-current magnitude is not sufficiently high, current limitation is not achieved.

A general-purpose current-limiting fuse is defined as a fuse that can interrupt all currents that range from the rated maximum interrupting current to the current that melts the fusible element in 1 hour. This type of fuse is not intended to provide protection against low-magnitude overload currents, because it can reliably interrupt only currents above approximately twice its continuous rating (for E-rated fuses), and usually above approximately three times its continuous rating (for non-E-rated fuses). Typical applications are for the protection of power transformers, potential transformers, and feeder circuits in primary switches. A typical time–current characteristic for this type of fuse makes selective coordination with other fuses easy but may be more difficult to coordinate with overcurrent relays.

Current-limiting fuses of the R-rated type are most commonly applied in motor starters using contactors that cannot interrupt high fault currents. The R designation is not related to the continuous-current rating, although each fuse does have a permissible continuous current that is published by the manufacturer. The R number is 1/100 of the number of amperes required to open the fuse in about 20 s. The fuse provides the necessary short-circuit protection but must be combined with an overload protective device to sense lower values of overcurrent that are within the capability of the contactor. Fuses of this type are generally designed to interrupt currents that melt the fuse elements in less than 100 s, but the fuse is not self-protecting on lower overcurrents (Fig. 5.2.2-12).

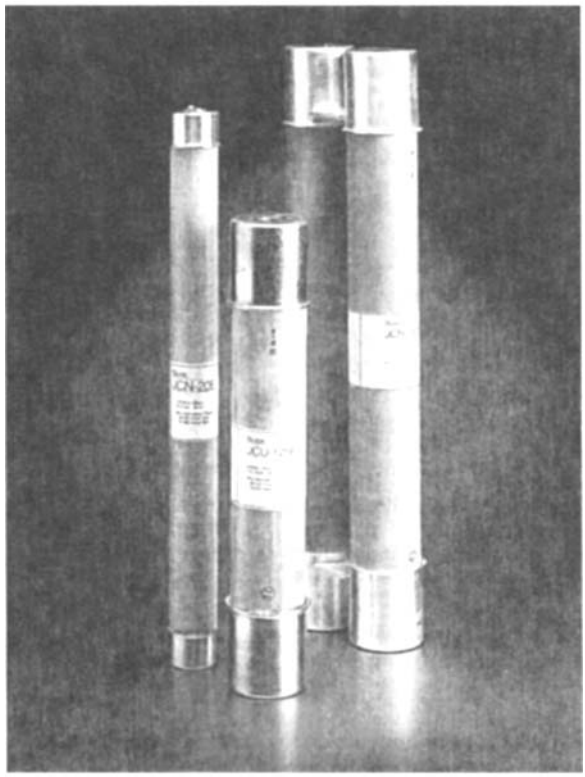

FIGURE 5.2.2-12 Current-limiting power fuse. (*Courtesy of Bussmann Company, with permission.*)

Solid-Material Power Fuses. This type of fuse uses densely molded, solid boric acid powder as the lining for the interrupting chamber. This solid-material lining liberates incombustible, highly deionized steam when subjected to the arc established by melting the fusible element. Solid-material power fuses have higher interrupting capacities than fiber-lined power fuses of identical physical dimensions, produce less noise, need less clearance in the path of the exhaust gases, and, importantly, can be applied with normal electrical clearance indoors or in enclosures when equipped with exhaust control devices. Exhaust control devices provide silent operation and contain all arc interruption products. Indoor mountings with solid-material power fuses can be furnished with an integral hook-stick-operated, load-current interrupting device, thus providing single-pole live switching in addition to fault-interrupting functions provided by the fuse. Many of these fuses also include an indicator that shows when the fuse has operated. These advantages, plus their availability in a wide range of current and interrupting ratings and time–current characteristics that conform to all applicable standards, have led to the wide use of solid-material power fuses in utility, industrial, and commercial power distribution systems (Fig. 5.2.2-13).

Electronic Power Fuses. This technological development in power fuses combines many of the features and benefits of power fuses and relays. Electronic fuses generally consist of two separate components: an electronic control module that provides the time–current characteristics

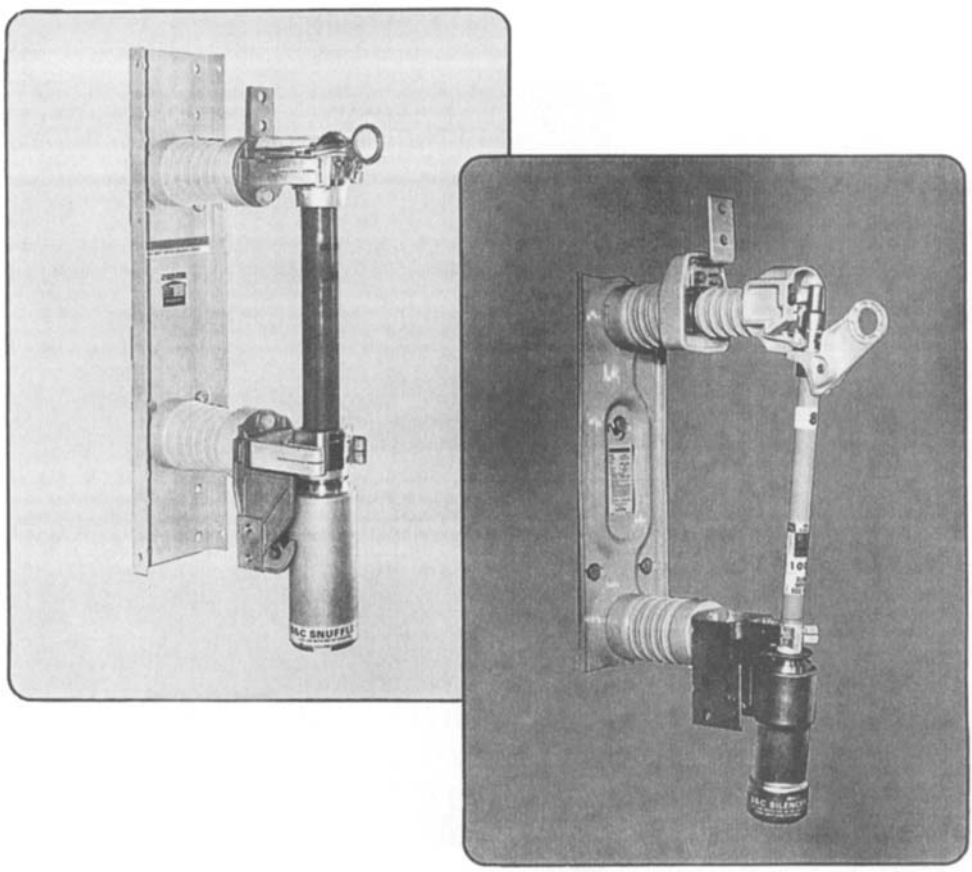

FIGURE 5.2.2-13 Solid-material power fuse. (*Courtesy of S&C Electric Company, with permission.*)

of the energy to initiate tripping, and an interrupting module that interrupts current when an overcurrent occurs. When joined together, these two modules are held in a suitable holder that fits in a mounting. A current transformer located within the control module powers the logic circuits employed in the control module that may have instantaneous tripping characteristics, time-delay tripping characteristics, or both. These two circuits may be used alone or in combination to provide a variety of time–current characteristics. When an overcurrent occurs, the control module triggers a high-speed gas generator that separates the main current path in the interrupting module and transfers the current into the current-interrupting ribbon elements, which then melts and burns back. Only the interrupting module is replaced following fuse operation.

Electronic power fuses are suitable for service entrance protection and coordination of industrial and commercial distribution circuits because these fuses have high current-carrying capability and incorporate unique time–current characteristics designed for superior coordination with source-side overcurrent relays and load-side feeder fuses. They are ideally suited for load-feeder protection and coordination in industrial, commercial, and utility substations because of their high continuous and interrupting ratings. Specific time–current characteristics are available for primary-side protection of transformers and for application at the heart of an underground loop system to provide backup protection for pad-mounted transformers that contain fuses with a limited interrupting capability. Indoor mountings with electronic fuses can be furnished with an integral hook-stick-operated, load-current interrupting device, thus providing for single-pole live switching in addition to the fault-interrupting functions provided by the fuse (Fig. 5.2.2-14).

Some electronic fuses also include indicators that make it easy to determine which fuse has operated. Because this fuse is available with many unique, time–current characteristics, it can easily coordinate with both line-side overcurrent relays and load-side power fuses.

FIGURE 5.2.2-14 Electronic power fuse. (*Courtesy of S&C Electric Company, with permission.*)

Low-Voltage Fuses (600 V and Less). Plug fuses are of three basic types, all rated 125 V or less to ground and up to a maximum of 30 A with an interrupting rating of 10,000 A (Fig. 5.2.2-15). Following are the three types:

1. Edison base with no time delay in which all ratings are interchangeable
2. Edison base with a time delay and interchangeable ratings
3. Type-S base, available in three noninterchangeable current ranges: 0 to 15, 16 to 20, and 21 to 30 A.

Cartridge fuses may be either renewable or nonrenewable. Nonrenewable fuses are factory-assembled and must be replaced after operating. Renewable fuses can be disassembled and the fusible element replaced. Renewable elements are usually designed to give a greater time delay than ordinary nonrenewable fuses, and in some designs the delay on moderate overcurrents is considerable. The renewable-type fuse is not available in ratings above 10,000 A.

Non-Current-Limiting Fuses (Class H). These fuses interrupt overcurrents up to 10,000 A but do not limit the current that flows in the circuit to the same extent as recognized current-limiting fuses. Generally, cartridge fuses should be used only in circuits in which the maximum available fault current is 10,000 A and the protected equipment is fully rated to withstand the peak available fault current associated with this fault duty, unless such fuses are specifically applied as part of an equipment combination that has been type-tested and designed for use at higher available fault-current levels.

Current-Limiting Fuses. Current-limiting fuses are intended for circuits where the available short-circuit current is beyond the withstand capability of downstream equipment or the interrupting rating of ordinary fuses or standard circuit breakers. An alternating current-limiting fuse safely interrupts all available currents within its interrupting rating, limits the clearing time at rated voltage within its current-limiting range to an interval equal to or less than the first major or symmetrical current loop duration, and limits peak let-through current to a value less than the peak current that would be possible if the fuses were replaced with a solid conductor of the same impedance. Therefore, a current-limiting fuse places a definite ceiling on the peak let-through current and thermal energy and provides equipment protection against damage from excessive magnetic stresses and thermal energy (see the ANSI/UL 198 series standards for maximum let-through limits).

These fuses are widely used in motor starters, fused circuit breakers, fused switches of motors and feeder circuits (for protection of busway and cable), and many other applications.

FIGURE 5.2.2-15 One-time general-purpose fuses. (*Courtesy of Bussmann Company, with permission.*)

Dual-Element or Time-Delay Fuses. A dual-element fuse has current-responsive elements of two different fusing characteristics in series in a single cartridge. The fuse has a one-time use in operation, and the fast-acting element responds to overcurrents that are in the short-circuit range. The time-delay element permits short-duration overloads but melts if these overloads are sustained. The most important application for these fuses is motor and transformer protection. they do not open on motor starting or transformer magnetizing inrush currents but still protect the motor and branch circuits from damage by sustained overloads. Table 5.2.2-2 summarizes fuse characteristics and ratings.

Protective Coordination

As noted earlier, protective overcurrent devices are required at various locations to protect the distribution system. Besides serving as a manual means of interrupting power at a particular location, for example, to do maintenance on or replace a device or piece of equipment, these devices automatically interrupt power to protect that equipment. Necessarily, as one moves out in the system, these protective devices must be installed in series with one another, and their interrupting settings must be coordinated to prevent a small problem on one branch of the system from causing the entire system to lose power. Refer to Sec. 10.6, "Electrical Systems in Laboratories," for a detailed discussion of this important activity.

Methods of Electrical Power Distribution. Once the service entrance and main distribution equipment for a building or a site are established, the means of distributing power throughout the facility must be determined. Refer to Art. 5.2.4, "Raceway and Cable Systems," for a detailed description of raceways, bus ducts, and so on.

Battery Sources

Where immediate power is required upon loss of utility power or where standby M-G set or cogeneration power sources are not available, battery-powered standby lighting units and/or uninterruptible power systems (UPSs) can be utilized. Refer to the Art. 5.2.3, "Emergency Power Supply Systems," for details about this equipment.

TABLE 5.2.2-2 Fuse Characteristics and Typical Ratings

Fuse Type	Voltage Range	Amperage Range	Time Delay	Interrupting Rating	Current Limiting	Comments
Misc.*	125, 250, 300, 500, 600 V		No		No	Different dimensions from UL class G,H,J,K, CC,T, or L.
Class H	250 or 600 V	Up to 600 A	Yes, if so labeled	Up to 10,000 A	No	Renewable or nonrenewable of copper or zinc link construction.
Class K	250 or 600 V	Up to 600 A		50,000 A 100,000 A or 200,000 A	No	High interrupting rating same physical sizes as type H.
Class R	250 or 600 V	Up to 600 A		200,000 A	Yes	Class H dimensions but with built-in rejection notches.
Class J	600 V or less	Up to 600 A	Yes, if so specified	200,000 A	Yes	Do not match Class H dimensions.
Class L	600 V or less	601 to 6000 A		200,000 A		Do not match Class H dimensions.

* Miscellaneous fuses are those manufactured for application in control circuits, special electronic or automotive equipment, and such.

Downstream Distribution Equipment

Electric power is distributed from the main service equipment described earlier via various types of raceway systems to remote distribution locations nearer the point of use. At these locations, downstream distribution equipment (i.e., motor control centers, distribution panels, lighting panels, and power panels) may be used to provide local distribution to equipment such as motors, lighting fixtures, receptacles, and the like.

Motor Control Centers. In lieu of individually mounting motor starters and doing the related control interface wiring in the field, starters can be located in tailor-made assemblies of conveniently grouped control equipment primarily used for power distribution and control of motors (Fig. 5.2.2-16). They contain all necessary buses, incoming line facilities, and safety features to afford the most convenience by saving space and labor and by providing adaptability to ever-changing conditions with a minimum of effort and a maximum of safety. NEMA ICS 2 governs the type of enclosure and wiring.[13] NEMA Type 1, 2, and 12 enclosures are generally available. Wiring of motor-control centers conforms to two NEMA classes and three types. Class I construction provides for no wiring by the manufacturer. Class II requires prewiring by the manufacturer with interlocking and other control wiring being completed between compartments of the center. With Type A, no terminal blocks are provided; with Type B, all connections within individual compartments are made to terminal blocks; and with Type C, all connections are made to a master terminal block located in the horizontal wiring trough at the top or bottom of the center. The ideal wiring specification for minimum field installation time and labor is NEMA Class II, Type C wiring. The wiring specification most frequently used by industrial contractors is Class I, Type B wiring.

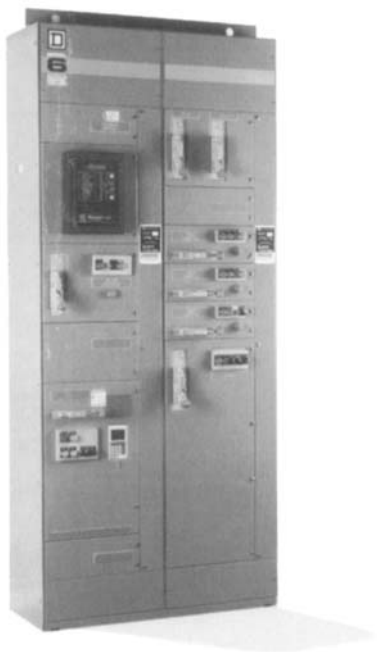

FIGURE 5.2.2-16 Motor control center. (*Courtesy of Square D Company, with permission.*)

NEMA ICS 2 specifies that a control center shall carry a short-circuit rating defined as the maximum available rms symmetrical current in amperes permissible at line terminals. The available short-circuit current at the line terminals of the motor control center is computed as the sum of maximum available current of the system at the point of connection and the short-circuit current contribution of the motors connected to the control center. Many manufacturers commonly show only the short-circuit rating of the bussing on the nameplate. Therefore, it is very important to establish the actual rating of the entire unit and, in particular, the plug-in units (i.e., circuit breakers, fusible disconnects, starters, etc.), especially for applications where available fault currents exceed 10,000 A.

Panelboards. The panelboard is usually the last piece of distribution equipment between the source and the load. Although some large loads are fed directly from the switchgear or switchboard, most loads are fed from a panelboard, which takes a large block of power right from a small service or through the distribution equipment of a large service and divides it to feed multiple loads (Fig. 5.2.2-17).

There are two basic types of panelboards: (1) for power, and (2) for lighting and appliances. The code specifically recognizes only lighting and appliance branch-circuit panelboards, which are clearly defined in Sec. 384-14; all others fall outside this definition. A lighting and appliance branch-circuit panelboard has more than 10 percent of its overcurrent devices rated 30 A or less, for which neutral connections are provided. Thus, a *power* panelboard that has all three-pole circuit breakers, more than 10 percent of the poles 30 A or less that feed only motor, and a neutral bar installed (provided) even though unused, is a *lighting and appliance panelboard,* as defined by the NEC. Conversely, a panelboard that feeds only outdoor 480-V HID lighting with two-pole circuit breakers and has no neutral is *not* a lighting and appliance panelboard according to the NEC.

Lighting panelboards range from the residential load-center type to the standard-duty type. The residential load center is a smaller panel that often uses half-size or twin circuit

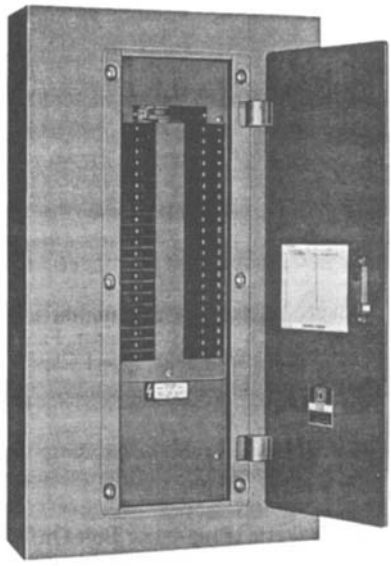

FIGURE 5.2.2-17 Typical panelboard. (*Courtesy of Square D Company, with permission.*)

Next Page

breakers. Fusible load centers are also available. Load centers generally have plug-in circuit breakers, smaller wiring gutters, simpler hardware, and are intended for lighter duty than standard panels. Standard-duty lighting panelboards generally have a choice of plug-in or bolt-on circuit breakers, heavy-duty hinges, latches and locks, 4-in minimum wiring gutters, and can accommodate many variations and accessories. Lighting and appliance panels are limited to a maximum of 42 overcurrent devices (circuit breaker poles or fuses) in any one enclosure, not counting those in the mains.

Power panelboards have no limitations except those set by the manufacturers resulting from physical limitations and the need to dissipate heat to meet UL requirements. Main bus ratings are usually limited to 1600 A, although larger units have been built. The number of poles is limited only by the sizes of the devices used and the space available in the enclosure. Some power panels are available with built-in motor starters combined with motor disconnect switches or circuit breakers. This motor-starter panelboard is a form of "poor man's motor control center," that provides far more convenience and lower cost than trough-mounted starters, but less flexibility than higher-cost motor control centers

Branch-circuit switches or circuit breakers are usually equipped with mechanical set-screw lug terminals approved for either copper or aluminum conductors. However, many specifiers do not accept mechanical terminations for aluminum conductors; they insist on compression connectors. Two manufacturers offer compression connectors or branch circuits as a UL-labeled alternate. Otherwise, some means of aluminum-to-copper adaptation is required, and it is important to provide adequate gutter space for these splices or adapter units. All manufacturers offer compression connectors for the main buses of both power and lighting panelboards when specified.

Both lighting and power panels can be UL-labeled for use as service entrance equipment, either with a main disconnect or in accordance with the six-disconnect rule, NEC Section 230-71. For direct application in systems with high available short-circuit currents, circuit-breaker lighting panels are available with fusible main-switch disconnects. With these panels, the current-limiting fuses will limit the fault currents to values that the branch circuit breakers can withstand. The main disconnects in these applications might also be integrally fused circuit breakers or current-limiting circuit breakers.

Panelboards are available with many modifications and special features or accessories. Among these are remote-control switches or lighting contactors, time clocks, split buses, subfeed or feed-through lugs, grounding bars for ground wires, and built-in ground-fault relays. Lighting panels can be supplied with ground-fault circuit interrupter-type breakers, and where used for switching 120-V fluorescent lighting, breakers must be switching-duty type (SWD).

Type SWD breakers are also available in 277-V ratings. Enclosure variations include raintight, dusttight, weatherproof or explosion-proof construction, increased gutter spaces, door-in-door trims (inner door over circuit breaker handles and outer door over wiring spaces), special locks, hinges and hardware, stainless-steel trim, and the like. In today's electronic environments, panels shielded and filtered against electromagnetic interference (electronic grade panels) are available at higher cost, where necessary.

Motor Starter Panelboards. Rather than using an individual mounting, a small number of motor starters can be grouped into a panelboard. Motor starter panelboards consist of combination units using either molded-case or motor circuit protector fusible disconnects. The combination starters are factory-wired and assembled. Class A provides no wiring external to the combination starter, and Class B provides control wiring to terminal blocks furnished near the side of each unit. When a large number of motors are to be controlled from one location or additional wiring between starters and to master terminal blocks is required, conventional motor control centers (MCCs) are most commonly used.

Multiple-Section Panelboards. Both lighting and appliance panelboards and power distribution panelboards that require more than one box are called *multiple-section panelboards.* Unless a main overcurrent device is provided in each section, each section should be furnished

Previous Page

with a main bus and terminals of the same rating for connection to one feeder. The three methods commonly used for interconnecting multiple-section panelboards are as follows:

1. *Gutter tapping.* Increased gutter width may be required. Tap devices are not furnished with the panelboard.
2. *Subfeeding.* A second set of main lugs (subfeeds) is provided directly beside the main lugs of each panelboard section, except the last in the lineup.
3. *Through-feeding.* A second set of main lugs (through-feed) is provided on the main bus at the end opposite from the main lugs of each section, except the last in the lineup. This method has the undesirable feature of allowing the current of the second panelboard section to flow through the main bus of the first section.

ARTICLE 5.2.3
EMERGENCY POWER SUPPLY SYSTEMS

Cornelius Regan, P.E., CLEP, Principal
C. Regan Associates, Rockland, Massachusetts

INTRODUCTION

The requirement for an alternative source of emergency or standby electric power is becoming more urgent as the need for electricity keeps growing, but at the same time the utility companies are cutting back on expanding their generation capacities. This results in power outages and low and unstable voltages during peak use, especially during the summer months when the use of electricity for air conditioning is at its highest. Other utility company outages result from cable failure, transformer failure, overloaded lines, and flooded manholes. Coupled with these outages are non–utility company and user-planned and unplanned outages, such as those caused by the weather and environmental conditions, inadequate electrical systems, floods, tornadoes, hurricanes, cyclones, flooded vaults, and downed trees, poles, and overhead wires. All of these events justify the installation of an on-site alternate source of electrical power, although it is required by code for most buildings.

Figure 5.2.3-1, taken from IEEE STD 446 1987, shows the average number of thunderstorm days per year for the United States in every geographic location. Figure 5.2.3-2, taken from the same IEEE standard, shows the tornado density in the southwestern United States. Both types of information are useful in determining the probability of power failures resulting from these natural events. Most utility companies that have proper shielding and surge arresters can provide service that is of equal reliability in any area.[1]

THE NEED FOR EMERGENCY POWER

The primary need for an alternate source of emergency or standby power, other than that required by code for life safety and life support, is to maintain continuous power to (1) security systems; (2) 24-hour production operations; (3) critical business computers that require 24-hour operation; (4) emergency air, sea, rail, and road transport services; (5) property protection systems such as fire alarms, fire pumps, and sprinkler systems; and (6) critical lighting

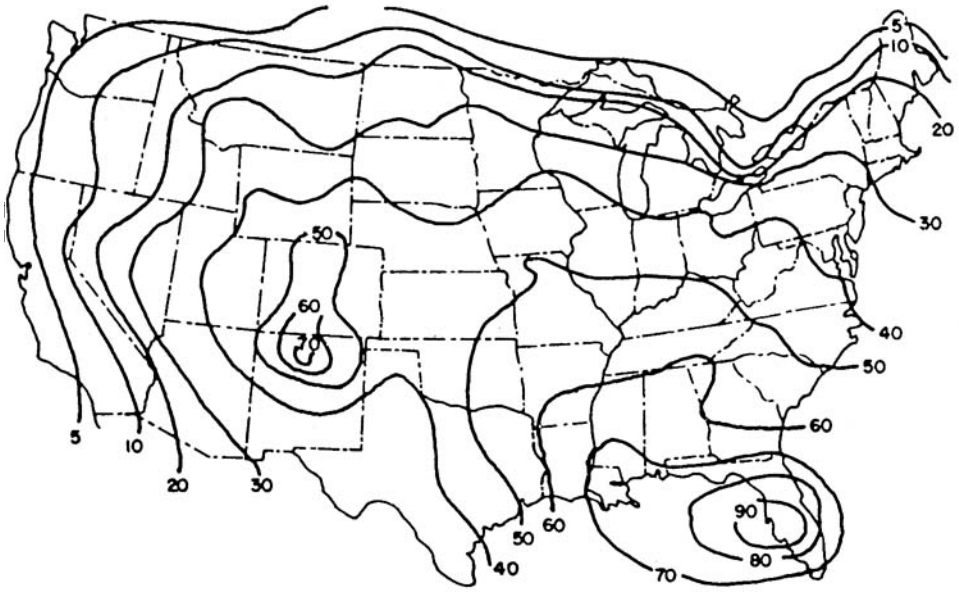

FIGURE 5.2.3-1 Average number of thunderstorm days per year from ANSI/IEEE Std 446-1987. (*Courtesy of Institute of Electrical and Electronics Engineers, Inc.*)

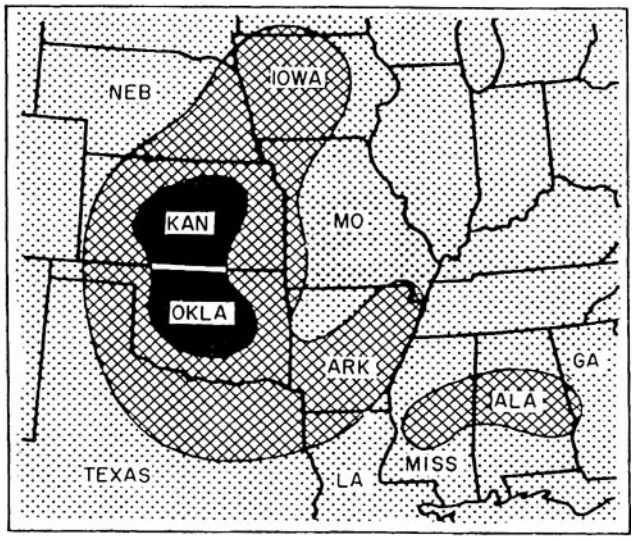

FIGURE 5.2.3-2 Approximate density of tornadoes from ANSI/IEEE Std 446-1987. Cross-hatched areas—100 to 200 in 40 years; black area—more than 200 in 40 years. (*Courtesy of Institute of Electrical and Electronics Engineers, Inc.*)

systems such as airport landing lights, warning lights, and transportation lighting. The alternate source can also be used for load sharing, peak shaving in conjunction with the utility company, and as an economic advantage to the user. The following codes and standards should be reviewed for emergency power requirements: NFPA 101, NFPA 110, NFPA 70, NFPA 111, OSHA, elevator codes, local and state codes, and IEEE-446.

Feasibility Study

Once the need has been established for an alternate emergency and standby power system, it is necessary to study the facility completely to assess its emergency power requirements. The study describes the type of occupancy (commercial, industrial, health care, etc.) (see NFPA 101 for building classifications), the physical characteristics of the building such as its floor area, the number of floors above and below grade, the location and quantity of elevators, the fire pump capacity, the smoke evacuation requirements, the emergency ventilation system requirements, and all other equipment and devices that must be operated in an emergency or fire (overhead doors, fire doors, vertical and horizontal transportation systems, fire dampers, etc.).

Information from this study, together with a conceptual design and equipment load list, forms the basis for selecting an emergency power supply for the facility. The source of power for the emergency power supply system may be a battery system, an on-site generator set, or a source of supply separate from the existing utility company or a source from another utility company.

An emergency power supply system (EPSS) consists of an emergency power source (EPS) that supplies power to an electrical distribution system consisting of overcurrent protective devices, conductors, transfer switches, disconnecting means of control, and supervisory devices up to the point of power use.

The EPS is the source of electric power of the required capacity and quality for an EPSS, including all of the related electrical and mechanical components of the proper size and/or capacity for generating the electric power required at the EPS output terminals. For a rotary energy converter, components of the EPS include a prime mover, a cooling system, a generator, an excitation system, a starting system, a control system, a fuel system, and a lube system (if used).[2] These components are discussed later.

The next tasks are to consider the design issues and equipment selection for the EPSS selected. A preliminary, one-line diagram is prepared that shows the existing utility service, the normal power distribution system, the EPS (this is the generator set complete with fuel, lube, and control system), and the EPSS (this includes the EPS and all associated cable and equipment up to the load side of the transfer switch necessary for a completely safe, reliable, and functional system).

Design Issues

EPS. The feasibility study that provides the basis for designing an EPSS is also the basis for an EPS. Because a diesel or gas generator, if approved by the authority having jurisdiction (AHJ), is the preferred source of emergency power for the life safety and critical branches of the emergency system, it does not necessarily mean that the design of an alternate power source should be limited to a single fuel generator. A generator set supplies power to the essential loads, as illustrated in Fig. 5.2.3-3; a generator set using fuels other than diesel oil could supply the nonemergency but economically critical loads.

Reliability. An on-site diesel generator is considered a more reliable source of power compared with a second utility feeder or other fuel-driven generator in case of a catastrophic disaster such as a hurricane, tornado or earthquake. The diesel generator has minimum piping. Readily available fuel is stored on-site, is stable, and can be stored for long periods without deterioration. There are also disadvantages to a diesel-driven generator such as noise, expense,

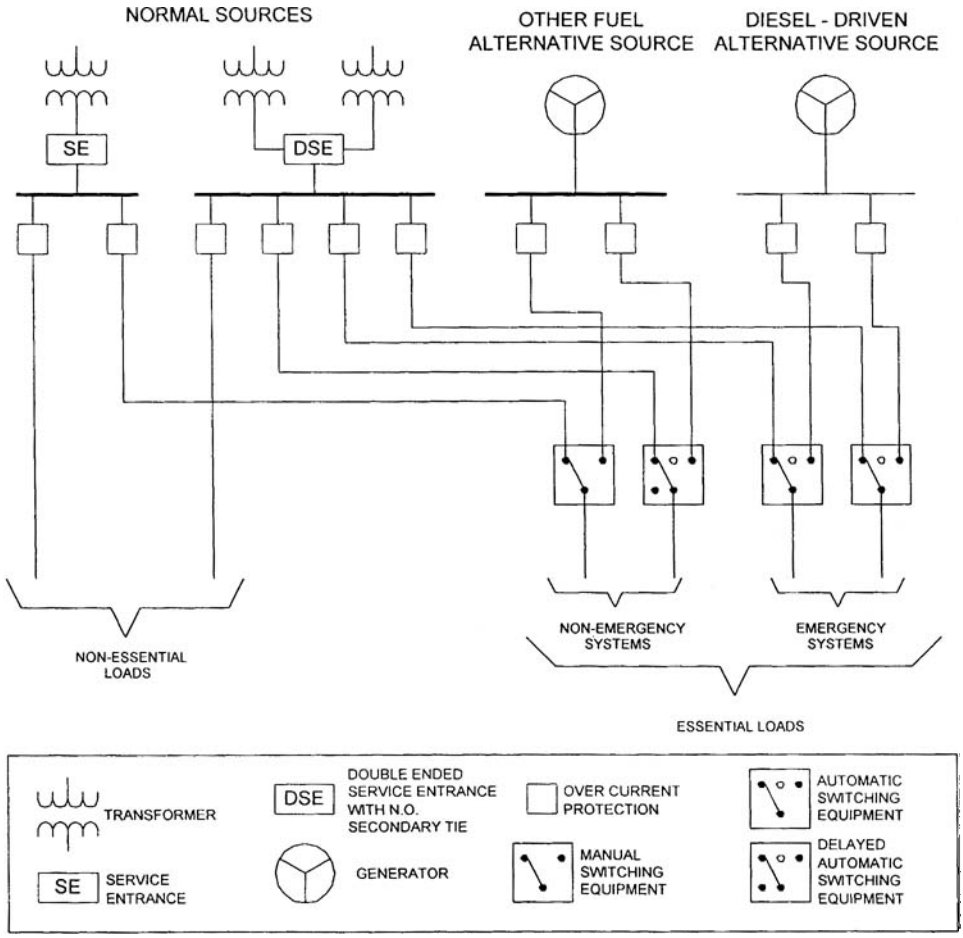

FIGURE 5.2.3-3 Electrical one-line diagram illustrating an EPSS. (*Courtesy of Motor and Generator Institute,* Healthcare Circuit News.)

and fuel odor. The pros and cons of each type of prime mover should be evaluated by an experienced engineering professional before selecting a generator set for each application.

Generator Capacity and Rating. An EPS must have enough capacity to adequately start and carry all loads simultaneously. This is different from legally required standby systems, which must have enough capacity to start and carry the loads of all equipment that is intended to be operated at one time. Optional standby systems have to be sized only to carry loads that are selected by the user.[3]

Peak Shaving. Emergency generating capacity is allowed for peak shaving or load sharing where automatic means is provided to assure adequate power to the emergency loads. After that, the legally required standby loads can be energized. There are no restrictions on the use of optional standby units for load sharing or peak shaving.[3] Peak shaving/load sharing operation may be acceptable for satisfying the test requirements described in the National Electric Code (NEC), Article 700.[4]

Generator Set Location. One of the most important issues in EPSS selection is where to locate the generator set. This decision is very often made for aesthetic reasons. The generator should be seismically located on-grade and centrally positioned in relation to the emergency loads and normal switchgear. Avoid locating generators in basements where they can be subjected to flooding or on a roof structure where they may be inaccessible in case of a fire. The generator room should be well ventilated; approximately 50 to 200 cfm of air are required per kilowatt of generator set capacity. This requirement should be considered before locating a generator in a space not easily ventilated such as a basement.

Generator Enclosure. The generator should be located in its own soundproofed room.

Fire Separation. The generator will have the minimum fire separation from the existing facility's normal electrical system, as dictated by state and local codes. Some states require 1-hour fire separation, and other states require 2-hour fire separation.

Emergency Feeders. The emergency feeders should not enter or traverse the normal electrical switchboard room, electrical vault, or manhole. The wiring from the EPSS to emergency loads shall be independent of all other wiring. All of the feeders emanating from the generator and generator distribution panel must have the minimum fire-rated protection stipulated by NEC Article 700. State and local codes or authorities having jurisdiction may invoke more restrictive requirements.

There are several methods of addressing the 1- or 2-hour fire separation criteria, but not all methods are approved or listed. Some authorities having jurisdiction, for example, do not accept conduit fire wraps, whereas others may. The use of fire-rated mineral-insulated (MI) cable is a widely accepted method of meeting fire separation criteria for emergency feeders. Another approach is to use architectural treatments such as listed fire-rated enclosures. Mineral-insulated cable may require less room to install than new fire-rated enclosures in existing facilities, but the required fire-rated treatment of its splice boxes and the necessity of closely following the manufacturer's recommended installation methods can make it a challenging installation as well. The engineer should carefully consider all such issues, including the cost of alternatives, before selecting the fire-rated treatment for each project.

Mechanical Issues

Engine Selection. The generator set, its starting battery, and their maintenance will always be the most critical parts of the EPS, but in some cases the application of the generator set makes it difficult for it to perform at its rated capacity.[5] These are the five requirements for a satisfactory installation:

1. A generator set should be sized so that it always operates at more than 30 percent of its capacity to avoid wet-stacking. NFPA 110 addresses the need to avoid wet stacking during regular load testing and also discusses the correlation between generator set loading and engine exhaust temperature. Load banks can also be rented or permanently installed to provide sufficient loading, provided that the installation can connect the load banks safely into the power system. If a load bank is normally used for load-testing a generator set, then provisions are necessary for switching off the load bank and allowing the essential power system loads to be powered from the generator, if an actual power outage occurs during the test period.
2. The generator should be located and isolated on a solid foundation.
3. The generator and its ancillary equipment must be accessible for maintenance and have the proper working clearance.

4. The generator must have a proper air supply.
5. The generator must have sufficient capacity to assume the steady-state emergency load without overheating, as well as the starting kilovolt amperes (SkVA) for motors and other high-inrush current loads, while maintaining voltage and frequency variations within the maximum and minimum parameters recommended by codes, manufacturers' requirements, NEMA standards for driven equipment, NFPA standards, and so forth.

Motor Loads. Special consideration must be given to motor loads because they can draw from 4 to 12 times their full-load running current when starting. The generator must have sufficient kilovolt amperes to start the motor loads on the emergency system. The total capacity of the generator is determined by adding the skVA of all the motors to be started simultaneously and the other loads that will be connected to the generator and using an acceptable voltage dip of between 10 and 30 percent. Single-phase loads should not exceed 50 percent of the generator rating and should be evenly balanced among the three phases of the generator.

The decision to purchase a four-stroke engine or a two-stroke engine requires a comparison of the user's needs with the advantages and disadvantages of each type of engine. Technical papers that discuss the pros and cons of each engine are available from the engine manufacturers, and it requires a detailed engineering analysis to sort out the salient points for each facility.

Derating. The generator should be derated for altitude and temperature; manufacturers provide this information.

Seismic Design Considerations. An EPS must be seismically supported in relation to the seismic zone in which it is located. Seismic zone maps are available to the engineers to assist them in this effort. Consideration must be given to the location of the EPS equipment both as it relates to the building structure and to the effects of an earthquake.[6]

Bolts, anchors, hangers, braces, and other restraining devices should be provided to limit earthquake-generated differential moments between the EPS nonstructural equipment and the building structure. However, the degree of isolation required for vibration and noise control of the EPS equipment should be maintained.[6]

Spring isolators could amplify the relatively small forces generated by an earthquake to a level that could damage the EPS. These isolators should incorporate seismic restraining devices whose requirements are determined by both the engineer and the supplier of the equipment. They must be secured to the equipment base and to the floor or foundation, and stops should be added to limit the motion of the isolators in all directions.[7]

Noise and Vibration.[7] Mechanical systems with mass and elasticity are capable of relative motion. When the motion is repetitive, it is vibration. Engines produce vibrations due to combustion forces, torque reaction, structural mass and stiffness combinations, and manufacturing tolerance on rotating components. These unbalanced forces create a range of undesirable conditions ranging from unwanted noise and high stress levels to ultimate failure of the engine or generator components.[7] To reduce or eliminate vibration and consequently noise, it is necessary to analyze the engine and generator for critical linear and torsional vibration.[7]

Noisy or shaky machines exhibit linear vibration. Torsional vibration is exhibited by high-frequency noise. However, machinery vibration is very complex and has many different frequencies. Measurements of velocity, acceleration, and displacement are used to diagnose problems.[7] Vibrations carried throughout an enclosure cause early failure of auxiliary equipment such as relays, switches, gauges, and piping.[7]

There are several methods for isolating vibration in an EPS such as the use of commercially available fabricated isolators or bulk isolators. These may be spring isolators, rubber isolators, or isolation of the block foundation.

Generator sets can withstand all self-induced vibrations, and no further isolation should be required merely to prolong their service life. However, severe vibrations from surrounding

equipment can harm a generator set that is inoperative for long periods of time. Bearings and shafts can beat out and ultimately fail if these vibrations are not isolated. Exterior vibrations rarely harm a running generator set. The method of isolating the unit is the same for exterior vibrations as it is for self-induced vibrations.[7]

Some rule-of-thumb guidelines are provided for generator set mounting. These general statements normally apply to all generator set mountings, but equipment manufacturer's recommendations must always be followed, and a registered structural engineer's design is required. If no isolation is required, the generator set may be placed directly on the mounting surface. This surface must be capable of supporting at least 25 percent more than the static vibratory loads. Unless the engine is driven equipment that imposes a side load, no anchor bolting should be required. Thin rubber or composition pads are suggested to minimize the unit's tendency to creep or fret the surface of the foundation.[8]

Noise levels must comply strictly with EPA and OSHA standards. Federal, state, and local noise control codes must be strictly adhered to for the installation and operation of an EPS. For example, New York City has its own code on noise control (New York City Noise Control Code).[9] The noise level permitted varies, depending on the zone in which the EPS is located (low-density residential, high-density residential, commercial/manufacturing). It also depends on whether the EPS is operating in the daytime or nighttime and the operating hours of the EPS.[9] These noise levels vary from a low of 50 dBA for a low-density residential area to a high of 150 dBA for 15 min of operation of an EPS.[9] These numbers are only representative of noise control levels and are presented here to provide a base of reference to typical noise levels.[9]

Methods of Reducing Noise.[9] There are several significant components in the total noise emanating from an engine-driven generator set.

Exhaust System. The muffler recommended by the muffler manufacturer cannot eliminate excessive exhaust system noise unless the entire system is solid, is without leaks, and is properly maintained. If the noise level is too high and the muffler is properly installed, it may help to install a packed stack, but replacement of the muffler is likely to be the best solution.

Cooling System. Noise created by intake and discharge cooling air can be reduced by silencers, and it can be less objectionable by directing it away from observers. A remote radiator removes both fan and air noise from the generator set location but may introduce new noise if coolant pumps are located with the generator set.

Fan Noise. Noise generated by the fan is increased by faults such as bent blades or damaged shrouds.

Engine Noise. Only a sound control housing can reduce noise emanating directly from the engine and its accessories. As a rule of thumb, any noise level requirement less than 70 dBA adds appreciably to the installation costs.

Noise Reduction Recommendations. Be sure that the muffler is recommended by the muffler manufacturer for the generator set rating and application. Direct the muffler discharge away from buildings or occupied areas. Use straight rather than curved stacks wherever possible. Minimize the flexible stack length. Changing the stack length may eliminate a sharp rapping sound.[9]

Cooling System. Most EPSs are cooled by radiators, whether they are engine-mounted or located remote from the EPS. The radiators are sized between 15 and 20 percent larger than the engine maximum full-load heat rejection to allow for overload conditions and EPS aging. Furthermore, if the EPS is installed indoors or in an enclosure, it will require additional ventilation and/or cooling to maintain the EPS at its operating temperatures.

Remote radiators are sometimes used when the EPS is installed indoors, mainly because of space limitations in the EPS room. If an EPS is located in a basement, it is usually difficult to bring in the required volume of air to cool the EPS, thus the need for a remote radiator. This entails extra piping, an increase in coolant pump horsepower, and if the radiator is not located in accordance with the manufacturer's recommendations, it may result in pump and seal leakage. Long pipe runs also result in clamped-rubber hose leaks. The overall reliability

of an EPS is reduced by a remote radiator installation. Also, the fan for the remote radiator must be supplied from the generator bus. This could result in a large parasitic load on the generator, depending on the generator capacity and the fan location.

Hot-well systems are used when the static head exceeds the manufacturer's recommendations or if the booster pump imposes an excessive dynamic head.[7] This occurs whenever the horizontal or vertical distance between the remote radiator exceeds the recommended limits. Hot-well systems are installed between the remote radiator and the EPS and must be installed in accordance with the manufacturer's recommendations.

Heat exchangers are also used instead of radiators to cool an EPS. Raw water flows through the exchanger counter to the coolant flow. This provides maximum heat transfer. Because heat exchangers use an outside utility water supply source, they are subject to disruption in the event of an earthquake. Consequently, an outside water supply is not considered a reliable source for EPS cooling. Also, unless the cooling water is obtained from an on-site well, this system cannot be used as a legally required emergency and standby system.

Fuel System. Refer to Art. 3.2.9, "Environmental Compliance and Issues Management," for a licensing-related discussion. Fuel storage tanks are usually located as close as possible to the EPS; however, if gasoline or LP fuel is used, it cannot be stored in the same room as the EPS. Storage tanks can be located in the base of the EPS if the fuel is diesel. Storage tanks can also be located above ground, indoors, outdoors, or buried in the ground. Ideally, the storage tank is located adjacent to the EPS where it requires the minimum piping, control valves, and pumps for operation.

It can be located in the same room as the generator if the fuel used is diesel. However, local building and fire insurance regulation codes must be checked to determine if the fuel storage tank can be located in the same room as the generator or in an adjacent room, outside the building, above ground or under ground.

Type of Fuel. Based on a comparative analysis, most emergency generators that supply power to life-safety circuits use diesel fuel. Other types that may be acceptable, depending upon local requirements, use gas or LP fuel.

Storage Tanks. The storage tank should be located as near to the generator as practicable. The fuel capacity of the tank should be established by evaluating the historical data on power outages for that area in conjunction with the availability of fuel. Careful analysis of these data will ensure that the generator has sufficient fuel to supply power to the EPSS based on the longest historical power outage.

Day Tank.[7] Auxiliary or day tanks are desirable if the main fuel tanks are located more than 50 ft (15.25 m) from the engine, are located above the engine, or are more than 12 ft (3.65 m) below the engine. Total suction head should not exceed 12 ft (3.65 m). Although a day tank does not aid the engine in fast starting, it offers a convenient and ready storage of fuel. Day tanks also provide a settling reservoir so that water and sediment can separate from the fuel. The auxiliary tank is located so that the level of the fuel is no higher than the fuel injection valves on the engine. The tank should be close enough to the engine to maintain a total suction lift of less than 12 ft (3.65 m).

Exhaust System. The exhaust pipe will extend past the height of the tallest adjacent building. State and local authorities strictly regulate the height of the exhaust pipe, as well as the emissions from the generator. Refer to Art. 3.2.9, "Environmental Compliance and Issues Management," for additional licensing-related discussion. Wet stacking is a field term to describe the existence of unburned fuel, carbon, or both in the exhaust system. It is caused by operating the EPS under a light load, as defined by the manufacturer. Its presence is often indicated by the presence of black smoke during engine operation.[6] This, of course, is a very subjective approach for determining the presence of wet stacking and consequently has created much controversy and confusion among owners, engineers, and contractors. NFPA 110 includes testing recommendations that are intended to assist users in avoiding wet stacking. These recommendations now include measuring the exhaust manifold temperature at the

exhaust ports and comparing those measurements with the manufacturer's recommendations.[10] If the engine shows signs of wet stacking, an engine *load run* test is mandatory for a period, as described by NFPA 110, 6-4.2.

Electrical Issues

Common-Mode Failure. When designing alternate or EPSSs, the most common error is installing emergency primary and secondary circuits in the same duct banks, manholes, pull boxes, cable trays, and so forth. Even though the cables for the normal power and the alternate/emergency power may be separated mechanically and may, in some cases, have the required fire rating, this alone may not be sufficient to prevent emergency power cable damage during a normal power cable fault. Whether emergency circuits are primary or secondary, they should be routed in separate duct banks, manholes, cable trays, and pull boxes, wherever possible, to prevent a fault in one system from affecting the other.

Battery and Battery Chargers. The battery is the heart of an EPS, and the battery charger maintains the battery's health. Therefore, it is very important to have the battery load tested and the specific gravity checked regularly. Because code requirements are only minimal requirements, more frequent checks on the heart of the EPS will improve the reliability of the system. The battery charger should be located as close as possible to the battery. The battery charger must be derated for altitude and ambient temperature. This information is readily available from manufacturers. The battery charger and battery pack should be seismically supported for the seismic zone in which they are located.

Grounding. Grounding is probably the least understood and sometimes the most confusing part of the electrical code. The proper grounding of a generator depends on the way it is connected to the normal building power source.

If the switch between the standby generator and utility sources (such as an automatic transfer switch, double-throw safety switch, or interlocked breakers) does not switch the neutral conductors, then the generator source would not be considered a separately derived system (refer to NEC Sec. 250-5), and the generator neutral should not be bonded to ground at the generator (see Fig. 5.2.3-4). A grounding electrode connection at the generator would not be required but could be provided as a supplemental grounding electrode system by the required normal equipment-grounding conductors routed with the phase conductors between the generator and the building utility service.

On the other hand, if a four-pole transfer switch is used and the neutral is switched with the phase conductors, no circuit conductors of the generator source (including the neutral) are solidly connected to the utility source conductors. Thus, the generator would be considered a separately derived system and should be grounded according to NEC Sec. 250-26 (the generator neutral is bonded to ground and a local grounding electrode connection is required). The grounding electrode connection at the generator would be connected to the utility service grounding electrode system by way of the normal equipment-grounding conductors required between the two systems (see Fig. 5.2.3-5).[3]

Emergency Distribution Equipment

Location. The generator should be located so that it is central to the emergency loads to which it is supplying power. The foundation will be seismically designed for the specific seismic zone in which the equipment will be located. In most cases, it is necessary to isolate the generator from the foundation. This will be determined after a detailed evaluation of the site and surrounding facilities. Refer to Sec. 5.1.3, "Structural," for further discussion of seismic design considerations.

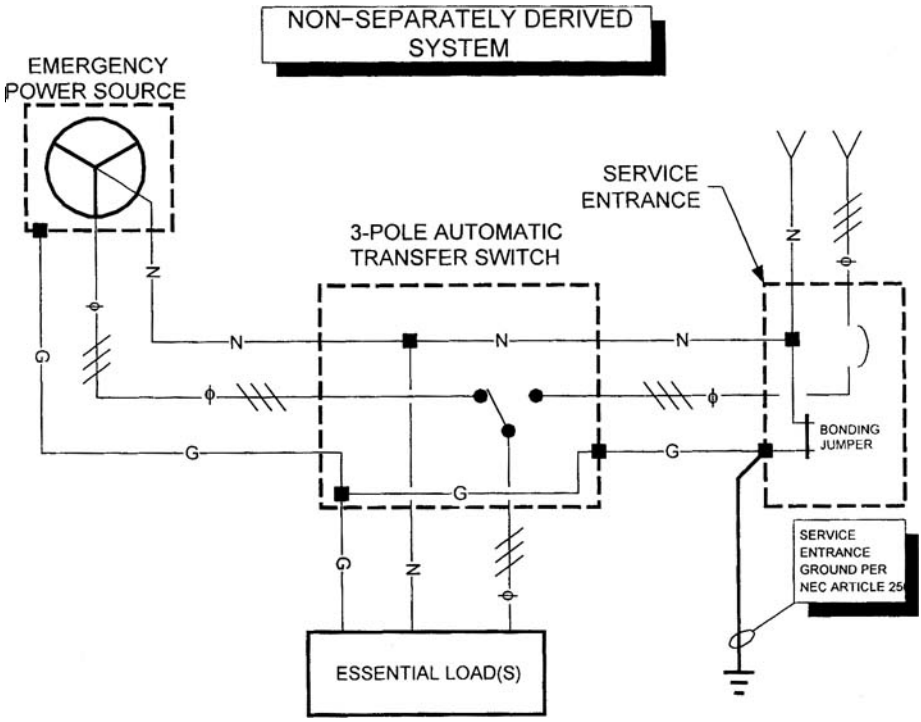

FIGURE 5.2.3-4 Generator grounding figure from NEC Handbook. (*Courtesy of National Fire Protection Association.*)

Fire Separation. A minimum fire separation must be installed between the EPSS and the normal power supply system, as stipulated by NEC Article 700. More restrictive requirements may be invoked by state and local codes or authorities having jurisdiction (see Fig. 5.2.3-6).

Protective Coordination. As with normal power distribution systems, coordination of overcurrent protective devices is extremely important in the EPSS. The overcurrent device nearest to the fault must open and clear the fault. A well-coordinated system isolates the fault at the source and prevents cascading operation of overcurrent devices in a short-circuit condition. The design engineer develops the coordinated system based on the one-line drawing of the EPSS and vendor information about the overcurrent device. This information should be checked, adjusted, and finalized during installation and an as-built coordinated system must be submitted to the design engineer for approval.

Voltage and Frequency Requirements. Emergency power supply systems are used in different locations and for different purposes. The requirement for one application may not be appropriate for other applications. NFPA 110 recommends two levels of equipment installation, performance, maintenance, and testing:

1. Level 1 defines the most stringent equipment performance requirements for applications where failure of the equipment to perform could result in loss of human life or serious injuries. All Level 1 equipment shall be permanently installed.[6]

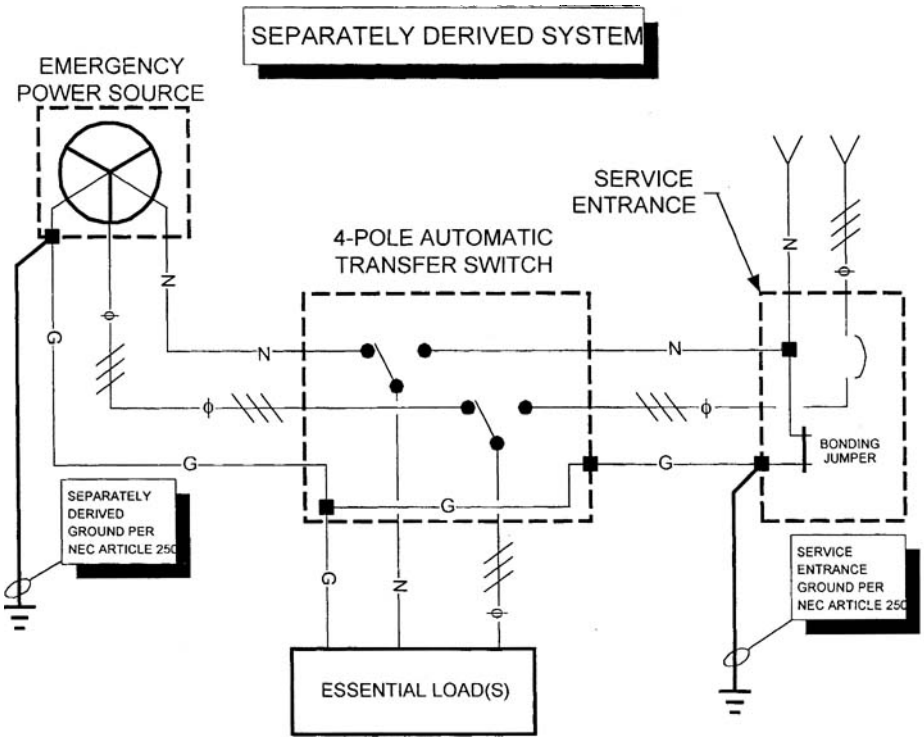

FIGURE 5.2.3-5 Generator grounding figure from NEC Handbook. (*Courtesy of National Fire Protection Association.*)

2. Level 2 defines equipment performance requirements for applications where failure of the EPSS to perform is less critical to human life and safety and where it is expected that the authority having jurisdiction will exercise its option to allow a higher degree of flexibility than provided by Level 1. All Level 2 equipment shall be permanently installed.[6]

The intent of Level 1 and Level 2 systems is to ensure that loads provided with EPSS are supplied with alternate power of a quality essentially equal to commercial power or acceptable for the load within the time specified for the type and for a duration specified for the class.[11] (See ANSI C84.1, *Standard for Voltage Ratings for Electrical Power Systems and Equipment.*)

Provisions for Expansion. The fact that the EPS might be used for peak shaving, load sharing, and/or for supplying nonessential loads during loss of the normal power source should be considered. This would justify allowing for expansion in generator capacity, keeping in mind the disadvantages of operating a generator that is oversized for the EPSS it is serving, such as wet stacking, carbon buildup, and possible water contamination.

The design engineer will not undersize a generator; therefore, the user has the ultimate responsibility for the loads put on the EPSS. It is recommended that regular load measurements be made during generator testing and that the loads be adjusted for maximum generator usage, including the SkVA for motors.

One cannot simply sample EPS loads to obtain an estimate of the actual emergency system demand. This sampling commonly occurs with a hand-held ammeter during a field walkdown.

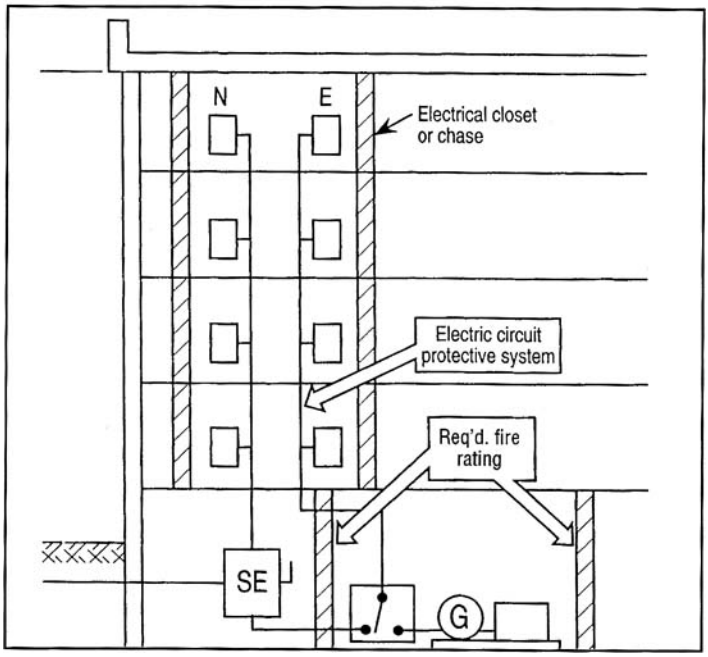

FIGURE 5.2.3-6 Enhanced protection is required for feeders to emergency equipment. One of the options is shown here for cases where a fire suppression system is not employed. Depending upon the actual configuration of the emergency system, a combination of fire suppression system, fire-resistance ratings, and electrical circuit protective systems may have to be used. (*Courtesy of* Electrical Construction and Maintenance Magazine: Practical Guide to Emergency, Standby and Other Auxiliary Systems.)

The time of day when EPS loads are sampled has an impact on the accuracy of the sampling. For example, if the maximum system demand load occurs for a short period in the afternoon, then just sampling the individual branch loading at other times of day would result in inaccurate results. Times of use load measurements of the essential system loads are very useful in predicting total system loading. These measurements can be made on the load sides of individual transfer switches or at other appropriate locations. One convenient approach using the ability of spreadsheets to add ranges graphically with stacked area graphs has been discussed with respect to health care facilities, but the approach can be applied to other types of facilities as well.[12]

Managing Emergency Power Load Growth. It is important to avoid the possibility of overloading the EPSS by adding loads indiscriminately. The facility manager should be aware of the spare margin in an EPSS, taking into account that unplanned load additions can occur during an actual emergency.

Control Monitoring and Alarms

Location of Alarm Equipment. A control panel for the EPS shall be provided as specified in NFPA 110 3-5.5.1.

Lighting Systems

Lighting. Sufficient light must be provided to illuminate the means of egress for safe and orderly evacuation of the building in the event of a loss of normal power, a fire in the building, or both. NFPA-101 and state and local codes set the requirements for illumination of means of egress.

The emergency illumination of a facility may be accomplished by either battery lighting units or by the part of the normal lighting system that is supplied by a prime mover-operated electric generator (EPS). It could also be supplied from both of these systems. The battery units should be so arranged so that failure of any unit does not leave the area in darkness. The emergency lighting fixtures supplied from the EPS shall be circuited so that failure of any light or circuit does not leave the area in darkness. Once you have satisfied the criteria for egress lighting, other areas should also be considered.

Lighting for 24-Hour Production Operation. Supplemental lighting for switchboard rooms and associated repair areas—a good design tip in switchboard and switchgear rooms and EPSS locations is to use lighted handle switches for emergency lighting if the emergency lighting is normally switched off when the space is unoccupied.

Perimeter Security Lighting. This includes transportation lights, traffic lights, warning lights, and so forth. High-voltage discharge lighting fixtures should not be used on emergency lighting circuits unless they are of the instant restrike type or are fitted with an auxiliary lamp that remains on during the restrike time of the high-voltage discharge-type fixture.

Table 5.2.3-1 from IEEE Std. 446-1987 provides typical areas to be illuminated for three separate criteria:

TABLE 5.2.3-1 Typical Emergency and Standby Lighting Recommendations

Standby*	Immediate Short-Term†	Immediate Long-Term‡
Security lighting	Evacuation lighting	Hazardous areas
Outdoor perimeters	Exit signs	Laboratories
Closed-circuit TV	Exit lights	Warning lights
Night-lights	Stairwells	Storage areas
Guard stations	Open areas	Process areas
Entrance gates	Tunnels	Warning lights
Production lighting	Halls	Beacons
Machine areas	Miscellaneous	Hazardous areas
Raw materials storage	Standby generator areas	Traffic signals
Packaging	Hazardous machines	Health care facilities
Inspection		Operating rooms
Warehousing		Delivery rooms
Offices		Intensive care areas
Commercial lighting		Emergency treatment areas
Displays		Miscellaneous
Product shelves		Switchgear rooms
Sales counters		Elevators
Offices		Boiler rooms
Miscellaneous		Control rooms
Switchgear rooms		
Landscape lighting		
Boiler rooms		
Computer rooms		

* An example of a standby lighting system is an engine-driven generator.
† An example of an immediate short-term lighting system is the common unit battery equipment.
‡ An example of an immediate long-term lighting system is a central battery bank rated to handle the required lighting load only until a standby engine-driven generator is placed on-line.

Codes, Rules, and Regulations

Many states and municipalities have adopted their own specific codes for emergency lighting, in addition to those set down by the following four organizations[13]:

1. *Occupational Safety and Health Administration (OSHA).* OSHA is charged with enforcing compliance and makes reference to the NEC and other NFPA codes.
2. *ANSI/NFPA 70, the National Electrical Code (NEC), Art. 700.* Sets forth the standard of practice for installation, operation, and maintenance of emergency lighting equipment.
3. *ANSI/NFPA 101, the Life Safety Code.* Concerns itself with the specification of locations where emergency lighting is considered essential to life safety and specifics on exit marking.
4. *Underwriter's Laboratories, Inc.* Tests and approves equipment to uniform performance standards as established by ANSI/UL 924 (IEEE, p. 54).[13]

Power Distribution

Power. Other than life safety equipment, the selection of equipment and systems to be installed in the EPSS depends on the type of occupancy of the building. Figure 5.2.3-7 could serve as a typical guide for an EPSS, but it is not intended as a recommendation.

Other Legally Required Standby Systems.[13] Other legally required standby systems are subject to similar special laws and regulations for emergency power. Some examples include the following:

- Controls for pressure vessels, such as boilers or ovens, where a failure may result in a life-endangering explosion or fire
- Air-supply systems for persons in a closed area
- Fire pumps, alarms, and systems
- Communications systems in hazardous areas
- Industrial processes in which the interruption of power would create a hazard to life

To meet these or other specialized emergency power requirements, the assistance of a registered professional engineer who is experienced in the particular problem area should be obtained (ANSI/IEEE Standard 446-1987, Chap. 3).[13]

The circuit for the EPSS shall be independent from all other circuits and shall not share the same raceway, junction box, or cabinet with other circuits.

Optional Standby Systems. Optional standby systems are intended to protect public or private facilities or property where life safety does not depend on the system's performance. Optional standby systems are intended to supply on-site power to selected loads either automatically or manually.[3]

These systems are installed in industrial and manufacturing facilities where a loss of power would result in a very expensive start-up procedure for computerized processing machinery. In some plants such as sugar refineries, it may take up to 24 hours to get the facility back on-line. In the food industry, large walk-in refrigerators and freezers would also be adversely affected. In commercial facilities such as office buildings, banks, hotels, utility companies, and stock brokerage firms, where day-to-day business depends on the computer, any extended outage would severely affect the operation and, in some cases, cause economic chaos.

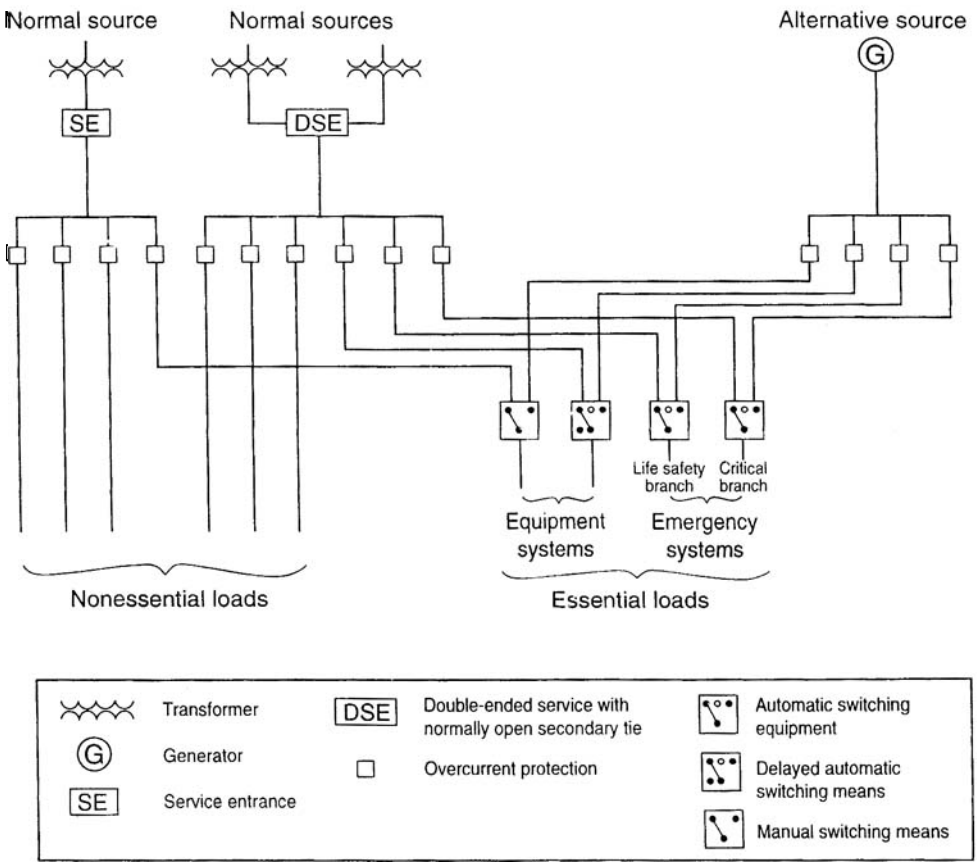

FIGURE 5.2.3-7 One-line diagram illustrating life safety system, equipment for delayed automatic connection, and other equipment for delayed manual connection. (*Courtesy of Motor and Generator Institute,* Healthcare Circuit News.)

Each facility is unique in its requirements for optional standby power. A study of the existing, normal electrical services, along with other available emergency sources, should be completed before any design is attempted. It is also necessary to have a very good understanding of the day-to-day operations of that facility. These form the basis for a design.

SYSTEM SELECTION

The selection of an EPSS is based on the type of occupancy of the building, as well as on its physical characteristics. However, once the emergency system requirements are satisfied, there are many designs to choose from. Refer to Arts. 5.2.1, "Service Entrances," and 5.2.2, "Electrical Distribution Systems," for a detailed treatment of the following three options:

1. Double-ended service with one generator
2. Single-ended service with one or more generators
3. Double-ended service with two levels of emergency service

Selection and Scope

Engine Generator. The selection of the EPS, as well as the scope of the EPSS, is based on the type of occupancy and the physical characteristics of the building.

Generator Set Sizing. Other than in hospitals, where the NEC requires sizing the generator set for the full capacity of the connected emergency system load, EPS capacity is based on the total connected life safety load, plus other designated emergency loads with appropriate demand factors. These designated loads may be automatic, delayed automatic, or manual transfer. The duration of the load is also an important factor in sizing the generator. This information can be obtained from utility bills, as well as from daily, weekly, and monthly load monitoring. This information is used to select the generator capacity and quantity required for best operating economy. An analysis of motor loads on the EPS is required to ensure that the generator has sufficient starting capacity for the motors. Table 5.2.3-2 from the Caterpillar *Application and Installation Manual* shows typical voltage dips for the applications listed.

Advantages and Disadvantages of Diesel-Driven Generators. Each engine generator vendor has its own criteria for the advantages versus disadvantages of diesel versus gas engine generators, but the following is an objective comparison from IEEE Std 446-1987, Chap. 4.[13] In evaluating the merits of diesel engine versus gas turbine prime movers, the following advantages and disadvantages of each should be considered:

- *Fuel supply.* Gas turbines and diesel engines can generally burn the same fuels (kerosene through No. 2 diesel).
- *Starting.* Where the application requires acceptance of 100 percent load in 10 s, diesel generator sets can be provided that can meet this requirement. Most gas turbine generators sets require more than 30 s.
- *Noise.* The gas turbine operates more quietly and has less vibration than the diesel engine.
- *Ratings.* The gas turbine is not readily available in sizes less than 500 kW, whereas diesel engine units range from 15 kW or lower.
- *Cooling.* Diesel engines in the larger sizes normally require water cooling, whereas gas turbines are normally air-cooled.
- *Installation.* Gas turbines are considerably lighter and smaller. Turbines also require less total cooling and combustion air and produce minimal vibration. Installation costs are normally less and rooftop applications are more feasible.

TABLE 5.2.3-2 Typical Voltage Dip Limitations

Application	Condition	Permissible Voltage Dip
Hospital, hotel, motel, apartments, libraries, schools, and stores	Lighting load, large Power load, large Flickering highly objectionable	2% Infrequent
Movie theaters	Lighting load, large Flickering objectionable Neon flashers erratic	3% (sound tone requires constant frequency) Infrequent
Bars and resorts	Power load, large Some flicker objectionable	5–10% Infrequent
Shops, factories, mills, laundries	Power load, large Some flicker objectionable	3–5% Frequent
Mines, oil fields, quarries, asphalt plants	Power load, large Flicker acceptable	25–30% Frequent

- *Cost.* First cost for diesel engines is lower than gas turbines, but overall installed cost sometimes becomes comparable due to the lower installation costs of the gas turbines.
- *Exercising.* The cyclic operating requirements under load are more rigid for diesel units than for gas turbines.
- *Maintenance.* The gas turbine is a simpler machine than a diesel engine. However, repair service for a diesel engine is generally more readily available than for a gas turbine.
- *Efficiency.* Under full load, the diesel engine operates more efficiently than a gas turbine. However, the reduced exercising requirements for the gas turbine normally make the turbine the lower fuel consumer in standby applications.
- *Frequency response.* The gas turbine generator is superior in full-load transient-frequency response. (ANSI/IEEE Std 446-1987, Chap. 4).[13]

Nonlinear Loading Issues. Harmonics are current or voltage waveforms generated at frequencies other than the fundamental frequency that, in most cases, is 60 cycles/s in the United States. Because all of our equipment is designed for 60-Hz operation, any other current or voltage at another frequency is not used by the load. Consequently, harmonic current circulates between the source and the load and is manifested by overheating of motors, transformers, generators, relays, coils, contacts, and conductors.

In the past, it was customary to oversize conductors, transformers, motors, and such to compensate for the heat generated by these unwanted currents and voltages. The better solution is to design the equipment to handle the harmonic content of the loads and/or install filters at strategic locations through the EPSS sized to filter out the unwanted frequencies. When sizing a generator, it is imperative that you know the harmonic content of all equipment that is to be connected to the EPS.

Various types of loads consisting of silicon-controlled rectifiers (SCR) (thyristors) present special problems for generator sets. The problems are generator stator heating and interference with the generator voltage system.[14]

The most commonly encountered SCR loads are battery chargers used with uninterruptible power supplies (UPS systems), solid-state, reduced-voltage, motor starters, and variable-frequency drive motor speed controls.[14] In general, generators with permanent magnet exciters provide the best performance for this type of load.[14] Other excitation systems typically require voltage regulator filtering, generator derating, or both, when used with this type of load.[14] Specifications for generator sets to be used with a load should include detailed information about the equipment to be operated so that the generator supplier can advise the correct size and options to ensure satisfactory performance.[14]

Switchgear. After the size of the generator set is established, the next task is selecting the emergency distribution equipment, switchboards, transfer switches, and generator control panels. If the EPS is used for other than pure emergency loads, such as for load sharing or peak sharing, then paralleling switchgear is also needed. Paralleling switchgear can also be used to parallel multiple generator sets with priority load shedding where desired.

The generator set output control panel can be programmed by using the paralleling switchgear to provide power to either one of these services and still maintain the emergency system on standby mode when normal power is lost. The switchgear lineup could be made up of the main circuit-breaker cubicle with associated ammeter, voltmeter, wattmeter, wall-hour meter, kVA, kW, and kVAR meters, distribution circuit-breaker cubicle, transfer switches, and synchronizing equipment cubicle, if needed. The transfer switches could also be located near the load that they serve (decentralized approach). This depends on the location of the normal power source in relation to the EPS and the loads that it serves. However, a central location is desirable for operating, maintaining, and testing these units.

Transfer Switches. Whereas the battery is the heart of the EPS, the automatic transfer switch is the brain of the EPSS. It receives input signals from various parts of the EPSS and

responds by transferring the electrical load from the normal source of power to the emergency source of power, instantaneously or within a set time delay. The manual transfer switch is used for planned load transfer and is controlled by the operating personnel.

There are two modes of operation for automatic transfer switches, the open transition transfer (OTT) and the closed transition transfer (CTT).

Open Transition Transfer.[3] In an OTT transfer, the power output is broken or interrupted before the transfer is made to the new source. There is a definite break in power as the load is taken off one source and connected to another. Although this type of transfer is quite simple, the resulting time delay between break-and-make creates a definite interruption of power to critical loads. Refer to the ASHE 1998 conference paper by Stymiest, Dean, and Seth for a detailed discussion of such issues.[15]

Closed Transition Transfer.[3] The most important advantage of the CTT transfer is that there is no interruption in power to a critical load, if both sources of power are energized. When using the CTT, both power sources are connected to the load before the break occurs. It is vital that the two sources have the same voltage and frequency and that they are synchronous. Therefore, a protective system is required to provide synchronization, making these transfer switches more complex than OTT types. A comparatively simple synchronizing system can be used, however, because the two sources are paralleled for only about 100 ms.

Closed Versus Open Transition Transfer Switches.[3] Depending on the situation, OTT and CTT switch operation may be identical or totally different. For example, if a normal power source fails, OTT and CTT switches will transfer the load to an EPS in the same manner, as can be seen by comparing (A), (B), and (C) in Figs. 5.2.3-8 and 5.2.3-9. They both operate in a break-before-make manner in such a circumstance.

Because the EPS must attain a prescribed voltage and frequency before transfer, there are typically 3 to 6 s before this source can be connected and the load powered. For equipment that cannot tolerate this small period of power loss, special backup systems are required, such as a UPS. Therefore, it should be understood that neither an OTT nor CTT is a substitute for a UPS.

When the normal power source is restored, however, OTT and CTT switch operations differ greatly. In the retransfer mode, the OTT switch [Fig. 5.2.3-10 (D) through (F)] operates again in a break-before-make manner, and the load again sees a momentary power outage varying from 50 to 500 ms (3 to 30 Hz), depending on the manufacturer.

On the other hand, the CTT switch (Fig. 5.2.3-10) retransfers the load in a make-before-break sequence because it senses that both power sources are now energized. In other words, the normal and emergency sources are momentarily paralleled during retransfer, typically for about 100 ms or less.

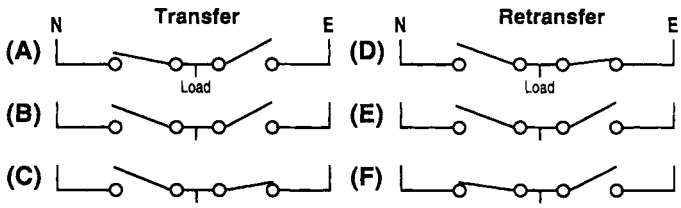

FIGURE 5.2.3-8 Operation of an open-transition transfer switch. During transfer, in (A) the load is connected to the normal source (N); in (B) the load is disconnected from the normal source; and in (C) the load is connected to the emergency source (E). When normal power is reestablished, retransfer takes place. In (D) the load is still connected to the emergency power; in (E) the load is disconnected from the emergency source; and in (F) the load is connected to the normal source. (*Courtesy of* Electrical Construction and Maintenance Magazine: Practical Guide to Emergency, Standby and Other Auxiliary Systems.)

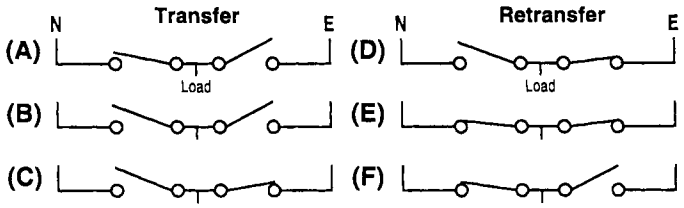

FIGURE 5.2.3-9 Operating sequence of a closed-transition automatic transfer switch. When transfer is required because of failure of the normal source, there is no paralleling of sources. On retransferring, both sources are available and there is a brief period (E) during which the sources are paralleled. (*Courtesy of* Electrical Construction and Maintenance Magazine: Practical Guide to Emergency, Standby and Other Auxiliary Systems.)

Testing an emergency source such as a generator set also results in different operational sequences between both types of switches. In this case, the main power source is still available. An OTT operates in the same fashion as if a normal power source failure had occurred. The switch functions in a break-before-make manner in both the transfer and retransfer modes. Again, the load is without power for a very small period of time during transfer.

For the CTT switch with provisions for testing (Fig. 5.2.3-10), a make-before-break operational sequence occurs because both power sources are energized. In this instance, the load does not see any power outage upon transfer to the generator for testing nor upon retransfer to the normal source

Batteries. Because the battery is the heart of the EPS, considerable care must be taken in selecting the right size of unit for the generator starting. It should be installed in a dry, well-ventilated area and must be accessible and have sufficient workspace for weekly, monthly, and yearly testing and maintenance.

Batteries are also used for tripping circuit breakers during an emergency load-shedding sequence, providing power for control systems and other emergency lighting needs. Metalwork, conduit, and wiring adjacent to the battery must withstand corrosive action.

The NEC has strict requirements for batteries that are used as a source of supply for emergency systems and legally required standby systems. IEEE Std-450 provides recommended monthly, quarterly, and yearly maintenance inspections. The battery charger maintains a float charge on the battery system. The level of the float charge must be obtained from the manufacturer and is based on the battery plate alloy and the specific gravity of the electrolyte. The

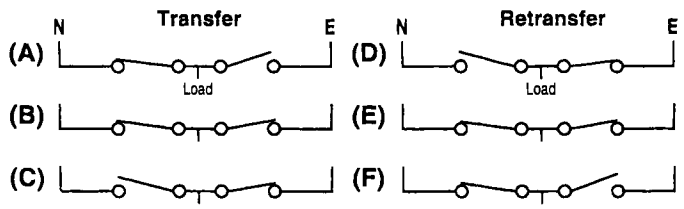

FIGURE 5.2.3-10 Closed-transition switch with provisions for testing is used when emergency source must be tested without power interruption to assure that it can carry the load. In the operating sequence, paralleling takes place both during the transfer sequence (B) and during retransfer (E). (*Courtesy of* Electrical Construction and Maintenance Magazine: Practical Guide to Emergency, Standby and Other Auxiliary Systems.)

float charge is critical to both the performance and life expectancy of the battery. The trickle charge, which is different from the float charge, is a charge given to a battery to maintain its fully charged condition when it is not supplying power to the load.

Battery chargers must be derated for both temperature and altitude (IEEE Std 446-1987, Fig. 34, p. 144).[1]

Uninterruptible Power Supply (UPS). A UPS by its description is a source of constant power. The NEC approves the use of UPS for supplying power to emergency and legally required standby systems. It is an integral part of the essential electrical system, and receives power from both the normal and alternate source. There are many types of UPS systems available on the market that can be classified under two categories: (1) static UPS and (2) rotary UPS. A UPS should be used only for loads that cannot tolerate a 10-s outage or for critical electronic equipment sensitive to voltage and frequency variation. There can be many configurations of a UPS. For example, a nonredundant or basic UPS or a redundant UPS provides a standby unit if the other UPS fails; a nonredundant UPS with static transfer switch increases the system's overall reliability, if a rectifier fails, by providing a static transfer around the faulted UPS; finally, a parallel redundant UPS is used where reliability is of paramount importance. Other system configurations can be designed on the basis of the owner's needs. Typical units from 30 to 600 kVA at 0.8 PF have an efficiency range between 77 and 90 percent. The efficiency improves as the kilovolt amperes increase. Because a UPS is an inherent generator of harmonics, the EPS must be designed to compensate for the extra heat load or by adding filters. (See discussion under harmonics.)

The static UPS is normally used as part of the emergency or legally required standby systems to provide power to critical loads during the 10-s period between which normal power is lost and the alternate power supply comes on-line. It also maintains a steady-state voltage and frequency during internal or external voltage variations. Typically, the standard unit has sufficient capacity to supply the designated load for 15 to 30 min. Larger units are available with up to 8 hours of capacity.

The UPS is an inherent generator of harmonic current due to the firing circuit of the SCR. Therefore, filtering is required in both the input and output of the UPS. The advantage of the rotary UPS is that it can provide clean power regardless of the quality of the input power.

The batteries for a UPS should be located on a well-designed, accessible battery rack in a well-ventilated room adjacent to the UPS. It is important to keep the power wiring between the UPS and the battery as short as possible to prevent power losses.

The layout of the battery rack should allow easy inspection of all of the battery terminals. The batteries should be mounted on a stair rack so that no battery is mounted directly over another. This allows for easy replacement, inspection, and maintenance, and common-mode failure where a battery fails (leaking acid, explosion, etc.) will have a minimum effect on the other batteries. It also provides better air circulation and heat dissipation. Based on the manufacturer's recommendations, some batteries can be mounted on vertical racks, if space requirements are an issue.

To size a battery for a UPS, you must know the kilovolt-amps (kVA) of the UPS and the power factor and efficiency of the inverter. Then, the battery kilowatts are equal to the UPS kVA multiplied by the power factor and divided by the inverter efficiency. There are other factors to consider in the design of a battery system for a UPS such as load growth, the voltage window of the UPS inverter, up-time required, battery room temperature, aging requirements, and end-of-life capacity. Before you can establish the battery capacity, the kVA of the UPS must be determined.

It is best to have a measured load as opposed to a calculated load in establishing this. However, this may not be possible for a new installation. In that case, it is necessary to identify all motor loads, resistive loads, and nonlinear loads. These loads are totaled, and the appropriate demand and diversity factors are applied to obtain the actual load. Then, it is necessary to specify the percentage of the load represented by the nonlinear load and the crest factor. It is incumbent on the manufacturer to supply any derating factors for its equipment.

Many UPS systems have an adjustable input-voltage-sensitivity window. Where such UPS systems are powered by generator sets, which are commonly less stable than electric utilities, the UPS sensitivity should be broadened to account for allowable input voltage variations without transferring from the generator power to the UPS internal batteries.

Designing for Maintenance

Preventive Maintenance.[1] Once it has been determined through reliability analysis that an emergency or standby power system is justified, available systems should be evaluated to select one that will economically satisfy the application requirements. Selection of the proper system requires that installation practices and maintenance procedures be sufficiently emphasized. After the system has been selected and the responsibility for it has been established, the plans for preventive maintenance should be completed. Preventive maintenance for electrical equipment consists of a system of planned inspections, testing, cleaning, drying, monitoring, adjusting, corrective modification, and minor repair to maintain equipment in optimum operating condition and with maximum reliability.[1] Without proper emphasis on maintenance from the design stage through to operation, the system can rapidly become unreliable and fail to meet the intended design goal.[1] Some of the maintenance problems experienced during start-up testing and operation result directly from inadequate input during the design process and design oversight. The most important of these is generator capacity—too small or too large. It is very important that the generator match the load it is serving, as well as the type of load. (See the section on generator sizing.)

Location of Generator. The gold standard for the generator location is on-grade, indoors or outdoors. Because this is premium space for most facilities and the generator installation does not add to the aesthetics of the building, it is usually relegated to a less adaptable space such as the basement or roof.

Locating the generators in the basement is a maintenance headache and also an economic and operational issue. The generator will require a complete ventilation system or air-conditioning system that will be supplied from the EPSS. The remote radiator fan is also supplied from the EPSS. These are parasitic loads that reduce the available generator capacity. These systems—extra fans, motors, pumps, valves, and piping—add to maintenance requirements. Special isolation systems must be designed to isolate the generator, muffler, and exhaust stack from the building structure. Provisions must be made for safe installation and removal of the generator. This will involve a structural design for a removable slab on a ceiling of the generator room and a crane boom for generator installation and removal.

Provision for Load Testing. Identifying the emergency loads or, if necessary, load banks that will be used for testing the generator should be considered. A control scheme should also be incorporated as part of this design that returns the generator to the emergency mode when an actual power outage occurs. This will reduce the maintenance effort during the weekly, monthly, and yearly testing periods.

Accessibility. The code requires a minimum of 3 ft of working clearance around the generator. Most designers follow the minimum requirements in order to meet the space restriction criteria of the project. When the generator is undergoing a major overhaul, it may be necessary to remove the engine and shaft. This requires a minimum of 6 to 8 ft of working clearance. Good design practices and past experience should dictate the working clearance around generators.

Maintenance Downtime. In designing an EPS, the fact that the generator and engine need to be off-line for regular yearly maintenance, emergency repairs, and even load sharing or peak sharing must be considered. In these instances, sufficient flexibility shall be built into the

Next Page

design to ensure that emergency power is available within the time required. Having more than one generator on a common bus is one way of meeting this criterion. Other ways of meeting this requirement would be provisions for a temporary generator tie-in. If the generator is being used for load sharing or peak shaving, a control scheme should be installed that would safely transfer the generator from load sharing/peak shaving to the EPS.

Normally, the design of an EPS system does not include provisions for installing a remote generator. Whenever the generator needs to be replaced or repaired, provisions for connecting a temporary generator should be available to the maintenance department.

Flexibility for Testing. Sufficient flexibility must be built into the EPS to allow for regular weekly, monthly, and yearly testing. This would include all of the features listed under the generator downtime and provide for testing when normal power is available, such as simulating a loss of normal power. Load testing has its own set of possible costly consequences, such as broken crankshafts, destroyed valve trains, bent rods, and failed breakers. However, the other side of the coin is that testing may bring to light incipient failures that would have occurred anyway later, perhaps during an actual normal power outage. It is good practice to switch loads in steps rather than in full-load applications, unless such full-load stepping is the intent of the test itself. In high-reliability applications such as hospitals, all transfer switches in the emergency system have bypass switches integral with the transfer switch. These bypass switches allow withdrawing the automatic transfer switch–operating mechanism for maintenance, troubleshooting, or repair without requiring that the load itself be taken out of service.[16]

Load Banks. Load bank connections to the EPS should be both automatic and manual. Extreme safety precautions must be exercised when using load banks.

Maintenance and Testing. The continuing reliability and integrity of the EPSS depend on an established program of routine maintenance and operational testing. The routine maintenance and operational testing program shall be based on the manufacturer's recommendations, instruction manuals, and the minimum requirements of NFPA 110, Chap. 6.[5]

The goal of preventive maintenance plans is to ensure that equipment is in optimum operating condition. Because the equipment is part of an emergency and standby system, it becomes more important and a greater challenge. Preventive maintenance now becomes a science of anticipation and prediction of failures. In this case, the following vital precautions should be taken:[1]

1. Make sure that the installation will not be subject to ventilation problems or obstructed by stored materials.[1]
2. Place regular test responsibilities on trained personnel, and schedule tests frequently to ensure operation when required.[1]
3. Gasoline and, to a lesser extent, diesel fuels deteriorate when stored for extended periods. Inhibitors can be used to reduce the rate of deterioration, but it is sound practice to operate a system using these fuels so that total operating time results in a complete fuel change every few months.[1]

Typical Maintenance Schedule. The following maintenance schedule from IEEE-446 is presented as a typical service guide for an 1800-rpm unit. It is not intended as a recommendation.

Every 25 h of operation (or 4 months):

- Adjust fan and alternator belt.
- Add oil to cup for distributor housing.
- Change oil in oil-type air filter.

Previous Page
Copyrighted Materials
Copyright © 2001 Knovel Retrieved from www.knovel.com

Every 50 h of operation (or 6 months):

- Drain and refill crankcase.
- Clean crankcase ventilation air cleaner.
- Clean dry-type air cleaners.
- Check transmission oil.
- Check battery.
- Clean external engine surface.
- Perform 25-h service (preceding).

Every 100 h of operation (or 8 months):

- Replace oil filter element.
- Check crankcase ventilator valve.
- Clean crankcase inlet air cleaner.
- Clean fuel filter.
- Replace dry-type air cleaner.
- Perform 25- and 50-h service (preceding).

Every 200 h of operation (or 12 months):

- Adjust distributor contact points.
- Check spark plugs for fouling and proper gap.
- Check timing.
- Check carburetor adjustments.
- Perform 25-, 50-, and 100-h service (preceding).

Every 500 h of operation (or 24 months):

- Drain and refill transmission.
- Replace crankcase ventilator valve.
- Replace one-piece-type fuel filter.
- Check valve-tappet clearance.
- Check crankcase vacuum.
- Check compression.
- Perform 25-, 50-, and 100-, and 200-h service (preceding).

ARTICLE 5.2.4
RACEWAY AND CABLE SYSTEMS

Joseph R. Flocco, Jr., P.E., Account Manager and Consulting Engineer
Siemens Energy and Automation, Inc., Alpharetta, Georgia

RACEWAY SYSTEMS

This article provides an overview of materials and methods used to distribute electrical power for lighting, heating, cooling, and power distribution. These systems are recognized and described in the National Electrical Code (NEC). The NEC is not a design guide but is used by local authorities to determine if a minimum level of reliability and safety has been achieved. Engineers, designers, and installers are cautioned to refer to the NEC for a complete treatment of permissible applications.

Nonmetallic Conduit

Nonmetallic conduit is available in polyvinyl chloride (PVC) and fiberglass varieties. These products are generally allowed in all installations except theaters. They are either directly buried or encased in concrete for added strength when passing under roadways or parking areas; these nonmetallic conduits are also useful for burial in soils that are corrosive, provided that the conduit is specifically listed for use when subjected to such chemicals. Concrete encasement is also used where these conduits enter a building to protect against shearing of the conduit by settling of the building above it. These products are commonly used for service entrance cable from the electric utility company, for large feeders under or between buildings, and for roadway and parking lot lighting. Schedule 80 PVC is a thick-walled PVC conduit that is directly buried when there is little danger of crushing or damage from traffic over the top of the ducts or excavations. Schedule 40 PVC, a thinner-walled plastic conduit, is encased in a concrete envelope and used underground to give added protection from heavy weights passing over the ducts and from excavation operations that might accidentally come in contact with it. When concrete encasement is used, conduits are generally spaced so that their connecting fittings are easily tightened and so that the spacing allows for heat dissipation from power flow in the conductors and for the concrete to flow adequately in and around each pipe during concrete pouring.

Metallic Conduit

Metallic conduit is available in several designations related to its thickness, strength, and ultimately its intended and allowed uses. Generally, the smallest trade size is ½ in.

Electrical metallic tubing (EMT). The least expensive of the metallic conduits and commonly referred to as *tubing*. It is limited to areas where it is not subject to physical damage, and if it is exposed, these are areas generally at least 8 ft above the floor. It is not generally used to support lighting fixtures.

Intermediate metal conduit (IMC). A thick, rigid conduit that uses threaded connections and preformed couplings and connectors. An IMC may be field-bent within NEC-allowed

radii, depending on the type of conductors that are going to be installed. Intermediate metal conduit is available in aluminum or steel in diameters up to 4 in. It can be used in all locations when listed for the intended location or environment.

Rigid metal conduit. The thickest wall conduit and, like the intermediate type, uses preformed couplings and connectors but can be field-bent within NEC requirements. Its maximum trade size is 6 in. Generally, rigid metal conduit is made of steel but may also be aluminum. A trade size of ⅜ in is allowed under certain conditions for motor installations. Aluminum conduit has the benefit of lower weight, which translates into easier installation and lower costs.

Cable Trays and Wireways

Cable trays and wireways are raceway systems that are capable of carrying the largest quantities of cables for power, instrumentation/control, and telephone/data. Cable trays include ladder, center-spline, or channel types. These systems consist of standard fittings and straight lengths in open and closed varieties. Large numbers of power-carrying conductors can be installed in these raceways without derating (lowering the ampacity rating of a conductor) when conductors are installed as required by the NEC. Cables for use in cable trays must be listed for such use.

Wireways. Enclosed, square, or rectangularly shaped raceways. Standard building wire may be installed, and they are often used in laboratories for installing multiple feeds to laboratory benches or when mounting multiple motor starters on a backboard and using and tapping a single feeder as their supply.

Flexible conduit. Used for connections to equipment. It allows for slight adjustments and limits transmission of vibrational noise from equipment to the building structure to which it is attached. Typically, jacketed liquid-type construction is used, especially in mechanical spaces where moisture may be present.

Conductors and Conductor Systems

These systems are the means by which power or signals are transmitted throughout the building or campus facility. Conductors are installed in raceways or include their own raceway system, as those described previously and listed as assemblies to carry power, control, or other electrical signals.

Building wire. Available in aluminum or copper with insulation made of various natural and man-made materials, including rubber and plastics. The materials used in constructing insulation determine (1) whether the cable can be used in wet or dry installations, for direct burial, or for installation above hung ceilings when not installed in raceway, and (2) its environmental temperature limitations and its ampacity within the material's temperature rise.

Mineral-insulated cables. Special fire-rated cables that are often used as emergency feeders and branch circuitry. The NEC also allows other means of establishing emergency circuits using standard conduit and cable, which are usually considered because they can offer some cost savings.

Armored cable. An assembly of insulated conductors enclosed in a flexible metallic covering. It is allowed in concealed and exposed installations in most types of locations and buildings. Because conductors and conduit are one package, it can be easier and less expensive to install compared with conduit systems and building wire. However, because

of its flexibility, it is likely that without well-written specifications requiring that the routing be "rectilinear," (i.e., parallel or perpendicular to the building structure), the cables may crisscross each other, particularly when installed above a hung ceiling.

Metal-clad cable. Used for circuits of 600 V and higher, as well as for special remote control and signaling cables. It also has a metallic sheath. It is suitable for all locations when it has a covering over the metal jacket that is UL-listed for the environment.

Busway (also incorrectly but commonly referred to as *bus duct*). An assembly of bare or insulated copper or aluminum conductor bars, rods, or tubes that are enclosed in a grounded-metal housing. Busway is available in ratings from 100 to 5000 A and has short-circuit ratings that allow using it as the main service entrance feeder.

Feeder busway. Used to distribute large amounts of power and more economical than conduit and wire in many cases. A little more effort and coordination is required when planning a job using busway. However, for feeders of 800 A and larger, busway offers significant savings in installed cost because of reduced labor, and it offers increased efficiency due to its lower impedance. It is more space-efficient and weighs one-third less than the equivalent cable-and-conduit installation.

Plug-in busway. Differs from feeder types only in its ability to attach, or plug in, devices that further distribute or consume the power being distributed. In a high-rise building, vertical bus risers are a common means of distributing power from floor to floor. The busway housing often serves as the equipment-grounding conductor (called *integral*), but some manufacturers also offer an insulated (called *internal*) ground bus, which may be an isolated ground type, if that is desired. Panelboards can be connected directly to the bus, but more often, enclosed fused switches or circuit breakers are installed. Standard conduit and wire feeders are then installed to panelboards from these devices. Direct connection of meters, motor starters, and cable drop boxes are other plug-in options often used to service large horizontal facilities, especially manufacturing types. It offers the same cost and energy advantages compared with conduit and wire as the feeder type. Recent listing rule changes have taken away a commonly used benefit of the plug-in busway—the ability to add new bus plugs without turning off the busway. Bus plugs now being shipped by manufacturers contain labels warning that they may be installed only on de-energized busways. These changes have occurred because of some isolated cases of bus plug failures during installation into energized busway that resulted in personnel injury and equipment failure.

ARTICLE 5.2.5
WIRING DEVICES

A. Todd Rocco, P.E., Principal
Diversified Consulting Engineers, Quincy, Massachusetts

INTRODUCTION

Electrical wiring devices are usually considered receptacles and switches but can also include safety switches and other devices used to connect equipment to the point of use. Wiring devices are engineered and designed to meet industry standards to provide years of safe and reliable service for the specified applications. This article provides a summary of industry standards and ratings, application ratings, and a description of the various types of wiring devices. Information about telephone and data wiring devices is provided in Art. 5.5.6, "Telecommunications and Data Distribution Systems." Occupancy sensors are described in Art. 5.3.1, "Lamps, Fixtures, and Humans—How They Relate."

Voltage and Current Ratings

American and Canadian wiring devices are designed for use at nominal voltages and currents. Codes require that switches and receptacles be labeled for the rated voltage and current at which they are applied. Devices that are not applied within their ratings violate the National Electrical Code (NEC) because they pose a potential personnel and physical safety hazard. For ac applications, the switch must have the appropriate ac voltage and current rating; for dc applications, a switch must be appropriately rated for dc voltage, current, and load type (e.g., a horsepower rating at the applicable voltage for a switch controlling a motor, or a fluorescent or incandescent rating at the applicable voltage for lighting applications). Receptacle ratings and configurations are presented in the next section.

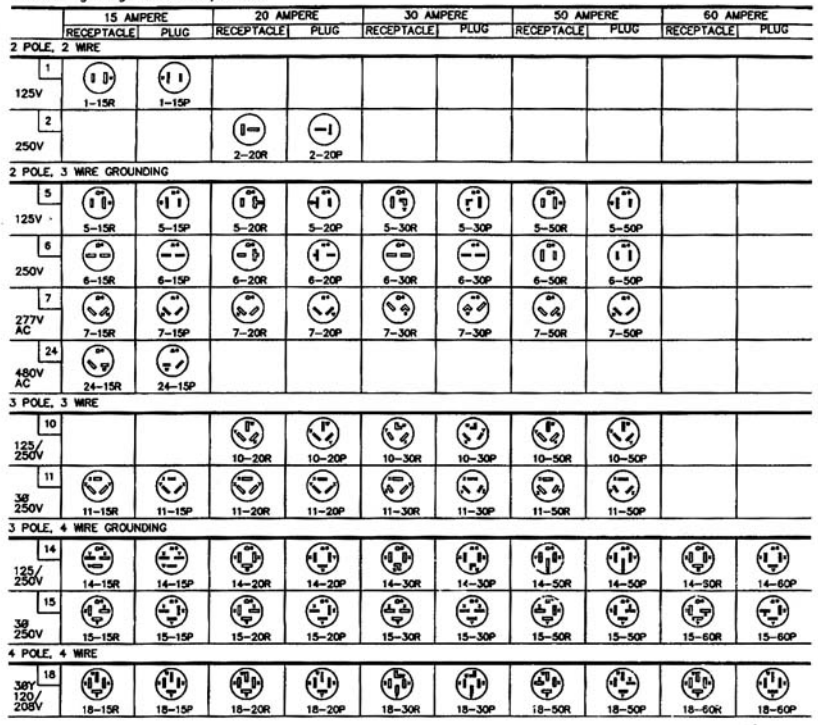
Some devices are side-wired with screw terminals, and some have combination side and back terminals. Some devices use an internal spring mechanism to hold the conductors; others use a side wiring screw that also adjusts an internal clamp. Typically, two back wire spaces are provided per side, but four spaces per side are also available for split switching of a device, such as a lamp. The design of modern wiring devices has evolved to facilitate safe and rapid installation by electricians.

NEMA Standards

Several industry standard organizations establish guidelines for safe construction, installation, and application of wiring devices. The National Electrical Manufacturers Association (NEMA) has established ratings and configurations to prevent the misapplication of plugs into the wrong receptacles and to ensure interchangeability among devices from different manufacturers. The means for preventing misapplication include blade (or pin) shape, configuration, and size. Figure 5.2.5-1 summarizes the configuration information established by NEMA. Each receptacle and plug rating has a unique NEMA configuration number that indicates whether it is locking or nonlocking and gives its voltage rating, number of wires, current rating, and type, as shown in the chart legend.

Other agencies that publish standards or recommended practices for wiring device performance or application include the American Boat & Yacht Council (ABYC), the Canadian Standards Association (CSA), the International Electrotechnical Commission (IEC), the National Electrical Code (NEC), Underwriters Laboratories, Inc. (UL), the Defense Electronic Supply Center (for federal specifications), and the Occupational Safety and Health Administration (OSHA).

TYPES OF WIRING DEVICES



There are several types of safe and reliable wiring devices for every application. In addition to electrical ratings, application considerations include environmental exposure, safety requirements, physical requirements, and service requirements.

The number of poles is the quantity of current-carrying connections. The number of wires indicates the total number of connections including the ground connection, if it exists. For example, two-pole, three-wire grounding indicates two current-carrying conductors and a ground connection, and two-pole, two-wire indicates two current-carrying conductors without a ground connection.

The number of wiring devices mounted in an outlet box is referred to as the *number of devices ganged together.* For example, one device is called a *single-gang outlet* and requires a single-gang device plate to cover the box and the energized parts of the device. Two devices are called a *double-gang,* or *two-gang, arrangement,* and so on. Cover plates are available in various device combinations to accommodate multiple ganged installations.

Straight-Blade Devices

Typical 15-A and 20-A, 125-V receptacles and plugs are part of a subset of wiring devices called *straight-blade devices.* Straight-blade devices are used where the plug is unlikely to be accidentally disconnected or does not pose a personnel or equipment safety hazard if it does become inadvertently disconnected. The left side of Fig. 5.2.5-1 presents the range of straight-blade wiring devices. Pin-and-sleeve devices are used for higher current applications.

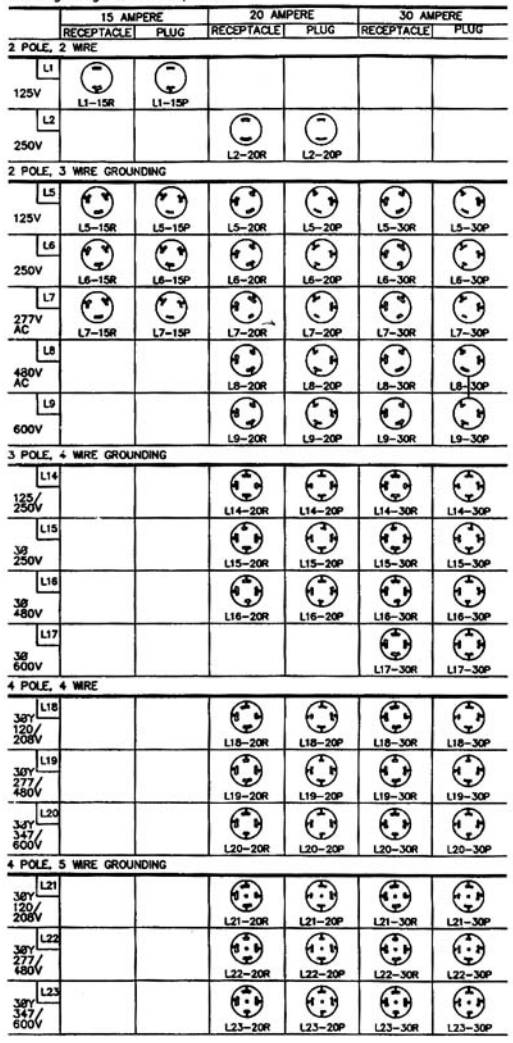


FIGURE 5.2.5-1 Wiring device NEMA configuration numbers. (*Courtesy of Hubbell Wiring Devices.*)

Single Receptacles

Single receptacles are typically used for dedicated applications to prevent other equipment from being connected to the circuit. The reasons for dedicated applications include circuit ampacity, remote switching of equipment, or eliminating the requirement for a ground-fault circuit interrupter (GFCI) where, for example, a fixed piece of equipment is not required to be GFCI-protected, but a portable piece of equipment would be required to be GFCI-protected. A common example is an automatic garage door opener, which is not required to have ground-fault protection if the receptacle is dedicated to that piece of equipment or is not accessible from the floor. However, receptacles for general use in a residential garage are required to have ground-fault protection. Another example is an overhead light fixture that is cord-connected and powered by a receptacle that is accessible from the floor in an area where receptacles are required to be ground-fault-protected. Therefore, the NEC requires that receptacles be ground-fault-protected where a person could use that receptacle, such as in commercial garages, rooftops, and kitchens.

Duplex Receptacles

Duplex receptacles are the most common receptacles. Connecting a duplex receptacle in a split-wiring configuration allows controlling one contact device in the outlet by a switch or other source and supplying the other contact device continuously (unswitched.) An example of a use for split wiring is controlling a lamp by a switch, while power is uninterrupted to an appliance connected to the other half of the same duplex receptacle.

Combination Receptacles

Combination receptacles are devices that have two receptacles each of different voltage ratings. A common application for a combination-type receptacle was for portable x-ray equipment that required 208 V, whereas the other receptacle was available for 120-V equipment. However, combination devices are no longer popular for safety reasons, and because x-ray equipment design no longer requires 208 V for portable x-ray equipment.

Ground-Fault Circuit-Interrupting (GFCI) Receptacles

Ground-fault circuit-interrupting receptacles are designed to disconnect the load when an imbalance is sensed above a certain threshold between the two current-carrying conductors. The imbalance occurs when a path, other than the intended path, of sufficiently low impedance exists and causes some of the current to flow through the other path. This other path could include equipment or personnel. The NEC has established a threshold current of 5 milliamperes (mA) for GCFI receptacles to protect personnel. This level produces a current below the threshold that causes ventricular fibrillation in a person who may be shocked by electrical current flowing from the person's hand to other extremities without involving any open wounds. A GFCI device that meets the 5-mA current threshold and operates within 25 ms is designated as a Class A GFCI, indicating that it is intended for personnel protection.

When Class A protection is desired locally for equipment, a GFCI without a receptacle can be installed similarly to a GFCI receptacle. These devices can be used for personnel protection from a single-phase motor or other device. When installing a GFCI for a motor, one should verify that the connected-motor horsepower rating is less than the device rating.

Tamper-Resistant Receptacles

Tamper-resistant receptacles are similar to standard receptacles except that they contain an internal switch that is intended to keep the receptacle deenergized until a plug is inserted. There are two switches per receptacle. Each switch is controlled by inserting an object into the other contact. This prevents a single object (like a screwdriver or knife) from being accidentally energized. For an object to become energized on one side, an object must be inserted into the contact to operate the switch on the other side.

Applications for tamper-resistant receptacles include child care areas, psychiatric patient areas, and prisons. Because this device is not tamperproof, additional precautions should be taken where personnel could defeat the tamper-resistant feature.

Transient Voltage Surge Suppression Receptacles

Transient voltage surge suppression (TVSS) receptacles (see Fig. 5.2.5-2) accept standard plugs and provide protection to the load from transient surges within a specified energy rating. Solid-state devices within the TVSS receptacle maintain the voltage at a specified limit during a transient surge. If the energy rating of the device is exceeded in either magnitude or duration, then the device no longer provides protection against similar transient modes. Many TVSS receptacles provide a visual or audible indication (LED or buzzer) that the protection is functional or is no longer functional due to a transient surge. It is important for the user to understand the meaning of the signal.

Isolated Ground Receptacles

Isolated ground receptacles provide electrical isolation from the equipment-grounding conductor contact and the device's mounting strap. To maintain isolation, a dedicated insulated

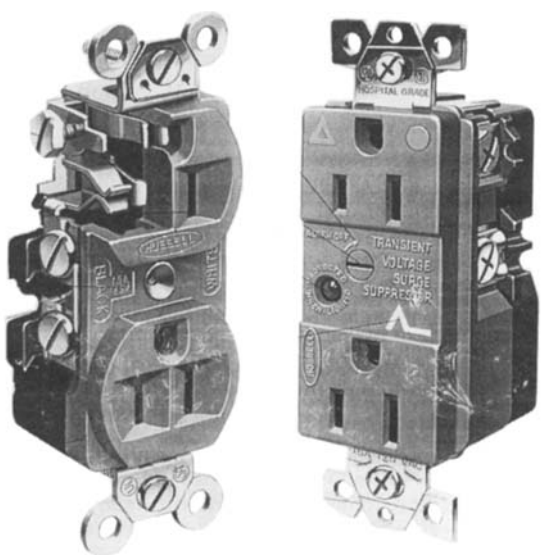

FIGURE 5.2.5-2 Isolated ground and TVSS receptacles. (*Courtesy of Hubbell Wiring Devices.*)

grounding conductor is required back to the power source at the panelboard. The mounting method for the receptacle and the device box equipment-grounding system are the same as for a standard receptacle (e.g., conduit). The purpose of the isolated ground is to minimize disturbances in the grounding system not caused by the equipment supplied. The isolated grounding circuit minimizes disturbances from another branch circuit, while still providing a ground path for personnel safety. These devices are marked with an orange triangle as required by the NEC.

Hazardous Locations

When a receptacle is required in an area that is classified as hazardous due to either a present hazard or potential hazard, special wiring devices and methods are required. These devices are designed to prevent explosions and fires. The devices typically provide a high-integrity seal when a plug is not installed, and automatically disconnect power to the load before the blades are removed to prevent any arcing that might ignite flammable or explosive materials.

Locking Devices

Locking devices consist of blades in circular configurations that accept plugs of a corresponding rating. The plugs are locked in place by a quarter turn clockwise after insertion. The locking feature provides a positive connection when subject to physical strain. Locking devices are available as either single or duplex receptacles.

A locking device is used where the plug might be accidentally disconnected or where inadvertently disconnecting it might pose a personnel or equipment safety hazard. The right side of Fig. 5.2.5-1 presents the range of twist-lock wiring devices.

Pin-and-Sleeve Devices

Pin-and-sleeve devices provide a positive locking connection that is watertight, depending on the style. Other features of pin-and-sleeve connectors are that they are available as three-, four-, and five-wire devices for all voltage configurations from 20 to 100 A, and the pins (contacts) are protected by the design of the connector body. Connectors for higher-current ratings are also available. This device could be used for a power connection to a temporary generator or for ship-to-shore connections in large vessels. Receptacles are available as an integral part of a fused or unfused safety switch.

Switches

Switches are available for variety of applications. Switch ratings must be matched to the load served (i.e., voltage rating, current rating, horsepower rating, or maximum lamp load based on lamp type). In addition, these ratings vary for ac and dc applications and must be specifically listed for the application.

Switches are available in three different styles: toggle, rocker, and push-button. This article focuses primarily on toggle switches, which are the most common style. However, rocker and push-button switches are available in many of the same types as the toggle switch.

Single-Pole Switches. Single-pole switches are the most common type of switch used. The single-pole switch is named for its contact configuration, one set of contacts that is closed to permit current flow in the on position, and open to stop current flow in the off position.

Double-Pole Switches. A double-pole switch is similar to a single-pole switch, but it has two sets of contacts. This type of switch is used to disconnect both conductors of a two-wire ungrounded circuit. A double-pole switch can also be used to control two circuits simultaneously.

Three-Way Switches. Three-way switches are used to control devices, typically lights or groups of lights, from two locations. It is not possible to tell if three-way switches are on or off from their physical positions. Three-way switches can also be used to control a load from two different sources or to control two loads from a single source.

Four-Way Switches. Four-way switches are used in conjunction with two three-way switches to control circuits from multiple locations. It is not possible to tell if three-way and four-way switches are on or off from their physical positions. Four-way switches can also be used to reverse polarity to a load (e.g., to reverse a dc motor's direction).

Pilot and Illuminated Switches. A pilot switch is used to indicate when a load is energized. Typically, the switch handle is lit, but some have an indicator lamp light located external to the handle. Illuminated switches have a lighted handle when the load is off, and that aids in finding the switch in a dark location. Illuminated switches can also be used to indicate when the load is off. Either switch can be used to indicate if the load in a remote area is on or off when controlled by three-way switches. Users of illuminated switches need to be aware that although the lamps, such as neon, have long lives, they can burn out. Therefore, independent verification that equipment is turned off should always be done for the safety of personnel and property.

Low-Voltage Switches. Low-voltage switches are used in conjunction with lighting relays to control large groups of lights. Using low-voltage wiring eliminates running line voltage wiring to each switch point, which can be advantageous when the distance for the switch circuits is relatively long. Low-voltage wiring also allows controlling the same lights from multiple locations with minimal wiring.

Combination Switches. Combination devices are used to operate two devices in a single-gang location. This is desirable when adding a switch or receptacle to an existing single-gang device box. Some combinations include a receptacle with a single-pole or three-way switch, a single-pole switch with a three-way switch, two single-pole switches, or two three-way switches.

Key-Operated Switches. Key-operated switches can be installed in locations to prevent unauthorized or unintentional operation of a switch.

Momentary-Contact Switches. Momentary-contact switches are designed so that the handle returns to its rest position when pressure is released. This type of switch can be used as a start-stop station or where momentary control of a load (e.g., a motor-operated projection screen) is desired. The alternative to a momentary-contact switch is the maintained-contact switch that is found in most installations.

Dimmers and Motor Speed Controls. Dimmers and speed controls are devices that can be adjusted by using a slide handle or a rotary knob to proportionally control a lighting or motor load. Older devices used rheostats (variable resistors) that dissipated energy in the switch while reducing the lighting load or speed of the controlled equipment. Modern devices use solid-state components to modify the waveform and thereby reduce energy utilization while reducing the lighting output or motor speed. These devices are designed for specified load types and ratings and should be applied to control only the designed load types. Dimmers are solid-state devices with typical ranges (for incandescent lamps) from 600 to 2000 W. Dimming

systems for fluorescent lighting are available but typically require special dimmable ballasts that are coordinated with fluorescent dimmers. Fluorescent dimmers for individual compact fluorescent lamps that do not require additional wiring are also available. Caution is required to make sure that stroboscopic effects are not noticeable with dimming.

Manual Motor Controllers. Manual motor controllers are used to control motors by using a toggle-type switch when automatic operation is not required. Manual motor controllers are also available with automatically resetting thermal protection to provide overload protection to small-horsepower motors.

Device Plates. Device plates are available in a variety of combinations for different applications. For example, toggle switch plates are available from single-gang to eight-gang. An example of a combination device plate includes one receptacle with two toggle switches.

Device plate materials include stainless steel, brass, aluminum, metallic, nylon, wood, and plastic. The application should be considered when specifying a device plate. Stainless steel is suitable for corrosive and high-use (abusive) applications. Brass and metallic plates are typically selected for appearance. Aluminum plates can be used where nonmagnetic and corrosion-resistant plates are required. Nylon plates are used primarily for safety considerations when a durable plate is required. Plates are available in many colors and with engraved lettering.

For weatherproof-when-not-in-use applications, plates with a snap cover protect the device when closed. For weatherproof-when-in-use applications, switch plates are available that allow operation of the switch without exposing the actual handle. For receptacles, the plate includes a hinged housing that allows protection while the receptacle is in use.

Temporary Wiring. NEC and OSHA regulations usually require that temporary wiring be GFCI-protected. Refer to the earlier section on GFCIs for more detail. Cord sets with integral GFCI devices are available for temporary power applications. These units feature high-visibility housings that are durable, sunlight-resistant, and water-resistant or watertight. The GFCI devices are available in either *manual reset* or *automatic reset,* which refers to operation when power is available or restored. Both types of devices require manually resetting the device after a ground-fault trip. Manual reset requires resetting the device after a loss of power. This is an additional safety feature where reenergizing the load after power failure could lead to personnel injury or property damage. The automatic type reenergizes the load once power is reapplied; this may be useful for a pump where it is desirable to restart the load once power is applied.

Power Distribution. Prefabricated power distribution equipment is available in a variety of configurations for temporary power applications. This equipment provides features similar to portable GFCI cord sets and can serve multiple loads. The supply ranges from 20 A, 125 V, to 50 A, 125 V/250 V, allowing simultaneous powering of several loads of different voltages.

Application Rating. Wiring devices are manufactured in different grades to match application requirements.

Residential Grade. Residential-grade receptacles are available in different subgrades, mainly home-center grade and higher contractor grade. Home-center grade should be used only in residential applications where minimal use is expected.

Commercial Grade, Specification Grade, and Heavy-Duty Grade. Mil specification grades (federal specifications) are some of the more durable grades. When specifying devices, verify that the manufacturer's designation will meet the job requirements.

Hospital-grade designation (also see the right side of Fig. 5.2.5-2) refers to receptacles that are designed with higher pullout tensions and other safety features. In addition, these recep-

tacles must meet the performance standards of Underwriters Laboratory Standard UL 498. A green dot on the front indicates that the receptacle is hospital grade.

Color and Style. Wiring devices are available in several colors to match the architecture of the installed area. Typical colors include black, brown, gray, ivory, and white. Other colors are reserved for specific representations, including blue for TVSS receptacles and orange receptacles for isolated ground installations. It is also common practice in many industries to specify red receptacles when they are supplied by emergency power.

ARTICLE 5.2.6
GROUNDING SYSTEMS

Paul Konz, P.E., Electrical Department Head
The Ritchie Organization, Newton, Massachusetts

Volumes of material have been written about grounding, and yet it is still very often misunderstood. The requirement to ground an electrical power system is based primarily upon personnel safety or the process that takes place in the facility. Although there are exceptions, grounding of electrical power systems and grounding of equipment for safety is required by the National Electrical Code (NEC). The most common exceptions to system grounding involve some manufacturing processes and isolated power systems in hospitals. Equipment grounding is just as important as the system ground. Proper grounding protects facility personnel from electric shock, ensures the operation of overcurrent protective devices, and helps prevent malfunction of sensitive electronic equipment.

GROUNDING ELECTRICAL SYSTEMS

The purpose of *system grounding,* or intentionally connecting a phase or neutral conductor to earth, is to control the voltage to earth, or ground, within predictable limits. It also provides for a flow of current that allows detecting an unwanted connection between system conductors and ground that may instigate operation of automatic devices."[1] Most electrical distribution systems employ a method of grounding the system neutral at one or more points. The two

methods of grounding are solid grounding and impedance grounding. The type of grounding system selected is based upon levels of available fault current and the type of protective devices used in the electrical distribution system. The most common systems in commercial buildings are solidly grounded systems. Figure 5.2.6-1 represents the diagrammatic grounding of a typical electrical distribution system. The system includes ground connections at the utility source, the main switchboard, downstream distribution panelboards, and the separately derived systems of step-down 480-208/120-V transformers.

Ungrounded Systems

Ungrounded systems are permitted under certain circumstances. Two of the most common, as stated earlier, are for manufacturing processes and hospital isolated power systems. In a manufacturing plant, where system outages can cause severe economic impact, the NEC permits the use of an ungrounded system. The facility operator risks personnel injury to ensure that the system is not interrupted from minor ground faults. To provide a level of personnel safety, the systems are equipped with ground-fault sensing equipment. The ground-fault indication allows operators to detect ground faults and prevent catastrophic failure. In hospitals where patient care areas are defined as wet locations, the NEC requires ground-fault protection. Under certain conditions, service disruption due to a ground fault can be a greater risk than the ground fault. Therefore, an exception to this requirement is the use of an isolated power system. In the ungrounded isolated power system, circuits are connected to a line isolation monitor that measures leakage current. When physiologically dangerous levels of leakage current occur, an alarm is sounded alerting the staff of the potential risk. Even when ungrounded systems are permitted by the NEC, levels of personnel protection and safety must be incorporated into the design.

Depending upon the service arrangement, system-grounding locations vary. Typically, the neutral conductor is grounded at the service entrance and is then referred to as the *grounded conductor.* Depending on the configuration of the service, the system-grounding location could be at the secondary of the service transformer or at the service-disconnecting device. NEC Art. 250 extensively describes system ground locations and requirements, the sizing of grounding electrode conductors, and bonding system and equipment grounds. Both design engineers and electricians use the requirements set forth in the NEC to ensure properly grounded systems.

Separately Derived System

The NEC defines a separately derived system as the following: a premises wiring system whose power is derived from a battery, solar photovoltaic system, or from a generator, transformer, or converter windings that have no direct electrical connection, including a solidly connected, grounded circuit conductor, to supply conductors originating in another system. In a commercial facility, the most common separately derived systems consist of delta-wye dry-type transformers that step the voltage down from 480 to 208/120 for receptacle power, generator systems installed with four-pole transfer switches, and uninterruptible power supplies (UPS). In each of these listed installations, the supply system ground is isolated from the downstream electrical distribution. A new system ground must be obtained at the location of the separately derived system usually by bonding the neutral of the separately derived system to the building grounding electrode system. It is important to bond the system ground of the separately derived system as near the installation as possible to ensure a low-impedance ground.

Grounding Electrode. A grounding electrode is defined as a conductor used to establish a ground and to connect electrical systems and or equipment to earth.[2] Ground electrodes consist of two types. The first group consists of underground metallic piping systems, building

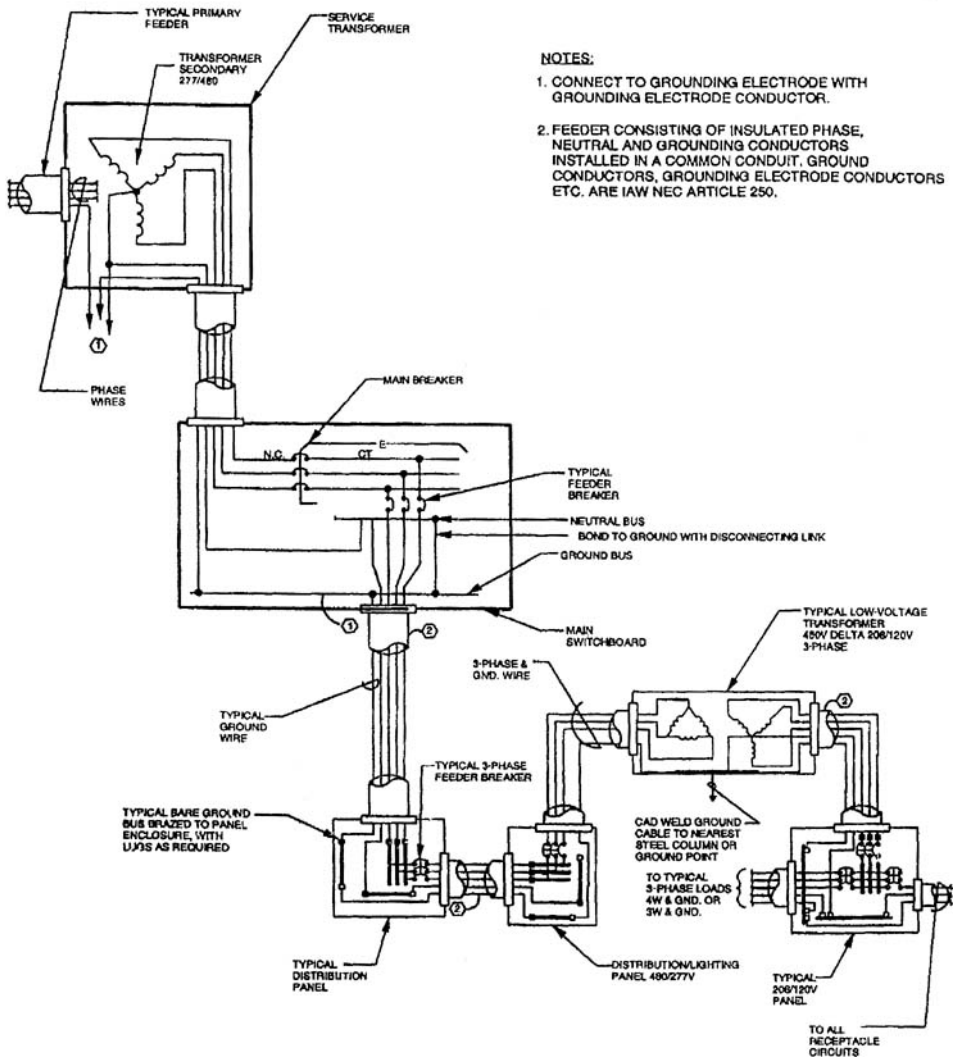

FIGURE 5.2.6-1 Typical grounded electrical distribution system. (*Courtesy of The Ritchie Organization.*)

steel systems, and other underground metal structures installed for purposes other than grounding. The second group comprises electrodes specifically designed for grounding purposes.[1] These electrodes consist of driven ground rods, Ufer grounds, ground counterpoises, and ground plates. NEC Art. 250-81 requires bonding all grounding electrodes to form a grounding-electrode system. The grounding electrodes for any given facility must be bonded together. The size of the bonding jumper is determined from NEC Art. 250-94. The objective of the grounding-electrode system is to minimize the resistance of the grounding electrode. Figure 5.2.6-2 illustrates the grounding-electrode system described by the National Electrical Code.

Due to varying soil resistivities and conditions, it is difficult to define a maximum ground resistance value. The NEC accepts a grounding-electrode value of 25 Ω or less. The objective

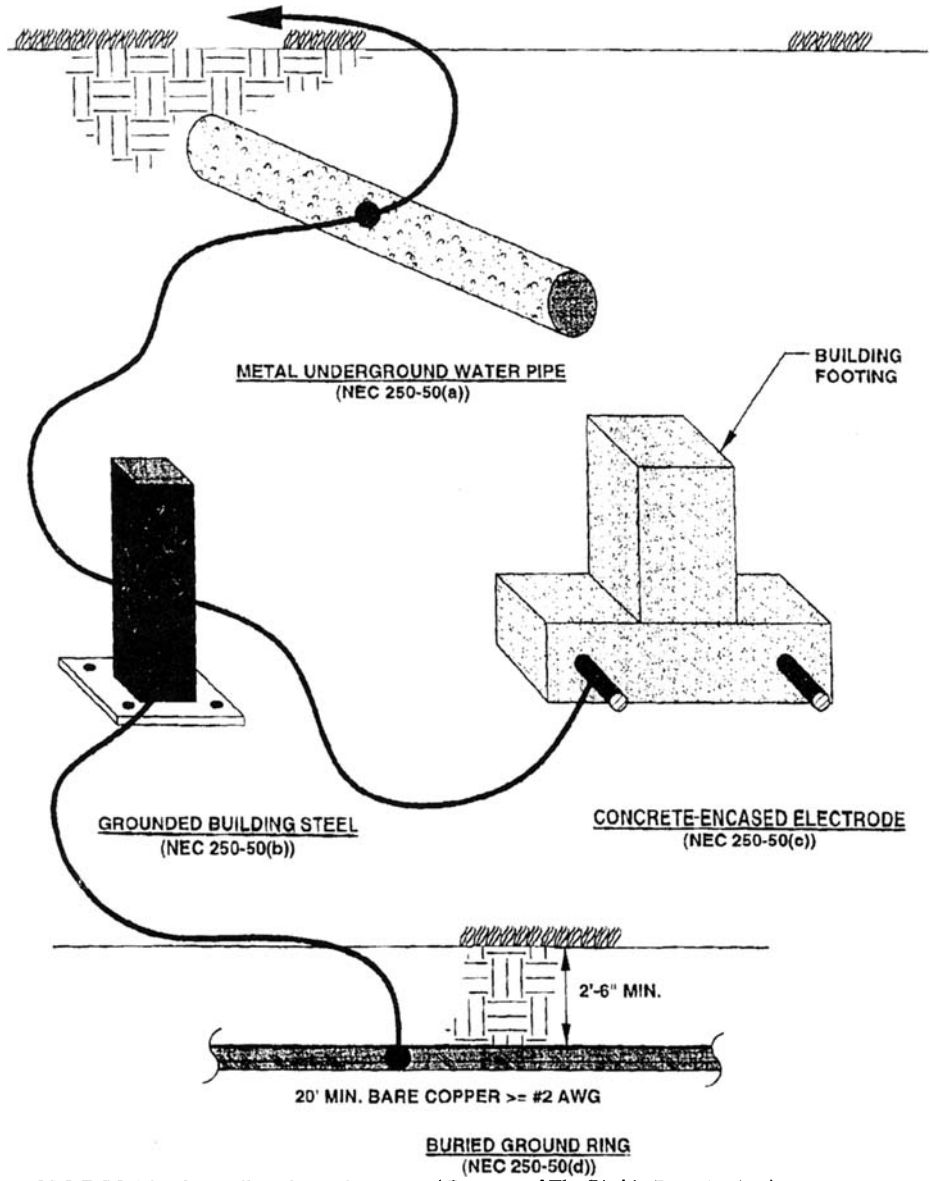

FIGURE 5.2.6-2 Grounding-electrode system. (*Courtesy of The Ritchie Organization.*)

is to minimize the resistance so as to limit the voltage to ground during a ground-fault condition. To complicate the process further, it is extremely difficult to measure the actual resistance of the grounding electrode system. The Institute of Electrical and Electronics Engineers (IEEE) has published a standard for measuring ground resistance: IEEE Standard 81-1983, *The Recommended Guide for Measuring Earth Resistivity, Ground Impedance, and Earth Surface Potentials of a Ground System.* The standard discusses the accepted methods of mea-

surement and their advantages and disadvantages. Regardless of which test method is used, "the system should be tested within a few months of completion of the system and after the soils have had a chance to consolidate around the electrodes. The test should be performed again at the time of building completion and then at periodic intervals (change of seasons) to provide baseline data for future testing comparisons.[3]

Equipment Grounding. Equipment grounding is defined as the "interconnection and grounding of the non-electrical metallic elements of a system."[1] Equipment ground systems reduce electric shock to personnel, provide adequate current-carrying capability to accept the ground-fault current permitted by the overcurrent device, and provide a low-impedance return path for ground-fault current that is necessary for timely operation of overcurrent devices. "Electric shock injuries result from contact with metallic components that are unintentionally energized."[4] Possible sources of potential shock include failed electrical insulation systems, damaged components, or improperly installed equipment. Such hazards are minimized by providing a low-impedance path to ground with an equipment-grounding system. Equipment-grounding systems must be sized and suitable to carry the available ground-fault current in the circuit. "All parts of the fault circuit including the terminations and other parts, must be capable of carrying the fault current without distress."[1] To ensure a low-impedance path to ground, it is essential that the equipment-grounding system be installed properly and maintained. Periodic inspections are recommended. Supervision of contractors is also important. Breakdowns in equipment-grounding system integrity often result from modifications to existing electrical distribution systems where ground connections are loosened or damaged when a new component or device is installed. Grounding systems should be tested periodically and when the system is modified.

Equipment-grounding methods are detailed in Art. 250 of the NEC. Additional requirements are often established for special applications. For example, branch circuits supplying patient areas in hospitals must have two separate equipment ground paths. It is important to note that the NEC requirements set a minimum level of installation to ensure personnel safety. It is good practice to provide equipment-grounding systems that exceed the NEC minimum requirements. The NEC permits the use of metal raceway systems as an equipment ground. Installing an additional ground conductor in the cabling provides an inexpensive safeguard against loose conduit connections or improperly installed equipment. "The intended overall purpose of the grounding rules is to achieve as nearly practical, a zero potential difference condition between equipment electrical grounding conductor, the frames of electrical equipment, metal raceways that enclose electrical conductors, and various items of exposed metal building frames and metal piping within the building."[1]

ARTICLE 5.2.7
CORROSION CONTROL BY CATHODIC PROTECTION

Cornelius Regan, P.E., CLEP (retired), and Harold L. Gordon, P.E.
Stone & Webster Engineering Corporation, Boston, Massachusetts

Cathodic protection is an electrochemical method to reduce or eliminate many forms of corrosion. It is commonly used to mitigate external corrosion on ship hulls, buried fuel oil piping and tanks, gas pipelines, carbon steel water lines, and other miscellaneous equipment such as heat exchangers. The most common form of corrosion occurs when two dissimilar metals are in contact in the presence of an electrolyte.[1] A battery represents a common example of dissimilar metal corrosion. A battery consists of a case (typically zinc for a flashlight battery) that serves as the anode and a rod (typically carbon) that serves as the cathode, both in an electrolyte (mild acid). When the anode and cathode are connected externally (as through a flashlight bulb), current flows in the external circuit from the rod (+) to the bulb to the case (−) through the electrolyte back to the cathode, completing the electrical circuit. Corrosion occurs where current leaves the anode and enters the electrolyte.

Cathodic protection is considered a specialized technical area within the electrical discipline. Systems are typically designed by either specialty cathodic-protection–consulting firms and by equipment vendors who provide turnkey services that include design, furnishing of materials, installation, and start-up services. This article provides an overview of the problems associated with corrosion and presents an introduction to cathodic protection technology. The major technical society dealing in cathodic protection is the National Association of Corrosion Engineers based in Houston, Texas. It is a good source for industry standards and recommended vendors.

CONDITIONS FOR CORROSION

Three conditions must exist for most forms of common corrosion to occur. First, there must be a difference in potential between two different metallic structures or between one part of a metallic structure and another. The area of higher potential (more positive) is the cathode; the area of lower potential (more negative) is the anode. This potential difference can be caused by many factors but most often results from the use of dissimilar metals. The second condition for corrosion is that there must be a metallic path that electrically connects the anode and the cathode. Finally, the anode and cathode must be in an electrically conducting electrolyte. This can be soil, water, or any other chemically suitable material. Thus, when

these three conditions exist, current flows from the anodic material into the electrolyte to the cathode and back to the anode via a direct electrical path. Corrosion occurs where the current leaves the anode and enters the electrolyte; the corrosion rate of steel is 20 lb A^{-1} $year^{-1}$. Corrosion rates are increased when the potential difference [electromagnetic field, (EMF)] between the anode and cathode is large (e.g., interconnecting buried aluminum pipe to copper pipe (0.5- to 0.8-V difference), or when the resistivity of the electrolyte is low. For example, clean dry soils have resistivity values that can range from 100,000 Ω/cm to well over 1 million Ω/cm. These soils are generally classified as relatively noncorrosive, and corrosion tends to be minimal because of the overall high circuit resistance. Corrosive soils and water, however, have resistivity values as low as 100 Ω/cm; the resistivity of seawater is 25 Ω/cm. Structures and equipment located in these environments can be subject to rapid corrosion. Additionally, facilities personnel can have a direct impact on corrosion rates. For example, the widespread use of deicing salts in northern environs can significantly decrease soil resistivities and cause increased corrosion to structures that otherwise would not be adversely affected.

Finally, local, state, and federal regulations may dictate the type of corrosion protection that is required. Title 49 of the Department of Transportation Regulations for hazardous materials pipelines mandates that new piping systems that transport hazardous materials such as natural gas (1) be provided with protective coatings, (2) be electrically isolated from any other structure, and (3) have a functioning cathodic protection system.

CORROSION CONTROL METHODS

Three principal methods are used to reduce or eliminate corrosion: (1) protective coatings, (2) insulating flanges, and (3) cathodic protection. Protective coatings reduce corrosion in two ways. First, metallic structures whose surfaces are completely coated do not corrode because there are no exposed locations on the structure for corrosion current to leave (the structure) and enter the electrolyte. Second, coatings significantly reduce the amount of cathodic protection current that the structure requires by reducing the total exposed surface area. For example, the ratio of required cathodic protection current for a coated structure (effective coating resistance of 100,000 Ω/ft^2) compared with an uncoated structure can be 3×10^{-4} less for the coated structure than the uncoated structure. In practice, there is no such thing as a perfect coating; thus, all coated structures are susceptible to some form of corrosion.

Insulating flanges operate by breaking the electrical path between anodic and cathodic structures. They are widely used in piping systems to isolate buried piping from aboveground piping. Aboveground piping is normally electrically grounded and creates dissimilar metal cells.

The third method for reducing corrosion is cathodic protection. Cathodic protection systems work by forcing dc current to flow from an external source (called the *anode*) through the electrolyte to the structure to be protected (called the *cathode*). When all exposed cathodic surfaces receive sufficient current, then corrosion is eliminated. The design of cathodic protection systems takes into account total current requirements, anode location, anode life, and other conditions, including operations and maintenance.

In practice, it has been found that all usual forms of corrosion are prevented when the cathodic protection makes a pipe or other metallic structure 0.25 to 0.30 V more negative than the soil or liquid surrounding the pipe.[1] There are two basic methods for applying cathodic protection: impressed current and sacrificial anode.

Impressed Current Systems

Impressed current systems use rectifiers to energize long-lived anodes that are positioned at critical locations to prevent corrosion. These systems are designed for long life and can produce high protective currents to eliminate even the worst problems. Anodes for impressed cur-

rent applications are constructed from high-silicon cast iron, graphite, or from more exotic materials such as platinized titanium, niobium, or mixed-metal oxides. Rectifiers generally are the power source for these systems. Rectifiers can be specified in dc output voltage, and current ranges from 4 V to 120 V and from 4 A to well over 400 A. Rectifier units are manufactured as air-cooled, oil-cooled, or can be constructed as explosion-proof for hazardous locations.

Sacrificial Anodes

Sacrificial anodes include magnesium and zinc for underground applications and aluminum alloys for seawater uses. They can be directly connected to the structure to be protected, or they can be grouped together and connected to the structure via cable connections and function because of their inherent anodic voltage with respect to other materials. For example, magnesium is the most anodic material followed by both zinc and aluminum. Sacrificial anodes are used for smaller surface areas or areas that are electrically shielded. Typically, less maintenance is required for sacrificial anodes than impressed current systems.

Impact of Electrical Grounding. Electrical grounding is required for the safety of personnel and for the proper and safe operation of equipment. However, electrical grounding can accelerate the corrosion of metals due to an increase in dissimilar metals. Grounding systems that typically include the bare-ground grid cable system and ground rods are generally constructed of copper, whereas buried metallic pipelines and tanks are generally constructed of carbon steel. Because most pipelines are installed with a protective coating, corrosion is concentrated at locations where the coating is damaged. These locations are called *coating holidays.*

Corrosion is aggravated when a carbon steel pipe is electrically connected to the grounding system because the corrosion is concentrated at the coating holiday. It is important, therefore, that precautions be taken to ensure that when the pipes are grounded in a corrosive environment, cathodic protection is installed to mitigate dissimilar metal corrosion.

Stray Currents. Stray currents cause one of the most severe forms of corrosion. Typically, stray currents are generated by two major sources: dc transit systems and interference currents caused by adjacent cathodic protection systems.

Dc transit stray currents are the most severe cause of rapid and potentially dangerous corrosion. Affected structures can range from underground pipelines, tunnels, foundations, reinforcing steel, underground conduits, and hydraulic elevator shafts. Corrosion currents in the thousands of amperes have been known to cause rapid failure of equipment. Because carbon steel corrodes at a rate of 20 lb A^{-1} $year^{-1}$, these large stray currents have caused failure of underground pipelines within days. It is essential, therefore, that this potentially diverse problem be quickly identified and that mitigative measures be implemented in a technically correct and thorough manner.

Stray currents from electric traction equipment may be reduced by welding sections of track together and by welding flexible connections across the track, joints which cannot otherwise be made electrically continuous. This reduces the electrical resistance of the track. Also, maintaining good, dry ballast below and between the ties helps to increase the resistance of the ground circuit, thus reducing stray currents.

The second major source of stray currents is due to the nearby presence of a functioning cathodic protection system. These systems can cause an interference condition on underground structures and equipment not connected to the cathodic protection system. Cathodic protection current always takes the path of least resistance. If a structure is in that path and is not part of the cathodic protection system, severe corrosion can occur where the current leaves the structure and enters the earth or water. Solutions to both of these forms of corrosion usually require extensive testing programs to identify and resolve.

Due to a decrease in the rights-of-way for new underground pipelines, many pipelines are being installed in a joint right-of-way with high-voltage transmission lines. This proximity to

the high-voltage line, however, can create several problems including adverse electrical conduction and induction effects. If pipelines are installed under high-voltage transmission lines, then a consultant who is familiar with this application should be contacted to provide the required expertise.

Maintenance

Proper maintenance of a cathodic protection system is essential to its proper performance. As part of any installation, provisions should be made for periodic testing. In the case of impressed current systems, rectifier outputs should be read and recorded often, possibly once per month. Structure-to-electrolyte measurements every 3 or 6 months may be adequate to ascertain whether the cathodic structure is receiving sufficient current. Sacrificial anode systems typically require less testing; however, anode current measurements should be made periodically to make certain that the anode is still functioning. Structure-to-electrolyte measurements to ascertain whether the cathodic structure is receiving sufficient current should be made every 3 or 6 months or the same as the impressed current system.

ARTICLE 5.2.8
ELECTRIC HEAT TRACING SYSTEMS

Cornelius Regan, P.E., CLEP
Stone and Webster Engineering Corporation (ret.), Boston, Massachusetts

Richard G. Brunner, P.E.
Stone and Webster Engineering Corporation, Boston, Massachusetts

INTRODUCTION

The terms *electric-resistance heat tracing, heat tracing, electric pipe heating,* and *trace heating* have all been used to describe the practice of following, or tracing, a pipeline with a heat source. Originally, a steam line fastened to the pipe provided pipe heating; today, however, most pipe heating is done with electric heating wire or cable. Generally, *heat tracing* means directly applying heat to pipes or vessels, as compared with space heating.

An electric freeze protection or process heating system consists of electric heaters (elements), controllers, sensors, a dedicated power system, transformers, panelboards, cables, and alarm devices. The electric heating elements generate heat, and when strapped to surfaces, they transfer heat by conduction and radiation.

The two major reasons for heat tracing are to prevent freezing and to maintain a fluid at a constant temperature. Electric heating is sometimes also used to "heat up" a pipeline to operating temperature.

For freeze protection, the electric heating cable is usually the variable-wattage parallel-circuit type. This cable has a composite heating element that regulates or varies its heat output with respect to its temperature and decreases its output as the temperature increases. Thus, it is self-limiting and ideal for freeze protection.

For process heat tracing or heat-up heat tracing at temperatures above freezing (32°F, 0°C), series heater heating elements are used that have a specific resistance at a given temperature. They are not self-limiting and may require more controls.

Electrical heat tracing can also be used for ice and snow melting. The same information that is required for pipe or tank heat tracing systems is also needed for its proper installation.

DESIGN

Design Requirements

All heat tracing design and installation must comply with the following codes and standards, where applicable:

- IEEE 515, *IEEE Standard for the Testing, Design, Installation, and Maintenance of Electrical-Resistance Heat Tracing for Industrial Applications,* Institute of Electrical and Electronics Engineers
- IEEE 622, *IEEE Recommended Practice for the Design and Installation of Heat Tracing Systems for Nuclear Power Generating Stations*

- National Electrical Code (NEC)
- National Electrical Manufacturers' Association (NEMA)
- National Electrical Safety Code (NESC)
- Occupational Safety and Health Administration (OSHA) Standards
- American National Standards Institute (ANSI)

As with all electrical equipment and systems, electric heat tracing systems must be listed if they are of a type that can be listed. Two sources for listing electric heat tracing systems are

1. Underwriters' Laboratories, Inc. (UL 746B)
2. Factory Mutual Research Corp. (FM)

The following nine design requirements must be known to design an efficient heat tracing system:

1. Temperatures—highest and lowest ambient process temperature to be maintained, and minimum and maximum operating temperatures
2. Size, length, and material of the pipes and vessels
3. Thickness of the thermal insulation
4. Type of fluid or gas being traced
5. Type of heat tracing—freeze protection, process-maintained temperature, heat-up, or prevention of condensation
6. High- and low-temperature alarm set points
7. Classification of the area (hazardous or nonhazardous) as defined in the NEC, Art. 500
8. Isometric pipe drawing showing locations of valves, hangers, and so on
9. Wind speed

Mechanical Requirements

The piping system must be accessible for installation and maintenance of the heat tracing system. The heat tracing system must be continuous through floors and walls (to obviate cold spots), should be segregated from other piping where possible, and should be supported on insulated clamps.

Electrical Requirements

The power supply for heat tracing circuits should come from dedicated transformers and distribution panels that provide independence. Connecting additional heating circuits to lighting panels for convenience should be avoided.

Grounding. An effective ground must be provided from the outer metallic covering of the heating cable to the power distribution system. If the sheath or braid covering the heating cable does not provide a ground path, ground-fault currents must be investigated.

Heating Elements. All heating elements should be selected to utilize a standard voltage: 120, 208, 240, 277, or 480 V, as applicable. The heating element protective sheath must be capable of withstanding the maximum pipe operating temperature, and the sheath temperature must not exceed the ignition temperature of any gas or vapor that could be present. The type and size of the heating element are selected on the basis of the pipe size, type, and temperatures.

Design Calculations

Rather than make fundamental thermal calculations each time that a heat loss determination is required, it is entirely practicable to use the universal design guides prepared by the major heat trace vendors. Heat tracing software available to users can give tabulated results for virtually every heat tracing condition, including various pipe and tank sizes, types of thermal insulation, wind and safety factors, and operating conditions.

Many heat loss formulas and sample calculations appear in IEEE Standard 515 and can be applied to parallel constant- and variable-wattage and series cables. Heat tracing installation should be designed under the supervision of a competent electrical engineer.

Isometric drawings should be prepared to facilitate heat trace application, showing pipe and tank size and insulation and length of runs. The amount of heat needed equals the heat loss of the system; thus, the thermal conductivity of the insulation, the dimensions of the pipe and insulation, and the temperature difference to be maintained must be known.

Control, Alarm, and Monitoring Systems

The control system provides the means to electrically energize and deenergize the heating elements in response to changing temperature conditions, and the alarm and monitoring systems provide information about the system's condition. Temperature alarms indicate operating conditions, and current and voltage detection monitor the condition of the heaters.

Freeze Protection Application

Most freeze protection is accomplished by using ambient temperature sensing to actuate the heat-traced circuits through a contactor. Some energy savings are possible by using variable-wattage cable. Another method is to sense pipe temperature.

Process Control Application

A critical process control system is redundantly traced and has two independent controllers for each pipe. These controllers should be physically and electrically isolated from each other.

Heat-Up Control Application

The heat required for an initial heat-up is greater than that for maintaining a normal operating level. Other requirements are identical.

Snow Melting Application

Heat is supplied to keep sidewalks clear of ice and snow.

EQUIPMENT SELECTION

Selection of Heater Element

The three basic types of heating cables are constant-wattage series-circuit, constant-wattage parallel-circuit, and variable-wattage parallel-circuit, as well as blankets and strip heaters. Each type has distinct advantages for different applications.

In operation, an electric heating cable develops a sheath temperature higher than the pipe or vessel and thereby heats the pipe. If the pipe temperature exceeds the temperature rating of the heater material, it is a major problem. Typically, thermoplastic elastomers have a maximum temperature rating of 121°C; fluorinated ethylenepropylene (FEP) Teflon, 204°C; Tefzel, 150°C; Kapton, 371°C; copper-sheathed mineral-insulated (MI) cable, 148°C; and Inconel and 304 stainless-steel MI cable, 537°C. Heater characteristics should be obtained from the manufacturer at the time of heater selection to avoid inappropriate application.

Constant-Wattage Series-Circuit Heating Cable. Mineral-insulated cable is recommended when it must operate under high-temperature conditions, is subject to high levels of radiation, or requires mechanical protection. For less rigorous applications, cables insulated with Teflon, Tefzel, or silicone rubber are available for various temperature limits.

Constant-Wattage Parallel-Circuit Heating Cable. Constant-wattage parallel-circuit cable is available in various insulating materials for different temperature limitations. Constant-wattage cable is advantageous for long cable lengths and can be cut to length in the field. Constant-wattage parallel-circuit heaters also come in blanket form. They are available in standard and custom sizes and are well suited for tanks, valves, flanges, and ducts.

Variable-Wattage Parallel-Circuit Heating Cable. Variable-wattage parallel-circuit cable is ideal for freeze protection and can also be cut to length in the field. It is also a good application for plastic and fiberglass-reinforced epoxy pipe because of the self-limiting temperature feature.

Strip Heaters. Strip heaters provide constant-wattage heat output and are available in a wide range of voltage, heat output, and size. They are used for convection air heating and clamp-on heat transfer applications.

Bulb and Capillary Thermostats. Bulb and capillary thermostats are the most commonly used mechanical controllers. They have limited load-switching capability, and the freezing temperature of the fluid may limit low-temperature operation. Copper, chrome-copper, and stainless-steel bulbs and capillaries are available and should be selected to suit the environment.

Bimetallic Thermostats. Bimetallic thermostats are factory-preset to temperature. They may be paralleled to sense temperature at several places along the pipe. Because they are factory-preset, they are not suitable for variable set-point applications.

Electronic Controllers. Electronic controllers may be located a significant distance from the heated pipes. They use resistance temperature detectors (RTDs), thermistors, or thermocouples to sense temperature and control the power circuits to the pipe heaters. They may be designed for either on/off or proportional control. On/off control turns power on at the low set point and off at the high set point. This results in some temperature overshoot or undershoot from the set-point temperatures because the temperature lags the heat input. Proportional control provides just enough power to maintain the set-point temperature and minimizes temperature cycling. Electronic controllers show the actual pipe temperature and the desired set-point temperature, usually as a digital display.

Microprocessor. Microprocessors have expanded the scope of control and alarm functions and permit management as well as control of heat tracing systems. The microprocessor is an independent system connected via communication lines to a central computer. The microprocessor provides data for temperature sensing and alarm, for the operator's display, and for power switching in the heat trace system. The computer periodically scans all sensors and provides an alarm and readout in the event of trouble.

Maintenance

No heat tracing system is complete until it is checked and tested in accordance with the codes and standards listed in this section and also with the manufacturer's recommendation. Records must be kept of the original readings for comparison with the periodic test readings. These readings will be helpful in spotting moisture penetration into the electrical system (gradual decline in isolation resistance) or physical damage to the heating cable (sharp decline in the insulation resistance). It is of paramount importance that the heater cable be completely tested before installation. This will prevent the installation of damaged heater cable whose cost is minimal when compared with the costs of cable installation and thermal insulation. The following insulation resistance testing is recommended and should be performed:

- Upon receipt of the heating cables
- Before the thermal insulation is installed
- After the thermal insulation is installed
- During periodic maintenance testing (as mentioned previously)

Temperature maintenance circuits should be checked at least twice a year. Freeze protection circuits should be checked before the season approaches that requires using them.

The following checks should be done periodically:

- Visually inspect the inside of connection boxes for corrosion, moisture, and loose connections.
- Check heating cable connections, grounding, and ensure that the heating cable connections are insulated from the connection box.
- Megger test at power connections to make sure that both bus wires are disconnected from the power source.
- Check circuit amperage and voltage.
- Check thermostats for moisture, corrosion, switch operation, and capillary damage.

Check for damage to insulation seals at valves and pumps, and so on. Also, check for leaks throughout the system.

All metal parts of temperature controls should be sprayed with a moisture repellent or corrosion repellent yearly. If a cable is damaged, it must be replaced in its entirety. Moisture may have migrated into the good section of the cable during the damage, and it may short out after repair of the damaged section.

ARTICLE 5.2.9
POWER QUALITY

A. Todd Rocco, P.E., Principal
Diversified Consulting Engineers, Quincy, Massachusetts

Power quality has become a prime concern of facilities engineers and managers because of the increasing use of voltage-sensitive electrical and electronic equipment. Compounding the need for awareness of this issue is that this same modern electrical and electronic equipment can be both the source and that which is affected by many of the power quality phenomena. This article presents a basic explanation of power quality and definitions, along with the reasons that power quality is a concern and a description of the power quality phenomena that cause equipment malfunction or misoperation. Voltage considerations for equipment include the susceptibility profile for computer equipment and the causes of sags, swells, and transients external or internal in a facility, such as lightning, power factor capacitor switching, improper wiring, or a motor starting. Design considerations and solutions are presented. The information presented is based on and refers to publications of the Institute of Electrical and Electronics Engineers, Inc. (IEEE) and other recognized industry standards and guidelines, in addition to information gathered from experience.

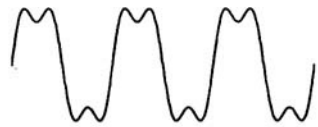
DEFINITIONS

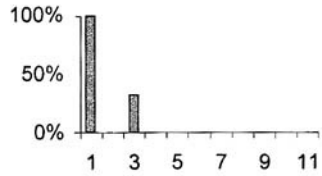
Power quality can be considered an electrical system abnormality that causes an undesirable result in system loads or components. The IEEE Standard 100, *Standard Dictionary of Electrical and Electronic Terms,*[1] provides definitions for various types of electrical disturbances, as shown in Table 5.2.9-1. The names, waveforms, and descriptions of common disturbances are also presented in Table 5.2.9-1.

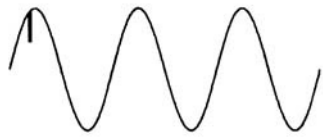
These and other terms are commonly used in inappropriate contexts. The reader should be aware that other interpretations of these terms exist and that terms should be questioned to reduce ambiguity. More detailed descriptions are presented in IEEE Standard 100,[2] IEEE Standard 1159,[3] and NFPA 70B.[4] Two articles that describe waveforms well are "Storing Power for Critical Loads" [*IEEE Spectrum* (June 1993)][5] and "Protecting Computers Against Transients" [*IEEE Spectrum* (April 1990)].[6] The IEEE Standard 1159-1995, *Recommended Practice for Power Quality Monitoring,* contains additional terms taken from other standards, which are being adopted more widely to be consistent with other international standards. This standard also includes a list of terms to avoid.

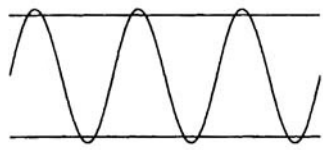
Work has also been done on the electric utility side of the meter. The Electric Power Research Institute (EPRI), a research and development organization funded by electric utilities, has developed indexes to describe the power quality level for electric utility distribution circuit areas. Facilities that are considering procuring *custom power* (a term that describes advanced

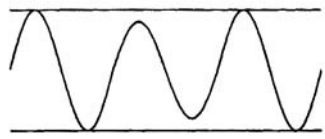
TABLE 5.2.9-1 Summary of Common Power Quality Disturbances and Associated Waveforms

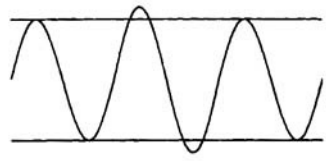


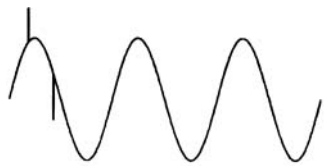


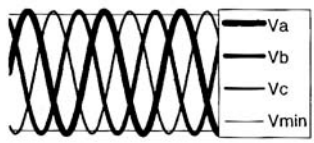


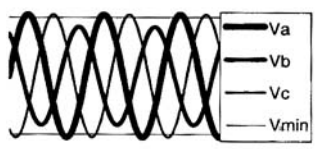


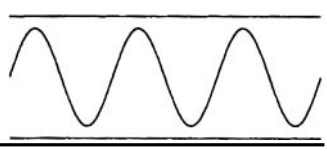












Disturbance Type	Description	Waveform
Harmonic distortion	Nonlinear distortion that appears as harmonics (i.e., harmonic components) of a single-frequency input.	
Harmonic components	The components of the harmonic content as expressed in terms of the order and root-mean-square (rms) values of the Fourier series terms describing the periodic function.	
Interruption	The complete loss of voltage for a time period. The time-base of the interruption is characterized as follows: —Instantaneous: 0.5–30 cycles —Momentary: 30 cycles–2 s —Temporary: 2s–2 min —Sustained: >2 min	
Notch	A switching (or other) disturbance of the normal power voltage waveform, lasting less than a half-cycle; which is initially of opposite polarity than the waveform, and is thus subtractive from the normal waveform in terms of the peak value of the disturbance voltage. This includes complete loss of voltage for up to a half-cycle.	
Overvoltage	An rms increase in the ac voltage, at the power frequency, for durations greater than a few seconds.	
Sag	An rms reduction in the ac voltage, at the power frequency, for durations from a half-cycle to a few seconds. Note: The IEC terminology is *dip*.	
Swell	An rms increase in the ac voltage, at the power frequency, for durations from a half-cycle to a few seconds.	

TABLE 5.2.9-1 Summary of Common Power Quality Disturbances and Associated Waveforms (Continued)

Disturbance Type	Description	Waveform
Transient	A subcycle disturbance in the ac waveform that is evidenced by a sharp brief discontinuity of the waveform. May be of either polarity and may be additive to or subtractive from the nominal waveform.	
Unbalanced load regulation	A specification that defines the maximum voltage difference between the three output phases that will occur when the loads on the three are of different levels.	
Unbalanced three-phase system	A three-phase system in which the rms value of at least one phase voltage (or current) or line-to-line voltage is significantly different from the others, or in which the phase angle displacement between any pair of phases significantly differs from 120°. Note: In an unbalanced three-phase system, negative or zero-sequence components exist.	
Undervoltage	An rms decrease in the ac voltage, at the power frequency, for durations greater than a few seconds.

technologies that can be applied to the utility system to improve the power quality delivered to utility customers) are advised to research the costs and benefits of alternative technologies.[7]

EQUIPMENT MALFUNCTION AND DAMAGE

Any of the electrical disturbances defined in the previous section can cause equipment malfunction or damage, but the most severe damage to equipment typically results from overvoltages or high-energy transients (impulses). Damage to electrical equipment is usually from long-term exposure to such conditions that can cause equipment (e.g., semiconductor devices, fluorescent ballasts, motors, and transformers) to operate above its designed temperature range, or electrical or mechanical stress on the system beyond the intended design. Interruptions to processes and damage to products during manufacturing are industrial examples of the result of sags (the most common power quality phenomena), swells, or interruptions. For

example, medical imaging equipment or industrial process controllers can be damaged by an interruption or sag if the equipment requires a sequenced shutdown procedure. Restoring the equipment to operation can take days if components are damaged, software is corrupted, or the product must be cleaned out of the machines, and the process slowly restarted. In addition to the effects of overvoltage and undervoltage conditions described for motors and other equipment, these conditions can also have a considerable financial impact on operating and maintenance costs of a facility's electrical system or cause a loss of revenue. Swells and overvoltage situations can cause premature equipment failure (e.g., lamps and motors). Sags and undervoltage situations, which are the most common types of power quality disturbances, can cause premature equipment failures, operational problems such as adjustable-speed drive tripping,[8] and higher electrical energy costs resulting from increased system losses.

The presence of significant levels of harmonic components may require derating motors, transformers, and other parts of the electrical system, including neutral conductors and panel ampacities. Other problems can include premature failures and misoperation of equipment.

Unbalanced load regulation (phase imbalance) along with transients, overvoltages, undervoltages, sags, and swells can cause the equipment's power supply to perform unsatisfactorily or be damaged, resulting in erratic or undesirable equipment operation. Table 5.2.9-2 summarizes the potential effects on equipment as fundamental as a motor and the failure that can result from various electrical disturbances.

Voltage Considerations

Standards and Guidelines. Standards and guidelines establish performance criteria for electrical power systems and equipment. The American National Standards Institute (ANSI) has standardized nominal voltages and voltage ranges for electrical power systems and equipment. Table 5.2.9-3 presents excerpts from Table 1 of the ANSI Standard C84.1a-1980 for

TABLE 5.2.9-2 Potential Effects on Motors and Resultant Failures From Electrical Disturbances

Disturbance Type	Potential Effects and Problem	Resultant Failure
Interruption	Reenergizing a motor while coasting causes severe torque and current transients.	Motor winding insulation failure due to heat or physical damage from high magnetic fields. Shaft, drive, or driven equipment damage from large torques.
	Frequent stops and starts can exceed motor duty cycle and temperature specifications and stress shafts.	Motor winding insulation failure from heat.
Phase imbalance	Excessive heating due to negative sequence (180° out of phase) currents.	Motor winding insulation failure from heat.
Sustained undervoltage and overvoltage	Excessive heating due to I^2R losses, and reduced fan cooling (undervoltage).	Motor winding failure from heat.
Sag and swell	Increased heating due to torque fluctuations and produces stresses on shafts.	Motor winding fails prematurely.
Transients	Excessive winding voltage causes insulation stress.	Motor winding insulation develops localized deterioration and failure.
Harmonics	Eddy current losses increase as square of harmonic number, and negative sequencing currents result in heating.	Motor winding fails prematurely; fluting of bearings.

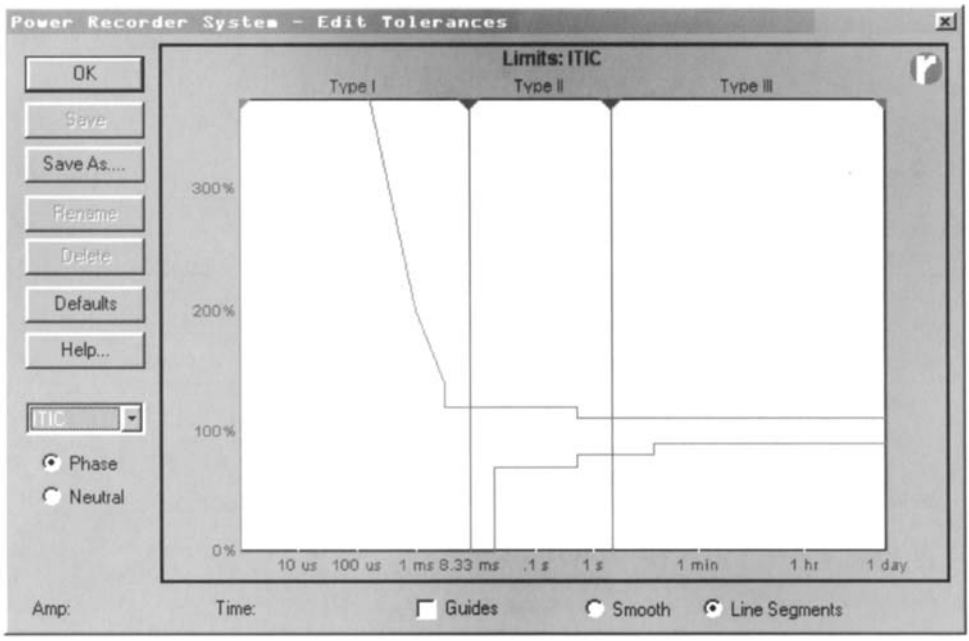
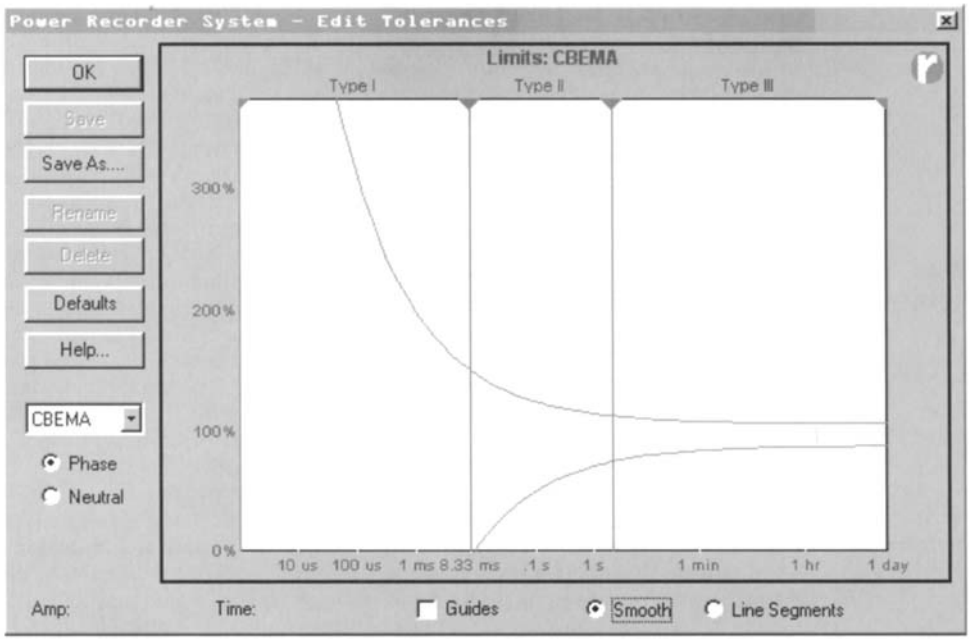
three-phase, four-wire systems.[9] Refer to IEEE Standard 241 for a thorough presentation of standard voltages.[10]

The Computer Business and Equipment Manufacturing Association (CBEMA) has established guidelines for voltage disturbances as a function of time for electronic equipment (Fig. 5.2.9-1). The CBEMA Curve, as it is commonly known, has been widely used but has been replaced by the Information Technology Industry Council (ITIC) curve. However, a much more useful set of curves can be found in IEEE Standard 1346.[11] This standard shows how to plot the power quality phenomena from a survey versus equipment susceptibility to determine how many problems to expect in a typical year.



Sources of Voltage Disturbances. There are many causes of voltage disturbances in facilities that can be caused by external or internal events. Recent surveys have found that most power quality phenomena result from disturbances within the facility itself. This brief summary is representative of common disturbances and causes of the disturbances.

Interruptions. Interruptions can be caused externally by weather-related events (ice, high wind, or lightning), traffic accidents that affect utility equipment such as power poles, distribution or transmission equipment malfunctions, or overloads that result in substation circuit-breaker operation or fuses blowing. Internal causes include equipment failures, improper wiring, or system overloads that result in circuit-breaker or fuse operations. Planned outages, also called shutdowns, are scheduled interruptions of selected portions of the power system.



Undervoltages and Overvoltages. The causes of undervoltages and overvoltages (externally or internally) include poor system voltage regulation (i.e., the inability to provide a voltage within a specified range for the anticipated load fluctuations), equipment malfunction, or system overload. The cyclical loading of an electrical system can cause overvoltage conditions during periods of minimum load or undervoltage during maximum load. Many facilities experience cyclical loading [e.g., steel mills, schools, office buildings, and commercial and health care facilities (treatment and support areas)]. Other external causes include planned utility voltage reduction (brownout).

Externally Generated Sags or Swells. Externally generated sags or swells can result from disturbances in the electric utility system. The causes are similar to those that cause interruptions but are buffered from the disturbance only by remoteness and the location of the fault relative to the protective equipment of the electrical system source(s) (breakers) and the facility. A swell can result when system load is abruptly reduced until the utility's voltage regulation system responds by lowering the system voltage. An unbalanced fault (in a three-phase system) can also cause a voltage increase on the unfaulted phase.

Internally Generated Sags or Swells. Internally generated sags or swells can be caused by motors that start and stop, the operation of other high-power loads, elevators, improper wiring and grounding, or system overloads and faults. Internally generated transient voltages

(a)

(b)

FIGURE 5.2.9-1 CBEMA and ITIC voltage tolerance curves. (*Courtesy of Reliable Power Meters, Inc.*)

can be caused by arcing contacts and poor connections (e.g., loose bus bar connections), loads such as copy machines, medical imaging equipment, adjustable-speed drives, and other equipment that draws high current for a very short duration.

Externally Generated Transient Voltages. Causes of externally generated transient voltages include utility system switching from capacitor bank operation, abnormalities, and lightning. The utility system abnormalities may include system faults, circuit reclosers (a practice utility companies use when a faulted line is reenergized with expectations that the fault has cleared), or equipment failures (depending on the duration, these events can also cause sags or interruptions). Lightning is another source of external transient voltages. Certain geographical areas are highly prone to lightning strikes. For example, some health care facilities in Florida have had power system disturbances caused by summertime lightning storms so often that their emergency generators operate more frequently than the required monthly testing.

Electromagnetically Conducted Disturbances. Electromagnetically conducted disturbances can be caused by a variety of equipment that produces an electromagnetic field that is conducted and disturbs other equipment. When a radiated electromagnetic field causes a disturbance, typically, it is not considered a power quality issue.[12]

Design Considerations and Solutions. Using a dedicated feeder is an effective practice for minimizing electrical disturbances from high-power devices. This provides a connection point where the system impedance is lower, thus improving voltage regulation.

Transient voltage surge suppression (TVSS) devices are designed to limit the system voltage to a specified level when the energy of the surge is less than the rating of the TVSS device. Therefore, the maximum anticipated surge energy should be calculated for the TVSS device to ensure that it is adequately sized. The location of the TVSS device connection depends on the source of the anticipated voltage transients. If protection is desired from external causes, then, typically, the equipment is installed at the electrical service. If protection is desired from internal causes, then the location of the TVSS device should be analyzed with respect to the cause of the disturbances and the equipment to be protected. Proper installation and grounding is necessary for such devices to be effective.

Power cables can emit electromagnetic fields that interfere with the operation of adjacent equipment. Conversely, power cables can also be subject to electromagnetic fields produced by adjacent equipment. To minimize these effects, cable routing (to reduce proximity) and cable configuration (to reduce magnetic fields) should be studied.

Electrical infrastructure, including the transformers, circuit protection, and wiring, may need to be derated if harmonic currents are high enough to cause significant losses (see "Harmonic Components," later in this chapter).

Power Quality and Grounding Audit

When facilities are experiencing problems caused by suspected power quality, the surest way to determine the causes and obtain the most appropriate solutions is to retain a qualified firm to conduct a power quality and grounding audit. Professionals in the field of power quality have known of the importance of power quality and grounding audits for many years, and this knowledge is becoming more widely disseminated to facilities managers as well. Faulty wiring and grounding cause many of the power quality problems in facility power systems, and an audit is often necessary to isolate the causes.[13] Performing a power quality and grounding audit a priori provides a benchmark to help identify any system changes.[14]

Harmonic Components. Harmonic components are emphasized in this section because the cause of some power quality problems can be traced to harmonic components. This section focuses on an explanation of both harmonic components and mitigation techniques on a fundamental engineering level that is technical enough to explain the issues. This depth is usually

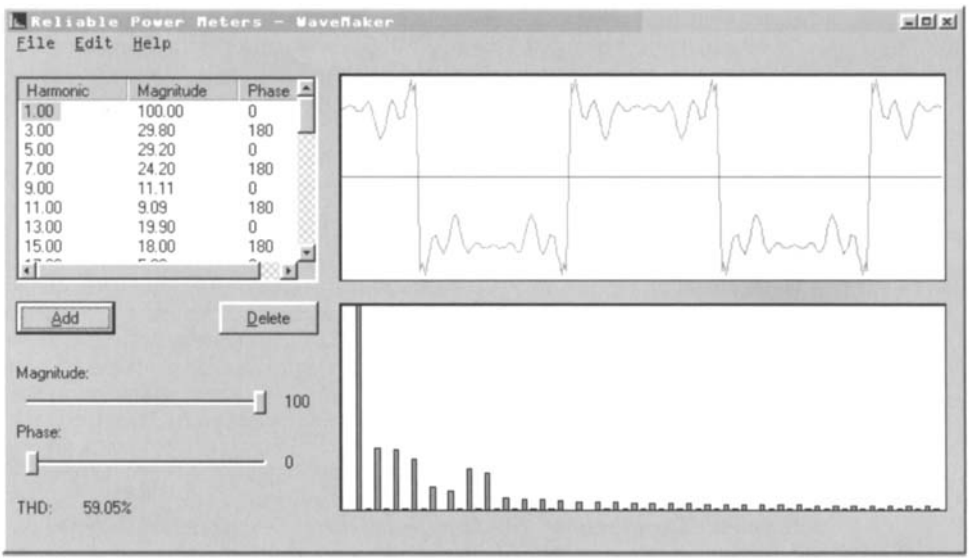
required to adequately understand and solve the actual source of the problem rather than the apparent problem. Sources of harmonic components are presented with solutions. The text includes background information and elementary concepts, including basic Fourier analysis (illustrating representations in both the frequency and time domains); causes of harmonic components; problems associated with harmonic components, including resonance; and solutions, including system design and mitigating techniques. Design techniques include equipment sizing (e.g., feeders, transformers, and panels) and applying K-rated transformers.

Understanding Harmonic Components. A harmonic is a frequency that is an integral multiple of a fundamental frequency. For example, perturbing (plucking) a guitar string makes the string oscillate at a predominant frequency and integral multiple frequencies based on the length of the guitar string. Other frequencies produced by the initial perturbation quickly decay because the string has an appropriate length for a certain note.

The harmonic number represents a frequency that is an integral multiple of the fundamental frequency. Therefore, the fundamental frequency can also be considered the first harmonic, contrary to the way to which harmonic components are typically referred (i.e., the first harmonic has sometimes been incorrectly called the "double of the fundamental frequency"). A mathematical technique to represent a periodic waveform using a linear combination of sine and cosine waveforms is called a *Fourier representation.* For example, Fig. 5.2.9-2 demonstrates that the summation of a fundamental frequency and the first seven odd harmonic components resembles a square wave. The Fourier representation provides an intuitive basis of the way harmonic components can distort the fundamental waveform.

Figure 5.2.9-2 illustrates the magnitudes of the fundamental frequency and the harmonic frequencies (note that the harmonic components are represented as integral multiples of the fundamental frequency). This representation provides straightforward data about the harmonic components. The Fourier transform converts the waveform from the time representation to the frequency representation.

Causes of Harmonic Components. Much of the equipment in the modern electrical environment, including computers, printers, copiers, fluorescent and high-intensity discharge



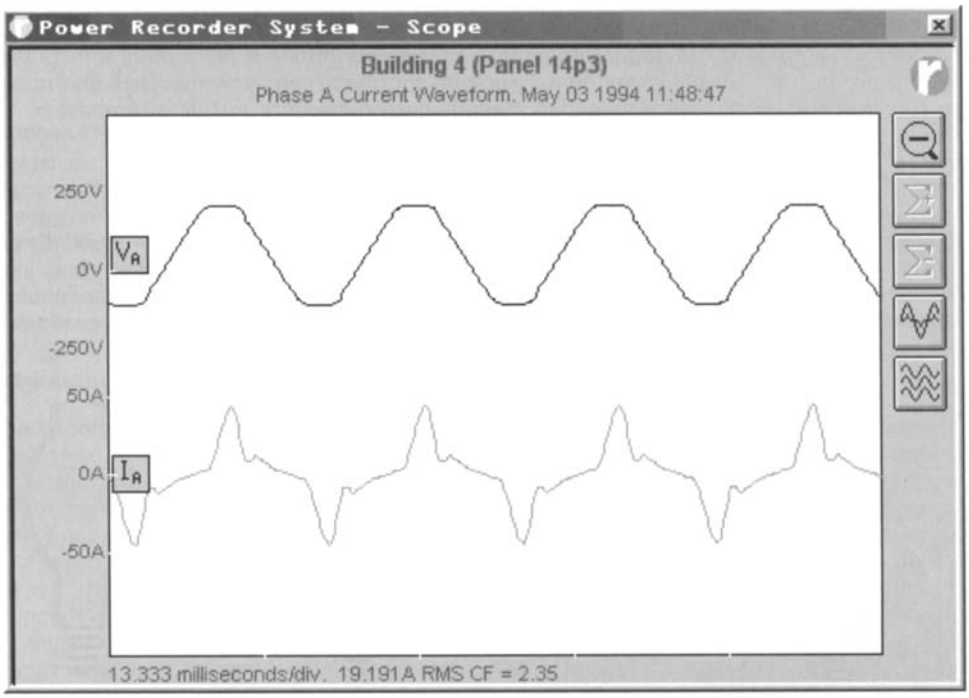


FIGURE 5.2.9-2 Example of square-wave voltage waveform and frequency spectrum. (*Courtesy of Reliable Power Meters, Inc.*)

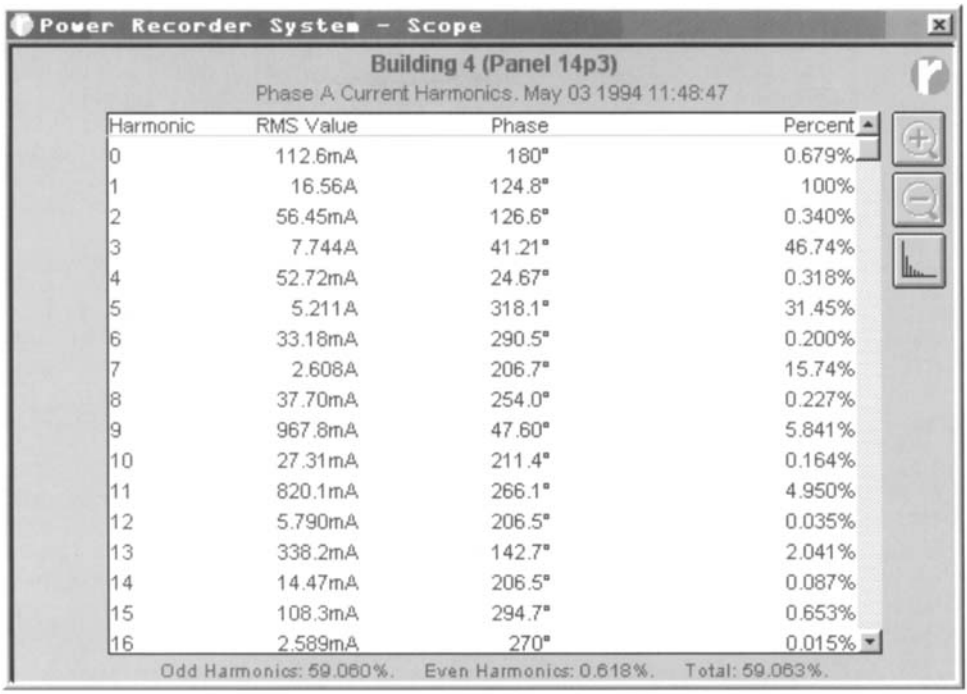
lighting, electronic instrumentation, uninterruptible power supplies, welders, adjustable-speed drives, solid-state controls, radiology equipment, and so on is classified as a nonlinear load. Nonlinear loads distort current and voltage waveforms by drawing current mainly at the peak of the voltage waveform. This flow of current is called *nonlinear* because the relationship between the voltage and the current is not constant and therefore must include other frequencies, in addition to the fundamental, to comprise the waveform. Figure 5.2.9-3 illustrates the current and voltage waveform distortion due to a nonlinear load. The current waveform shown is not a pure sine wave and comprises many harmonic components. This nonlinear current can also cause voltage distortion, as shown in Fig. 5.2.9-3.

Resonance. Resonance is a condition in which an ideal system (i.e., no losses) oscillates. Electrical, as well as mechanical, structural, and other systems can have natural resonant frequencies. A classic example of resonance in a structural system is the suspension bridge in Washington State that was perturbed by the wind (which provided the energy required to start the bridge oscillating), and the amplitude of the oscillations increased until the bridge self-destructed.

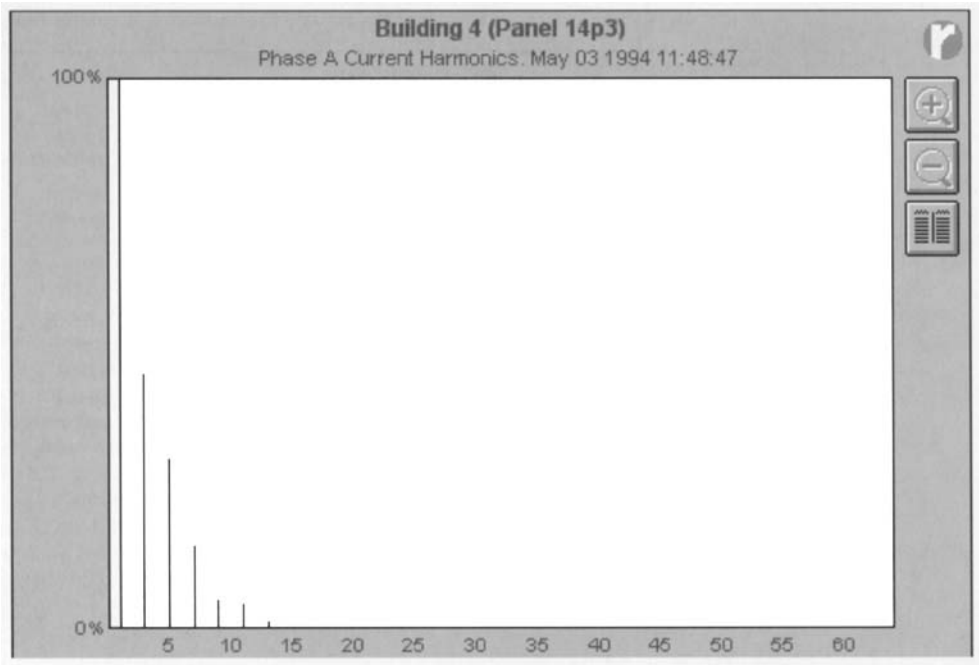


Electrical power systems have natural resonant frequencies based on the system inductance and capacitance. Like the bridge example, an electrical system needs to be excited near a resonant frequency before resonance starts.

Problems Associated with Harmonic Components and Concerns. Resonance occurs when a harmonic produced by a nonlinear load excites the system at (or near) the resonant point. Although the system has losses that make the resonance decay, it continues to provide harmonic components while the nonlinear load is connected, and the system remains in reso-

(a)

FIGURE 5.2.9-3 Example of (*a*) nonlinear load voltage and current waveforms, (*b*) frequency spectrum, and (*c*) contents. (*Courtesy of Reliable Power Meters, Inc.*)



(b)

FIGURE 5.2.9-3 (*Continued*) (*Courtesy of Reliable Power Meters, Inc.*)

nance. Resonance decays when the nonlinear load is disconnected or the system resonant frequency changes sufficiently to a frequency that is not excited by the harmonic components. The system resonance frequency can change by applying inductive loads like relatively large motors. Capacitance is usually introduced into the system to improve the power factor. The capacitance can also change (e.g., from automatic power factor correction equipment) which also changes the system's resonant frequency. This resonance can result in overvoltage conditions and other stresses on the system.

Effects on Electrical System. The presence of harmonic components in an electrical system reduces the system's ability to carry the design load. For example, cable ampacity, transformer capacity, and circuit-breaker capacity are all reduced by harmonic components. A cause of the capacity reduction can be demonstrated by the total increase in current magnitude illustrated in Fig. 5.2.9-3. Another cause is that the increase in frequency increases cable and transformer losses. This phenomenon is known as the *skin effect,* which describes the way electrons move to the outer surface of a conductor as a function of frequency. The operating temperature of electrical equipment increases as equipment losses increase. Eddy current losses in transformers increase as the square of the harmonic number. Hence, higher-order harmonic components cause much larger losses, which results in increased heating of the transformer.

Potential Problems of Harmonic Components. Harmonic components can cause serious problems in electrical equipment, especially if resonance occurs. Harmonic components alone, but more so during resonance, can overload equipment (e.g., cables, transformers, and panels). The overload can go undetected until serious damage or failure occurs. For example,

(c)

FIGURE 5.2.9-3 (*Continued*) (*Courtesy of Reliable Power Meters, Inc.*)

a capacitor connected to a motor for power factor correction could be part of the resonant system. This condition can cause a high current to flow in the capacitor and in its connection leads and cause excessively high current until either an overcurrent device opens or something else burns sufficiently to open the circuit (see the following examples). Examples of other high-current situations that can go undetected are: transformers that are overloaded due to the harmonic components, but the overload is not apparent to the overcurrent device; and panelboard neutrals and shared neutrals (e.g., in a furniture partition system), because only the phase currents are monitored for overcurrent. When single-phase loads are supplied from different phases of the same three-phase source, harmonic components whose number is divisible by three [referred to as *triplen harmonic currents* (e.g., 3, 6, 9, 12, 15 . . .)] will add together in the neutral conductor. The even triplens cancel each other out, whereas the odd triplens mutually contribute to increased current. The result can be a neutral current that is higher than that of the phase conductors. This is why the NEC recommends neutral conductors larger than the associated phase conductors when significant harmonic levels are present.

Nuisance Tripping. Some electronic circuit breakers (dating back to the time when the technology was introduced) use a current-sensing method based on the waveform peak rather than on the root-mean-square (rms) value. When the current waveform is linear, this method provides satisfactory protection. However, when the current waveform is nonlinear, the ratio between the peak value and the rms value is no longer valid. The result can be a nuisance trip—the circuit breaker opens from what was improperly detected as an overload, despite the fact that an overload never occurred.

Effects on Conductors. The increased heating due to the skin effect, the proximity effect, and the conductor impedance, all of which increase with frequency, reduces the effective ampacity of conductors.

Effects on Transformers. Transformer losses increase due to increased eddy currents (which increase by the square of the load and frequency) and hysteresis losses (which increase with frequency). In addition, transformers can also be part of a resonant circuit that increases the load on the transformer.

Effects on Capacitors. Capacitors can experience load increases due to the harmonic voltages, additional heating from an increase in dielectric losses, overvoltage conditions, shortened life expectancy, and possible failure from a resonant condition.

Effects on Motors. The effect of harmonic components on motors should be considered because of the high probability that they could be exposed to harmonic components, the capital investment, and the potential downtime due to a failure. Large facilities typically have three-phase motors that are supplied by a 480-V system. These motors are typically exposed to harmonic components produced by an adjustable-speed drive (ASD) for this motor or for adjacent motors. The harmonic components produced by an ASD with rectifier input is a function of how continuous the current draw is. This current waveform depends on the number of paths of conduction (or poles). A six-pulse converter produces harmonic currents of the 5th, 7th, 11th, 13th, 17th, 19th, and so on. A 12-pulse converter produces harmonic currents of the 11th, 13th, 23rd, 25th, and so on, and the total harmonic distortion is lower than the six-pulse converter because the current waveform is a closer representation of a sinusoid. Intuitively, based on the Fourier representation of both current waveforms, the 12-pulse converter will have less harmonic content (because it is closer to a sinusoid), and the fundamental frequency will be predominant. A motor will operate at a higher temperature for the same reasons as described for a transformer, but, in addition, other heating issues involve the rotating magnetic field of the motor.

The rotation of a motor's magnetic field is due to the alternating current supplied to the motor. When the motor is supplied by a linear current waveform, the resultant magnetic field is also linear; that is, one magnetic field that causes the mechanical rotation is rotating. When the motor is supplied by a nonlinear current waveform, several fields are rotating, one corresponding to each harmonic, as demonstrated by the Fourier representation. The negative-sequence harmonic components cause the magnetic field to rotate in the direction opposite to the positive-sequence harmonic components. Therefore, the sum of the harmonic components causes rotating magnetic fields in both directions. This results in additional heat in the motor, increasing insulation and bearing temperatures and thereby reducing motor life. In addition, losses are greater due to harmonic components, including higher losses due to the skin effect and eddy currents.

Harmonic currents can also be induced in grounded motor shafts. These harmonic currents result in damage to the bearings, called *fluting.* This can result in premature failure of the motor bearings.[1]

Examples. Practical examples are presented from actual troubleshooting and analysis of power quality problems, demonstrating problems associated with power quality and also data to indicate that power quality should not have been the cause of equipment malfunction.

High-Current THD with Low-Circuit Current. The total harmonic distortion (THD) quantifies the harmonic content with respect to the total or fundamental voltage or current. However, the current THD can be misleading by itself. Figure 5.2.9-4 illustrates a circuit where the current THD is nearly 500 percent. Based on the current THD, it may appear that this is a problem. However, the total current is less than the circuit ampacity, and Fig. 5.2.9-4 illustrates that the voltage waveform distortion is negligible.

Power Factor and Resonance. When power factor correction capacitors are connected to a power system, a resonant frequency can exist at which the capacitive and inductive reactances are equal. This frequency can cause high impedance on the system bus, and voltage distortion can result because the high impedance will not shunt this resonant current. In addition, high current will flow between the inductive and capacitive resonating components. Figure 5.2.9-5 illustrates a system that had a resonance condition around the 17th harmonic. The facility had power factor–correcting capacitor banks for each chiller motor. When ASDs were installed in

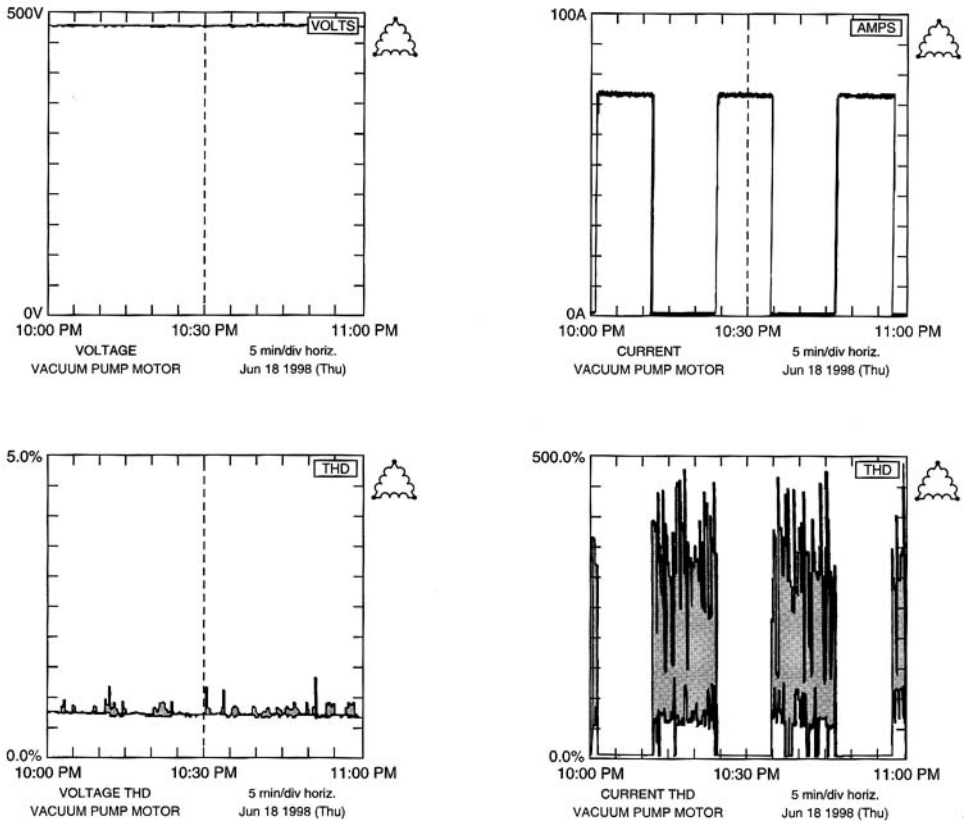


FIGURE 5.2.9-4 Example of nonlinear load current waveform, frequency spectrum, and total harmonic distortion. (*Courtesy of Diversified Consulting Engineers.*)

the building, the capacitors started to burn out. The current THD graph demonstrates that the circuit resonance was caused by the ASD exciting the circuit near its resonant frequency (in this case, the 17th harmonic).

Elevated Neutral Voltage. The odd triplen harmonic components produced in a three-phase system when supplying rectified-input, single-phase loads are additive and make the neutral conductor possibly carry more load than the phase conductors. The harmonic components can cause an excessive neutral voltage drop. The voltage drop will elevate the neutral with respect to ground (because the ground conductor is intended as a non-current-carrying conductor). This potential between the neutral and ground can cause misoperation of sensitive electronic equipment, even though the voltage supplied to the equipment may be within its specified voltage range.

Solutions

There are several ways to reduce harmonic components and improve power quality. This section presents some practical methods.

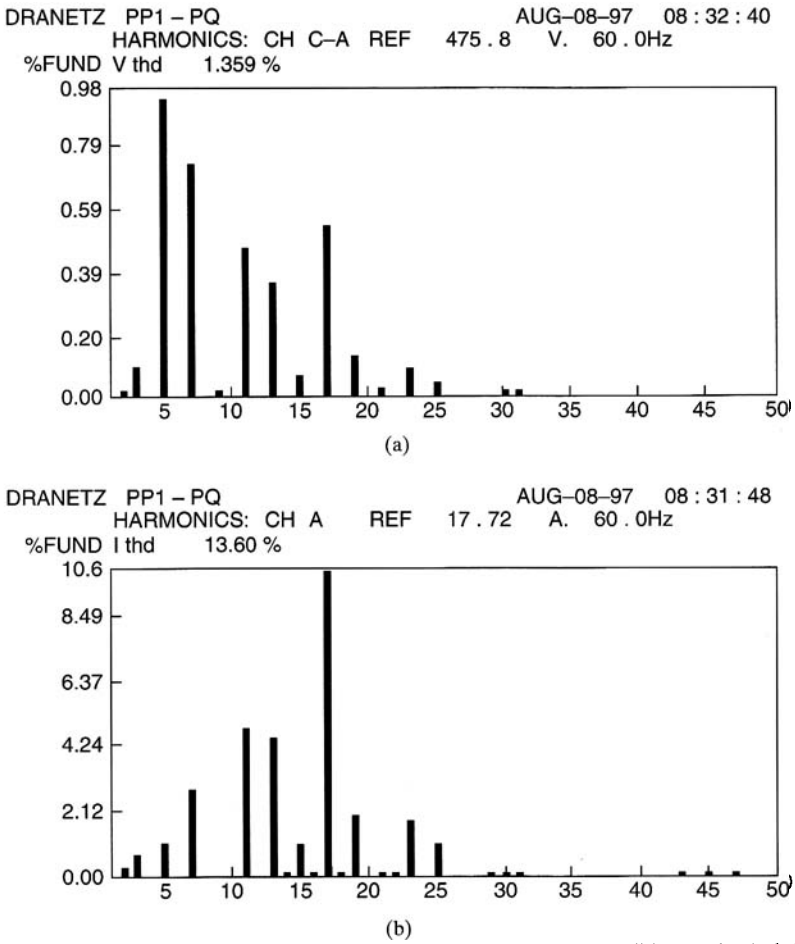

FIGURE 5.2.9-5 Example of current frequency spectrum with resonance condition at the 17th harmonic. (*Courtesy of Diversified Consulting Engineers.*)

System Design. There are many considerations for electrical systems with nonlinear loads. The basic premise is to understand the load and the way it will affect the electrical system and equipment that may be susceptible to harmonic components. The fundamental cause of harmonic components in an electrical system is seen as an increase in load due to the harmonic currents. The concern for other equipment lies in what way the harmonic components could cause an undesirable result (e.g., computer data loss, misoperation of process equipment). This section introduces some techniques for use when a circuit supplies nonlinear loads.

K-Factor and Transformer Sizing. The K-factor-rated transformer is a class of transformer designed specifically to satisfactorily supply nonlinear loads. This transformer is designed to handle a neutral current higher than the phase current, as specified by its K-factor. Standardized K-factors have been established in ANSI/IEEE 57.110, which specifies the harmonic content for a transformer load.[15] For example, a K-4-rated transformer should be capable of supplying loads of 100 percent at the fundamental frequency (60 Hz), 16 percent for the 3rd harmonic current, 10 percent for the 5th harmonic, 7 percent for the 9th harmonic, and specified values continue to the 25th harmonic.

A standard transformer may be used to supply a nonlinear load but should be properly derated, a process that is comprehensively covered in ANSI/IEEE 57.110. The transformer derating is based on calculating the rms current of the load (considering the fundamental current plus the harmonic current values) and establishing the transformer rating to achieve a normal service life.

Electrical Equipment Derating. Harmonic components can cause a load current higher than the fundamental frequency, as calculated for the transformer capability. A method similar to ANSI/IEEE 57.110 for calculating the rms current of the load can be applied to circuit breakers, feeders, panelboards, branch circuits, and outlets. Based on the rms current, the equipment rating can be reduced so that the heating effects from the I^2R losses (and other factors) do not make the equipment operate above its designed temperature.

Circuit breakers should be rms sensing and derated if recommended by the manufacturer. Feeder and panelboard maximum-phase current may have to be limited to less than their ratings to keep the neutral current within the equipment's ampacity. A common practice is to increase the size (some say double) of the neutral conductor and panelboard neutral bus. To provide a well-engineered and cost-effective system, the load characteristics should be reviewed to calculate the neutral current and determine the appropriate rating(s). If a K-factor is calculated for the transformer, it can also be used to size the neutral conductor and the panelboard neutral bus for wye-connected (three-phase, four-wire) loads. The K-factor can be used similarly to determine the phase currents for delta-connected (three-phase, three-wire) loads.

Mitigation Techniques. ANSI/IEEE Standard 519 establishes two criteria: "a limitation on the harmonic current that a user can transmit into the utility system," and "specifies the quality of the voltage that the utility must furnish the user."[16] This standard does not apply to the electrical system within a facility, even though many use it as a guideline for establishing limits within a facility.

Branch Circuit Configuration. A common problem (particularly in an office environment) is the effect of harmonic components on branch circuit wiring with a common (shared) neutral. The problem is that the triplen harmonic components cause a higher-than-expected neutral current based on balancing the load on the phase conductors. The effects can be as serious as an overheated neutral or cause erroneous operation of equipment (refer to "Elevated Neutral Voltage" in the previous section). A simple way to eliminate these problems is to run the branch circuits individually back to the panel, rather than together using a common neutral. This limits the effects of the triplen harmonic components to the panelboard and upstream, thereby eliminating the hazards of overheated neutral branch circuits.

Filters. A filter can be an effective way to reduce harmonic components. However, passive filters (i.e., inductors or capacitors) are typically matched to the system. When applied to loads that are not operated continuously, all load scenarios for the system should be studied. There are two basic types of filters: (1) shunt filters that act as a sink (i.e., a short circuit) for the harmonic components, and (2) series filters that allow current of desired frequency to flow, but block the undesired harmonic components. Active filters are electronic devices that can sense the load harmonic components and produce and inject a current that is 180° out of phase, thereby canceling the undesired harmonic components.

Telephone Interference. Telephones or other devices may be affected by interference from the electric and magnetic fields produced by harmonic components. Mitigation of the harmonic components, grounding, filtering for the affected equipment, or physical separation are effective means of reducing interference. The TIF weighting factor quantifies the frequencies that can cause interference in a telephone.

Isolation Transformers. Isolation transformers were primarily used for personnel safety or to provide electrical isolation before the problems associated with nonlinear loads became well known. An isolation transformer provides a separately derived system that limits the ground and neutral circulating currents and makes the system less susceptible to power quality issues. When an isolation transformer includes an electrostatic shield, it attenuates the

common-mode noise (i.e., it reduces the amount of common-mode noise that transfers from one winding to the other). Transformers are more susceptible to passing high-frequency noise due to their improved coupling characteristics as frequency increases. The ability of a device to attenuate the common-mode noise is quantified as the common-mode rejection ratio.

Drive Isolation Transformers. Drive isolation transformers are used to introduce impedance between the facility power system and the load. As the power circuit of an ASD switches, it may short two phases together for a short duration, an action known as *commutation.* The impedance of the isolation transformer reduces notching on the facility's electrical system caused by commutation, thereby reducing the harmonic content of the supply. If the transformer has an electrostatic shield, it will attenuate the high-frequency, common-mode noise, as previously described for the isolation transformer.

Voltage-regulating transformers are also available that keep the output voltage envelope (the difference between minimum and maximum voltage) within a smaller range than the broader input voltage envelope.
