

# Foundations of Multidimensional and Metric Data Structures

Hanan  
Samet

With applications in computer graphics and visualization, databases, geographic information systems (GIS) and spatial databases, game programming, image processing and computer vision, pattern recognition, solid modelling and computational geometry, similarity retrieval and multimedia databases, VLSI design, and search aspects of bioinformatics.

# **Foundations of Multidimensional and Metric Data Structures**

## The Morgan Kaufmann Series in Computer Graphics and Geometric Modeling

*Foundations of Multidimensional and Metric Data Structures.* Hanan Samet

*Complete Maya Programming Volume II: An In-depth Guide to 3D Fundamentals, Geometry, and Modeling.* David A. D. Gould

*High Dynamic Range Imaging: Data Acquisition, Manipulation, and Display.* Erik Reinhard, Greg Ward, Sumanta Pattanaik, and Paul Debevec

*MEL Scripting for Maya Animators, Second Edition.* Mark R. Wilkins and Chris Kazmier

*Advanced Graphics Programming Using OpenGL.* Tom McReynolds and David Blythe

*Digital Geometry: Geometric Methods for Digital Picture Analysis.* Reinhard Klette and Azriel Rosenfeld

*Digital Video and HDTV: Algorithms and Interfaces.* Charles Poynton  
*Real-Time Shader Programming.* Ron Fosner

*Texturing & Modeling: A Procedural Approach, Third Edition.* David S. Ebert, F. Kenton Musgrave, Darwyn Peachey, Ken Perlin, and Steven Worley

*Geometric Tools for Computer Graphics.* Philip Schneider and David H. Eberly

*Understanding Virtual Reality: Interface, Application, and Design.* William B. Sherman and Alan R. Craig

*Jim Blinn's Corner: Notation, Notation, Notation.* Jim Blinn

*Level of Detail for 3D Graphics.* David Luebke, Martin Reddy, Jonathan D. Cohen, Amitabh Varshney, Benjamin Watson, and Robert Huebner

*Pyramid Algorithms: A Dynamic Programming Approach to Curves and Surfaces for Geometric Modeling.* Ron Goldman

*Non-Photorealistic Computer Graphics: Modeling, Rendering, and Animation.* Thomas Strothotte and Stefan Schlechtweg

*Curves and Surfaces for CAGD: A Practical Guide, Fifth Edition.* Gerald Farin

*Subdivision Methods for Geometric Design: A Constructive Approach.* Joe Warren and Henrik Weimer

*Computer Animation: Algorithms and Techniques.* Rick Parent

*The Computer Animator's Technical Handbook.* Lynn Pockock and Judson Rosebush

*Advanced RenderMan: Creating CGI for Motion Pictures.* Anthony A. Apodaca and Larry Gritz

*Curves and Surfaces in Geometric Modeling: Theory and Algorithms.* Jean Gallier

*Andrew Glassner's Notebook: Recreational Computer Graphics.* Andrew S. Glassner

*Warping and Morphing of Graphical Objects.* Jonas Gomes, Lucia Darsa, Bruno Costa, and Luiz Velho

*Jim Blinn's Corner: Dirty Pixels.* Jim Blinn

*Rendering with Radiance: The Art and Science of Lighting Visualization.* Greg Ward Larson and Rob Shakespeare

*Introduction to Implicit Surfaces.* Edited by Jules Bloomenthal

*Jim Blinn's Corner: A Trip Down the Graphics Pipeline.* Jim Blinn

*Interactive Curves and Surfaces: A Multimedia Tutorial on CAGD.* Alyn Rockwood and Peter Chambers

*Wavelets for Computer Graphics: Theory and Applications.* Eric J. Stollnitz, Tony D. DeRose, and David H. Salesin

*Principles of Digital Image Synthesis.* Andrew S. Glassner

*Radiosity & Global Illumination.* François X. Sillion and Claude Puech

*User Interface Management Systems: Models and Algorithms.* Dan R. Olsen, Jr.

*Making Them Move: Mechanics, Control, and Animation of Articulated Figures.* Edited by Norman I. Badler, Brian A. Barsky, and David Zeltzer

*Geometric and Solid Modeling: An Introduction.* Christoph M. Hoffmann

*An Introduction to Splines for Use in Computer Graphics and Geometric Modeling.* Richard H. Bartels, John C. Beatty, and Brian A. Barsky

## The Morgan Kaufmann Series in Data Management Systems

Series Editor: Jim Gray, Microsoft Research

- Foundations of Multidimensional and Metric Data Structures.* Hanan Samet
- Database Modeling and Design: Logical Design, Fourth Edition.* Toby J. Teorey, Sam S. Lightstone and Thomas P. Nadeau
- Joe Celko's SQL for Smarties: Advanced SQL Programming, Third Edition.* Joe Celko
- Moving Objects Databases.* Ralf Güting and Markus Schneider
- Joe Celko's SQL Programming Style.* Joe Celko
- Data Mining, Second Edition: Concepts and Techniques.* Ian Witten and Eibe Frank
- Fuzzy Modeling and Genetic Algorithms for Data Mining and Exploration.* Earl Cox
- Data Modeling Essentials, Third Edition.* Graeme C. Simsion and Graham C. Witt
- Location-Based Services.* Jochen Schiller and Agnès Voisard
- Database Modeling with Microsoft Visio for Enterprise Architects.* Terry Halpin, Ken Evans, Patrick Hallock, Bill Maclean
- Designing Data-Intensive Web Applications.* Stephano Ceri, Piero Fraternali, Aldo Bongio, Marco Brambilla, Sara Comai, and Maristella Matera
- Mining the Web: Discovering Knowledge from Hypertext Data.* Soumen Chakrabarti
- Advanced SQL: 1999-Understanding Object-Relational and Other Advanced Features.* Jim Melton
- Database Tuning: Principles, Experiments, and Troubleshooting Techniques.* Dennis Shasha and Philippe Bonnet
- SQL: 1999-Understanding Relational Language Components.* Jim Melton and Alan R. Simon
- Information Visualization in Data Mining and Knowledge Discovery.* Edited by Usama Fayyad, Georges G. Grinstein, and Andreas Wierse
- Transactional Information Systems: Theory, Algorithms, and Practice of Concurrency Control and Recovery.* Gerhard Weikum and Gottfried Vossen
- Spatial Databases: With Application to GIS.* Philippe Rigaux, Michel Scholl, and Agnes Voisard
- Information Modeling and Relational Databases: From Conceptual Analysis to Logical Design.* Terry Halpin
- Component Database Systems.* Edited by Klaus R. Dittrich and Andreas Geppert
- Managing Reference Data in Enterprise Databases: Binding Corporate Data to the Wider World.* Malcolm Chisholm
- Data Mining: Concepts and Techniques.* Jiawei Han and Micheline Kamber
- Understanding SQL and Java Together: A Guide to SQLJ, JDBC, and Related Technologies.* Jim Melton and Andrew Eisenberg
- Database: Principles, Programming, and Performance, Second Edition.* Patrick and Elizabeth O'Neil
- The Object Data Standard: ODMG 3.0.* Edited by R. G. G. Cattell and Douglas K. Barry
- Data on the Web: From Relations to Semistructured Data and XML.* Serge Abiteboul, Peter Buneman, and Dan Suciu
- Data Mining: Practical Machine Learning Tools and Techniques with Java Implementations.* Ian Witten and Eibe Frank
- Joe Celko's SQL for Smarties: Advanced SQL Programming, Second Edition.* Joe Celko
- Joe Celko's Data and Databases: Concepts in Practice.* Joe Celko
- Developing Time-Oriented Database Applications in SQL.* Richard T. Snodgrass
- Web Farming for the Data Warehouse.* Richard D. Hackathorn
- Management of Heterogeneous and Autonomous Database Systems.* Edited by Ahmed Elmagarmid, Marek Rusinkiewicz, and Amit Sheth
- Object-Relational DBMSs: Tracking the Next Great Wave, Second Edition.* Michael Stonebraker and Paul Brown, with Dorothy Moore
- A Complete Guide to DB2 Universal Database.* Don Chamberlin
- Universal Database Management: A Guide to Object/Relational Technology.* Cynthia Maro Saracco
- Readings in Database Systems, Third Edition.* Edited by Michael Stonebraker and Joseph M. Hellerstein
- Understanding SQL's Stored Procedures: A Complete Guide to SQL/PSM.* Jim Melton
- Principles of Multimedia Database Systems.* V. S. Subrahmanian
- Principles of Database Query Processing for Advanced Applications.* Clement T. Yu and Weiyi Meng
- Advanced Database Systems.* Carlo Zaniolo, Stefano Ceri, Christos Faloutsos, Richard T. Snodgrass, V. S. Subrahmanian, and Roberto Zicari
- Principles of Transaction Processing.* Philip A. Bernstein and Eric Newcomer
- Using the New DB2: IBM's Object-Relational Database System.* Don Chamberlin
- Distributed Algorithms.* Nancy A. Lynch
- Active Database Systems: Triggers and Rules For Advanced Database Processing.* Edited by Jennifer Widom and Stefano Ceri
- Migrating Legacy Systems: Gateways, Interfaces, & the Incremental Approach.* Michael L. Brodie and Michael Stonebraker
- Atomic Transactions.* Nancy Lynch, Michael Merritt, William Weihl, and Alan Fekete
- Query Processing for Advanced Database Systems.* Edited by Johann Christoph Freytag, David Maier, and Gottfried Vossen
- Transaction Processing: Concepts and Techniques.* Jim Gray and Andreas Reuter
- Building an Object-Oriented Database System: The Story of O2.* Edited by François Bancilhon, Claude Delobel, and Paris Kanellakis
- Database Transaction Models for Advanced Applications.* Edited by Ahmed K. Elmagarmid
- A Guide to Developing Client/Server SQL Applications.* Setrag Khoshafian, Arvola Chan, Anna Wong, and Harry K. T. Wong
- The Benchmark Handbook for Database and Transaction Processing Systems, Second Edition.* Edited by Jim Gray
- Camelot and Avalon: A Distributed Transaction Facility.* Edited by Jeffrey L. Eppinger, Lily B. Mummert, and Alfred Z. Spector
- Readings in Object-Oriented Database Systems.* Edited by Stanley B. Zdonik and David Maier

Foreword . . . . .	xv
Preface . . . . .	xvii
<b>1 Multidimensional Point Data . . . . .</b>	<b>1</b>
1.1 Introduction . . . . .	5
1.2 Range Trees . . . . .	14
1.3 Priority Search Trees . . . . .	19
1.4 Quadrees . . . . .	28
1.4.1 Point Quadrees . . . . .	28
1.4.1.1 Insertion . . . . .	28
1.4.1.2 Deletion . . . . .	31
1.4.1.3 Search . . . . .	36
1.4.2 Trie-Based Quadrees . . . . .	37
1.4.2.1 MX Quadtree . . . . .	38
1.4.2.2 PR Quadrees . . . . .	42
1.4.3 Comparison of Point and Trie-Based Quadrees . . . . .	47
1.5 K-d Trees . . . . .	48
1.5.1 Point K-d Trees . . . . .	50
1.5.1.1 Insertion . . . . .	50
1.5.1.2 Deletion . . . . .	52
1.5.1.3 Search . . . . .	55
1.5.1.4 Point K-d Tree Variants . . . . .	57
1.5.2 Trie-Based K-d Trees . . . . .	70
1.5.2.1 PR K-d Tree . . . . .	71
1.5.2.2 Sliding-Midpoint K-d Tree . . . . .	72
1.5.2.3 Bucket PR K-d Tree and PMR K-d Tree . . . . .	74
1.5.2.4 Path-Compressed PR K-d Tree . . . . .	75
1.5.2.5 Path-Level Compressed PR K-d Tree . . . . .	77
1.5.2.6 BD-Trees . . . . .	79
1.5.2.7 Balanced Box-Decomposition Tree (BBD-Tree) . . . . .	83
1.5.3 Conjugation Tree . . . . .	88
1.6 One-Dimensional Orderings . . . . .	90
1.7 Bucket Methods . . . . .	95
1.7.1 Tree Directory Methods . . . . .	96
1.7.1.1 K-d-B-Tree . . . . .	98
1.7.1.2 Hybrid Tree . . . . .	101
1.7.1.3 LSD Tree . . . . .	102
1.7.1.4 hB-Tree . . . . .	106
1.7.1.5 K-d-B-Tries . . . . .	110
1.7.1.6 BV-Tree . . . . .	116
1.7.1.6.1 Definition . . . . .	117
1.7.1.6.2 Building a BV-Tree . . . . .	120

1.7.1.6.3	Searching a BV-Tree . . . . .	122
1.7.1.6.4	Performance . . . . .	125
1.7.1.6.5	Summary . . . . .	127
1.7.1.7	Static Methods . . . . .	129
1.7.2	Grid Directory Methods . . . . .	130
1.7.2.1	Grid File . . . . .	131
1.7.2.2	EXCELL . . . . .	137
1.7.2.3	Linear Hashing . . . . .	140
1.7.2.3.1	Adapting Linear Hashing to Multidimensional Data . . . . .	140
1.7.2.3.2	Multidimensional Extendible Hashing (MDEH) . . . . .	146
1.7.2.3.3	Dynamic Z Hashing . . . . .	150
1.7.2.3.4	Linear Hashing with Partial Expansions (LHPE) . . . . .	152
1.7.2.4	Alternative Implementations of Linear Hashing . . . . .	152
1.7.2.4.1	Quantile Hashing . . . . .	153
1.7.2.4.2	Piecewise Linear Order Preserving (PLOP) Hashing . . . . .	154
1.7.2.4.3	Spiral Hashing . . . . .	156
1.7.2.4.4	Summary . . . . .	159
1.7.2.5	Comparison . . . . .	160
1.7.3	Storage Utilization . . . . .	163
1.8	PK-Trees . . . . .	164
1.8.1	Motivation . . . . .	165
1.8.2	Overview . . . . .	167
1.8.3	Definition . . . . .	169
1.8.4	Comparison with Bucket Methods . . . . .	170
1.8.5	Operations . . . . .	171
1.8.5.1	Representation and Searching . . . . .	172
1.8.5.2	Insertion . . . . .	172
1.8.5.3	Deletion . . . . .	178
1.8.6	Discussion . . . . .	181
1.9	Conclusion . . . . .	184

**2 Object-Based and Image-Based Image Representations . . . . . 191**

2.1	Interior-Based Representations . . . . .	193
2.1.1	Unit-Size Cells . . . . .	194
2.1.1.1	Cell Shapes and Tilings . . . . .	196
2.1.1.2	Ordering Space . . . . .	199
2.1.1.3	Array Access Structures . . . . .	202
2.1.1.4	Tree Access Structures . . . . .	203
2.1.2	Blocks . . . . .	204
2.1.2.1	Decomposition into Arbitrarily Sized Rectangular Blocks . . . . .	205
2.1.2.2	Medial Axis Transformation (MAT) . . . . .	208
2.1.2.3	Irregular Grid . . . . .	210
2.1.2.4	Region Quadtree and Region Octree . . . . .	211
2.1.2.5	ATree . . . . .	220
2.1.2.6	Bintree . . . . .	221
2.1.2.7	Adaptation of the Point Quadtree for Regions . . . . .	222
2.1.2.8	Adaptation of the K-d Tree for Regions . . . . .	223
2.1.2.9	X-Y Tree, Treemap, and Puzzletree . . . . .	225
2.1.2.10	Hexagonal Blocks . . . . .	230
2.1.2.11	Triangular Blocks . . . . .	231
2.1.3	Nonorthogonal Blocks . . . . .	232
2.1.3.1	BSP Tree . . . . .	233
2.1.3.2	K-Structure . . . . .	237
2.1.3.3	Separating Chain . . . . .	242
2.1.3.3.1	Overview . . . . .	242
2.1.3.3.2	Layered Dag . . . . .	248
2.1.4	Arbitrary Objects . . . . .	254
2.1.4.1	Coverage-Based Splitting . . . . .	255
2.1.4.2	Density-Based Splitting . . . . .	260
2.1.5	Hierarchical Interior-Based Representations . . . . .	264

2.1.5.1	Image-Based Hierarchical Interior-Based Representations (Pyramids)	266
2.1.5.2	Object-Based Hierarchical Interior-Based Representations (R-trees, Bounding Box Hierarchies)	270
2.1.5.2.1	Overview	271
2.1.5.2.2	Ordering-Based Aggregation Techniques	275
2.1.5.2.3	Extent-Based Aggregation Techniques	282
2.1.5.2.4	R*-Tree	289
2.1.5.2.5	Bulk Insertion	296
2.1.5.2.6	Bulk Loading	299
2.1.5.2.7	Shortcomings and Solutions	301
2.1.5.3	Disjoint Object-Based Hierarchical Interior-Based Representations (k-D-B-Tree, R <sup>+</sup> -Tree, and Cell Tree)	304
2.2	Boundary-Based Representations	312
2.2.1	The Boundary Model (BRep)	315
2.2.1.1	Overview	315
2.2.1.2	Edge-Based Methods Using Winged Edges	317
2.2.1.3	Vertex-Based and Face-Based Methods Using Laths	329
2.2.1.3.1	Lath Data Structures for Manifold Objects	331
2.2.1.3.2	Lath Data Structures for Meshes with Boundaries	336
2.2.1.3.3	Summary	341
2.2.1.4	Voronoi Diagrams, Delaunay Graphs, and Delaunay Triangulations	346
2.2.1.5	Constrained and Conforming Delaunay Triangulations	350
2.2.1.6	Delaunay Tetrahedralizations	352
2.2.1.7	Applications of the Winged-Edge Data Structure (Triangle Table, Corner Table)	353
2.2.2	Image-Based Boundary Representations	355
2.2.2.1	Line Quadtree	356
2.2.2.2	MX Quadtree and MX Octree	357
2.2.2.3	Edge Quadtree	359
2.2.2.4	Face Octree	361
2.2.2.5	Adaptively Sampled Distance Fields	362
2.2.2.6	PM Quadtrees	365
2.2.2.7	PM Octree	369
2.2.2.8	Bucket PM Quadtree and PMR Quadtree	374
2.2.2.9	Sector Tree	377
2.2.2.10	Cone Tree	380
2.2.3	Object-Based Boundary Representations	382
2.2.3.1	Strip Tree, Arc Tree, and BSPR	382
2.2.3.2	Prism Tree	386
2.2.3.3	HAL Tree	389
2.2.3.4	Simplification Methods and Data Structures	391
2.2.4	Surface-Based Boundary Representations	399
2.3	Difference-Based Compaction Methods	408
2.3.1	Runlength Encoding	409
2.3.2	Chain Code	416
2.3.3	Vertex Representation	417
2.4	Historical Overview	423
<b>3</b>	<b>Intervals and Small Rectangles</b>	<b>427</b>
3.1	Plane-Sweep Methods and the Rectangle Intersection Problem	428
3.1.1	Segment Tree	430
3.1.2	Interval Tree	434
3.1.3	Priority Search Tree	439
3.1.4	Alternative Solutions and Related Problems	443
3.2	Plane-Sweep Methods and the Measure Problem	447
3.3	Point-Based Methods	453
3.3.1	Representative Points	453
3.3.2	Collections of Representative Points	459
3.3.2.1	Corner Stitching	459

3.3.2.2	Balanced Four-Dimensional K-d Tree . . . . .	460
3.3.2.3	Grid File . . . . .	462
3.3.2.4	LSD Tree . . . . .	463
3.3.2.5	Two-Dimensional Representations . . . . .	463
3.3.3	Summary . . . . .	464
3.4	Area-Based Methods . . . . .	466
3.4.1	MX-CIF Quadtree . . . . .	466
3.4.1.1	Definition . . . . .	466
3.4.1.2	Operations . . . . .	468
3.4.1.3	Comparison with Other Representations . . . . .	473
3.4.2	Alternatives to the MX-CIF Quadtree . . . . .	474
3.4.3	Multiple Quadtree Block Representations . . . . .	480
<b>4</b>	<b>High-Dimensional Data . . . . .</b>	<b>485</b>
4.1	Best-First Nearest Neighbor Finding . . . . .	490
4.1.1	Motivation . . . . .	491
4.1.2	Search Hierarchy . . . . .	492
4.1.3	Algorithm . . . . .	493
4.1.4	Algorithm with Duplicate Instances of Objects . . . . .	499
4.1.5	Algorithm Extensions ( <i>K</i> -Nearest, <i>K</i> -Farthest, Skylines) . . . . .	502
4.1.6	Nearest Neighbors in a Spatial Network . . . . .	508
4.1.7	Related Work . . . . .	516
4.2	The Depth-First <i>K</i> -Nearest Neighbor Algorithm . . . . .	517
4.2.1	Basic Algorithm . . . . .	518
4.2.2	Pruning Rules . . . . .	521
4.2.3	Effects of Clustering Methods on Pruning . . . . .	529
4.2.4	Ordering the Processing of the Elements of the Active List . . . . .	534
4.2.5	Improved Algorithm . . . . .	538
4.2.6	Incorporating MAXNEARESTDIST in a Best-First Algorithm . . . . .	548
4.2.7	Example . . . . .	553
4.2.8	Comparison . . . . .	554
4.3	Approximate Nearest Neighbor Finding . . . . .	557
4.4	Multidimensional Indexing Methods . . . . .	566
4.4.1	X-Tree . . . . .	566
4.4.2	Bounding Sphere Methods: Sphere Tree, SS-Tree, Balltree, and SR-Tree . . . . .	567
4.4.3	Increasing the Fanout: TV-Tree, Hybrid Tree, and A-Tree . . . . .	572
4.4.4	Methods Based on the Voronoi Diagram: OS-Tree . . . . .	573
4.4.5	Approximate Voronoi Diagram (AVD) . . . . .	580
4.4.6	Avoiding Overlapping All of the Leaf Blocks . . . . .	585
4.4.7	Pyramid Technique . . . . .	587
4.4.8	Methods Based on a Sequential Scan . . . . .	592
4.5	Distance-Based Indexing Methods . . . . .	598
4.5.1	Distance Metric and Search Pruning . . . . .	600
4.5.2	Ball Partitioning Methods . . . . .	604
4.5.2.1	Vp-Tree . . . . .	604
4.5.2.1.1	Structure . . . . .	604
4.5.2.1.2	Search . . . . .	606
4.5.2.2	Vp <sup>sb</sup> -Tree . . . . .	607
4.5.2.3	Mvp-Tree . . . . .	608
4.5.2.4	Other Methods Related to Ball Partitioning . . . . .	609
4.5.3	Generalized Hyperplane Partitioning Methods . . . . .	613
4.5.3.1	Gh-Tree . . . . .	613
4.5.3.2	GNAT . . . . .	616
4.5.3.3	Bisector Tree and Mb-Tree . . . . .	617
4.5.3.4	Other Methods Related to Generalized Hyperplane Partitioning . . . . .	622
4.5.4	M-Tree . . . . .	624
4.5.4.1	Structure . . . . .	624
4.5.4.2	Search . . . . .	626
4.5.5	Sa-Tree . . . . .	629
4.5.5.1	Definition . . . . .	630
4.5.5.2	Search . . . . .	633

4.5.6	kNN Graph . . . . .	637
4.5.7	Distance Matrix Methods . . . . .	643
4.5.7.1	AESA . . . . .	643
4.5.7.2	LAESA . . . . .	646
4.5.7.3	Other Distance Matrix Methods . . . . .	647
4.5.8	SASH: Indexing without Using the Triangle Inequality . . . . .	650
4.6	Dimension Reduction Methods . . . . .	662
4.6.1	Searching in the Dimension Reduced Space . . . . .	664
4.6.1.1	Range Queries . . . . .	664
4.6.1.2	Nearest Neighbor Queries . . . . .	665
4.6.2	Using Only One Dimension . . . . .	668
4.6.3	Representative Point Methods . . . . .	670
4.6.4	Transformation into a Different and Smaller Feature Set . . . . .	671
4.6.4.1	SVD . . . . .	671
4.6.4.2	Discrete Fourier Transform (DFT) . . . . .	676
4.6.5	Summary . . . . .	685
4.7	Embedding Methods . . . . .	685
4.7.1	Introduction . . . . .	687
4.7.2	Lipschitz Embeddings . . . . .	691
4.7.2.1	Definition . . . . .	691
4.7.2.2	Selecting Reference Sets . . . . .	692
4.7.2.3	Example of a Lipschitz Embedding . . . . .	693

# Foreword

---

Jim Gray, Microsoft Research

This book organizes the bewildering array of spatial and multi-dimensional indexing methods into a coherent field. Hanan Samet is the dean of “spatial data indexing.” His two previous books have been the essential reference works for over a decade. This book unifies those previous books, and places the field in the broader context of indexing and searching for information in any metric space.

The book is encyclopedic. Nonetheless, it reads very well as a textbook that systematically develops the ideas. The four major chapters (points, objects, multidimensional intervals including rectangles, and high-dimensional data), are concise, copiously illustrated, and have exercises at the end of each section with detailed answers at the end of the book. The book includes tutorials on B-trees, linear hashing, and spiral hashing, has a huge bibliography (over 2,000 references), a detailed index compiled by the author, and a website (<http://www.cs.umd.edu/~hjs/quadtree/>) with demonstration programs and datasets.

There is no question that mastering this book will take time—but this book will be invaluable for those of us who struggle with spatial data, or with scientific datasets, or with graphics and vision problems involving volumetric queries, or with higher-dimensional datasets common in data mining.

# Preface

---

The representation of multidimensional data is an important issue in diverse fields including database management systems (e.g., spatial databases, multimedia databases), computer graphics, game programming, computer vision, geographic information systems (GIS), pattern recognition, similarity searching (also known as similarity retrieval), solid modeling, computer-aided design (CAD), robotics, image processing, computational geometry, finite-element analysis, and numerous others. The key idea in choosing an appropriate representation is to facilitate operations such as search. This means that the representation involves sorting the data in some manner to make it more accessible. In fact, the term *access structure* or *index* is often used as an alternative to the term *data structure* in order to emphasize the importance of the connection to sorting.

The most common definition of “multidimensional data” is a collection of points in a higher dimensional space (i.e., greater than 1). These points can represent locations and objects in space as well as more general records where each attribute (i.e., field) corresponds to a dimension and only some, or even none, of the attributes are locational. As an example of nonlocational point data, consider an employee record that has attributes corresponding to the employee’s name, address, sex, age, height, weight, and social security number. Such records arise in database management systems and can be treated as points in, for this example, a seven-dimensional space (i.e., there is one dimension for each attribute), although the different dimensions have different type units (i.e., name and address are strings of characters; sex is binary; while age, height, weight, and social security number are numbers). Note that the address attribute could also be interpreted in a locational sense using positioning coordinates such as latitude and longitude readings although the stringlike symbolic representation is far more common.

When multidimensional data corresponds to locational data, we have the additional property that all of the attributes usually have the same unit (possibly with the aid of scaling transformations), which is distance in space. In this case, we can combine the distance-denominated attributes and pose queries that involve proximity. For example, we may wish to find the closest city to Chicago within the two-dimensional space from which the locations of the cities are drawn. Another query seeks to find all cities within 50 miles of Chicago. In contrast, such queries are not very meaningful when the attributes do not have the same type. Nevertheless, other queries such as range queries that seek, for example, all individuals born between 1940 and 1960 whose weight ranges between 150 and 200 pounds are quite common and can be posed regardless of the nature of the attributes.

When multidimensional data spans a continuous physical space (i.e., an infinite collection of locations), the issues become more interesting. In particular, we are no longer just interested in the locations of objects, but, in addition, we are also interested in the space that they occupy (i.e., their extent). Some example objects with extent include lines (e.g., roads, rivers), intervals (which can correspond to time as well as

space), regions of varying shape and dimensionality (e.g., lakes, counties, buildings, crop maps, polygons, polyhedra), and surfaces. The objects (when they are not points) may be disjoint or could even overlap.

Spatial multidimensional data is generally of relatively low dimension. However, there are many application domains where the data is of considerably higher dimensionality and is not necessarily spatial. This is especially true in databases for application domains such as multimedia and bioinformatics data, to name just two, where the data is a set of objects, and the high dimensionality is a direct result of attempts to describe the objects via a collection of features that characterize them (also known as a *feature vector*). For example, in the case of image data, some commonly used features include color, color moments, textures, shape descriptions, and so on, expressed using scalar values. Although such data falls into the class of point data, it often requires using very different representations than those that are traditionally used for point data. The problem is often attributed to the *curse of dimensionality* [159], which simply means that the indexing methods do not do as good a job of facilitating the retrieval of the objects that satisfy the query as is the case when the data has lower dimensionality.

The above discussion of nonspatial data of high dimensionality has been based on the premise that we know the features that describe the objects (and hence the dimensionality of the underlying feature space). In fact, it is usually quite difficult to identify the features, and thus we frequently turn to experts in the application domain from which the objects are drawn for assistance in this process. Nevertheless, often the features cannot be easily identified even by the domain experts. In particular, sometimes the only information available is a distance function that indicates the degree of similarity (or dissimilarity) between all pairs of objects in the database as well as how to compute the similarity between objects in the domain. Usually the distance function  $d$  is required to obey the triangle inequality, be nonnegative, and be symmetric, in which case it is known as a *metric* (also referred to as a *distance metric*). In this case, we resort to what are termed metric or distance-based representations, which differ from the more conventional representations in that the objects are now sorted with respect to their distance from a few key objects, known as *pivots*, rather than with respect to some commonly known reference point (e.g., the origin in the spatial domain), which may not necessarily be associated with any of the objects.

This book is about the representation of data such as that described above. It is organized into four chapters. Each chapter is like a part, sometimes as big as a book. Chapter 1 deals with the representation of point data, usually of low dimensionality. One of the keys to the presentation in this chapter is making a distinction between whether the representation organizes the data (e.g., a binary search tree) or the embedding space from which the data is drawn (e.g., a trie). Considerable attention is also devoted to issues that arise when the volume of the data is so high that it cannot fit in memory, and hence the data is disk resident. Such methods are characterized as bucket methods and have been the subject of extensive research in the database community.

Chapter 2 deals with the representation of objects. It focuses on object-based and image-based representations. These distinctions are analogous to those made in computer graphics where algorithms and decompositions of objects are characterized as being object-based or image-based corresponding to whether the representations result from the decomposition of the objects or the environment in which the objects are embedded, respectively. The central theme in this chapter is how the representations deal with the key queries of where and what—that is, given an object, we want to know its location, and, given a location, we want to know the identity of the object (or objects) of which it is a member. Efficiently responding to these queries, preferably with one representation, has motivated many researchers in computer graphics and related fields such as computer vision, solid modeling, and spatial databases, to name a few. This leads, in part, to a distinction between representations on the basis of being either object hierarchies, of which the R-tree [791] and its variants (commonly used in database applications) are examples, or space hierarchies, of which the pyramid and its variants (commonly

used in computer vision applications) are examples. The representations that have been developed can also be differentiated on the basis of whether the objects are represented by their interiors or by their boundaries.

Chapter 3 deals with the representation of intervals and small rectangles. These representations are applicable in a number of important areas. For example, they are used in very large-scale integration (VLSI) design applications (also known as CAD), where the objects are modeled as rectangles for the sake of simplicity. The number of objects in these applications is quite large, and the size of the objects is several orders of magnitude smaller than that of the space from which they are drawn. This is in contrast to cartographic applications, where the sizes of the objects are larger. These representations are also used in game programming applications (e.g., [475, 476, 1025, 1456, 1890]), where their deployment is motivated by the fact that the objects are in spatial registration, thereby enabling efficient calculation of set-theoretic operations while not being as sensitive to changes in position as is the case for some other hierarchical representations that are based on a regular decomposition of the underlying space (e.g., the region quadtree). The representation of intervals is also of interest for applications that involve temporal data where intervals play a role (e.g., [951]). They can also be used for the representation of moving objects, which finds use in spatiotemporal databases (e.g., [21, 950, 1057, 1092, 1305, 2013] and the text of Güting and Schneider [790]).

Chapter 4 deals with the representation of high-dimensional data where the data is not spatial and the actual dimensionality of the data is also an issue. The key is that the data usually consists of features where the number and identity of the features that should be represented is not always clear. In particular, this data arises in applications such as multimedia, where the use of a large number of features to describe the objects is based on the premise that by increasing the number of features we are increasing our ability to differentiate between the objects for retrieval. An alternative is to make use of a distance function that measures the similarity (or dissimilarity) between the objects. A discussion of a number of distance-based indexes is included here.

Chapter 4 is motivated by the important problem of *similarity searching*—the process of finding and retrieving objects that are similar to a given object or set of objects. This process invariably reduces to finding the nearest or  $k$  nearest neighbors, and hence a considerable amount of attention is paid to this query by showing how to perform it efficiently for both distance-based and multidimensional indexing methods. The observation that, for high-dimensional data, the use of multidimensional indexing methods often fails to yield any improvement in performance over a simple sequential scan of the data is also addressed. This is in part due to the cost of computing distance in high dimensions, the nature of the data distribution, and the relatively low volume of available data vis-à-vis its dimensionality (i.e., the curse of dimensionality). One response is to take note of the observation that the “inherent dimensionality” of a dataset is often much lower than that of the underlying space. In particular, this has led to the development of techniques to reduce the dimensionality of the data using methods such as Singular Value Decomposition (SVD). An alternative solution that is discussed is how to make use of contractive embedding methods that embed the data in a lower-dimensional space, and then make use of a filter-and-refine algorithm in conjunction with multidimensional indexing methods to prune irrelevant candidates from consideration.

Many of the data structures that are presented in the four chapters are hierarchical. They are based either on the principle of recursive decomposition (similar to *divide-and-conquer* methods [27]) or on the aggregation of objects into hierarchies. Hierarchical data structures are useful because of their ability to focus on the interesting subsets of the data. This focusing results in an efficient representation and in improved execution times.

Hierarchical representations of spatial data were the subject of one of my earlier books [1637]. It dealt with the four basic spatial data types: points, rectangles, lines, and volumes. Many of these representations were based on variants of the quadtree and

octree data structure that have been applied to many problems in a variety of domains. In this case, the term *quadtree* was used in a general sense to describe a class of representations whose common property was that they were based on the principle of recursive decomposition of space. They were differentiated on the following bases:

1. The type of data they are used to represent
2. The principle guiding the decomposition process
3. The resolution (variable or not)

This book is a considerable expansion of [1637] with approximately 10% overlap. Nevertheless there still remains a considerable amount of material from [1637] that has not been included in this book (e.g., from Chapters 4 and 5). One of the features of [1637] was the inclusion of detailed code for building and updating a number of data structures (at least one for each of the spatial data types point, lines, and rectangles). This code is also present in this book but is now part of the exercises and their solutions. In addition, the VASCO (Visualization and Animation of Spatial Constructs and Operations) [243, 244, 245, 246]) set of JAVA applets is available for use to illustrate many operations for a large number of the data structures presented in the current book (see <http://www.cs.umd.edu/~hjs/quadtree/index.html>). Readers interested in seeing how these methods are used in the context of an application should try the SAND Internet Browser [1644] at the same URL, which provides an entry point to explore their use in a geographic information system (GIS). The SAND Internet Browser is part of a considerably more complex system rooted in the QUILT quadtree GIS [1732], the SAND spatial database engine [71, 73], and the SANDTcl scripting tool for building spatial database applications [568, 570].

One substantial difference in the current book from [1637] is the inclusion of a part on high-dimensional data, representing approximately one third of the text (Chapter 4). In addition, almost all of the material on object-based and image-based representations in Chapter 2 is new. It is interesting to note that this material and the observation that most object representations are motivated by the desire to respond to the *what* and *where* queries served as the motivation for this book. Similarly, much of the material on point-based representations in Chapter 1 is also new with a particular emphasis on bucketing methods. In the case of linear hashing and spiral hashing, the explanations of the methods have been moved to Appendix B and C, respectively, while Chapter 1 focuses on how to adapt them to multidimensional data. Since the B-tree is really a fundamental foundation of the various bucket methods in Chapter 1 and of hierarchical object-based interior representations such as the R-tree in Chapter 2, an overview of B-trees has been included as Appendix A. This was motivated by our past experience with [1637], which revealed that often the extent to which readers were familiar with the B-tree did not match our expectations. Only Chapter 3, which deals with intervals and collections of rectangles, can be considered as both an update and an expansion of material in [1637] as it also contains a substantial number of new representations.

The main focus of this book is on representations and indexing methods rather than the execution of operations using them, which is the primary focus of another one of my books [1636]. Nevertheless, a few operations are discussed in greater detail. In particular, substantial coverage is given to the *k*-nearest neighbor finding operation in Sections 4.1 and 4.2 in Chapter 4. Its use in similarity searching is the main reason for the development of most of the representations discussed in this chapter. The related point location problem is also discussed in great detail in Sections 2.1.3.2 and 2.1.3.3 of Chapter 2. Another operation that is discussed in some detail (in Section 2.2.3.4 of Chapter 2) is simplification of surface data for applications in computer graphics and visualization. We assume that the representations and operations that we discuss are implemented in a serial environment although there has been a considerable interest in implementations in a parallel environment (e.g., [210, 213, 373, 470, 524, 532, 862, 898, 916, 997, 1182, 1719, 2006] and related references cited therein), as well as in making use of graphics processing units (GPU) (e.g., [739, 1146, 1815]).

Nevertheless there remain many topics for which justice requires a considerably more thorough treatment. However, due to space limitations, detailed discussion of them has been omitted, and, instead, the interested reader is referred to the appropriate literature. For example, surface representations are discussed in the context of boundary-based representations in Section 2.2 of Chapter 2. These are known as topological data structures. However, the area is much richer than what is covered here as can be seen by referring to the collection of papers edited by Rana [1536]. The presentation in Chapter 2 mentions simplification methods and data structures (Section 2.2.3.4) and hierarchical surface-based boundary representations (Sections 2.2.2–2.2.4). Simplification methods are also known as *Level of Detail (LOD) methods* and are reviewed comprehensively in the text by Luebke, Reddy, Cohen, Varshney, Watson, and Huebner [1212]. Additional work from the perspective of geometric modeling can be found in the texts by Bartels, Beatty, and Barsky [131], Mortenson [1316], Goldman [716], Farin [596], and Warren and Weimer [1962]. Many of the topics discussed here can also be classified under the category of *visual computing* (e.g., see Nielsen [1372]). Another related area in which our coverage is intentionally limited is real-time collision detection where speed is of the essence, especially in applications such as game programming. For a thorough treatment of this topic, see the recent texts by van den Bergen [198] and Ericson [564]. Similarly, representations for spatiotemporal data and moving objects are not discussed in great detail, and interested readers are referred to some of the references mentioned earlier.

Solid modeling is another rich area where the presentation has been limited to the boundary model (BRep), found in Section 2.2.1 of Chapter 2, which also includes a detailed discussion of variants of the winged-edge representation. For more detailed expositions on this and related topics, see the books by Mäntylä [1232], Hoffmann [870], and Paoluzzi [1457]. See also some early influential survey articles by Requicha [1555], Srihari [1798], and Chen and Huang [345]. Of course, there is also a much greater connection to computer graphics than that which is made in the text. This connection is explored further in another of my books [1636] and is also discussed in some early surveys by Overmars [1442] and Samet and Webber [1666, 1667].

Results from computational geometry, although related to many of the topics covered in this book, are only presented in the context of representations for intervals and collections of small rectangles (Sections 3.1 and 3.2 of Chapter 3) and the point location problem (Sections 2.1.3.2 and 2.1.3.3 of Chapter 2). For more details on early work involving some of these and related topics, the interested reader is encouraged to consult the texts by Preparata and Shamos [1511], Edelsbrunner [540], Boissonnat and Yvinec [230], and de Berg, van Kreveld, Overmars, and Schwarzkopf [196], as well as the early collections of papers edited by Preparata [1509] and Toussaint [1884]. See also the surveys and problem collections by Edelsbrunner [539], O’Rourke [1423], and Toussaint [1885]. This work is closely related to earlier research on searching as surveyed by Bentley and Friedman [173], the text of Overmars [1440], and Mehlhorn’s [1282] text, which contains a unified treatment of multidimensional searching. For a detailed examination of similar and related topics in the context of external memory and massive amounts of data, see the survey of Vitter [1933].

Many of the data structures described in this book find use in spatial databases, geographic information systems (GIS), and multimedia databases. The close relationship between spatial databases and geographic information systems is evidenced by recent texts that combine results from the areas, such as those of Laurini and Thompson [1113], Worboys [2023], Günther [773], Rigaux, Scholl, and Voisard [1562], and Shekhar and Chawla [1746], as well as the surveys of Güting [784], Voisard and David [1938], and Shekhar, Chawla, Ravada, Fetterer, Liu, and Lu [1747].

For a slightly different perspective, see the text of Subrahmanian [1807], which deals with multimedia databases. Another related area where these data structures have been used is constraint databases, which are discussed in great detail in the recent text by Revesz [1559]. Note that, with the exception of the nearest neighbor finding operation, which is common to many of the fields spanned by this book, we do not discuss the

---

**Preface** numerous spatial database operations whose execution is facilitated by the data structures presented in this text, such as, for example, spatial join (e.g., [89, 262, 261, 772, 1072, 894, 934, 1195, 1207, 1223, 1415, 1474, 2076] as well as in a recent survey [935]), which are covered in some of the previously cited references.

In a similar vein, a number of survey articles have been written that deal with the representations that are described in this book from a database perspective, such as the one by Gaede and Günther [670]. The survey article by Samet [1642], however, combines a computer graphics/computer vision perspective with a database perspective. See also the earlier surveys by Nagy and Wagle [1335], Samet and Rosenfeld [1647], Peuquet [1490], and Samet [1628, 1632]. Others, such as Chávez, Navarro, Baeza-Yates, and Marroquín [334], Böhm, Berchtold, and Keim [224], Hjaltason and Samet [854, 855], and Clarkson [401], are oriented towards similarity searching applications.

The material in this book also has a strong connection to work in image processing and computer vision. In particular, the notion of a pyramid (discussed in Section 2.1.5.1 of Chapter 2) has a rich history, as can be seen in the collection of articles edited by Tanimoto and Klinger [1844] and Rosenfeld [1573]. The connection to pattern recognition is also important and can be seen in the survey by Toussaint [1882]. The pioneering text by Rosenfeld and Kak [1574] is a good early treatment of image processing and should be consulted in conjunction with the more recent text by Klette and Rosenfeld [1034], which makes the connection to digital geometry.

Nevertheless, given the broad and rapidly expanding nature of the field, I am bound to have omitted significant concepts and references. In addition, at times I devote a disproportionate amount of attention to some concepts at the expense of others. This is principally for expository purposes; in particular, I feel that it is better for the reader to understand some structures well rather than to receive a quick runthrough of buzzwords. For these indiscretions, I beg your pardon and still hope that you bear with me.

Usually my approach is an algorithmic one. Whenever possible, I have tried to motivate critical steps in the algorithms by a liberal use of examples. This is based on my strong conviction that it is of paramount importance for the reader to see the ease with which the representations can be implemented and used. At times, some algorithms are presented using pseudo-code so that readers can see how the ideas can be applied. I have deliberately not made use of any specific programming language in order to avoid dating the material while also acknowledging the diverse range in opinion at any given instance of time as to which language is appropriate. The main purpose of the pseudo-code is to present the algorithm clearly. The pseudo-code is algorithmic and is a variant of the ALGOL [1346] programming language, which has a data structuring facility incorporating pointers and record structures. I do not make use of object orientation although my use of record structures is similar in spirit to rudimentary classes in SIMULA [437] and FLEX [1008], which are the precursors of modern object-oriented methods. I make heavy use of recursion. This language has similarities to C [1017], C++ [1805], Java (e.g., [93]), PASCAL [952], SAIL [1553], and ALGOL W [137]. Its basic features are described in Appendix D. However, the actual code is not crucial to understanding the techniques, and it may be skipped on a first reading. The index indicates the page numbers where the code for each algorithm is found.

In many cases I also give an analysis of the space and time requirements of different data structures and algorithms. The analysis is usually of an asymptotic nature and is in terms of *big O* and  $\Omega$  notation [1043]. The *big O* notation denotes an upper bound. For example, if an algorithm takes  $O(\log_2 N)$  time, then its worst-case behavior is never any worse than  $\log_2 N$ . The  $\Omega$  notation denotes a lower bound. As an example of its use, consider the problem of sorting  $N$  numbers. When we say that sorting is  $\Omega(N \cdot \log_2 N)$  we mean that given any algorithm for sorting, there is some set of  $N$  input values for which the algorithm will require at least this much time.

At times, I also describe implementations of some of the data structures for the purpose of comparison. In such cases, counts such as the number of fields in a record are often given. However, these numbers are only meant to clarify the discussion. They are

not to be taken literally, as improvements are always possible once a specific application is analyzed more carefully.

Each section contains a substantial number of exercises. Many of the exercises develop the material in the text further as a means of testing the reader's understanding, as well as suggesting future directions. When the exercise or its solution is not my own, I have credited its originator by preceding it with their name. The exercises have not been graded by difficulty. Usually, their solution does not require any mathematical skills beyond the undergraduate level. However, while some of the exercises are quite straightforward, the solutions to others require some ingenuity. Solutions, or references to papers that contain the solutions, are provided for a substantial number of the exercises that do not require programming. Of course, the reader is counseled to try to solve the exercises before turning to the solutions. The solutions are presented here as it is my belief that much can be learned by self-study (both for the student and, even more so, for the author!). The motivation for pursuing this approach was my wonderful experience on my first encounter with the rich work on data structures by Knuth [1044, 1045, 1046].

An extensive bibliography is provided. It contains entries for both this book and its companion predecessors [1636, 1637]. Each reference is annotated with one or more keywords and a list of the numbers of the book sections in which it is cited in the current text (denoted by *F*) or either of the other two texts (denoted by *D* for [1637] and *A* for [1636]) as well as in the exercises and solutions. Not all of the references that appear in the bibliography are cited in the text. They are included for the purpose of providing readers the ability to access as completely as possible the body of literature relevant to the topics discussed in the books. In order to increase the usefulness of these uncited references (as well as all of the references), a separate keyword index is provided that indicates some of the references in the bibliography that discuss them. Of course, this list is not exhaustive. For the more general categories (e.g., "points"), a second level index entry is often provided to narrow the search in locating relevant references. In addition, a name and credit index is provided that indicates the page numbers in this book on which each author's work is cited or a credit (i.e., acknowledgement) is made (e.g., in the main text, preface, appendices, exercises, or solutions).

My target audience is a varied one. The book is designed to be of use to professionals who are interested in the representation of spatial and multidimensional data and have a need for an understanding of the various issues that are involved so that they can make a proper choice in their application. The presentation is an algorithmic one rather than a mathematical one although the execution time and storage requirements are discussed. Nevertheless, the reader need not be a programmer nor a mathematician to appreciate the concepts described here. The material is useful not just to computer scientists. It is useful for applications in a diverse range of fields including geography, high-energy physics, engineering, mathematics, games, multimedia, bioinformatics, and other disciplines where location or the concept of a metric are important. The book can also be used in courses on a number of topics including databases, geographic information systems (GIS), computer graphics, computational geometry, pattern recognition, and so on, where the discussion of the data structures that it describes supplements existing material or serves as the central topic of the course. The book can also be used in a second course on data structures where the focus is on multidimensional and metric data structures. The organization of the material to be covered in these courses is discussed in greater detail below.

## A Guide to the Instructor

This book can be used in a course on representations for multidimensional and metric data in multimedia databases, most likely at the graduate level. Such a course would include topics from the various parts as is appropriate to match the interests of the students. It would most likely be taught within a database framework, in which case the focus

would be on the representation of points as in Chapter 1 and high-dimensional data in Chapter 4. In particular, the emphasis would be on bucket methods (Sections 1.1, 1.7, and 1.8 of Chapter 1), multidimensional indexing methods for high-dimensional data (Section 4.4 of Chapter 4), and distance-based indexing methods (Section 4.5 of Chapter 4). In addition, quite a bit of attention should be focused on representations based on object hierarchies such as the R-tree (Section 2.1.5.2 of Chapter 2).

The book can also be used in a computer graphics/computer vision/solid modeling framework, as well as part of a game programming course, in which case the emphasis would be on Chapters 2 and 3. In addition, it should include the discussion of some of the more basic representations of point data from Sections 1.1 and 1.4–1.6 of Chapter 1. Such a course could serve as a prerequisite to courses in computer graphics and solid modeling, computational geometry, database management systems (DBMS), multidimensional searching, image processing, and VLSI design applications. More specifically, such a course would include the discussions of interior-based representations of image data in Sections 2.1.1–2.1.3 of Chapter 2 and representations of image data by their boundaries in Sections 2.2.2 and 2.2.3 of Chapter 2. The representation of two-dimensional regions such as chain codes in Section 2.3.2 of Chapter 2 and polygonal representations in Section 2.2.2 of Chapter 2 and the use of point methods for focusing the Hough Transform in Section 1.5.1.4 of Chapter 1 should also be included as they are relevant to image processing.

The discussions of plane-sweep methods and their associated data structures such as the segment tree, interval tree, and priority search tree in Sections 3.1 and 3.2 of Chapter 3, and of point location and associated data structures such as the K-structure and the layered dag in Sections 2.1.3.2 and 2.1.3.3, respectively, of Chapter 2, are all relevant to computational geometry. Other relevant topics in this context are the Voronoi Diagram and the Delaunay triangulation and tetrahedralization in Sections 2.2.1.4–2.2.1.7 of Chapter 2 as well as the approximate Voronoi diagram (AVD) in Section 4.4.5 of Chapter 4. The discussion of boundary-based representations such as the winged-edge data structure in Sections 2.2.1.1–2.2.1.3 of Chapter 2 is also relevant to computational geometry as well as to solid modeling. In addition, observe that the discussions of rectangle-representation methods and plane-sweep methods in Chapter 3 are of use for VLSI design applications.

Moreover, it is worth repeating the earlier comment that the discussion of bucket methods such as linear hashing, spiral hashing, grid file, and EXCELL, discussed in Sections 1.7 and 1.8 of Chapter 1, as well as the various variants of object hierarchies as typified by the R-tree in Section 2.1.5.2 of Chapter 2, are important in the study of database management systems. The discussion of topics such as k-d trees in Section 1.5 of Chapter 1, range trees in Section 1.2 of Chapter 1, priority search trees priority search tree in Section 1.3 of Chapter 1, and point-based rectangle representations in Section 3.3 of Chapter 3 are all relevant to multidimensional searching.

Another potential venue for using the book is a course on representations for spatial data either in a geography department where it would be part of a curriculum on geographic information systems (GIS) or within the context of course on spatial databases in a computer science department. Again, the material that would be covered would be a combination of that which is covered in a multimedia database course and the computer graphics/computer vision/solid modeling or game programming course. In this case, much of the material on the representation of high-dimensional data in Chapter 4 would be omitted although the material on nearest neighbor finding and approximate nearest neighbor finding (Sections 4.1–4.3 of Chapter 4) would be included. In addition, a greater emphasis would be placed on the representation of objects by their interiors (Section 2.1 of Chapter 2) and by their boundaries (Section 2.2 of Chapter 2).

This book could also be used in a second data structures course. The emphasis would be on the representation of spatial data. In particular, the focus would be on the use of the principle of “divide-and-conquer.” Hierarchical data structures provide a good demonstration of this principle. In this case, the choice of topics is left to the

instructor although one possible organization of topics would choose some of the simpler representations from the various chapters as follows.

From Chapter 1, some interesting topics include the fixed-grid method and some of its variants (Section 1.1); numerous variants of quadtrees such as the point quadtree (Section 1.4.1), PR quadtree (Section 1.4.2.2), k-d tree (Section 1.5), and variants thereof (Sections 1.5.1.4, 1.5.2.1, and 1.5.2.3); bucket methods such as the grid file (Section 1.7.2.1), EXCELL (Section 1.7.2.2), linear hashing (Section 1.7.2.3.1 and Appendix B); range trees (Section 1.2); priority search trees for points (Section 1.3); and the comparison of some of the structures (Section 1.9).

From Chapter 2, some interesting topics include the opening matter (preambles of both the chapter and of Section 2.1); unit-size cells (Section 2.1.1 with the exception of the discussion of cell shapes and tilings in Section 2.1.1.1); blocks (Sections 2.1.2.1–2.1.2.9); BSP tree (Section 2.1.3.1); winged-edge data structure (Sections 2.2.1.1 and 2.2.1.2); image-based boundary representations such as the MX quadtree and MX octree (Section 2.2.2.2), PM quadtree (Section 2.2.2.6), and PM octree (Section 2.2.2.7); and hierarchical object-based interior representations such as the R-tree (Section 2.1.5.2.1).

From Chapter 3, some interesting topics include the discussion of plane-sweep methods and data structures such as the segment tree (Section 3.1.1), interval tree (Section 3.1.2), and the priority search tree for rectangles and intervals (Section 3.1.3) and the MX-CIF quadtree (Section 3.4.1).

From Chapter 4, the most interesting topic is the incremental nearest neighbor algorithm (Sections 4.1.1–4.1.3). A brief introduction to distance-based indexing methods is also appropriate. In this case the most appropriate representations for inclusion are the vp-tree (Sections 4.5.2.1.1 and 4.5.2.1.1), the gh-tree (Section 4.5.3.1), and the mb-tree (Section 4.5.3.3).

Throughout the book, both worst-case optimal methods and methods that work well in practice are emphasized. This is in accordance with my view that the well-rounded computer scientist should be conversant with both types of algorithms. It is clear that the material in this book is more than can be covered in one semester. Thus the instructor will invariably need to reduce it as necessary. For example, in many cases, the detailed examples can be skipped or used as a basis of a term project or programming assignments.

Note that regardless of the course in which this book is used, as pointed out earlier, the VASCO [243, 244, 245, 246] set of JAVA applets can be used to illustrate many operations for a large number of the data structures presented in the current book (see <http://www.cs.umd.edu/~hjs/quadtree/index.html>). In particular, for point data, it includes the point quadtree, k-d tree (also known as a point k-d tree), MX quadtree, PR quadtree, bucket PR quadtree, PR k-d tree, bucket PR k-d tree, PMR quadtree, PMR k-d tree, 2-d range tree (also known as a two-dimensional range tree), priority search tree, R-tree, and the PK-tree. For line data, it includes the  $PM_1$  quadtree,  $PM_2$  quadtree,  $PM_3$  quadtree, PMR quadtree, bucket PM quadtree, and the R-tree. For collections of rectangles, it includes the MX-CIF quadtree, rectangle quadtree, bucket rectangle quadtree (also known as a bucket rectangle PM quadtree), PMR rectangle quadtree (also known as a PMR rectangle quadtree), PMR rectangle k-d tree, and R-tree. For all of these data structures, students can see how they are built step by step, and also how queries such as deletion, finding nearest neighbors, and overlap queries (which include the more general range query and corridor or buffer queries) are supported. In each case, the operation proceeds incrementally. Finally, an applet is also provided for the region quadtree that shows how it can be constructed from other region representations such as rasters and chain codes as well as how to obtain them from the region quadtree.

Instructors who adopt this book in a course are also welcome to use a comprehensive set of lecture notes in the form of Powerpoint/PDF presentations that help clarify many of the concepts presented in the book.

Over the years I have received help from many people, and for this I am extremely grateful to them. In particular, I would like to acknowledge the assistance and friendship of Gísli R. Hjaltason, whose sharp insight and critical thinking helped me clarify many of the concepts presented in this book over a very long time period during which we had daily discussions and interactions. He also set up all of the  $\LaTeX$  typesetting macros that made it easy to assemble this book as well as drawing many of the figures and the original slides that accompany much of the text. I am deeply indebted to him. I would also like to acknowledge the many useful and critical discussions that I have had with Houman Alborzi as well as unstinting help in getting the final manuscript together. In addition, I have also been helped immensely by Jagan Sankaranarayanan, as well as Frantisek Brabec, Frank Morgan, and William Cheng in the preparation of the figures and the associated technical issues, and Brian Norberg in the preparation of the Powerpoint versions of many of the slides that accompany much of the text. I am deeply appreciative to Janice Perrone for providing logistical support in various daily tasks in which she was cheerfully assisted by David Madoo. I am grateful to Richard R. Muntz for generously providing office space, computer access, parking, mailing facilities, and most importantly being a sounding board at UCLA during many visits there. The system to compile the exhaustive bibliography was set up by Ron Sivan, and in the actual compilation process I was ably assisted by Nazanin Poorfarhani, Sze-Kit Hsu, Rene McDonald, and Astrid Hellmuth. Phil Bernstein, Per-Åke Larson, and Carlo Zaniolo graciously provided last-minute access to their personal library of conference proceedings to enable me to double-check some of my bibliography; of course, any errors are my responsibility.

At the same time, I would also like to thank again Robert E. Webber, Markku Tamminen, and Michael B. Dillencourt, who gave me much help in my first two books [1636, 1637], thereby making it much easier to write this book. I have also been extremely fortunate to work with Azriel Rosenfeld over the past thirty years. His dedication and scholarship have been a true inspiration to me. I deeply cherish our association. Finally, I want to also thank Gary D. Knott who introduced me to the field of multidimensional data structures by asking “how to delete in point quadtrees,” and Charles R. Dyer who provided much interaction in the initial phase of my research when my focus was on computer vision applications of such data structures.

During the time that this book was written, my research was supported, in part, by the National Science Foundation, the Department of Energy, the Office of Policy Development and Research of the Department of Housing and Urban Development, and Microsoft Research. In particular, I would like to thank Tom Barclay, Larry Brandt, Dan Fay, Robert Grafton, Jim Gray, Dan Hitchcock, Howard Moraff, Rita Rodriguez, Mukesh Singhal, Jonathan Sperling, Bhavani Thuraisingham, Kentaro Toyama, and Maria Zemankova. I would also like to thank the support in previous years of the National Science Foundation, Defense Mapping Agency, US Army Engineering Topographic Laboratory, and the Harry Diamond Laboratory. In particular, I would like to thank Richard T. Antony, Su-Shing Chen, Y. T. Chien, Hank Cook, Phil J. Emmerman, Fred Esch, Joe Rastatter, Alan Saalfeld, and Larry Tokarcik. I am very appreciative of the support of all of them.

Aside, from the individuals named above, I have also benefited from discussions with many people over the past years. They have commented on various parts of the book and include Chuan-Heng Ang, Walid G. Aref, Lars Arge, John Arras, Renato Barrera, S. K. Bhaskar, Pedja Bogdanovich, Kaushink Chakrabarti, William Cheng, Larry S. Davis, Wiebren de Jonge, Daniel DeMenthon, Leila De Floriani, Michael B. Dillencourt, Sydney D’Silva, Claudio Esperança, Hakan Ferhatosmanoglu, Andre Folkers, Guilherme Fonseca, Mike W. Freeston, B. Brent Gordon, Eric Haines, Andreas Henrich, Michael E. Houle, Glenn S. Iwerks, Edwin Jacox, Ibrahim Kamel, Laveen N. Kanal, Simon Kasif, Benjamin B. Kimia, Hans-Peter Kriegel, Sam Lamphier, Nati

Linial, Paola Magillo, Maurizio Martelli, Songrit Maneewongvatana, Sharad Mehrotra, Daniel P. Miranker, David M. Mount, Richard R. Muntz, Michael Murphy, Brad G. Nickerson, Helmut Noltemeier, Aris M. Ouksel, Valerio Pascucci, Franco P. Preparata, Ari Rappoport, Manjit Ray, Azriel Rosenfeld, Peter Scheuermann, Günther F. Schrack, George Scott, Bernhard Seeger, Ben Shneiderman, Aya Soffer, Matti Tikkanen, Thatcher Ulrich, Amitabh Varshney, Robert E. Webber, Isaac Weiss, Peter Widmayer, Changjiang Yang, and Kaizhong Zhang.

The final preparation of the book was greatly aided by the helpful reviews of Charles R. Dyer, Jim Gray, Dinesh Manocha, Peter Revesz, Peter Scheuermann, Claudio T. Silva, and Bretton Wade. Their help and interest is very much appreciated. Similarly, I have been very fortunate to work with Diane Cerra of Morgan Kaufmann Publishers, who has been very patient with me during the many years that we have talked about the book, and I appreciate her confidence that it would happen. Most importantly, I am very grateful for her enthusiasm and for enabling me to reach my intended audience by ensuring the production of a book that is affordable while also being of the highest technical and production quality. During the years that I have been working on this book I have also benefited from discussions with representatives of other publishers and I am appreciative of the time they took to discuss the book with me. In particular, I would like to thank Peter Gordon, Alfred Hofmann, Ingeborg Mayer, David Pallai, Alice Peters, Simone Taylor, and Hans Wossner.

I was very fortunate to have the assistance of Ken DellaPenta in copy editing the book. Ken was amazing in terms of the number of technical errors that he caught, besides teaching me the Chicago Style and having the patience to answer my numerous questions. The actual composition and final layout of the book was ably handled by Paul C. Anagnostopoulos of Windfall Software, who capably incorporated the  $\LaTeX$  macros and scripts that we developed into a viable system that could turn out the final version of the book using the  $Zz\TeX$  system. I also appreciated his valuable technical advice. Darice Moore exhibited great patience in managing the interactions between the art house, the author, and compositor on getting the figures into shape. The production end was ably coordinated by Alan Rose, who kept us all on schedule and tactfully refereed the numerous production issues that invariably arise in such a big effort.

I would also like to acknowledge discussions with the following additional people on my other two books, which also had an effect on the contents of this book: James Arvo, Harvey H. Atkinson, Thor Bestul, Sharat Chandran, Chiun-Hong Chien, Jiang-Hsing Chu, Roger D. Eastman, Herbert Edelsbrunner, Christos Faloutsos, George (Gyuri) Fekete, Kikuo Fujimura, John Gannon, John Goldak, Erik G. Hoel, Liuqing Huang, Frederik W. Jansen, Ajay Kela, David Kirk, Per-Åke Larson, Dani Lischinski, Don Meagher, Randal C. Nelson, Glenn Pearson, Ron Sacks-Davis, Timos Sellis, Clifford A. Shaffer, Deepak Sherlekar, Li Tong, Brian Von Herzen, and David S. Wise.

Last, but not least, I would like to express my thanks and appreciation to my wife, Leila, for her love, encouragement, support, confidence, and patience during the too many years that this book took to complete. I would also like to thank my parents, Julius Samet and Lotte Samet, and in-laws, Ario De Floriani and Dalma Paravagna, for their support and belief in me, as well as my Uncle Seev Berlinger for his inspiration and imbuing me with the notion that your work should also be fun, as if it was your hobby. To all of them, I owe a lot and am forever indebted.

# Multidimensional Point Data

---

The representation of multidimensional point data is a central issue in database design, as well as applications in many other fields, including computer graphics, computer vision, computational geometry, image processing, geographic information systems (GIS), pattern recognition, very large scale integration (VLSI) design, and others. These points can represent locations and objects in space, as well as more general records. As an example of a general record, consider an employee record that has attributes corresponding to the employee's name, address, sex, age, height, weight, and Social Security number. Such records arise in database management systems and can be treated as points in, for this example, a seven-dimensional space (i.e., there is one dimension for each attribute or key<sup>1</sup>), albeit the different dimensions have different type units (i.e., name and address are strings of characters; sex is binary; and age, height, weight, and Social Security number are numbers).

Formally speaking, a database is a collection of records, termed a *file*. There is one record per data point, and each record contains several attributes or keys. In order to facilitate retrieval of a record based on some of the values of attributes,<sup>2</sup> we assume the existence of an ordering for the range of values of each of these attributes. In the case of locational or numeric attributes, such an ordering is quite obvious because the values of these attributes are numbers. In the case of alphanumeric attributes, the ordering is usually based on the alphabetic sequence of the characters making up the attribute value. Other data such as color could be ordered by the characters making up the name of the color or, possibly, the color's wavelength. It should be clear that finding an ordering for the range of values of an attribute is generally not an issue; the only issue is what ordering to use!

The representation that is ultimately chosen for this collection depends, in part, on answers to the following questions:

1. What is the type of the data (e.g., is it discrete, is it continuous, is its domain finite)?
2. What operations are to be performed on the data?
3. Should we organize the data or the embedding space from which the data is drawn?

---

<sup>1</sup> We use the terms *key* and *attribute* (as well as *field*, *dimension*, *coordinate*, and *axis*) interchangeably in this chapter. We choose among them based on the context of the discussion, while attempting to be consistent with their use in the literature.

<sup>2</sup> This is also known as *secondary key retrieval* (e.g., [1046]) to distinguish it from *primary key retrieval*. In secondary key retrieval, the search is based on the value of more than just one attribute, as is the case in traditional searching applications where we are dealing with one-dimensional data.

4. Is the database static or dynamic (i.e., can the number of data points grow and shrink at will)?
5. Can we assume that the volume of data is sufficiently small so that it can all fit in main memory, or should we make provisions for accessing disk-resident data?

The type of the data is an important question. Of course, we must distinguish between data consisting of one and several attributes. Classical attribute values include bits, integers, real numbers, complex numbers, characters, strings, and so on. There is also the issue of whether the domain from which the data is drawn is finite (i.e., bounded) or not. This distinction is used, in part, to determine which of the data organizations in question 3 can be used. An alternative differentiation is on the basis of whether the data is discrete or continuous. In the case of data that is used in conventional scientific computations, discrete data corresponds to integers, while continuous data corresponds to real and complex numbers. In the case of spatial data, we have discrete data (by which we mean distinct samples or instances) such as points (which is the subject of this chapter and, to a lesser extent, Chapter 4), while continuous data consists of objects that take up space such as line segments, areas, surfaces, volumes, and so on (which are the subject of Chapter 2 and, to a lesser extent, Chapter 3). Similarly, temporal data can also be differentiated on the basis of whether it is discrete or continuous. In particular, concepts such as event time and transaction time are indicative of a discrete approach, while concepts such as rates are more indicative of a continuous approach in that they recognize that the data is constantly changing over time. In this book, we do not deal with temporal data (e.g., [951]) or the closely related concept of spatiotemporal data (e.g., [21, 950, 1305]).

The distinction in question 3 is formulated in terms of the notion of an *embedding space*. The embedding space is determined by the span of values of the data. For example, suppose that we have a set of employee records with a state-valued attribute called `STATE` whose embedding space is the set of names of the 50 U.S. states. In this case, our distinction is between organizing the employee records on the basis of the value of the `STATE` attribute (e.g., all employee records whose `STATE` attribute value starts with letters A–M in one group and all employee records whose `STATE` attribute value starts with letters N–Z in another group) or organizing the employee records on the basis of the value of this attribute for the record of a particular employee (e.g., if employee records are grouped into two groups based on whether the first letter of the value of their `STATE` attribute is less than or equal to the first letter of the value of the `STATE` attribute for the record corresponding to an employee named “John Smith”).

As another example, in the case of a computer architecture where the representation of each data item is implemented by one word of 32 bits, then, for simple integer data, the embedding space spans the values 0 to  $2^{32} - 1$ , while it is considerably larger for real data, where it depends on the way in which the representation of simple real data is implemented (i.e., in the case of floating-point representation, the number of bits allocated to the mantissa and to the exponent). In both cases of the example above, the embedding space is said to be finite.

The distinction made in question 3 is often used to differentiate between one-dimensional searching methods (e.g., [1046]) that are tree-based from those that are trie-based. In particular, a *trie* [251, 635] is a branching structure in which the value of each data item or key is treated as a sequence of  $j$  characters, where each character has  $M$  possible values. A node at depth  $k - 1$  ( $k \geq 1$ ) in the trie represents an  $M$ -way branch depending on the value of the  $k$ th character (i.e., it has  $M$  possible values). Some (and at times all) of the data is stored in the leaf nodes, and the shape of the trie is independent of the order in which the data is processed.

For example, address computation methods such as radix searching [1046] (also known as *digital searching* and yielding structures known as *digital trees*) are instances of trie-based methods, since the boundaries of the partition regions of similarly valued

data that result from the partitioning (i.e., branching) process are drawn from among locations that are fixed regardless of the content of the file. Therefore, these trie-based methods are said to organize the data on the basis of the embedding space from which they are drawn. Because the positions of the boundaries of the regions are fixed, the range of the embedding space from which the data is drawn must be known (said to be *bounded*). On the other hand, in one dimension, the binary search tree [1046] is an example of a tree-based method since the boundaries of different regions in the search space are determined by the data being stored. Such methods are said to *organize the data* rather than the embedding space from which the data is drawn. Note that although trie-based methods are primarily designed to organize integer-valued data since the partition values (i.e., the boundaries of the partition regions) are also integer valued, nevertheless they can also be used to organize real-valued data, in which case the real-valued data are compared to predetermined partition values (e.g., 0.5, 0.25, 0.75, in the case of real numbers between 0 and 1), which, again, are the boundaries of the partition regions. Of course, the data must still be bounded (i.e., its values must be drawn from within a given range).

The extension of a trie to multidimensional data is relatively straightforward and proceeds as follows. Assume  $d$ -dimensional data where each data item consists of  $d$  character sequences corresponding to the  $d$  attributes. Each character of the  $i$ th sequence has  $M_i$  possible values. A node at depth  $k - 1$  ( $k \geq 1$ ) in the multidimensional trie represents an  $\prod_{i=1}^d M_i$ -way branch, depending on the value of the  $k$ th character of each of the  $d$  attribute values.<sup>3</sup> For attributes whose value is of numeric type, which is treated as a sequence of binary digits, this process is usually a halving process in one dimension, a quartering process in two dimensions, and so on, and is known as *regular decomposition*. We use this characterization frequently in our discussion of multidimensional data when all of the attributes are locational.

Disk-resident data implies grouping the data (either the underlying space based on the volume—that is, the amount—of the data it contains or the points, hopefully, by the proximity of their values) into sets (termed *buckets*), corresponding to physical storage units (i.e., pages). This leads to questions about their size and how they are to be accessed, including the following:

1. Do we require a constant time to retrieve a record from a file, or is a logarithmic function of the number of records in the file adequate? This is equivalent to asking if the access is via a directory in the form of an array (i.e., direct access) or in the form of a tree (i.e., a branching structure).
2. How large can the directories be allowed to grow before it is better to rebuild them?
3. How should the buckets be laid out on the disk?

In this chapter, we examine several representations that address these questions. Our primary focus is on dynamic data, and we concentrate on the following queries:

1. Point queries that determine if a given point  $p$  is in the dataset. If yes, then the result is the address corresponding to the record in which  $p$  is stored. This query is more accurately characterized as an *exact match query* in order to distinguish it from the related point query in the context of objects that finds all the objects that contain a given point (see, e.g., Section 3.3.1 of Chapter 3).
2. Range queries (e.g., region search) that yield a set of data points whose specified keys have specific values or values within given ranges. These queries include the partially specified query, also known as the *partial match query* and the *partial range query*, in which case unspecified keys take on the range of the key as their domain.
3. Boolean combinations of 1 and 2 using the Boolean operations **and**, **or**, and **not**.

---

<sup>3</sup> When the  $i$ th character sequence has less than  $k$  characters, there is no corresponding branching at depth  $k - 1$  for this attribute.

When multidimensional data corresponds to locational data, we have the additional property that all of the attributes have the same unit, which is distance in space.<sup>4</sup> In this case, we can combine the attributes and pose queries that involve proximity. Assuming a Euclidean distance metric, for example, we may wish to find all cities within 50 miles of Chicago. This query is a special case of the range query, which would seek all cities within 50 miles of the latitude position of Chicago and within 50 miles of the longitude position of Chicago.<sup>5</sup> A related query seeks to find the closest city to Chicago within the two-dimensional space from which the locations of the cities are drawn—that is, a nearest neighbor query, also sometimes referred to as the *post office problem* (e.g., [1046, p. 563]). This problem arises in many different fields, including computer graphics, where it is known as a *pick query* (e.g., [622]); in coding, where it is known as the *vector quantization problem* (e.g., [747]); and in pattern recognition, as well as machine learning, where it is known as the *fast nearest-neighbor classifier* (e.g., [514]). We do not deal with such queries in this chapter (but see [846, 848, 854] and Sections 4.1 and 4.2 of Chapter 4).

NAME	X	Y
Chicago	35	42
Mobile	52	10
Toronto	62	77
Buffalo	82	65
Denver	5	45
Omaha	27	35
Atlanta	85	15
Miami	90	5

Figure 1.1  
Sample list of cities with their x and y coordinate values.

In contrast, proximity queries are not very meaningful when the attributes do not have the same type or units. For example, it is not customary to seek all people with age-weight combination less than 50 year-pounds (year-kilograms) of that of John Jones, or the person with age-weight combination closest to John Jones because we do not have a commonly accepted unit of year-pounds (year-kilograms) or a definition thereof.<sup>6</sup> It should be clear that we are not speaking of queries involving Boolean combinations of the different attributes (e.g., range queries), which are quite common.

The representations that we describe are applicable to data with an arbitrary number of attributes  $d$ . The attributes need not be locational or numeric, although all of our examples and explanations assume that all of the attributes are locational or numeric. In order to be able to visualize the representations, we let  $d = 2$ . All of our examples make use of the simple database of records corresponding to eight cities given in Figure 1.1.<sup>7</sup> Each record has three attributes, NAME, X, and Y, corresponding to their name and location. We assume that our queries retrieve only on the basis of the values of the X and Y attributes. Thus,  $d = 2$ , and no ordering is assumed on the NAME field. In particular, the NAME field is just used to aid us in referring to the actual locations and is not really part of the record when we describe the various representations in this chapter. Some of these representations can also be adapted to handle records where the attributes are nonlocational, as long as an ordering exists for their range of values. Moreover, Section 4.5 of Chapter 4 contains a discussion of how some of these representations can be adapted to handle records where the only information available is the relative distance between pairs of records.

<sup>4</sup> The requirement that the attribute value be a unit of distance in space is stronger than one that merely requires the unit to be a number. For example, if one attribute is the length of a pair of pants and the other is the width of the waist, then, although the two attribute values are numbers, the two attributes are not locational.

<sup>5</sup> The difference between these two formulations of the query is that the former admits a circular search region, while the latter admits a rectangular search region. In particular, the latter query is applicable to both locational and nonlocational data, while the former is applicable only to locational data.

<sup>6</sup> This query is further complicated by the need to define the distance metric. We have assumed a Euclidean distance metric. However, other distance metrics such as the City Block (also known as Manhattan) and the Chessboard (also known as maximum value) could also be used.

<sup>7</sup> Note that the correspondence between coordinate values and city names is not geographically accurate. We took this liberty so that the same example could be used throughout the chapter to illustrate a variety of concepts.

## 1.1 Introduction

There are many possible representations for a file of multidimensional point data. The feasibility of these representations depends, in part, on the number of attributes and their domains. At one extreme is a pure bitmap representation of the attribute space, with one bit reserved for each possible record (i.e., combination of attribute values) in the multidimensional point space to indicate whether it is present in the file. This representation is useful when the number of attributes  $d$  is small (i.e.,  $d \leq 2$ ) and the domains of the attributes are discrete and small (e.g., binary). Unfortunately, most applications have continuous domains, and the number of attributes exceeds two. Thus, we must look for other solutions.

The simplest way to store point data is in a sequential list. In this case, no ordering is assumed for any of the attributes. As an example, consider the set of records consisting of eight cities and their locations specified by their  $x$  and  $y$  coordinate values as shown in Figure 1.1. Given  $N$  records and  $d$  attributes to search on, an exact match query in such a data structure takes  $O(N \cdot d)$  time since, in the worst case, the values of all of the attributes of each record must be examined (see Exercise 4).

Another very common technique is the *inverted file* [1046]. In this case, the roles of the records and the attributes are inverted: instead of keeping track of the values of the attributes of each record, we keep track of all records that have a particular value for a given attribute. In order to facilitate retrieval, all the records are sorted for the attribute on the basis of its value. The result is known as an *inverted list*. Often there are as many inverted lists as there are attributes.

There are many ways of implementing the inverted file. The simplest way is to maintain separate sorted lists for each attribute. For example, Figure 1.2 is such a representation for the data of Figure 1.1. There are two sorted lists: one for the  $x$  coordinate value and one for the  $y$  coordinate value. Note that the data stored in the lists are pointers into the set of records in Figure 1.1. Figure 1.2 makes use of sequential allocation for the inverted lists. We can also make use of linked allocation. In this case, we associate with each record as many linked lists as we have attributes, with the lists being linked in increasing or decreasing order of the values of the corresponding attributes. The result is known as a *multilist* (e.g., [1046]).

The most common use of the inverted list is to prune the search with respect to one key. In essence, the endpoints of the desired range for one key can be located very efficiently by using its corresponding sorted list. For example, this could be done by using a binary search with the aid of data structures such as the range tree [167, 176] (one-dimensional and the more general multidimensional range trees), as discussed in Section 1.2. When trying to execute a range query with respect to several keys, this resulting list is searched by brute force to obtain the records that satisfy the full range query (i.e., for the remaining keys). The average search has been shown in [649] to take  $O(N^{1-1/d})$  time, under certain assumptions. This approach of making use of a sorted list for each coordinate has also been employed by Friedman, Baskett, and Shustek [649] (see also Section 4.6.1 in Chapter 4) as well as Nene and Nayar [1364], in conjunction with an algorithm to find neighbors in high-dimensional spaces (for other representations of such data, see Section 4.4 in Chapter 4).

It should be clear that the inverted list is not particularly useful for range queries involving several attributes because it can speed up the search for only one of the attributes (termed the *primary* attribute). Of course, we could execute the range query by performing a separate range query for each attribute and then intersect the result, but this is quite wasteful. The number of intersections can be reduced by sorting the records by applying a lexicographic ordering on the attributes, thereby forming a *combined index* [1214]. In essence, we have combined the attributes into a superattribute.

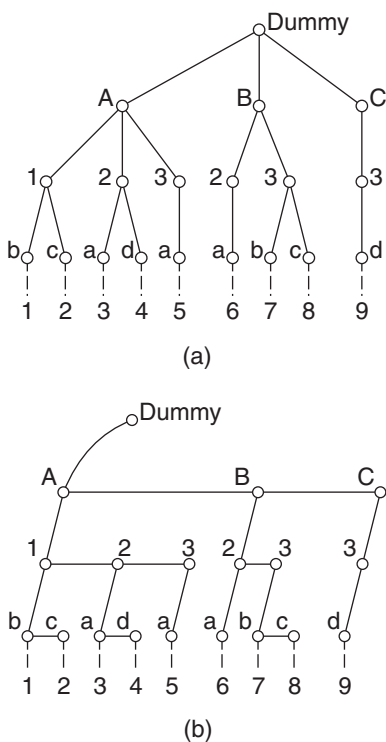

Figure 1.4  
(a) The multiattribute tree (MAT) and (b) the doubly chained tree (DCT) corresponding to the file with three different attributes given in Figure 1.3.

The combined index is of limited value because it is useful only for a restricted subset of range queries where the values of the nonprimary attributes are left unspecified. In particular, given a record with  $d$  different attributes, the combined index enables the consecutive retrieval of records that satisfy range queries where a range is given for the primary attribute, exact matches are required for the values of the next  $i$  nonprimary attributes in lexicographic order, and the values of the remaining  $d - 1 - i$  nonprimary attributes in lexicographic order are left unspecified. Thus, we have a variant of a partial match query (with respect to some of the nonprimary attributes in lexicographic order) and a partial range query (with respect to the remaining nonprimary attributes in lexicographic order). Nevertheless, using the combined index does result in replacing the need to intersect the results of range queries on the inverted lists of the individual attributes by the need to take the union of shorter lists that are disjoint.

Greater flexibility can be obtained by increasing the number of combined indexes by permuting the order in which the attributes are combined in the lexicographic order. The result is that a greater variety of partial range (i.e., partial match) queries can be handled. For example, with three attributes A, B, and C, all possible partial range (i.e., partial match) queries could be handled by making use of the following three lexicographically ordered combined indexes: ABC, BCA, and CAB. In general, given  $d$  attributes, it can be shown [1214] that we need  $\binom{d}{\lfloor (d+1)/2 \rfloor}$  combined indexes to handle all possible partial range (i.e., partial match) queries (see Exercise 2). Shneiderman [1757] describes the *reduced combined index*, which structures the combined indexes in a treelike manner and thereby reduces their size, although their number is unchanged.

As we saw above, in order to achieve greater flexibility, the number of necessary combined indexes grows at a much faster rate than the number of attributes. Several alternative solutions have been proposed. These solutions can be decomposed into two classes. One class of solutions imposes an access structure on the values of the primary attribute, and then imposes another access structure on the remaining attributes in succession (often a recursive imposition of the same access structure) for each of the values of the first attribute. In essence, the combined index is being augmented with some form of random access so that the data can be accessed without being constrained totally by the inherent lexicographical order. Some examples of this approach include the doubly chained tree (DCT), which is closely related to the multiattribute tree and its variants, the quintary tree, the multidimensional B-tree (MDBT), and the kB-tree, as well as the multidimensional range tree and the priority search tree. The second class of solutions modifies the bitmap representation to form  $d$ -dimensional cells of ranges of attribute values so that all points whose attribute values fall within the range associated with cell  $c$  are associated with  $c$ . This is analogous to a compressed bitmap representation. A key difference between the two classes is that, in the first class, there exists an explicit ordering on the attributes, while no such ordering exists in the second class.

We first discuss briefly the first class of solutions. All of the members of this class of solutions are based on the same principle of constructing a skeleton  $m$ -ary tree that has one level per attribute. The first level consists of one child for each of the  $m$  different values of the first attribute (i.e., the primary attribute). Each child of the root, say child  $i$  with value  $a$  for the first attribute, serves as the root of a subtree with one child for each of the possible values of the second attribute given the value  $a$  for the first attribute. This process is repeated for the remaining children of the root and the remaining attributes for a total of  $d$  levels, assuming  $d$  attributes and that the root is at level 0. The result is characterized as a *multiattribute tree*<sup>8</sup> (e.g., [996]), although the representation predates the usage of the term. For example, given the file with three different attributes in Figure 1.3, Figure 1.4(a) is the corresponding multiattribute tree. Note that the multiattribute tree is similar to a trie, which forms the basis of digital searching (recall the discussion in the opening of this chapter). The difference is that

<sup>8</sup> Also sometimes denoted *MAT* but not here in order to avoid confusion with the medial axis transformation discussed in Section 2.1.2.2 of Chapter 2.

each node in the multiattribute tree only has as many children as there are different values for the attribute in the current set of records, instead of one child for each possible value of the attribute, as in the trie.

There are many implementations of the multiattribute tree. A simple implementation known as the *doubly chained tree* (DCT) [1817] links the children of each node (i.e., the *filial set* [1686]) instead of having a pointer from the root of each subtree to all of its children (see also [928, 961, 1365]). The result is that the  $m$ -ary tree is represented as a binary tree and is known as the *natural correspondence between a forest and a binary tree* [1044, p. 334], where the multiattribute tree serves as the forest. For example, Figure 1.4(b) is the doubly chained tree corresponding to the file with three different attributes given in Figure 1.3. Many variations on the implementation of the doubly chained tree have been proposed to enhance its performance in a database system (e.g., [305]). For example, often there is an additional pointer associated with each node that points back to the level containing the node's predecessor (i.e., an ancestor or parent link). Kashyap, Subas, and Yao [996] order the attributes in the doubly chained tree according to their probability of occurrence in a query, with the most likely ones being placed closer to the root. In addition, they propose to store records in pages in lexicographic order—that is, if record  $i$  is lexicographically lower than record  $j$ , then the page containing  $i$  is at a lower address than the page containing  $j$ . Further improvements are obtained by focusing on the pointer structure of the multiattribute tree such as removing redundant pointers [728].

Despite the various enhancements of the doubly chained tree described above, the worst-case execution time of an exact match query (i.e., point query) is still  $O(N)$  due to the need to apply sequential search at each level (see Exercises 3 and 4). This worst-case execution time has been reduced to  $O(d \cdot \log_2 N)$  time by Lien, Taylor, and Driscoll [1167], who replaced the linked list at each level of the doubly chained tree by a height-balanced binary search tree such as an AVL tree [15]<sup>9</sup> (see Exercise 5). The drawback of the height-balanced binary search tree solution is that the balancing is only applied at the individual levels of the structure corresponding to the attributes instead of over the entire tree.

This drawback is addressed by the *quintary tree* [1133], which applies balancing over all the attributes (i.e., a form of “weight balancing”). In particular, assuming  $d$  attributes and a file of  $N$  records, the root node corresponds to the value of the first attribute, say  $x_d = h$ , forming a hyperplane. This hyperplane partitions the file into two subfiles,  $L$  and  $R$ , of at most  $N/2$  records, instead of partitioning the different values of the first attribute into two sets of equal size as is done in the height-balanced binary search tree solution. In addition to the two subfiles  $L$  and  $R$ , assuming a  $d$ -dimensional space, we also project  $L$  and  $R$  onto the hyperplane, thereby forming two additional subfiles,  $LH$  and  $RH$ , in the  $(d - 1)$ -dimensional hyperplane. These four subfiles (i.e.,  $L$ ,  $R$ ,  $LH$ , and  $RH$ ), as well as the subfile  $H$  of the records that lie on the hyperplane, form the subtrees of each node in the structure for a total of five subtrees, hence the term *quintary*. Note that when  $L$  and  $R$  correspond to one-dimensional data, then  $LH$  and  $RH$  are just sets of pointers to the records corresponding to the elements of  $L$  and  $R$ , respectively. The idea of projection is rooted in the empirical cumulative distribution function tree (ECDF tree) of Bentley and Shamos [180], which is used to determine the number of  $d$ -dimensional points dominated by a given query point (see Exercises 12 and 13).

Observe that the manner in which the quintary tree is constructed (i.e., the use of “weight balancing”) ensures that at each node comparison approximately one-half of the records represented by the node's corresponding subfile will be pruned from consideration. This enables it to attain an  $O(d + \log_2 N)$  execution time for an exact match query (see Exercise 8). Partial range queries for which the values of  $s$  out of  $d$  attributes are specified can take as much as  $O(3^{d-s} \cdot (s + \log_2 N) + F)$  time, where  $F$  is

<sup>9</sup> The AV stands for Adelson-Velsky and the L stands for Landis, the originators of the structure.

the number of records found. This worst case arises when the  $s$  specified attributes are found at the deepest levels of the tree (see Exercise 9). Range queries take  $O((\log_2 N)^d + F)$  time, where  $F$  is the number of records found (see Exercise 10).

The quintary tree has several drawbacks. First, it requires  $O(N \cdot (\log_2 N)^d)$  space (see Exercise 6) and the same order of time to build (see Exercise 7). Second, it is primarily a static structure since insertions and deletions are quite costly as the amount of space that is needed implies that each record is represented  $O((\log_2 N)^d)$  times. Clearly, despite having a good execution time behavior for the queries, a representation such as the quintary tree is not practical.

The desire to have both a dynamic behavior and to reduce the time needed to perform an exact match query to be  $O(\log_2 N)$  has led to the use of B-trees [414] (see Appendix A) at each level of the doubly chained tree instead of height-balanced binary search trees. This is the basis of the multidimensional B-tree (MDBT) [1686] and kB-tree [786, 787] methods. Note that use of a multiway tree such as a B-tree also overcomes one of the drawbacks of binary trees: at each step of a search there are only two possible outcomes as there are only two children. In particular, the binary decision process can slow execution when each transition to a child corresponds to a disk access. Thus use of B-trees results in a significant reduction in the depth of the tree.

The *multidimensional B-tree* (MDBT) [1434, 1686] is a hierarchy of B-trees where the root of the hierarchy is a B-tree for the primary attribute. As in the doubly chained tree, for each distinct value  $v$  of the primary attribute  $p$ , there is a link to a distinct B-tree (corresponding to its filial set) for the values of the next attribute of all records for which  $p = v$ . This process is applied recursively to the remaining attributes. Therefore, for  $d$ -dimensional data, we have a hierarchy of B-trees that is  $d$  levels deep. The MDBT links the roots of all B-trees at each level, as well as providing an entry point at each level to the start of each such list. This facilitates partial range (i.e., partial match) queries that require sequential processing at each level. Formally, all filial sets (i.e., the roots of B-trees) at the same level  $i$  are linked in increasing order of their corresponding attribute values in their ancestor filial set at level  $i - 1$ . This ordering is recursive in the sense that the result is a lexicographic ordering of all of the B-trees at level  $i$  on the basis of the attribute values at levels 1 through  $i - 1$ .

For a B-tree of order  $M$  with  $N$  records, Scheuermann and Ouksel [1686] show that the height of the MDBT is  $\log_M N$  under the assumption that the values of an attribute are uniformly distributed within its corresponding range and are independent of the other attribute values. However, when all of the records have different values for all of the attributes, the MDBT consists of a B-tree of height  $\log_M N$  for the primary attribute, and each value of the primary attribute in this B-tree is connected to only one value at the next level, which in turn is connected to only one value, and so on. In other words, all the B-trees at the remaining levels for the remaining attributes are of height 1. Thus, the total height of the MDBT for this case is  $(\log_M N) + d$  [1686]. Moreover, in the worst case, the height of the MDBT can be as high as  $O(d \cdot \log_M N)$  (see Exercise 17).

The difference in these height values for the MDBT is overcome by the *kB-tree* of Güting and Kriegel [786, 787], which was developed independently of the MDBT. The kB-tree, like the MDBT, is also a hierarchy of B-trees where, whenever the B-trees at a particular level are of a different height, then these trees are repositioned (using techniques analogous to balancing in binary search trees) in such a way that the total height of the tree is never greater than  $(\log_M N) + d$ . This means that B-trees at the various levels, with the exception of those at the deepest level, do not have the property that all leaf nodes are at the same distance from the root. Such B-trees are known as *biased B-trees* [163]. Thus, the kB-tree is able to adapt better to the distribution of the records than the MDBT, while incurring a higher update cost than the MDBT. Performance studies encompassing updates, storage utilization, point queries (exact match), and range queries, including partial range (i.e., partial match), showed the relative performance of

the kB-tree and MDBT to be comparable with a small edge (a few percentage points) for the kB-tree [1077, 1078].

The key difference between the kB-tree and the MDBT is that the kB-tree is balanced over all attributes, in contrast to the MDBT, which is only balanced within an attribute. Thus, we see that the kB-tree has been developed in the same spirit as the quintary tree in the sense that it makes use of a special case of weight balancing that is often applied to binary trees. However, unlike the quintary tree, where insertions and deletions destroy the balance, the kB-tree is able to maintain the balance in a dynamic environment.

Recall that in order to facilitate sequential processing, the roots of the B-trees at the levels of the MDBT are linked. This can also be done for the kB-tree. Further improvements in the speed can be obtained by defining a variant of the  $B^+$ -tree, termed a  $kB^+$ -tree [1076], which stores appropriate prefixes at the different levels of the resulting tree.

The multidimensional range tree [167, 176] imposes a one-dimensional range tree on the primary attribute, and then stores multidimensional range trees for the remaining attributes in the internal nodes of the one-dimensional range tree of the primary attribute. It is similar in spirit to the MDBT with the following difference: in the multidimensional range tree, there is a link in each node to a distinct multidimensional range tree for the remaining attributes, while in the MDBT, this link is to an MDBT, for the remaining attributes, with the same value of the first attribute. The multidimensional range tree is discussed in Section 1.2. The priority search tree [1266] forms the basis of another solution known as the *range priority tree* [535], which is also related to the range tree. The priority search tree makes use of a binary search tree whose leaf nodes form a one-dimensional range tree for one attribute, while its internal nodes form a heap for the remaining attribute. Such methods are discussed in Section 1.3.

The second class of solutions, and the one we focus on in the remaining sections of this chapter, modifies the bitmap representation to form  $d$ -dimensional cells of ranges of attribute values so that all points whose attribute values fall within the range associated with cell  $c$  are associated with  $c$ . This is analogous to a compressed bitmap representation.

The compressed bitmap representation has its roots in the multiattribute tree. As we saw above, one of the drawbacks of the multiattribute tree and its variants is that responding to queries requires some searching at each level of the tree. The use of a treelike structure with pointers speeds up the search process by limiting where the search takes place in contrast to the need to intersect the result of range queries on the inverted lists corresponding to the individual attributes when using the inverted file method. Nevertheless, the pointers do take up space. Pointers are not needed if we know that the number of children of each node at any given level is a constant. In particular, now the tree can be represented as a sequence of the nodes obtained via a depth-first traversal of the multiattribute tree (analogous to a lexicographical ordering of the relevant attribute values), and the appropriate children of each node are accessed by knowledge of the number of children that are present at each level.

Unfortunately, the requirement that the number of children of each node at any given level be a constant is somewhat difficult to satisfy in general as we cannot guarantee that the number of different values for each attribute is constant with respect to the value of its ancestor attribute in the multiattribute tree. However, if each child node in the tree corresponds to a range of values, then we can guarantee that the number of children at each level of each node is a constant. The result is that the leaf nodes correspond to  $d$ -dimensional cells that contain all the records (i.e., points) whose attribute values fall within the ranges that make up the boundaries of the cells. The resulting structure is known as the *multidimensional directory* (MDD) [1183]. Figure 1.5(a) is an example of a possible partition of a two-dimensional space that is induced by an MDD. The MDD has also been applied to high-dimensional data by McNames [1271] in the development of the principal axis tree (PAT), in which case the partition lines are no longer orthogonal. Instead, they are determined by recursively finding the directions of greatest variation in

Figure 1.5  
Example of a possible partition of a two-dimensional space that is induced by an MDD (a) when the partition lines are parallel to the coordinate axes and (b) when the partition lines have an orientation determined by the directions of greatest variation in the data within each region.

the data (termed the *principal axes*). Figure 1.5(b) is an example of such a partition in two dimensions. For more details about the principal axis tree, see Section 1.5.1.4.

When the number of different values of a particular attribute  $a$  is high in contrast to the number of ranges of values of  $a$ , then  $a$  is usually sufficient by itself to differentiate between the points. In this case, Liou and Yao [1183] suggest that  $a$  should not be included in the MDD, and instead the values of  $a$  are accessed via an inverted list. The resulting combination of the MDD and the inverted list is characterized as being a hybrid variant of the MDD [1183]. Formally, assuming a total of  $N$  records,  $G$  grid cells, and  $b_a$  ranges of values for  $a$ , and letting  $|a|$  denote the number of different values for  $a$  in the dataset, then the hybrid variant of the MDD is used when  $N/|a| \ll G/b_a$ . For a discussion of how to choose the number of ranges for the attribute values, see [1183].

Although each attribute in the MDD is partitioned into the same number of ranges of values, the actual ranges differ for each range of values for the ancestor attribute in the multiattribute tree. This is a direct result of the fact that the order in which the attributes in the multiattribute tree are examined is important. The fixed-grid method (e.g., [173, 1046, 1584], also termed *multipaging* [1287, 1288]), avoids this difference by ensuring that each attribute is partitioned into the same ranges of values regardless of the ranges of values for the other attribute values. In other words, the fixed-grid method partitions the space from which the data is drawn into rectangular cells by overlaying it with a grid. Thus, the order in which the attributes in the multiattribute tree are examined is no longer relevant. Each grid cell  $c$  contains a pointer to another structure (e.g., a list) that contains the set of points that lie in  $c$ . Associated with the grid is an access structure to enable the determination of the grid cell associated with a particular point  $p$ . This access structure acts like a directory and is usually in the form of a  $d$ -dimensional array with one entry per grid cell or a tree with one leaf node per grid cell.

There are two ways of building a fixed grid. We can either subdivide the space into equal-sized grid cells or place the subdivision lines at arbitrary positions that are dependent on the underlying data. In essence, the distinction is between organizing the data to be stored and organizing the embedding space from which the data is drawn [1376]. In particular, when the grid cells are equal sized (termed a *uniform grid*), use of an array access structure is quite simple and has the desirable property that the grid cell associated with point  $p$  can be determined in constant time.

Figure 1.6 is an example of a uniform-grid representation corresponding to the data of Figure 1.1 with each grid cell having size  $20 \times 20$ . Assuming a  $100 \times 100$  coordinate space, we have 25 squares of equal size. Assuming further that the origin is at the lower-left corner of the coordinate space, we adopt the convention that each square is open with respect to its upper and right boundaries and closed with respect to its lower and left boundaries (e.g., the point (60,75) is contained in the square centered at (70,70)). Also, all data points located at grid intersection points are said to be contained in the cell for which they serve as the SW corner (e.g., the point (20,20) is contained in the square centered at (30,30)).

When the width of each grid cell is twice the search radius for a rectangular range query,<sup>10</sup> then the average search time is  $O(F \cdot 2^d)$ , where  $F$  is the number of points that have been found [182]. The factor  $2^d$  is the maximum number of cells that must be accessed when the search rectangle is permitted to overlap more than one cell. For example, to locate all cities within a  $20 \times 20$  square centered at (32,37), we must examine the cells centered at (30,30), (50,30), (30,50), and (50,50). Thus, four cells are examined and, for our example database, the query returns Chicago and Omaha.

Multipaging [1287, 1288] is one of several examples of the fixed-grid method when the grid cells are not equal sized. In this case, in order to be able to use an array access

---

<sup>10</sup> This method can also be described as yielding an *adaptive uniform grid*, where the qualifier “adaptive” serves to emphasize that the cell size is a function of some property of the points (e.g., [632, 634]).

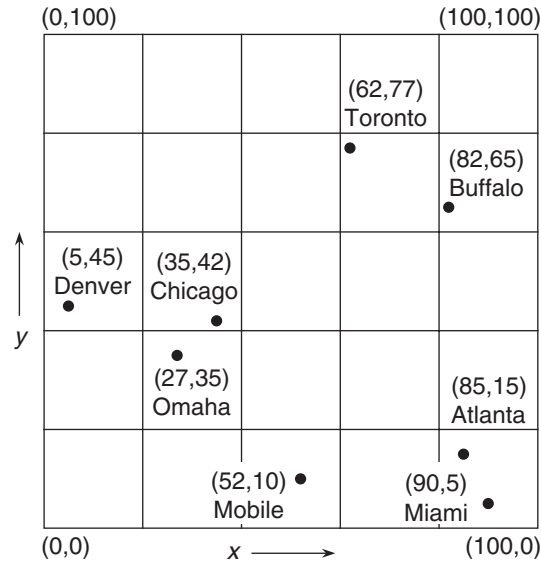

Figure 1.6  
Uniform-grid representation corresponding to the data of Figure 1.1 with a search radius of 20.

structure, we must have a way of keeping track of their size so that we can determine the entry of the array access structure corresponding to the grid cell associated with point  $p$ . One way to do this is to make use of what are termed *linear scales* [1376] (also known as *axial directories* and *axial arrays* [1288]), which indicate the positions of the grid lines (or partitioning hyperplanes in  $d > 2$  dimensions). Given a point  $p$ , we determine the grid cell in which  $p$  lies by finding the “coordinates” of the appropriate grid cell. The linear scales are usually implemented as one-dimensional trees containing ranges of values.

The use of an array access structure is fine as long as the data is static. When the data is dynamic, it is likely that some of the grid cells become too full while other grid cells are empty. This means that we need to rebuild the grid (i.e., further partition the grid or reposition the grid partition lines or planes) so that the various grid cells are not too full. However, this creates many more empty grid cells as a result of repartitioning the grid (i.e., empty grid cells are split into more empty grid cells). In this case, we have two alternatives.

The first alternative is to merge spatially adjacent empty grid cells into larger empty grid cells while splitting grid cells that are too full, thereby making the grid adaptive. The result is that we no longer make use of an array access structure to retrieve the grid cell that contains query point  $p$ . Instead, we make use of a tree access structure in the form of a  $k$ -ary tree, where  $k$  is usually  $2^d$ . Thus, we have married a  $k$ -ary tree with the fixed-grid method. This is the basis of the point quadtree [614], as well as trie-based representations such as the MX quadtree [1628] and the PR quadtree [1413, 1637], which are all multidimensional generalizations of binary trees. They are discussed in Section 1.4.

As the dimensionality of the space increases, each level of decomposition of the quadtree results in many new cells since the fanout value of the tree is high (i.e.,  $2^d$ ). This is alleviated by making use of a  $k$ -d tree [164, 168]. This is a binary tree, where at each level of the tree, we subdivide along just one of the attributes. This is discussed in Section 1.5.

The second alternative is to assign an ordering to all the grid cells and to impose a tree access structure on the elements of the ordering that correspond to nonempty grid cells. The effect of this alternative is analogous to using a mapping from  $d$  dimensions

to one dimension, and then applying one of the one-dimensional access structures, such as a B-tree or a balanced binary tree, to the result of the mapping.<sup>11</sup> This is the subject of Section 1.6. Note that this alternative is applicable regardless of whether the grid cells are equal sized. Of course, if the grid cells are not equal sized (not discussed here), then we must also record their size in the element of the access structure.

At times, in the dynamic situation, the data volume becomes so large that a conventional tree access structure (i.e., with the limited fanout values described above) is inefficient. In particular, the grid cells can become so numerous that they cannot all fit into memory, thereby causing them to be grouped into sets (which we termed *buckets*) corresponding to physical storage units (i.e., pages) in secondary storage. This is the subject of Sections 1.7 and 1.8. In the case of a tree access structure, each bucket usually corresponds to a contiguous set of grid cells that forms a hyperrectangle in the underlying space. The problem is that, depending on the implementation of the tree access structure, each time we must follow a pointer, we may need to make a disk access.

This problem can be resolved in two ways. The first way is to retain the use of the tree access structure, say  $T$ , and also to aggregate the internal (i.e., nonleaf) nodes of  $T$  into buckets, thereby forming a multiway tree in the spirit of a B-tree (see Appendix A). The buckets whose contents are internal nodes of  $T$  correspond to subtrees of  $T$ , and their fanout value corresponds to the sum of the number of possible branches at the deepest level of each of the subtrees. The resulting structure is now a tree of buckets with a large fanout value, frequently referred to as a *tree directory*. Examples of such structures are the R-tree and the  $R^+$ -tree, which are discussed in great detail in Sections 2.1.5.2 and 2.1.5.3 of Chapter 2, respectively, as well as the k-d-B-tree, LSD tree, hB-tree, k-d-B-trie, and BV-tree, which are discussed in Section 1.7.1. In these structures, the buckets are formed by a grouping process that is applied in a top-down manner so that each bucket has a maximum number of elements. In contrast, in PK-tree methods, discussed in Section 1.8, the buckets are formed by a grouping process that is applied in a bottom-up manner so that each bucket has a minimum number of elements.

The second way is to return to the use of an array access structure. One difference from the array used with the static fixed-grid method described earlier is that now the array access structure (termed a *grid directory*) may be so large (e.g., when  $d$  gets large) that it resides on disk as well (although this is not the case for all of the representations that we present). Another difference is that the structure of the grid directory can be changed as the data volume grows or contracts. Each grid cell (i.e., an element of the grid directory) contains the address of a bucket (i.e., page) where the points associated with the grid cell are stored. Notice that a bucket can correspond to more than one grid cell. Thus, any page can be accessed by two disk operations: one to access the grid cell and one more to access the actual bucket. The mechanics of the management of the growth of the access structure is the interesting issue here and is the subject of Section 1.7.2.

Section 1.9 contains a comparison of the various representations that we present. It also discusses briefly how to adapt the representations to handle nonlocational attributes. In general, the representations that we have presented are good for range searching (e.g., finding all cities within 80 miles of Atlanta) as they act as pruning devices on the amount of search that will be performed. In particular, many points will not be examined since the grid cells that contain them lie outside the query range. Most of these representations are generally very easy to implement and have good expected execution times, although the execution times of algorithms that use some of them are often quite difficult to analyze from a mathematical standpoint. However, their worst cases, despite being rare, can be quite bad. This is especially true for the second class of solutions that were based on

---

<sup>11</sup> These mappings have been investigated primarily for purely locational or numeric multidimensional point data, in which case they can also be applied directly to the key values. They cannot be applied directly to the key values for nonlocational point data; instead, they can be applied only to the grid cell locations.

modifying the bitmap representation. These worst cases can be avoided by making use of members of the first class of solutions that were variants of range trees and priority search trees.

### Exercises

1. Given a file containing  $N$  records with  $d$  attributes, implemented as an inverted list, prove that the average search for a particular record is  $O(N^{1-1/d})$ .
2. Given  $d$  attributes, show that  $\binom{d}{\lfloor (d+1)/2 \rfloor}$  combined indexes are needed to handle all possible partial range (i.e., partial match) queries.
3. Given  $N$  records and  $d$  attributes, show that the worst-case execution time of an exact match query in a doubly chained tree is  $O(N)$ .
4. In the text, we mentioned that given  $N$  records and  $d$  attributes, the worst-case execution time of an exact match query in a sequential list takes  $O(N \cdot d)$  time. An argument could be made that since  $d$  is a constant value, the query takes  $O(N)$  time and thus is of the same order of magnitude as when it is executed on a doubly chained tree. Explain why such an argument fails.
5. Given  $N$  records and  $d$  attributes, show that the worst-case execution time of an exact match query, when the linked list at each level of the doubly chained tree has been replaced by a height-balanced binary search tree, is  $O(d \log_2 N)$ .
6. Prove that the quintary tree for  $N$  records and  $d$  attributes requires  $O(N \cdot (\log_2 N)^d)$  space.
7. Prove that building a quintary tree for  $N$  records and  $d$  attributes takes  $O(N \cdot (\log_2 N)^d)$  time.
8. Prove that an exact match query in a quintary tree with  $N$  records and  $d$  attributes takes  $O(d + \log_2 N)$  time.
9. Prove that a partial range query in a quintary tree with  $N$  records and  $d$  attributes, where the values of  $s$  out of  $d$  attributes are specified, takes  $O(3^{d-s} \cdot (s + \log_2 N) + F)$  time, where  $F$  is the number of records found.
10. Performing a range query in a quintary tree takes advantage of the auxiliary trees that are attached to each node. The algorithm is recursive [1133]. Assume that the ranges of the individual attribute values are given by  $[l_i, r_i] (1 \leq i \leq d)$ . Let  $x$  denote the partitioning value at the root, and assume that the root partitions along attribute  $d$ . If  $x$  is not in the range  $[l_d, r_d]$ , then we descend to the  $L$  or  $R$  trees as is appropriate. Otherwise, we subdivide the interval into the two subintervals  $[l_d, x]$  and  $(x, r_d]$  and descend to the  $L$  and  $R$  trees, respectively, as well as descend the  $H$  tree. However, the next partition of these subintervals only results in descending the  $H$ ,  $L$ , and  $RH$  trees or the  $H$ ,  $R$ , and  $LH$  trees. For example, the next partition of the subinterval  $[l_d, x]$  into  $[l_d, w]$  and  $(w, x)$  only needs to descend the trees  $H$ ,  $L$ , and  $RH$  (instead of  $R$ ) because the interval  $(w, x)$  lies completely within  $[l_d, r_d]$ . Thus, we can ignore the value of attribute  $d$  by just considering the projections of the subfile on the  $R$  tree (i.e., the  $RH$  tree). This process is applied recursively at all levels. Prove that this algorithm takes  $O((\log_2 N)^d + F)$  time, where  $F$  is the number of records found.
11. Modify the range query algorithm given in Exercise 10 in a quintary tree to work for a partial range query, where  $s$  out of  $d$  ranges of attribute values are specified. Show that it takes  $O(3^{d-s} \cdot (\log_2 N)^s + F)$  time, where  $F$  is the number of records found.
12. The quintary tree is based on the ECDF tree of Bentley and Shamos [180]. The ECDF tree is used to indicate how many points are dominated by a query point  $q$ , where the point  $x = (x_1, x_2, \dots, x_d)$  is said to be *dominated* by  $q = (q_1, q_2, \dots, q_d)$  if and only if  $x_i \leq q_i$  for  $i = 1, 2, \dots, d$ . This number is called the *ranking* of  $q$  and is also referred to as the *empirical cumulative distribution function*, hence the name of the data structure. The ECDF tree is constructed as follows. Find a hyperplane along one of the attributes  $a_i$  with the equation  $a_i = r$  that divides the set of data into two subsets,  $A$  and  $B$ , where all elements of  $A$  have  $a_i$  values less than  $r$ , and all elements of  $B$  have  $a_i$  values greater than or equal to  $r$ . In addition, a set  $C$  is created of one lower dimension by projecting all elements of  $A$  onto the partitioning hyperplane. This process is applied recursively until we have either one point left or a subset with dimension one (i.e., just one attribute). Thus, the ECDF tree is a ternary tree. Associated

with each node is a number equal to one plus the number of records that lie in the left subtree (i.e.,  $A$  using the above notation). Show how, using this information, the ranking (i.e., ECDF) of  $q$  can be computed in  $O((\log_2 N)^d)$  time for  $N$  records in a  $d$ -dimensional space.

13. Given  $N$  records in a  $d$ -dimensional space, show that the amount of space needed to store an ECDF tree is  $O(N \cdot (\log_2 N)^{d-1})$ .
14. How would you use the ECDF tree to determine the number of  $d$ -dimensional points in a hyperrectangular query region with corners at  $p = (p_1, p_2, \dots, p_d)$  and  $q = (q_1, q_2, \dots, q_d)$  (i.e., a range query)?
15. How would you perform a range query in an MDBT?
16. How would you perform a partial range (i.e., partial match) query in an MDBT?
17. Given a file containing  $N$  records with  $d$  keys apiece, implemented as an MDBT with B-trees of order  $M$ , prove that the height can be as high as  $O(d \cdot \log_M N)$ .
18. Given a file containing records with  $d$  keys apiece, implemented using the uniform grid method such that each cell has a width equal to twice the search radius of a rectangular range query, prove that the average time for the range query is  $O(F \cdot 2^d)$ , where  $F$  is the number of records found and  $2^d$  is the number of cells that must be accessed.
19. Assume a file containing records with  $d$  keys apiece and implemented using the fixed-grid method such that each cell has width equal to the search radius of a rectangular range query. Prove that the average time for the range query is  $O(F \cdot 3^d / 2^d)$ , where  $F$  is the number of records found and  $3^d$  is the number of cells that must be accessed.

## 1.2 Range Trees

The multidimensional range tree of Bentley and Maurer [167, 176] is an asymptotically faster search structure than the point quadtree and the k-d tree; however, it has significantly higher space requirements. It stores points and is designed to detect all points that lie in a given range.

The range tree is best understood by first examining the one-dimensional range searching problem. A one-dimensional range tree is a balanced binary search tree where the data points are stored in the leaf nodes and the leaf nodes are linked in sorted order by use of a doubly linked list. The nonleaf nodes contain midrange values that enable discriminating between the left and right subtrees. For example, Figure 1.7 is the one-dimensional range tree for the data of Figure 1.1 when it is sorted according to values of

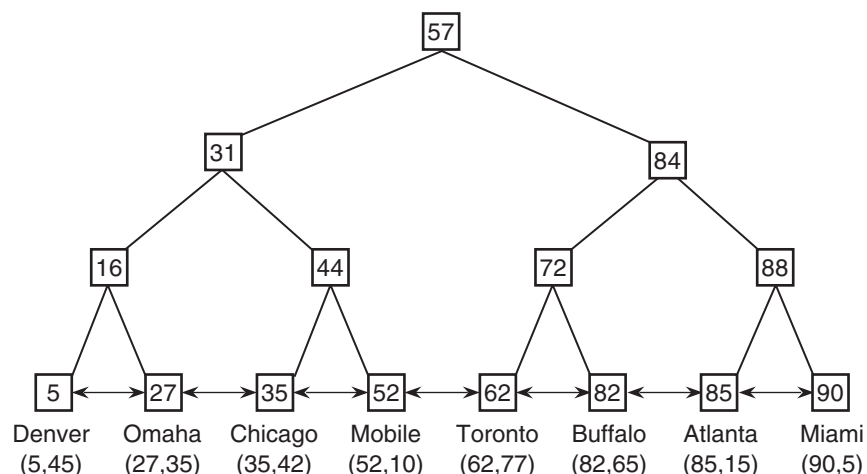

Figure 1.7  
One-dimensional range tree for the  $x$  coordinate values of the data of Figure 1.1.

the  $x$  coordinate. A range search for  $[B : E]$  is performed by procedure `RANGESearch`. It searches the tree and finds the node with either the largest value  $\leq B$  or the smallest value  $\geq B$ , and then follows the links until reaching a leaf node with a value greater than  $E$ . For  $N$  points, this process takes  $O(\log_2 N + F)$  time and uses  $O(N)$  space.  $F$  is the number of points found.

Procedure `RANGESearch` assumes that each node has six fields, `LEFT`, `RIGHT`, `VALUE`, `PREV`, `NEXT`, and `MIDRANGE`. `LEFT(P)` and `RIGHT(P)` denote the left and right children, respectively, of nonleaf node  $P$  (they are null in the case of a leaf node). `VALUE` is an integer indicating the value stored in the leaf node. `PREV(P)` and `NEXT(P)` are meaningful only for leaf nodes, in which case they are used for the doubly linked list of leaf nodes sorted in nondecreasing order. In particular, `PREV(P)` points to a node with value less than or equal to `VALUE(P)`, while `NEXT(P)` points to a node with value greater than or equal to `VALUE(P)`. `MIDRANGE(P)` is a variant of a discriminator between the left and right subtrees—that is, it is greater than or equal to the values stored in the left subtree, and less than or equal to the values stored in the right subtree (see Exercise 2). The `MIDRANGE` field is meaningful only for nonleaf nodes. Note that by making use of a `NODETYPE` field to distinguish between leaf and nonleaf nodes, we can use the `LEFT`, `RIGHT`, and `MIDRANGE` fields to indicate the information currently represented by the `PREV`, `NEXT`, and `VALUE` fields, respectively, thereby making them unnecessary.

```

1 procedure RANGESearch( $B, E, T$ )
2 /* Perform a range search for the one-dimensional interval  $[B : E]$  in the one-
   dimensional range tree rooted at  $T$ . */
3 value integer  $B, E$ 
4 value pointer node  $T$ 
5 if ISNULL( $T$ ) then return
6 endif
7 while not ISLEAF( $T$ ) do
8    $T \leftarrow$  if  $B \leq$  MIDRANGE( $T$ ) then LEFT( $T$ )
9     else RIGHT( $T$ )
10   endif
11 enddo
12 if not ISNULL( $T$ ) and VALUE( $T$ ) <  $B$  then  $T \leftarrow$  NEXT( $T$ )
13 endif
14 while not ISNULL( $T$ ) and VALUE( $T$ )  $\leq E$  do
15   output VALUE( $T$ )
16    $T \leftarrow$  NEXT( $T$ )
17 enddo

```

For example, suppose we want to perform a range search for  $[28:62]$  on the one-dimensional range tree in Figure 1.7. In this example, we assume that the `VALUE` field of the leaf nodes contains only the  $x$  coordinate values. We first descend the tree to locate, in this case, the node with the largest value  $\leq 28$  (i.e.,  $(27,35)$ ). Next, following the `NEXT` links, we report the points  $(35,42)$ ,  $(52,10)$ , and  $(62,77)$ . We stop when encountering  $(82,65)$ .

A two-dimensional range tree is a binary tree of binary trees. It is formed in the following manner. First, sort all of the points along one of the attributes, say  $x$ , and store them in the leaf nodes of a balanced binary search tree (i.e., a range tree), say  $T$ . With each node of  $T$ , say  $I$ , associate a one-dimensional range tree, say  $T_I$ , of the points in the subtree rooted at  $I$ , where now these points are sorted along the other attribute, say  $y$ .<sup>12</sup> For example, Figure 1.8 is the two-dimensional range tree for the data of Figure 1.1,

---

<sup>12</sup> Actually, there is no need for the one-dimensional range tree at the root or its two children (see Exercise 6). Also, there is no need for the one-element, one-dimensional range trees at the leaf nodes, as the algorithms can make a special check for this case and use the data that is already stored in the leaf nodes (but see Exercise 5).

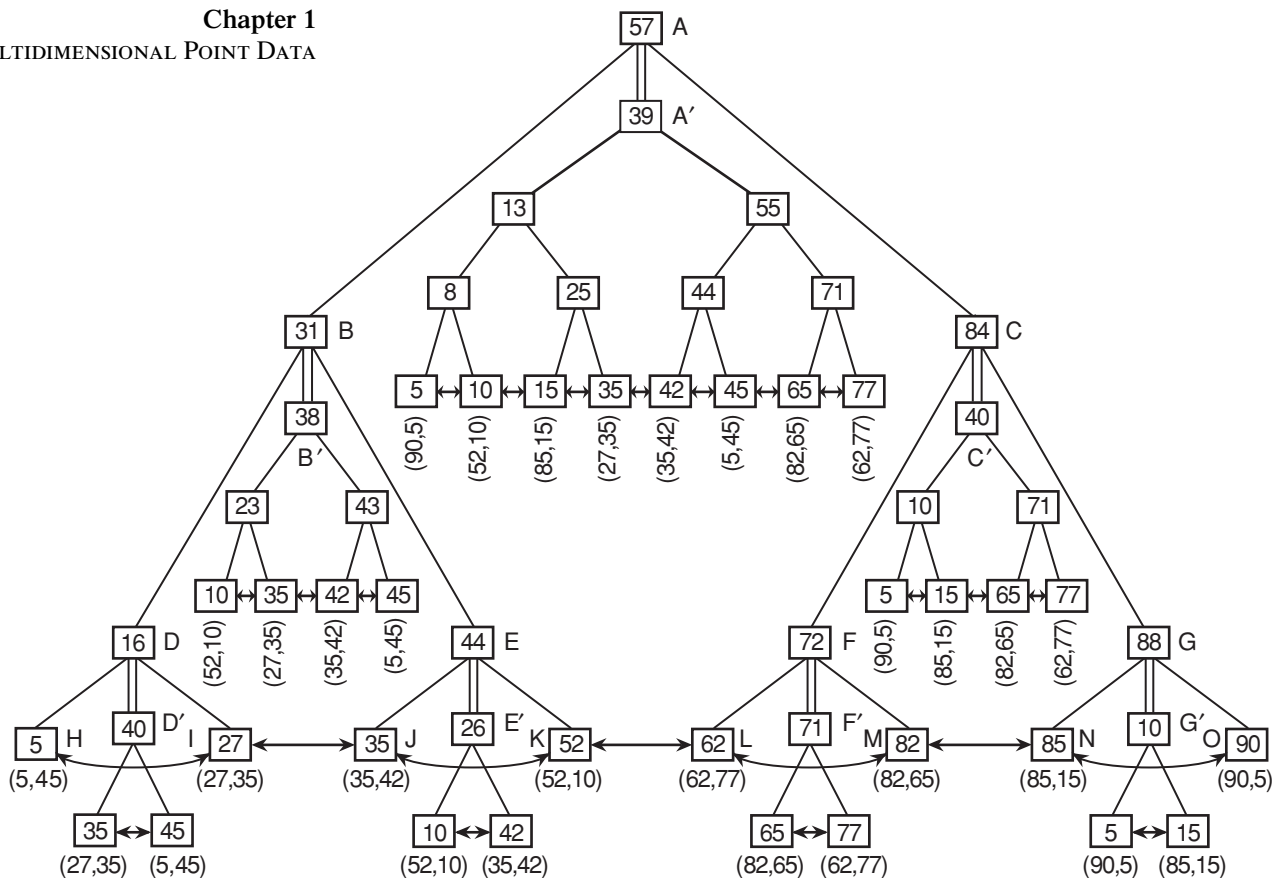

Figure 1.8  
Two-dimensional range tree for the data of Figure 1.1.

where the  $x$  coordinate serves as the primary sort attribute. Notice the use of double vertical lines to indicate a link to the one-dimensional range tree associated with each nonleaf node, thereby distinguishing them from the single vertical lines used to indicate links to left and right children in the two trees. For  $N$  points, the two-dimensional range tree uses  $O(N \cdot \log_2 N)$  space (see Exercise 7) and requires  $O(N \cdot \log_2 N)$  time to build (see Exercise 8).

A range search for  $([B_x : E_x], [B_y : E_y])$  is performed by procedure 2DSEARCH, given below. It makes use of procedure 1DSEARCH, a variant of procedure RANGESearch not given here.<sup>13</sup> Procedure 2DSEARCH starts by descending the tree in search of the closest nonleaf node  $Q$  (in terms of the number of links that are descended) to the root whose midrange value lies between  $B_x$  and  $E_x$ . Let  $L_x$  and  $R_x$  be the leaf nodes in the two-dimensional range tree that are reported by a search for  $B_x$  and  $E_x$ , respectively, regardless of whether  $B_x$  and  $E_x$  are actually stored there.  $L_x$  and  $R_x$  are termed *boundary nodes*. For example, using Figure 1.8, if  $B_x$  is 24 and  $E_x$  is 74, then  $L_x$  and  $R_x$  are the leaf nodes containing (27,35) and (82,65), respectively.  $Q$  is known as the *nearest common ancestor* of  $L_x$  and  $R_x$  in  $T$  (hence the farthest from the root in terms of node links). Let  $\{L_i\}$  and  $\{R_i\}$  denote the sequences of nodes (excluding  $Q$ ) that form the paths in  $T$  from  $Q$  to  $L_x$  and from  $Q$  to  $R_x$ , respectively.

Procedure 2DSEARCH assumes that each node has five fields: LEFT, RIGHT, MIDRANGE, RANGETREE, and POINT. LEFT, RIGHT, and MIDRANGE have the same meaning as in the one-dimensional range tree with the exception that MIDRANGE discriminates on the basis of the values of the  $x$  coordinate of the points represented by

<sup>13</sup> The difference is that in 1DSEARCH, the leaf nodes are points in two-dimensional space, while in RANGESearch, the leaf nodes are points in one-dimensional space.

the tree.  $\text{RANGETREE}(P)$  is the one-dimensional range tree for  $y$  that is stored at node  $P$ .  $\text{POINT}$  is a pointer to a record of type *point* that stores the point that is associated with a leaf node. A *point* record has two fields,  $\text{XCOORD}$  and  $\text{YCOORD}$ , that contain the values of the  $x$  and  $y$  coordinates, respectively, of the point. The  $\text{POINT}$  field is not used for nonleaf nodes in the tree. Note that by making  $\text{2DSEARCH}$  a bit more complicated, we can get by with just one of the  $\text{POINT}$  and  $\text{RANGETREE}$  fields (see Exercise 5).

For each node  $P$  that is an element of  $\{L_i\}$ , such that  $\text{LEFT}(P)$  is also in  $\{L_i\}$ ,  $\text{2DSEARCH}$  performs a one-dimensional range search for  $[B_y : E_y]$  in the one-dimensional range tree for  $y$  associated with node  $\text{RIGHT}(P)$ . For each  $P$  that is an element of  $\{R_i\}$ , such that  $\text{RIGHT}(P)$  is also in  $\{R_i\}$ ,  $\text{2DSEARCH}$  performs a one-dimensional range search for  $[B_y : E_y]$  in the one-dimensional range tree for  $y$  associated with node  $\text{LEFT}(P)$ . A final step checks (using procedure  $\text{INRANGE}$  not given here) if the points associated with the boundary nodes (i.e., leaves)  $L_x$  and  $R_x$  are in the two-dimensional range.

```

1  procedure 2DSEARCH( $B_x, E_x, B_y, E_y, T$ )
2  /* Perform a range search for the two-dimensional interval ( $[B_x : E_x],$ 
    $[B_y : E_y]$ ) in the two-dimensional range tree rooted at  $T$ . */
3  value integer  $B_x, E_x, B_y, E_y$ 
4  value pointer node  $T$ 
5  pointer node  $Q$ 
6  if ISNULL( $T$ ) then return
7  endif
8  while not ISLEAF( $T$ ) do /* Find nearest common ancestor */
9    if  $E_x < \text{MIDRANGE}(T)$  then  $T \leftarrow \text{LEFT}(T)$ 
10   elseif  $\text{MIDRANGE}(T) < B_x$  then  $T \leftarrow \text{RIGHT}(T)$ 
11   else exit_while_loop /* Found nearest common ancestor */
12   endif
13 enddo
14 if ISLEAF( $T$ ) then
15   if  $\text{INRANGE}(\text{POINT}(T), B_x, E_x, B_y, E_y)$  then
16     output VALUE( $T$ )
17   endif
18 else /*  $T$  is a nonleaf node and must process its subtrees */
19    $Q \leftarrow T$  /* Save value to process other subtree */
20    $T \leftarrow \text{LEFT}(T)$ 
21   while not ISLEAF( $T$ ) do /* Process the left subtree */
22     if  $B_x \leq \text{MIDRANGE}(T)$  then
23        $\text{IDSEARCH}(B_y, E_y, \text{RANGETREE}(\text{RIGHT}(T)))$ 
24        $T \leftarrow \text{LEFT}(T)$ 
25     else  $T \leftarrow \text{RIGHT}(T)$ 
26     endif
27   enddo
28   if  $\text{INRANGE}(\text{POINT}(T), B_x, E_x, B_y, E_y)$  then
29     output VALUE( $T$ )
30   endif
31    $T \leftarrow \text{RIGHT}(Q)$ 
32   while not ISLEAF( $T$ ) do /* Process the right subtree */
33     if  $\text{MIDRANGE}(T) \leq E_x$  then
34        $\text{IDSEARCH}(B_y, E_y, \text{RANGETREE}(\text{LEFT}(T)))$ 
35        $T \leftarrow \text{RIGHT}(T)$ 
36     else  $T \leftarrow \text{LEFT}(T)$ 
37     endif
38   enddo
39   if  $\text{INRANGE}(\text{POINT}(T), B_x, E_x, B_y, E_y)$  then
40     output VALUE( $T$ )
41   endif
42 endif

```

Figure 1.9  
Example two-dimensional range tree to illustrate two-dimensional range searching.

For example, the desired closest common ancestor of  $L_x$  and  $R_x$  in Figure 1.9 is Q. One-dimensional range searches would be performed in the one-dimensional range trees rooted at nodes A, B, D, E, F, and H since  $5 \{L_i\} = \{L_1, L_2, L_3, L_4, L_x\}$  and  $\{R_i\} = \{R_1, R_2, R_3, R_4, R_x\}$ . For  $N$  points, procedure 2DSEARCH takes  $O(\log_2^2 N + F)$  time, where  $F$  is the number of points found (see Exercise 9).

As a more concrete example, suppose we want to perform a range search for  $([25:85],[8:16])$  on the two-dimensional range tree in Figure 1.8. We first find the nearest common ancestor of 25 and 85, which is node A. The paths  $\{L_i\}$  and  $\{R_i\}$  are given by  $\{B, D, I\}$  and  $\{C, G, N\}$ , respectively. Since B and B's left child (i.e., D) are in the path to 25, we search the range tree of B's right child (i.e., E) and report  $(52, 10)$  as in the range. Similarly, since C and C's right child (i.e., G) are in the path to 85, we search the one-dimensional range tree of C's left child (i.e., F), but do not report any results as neither  $(62, 77)$  nor  $(82, 65)$  is in the range. Finally, we check if the boundary nodes  $(27, 35)$  and  $(85, 15)$  are in the range, and report  $(85, 15)$  as in the range.

The range tree also can be adapted easily to handle  $k$ -dimensional data. In such a case, for  $N$  points, a  $k$ -dimensional range search takes  $O(\log_2^k N + F)$  time, where  $F$  is the number of points found. The  $k$ -dimensional range tree uses  $O(N \cdot \log_2^{k-1} N)$  space (see Exercise 10) and requires  $O(N \cdot \log_2^{k-1} N)$  time to build (see Exercise 11).

### Exercises

1. Is there a difference between a balanced binary search tree, where all the data is stored in the leaf nodes, and a one-dimensional range tree?
2. The MIDRANGE field in the one-dimensional range tree was defined as a variant of a discriminator between the left and right subtrees in the sense that it is greater than or equal to the values stored in the left subtree, and less than or equal to the values stored in the right subtree. Why not use a simpler definition, such as one that stipulates that the MIDRANGE value is greater than all values in the left subtree and less than or equal to all values in the right subtree?
3. Why does procedure 2DSEARCH provide the desired result?
4. Prove that no point is reported more than once by the algorithm for executing a range query in a two-dimensional range tree.
5. Procedure 2DSEARCH makes use of a representation of the two-dimensional range tree where each node has a POINT and RANGETREE field. In fact, the POINT field is defined only for leaf nodes, while the RANGETREE field points to a one-dimensional range tree of just one node for leaf nodes. Rewrite 2DSEARCH, 1DSEARCH, and INRANGE so that they do not use a POINT field, and hence interpret the RANGETREE field appropriately.
6. Show that the one-dimensional range trees at the first two levels (i.e., at the root and the two children of the root) of a two-dimensional range tree are never used in procedure 2DSEARCH.
7. Show that  $O(N \cdot \log_2 N)$  space suffices for a two-dimensional range tree for  $N$  points.
8. Show that a two-dimensional range tree can be built in  $O(N \cdot \log_2 N)$  time for  $N$  points.
9. Given a two-dimensional range tree containing  $N$  points, prove that a two-dimensional range query takes  $O(\log_2^2 N + F)$  time, where  $F$  is the number of points found.
10. Given a  $k$ -dimensional range tree containing  $N$  points, prove that a  $k$ -dimensional range query takes  $O(\log_2^k N + F)$  time, where  $F$  is the number of points found. Also, show that  $O(N \cdot \log_2^{k-1} N)$  space is sufficient.
11. Show that a  $k$ -dimensional range tree can be built in  $O(N \cdot \log_2^{k-1} N)$  time for  $N$  points.
12. Write a procedure to construct a two-dimensional range tree.

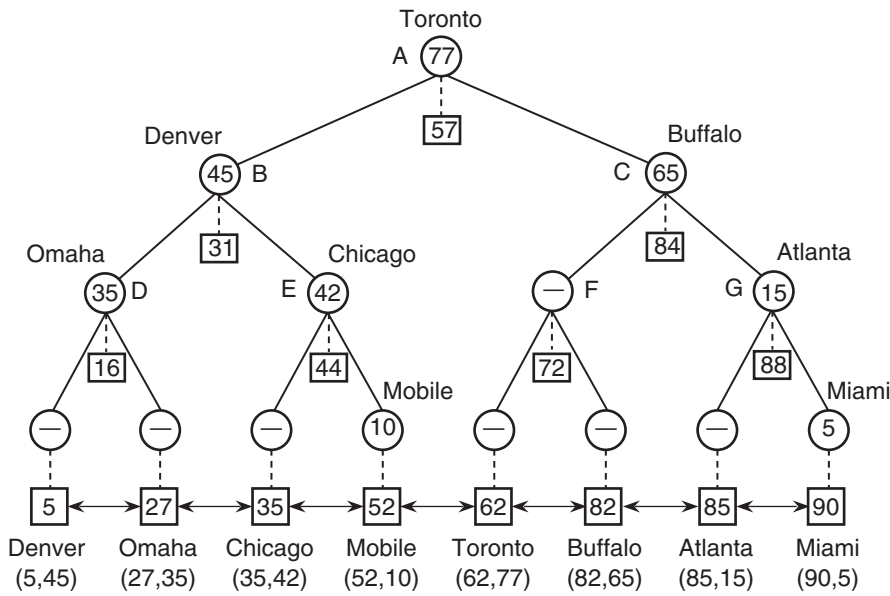

Figure 1.10  
Priority search tree for the data of Figure 1.1. Each leaf node contains the value of its  $x$  coordinate in a square box. Each nonleaf node contains the appropriate  $x$  coordinate midrange value in a square box using a link drawn with a broken line. Circular boxes indicate the value of the  $y$  coordinate of the point in the corresponding subtree with the maximum value for its  $y$  coordinate that has not already been associated with a node at a shallower depth in the tree.

### 1.3 Priority Search Trees

The *priority search tree* is a data structure that is designed for solving queries involving semi-infinite ranges in two-dimensional space. A typical semi-infinite range query has a range of the form  $([B_x : E_x], [B_y : \infty])$ . It is built in the following manner. Sort all the points along the  $x$  coordinate and store them in the leaf nodes of a balanced binary search tree, say  $T$ . We use a one-dimensional range tree in our formulation,<sup>14</sup> although in some applications (e.g., the rectangle intersection problem as discussed in Section 3.1.3 of Chapter 3), the requirement of being able to insert and delete points in  $O(\log_2 N)$  time, while still requiring the  $O(N \cdot \log_2 N + F)$  search behavior, causes the balanced binary search tree to be implemented using more complicated structures, such as a “red-black” balanced binary tree [766] (see Appendix A), although in actuality, any variant of a balanced binary tree could be used. Store midrange  $x$  coordinate values in the nonleaf nodes. Next, proceed from the root node toward the leaf nodes. Associate with each node  $I$  of  $T$  the point in the subtree rooted at  $I$  with the maximum value for its  $y$  coordinate that has not already been associated with a node at a shallower depth in the tree. If no such point exists, then leave the node empty. For  $N$  points, this structure uses  $O(N)$  space (see Exercise 1) and requires  $O(N \cdot \log_2 N)$  time to build (see Exercise 7).

For example, Figure 1.10 is the priority search tree for the data of Figure 1.1. In the figure, square boxes contain the relevant  $x$  coordinate values (e.g., the midrange values in the nonleaf nodes), while circular boxes contain the relevant  $y$  coordinate values (e.g., the maximums). Notice that the leaf nodes contain the points and are shown as linked together in ascending order of the  $x$  coordinate value. The links for the  $x$  coordinate values are used only if we conduct a search for all points within a given range of  $x$  coordinate values. They are not used in the execution of the semi-infinite range query, and thus they are frequently omitted from the implementation of the priority search tree.

<sup>14</sup> A Cartesian tree [1944] is an alternative. See Exercises 21 and 22.

It is not easy to perform a two-dimensional range query of the form  $([B_x : E_x], [B_y : E_y])$  with a priority search tree. The problem is that only the values of the  $x$  coordinate are sorted. In other words, given a leaf node  $C$  that stores point  $(x_C, y_C)$ , we know that the values of the  $x$  coordinate of all nodes to the left of  $C$  are smaller than or equal to  $x_C$  and the values of all those to the right of  $C$  are greater than or equal to  $x_C$ . On the other hand, with respect to the values of the  $y$  coordinate, we know only that all nodes below nonleaf node  $D$  with value  $y_D$  have values less than or equal to  $y_D$ ; the  $y$  coordinate values associated with the remaining nodes in the tree that are not ancestors of  $D$  may be larger or smaller than  $y_D$ .

This is not surprising because a priority search tree is really a variant of a one-dimensional range tree in  $x$  (see Exercise 1 in Section 1.2) and a heap (i.e., priority queue) [1046] in  $y$ . A heap<sup>15</sup> enables finding the maximum (minimum) value in  $O(1)$  time. More generally the largest (smallest)  $F$  out of  $N$  values can be determined in  $O(F)$  time, but the  $F$  values are not sorted. Whether the heap is used to find the largest or smallest values depends on how it is constructed. The way in which we specify the priority search tree here enables finding the largest values.

Nevertheless, despite the difficulty in using priority search trees to perform a two-dimensional range query, priority search trees make it very easy to perform a semi-infinite range query of the form  $([B_x : E_x], [B_y : \infty])$ . The control structure is quite similar to that of procedure 2DSEARCH. Descend the tree looking for the nearest common ancestor of  $B_x$  and  $E_x$ , say  $Q$ . Apply the following tests during this descent, letting  $P$  be the point associated with the examined node, say  $T$ . If no such  $P$  exists, then we are finished with the entire subtree rooted at  $T$  as all points in  $T$ 's subtrees have already been examined and reported as is appropriate. Examine the  $y$  coordinate value of  $P$ , say  $P_y$ . If  $P_y < B_y$ , then we are finished with the entire subtree rooted at  $T$  since  $P$  is the point with the maximum  $y$  coordinate value in  $T$ . Otherwise (i.e.,  $P_y \geq B_y$ ), check if the  $x$  coordinate value of  $P$  (i.e.,  $P_x$ ) is in the range  $[B_x : E_x]$ , and if yes, then  $P$  satisfies the query and is reported. At this point, determine if  $T$  is the nearest common ancestor by checking if  $B_x$  and  $E_x$  lie in  $T$ 's left and right subtrees, respectively. If  $T$  is not the nearest common ancestor, then continue the descent in the left (right) subtree of  $T$  if  $E_x$  ( $B_x$ ) is in the left (right) subtree of  $T$ .

Once  $Q$  has been found, process the left and right subtrees of  $Q$  using the appropriate step below, where  $T$  denotes the node currently being examined. In both cases, we apply the same sequence of tests described above to determine if an exit can be made due to having processed all points in the subtrees or if all remaining points are not in the  $y$  range.

1. Left subtree of  $Q$ : Check if  $B_x$  lies in the left subtree of  $T$ . If it does, then all of the points in the right subtree of  $T$  are in the  $x$  range, and we just check if they are in

---

<sup>15</sup> Briefly, a *binary heap* (usually referred to as simply a *heap*) is a variant of a binary search tree that has the property that the value of a node is greater than or equal to that of its two children. It can be implemented in a number of ways, including, when the tree is complete, as a mapping into an array so that all nodes at a given level are stored consecutively and immediately after the nodes at the preceding level. The advantage is that no pointers are needed. We can also define a  $d$ -heap, where a binary heap is the special case that  $d = 2$ . There are also binomial heaps [1943] and Fibonacci heaps [636]. They differ in the execution times of the operations that are performed on them. In particular, the principal differences between the binary heap and the binomial heap are that the union operation is  $\Theta(n)$  for the former and  $O(\log n)$  for the latter, while finding the maximum (minimum if the heap is defined so that the value of a node is less than or equal to that of its two children) is  $\Theta(1)$  for the former and  $O(\log n)$  for the latter. Fibonacci heaps have the property that the execution times of all operations are amortized and are  $\Theta(1)$  for any operation that does not involve deletion (including union), while those that do involve deletion are  $O(\log n)$ . A particularly important property of the Fibonacci heap vis-à-vis the binary heap and the binomial heap is that the decrease-key operation is  $\Theta(1)$  for the Fibonacci heap, while it is  $\Theta(\log n)$  for both the binary and binomial heaps. This operation finds use when we want to decrease the value of the key attribute and to minimize the work needed to restructure the heap.

- the  $y$  range, while recursively applying this step to the left subtree of  $T$ . Otherwise, recursively apply this step to the right subtree of  $T$ .
- Right subtree of  $Q$ : Check if  $E_x$  lies in the right subtree of  $T$ . If it does, then all of the points in the left subtree of  $T$  are in the  $x$  range, and we just check if they are in the  $y$  range, while recursively applying this step to the right subtree of  $T$ . Otherwise, recursively apply this step to the left subtree of  $T$ .

The actual search process is given by procedure PRIORITYSEARCH. It assumes that each node has five fields: POINT, MIDRANGE, LEFT, RIGHT, and HEAPMAX. POINT, MIDRANGE, LEFT, and RIGHT have the same meaning as in the two-dimensional range tree. HEAPMAX is defined for all nodes. In particular, for any node  $I$ , HEAPMAX( $I$ ) points at the node  $C$  in the subtree  $S$  rooted at  $I$  such that YCOORD(POINT( $C$ )) is greater than or equal to YCOORD(POINT( $D$ )) for any other node  $D$  in  $S$ , such that neither  $C$  nor  $D$  is associated with a node at a depth in the tree that is shallower than the depth of  $I$ . As in the two-dimensional range tree, the POINT field is not used for nonleaf nodes in the tree, and, in fact, by making PRIORITYSEARCH a bit more complicated, we can get by with just one of the POINT and HEAPMAX fields (see Exercise 4).

PRIORITYSEARCH makes use of two auxiliary procedures, OUTOFRANGEY and YSEARCH. OUTOFRANGEY determines if all points in a subtree have already been output or if they are all outside the  $y$  range. YSEARCH performs a one-dimensional range search for the semi-infinite interval with respect to the  $y$  range.

```

1  procedure PRIORITYSEARCH( $B_x, E_x, B_y, T$ )
2  /* Perform a semi-infinite range search for the two-dimensional interval
   ([ $B_x : E_x$ ], [ $B_y : \infty$ ]) in the priority search tree rooted at  $T$ . */
3  value integer  $B_x, E_x, B_y$ 
4  value pointer node  $T$ 
5  pointer node  $Q$ 
6  if ISNULL( $T$ ) then return
7  while true do /* Find nearest common ancestor */
8    if OUTOFRANGEY(HEAPMAX( $T$ ),  $B_y$ ) then return
9    elseif  $B_x \leq$  XCOORD(POINT(HEAPMAX( $T$ ))) and
      XCOORD(POINT(HEAPMAX( $T$ )))  $\leq E_x$  then
10     output POINT(HEAPMAX( $T$ ))
11   endif
12   if ISLEAF( $T$ ) then return
13   elseif  $E_x <$  MIDRANGE( $T$ ) then  $T \leftarrow$  LEFT( $T$ )
14   elseif MIDRANGE( $T$ )  $< B_x$  then  $T \leftarrow$  RIGHT( $T$ )
15   else exit_while_loop /* Found nearest common ancestor */
16   endif
17 enddo
18 /*  $T$  is a nonleaf node and must process its subtrees */
19  $Q \leftarrow T$  /* Save value to process other subtree */
20  $T \leftarrow$  LEFT( $T$ )
21 while true do /* Process the left subtree */
22   if OUTOFRANGEY(HEAPMAX( $T$ ),  $B_y$ ) then exit_while_loop
23   elseif  $B_x \leq$  XCOORD(POINT(HEAPMAX( $T$ ))) then
24     output POINT(HEAPMAX( $T$ ))
25   endif
26   if ISLEAF( $T$ ) then exit_while_loop
27   elseif  $B_x \leq$  MIDRANGE( $T$ ) then
28     YSEARCH(RIGHT( $T$ ),  $B_y$ )
29      $T \leftarrow$  LEFT( $T$ )
30   else  $T \leftarrow$  RIGHT( $T$ )
31   endif
32 enddo

```

```

33  $T \leftarrow \text{RIGHT}(Q)$ 
34 while true do /* Process the right subtree */
35   if  $\text{OUTOFRANGEY}(\text{HEAPMAX}(T), B_y)$  then return
36   elseif  $\text{XCOORD}(\text{POINT}(\text{HEAPMAX}(T))) \leq E_x$  then
37     output  $\text{POINT}(\text{HEAPMAX}(T))$ 
38   endif
39   if  $\text{ISLEAF}(T)$  then return
40   elseif  $\text{MIDRANGE}(T) \leq E_x$  then
41      $\text{YSEARCH}(\text{LEFT}(T), B_y)$ 
42      $T \leftarrow \text{RIGHT}(T)$ 
43   else  $T \leftarrow \text{LEFT}(T)$ 
44   endif
45 enddo

1 Boolean procedure  $\text{OUTOFRANGEY}(P, B_y)$ 
2 /* Check if all relevant points have already been output or if the y coordinate
   values of all points in the subtrees are too small. */
3 value pointer node  $P$ 
4 value integer  $B_y$ 
5 return(if  $\text{ISNULL}(P)$  then TRUE
6         else  $\text{YCOORD}(\text{POINT}(P)) < B_y$ 
7         endif)

1 recursive procedure  $\text{YSEARCH}(T, B_y)$ 
2 /* Perform a one-dimensional range search for the semi-infinite interval
    $[B_y : \infty]$  in the priority search tree rooted at  $T$ . */
3 value pointer node  $T$ 
4 value integer  $B_y$ 
5 if  $\text{ISNULL}(T)$  then return
6 elseif  $\text{OUTOFRANGEY}(\text{HEAPMAX}(T), B_y)$  then return
7 else
8   output  $\text{POINT}(\text{HEAPMAX}(T))$ 
9    $\text{YSEARCH}(\text{LEFT}(T), B_y)$ 
10   $\text{YSEARCH}(\text{RIGHT}(T), B_y)$ 
11 endif

```

For  $N$  points, performing a semi-infinite range query in this way takes  $O(\log_2 N + F)$  time.  $F$  is the number of points found (see Exercise 2). To answer the two-dimensional range query  $([B_x : E_x], [B_y : E_y])$ , perform the semi-infinite range query  $([B_x : E_x], [B_y : \infty])$  and discard all points  $(x, y)$  such that  $y > E_y$ .

As an example of the execution of a semi-infinite range query, suppose that we want to search for  $([35:83], [50:\infty])$  in the priority search tree in Figure 1.10. We use Figure 1.11(a) to illustrate the space decomposition induced by the priority search tree of Figure 1.10. In the figure, horizontal lines correspond to the partitions caused by the `HEAPMAX` field values in the tree. The vertical lines correspond to the partitions caused by the `MIDRANGE` field values associated with the nonleaf nodes that have at least one child whose `HEAPMAX` field is not `NIL`.

The search proceeds as follows. We descend the tree starting at the root (i.e., **A**). The point associated with **A** is Toronto with a  $y$  coordinate value of 77, which is in the  $y$  range. The  $x$  coordinate value of Toronto is 62, which is in the range. Next, we find that **A** is indeed the nearest common ancestor since the midrange value is 57, which is between the  $x$  range values of 35 and 83. Thus, we prepare to descend both of **A**'s left and right children.

We immediately cease processing the left subtree of **A** (i.e., **B**) since the maximum of the  $y$  coordinate values in **B**'s subtrees is 45, which is less than the lower bound of the semi-infinite range of  $y$  (i.e., 50). Next, we process the root of the right subtree of **A**

(i.e., C). The point associated with C is Buffalo, with a  $y$  coordinate value of 65, which is in the  $y$  range. The  $x$  coordinate value of Buffalo is 82, which is in the  $x$  range, and thus we output Buffalo as in the two-dimensional range. Next, we examine the midrange value of C, which is 84. This means that we need to descend only the left subtree of C (i.e., rooted at F) since the right subtree of C (i.e., rooted at G) is out of the  $x$  range. However, since there is no point associated with F, processing ceases because all nodes in F's subtrees have already been examined. Thus, the result is that points (62,77) and (82,65) are in the range  $([35:83],[50:\infty])$ .

Edelsbrunner [535] introduces a variation on the priority search tree, which we term a *range priority tree*, to obtain an  $O(\log_2 N + F)$  algorithm for range searching in a two-dimensional space. Define an *inverse priority search tree* to be a priority search tree  $S$  such that with each node of  $S$ , say  $I$ , we associate the point in the subtree rooted at  $I$  with the minimum (instead of the maximum!) value for its  $y$  coordinate that has not already been stored at a shallower depth in the tree. For example, Figure 1.12 is the inverse priority search tree corresponding to Figure 1.10, and Figure 1.11(b) is the space decomposition induced by it. The range priority tree is a balanced binary search tree (i.e., a one-dimensional range tree), say  $T$ , where all the data points are stored in the leaf nodes and are sorted by their  $y$  coordinate values. With each nonleaf node of  $T$ , say  $I$ , that is a left child of its father, we store a priority search tree of the points in the subtree rooted at  $I$ . With each nonleaf node of  $T$ , say  $I$ , that is a right child of its father, we store an inverse priority search tree of the points in the subtree rooted at  $I$ . For  $N$  points, the range priority tree uses  $O(N \cdot \log_2 N)$  space (see Exercise 13) and requires  $O(N \cdot \log_2 N)$  time to build (see Exercises 14 and 15). However, unlike the priority search tree, dynamic updates (i.e., insertion and deletion) take  $O(\log_2^2 N)$  time [535].

For example, Figure 1.13 is the range priority tree for the data of Figure 1.1, where the  $y$  coordinate serves as the primary sort attribute. Notice the use of double lines to indicate a link to the priority and inverse priority search trees associated with each nonleaf node, thereby distinguishing them from the single lines used to indicate links to left and right children in the two trees. In the figure, square boxes contain the relevant one-dimensional

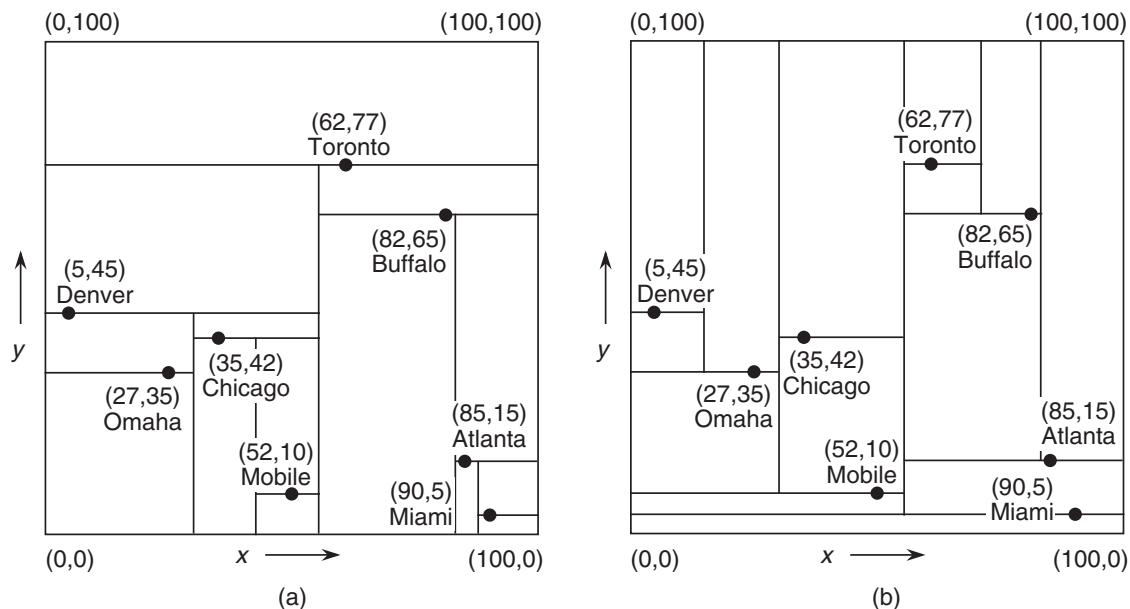

Figure 1.11  
Space decomposition induced by (a) the priority search tree of Figure 1.10 and (b) the inverse priority search tree of Figure 1.12. Horizontal lines correspond to the partitions caused by the HEAPMAX field values in the tree. Vertical lines correspond to the partitions caused by the MIDRANGE field values associated with the nonleaf nodes that have at least one child whose HEAPMAX field is not NIL.

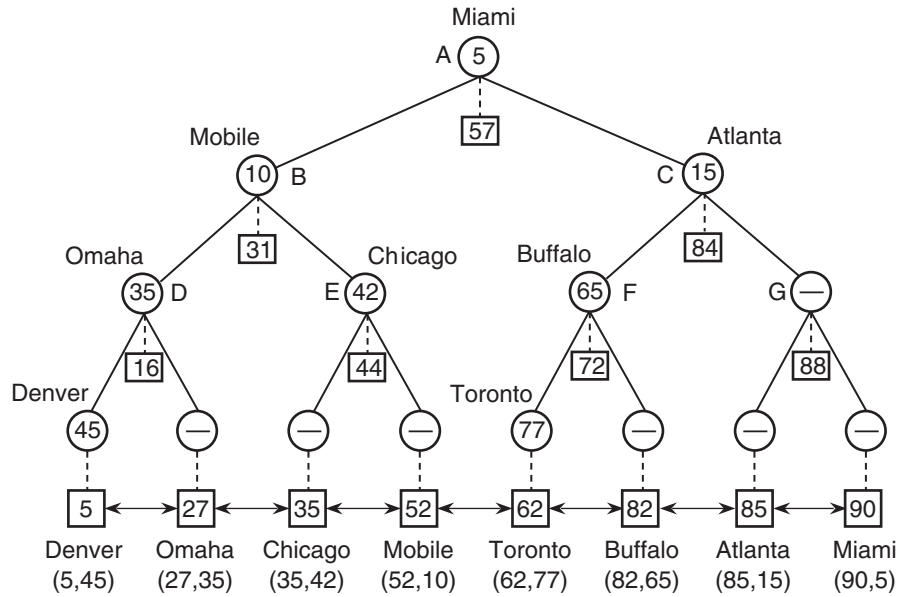

Figure 1.12  
Inverse priority search tree for the data of Figure 1.1. Each leaf node contains the value of its  $x$  coordinate in a square box. Each nonleaf node contains the appropriate  $x$  coordinate midrange value in a box using a link drawn with a broken line. Circular boxes indicate the value of the  $y$  coordinate of the point in the corresponding subtree with the minimum value for its  $y$  coordinate that has not already been associated with a node at a shallower depth in the tree.

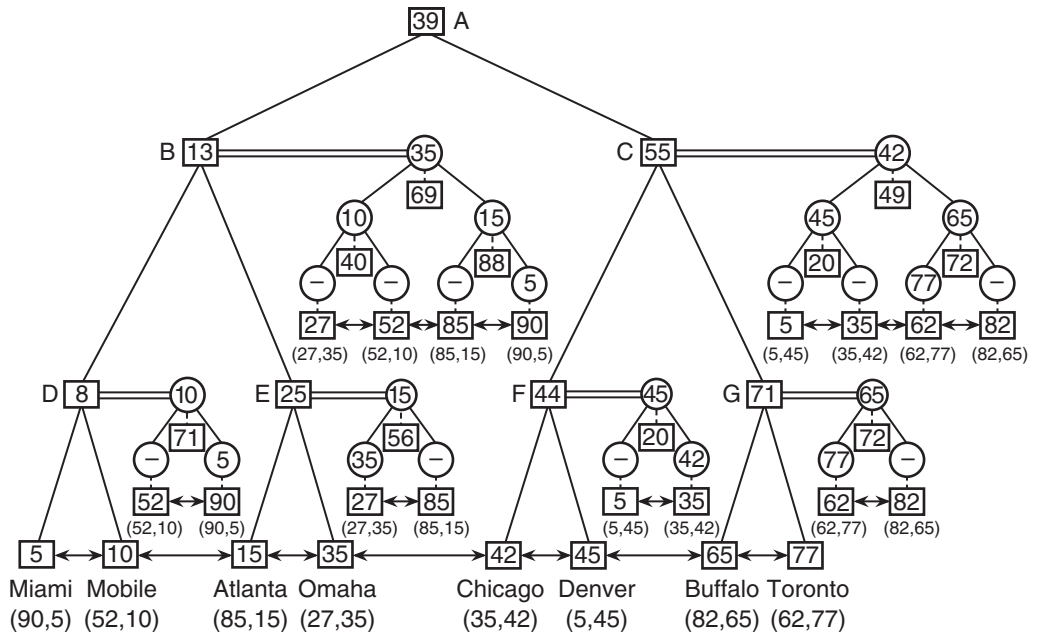

Figure 1.13  
Range priority tree for the data of Figure 1.1. Square boxes contain the relevant one-dimensional range tree values (midrange values in the nonleaf nodes), and circular boxes contain the relevant heap values. The square boxes containing the midrange values in the priority and inverse priority search trees are linked to the appropriate nonleaf node by a broken line. Double horizontal lines indicate a link to the priority and inverse priority search trees associated with each nonleaf node, thereby distinguishing them from the single lines used to indicate links to left and right children in the two trees.

range tree values (e.g., the midrange values in the nonleaf nodes); circular boxes contain the relevant heap values (i.e., maximums for the priority search tree and minimums for the inverse priority search tree). Notice that, as in the priority search tree, the leaf nodes contain the points and are shown as linked together in ascending order of the  $x$  coordinate value. Again, as in the priority search tree, the links for the  $x$  coordinate values are used only if we conduct a search for all points within a given range of  $x$  coordinate values. They are not used in the execution of the two-dimensional range query, and thus they are frequently omitted from the implementation of the range priority tree.

Performing a range query for  $([B_x : E_x], [B_y : E_y])$  using a range priority tree is done in the following manner (see also Exercise 12). We descend the tree looking for the nearest common ancestor of  $B_y$  and  $E_y$ , say  $Q$ . The values of the  $y$  coordinate of all points in the left child of  $Q$  are less than or equal to  $E_y$ . We want to retrieve just the ones that are greater than or equal to  $B_y$ . We can obtain them with the semi-infinite range query  $([B_x : E_x], [B_y : \infty])$ . This can be done by using the priority search tree associated with the left child of  $Q$ . The priority search tree is good for retrieving all points with a specific lower bound since it stores an upper bound and hence irrelevant values can be easily pruned.

Similarly, the values of the  $y$  coordinate of all points in the right child of  $Q$  are greater than or equal to  $B_y$ . We want to retrieve just the ones that are less than or equal to  $E_y$ . We can obtain them with the semi-infinite range query  $([B_x : E_x], [-\infty : E_y])$ . This can be done by using the inverse priority search tree associated with the right child of  $Q$ . The inverse priority search tree is good for retrieving all points with a specific upper bound since it stores a lower bound and hence irrelevant values can be easily pruned. Thus, for  $N$  points, the range query takes  $O(\log_2 N + F)$  time, where  $F$  is the number of points found (see Exercise 17).

As an example, suppose we want to perform a range search for  $([25:60], [15:45])$  on the range priority tree in Figure 1.13. We first find the nearest common ancestor of 15 and 45, which is node A. Second, we search for  $([25:60], [15:\infty])$  in the priority search tree attached to the left child of A (i.e., B), say  $p$ . The point (27,35) is associated with the root of  $p$ , and it is in the range. Hence, it is output. The left subtree of  $p$  is rejected because the  $y$  coordinate value associated with its root (i.e., 10) is less than the lower limit of the search range in  $y$  (i.e., 15). The elements of the right subtree of  $p$  are rejected because their  $x$  coordinate values are outside of the search range. Third, we search for  $([25:60], [-\infty:45])$  in the inverse priority search tree attached to the right child of A (i.e., C), say  $q$ . The point (35,42) is associated with the root of  $q$ , and it is in the range. Hence, it is output. The elements of the left subtree of  $q$  that have not been reported already (i.e., (5,45)) are rejected because their  $x$  coordinate values are outside of the search range. The right subtree of  $q$  is rejected because the  $y$  coordinate value associated with its root (i.e., 65) is greater than the upper limit of the search range in  $y$  (i.e., 45).

### Exercises

1. Prove that a priority search tree for  $N$  points uses  $O(N)$  space.
2. Prove that for a priority search tree with  $N$  points, a semi-infinite range query can be performed in  $O(\log_2 N + F)$  time, where  $F$  is the number of points found.
3. Procedure PRIORITYSEARCH can be made considerably shorter by changing its structure slightly, as given below by procedure PRIORITYSEARCH2. The difference is that procedure PRIORITYSEARCH2 does not make explicit use of the result of finding the nearest common ancestor. This forces the repeated comparison of  $B_x$  and  $E_x$  with the MIDRANGE field value of the node even after the nearest common ancestor has been determined. However, it does enable procedure PRIORITYSEARCH2 to make use of recursion as there is no longer a need to distinguish between processing the right and left children of the nearest common ancestor, as well as testing if the node and its left child are on the path from the nearest common ancestor to  $B_x$ , or testing if the node and its right child are on the path from the nearest common

ancestor to  $E_x$ . Prove that for  $N$  points, procedure PRIORITYSEARCH2 executes the semi-infinite range query in  $O(\log_2 N + F)$  time, where  $F$  is the number of points found. Which of PRIORITYSEARCH and PRIORITYSEARCH2 performs fewer comparison operations?

```

1  recursive procedure PRIORITYSEARCH2( $B_x, E_x, B_y, T$ )
2  /* Perform a semi-infinite range search for the two-dimensional interval
   ([ $B_x : E_x$ ], [ $B_y : \infty$ ]) in the priority search tree rooted at  $T$ . */
3  value integer  $B_x, E_x, B_y$ 
4  value pointer node  $T$ 
5  if ISNULL( $T$ ) then return
6  elseif ISNULL(HEAPMAX( $T$ )) then return
7  /* All relevant points have already been output */
8  elseif YCOORD(POINT(HEAPMAX( $T$ ))) <  $B_y$  then return
9  /* y coordinate values of all points in the subtrees are too small */
10 elseif  $B_x \leq$  XCOORD(POINT(HEAPMAX( $T$ ))) and
    XCOORD(POINT(HEAPMAX( $T$ )))  $\leq E_x$  then
11     output POINT(HEAPMAX( $T$ ))
12 endif
13 if  $B_x \leq$  MIDRANGE( $T$ ) then
14     if MIDRANGE( $T$ )  $\leq E_x$  then
15         PRIORITYSEARCH2( $B_x, E_x, B_y, LEFT(T)$ )
16         PRIORITYSEARCH2( $B_x, E_x, B_y, RIGHT(T)$ )
17     else PRIORITYSEARCH2( $B_x, E_x, B_y, LEFT(T)$ )
18     endif
19 else PRIORITYSEARCH2( $B_x, E_x, B_y, RIGHT(T)$ )
20 endif

```

4. Procedure PRIORITYSEARCH makes use of a representation of the two-dimensional range tree, where each node has a POINT and HEAPMAX field. In fact, the POINT field is defined only for leaf nodes, while the HEAPMAX field is defined for both leaf and nonleaf nodes. In particular, for leaf nodes, the HEAPMAX field either points to NIL or to itself; for nonleaf nodes, it points to either NIL or to a leaf node for which it is immediately dereferenced to obtain the corresponding POINT field value. Rewrite PRIORITYSEARCH, YSEARCH, and OUTOFRANGEY so that they do not use a POINT field, and hence interpret the HEAPMAX field appropriately.
5. In the original presentation of the priority search tree, two variants are defined [1266]. The first variant, which is the one described in the text, makes use of a one-dimensional range tree on the  $x$  coordinate value and stores midrange  $x$  coordinate values in the nonleaf nodes. The second variant does not store the midrange values. Instead, it is based on a trie search where the domain of the  $x$  coordinate value is repeatedly halved. Thus, the  $x$  coordinate values of all points in the left subtree are less than the partition value, while those of all points in the right subtree are greater than or equal to the partition value. This means that the midrange values are implicit to the tree. Prove that, in this case, no two data points in the priority search tree can have the same  $x$  coordinate value.
6. Suppose that you are using the second variant of the priority search tree as described in Exercise 5. Therefore, by the time we reach the final partition, there is just one value left. How can you get around the restriction that no two data points in a priority search tree have the same  $x$  coordinate value?
7. Prove that the construction of a priority search tree takes  $O(N \cdot \log_2 N)$  time for  $N$  points.
8. Write a procedure to construct a priority search tree.
9. Write a procedure to construct an inverse priority search tree.
10. Modify procedure PRIORITYSEARCH to deal with an inverse priority search tree.
11. Can you extend the priority search tree to handle  $k$ -dimensional data? If yes, show how you would do it.
12. Consider the search for  $([B_x : E_x], [B_y : E_y])$  in a range priority tree. The algorithm that we outlined first finds the nearest common ancestor  $Q$  of  $B_y$  and  $E_y$ , and the second step searches

for  $([B_x : E_x], [B_y : \infty])$  in the priority search tree, say  $p$ , attached to the left child  $L$  of  $Q$ . Note that  $p$  is a superset of the objects that can satisfy the query. Making use of this observation, why can we not simplify the algorithm by descending as many right links of the left child  $L$  of  $Q$  as possible, until we encounter a nonleaf node  $S$  for which  $B_y$  is in the left subtree? Similarly, for the third step of the algorithm, the subsequent search is for  $([B_x : E_x], [-\infty : E_y])$  in the priority search tree, say  $p$ , attached to the right child  $R$  of  $Q$ . Again, we note that  $p$  is a superset of the objects that can satisfy the query. Making use of this observation, why can we not simplify the search by descending as many left links of the right child  $R$  of  $Q$  as possible, until we encounter a nonleaf node  $S$  for which  $E_y$  is in the right subtree?

13. Prove that a range priority tree for  $N$  points uses  $O(N \cdot \log_2 N)$  space.
14. Prove that the construction of a range priority tree takes  $O(N \cdot \log_2 N)$  time for  $N$  points.
15. There are several ways of constructing a range priority tree with different execution times. As we pointed out in the text, for  $N$  points, the range priority tree can be constructed in  $O(N \cdot \log_2 N)$  time (see Exercise 14). However, we could also build it in  $O(N \cdot \log_2^2 N)$  time by constructing  $2^i$  priority search trees at levels  $i$  ( $1 \leq i \leq \log_2 N - 1$ ). Describe this method in greater detail, and show that it takes  $O(N \cdot \log_2^2 N)$  time.
16. Prove that insertion and deletion in a range priority tree with  $N$  points can be done in  $O(\log_2^2 N)$  time.
17. Prove that for a range priority tree with  $N$  points, a two-dimensional range query can be performed in  $O(\log_2 N + F)$  time, where  $F$  is the number of points found.
18. Can you extend the range priority tree to handle  $k$ -dimensional range queries? What is the order of the execution time of the query? How much space does it use?
19. Write a procedure to construct a range priority tree.
20. Write a procedure to search a range priority tree for a rectangular search region.
21. In the text, we characterized a priority search tree as a variant of a one-dimensional range tree in  $x$  and a heap (i.e., priority queue) in  $y$ . The priority search tree is somewhat wasteful of space as the nonleaf nodes duplicate some of the information stored in the leaf nodes. Vuillemin [1944] defines a *Cartesian tree*, which is a binary search tree in  $x$  and a heap in  $y$ . In this case, each point  $(a, b)$  is stored at just one node—that is, both nonleaf and leaf nodes contain data.<sup>16</sup> Construct a Cartesian tree for the data of Figure 1.1. Note that every conventional one-dimensional binary search tree that is constructed dynamically as the data is encountered (i.e., the first data item that is encountered serves as the root, the second data item is inserted as the right or left child of the root as is appropriate, etc.) is in fact a Cartesian tree, where there is a binary search tree on the one-dimensional data (represented as the  $x$  coordinate value) and a heap on the relative time (represented by the  $y$  coordinate value) at which the various elements were inserted in the binary search tree, with a higher priority being given to the elements that were inserted first.
22. Is the Cartesian tree defined in Exercise 21 unique? In other words, can you apply rotation operations to it to make it balanced?

---

<sup>16</sup> The *treap* [69, 1712] has the same structure as the Cartesian tree and is used by Aragon and Seidel to define what they term a *weighted randomized search tree*—a search structure for one-dimensional data with expected  $O(\log N)$  behavior for search and update operations. The expected costs are independent of the data. In particular, a weighted, randomized search tree is defined as a treap where the key (i.e., analogous to the  $x$  coordinate value) is defined by the data, and the priority (represented by the  $y$  coordinate value) is a distinct, random value fixed when the corresponding element was inserted in the binary search tree. This formulation has the same execution time behavior for performing search and update operations as the skip list [1520], which has also been applied to a  $k$ -d tree [1204] for half-space range search, as well as to a PR quadtree [561] for a number of operations, including point location, approximate range searching, and approximate nearest neighbor finding.

## 1.4 Quadrees

Recall from Section 1.1 that the quadtree is the result of imposing a tree access structure on a grid so that spatially adjacent empty grid cells are merged into larger empty grid cells. In essence, it is equivalent to marrying a  $k$ -ary tree, where  $k = 2^d$ , with the fixed grid. There are two types of quadtrees. The first is a point quadtree [614] where the subdivision lines are based on the values of the data points. The second is trie-based and forms a decomposition of the embedding space from which the data points are drawn.

In the rest of this section, we elaborate further on the differences between the point quadtree and the trie-based quadtree by showing how they are updated (i.e., node insertion and deletion) and how they are used for region searching. In particular, Section 1.4.1 presents the point quadtree. Section 1.4.2 discusses trie-based quadtrees, such as the PR and MX quadtrees. Section 1.4.3 contains a brief comparison of the point, PR, and MX quadtrees.

### 1.4.1 Point Quadtrees

In two dimensions, the point quadtree, invented by Finkel and Bentley [614], is just a two-dimensional binary search tree. The first point that is inserted serves as the root, and the second point is inserted into the relevant quadrant of the tree rooted at the first point. Clearly, the shape of the tree depends on the order in which the points were inserted. For example, Figure 1.14 is the point quadtree corresponding to the data of Figure 1.6.

The rest of this section is organized as follows. Section 1.4.1.1 shows how to insert a point into a point quadtree. Section 1.4.1.2 discusses how to delete a point from a point quadtree. Section 1.4.1.3 explains how to do region searching in a point quadtree.

#### 1.4.1.1 Insertion

Inserting record  $r$  with key values  $(a, b)$  into a point quadtree is very simple. The process is analogous to that for a binary search tree. First, if the tree is empty, then allocate a new node containing  $r$ , and return a tree with it as its only node. Otherwise, search the tree for a node  $h$  with a record having key values  $(a, b)$ . If  $h$  exists, then  $r$  replaces the record associated with  $h$ . Otherwise, we are at a NIL node, which is a child of type  $s$  (i.e.,

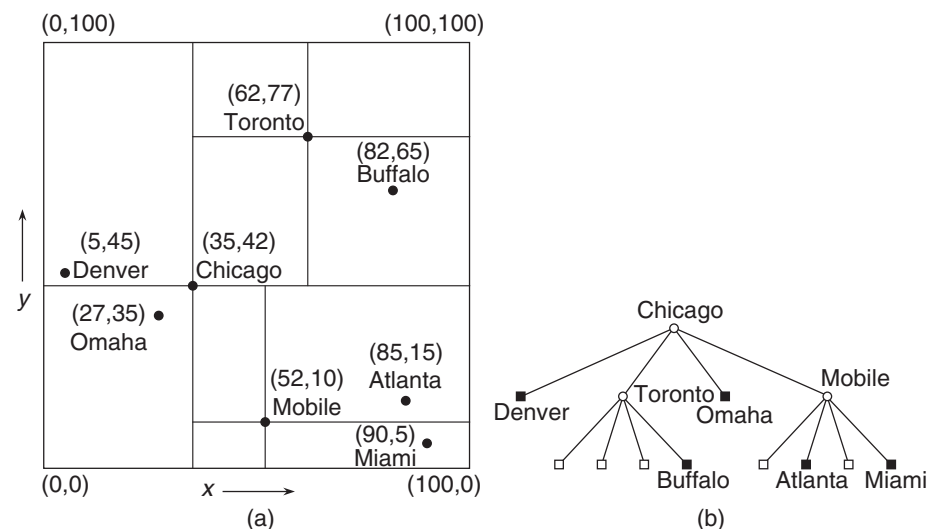

Figure 1.14  
A point quadtree and the records it represents corresponding to the data of Figure 1.1:  
(a) the resulting partition of space and (b) the tree representation.

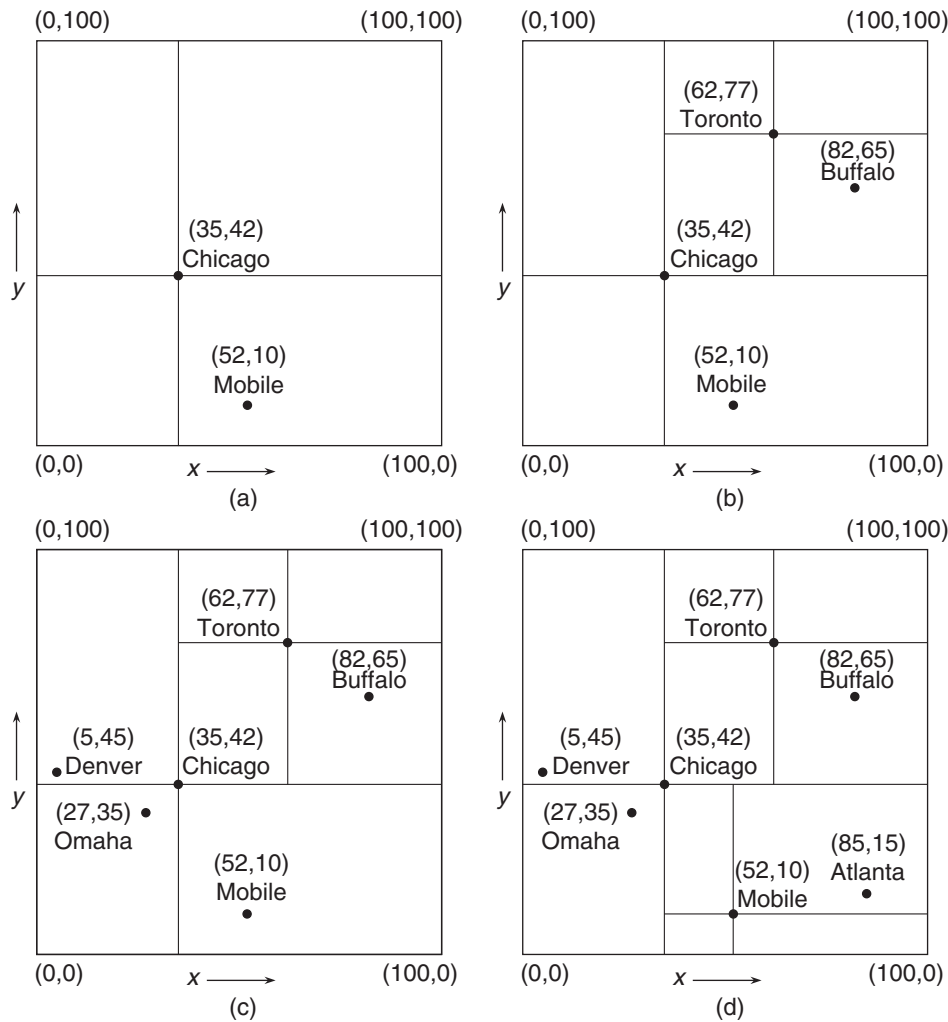

Figure 1.15  
Sequence of partial block decompositions showing how a point quadtree is built when adding (a) Chicago and Mobile, (b) Toronto and Buffalo, (c) Denver and Omaha, and (d) Atlanta, corresponding to the data of Figure 1.1.

NW, NE, SW, or SE, as appropriate) of node  $c$ . This is where we make the insertion by allocating a new node  $t$  containing  $r$  and make  $t$  an  $s$  child of node  $c$ . The only difference from the binary search tree is the need to perform four-way comparisons at each node of the tree. In particular, at each node  $q$  with key values  $(e, f)$ , we must determine the quadrant of the subtree rooted at  $q$  in which  $r$  lies. This is done by determining the position of point  $(a, b)$  with respect to  $(e, f)$ . For example, the tree in Figure 1.14 was built for the sequence Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami. Figure 1.15 shows how the tree was constructed in an incremental fashion for these cities by giving the appropriate block decompositions. In particular, Figure 1.15(a) corresponds to the tree after insertion of Chicago and Mobile, Figure 1.15(b) to the tree after insertion of Toronto and Buffalo, Figure 1.15(c) to the tree after insertion of Denver and Omaha, and Figure 1.15(d) to the tree after insertion of Atlanta.

To cope with data points that lie directly on one of the quadrant lines emanating from a data point, say  $P$ , we adopt the same conventions that were used for the grid method: the lower and left boundaries of each block are closed, while the upper and right boundaries of each block are open. For example, in Figure 1.14, insertion of Memphis with coordinate values  $(35,20)$  would lead to its placement somewhere in quadrant SE of the tree rooted at Chicago (i.e., at  $(35,42)$ ).

The amount of work expended in building a point quadtree is equal to the total path length (TPL) [1044] of the tree as it reflects the cost of searching for all of the elements. Finkel and Bentley [614] have shown empirically that for  $N$  points, the TPL of a point quadtree under random insertion is roughly proportional to  $N \cdot \log_4 N$ , which yields an average cost  $O(\log_4 N)$  of inserting, as well as searching for (i.e., a point query), a point. Devroye [484, 485] shows that the expected height of a point quadtree is logarithmic and asymptotic to  $2c/d \ln N$ , where  $c = 4.31107$ . Devroye and Laforest [486], as well as Flajolet, Gonnet, Puech, and Robson [618] have shown independently that the asymptotic expected cost of inserting the  $i$ th node in a random  $d$ -dimensional point quadtree is  $(2/d) \ln i + O(1)$ . Flajolet and Lafforgue [620] have made these results more precise by showing that random search has a logarithmic mean, and variance and is asymptotically distributed as a normal variable for all dimensions. Moreover, Flajolet, Labelle, Laforest and Salvy [619] have shown that these expected costs have explicit expressions and thus can be quantified precisely. Of course, the extreme case is much worse (see Exercise 9) and is a function of the shape of the resulting point quadtree. This is dependent on the order in which nodes are inserted into it. The worst case arises when each successive node is the child of the currently deepest node in the tree. Consequently, there has been some interest in reducing the TPL. Two techniques for achieving this reduction are described below.

Finkel and Bentley [614] propose one approach that assumes that all the nodes are known a priori. They define an *optimized point quadtree* so that given a node  $A$ , no subtree of  $A$  accounts for more than one-half of the nodes in the tree rooted at  $A$ . Building an optimized point quadtree from a file requires that the records in the file be sorted primarily by one key and secondarily by the other key. The root of the tree is set to the median value of the sorted file, and the remaining records are regrouped into four subcollections that will form the four subtrees of  $A$ . The process is applied recursively to the four subtrees.

This technique works because all records preceding  $A$  in the sorted list will lie in the NW and SW quadrants (assuming that the  $x$  coordinate value serves as the primary key), and all records following  $A$  will lie in the NE and SE quadrants. Thus, the requirement that no subtree can contain more than one-half of the total number of nodes is fulfilled. Of course, this construction method still does not guarantee that the resulting tree will be complete<sup>17</sup> (see Exercise 3).

The optimized point quadtree requires that all of the data points are known a priori. Overmars and van Leeuwen [1444] discuss an alternative approach that is a dynamic formulation of the above method—that is, the optimized point quadtree is built as the data points are inserted into it. The algorithm is similar to the one used to construct the conventional point quadtree, except that every time the tree fails to meet a predefined balance criterion, the tree is partially rebalanced using techniques similar to those developed by Finkel and Bentley to build the optimized point quadtree (for more details, see Exercise 6).

### Exercises

Assume that each point in a point quadtree is implemented as a record of type *node* containing six fields. The first four fields contain pointers to the node's four children, corresponding to the directions (i.e., quadrants) NW, NE, SW, and SE. If  $P$  is a pointer to a node, and  $I$  is a quadrant, then these fields are referenced as  $\text{CHILD}(P, I)$ . We can determine the specific quadrant in

---

<sup>17</sup> A  $t$ -ary tree containing  $N$  nodes is *complete* if we can map it onto a one-dimensional array so that the first element consists of the root, the next  $t$  elements are the roots of its  $t$  subtrees ordered from left to right, the next  $t^2$  elements are the roots of all of the subtrees of the previous  $t$  elements again ordered from left to right, etc. This process stops once  $N$  is exhausted. Thus, each level of the tree, with the exception of the deepest level, contains a maximum number of nodes. The deepest level is partially full but has no empty positions when using this array mapping. For more details, see Knuth [1044, pp. 400–401].

which a node, say  $P$ , lies relative to its father by use of the function  $\text{CHILDTYPE}(P)$ , which has a value of  $I$  if  $\text{CHILD}(\text{FATHER}(P), I) = P$ .  $\text{XCOORD}$  and  $\text{YCOORD}$  contain the values of the  $x$  and  $y$  coordinates, respectively, of the point. The empty point quadtree is represented by  $\text{NIL}$ .

1. Give an algorithm  $\text{PTCOMPARE}$  to determine the quadrant of a quadtree rooted at  $r$  in which point  $p$  lies.
2. Give an algorithm  $\text{PTINSERT}$  to insert a point  $p$  in a point quadtree rooted at node  $r$ . Make use of procedure  $\text{PTCOMPARE}$  from Exercise 1. There is no need to make use of the  $\text{CHILDTYPE}$  function.
3. Suppose that you could construct the optimized point quadtree (i.e., minimal depth) for  $N$  nodes. What is the worst-case depth of an optimized point quadtree?
4. What is the maximum TPL in an optimized point quadtree?
5. Analyze the running time of the algorithm for constructing an optimized point quadtree.
6. In the text, we intimated that the optimized point quadtree can also be constructed dynamically. Given  $\delta$  ( $0 < \delta < 1$ ), we stipulate that every nonleaf node with a total of  $m$  nodes in its subtrees has at most  $\lceil m/(2 - \delta) \rceil$  nodes in each subtree. Give an algorithm to construct such a point quadtree.
7. Prove that the depth of the optimized point quadtree constructed in Exercise 6 is always at most  $\log_{2-\delta} n + O(1)$  and that the average insertion time in an initially empty data structure is  $O(\frac{1}{\delta \log_2^2 N})$ .  $n$  denotes the number of nodes currently in the tree, and  $N$  is the total number of nodes that have been inserted.
8. The TPL can also be reduced by applying balancing operators analogous to those used to balance binary search trees. Give the point quadtree analogs of the single and double rotation operators [1046, p. 461].
9. What is the worst-case cost of building a point quadtree of  $N$  nodes?

Figure 1.16  
Idealized point quadtree deletion situation.

### 1.4.1.2 Deletion

There are several ways of deleting nodes in two-dimensional point quadtrees. The first, suggested by Finkel and Bentley [614], is quite simple in that we reinsert all nodes of the tree rooted at the deleted node. This is usually a very expensive process, unless the deleted node is a leaf node or its children are leaf nodes. In the rest of this section we describe a more complex, and more efficient, process developed by Samet [1618]. It may be skipped on an initial reading.

Ideally, we want to replace the deleted node (say  $A$  at  $(x_A, y_A)$ ) with a node (say  $B$  at  $(x_B, y_B)$ ), such that the region between the lines  $x = x_A$  and  $x = x_B$  and the region between the lines  $y = y_A$  and  $y = y_B$  are empty. The shaded area in Figure 1.16 illustrates this concept for nodes  $A$  and  $B$  in that  $A$  is deleted and replaced by  $B$ . We use the term *hatched* to describe the region that we would like to be empty. Unfortunately, finding a node that will lead to an empty hatched region involves a considerable amount of searching. In fact, it is not uncommon that such a node fails to exist (e.g., when deleting node  $A$  in Figure 1.17).

The algorithm we describe proceeds in a manner analogous to the method for binary search trees. For example, for the binary search tree of Figure 1.18, when node  $A$  is to be deleted, it can be replaced by one of nodes  $D$  or  $G$ —the two “closest” nodes in value. In the case of a point quadtree (e.g., Figure 1.17), it is not clear which of the remaining nodes should replace  $A$ . This is because no node is simultaneously the closest in both the  $x$  and  $y$  directions. We notice that no matter which of the nodes is chosen, some of the nodes will assume different positions in the new tree. For example, in Figure 1.17, if  $L$  replaced  $A$ , then  $J$  would no longer occupy the NW quadrant with respect to the root (which is now  $L$  instead of  $A$ ) and thus  $J$  would need to be reinserted, along with some of its subtrees, in the quadrant rooted at  $F$ . Similarly,  $E$  and  $I$  would have to be reinserted, along with some of their subtrees, in the quadrant rooted at  $N$ .

Figure 1.17  
A point quadtree and the records it represents: (a) the resulting partition of space and (b) the tree representation.

Example binary search tree.

Figure 1.19  
Example of the application of the candidate determination procedure to the NE quadrant of node A.

Figure 1.20  
Example of a point quadtree with no "closest" terminal node.

Figure 1.21  
Example of a point quadtree with two nodes being "closest" to their bordering axes.

Our algorithm determines four candidate nodes for the replacement node, one for each quadrant, as follows. Let the primitive  $OPQUAD(i)$  denote the quadrant that is 180 degrees apart from quadrant  $i$  (e.g.,  $OPQUAD('NW') = 'SE'$ ). The candidate in quadrant  $i$  of the root  $r$  is obtained by starting at the node  $CHILD(r, i)$  and repeatedly following the branch corresponding to  $OPQUAD(i)$  until encountering a node having no subtree along this branch. Figure 1.19 shows how node B is selected as the candidate node from the NE quadrant of node A in an example where the NE child of A is D, the SW child of D is C, and the SW child of C is B. Note that this example is unrelated to the one in Figure 1.17. As a more complex example, in Figure 1.17, the candidates are B, J, M, and N.

Once the set of candidate nodes is found, an attempt is made to find the "best" candidate, which becomes the replacement node. There are two criteria for choosing the best candidate. Criterion 1 stipulates the choice of the candidate that is closer to each of its bordering axes than any other candidate and that is on the same side of these axes, if such a candidate exists. For example, in Figure 1.17, node B is the best candidate according to this criterion. Note that the situation may arise that no candidate satisfies criterion 1 (e.g., Figure 1.20) or that several candidates satisfy it (e.g., B and D in Figure 1.21). In such a case, criterion 2 chooses the candidate with the minimum  $L_1$  metric value. Criterion 2 is also known as the *City Block metric* (or the *Manhattan metric*).

The  $L_1$  metric is the sum of the displacements from the bordering  $x$  and  $y$  axes. To justify its use, we assume that the nodes are uniformly distributed in the two-dimensional space. Our goal is to minimize the area, that which is obtained by removing from the hatched region the rectangle whose opposite vertices are the root and candidate nodes (e.g., nodes A and B, respectively, in Figure 1.16).

Assume that the two-dimensional space is bounded, having sides of length  $L_X$  and  $L_Y$  parallel to the  $x$  and  $y$  axes, respectively. Let this space be centered at the node to be deleted. Assume further that the candidate node is at a distance of  $d_X$  and  $d_Y$  from the  $x$  and  $y$  axes, respectively. Under these assumptions, the remaining area is  $L_X \cdot d_Y + L_Y \cdot d_X - 2 \cdot d_X \cdot d_Y$  (see Figure 1.22). We can ignore the area of the rectangle with sides  $d_X$  and  $d_Y$  because the candidate selection process guarantees that it is empty. As  $L_X$  and  $L_Y$  increase, as occurs in the general problem domain, the contribution of the  $2 \cdot d_X \cdot d_Y$  term becomes negligible, and the area is proportional to the sum of  $d_X$  and  $d_Y$ .<sup>18</sup>

Criterion 2 is not sufficient by itself to insure that the selected candidate partitions the space so that the hatched region contains no other candidate. For example, see Figure 1.23, in which O has been deleted, and A satisfies criterion 2, but only C satisfies criterion 1. A pair of axes through C leaves all other candidates outside the hatched region, while a pair of axes through A results in B's being in the hatched region.

If no candidate is found to satisfy criterion 1, then criterion 2 guarantees that at least one of the candidates, say X, has the property that no more than one of the remaining candidates occupies the hatched region between the original axes and the axes passing through X. To see this, we examine Figure 1.20 and note that whichever candidate is selected to be the new root (say C in the NW quadrant), then the candidate in the opposite quadrant (i.e., SE) lies outside of the hatched region. In addition, the candidate in a quadrant on the same side of an axis as C, and to which axis C is closer (i.e., B), lies outside of the hatched region.

We are now ready to present the deletion algorithm. It makes use of the properties of the space obtained by the new partition to reduce the number of nodes requiring reinsertion. The algorithm consists of two procedures,  $ADJQUAD$  and  $NEWROOT$ . Let A be the node to be deleted, and let I be the quadrant of the tree containing B, the replacement node for A. Note that no nodes in quadrant  $OPQUAD(I)$  need to be

<sup>18</sup> Actually, this statement holds only for  $L_X = L_Y$ . However, this approximation is adequate for the purpose of this discussion.

reinserted. Now, separately process the two quadrants adjacent laterally to quadrant  $I$  using procedure ADJQUAD, followed by application of procedure NEWROOT to quadrant  $I$ .

Procedure ADJQUAD proceeds as follows. Examine the root of the quadrant, say  $R$ . If  $R$  lies outside of the hatched region, then two subquadrants can automatically remain in the quadrant and need no further processing while the remaining subquadrants are separately processed by a recursive invocation of ADJQUAD. Otherwise, the entire quadrant must be reinserted into the quadtree that was formerly rooted at  $A$ .

As an example of the effect of applying ADJQUAD to the two quadrants laterally adjacent to the quadrant containing the replacement node, consider Figure 1.17, where node  $A$  is deleted and replaced by node  $B$  in the NE quadrant.  $J$  and the subquadrant rooted at  $K$  remain in the NW quadrant, while the subquadrant rooted at  $L$  is recursively processed. Eventually,  $L$  must be reinserted into the tree rooted at  $M$ . The SE quadrant of  $A$  (rooted at  $N$ ) does not require reinsertion. The result of these manipulations is given in Figure 1.24, which shows the outcome of the entire deletion. Below, we explain how the contents of the quadrant containing the replacement node have been processed (i.e.,  $I$  or NE in the example of Figure 1.17).

Once the nodes in the quadrants adjacent to quadrant  $I$  have been processed by ADJQUAD, we apply procedure NEWROOT to the nodes in  $I$ . Clearly, all of the nodes in subquadrant  $I$  of  $I$  will retain their position. Thus, NEWROOT must be applied only to the remaining subquadrants of  $I$ . NEWROOT starts by invoking ADJQUAD to process the subquadrants adjacent laterally to subquadrant  $I$ . This is followed by an iterative reinvocation of NEWROOT to subquadrant OPQUAD( $I$ ). This iterative reinvocation process continues until an empty link in direction OPQUAD( $I$ ) is encountered (i.e., at this point, we are at  $B$ , the node replacing the deleted node). Now, insert the nodes in the subquadrants adjacent to subquadrant  $I$  of the tree rooted at  $B$  in the quadrants adjacent to quadrant  $I$  of the tree rooted at  $A$ . Recall that by virtue of the candidate selection process, subquadrant OPQUAD( $I$ ) of the tree rooted at  $B$  is empty. Also, subquadrant  $I$  of the tree rooted at  $B$  replaces subquadrant OPQUAD( $I$ ) of the previous father node of  $B$ .

Figure 1.25 illustrates the subquadrants that NEWROOT calls ADJQUAD (labeled ADJ) to process when node  $O$  is deleted and the resulting tree is rooted at node  $4$ . For the example of Figure 1.17, where node  $A$  is deleted and whose result is shown in Figure 1.24, application of NEWROOT results in the tree rooted at  $G$  being left alone. Trees rooted at  $H$  and  $I$  are processed by ADJQUAD. Trees rooted at  $D$  and  $E$  are reinserted in quadrants NW and SE, respectively. The tree rooted at  $C$  replaces  $B$  as the child of  $F$  in subquadrant SW.

The open and closed conventions that we adopted in Section 1.4.1.1 may at times result in the inability to apply procedure NEWROOT. This is the case when at least one of the coordinate values of the point associated with the replacement node  $B$  and the root  $F$  of the quadrant  $I$  of the deleted node  $A$  that contains  $B$  are identical. In this case, the entire subtree rooted at  $F$  must be reinserted into the quadtree rooted at  $B$ . We must check for this situation at all stages where procedure NEWROOT could possibly be applied. For example, it must be checked at nodes 1, 2, and 3 in Figure 1.25. Using our open and closed conventions that the lower and left boundaries of each block are closed, while the upper and right boundaries of each block are open, means that this situation can never arise when the replacement node is in the NE quadrant of the deleted node. However, it can easily arise in the remaining cases. For example, suppose that we are deleting node  $A$  at  $(0,0)$  and let  $B$  at  $(-5,3)$  in the NW quadrant of  $A$  be the replacement node. Moreover, let  $F$  at  $(-5,5)$  be the NW child of  $A$ . Before replacing  $A$  by  $B$ ,  $F$  was in the NW quadrant of  $A$ . Once we replace  $A$  by  $B$ ,  $F$  is in the NE quadrant of  $B$  due to the open and closed conventions, and thus we have to reinsert the entire subtree rather than take advantage of the pruning that is afforded by use of NEWROOT. For more examples, see Exercise 3.

## Section 1.4 QUADTREES

Figure 1.22  
Example of a two-dimensional space.

Figure 1.23  
Example of the insufficiency of criterion 2 for an empty hatched region.

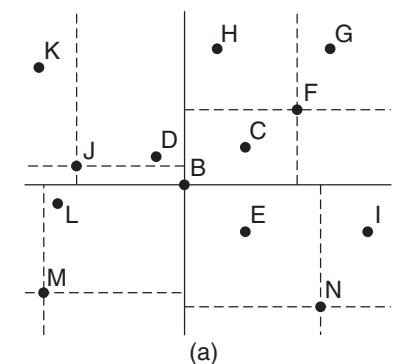

Figure 1.24  
Result of deleting node  $A$  from the point quadtree of Figure 1.17 and replacing it with node  $B$ : (a) the resulting partition of space and (b) the tree representation.

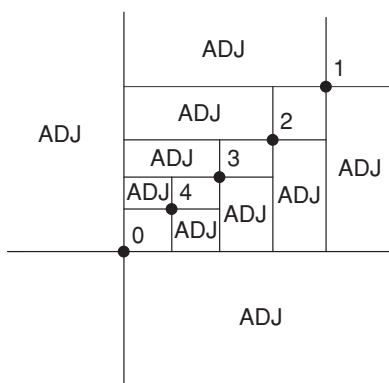

Figure 1.25  
Subquadrants processed by procedure ADJQUAD (labeled ADJ) when node 0 is deleted and replaced by node 4.

Theoretical and empirical results for the above deletion method are described by Samet [1618]. It is shown theoretically that for data that is uniformly distributed, the average number of nodes requiring reinsertion is reduced by a factor of  $5/6$  (i.e., 83%) when the replacement node satisfies criteria 1 and 2. The relaxation of the requirement that the replacement node must satisfy criteria 1 and 2, and its substitution by a random selection of one of the candidates as the replacement node, caused the factor by which the average number of nodes required reinsertion to decrease to  $2/3$  (i.e., 67%). Of course, the candidate selection process becomes considerably simpler in this case.

The empirical tests led to the following interesting observations. First, the number of comparison operations is proportional to  $\log_4 N$  versus a considerably larger factor when using the deletion method of Finkel and Bentley [614]. Second, the total path length (TPL) of the tree after deletion using Samet's method [1618] decreases slightly, whereas when Finkel and Bentley's method [614] is used, the TPL increases significantly. This data is important because it correlates with the effective search time (see also [182, 1132]). In other words, the smaller the TPL, the more quickly a node can be accessed.

It is interesting to observe that one of the main reasons for the complexity of deletion in point quadtrees is the fact that the data points also serve to partition the space from which they are drawn. The *pseudo quadtree* of Overmars and van Leeuwen [1444] simplifies deletion by using arbitrary points that are not in the set of data points being represented for the partitioning process. The pseudo quadtree is constructed by repeatedly partitioning the space into quadrants, subquadrants, and so on, until each subquadrant contains at most one data point of the original set. This means that the data points occur as leaf nodes of the pseudo quadtree. The partition points are chosen in a manner that splits the remaining set in the most balanced way.

Overmars and van Leeuwen show that for any  $N$  data points in a  $d$ -dimensional space, there exists a partitioning point such that every quadrant contains at most  $\lceil N/(d+1) \rceil$  data points. They also demonstrate that the resulting pseudo quadtree has a depth of at most  $\lceil \log_{d+1} N \rceil$  and can be built in  $O(N \cdot \log_{d+1} N)$  time. For example, Figure 1.26 is the pseudo quadtree corresponding to the data of Figure 1.1. Efficient deletion and insertion in a pseudo quadtree require that the bound on the depth be weakened slightly (see Exercise 16).

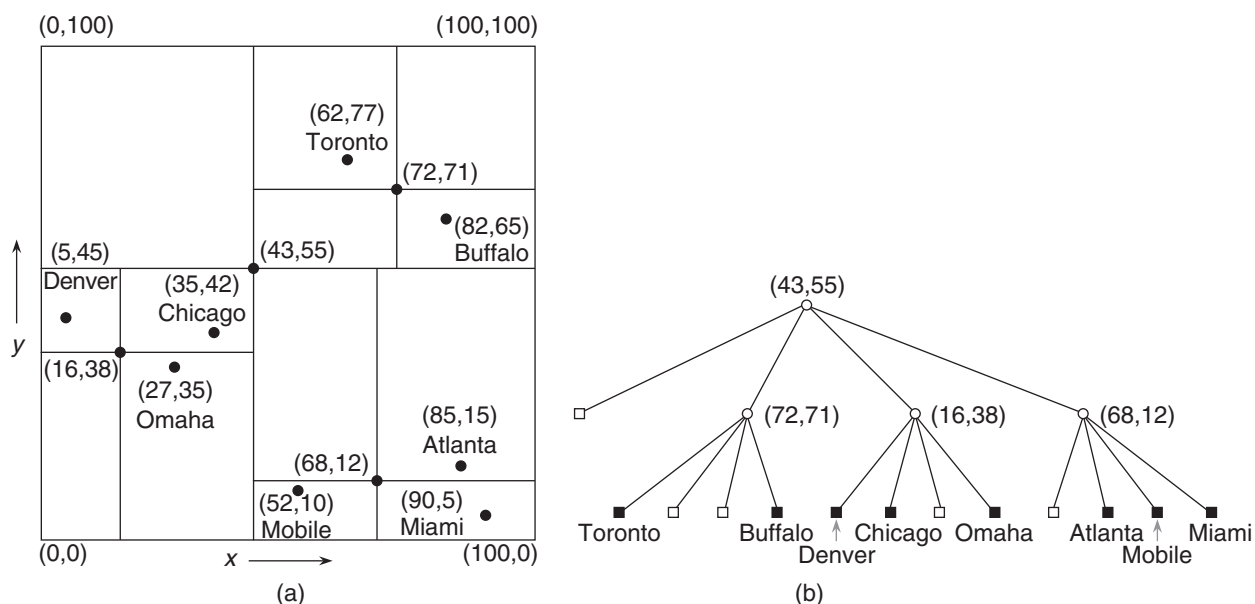

Figure 1.26  
A pseudo quadtree and the records it represents corresponding to the data of Figure 1.1: (a) the resulting partition of space and (b) the tree representation.

1. Assuming the same quadtree node implementation as in the exercises in Section 1.4.1.1, and that  $p$  points to the child in quadrant  $q$  of the node to be deleted, give an algorithm FINDCANDIDATE to determine the candidate in quadrant  $q$ .
2. Assuming the same quadtree node implementation as in the exercises in Section 1.4.1.1, give an algorithm PTDELETE for deleting a point stored in a node  $p$  from a point quadtree rooted at node  $r$ . The node does not have a FATHER field, although you may make use of the CHILDTYPE function. Make use of procedure PTCOMPARE from Exercise 1 in Section 1.4.1.1. Procedure PTDELETE implements procedures ADJQUAD and NEWROOT as described in the text. You can simplify the task by making use of primitives CQUAD( $q$ ) and CCQUAD( $q$ ), which yield the adjacent quadrants in the clockwise and counterclockwise directions, respectively, to quadrant  $q$ . Also, assume the existence of procedure INSERTQUADRANT( $t, p$ ), which inserts the nodes of the subtree rooted at node  $t$  in the subtree rooted at node  $p$ .
3. In the text, we pointed out that the open and closed conventions for the quadrants that we adopted in Section 1.4.1.1 may at times result in the inability to apply procedure NEWROOT. Using our conventions that the lower and left boundaries of each block are closed, while the upper and right boundaries of each block are open, we pointed out that this situation could not arise if the replacement node is in the NE quadrant of the deleted node. We gave an example of the occurrence of this situation when the replacement node B was in the NW quadrant of the deleted node A. Give examples of when this situation could arise when B is in the SE and SW quadrants of A, which is assumed to be at (0,0).
4. Suppose that a point quadtree node is implemented as a record with a FATHER field containing a pointer to its father. Modify procedure PTDELETE in the solution to Exercise 2 to take advantage of this additional field.
5. Let  $T$  be a tree containing  $N$  nodes with TPL( $T$ ) denoting its total path length. Prove that the sum of the sizes of its subtrees is TPL( $T$ ) +  $N$ . Show that this result holds for binary search trees and point quadtrees as well.
6. Define a *nontrivial* subtree to be a subtree with two or more nonempty subtrees. Let  $Q(N)$  be the expected nontrivial subtree size in a complete point quadtree of  $N$  nodes. Prove that as  $N$  gets large,  $Q(N)$  is  $4 \cdot \log_4\left(\frac{3}{4} \cdot N\right) - 4/3$ . Do not take the root of the subtree into account. Note that  $Q(N)$  is the cost of deletion when the method of Finkel and Bentley [614] is used. A complete point quadtree is used because such a configuration minimizes the average cost of deletion in this case since, recalling Exercise 5, the sum of the subtree sizes for a given tree  $T$  containing  $N$  nodes is TPL( $T$ ) +  $N$ . This quantity is at a minimum when  $T$  is a complete tree.
7. Assuming a complete point quadtree of  $N$  nodes, let  $r(N)$  denote the proportion of nodes that do not require reinsertion when using the deletion method of Samet [1618]. Let  $A$  and  $B$  be the deleted and replacement node, respectively, where  $B$  is a node returned by the candidate determination procedure (see procedure FINDCANDIDATE in Exercise 1). Assume further that the nodes are partitioned uniformly throughout the partition of the two-dimensional space rooted at  $A$ . Use a value of 1/2 for the probability that a node needs to be reinserted. Show that when  $B$  satisfies criteria 1 and 2, then  $r(N)$  is 5/6 or 3/4, depending on whether none of the adjacent quadrants has its candidate replacement node in the hatched region. Similarly, show that  $r(N)$  is 2/3 when the replacement node is chosen at random from the set of nodes returned by procedure FINDCANDIDATE.
8. Can you prove that the point quadtree deletion algorithm given by procedures ADJQUAD and NEWROOT is  $O(\log_4 N)$ ?
9. Why do the resulting trees get bushier when the point quadtree deletion algorithm given by procedures ADJQUAD and NEWROOT is used?
10. Extend the deletion method of Samet [1618] to handle  $d$ -dimensional point quadtrees and compute  $r(N)$ .

Problem: Find all nodes within radius  $r$  of point  $A$   
 Solution: If the root is in region  $l$  ( $l=1\dots 13$ ), then continue to search in the quadrant specified by  $l$

Relationship between a circular search space and the regions in which a root of a quadtree may reside.

11. Write an algorithm, BUILDPSEUDOQUADTREE, to construct a pseudo quadtree for two-dimensional data.
12. Given a set of  $N$  points in  $d$ -dimensional space, prove that there exists a partitioning point such that every quadrant contains  $\lceil N/(d+1) \rceil$  points.
13. Given a set of  $N$  points in  $d$ -dimensional space, prove that there exists a pseudo quadtree for it with a depth of at most  $\lceil \log_{d+1} N \rceil$ .
14. Show that the upper bound obtained in Exercise 13 is a strict upper bound in that there exists a configuration of  $N$  points such that there is no corresponding pseudo quadtree with a depth less than  $\lceil \log_{d+1} N \rceil$ .
15. Prove that the pseudo quadtree of Exercise 13 can be built in  $O(N \cdot \log_{d+1} N)$  time.
16. Prove that for any fixed  $\delta$  ( $0 < \delta < 1$ ) there is an algorithm to perform  $N$  insertions and deletions in an initially empty  $d$ -dimensional pseudo quadtree such that its depth is always at most  $\log_{d+1-\delta} n + O(1)$  and that the average transaction time is bounded by  $O(\frac{1}{\delta \log_2 N})$ .  $n$  denotes the number of nodes currently in the tree.

### 1.4.1.3 Search

The point quadtree, as well as the trie-based quadtree, is suited for applications that involve proximity search. A typical query seeks all nodes within a specified distance of a given data point—such as all cities within 50 miles of Washington, D.C. Since the mechanics of the search are the same for both point and trie-based quadtrees, in the rest of this discussion we use the term *quadtree* unless a distinction between the different quadtrees is necessary, in which case we restore the appropriate qualifier. The efficiency of the quadtree data structure lies in its role as a pruning device on the amount of search that is required. Thus, many records will not need to be examined.

For example, suppose that in the hypothetical database of Figure 1.1, we wish to find all cities within eight units of a data point with coordinate values (83,10). In such a case, there is no need to search the NW, NE, and SW quadrants of the root (i.e., Chicago located at (35,42)). Thus, we can restrict our search to the SE quadrant of the tree rooted at Chicago. Similarly, there is no need to search the NW and SW quadrants of the tree rooted at Mobile (i.e., located at (52,10)).

As a further illustration of the amount of pruning of the search space that is achievable with the quadtree, we make use of Figure 1.27. In particular, given the problem of finding all nodes within radius  $r$  of point  $A$ , the figure indicates which quadrants need not be examined when the root of the search space, say  $R$ , is in one of the numbered regions. For example, if  $R$  is in region 9, then all but its NW quadrants must be searched. If  $R$  is in region 7, then the search can be restricted to the NW and NE quadrants of  $R$ .

Similar techniques can be used to search for data points in any connected figure. For example, Finkel and Bentley [614] give algorithms for searching within a rectangular window of arbitrary size (also known as a *window query*). These algorithms are more general than the query that we examined here because they are applicable to both locational and nonlocational data. For example, such a query would seek to find all cities within 50 miles of the latitude position of Washington, D.C., and within 50 miles of the longitude position of Washington, D.C. The difference between these two formulations of the query is that the former admits a circular search region, while the latter admits a rectangular search region. In particular, the latter query is applicable to both locational and nonlocational data, while the former is applicable only to locational data. As a concrete example, suppose that we wish to find all people of a height between 5 and 6 feet (152.4 and 182.88 cm) and of a weight between 150 and 180 pounds (68 and 82 kg).

To handle more complex search regions, such as those formed by arbitrary hyperplanes (rather than ones that are parallel to one of the attribute axes, as in our examples), as well as convex polygons, Willard [2000] defines a *polygon tree*, where the  $x$ - $y$  plane

is subdivided by  $J$  lines that need not be orthogonal, although there are other restrictions on these lines (see Exercise 6). When  $J = 2$ , the result is a point quadtree with nonorthogonal axes.

Thus, we see that quadtrees can be used to handle all three types of queries specified by Knuth [1046]. Range and Boolean queries are described immediately above, while simple queries (e.g., what city is located at a given pair of coordinate values) are a byproduct of the point quadtree insertion process described earlier. Nearest neighbor queries, as well as  $k$ -nearest neighbor queries, are also feasible [846, 848].

The cost of search in a point quadtree has been studied by Bentley, Stanat, and Williams [182] (see Exercise 2) and Lee and Wong [1132]. In particular, Lee and Wong show that in the worst case, range searching in a complete two-dimensional point quadtree takes  $O(2 \cdot N^{1/2})$  time. This result can be extended to  $d$  dimensions to take  $O(d \cdot N^{1-1/d})$  time and is derived in a manner analogous to that for a  $k$ -d tree, as discussed in Section 1.5. Note that complete point quadtrees are not always achievable, as seen in Exercise 3 in Section 1.4.1.1. Partial range queries can be handled in the same way as range searching. Lee and Wong [1132] show that when ranges for  $s$  out of  $d$  keys are specified, then the algorithm has a worst-case running time of  $O(s \cdot N^{1-1/d})$ .

### Exercises

1. Write a procedure `PTREGIONSEARCH` that performs a region search for a circular region in a point quadtree. Repeat for a rectangular region.
2. Bentley and Stanat [181] define a *perfect point quadtree* of height  $m$  as a point quadtree with (1)  $4^i$  nodes at level  $m - i$ , where the root is at level  $m$ ,  $0 \leq i \leq m - 1$ , and (2) every node at the centroid of the finite space spanned by its subtrees. Assume a search space of  $[0, 1]^2$  and a rectangular search region of sides of length  $x$  and  $y$ , where  $x$  and  $y$  are in  $[0, 1]$ . Find the expected number of nodes that are visited in a perfect point quadtree of height  $m$  when a region search procedure is applied to the above search region.
3. Bentley and Stanat [181] also define the concept of *overwork* of a search algorithm as the difference between the number of records visited and the number of records in the search region. Assume a search space of  $[0, 1]^2$  with  $N$  records and a square search region of side length  $x$ , where  $x$  is in  $[0, 1]$ . Compare the amount of overwork for an inverted list (i.e., inverted file) and a perfect point quadtree.
4. Prove that the worst-case running time for a partial range query, such that ranges for  $s$  out of  $d$  keys are specified, is  $O(s \cdot N^{1-1/d})$ .
5. Perform an average case analysis for a region query in a point quadtree.
6. What are the restrictions on the choice of subdivision lines in Willard's polygon tree [2000]?

## 1.4.2 Trie-Based Quadtrees

From Section 1.4.1 we saw that for the point quadtree, the points of decomposition are the data points themselves (e.g., in Figure 1.14, Chicago at location (35,42) subdivides the two-dimensional space into four rectangular regions). Requiring that the regions resulting from the subdivision process be of equal size (congruent, to be precise) leads to a trie-based quadtree.

Trie-based quadtrees are closely related to the region quadtree representation of region data (see Section 2.1.2.4 in Chapter 2). Region quadtrees are built on the basis of recursively decomposing a region into four congruent blocks and stopping the decomposition whenever the block is homogeneous. In the case of region data, the homogeneity condition usually means that the area spanned by the block belongs to just one region (assuming that the underlying regions do not overlap). For example, Figure 1.28 shows a region and its corresponding region quadtree. There are many possible adaptations of the homogeneity condition for point data. For example, if we treat the points as elements

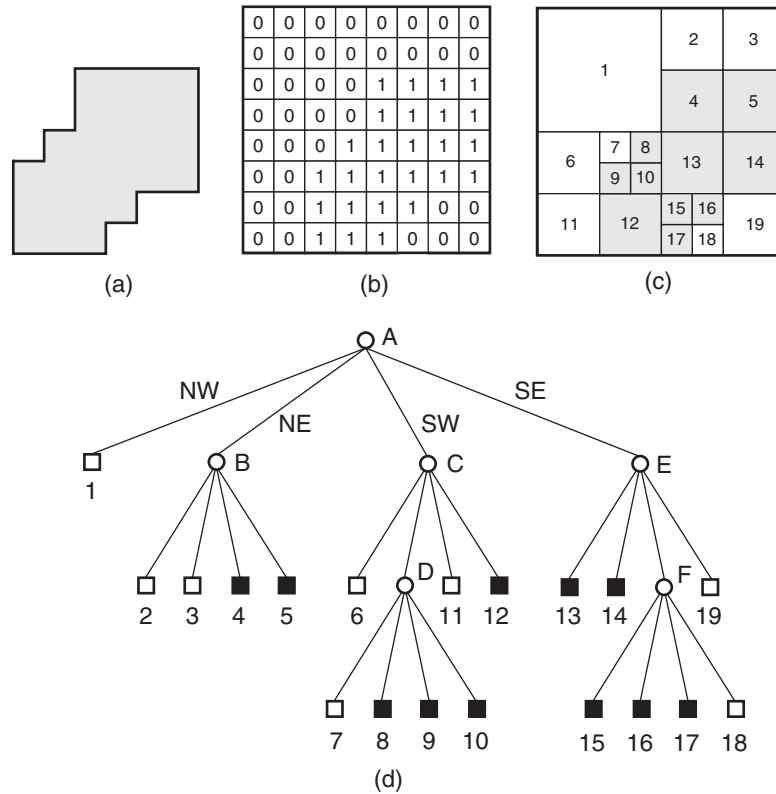

Figure 1.28  
(a) Sample region, (b) its binary array representation, (c) its maximal blocks with the blocks in the region being shaded, and (d) the corresponding quadtree.

in a square matrix, then the homogeneity condition could be that the block contains no more than  $b$  nonzero elements (when  $b = 1$ , we have a PR quadtree). Alternatively, we could stipulate that all elements in the block must be zero or that the block contains just one element, which must be nonzero (an MX quadtree).

Although, conceivably, there are many other ways of adapting the region quadtree to represent point data, our presentation focuses on the MX and PR quadtrees. In particular, we discuss the MX quadtree in Section 1.4.2.1 and the PR quadtree in Section 1.4.2.2. We outline how they are created and updated as well as give a brief review of some of their applications. We omit a discussion of search operations because they are performed in the same manner as for a point quadtree (see Section 1.4.1.3).

### 1.4.2.1 MX Quadtree

There are several ways of adapting the region quadtree to represent point data. If the domain of the data points is discrete, and all attribute values are discrete and have the same type and range, then we can treat the data points as if they were black pixels in a region quadtree corresponding to a square image. An alternative characterization is to treat the data points as nonzero elements in a square matrix. We shall use this characterization in the subsequent discussion. In fact, we use the term *MX quadtree* to describe the structure on account of the analogy to the matrix (where *MX* denotes matrix), although the term *MX quadtree* would probably be more appropriate.

The MX quadtree is organized in a similar way to the region quadtree. The difference is that leaf nodes are black, corresponding to regions of size  $1 \times 1$ , or empty (i.e., white and represented by NIL), in which case there is no restriction on their size. The leaf nodes correspond to the presence or absence, respectively, of a data point in the

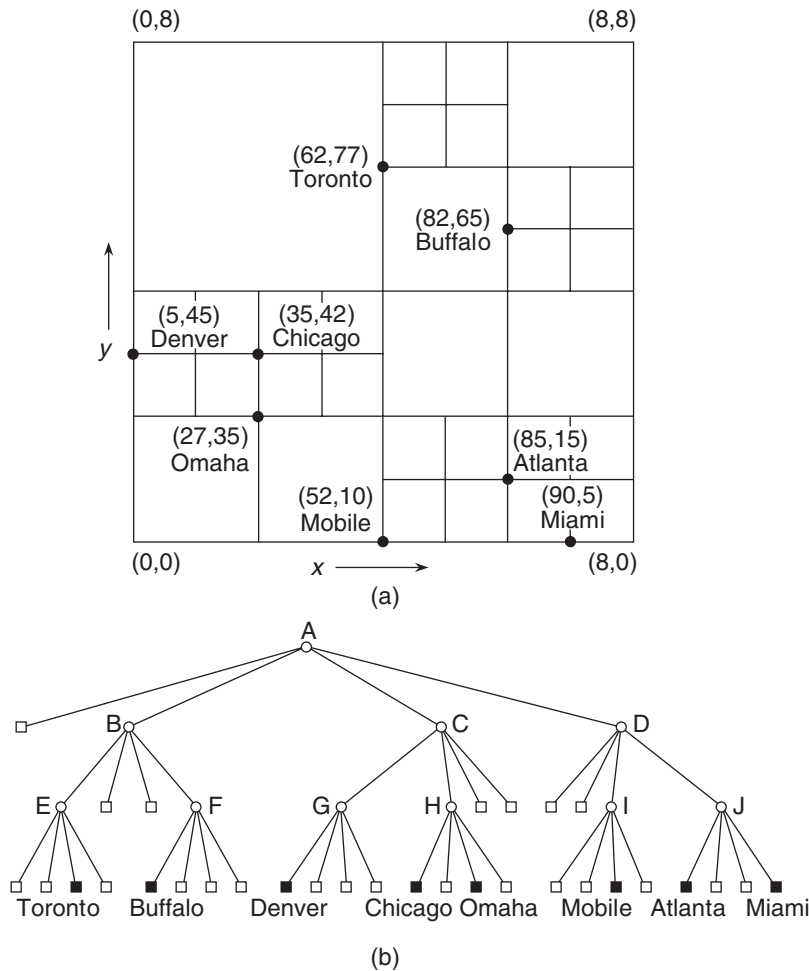

Figure 1.29  
An MX quadtree and the records it represents corresponding to the data of Figure 1.1:  
(a) the resulting partition of space and (b) the tree representation.

appropriate position in the matrix. For example, Figure 1.29 is the  $2^3 \times 2^3$  MX quadtree corresponding to the data of Figure 1.1. It is obtained by applying the mapping  $f$ , such that  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$ , to the  $x$  and  $y$  coordinate values, respectively. The result of the mapping is reflected in the coordinate values in the figure.

Each data point in an MX quadtree corresponds to a  $1 \times 1$  square. For ease of notation and operation using modulo and integer division operations, the data point is associated with the lower-left corner of the square. This adheres to the general convention followed throughout the text that the lower and left boundaries of each block are closed while the upper and right boundaries of each block are open. We also assume that the lower-left corner of the matrix is located at  $(0,0)$ . Note that, unlike the region quadtree, when a nonleaf node has four black children, they are not merged. This is natural since a merger of such nodes would lead to a loss of the identifying information about the data points, as each data point is different. On the other hand, the empty leaf nodes have the absence of information as their common property, so four white children of a nonleaf node can be safely merged.

Data points are inserted into an MX quadtree by searching for them. This search is based on the location of the data point in the matrix (e.g., the discretized values of its  $x$  and  $y$  coordinates in our city database example). It is achieved by recursively descending the

tree while comparing the location of the point with the implied coordinate values<sup>19</sup> of the root of the subtree being descended. The result of this comparison indicates which of the four subtrees is to be descended next. The search terminates when we have encountered a leaf node. If this leaf node is occupied by another record  $s$ , then  $s$  is replaced by a record corresponding to the data point being inserted (although the location is the same, some of the nonlocational attribute information may have changed). If the leaf node is NIL, then we may have to subdivide the space spanned by it repeatedly until it is a  $1 \times 1$  square. This will result in the creation of nonleaf nodes. This operation is termed *splitting*. For a  $2^n \times 2^n$  MX quadtree, splitting will have to be performed at most  $n$  times.

The shape of the resulting MX quadtree is independent of the order in which data points are inserted into it. However, the shapes of the intermediate trees do depend on the order. For example, Figure 1.30(a–d) shows how the tree was constructed in incremental fashion for Chicago, Mobile, Toronto, and Buffalo by giving the appropriate block decompositions.

Deletion of nodes from MX quadtrees is considerably simpler than for point quadtrees since all records are stored in the leaf nodes. This means that we do not have to be concerned with rearranging the tree as is necessary when a record stored in a nonleaf node is being deleted from a point quadtree. For example, to delete Omaha from the MX quadtree of Figure 1.29, we simply set the SW child of its father node, H, to NIL. Deleting Toronto is slightly more complicated. Setting the SW child of its father node, E, to NIL is not enough. We must also perform merging because all four children of E are NIL after deletion of Toronto. This leads to replacing the NW child of E's father, B, by NIL and returning nonleaf node E to the free storage list. This process is termed *collapsing* and is the counterpart of the splitting operation that was necessary when inserting a record into an MX quadtree.

Collapsing may take place over several levels. In essence, we apply the collapsing process repeatedly until we encounter a nearest common ancestor with an additional non-NIL child. As collapsing takes place, the affected nonleaf nodes are returned to the free storage list. For example, suppose that after deleting Toronto from Figure 1.29, we also delete Buffalo. The subsequent deletion of Buffalo means that nodes F and B are subjected to the collapsing process, with the result that the NE child of node A is set to NIL, and nonleaf nodes B and F are returned to the free storage list. The execution time of the deletion process is bounded by two times the depth of the quadtree. This upper bound is attained when the nearest common ancestor for the collapsing process is the root node.

Performing a range search in an MX quadtree is done in the same way as in the point quadtree. The worst-case cost of searching for all points that lie in a rectangle whose sides are parallel to the quadrant lines is  $O(F + 2^n)$ , where  $F$  is the number of points found and  $n$  is the maximum depth (see Exercise 5).

The MX quadtree is used in several applications. It can serve as the basis of a quadtree matrix manipulation system (see Exercises 6–10). The goal is to take advantage of the sparseness of matrices to achieve space and execution time efficiencies (e.g., [1, 647, 2007, 2010, 2011]). Algorithms for matrix transposition and matrix multiplication that take advantage of the recursive decomposition are easy to develop. Letellier [1150] makes use of the MX quadtree to represent silhouettes of hand motions to aid in the telephonic transmission of sign language for the hearing impaired. The region quadtree formulation of Hunter and Steiglitz [901, 905] (see Section 2.2.2.2 of Chapter 2) utilizes a three-color variant of the MX quadtree to represent digitized simple polygons. De Coulon and Johnsen [451] describe the use of the MX quadtree in the coding of black-and-white facsimiles for efficient transmission of images.

---

<sup>19</sup> The coordinate values are implied because they are not stored explicitly as they can be derived from knowledge of the width of the space spanned by the MX quadtree and the path from the root that has been descended. This is one of the properties of a trie.

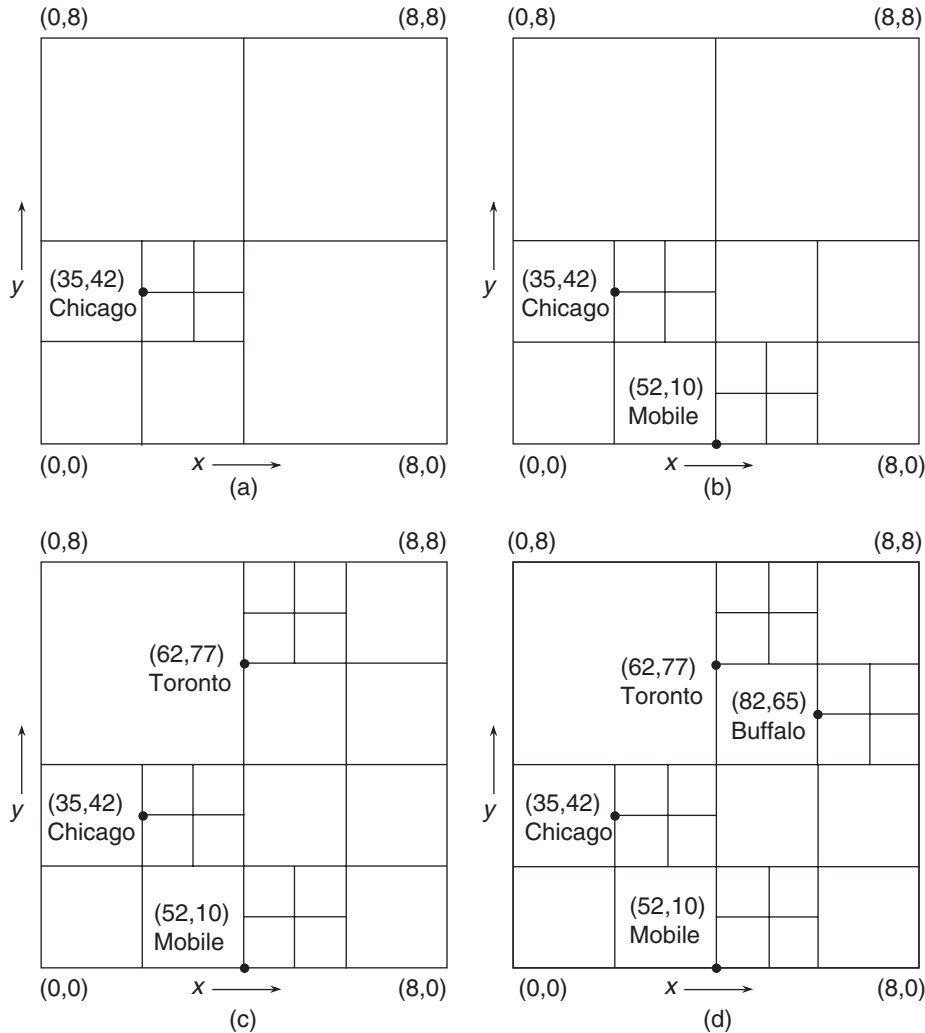

Figure 1.30 Sequence of partial block decompositions showing how an MX quadtree is built when adding (a) Chicago, (b) Mobile, (c) Toronto, and (d) Buffalo, corresponding to the data of Figure 1.1.

### Exercises

In the following exercises assume that each point in an MX quadtree is implemented as a record of type *node* containing five fields. The first four fields contain pointers to the node's four children, corresponding to the directions (i.e., quadrants) NW, NE, SW, and SE. If  $P$  is a pointer to a node, and  $I$  is a quadrant, then these fields are referenced as  $CHILD(P, I)$ . The fifth field,  $NODETYPE$ , indicates whether the node contains a data point (BLACK), is empty (WHITE), or is a nonleaf node (GRAY). There is no need to store information about the coordinate values of the data point since this is derivable from the path to the node from the root of the MX quadtree. The empty MX quadtree is represented by NIL.

1. Give an algorithm **MXCOMPARE** to determine the quadrant of a block of width  $2 \times w$  centered at  $(w, w)$  in which a point  $(x, y)$  lies.
2. Give an algorithm **MXINSERT** for inserting a point  $p$  into an MX quadtree rooted at node  $r$  that spans a space of width  $w$ . Make use of procedure **MXCOMPARE** from Exercise 1.
3. Give an algorithm **MXDELETE** for deleting data point  $(x, y)$  from an MX quadtree rooted at node  $r$  that spans a space of width  $w$ . Make use of procedure **MXCOMPARE** from Exercise 1.
4. Write an algorithm to perform a range search for a rectangular region in an MX quadtree.

5. Show that the worst-case cost of performing a range search in an MX quadtree is  $O(F + 2^n)$ , where  $F$  is the number of points found, and  $n$  is the maximum depth. Assume a rectangular query region.
6. Letting  $a_{ij}$  and  $b_{ij}$  denote the elements of row  $i$  and column  $j$  of matrices  $A$  and  $B$ , respectively, the transpose of matrix  $A$  is matrix  $B$  with  $b_{ij} = a_{ji}$ . Give an algorithm to transpose a matrix represented by an MX quadtree.
7. How many interchange operations are needed to transpose an MX quadtree representation of a  $2^n \times 2^n$  matrix so that it is not sparse (i.e., all blocks are of size 1)?
8. Compare the savings in space and time when a matrix is represented as an MX quadtree and as an array. Use the time required to perform a transpose operation as the basis of the comparison. You should assume the worst case, which occurs when there is no sparseness (i.e., all blocks are of size 1).
9. Give an algorithm for multiplying two matrices stored as MX quadtrees.
10. Unless there is a large number of square blocks of zeros, the MX quadtree is not a particularly attractive representation for matrix multiplication. The problem is that this is inherently a row and column operation. One possible alternative is to make use of a runlength representation (see Section 2.1.2.1 of Chapter 2, where it is termed a *runlength encoding* and is also known as a *runlength code*). This is a one-dimensional aggregation of consecutive, identically valued elements into blocks. The problem is that we would ideally like to have both the rows and columns encoded using this technique. Can you see a problem with using such a dual representation?

### 1.4.2.2 PR Quadtrees

The MX quadtree is feasible as long as the domain of the data points is discrete and finite. If this is not the case, then the data points cannot be represented using the MX quadtree because the minimum separation between the data points is unknown. This observation leads to an alternative adaptation of the region quadtree to point data, which associates data points (which need not be discrete) with quadrants. We call it a *PR quadtree* ( $P$  for point and  $R$  for region), although the term *PR quadtree* would probably be more appropriate.

The PR quadtree is organized in the same way as the region quadtree. The difference is that leaf nodes are either empty (i.e., white) or contain a data point (i.e., black) and its coordinate values. A leaf node's corresponding block contains at most one data point. For example, Figure 1.31 is the PR quadtree corresponding to the data of Figure 1.1. To cope

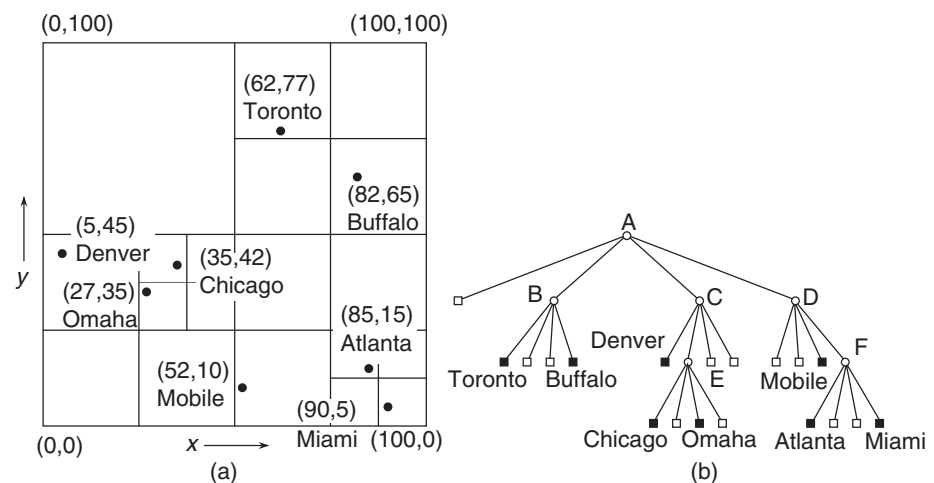

Figure 1.31  
A PR quadtree and the records it represents corresponding to the data of Figure 1.1: (a) the resulting partition of space and (b) the tree representation.

with data points that lie directly on one of the quadrant lines emanating from a subdivision point, we adopt the convention that the lower and left boundaries of each block are closed, while the upper and right boundaries of each block are open. For example, in Figure 1.31, a point located at  $(50,30)$  would lie in quadrant SE of the tree rooted at  $(50,50)$ .

A record  $r$  corresponding to data point  $(a,b)$  is inserted into a PR quadtree by searching for it. This is achieved by recursively descending the tree by comparing the location of the point with the location of the root of the subtree being descended. Note that the locations of the roots of the subtrees are not stored explicitly in the tree because they can be derived from knowledge of the space spanned by the PR quadtree and the path from the root that has been descended so far (this is one of the properties of a trie). If such a node  $t$  exists (i.e., containing  $(a,b)$ ), then  $r$  replaces the record associated with  $t$ .

Actually, we don't really search for  $r$ . Instead, we search for the block  $h$  in which  $r$  belongs (i.e., a leaf node). If  $h$  is already occupied by another record  $s$  with different  $x$  and  $y$  coordinate values, say  $(c,d)$ , then we must subdivide the block repeatedly (termed *splitting*) until records  $r$  and  $s$  no longer occupy the same block. This may cause a large number of subdivision operations, especially if the two points  $(a,b)$  and  $(c,d)$  are both contained in a very small quadtree block. A necessary, but insufficient, condition for this situation to arise is that the Euclidean distance between  $(a,b)$  and  $(c,d)$  is very small. As a result, we observe that every nonleaf node in a PR quadtree of a dataset consisting of more than one data point has at least two descendant leaf nodes that contain data points.

It should be clear that the shape of the resulting PR quadtree is independent of the order in which data points are inserted into it. However, the shapes of the intermediate trees do depend on the order. For example, the tree in Figure 1.31 was built for the sequence Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami. Figure 1.32(a–d) shows how the tree was constructed in an incremental fashion for Chicago, Mobile, Toronto, and Buffalo by giving the appropriate block decompositions.

Deletion of nodes in PR quadtrees is considerably simpler than for point quadtrees since all records are stored in the leaf nodes. This means that there is no need to be concerned with rearranging the tree as is necessary when records stored in nonleaf nodes are being deleted from point quadtrees. For example, to delete Mobile from the PR quadtree in Figure 1.31, we simply set the SW child of its father node, D, to NIL.

Continuing this example, deleting Toronto is slightly more complicated. Setting the NW child of its father node, B, to NIL is not enough since now we violate the property of the PR quadtree that each nonleaf node in a PR quadtree of more than one record has at least two descendant leaf nodes that contain data points. Thus, we must also reset the NE child of A to point to Buffalo and return nonleaf node B to the free storage list. This process is termed *collapsing* and is the counterpart of the splitting operation that was necessary when inserting a record in a PR quadtree.

At this point, it is appropriate to elaborate further on the collapsing process. Collapsing can take place only when the deleted node has exactly one brother that is a non-NIL leaf node and has no brothers that are nonleaf nodes. When this condition is satisfied, we can perform the collapsing process repeatedly until we encounter the nearest common ancestor that has more than one child. As collapsing occurs, the affected nonleaf nodes are returned to the free storage list.

As an example of collapsing, suppose that we delete Mobile and Atlanta in sequence from Figure 1.31. The subsequent deletion of Atlanta results in Miami's meeting the conditions for collapsing to take place. Miami's nearest ancestor with more than one child is A. The result of the collapsing of Miami is that Miami becomes the SE child of A. Moreover, nonleaf nodes D and F become superfluous and are returned to the free storage list. The execution time of the deletion process is bounded by two times the depth of the quadtree. This upper bound is achieved when the nearest ancestor for the collapsing process is the root node.

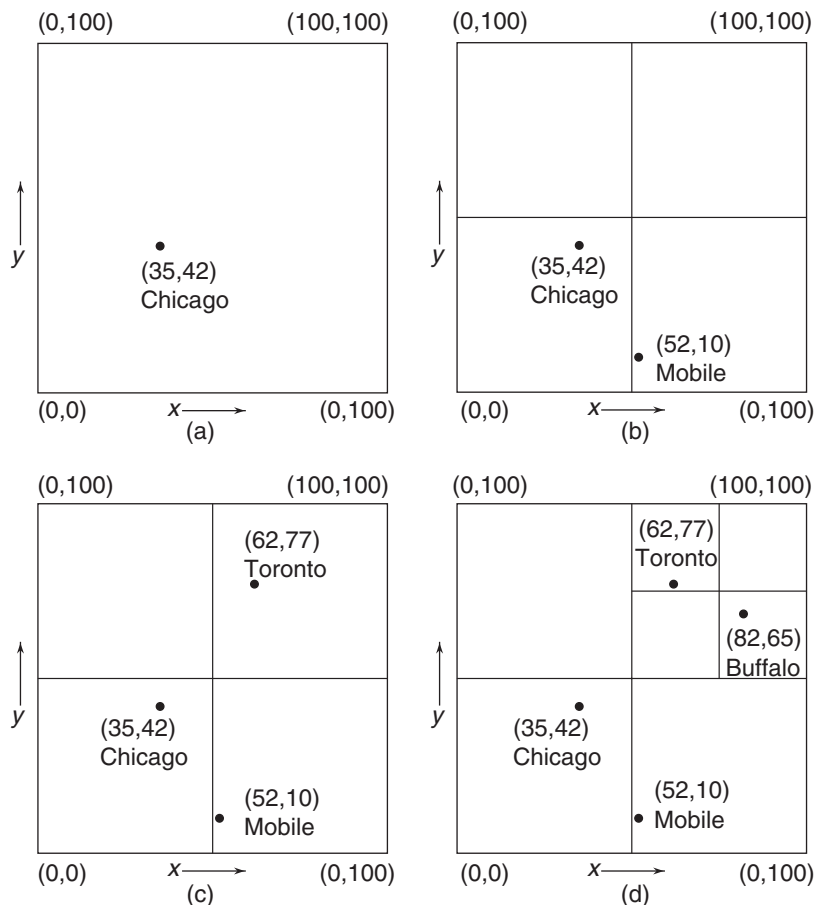

Figure 1.32 Sequence of partial block decompositions showing how a PR quadtree is built when adding (a) Chicago, (b) Mobile, (c) Toronto, and (d) Buffalo, corresponding to the data of Figure 1.1.

Analyzing the cost of insertion and deletion of nodes in a PR quadtree depends on the data points already in the tree. In particular, this cost is proportional to the maximum depth of the tree. For example, given a square region of side length  $s$ , such that the minimum Euclidean distance separating two points is  $d$ , the maximum depth of the quadtree can be as high as  $\lceil \log_2((s/d) \cdot \sqrt{2}) \rceil$ . Assuming that the data points are drawn from a grid of size  $2^n \times 2^n$ , for  $N$  data points the space requirements can be as high as  $O(N \cdot n)$ . This analysis is somewhat misleading because  $N$  and  $n$  do not necessarily grow in an independent manner. Often, the case is that the space requirements are proportional to  $N$  (see Exercises 5 and 6).

Performing a range search in a PR quadtree is done in basically the same way as in the MX and point quadtrees. The worst-case cost of searching for all points that lie in a rectangle whose sides are parallel to the quadrant lines is  $O(F + 2^n)$ , where  $F$  is the number of points found, and  $n$  is the maximum depth (see Exercise 8).

The PR quadtree is used in several applications. Anderson [49] makes use of a PR quadtree (termed a *uniform quadtree*) to store endpoints of line segments to be drawn by a plotter. The goal is to reduce pen plotting time by choosing the line segment to be output next whose endpoint is closest to the current pen position.

Rosenfeld, Samet, Shaffer, and Webber [1577] make use of the PR quadtree in a geographic information system as a means of representing point data in a consistent manner with region data that is represented using region quadtrees. In this way, queries can be made on different datasets that are partitioned at the same locations, assuming that

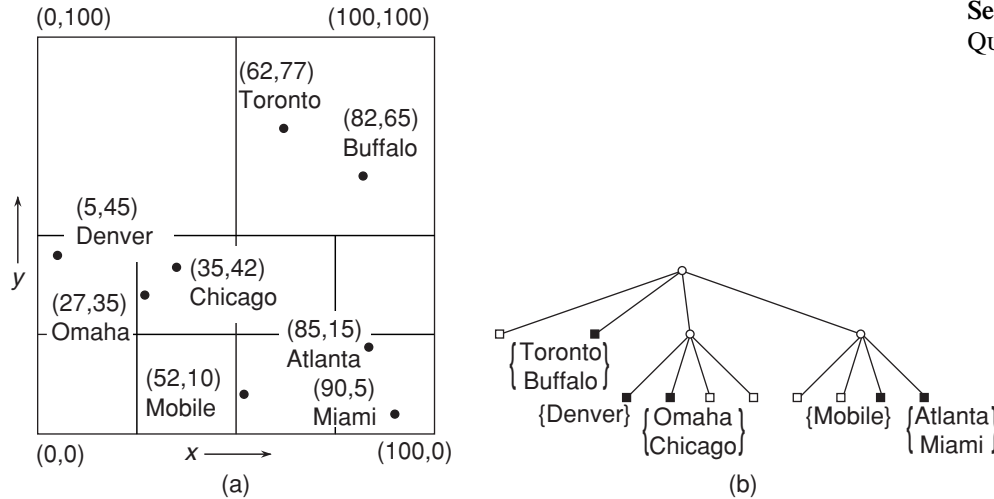

Figure 1.33  
A bucket PR quadtree and the records it represents corresponding to the data of Figure 1.1 for bucket size 2: (a) the resulting partition of space and (b) the tree representation.

the space spanned by the datasets is of the same size and relative to the same origin. This enables answering queries such as finding all cities in wheat-growing regions by simply overlaying the crop map (represented by a region quadtree) and the city map (represented by a PR quadtree, assuming that the cities are treated as points). The overlay operation is implemented by traversing the two trees in tandem and making descents only if two nonleaf nodes in the same position in the tree are encountered (for more details, see [1636, Chapter 6]).

When the data is not uniformly distributed (e.g., when it is clustered), then the PR quadtree may contain many empty nodes, which in this case will cause it to become unbalanced. The imbalance may be overcome by aggregating the blocks corresponding to the nodes into larger blocks termed *buckets*. This is achieved by varying the decomposition rule so that a block is split only if it contains more than  $b$  points, where  $b$  is termed the *bucket capacity* [1258]. We use the term *bucket PR quadtree* to describe this representation. It should be clear that increasing the number of points permitted in a block reduces the dependence of the maximum depth of the PR quadtree on the minimum Euclidean distance separation of two distinct points to that of two sets of  $b$  points. For example, Figure 1.33 is the bucket PR quadtree corresponding to the data of Figure 1.1 when the bucket capacity is 2.

Nelson and Samet [1361, 1362] analyze the distribution of nodes in a bucket PR quadtree in terms of their occupancies for various values of the bucket capacity.<sup>20</sup> They model a quadtree as a collection of populations in which each population represents the set of nodes in the quadtree that have a particular occupancy. Thus, the set of all empty nodes constitutes one population, the set of all nodes containing a single point constitutes another population, and so on. Note that the individual populations contain nodes of different sizes.

As points are added to the bucket PR quadtree, each population grows in a manner that depends on the other populations. For example, when the bucket capacity is  $c$ , the probability of producing a new node with occupancy  $i$  depends both on the fraction of nodes with occupancy  $i - 1$  and on the population of full nodes (occupancy  $c$ ), since nodes of any occupancy can be produced when a full node splits.

<sup>20</sup> The rest of the discussion in this section is somewhat technical and may be skipped.

The result of the analysis is the determination of a steady state where the proportions of the various populations are constant under addition of new points according to some data model (e.g., uniform distribution, Gaussian distribution). This steady state is taken as a representative distribution of populations from which expected values for structure parameters such as average node occupancies, are calculated.

The population model is an alternative to the use of a statistical analysis to define a “typical” structure. The statistical analyses are based on the computation, relative to some model of data distribution, of statistical sums over the space of possible data structure configurations. Statistical analyses for uniformly distributed data have been applied by Fagin, Nievergelt, Pippenger, and Strong to extendible hashing [579], Flajolet and Puech [621] to tries, Regnier to the grid file (see Section 1.7.2.1) [1550], and Tamminen to EXCELL (see Section 1.7.2.2) [1827].

The advantage of the population model is that dependencies between various populations and the steady state can be determined with relative ease. Moreover, the method is sufficiently flexible that it can be applied to other data structures in which the decomposition is determined adaptively by the local concentration of the data.

Nelson and Samet [1361, 1362] computed the average bucket occupancies for several different bucket capacities when points were generated under a uniform distribution. They found that the theoretical occupancy predictions were consistently slightly higher than the experimental values and that the size of the discrepancy had a cyclical structure. They use the terms *aging* and *phasing*, respectively, to describe these phenomena. They are explained briefly below.

The population model of bucket splitting assumes that the probability of a point falling into a node of type  $n_i$  (i.e., occupancy  $i$ ) is proportional to the fraction of the total type  $n_i$  nodes. This means that the average size of a node is independent of its occupancy. In actuality, we have the situation that nodes with a larger area are formed before the nodes with a smaller area—hence, the origin of the term *aging*. These larger nodes will tend to have a slightly higher average occupancy than the smaller nodes. Therefore, to maintain a steady-state situation, the fraction of high occupancy nodes must be less than predicted by the model, with the result that we have more lower-occupancy nodes, thereby yielding a smaller average bucket occupancy.

When nodes are drawn from a uniform distribution, the nodes in the quadtree will tend to split and fill in phase with a logarithmic period repeating every time the number of points increases by a factor of four. In particular, all nodes of the same size tend to fill up and split at the same time. This situation is termed *phasing*. It explains why the average bucket occupancy for a fixed bucket size oscillates with the number of data points. In contrast, when the distribution of points is nonuniform (e.g., Gaussian), then, initially, there is oscillatory behavior; however, it damps out as node populations in regions of different densities get out of phase.

Ang and Samet [53, 55] propose an analysis technique that they term *approximate splitting* to calculate the approximate values of the average node distribution, which enables them to obtain an approximation of the population frequency distribution. This method was demonstrated to account for the aging and phasing phenomena and resulted in a closer match between the predicted and actual average node occupancies.

### Exercises

In the following exercises assume that each point in a PR quadtree is implemented as a record of type *node* containing seven fields. The first four fields contain pointers to the node’s four children corresponding to the four quadrants. If  $P$  is a pointer to a node, and  $I$  is a quadrant, then these fields are referenced as  $\text{CHILD}(P, I)$ . The fifth field,  $\text{NODETYPE}$ , indicates whether the node contains a data point (BLACK), is empty (WHITE), or is a nonleaf node (GRAY).  $\text{XCOORD}$  and  $\text{YCOORD}$  contain the  $x$  and  $y$  coordinate values, respectively, of the data point. The empty PR quadtree is represented by NIL.

1. Give an algorithm **PRCOMPARE** to determine the quadrant of a block centered at  $(x, y)$  in which a point  $p$  lies.
2. Give an algorithm **PRINSERT** for inserting a point  $p$  in a PR quadtree rooted at node  $r$ , where  $r$  corresponds to an  $lx \times ly$  rectangle centered at  $(x, y)$ . Make use of procedure **PRCOMPARE** from Exercise 1.
3. Give an algorithm **PRDELETE** for deleting data point  $p$  from a PR quadtree rooted at node  $r$ , where  $r$  corresponds to an  $lx \times ly$  rectangle centered at  $(x, y)$ . Make use of procedure **PRCOMPARE** from Exercise 1.
4. Assume that the minimum Euclidean distance separating two points is  $d$ . Given a square region of side length  $s$ , show that  $\lceil \log_2((s/d) \cdot \sqrt{2}) \rceil$  is the maximum depth of the PR quadtree.
5. Suppose that you are given  $N$  data points drawn from a grid of size  $2^n \times 2^n$ . Construct an example PR quadtree that uses  $O(N \cdot n)$  space.
6. Under what situation does the PR quadtree use space proportional to  $N$ ?
7. Write an algorithm to perform a range search for a rectangular region in a PR quadtree.
8. Show that the worst-case cost of performing a range search in a PR quadtree is  $O(F + 2^n)$ , where  $F$  is the number of points found and  $n$  is the maximum depth. Assume a rectangular query region.

Exercises 9–16 are based on an analysis of PR quadtrees performed by Hunter [902].

9. Assume that you are given point data that is uniformly distributed in the unit square. What is the probability of a node at depth  $k$  containing a particular point?
10. Continuing the previous exercise, for a collection of  $v$  points, what is the probability that none of them lies in a given cell at depth  $k$ ?
11. What is the probability that exactly one of the  $v$  points lies in a given cell at depth  $k$ ?
12. What is the probability that a given cell at depth  $k$  contains two or more points (i.e., it corresponds to a parent node)?
13. Each node that contains two or more points must be a nonleaf node and hence will have four children. From the probability of the existence of a nonleaf node at depth  $k$ , derive the expected total number of nodes (i.e., leaf plus nonleaf nodes) at depth  $k + 1$ .
14. From the expected number of nodes at depth  $k + 1$ , derive the expected number of nodes in the entire PR quadtree, say  $E$ . Can you find a closed-form solution to it?
15. Calculate the ratio of  $E/v$ , the expected number of nodes per point. Does it converge?
16. Extend these results to data that is uniformly distributed in the  $m$ -dimensional unit hypercube.

### 1.4.3 Comparison of Point and Trie-Based Quadtrees

A comparison of point and trie-based quadtrees reduces, in part, to a comparison of their decomposition methods. In this discussion, we refer to the MX and PR quadtrees as trie-based quadtrees unless they differ in the context of the discussion. The trie-based quadtrees rely on regular decomposition (i.e., subdivision into four congruent rectangular regions). Data points are associated only with leaf nodes in trie-based quadtrees, whereas for point quadtrees, data points can also be stored at nonleaf nodes. This leads to a considerably simpler node deletion procedure for trie-based quadtrees. In particular, there is no need to be concerned about rearranging the tree, as is the case when nonleaf nodes are being deleted from a point quadtree.

A major difference between the two quadtree types is in the size of the rectangular regions associated with each data point. For the trie-based quadtrees, the space spanned by the quadtree is constrained to a maximum width and height. For the point quadtree, the space is rectangular and may, at times, be of infinite width and height. For the MX quadtree, this region must be a square with a particular size associated with it. This size is

fixed at the time the MX quadtree is defined and is the minimum permissible separation between two data points in the domain of the MX quadtree (equivalently, it is the maximum number of elements permitted in each row and column of the corresponding matrix). For the PR quadtree, this region is also rectangular, but its size depends on what other data points are currently represented by nodes in the quadtree.

In the case of the MX quadtree, there is a fixed discrete coordinate system associated with the space spanned by the quadtree, whereas no such limitation exists for the PR quadtree. The advantage of such a fixed coordinate system is that there is no need to store coordinate information with a data point's leaf node. The disadvantage is that the discreteness of the domain of the data points limits the granularity of the possible differentiation between data points.

The size and shape of a quadtree are important from the standpoint of the efficiency of both space requirements and search operations. The size and shape of the point quadtree is extremely sensitive to the order in which data points are inserted into it during the process of building it. Assuming that the root of the tree has a depth of 0, this means that for a point quadtree of  $N$  records, its maximum depth is  $N - 1$  (i.e., one record is stored at each level in the tree), and its minimum depth is  $\lceil \log_4((3 \cdot N + 1)/4) \rceil$  (i.e., each level in the tree is completely full).

In contrast, the shape and size of the trie-based quadtrees is independent of the insertion order. For the MX quadtree, all nodes corresponding to data points appear at the same depth in the quadtree. The depth of the MX quadtree depends on the size of the space spanned by the quadtree and the maximum number of elements permitted in each row and column of the corresponding matrix. For example, for a  $2^n \times 2^n$  matrix, all data points will appear as leaf nodes at a depth of  $n$ .

The size and shape of the PR quadtree depend on the data points currently in the quadtree. The minimum depth of a PR quadtree for  $N > 1$  data points is  $\lceil \log_4 N \rceil$  (i.e., all the data points are at the same depth), while there is no upper bound on the depth in terms of the number of data points. Recall from Section 1.4.2.2 that for a square region of side length  $s$ , such that the minimum Euclidean distance separating two points is  $d$ , the maximum depth of the PR quadtree can be as high as  $\lceil \log_2((s/d) \cdot \sqrt{2}) \rceil$ .

The volume of data also plays an important part in the comparison between the point and trie-based quadtrees. When the volume is very high, the MX quadtree loses some of its advantage since an array representation may be more economical in terms of space, as there is no need for links. Although the size of the PR quadtree was seen to be affected by the clustering of data points, especially when the number of data points is relatively small, this is not a factor in the size of a point quadtree. However, when the volume of data is large and uniformly distributed, the effect of clustering is lessened, and there should not be much difference in the space requirements between the point and PR quadtrees.

### Exercises

1. Use the uniform distribution over  $[0,1]$  to construct two-dimensional point quadtrees, MX quadtrees, and PR quadtrees, and compare them using the criteria set forth in this section. For example, compare their total path length, maximum depth, and so on.
2. Perform an average case analysis of the cost of a partial range query (a subset of the range query) for a point quadtree and a PR quadtree when the attributes are independent and uniformly distributed.

## 1.5 K-d Trees

As the dimensionality (i.e., number of attributes)  $d$  of the underlying space increases, each level of decomposition of the quadtree results in many new cells since the fanout value of the tree is high (i.e.,  $2^d$ ). This is alleviated by making use of variants of a  $k$ - $d$

*tree* [164], a term in which  $k$  originally denoted the dimensionality of the space being represented. However, in many applications, the convention is to let the value of  $d$  denote the dimension, and this is the practice we have chosen to follow here. In principle, the  $k$ - $d$  tree is a binary tree where the underlying space is partitioned on the basis of the value of just one attribute at each level of the tree instead of on the basis of the values of all  $d$  attributes, thereby making  $d$  tests at each level, as is the case for the quadtree. In other words, the distinction from the quadtree is that, in the  $k$ - $d$  tree, only one attribute (or key) value is tested when determining the direction in which a branch is to be made.

Restricting the number of attributes that are tested at each level of the tree has several advantages over the quadtree. First, we make just one test at each level instead of  $d$  tests. Second, each leaf node in the quadtree is rather costly in terms of the amount of space required due to a multitude of NIL links. In particular, the node size gets rather large for a  $d$ -dimensional tree since at least  $d + 2^d$  words (assuming that each pointer is stored in one word) are required for each node. Third, algorithms can be simplified because, at each recursive step, we have only two options since each node partitions the underlying space into only two parts. Finally, the same data structure (pointerwise) can be used to represent a node for all values of  $d$ , notwithstanding the partitioning axis values, which may need to be stored for some variants of the  $k$ - $d$  tree.

The disadvantage of replacing a test of  $d$  values by a sequence of  $d$  tests is that, in the case of a  $k$ - $d$  tree, decomposition in  $d$ -dimensional space has now become a sequential process as the order in which the various axes (i.e., attributes) are partitioned is important. In contrast, this ordering is of no consequence in the case of a quadtree because all  $d$  axes are partitioned simultaneously (i.e., in parallel). This lack of ordering has an advantage in a parallel environment: the key comparison operation can be performed in parallel for the  $d$  key values. Therefore, we can characterize the  $k$ - $d$  tree as a superior serial data structure and the quadtree as a superior parallel data structure. For a discussion of the use of quadtrees for representing points in a multiprocessor environment, see Linn [1182]; Bestul [210] discusses their use in a data-parallel environment (e.g., [217]); Wise (e.g., [2006, 2008, 2009]) discusses their use for representing matrices in a parallel processing environment. There has also been a considerable amount of work on the processing of quadtree representations of region data in a parallel environment (e.g., [213, 373, 470, 524, 532, 898, 916, 997, 1719]).

The idea of replacing a test of  $d$  attribute values by a sequence of  $d$  tests is applicable to both point quadtrees and trie-based quadtrees, although it is applied more often to point quadtrees. The use of the term *k-d tree* to refer to the data structure is somewhat confusing as this term is used uniformly to refer to the point quadtree adaptation, whereas a consistent use of our terminology would result in terming it a *point k-d tree*. In fact, we will use this term whenever we need to differentiate it from the trie-based adaptation. There is no consistent terminology for the trie-based variant, although *k-d trie* would probably be the most appropriate. The region quadtree counterpart of the  $k$ - $d$  tree is termed a *bintree* [1828].

In the rest of this section, we discuss several different variations of the  $k$ - $d$  tree with a particular emphasis on the point  $k$ - $d$  tree (i.e., the one that organizes the data to be stored rather than the embedding space from which the data is drawn). Section 1.5.1 discusses the point  $k$ - $d$  tree, and Section 1.5.2 presents several variants of the trie-based  $k$ - $d$  tree. There has also been an attempt to develop a hybrid splitting strategy [824] that combines the point  $k$ - $d$  tree and the trie-based  $k$ - $d$  tree to deal with situations where one approach is preferable to another in terms of worst-case tree depth, and so on. We do not discuss this approach further here. On another front, although it is beyond the scope of our discussion, we mention that lately there has been some interest in issues arising from the implementation of  $k$ - $d$  trees in a peer-to-peer (P2P) setting (e.g., [676]).

## 1.5.1 Point K-d Trees

There are many variations of the point k-d tree. Their exact structure depends on the manner in which they deal with the following issues:

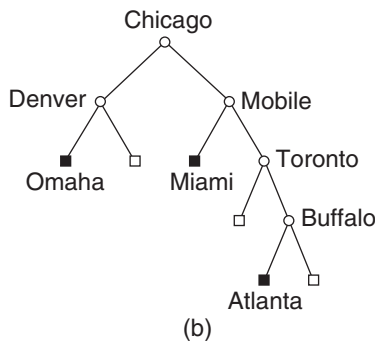

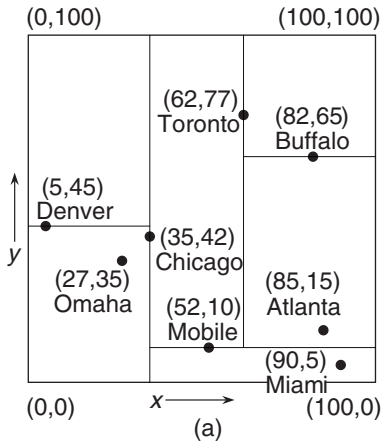

Figure 1.34

A k-d tree ( $d=2$ ) and the records it represents corresponding to the data of Figure 1.1: (a) the resulting partition of space and (b) the tree representation.

1. Is the underlying space partitioned at a position that overlaps a data point, or may the position of the partition be chosen at random? Recall that trie-based methods restrict the positions of the partitions points, thereby rendering moot the question of whether the partition actually takes place at a data point.
2. Is there a choice as to the identity of the partition axis (i.e., the attribute or key being tested)? If we adopt a strict analogy to the quadtree, then we have little flexibility in the choice of the partition axis in the sense that we must cycle through the  $d$  different dimensions every  $d$  levels in the tree, although the relative order in which the different axes are partitioned may differ from level to level and among subtrees.

The most common variant of the k-d tree (and the one we focus on in this section) partitions the underlying space at the data points and cycles through the different axes in a predefined and constant order. When we can apply the partitions to the underlying space in an arbitrary order rather than having to cycle through the axes, then we preface the name of the data structure with the qualifier *generalized*. For example, a generalized k-d tree also partitions the underlying space at the data points; however, it need not cycle through the axes. In fact, it need not even partition all of the axes (e.g., only partition along the axes that are used in queries [172]). In our discussion, we assume two-dimensional data, and we test  $x$  coordinate values at the root and at even depths (given that the root is at depth 0) and  $y$  coordinate values at odd depths.

We adopt the convention that when node  $P$  is an  $x$ -discriminator, then all nodes having an  $x$  coordinate value less than that of  $P$  are in the left child of  $P$  and all those with  $x$  coordinate values greater than or equal to that of  $P$  are in the right child of  $P$ . A similar convention holds for a node that is a  $y$ -discriminator. Figure 1.34 illustrates the k-d tree corresponding to the same eight nodes as in Figure 1.1.

In the definition of a discriminator, the problem of equality of particular key values is resolved by stipulating that records that have the same value for a particular key are in the right subtree. As an alternative, Bentley [164] defines a node in terms of a *superkey*. Given a node  $P$ , let  $K_0(P)$ ,  $K_1(P)$ , and so on, refer to its  $d$  keys. Assuming that  $P$  is a  $j$ -discriminator, then for any node  $Q$  in the left child of  $P$ ,  $K_j(Q) < K_j(P)$ ; and likewise, for any node  $R$  in the right child of  $P$ ,  $K_j(R) > K_j(P)$ . In the case of equality, a superkey,  $S_j(P)$ , is defined by forming a cyclical concatenation of all keys starting with  $K_j(P)$ . In other words,  $S_j(P) = K_j(P) K_{j+1}(P) \dots K_{d-1}(P) K_0(P) \dots K_{j-1}(P)$ . Now, when comparing two nodes,  $P$  and  $Q$ , we turn to the left when  $S_j(Q) < S_j(P)$  and to the right when  $S_j(Q) > S_j(P)$ . If  $S_j(Q) = S_j(P)$ , then all  $d$  keys are equal, and a special value is returned to so indicate. The algorithms that we present below do not make use of a superkey.

The rest of this section is organized as follows. Section 1.5.1.1 shows how to insert a point into a k-d tree. Section 1.5.1.2 discusses how to delete a point from a k-d tree. Section 1.5.1.3 explains how to do region searching in a k-d tree. Section 1.5.1.4 discusses some variants of the k-d tree that provide more flexibility as to the positioning and choice of the partitioning axes.

## 1.5.1.1 Insertion

Inserting record  $r$  with key values  $(a, b)$  into a k-d tree is very simple. The process is essentially the same as that for a binary search tree. First, if the tree is empty, then allocate a new node containing  $r$ , and return a tree with  $r$  as its only node. Otherwise, search the tree for a node  $h$  with a record having key values  $(a, b)$ . If  $h$  exists, then  $r$  replaces the record associated with  $h$ . Otherwise, we are at a NIL node that is a child of type  $s$  (i.e., 'LEFT' or 'RIGHT', as appropriate) of node  $c$ . This is where we make the insertion by

Figure 1.35 Sequence of partial k-d tree space partitions demonstrating the addition of (a) Chicago and Mobile, (b) Toronto, (c) Buffalo, and (d) Denver and Omaha, corresponding to the data of Figure 1.1.

allocating a new node  $t$  containing  $r$  and make  $t$  an  $s$  child of node  $c$ . The only difference from the binary search tree is that we compare  $x$  coordinate values at the root and at even depths of the tree and  $y$  coordinate values at odd depths of the tree. Bentley [164] shows that given  $N$  points, the average cost of inserting, as well as searching for (i.e., an exact match query), a node is  $O(\log_2 N)$ .

As in the case of point quadtrees, the shape of the resulting k-d tree depends on the order in which the nodes are inserted into it. Figure 1.34 is the k-d tree for the sequence Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami. Figure 1.35(a–d) shows how the tree was constructed in an incremental fashion for these cities by giving the appropriate space partitions. In particular, Figure 1.35(a) corresponds to the space partition after insertion of Chicago and Mobile, Figure 1.35(b) to the space partition after insertion of Toronto, Figure 1.35(c) to the space partition after insertion of Buffalo, and Figure 1.35(d) to the space partition after insertion of Denver and Omaha.

It should be clear that in the insertion process described here, each node partitions the portion of the plane in which it resides into two parts. Thus, in Figure 1.34, Chicago divides the plane into all nodes whose  $x$  coordinate value is less than 35 and all nodes whose  $x$  coordinate value is greater than or equal to 35. In the same figure, Denver divides the set of all nodes whose  $x$  coordinate value is less than 35 into those whose  $y$  coordinate value is less than 45 and those whose  $y$  coordinate value is greater than or equal to 45.

As in the case of the point quadtree, the amount of work expended in building a k-d tree is equal to the total path length (TPL) of the tree as it reflects the cost of searching for all of the elements. Bentley [164] shows that the TPL of a k-d tree built by inserting  $N$  points in random order into an initially empty tree is  $O(N \cdot \log_2 N)$  and thus the average cost of inserting a node is  $O(\log_2 N)$ . The extreme cases are worse since the shape of the k-d tree depends on the order in which the nodes are inserted into it, thereby affecting the TPL.

### Exercises

Assume that each point in the k-d tree is implemented as a record of type *node* containing three plus  $d$  fields. The first two fields, LEFT and RIGHT contain pointers to the node's two children, corresponding to the directions 'LEFT' and 'RIGHT', respectively. If  $P$  is a pointer to a node, and  $I$  is a direction, then these fields are referenced as CHILD( $P, I$ ). At times, these two fields are also referred to as LOCHILD( $P$ ) and HICCHILD( $P$ ), corresponding to the left and right children, respectively. We can determine the side of the tree in which a node, say  $P$ , lies relative to its father by use of the function CHILDTYPE( $P$ ), which has a value of  $I$  if CHILD(FATHER( $P$ ),  $I$ ) =  $P$ . COORD is a one-dimensional array containing the values of the  $d$  coordinates of the data point. If  $P$  is a pointer to a node, and  $I$  is a coordinate name, then these fields are referenced as COORD( $P, I$ ). The DISC field indicates the name of the coordinate on whose value the node discriminates (i.e., tests). The DISC field is not always necessary as, for example, when the relative order in which the different axes (i.e., coordinates) are partitioned is constant. In this case, it is easy to keep track of the discriminator type of the node being visited as the tree is descended. The empty k-d tree is represented by NIL.

1. Give an algorithm KDCOMPARE to determine the child of a k-d tree rooted at  $r$  in which point  $p$  lies.
2. Give an algorithm KDINSERT to insert a point  $p$  in a k-d tree rooted at node  $r$ . Make use of procedure KDCOMPARE from Exercise 1. There is no need to make use of the CHILDTYPE function.
3. Modify procedures KDCOMPARE and KDINSERT to handle a k-d tree node implementation that makes use of a superkey in its discriminator field.
4. Prove that the TPL of a k-d tree of  $N$  nodes built by inserting the  $N$  points in a random order is  $O(N \cdot \log_2 N)$ .
5. Give the k-d tree analogs of the single and double rotation operators for use in balancing a binary search tree [1046, p. 461]. Make sure that you handle equal key values correctly.

Figure 1.36  
(a) Example of a two-dimensional k-d tree whose (b) right child is not a k-d tree.

Figure 1.37  
(a) Example of a binary search tree and (b) the result of deleting its root.

### 1.5.1.2 Deletion

Deletion of nodes from k-d trees is considerably more complex than it is for binary search trees. Observe that, unlike the binary search tree, not every subtree of a k-d tree is itself a k-d tree. For example, although Figure 1.36(a) is a k-d tree, its right subtree (see Figure 1.36(b)) is not a k-d tree. This is because the root node in a two-dimensional k-d tree discriminates on the value of the  $x$  coordinate, while both children of the root node in Figure 1.36(b) have  $x$  coordinate values that are larger than that of the root node. Thus, we see that special care must be taken when deleting a node from a k-d tree.

In contrast, when deleting a node from a binary search tree, we simply move a node and a subtree. For example, deleting node 3 from Figure 1.37(a) results in replacing node 3 with node 4 and replacing the left subtree of 8 by the right subtree of 4 (see Figure 1.37(b)). However, this cannot be done, in general, in a k-d tree as the nodes with values 5 and 6 might not have the same relative relationship at their new depths.

Deletion in a k-d tree can be achieved by the following recursive process. We use the k-d tree in Figure 1.38 to illustrate our discussion, and thus all references to nodes can be visualized by referring to the figure. Let us assume that we wish to delete the node (a,b) from the k-d tree. If both subtrees of (a,b) are empty, then replace (a,b) with the empty

tree. Otherwise, find a suitable replacement node in one of the subtrees of  $(a,b)$ , say  $(c,d)$ , and recursively delete  $(c,d)$  from the k-d tree. Once  $(c,d)$  has been deleted, replace  $(a,b)$  with  $(c,d)$ .

At this point, it is appropriate to comment on what constitutes a “suitable” replacement node. Recall that an  $x$ -discriminator is a node that appears at an even depth, and hence partitions its space based on the value of its  $x$  coordinate. A  $y$ -discriminator is defined analogously for nodes at odd depths. Assume that  $(a,b)$  is an  $x$ -discriminator. We know that every node in  $(a,b)$ 's right subtree has an  $x$  coordinate with a value greater than or equal to  $a$ . The node that will replace  $(a,b)$  must bear the same relationship to the subtrees of  $(a,b)$ . Using the analogy with binary search trees, it would seem that we would have a choice with respect to the replacement node. It must either be the node in the left subtree of  $(a,b)$  with the largest  $x$  coordinate value or the node in the right subtree of  $(a,b)$  with the smallest  $x$  coordinate value.

Actually, we do not really have a choice as the following comments will make clear. If we use the node in the left subtree of  $(a,b)$  with the maximum  $x$  coordinate value, say  $(c,d)$ , and if there exists another node in the same subtree with the same  $x$  coordinate value, say  $(c,h)$ , then when  $(c,d)$  replaces node  $(a,b)$ , there will be a node in the left subtree of  $(c,d)$  that does not belong there by virtue of having an  $x$  coordinate value of  $c$ . Thus, we see that, given our definition of a k-d tree, the replacement node must be chosen from the right subtree. Otherwise, a duplicate  $x$  coordinate value will disrupt the proper interaction between each node and its subtrees. Note that the replacement node need not be a leaf node.

The only remaining question is how to handle the case when the right subtree of  $(a,b)$  is empty. We use the k-d tree in Figure 1.39 to illustrate our discussion, and thus all references to nodes can be visualized by referring to the figure. This is resolved by the following recursive process. Find the node in the left subtree of  $(a,b)$  that has the smallest value for its  $x$  coordinate, say  $(c,d)$ . Exchange the left and right subtrees of  $(a,b)$ , replace the coordinate values of  $(a,b)$  with  $(c,d)$ , and recursively apply the deletion procedure to node  $(c,d)$  from its prior position in the tree (i.e., in the previous left subtree of  $(a,b)$ ).

With the aid of Figures 1.38 and 1.39, we have shown that the problem of deleting a node  $(a,b)$  from a k-d tree is reduced to that of finding the node with the smallest  $x$  coordinate value in a subtree of  $(a,b)$ . Unfortunately, locating the node with the minimum  $x$  coordinate value is considerably more complex than the analogous problem for a binary search tree. In particular, although the node with the minimum  $x$  coordinate value must be in the left subtree of an  $x$ -discriminator, it could be in either subtree of a  $y$ -discriminator. Thus, search is involved, and care must be taken in coordinating this search so that when the deleted node is an  $x$ -discriminator at depth 0, only one of the two subtrees rooted at each odd depth is searched. This is done using procedure `FINDDMINIMUM` (see Exercise 1).

As can be seen from the discussion, deleting a node from a k-d tree can be costly. We can obtain an upper bound on the cost in the following manner. Clearly, the cost of deleting the root of a subtree is bounded from above by the number of nodes in the subtree. Letting  $TPL(T)$  denote the total path length of tree  $T$ , it can be shown that the sum of the subtree sizes of a tree is  $TPL(T) + N$  (see Exercise 5 in Section 1.4.1.2).

Bentley [164] proves that the TPL of a k-d tree built by inserting  $N$  points in a random order is  $O(N \cdot \log_2 N)$ , which means that the average cost of deleting a randomly selected node from a randomly built k-d tree has an upper bound of  $O(\log_2 N)$ . This relatively low value for the upper bound reflects the fact that most of the nodes in the k-d tree are leaf nodes. The cost of deleting root nodes is considerably higher. Clearly, it is bounded by  $N$ . Its cost is dominated by the cost of the process of finding a minimum element in a subtree, which is  $O(N^{1-1/d})$  (see Exercise 6), since on every  $d$ th level (starting at the root), only one of the two subtrees needs to be searched.

## Section 1.5 K-D TREES

Figure 1.38  
Example of a k-d tree illustrating why the replacement node should be chosen from the right subtree of the tree containing the deleted node.

Figure 1.39  
(a) Example k-d tree and (b) the result of deleting  $(a,b)$  from it.

As an example of the deletion process, consider the k-d tree in Figure 1.40(a, b). We wish to delete the root node A at (20,20). Assume that A is an  $x$ -discriminator. The node in the right subtree of A with a minimum value for its  $x$  coordinate is C at (25,50). Thus, C replaces A (see Figure 1.40(c)), and we recursively apply the deletion procedure to C's position in the tree. Since C's position was a  $y$ -discriminator, we seek the node with a minimum  $y$  coordinate value in the right subtree of C. However, C's right subtree was empty, which means that we must replace C with the node in its left subtree that has the minimum  $y$  coordinate value.

D at (35,25) is the node in the left subtree that satisfies this minimum value condition. It is moved up in the tree (see Figure 1.40(d)). Since D was an  $x$ -discriminator, we replace it by the node in its right subtree having a minimum  $x$  coordinate value. H at (45,35) satisfies this condition, and it is moved up in the tree (see Figure 1.40(e)). Again, H is an  $x$ -discriminator, and we replace it by I, the node in its right subtree with a minimum  $x$  coordinate value. Since I is a leaf node, our procedure terminates. Figure 1.40(f, g) shows the result of the deletion process.

In the above discussion, we had to make a special provision to account for our definition of a k-d tree node as a partition of space into two parts, one less than the key value tested by the node and one greater than or equal to the key value tested by the node. Defining a node in terms of a superkey alleviates this problem since we no longer always have to choose the replacing node from the right subtree. Instead, we now

Figure 1.40 Example illustrating deletion in k-d trees where “?” indicates the node being deleted: (a) the original k-d tree, (b–f) successive steps in deleting node A, (g) the final k-d tree.

have a choice. The best algorithm is one that flip-flops between the left and right children, perhaps through the use of a random-number generator (see Exercise 5). Of course, node insertion and search are slightly more complex since it is possible that more than one key will have to be compared at each level in the tree (see Exercise 3 in Section 1.5.1.1 and Exercise 3 in Section 1.5.1.3).

### Exercises

1. Given a node  $P$  in a k-d tree that discriminates on key  $D$ , write an algorithm, `FINDDMINIMUM`, to compute the  $D$ -minimum node in its left subtree. Repeat for the right subtree of  $P$ . Generalize your algorithm to work for either of the two subtrees.
2. Assuming the same k-d tree node implementation as in the exercises in Section 1.5.1.1, give an algorithm `KDDELETE` for deleting a point  $p$  from a k-d tree rooted at node  $r$ . The node does not have a `FATHER` field, although you may make use of the `CHILDTYPE` function. Make use of procedures `KDCOMPARE` and `FINDDMINIMUM` from Exercise 1 in Section 1.5.1.1 and Exercise 1 above, respectively.
3. Modify procedure `KDDELETE` in the solution to Exercise 2 to make use of a variant of `FINDDMINIMUM` that, in addition to returning the  $D$ -minimum node  $t$ , also returns  $t$ 's `CHILDTYPE` values relative to its father  $f$ , as well as  $f$ .
4. Suppose that a k-d tree node is implemented as a record with a `FATHER` field containing a pointer to its father. Modify procedure `KDDELETE` in the solution to Exercise 2 to take advantage of this additional field.
5. Modify procedure `KDDELETE` in the solution to Exercise 2 to handle a k-d tree node implementation that makes use of a superkey in its discriminator field.
6. Prove that the cost of finding a  $D$ -minimum element in a k-d tree is  $O(N^{1-1/d})$ .

### 1.5.1.3 Search

Like quadtrees, k-d trees are useful in applications involving search. Again, we consider a typical query that seeks all nodes within a specified distance of a given point. The k-d tree data structure serves as a pruning device on the amount of search that is required; that is, many nodes need not be examined. To see how the pruning is achieved, suppose we are performing a region search of distance  $r$  around a node with coordinate values  $(a, b)$ . In essence, we want to determine all nodes  $(x, y)$  whose Euclidean distance from  $(a, b)$  is less than or equal to  $r$ —that is,  $r^2 \geq (a - x)^2 + (b - y)^2$ .

Clearly, this is a circular region. The minimum  $x$  and  $y$  coordinate values of a node in this circle cannot be less than  $a - r$  and  $b - r$ , respectively. Similarly, the maximum  $x$  and  $y$  coordinate values of a node in this circle cannot be greater than  $a + r$  and  $b + r$ , respectively. Thus, if the search reaches a node with coordinate values  $(e, f)$ , and `KDCOMPARE` $((a - r, b - r), (e, f)) = \text{'RIGHT'}$ , then there is no need to examine any nodes in the left subtree of  $(e, f)$ . Similarly, the right subtree of  $(e, f)$  need not be searched when `KDCOMPARE` $((a + r, b + r), (e, f)) = \text{'LEFT'}$ .

For example, suppose that we want to use the k-d tree in Figure 1.34 of the hypothetical database of Figure 1.1 to find all cities within three units of a point with coordinate values  $(88, 6)$ . In such a case, there is no need to search the left subtree of the root (i.e., Chicago with coordinate values  $(35, 42)$ ). Thus, we need examine only the right subtree of the tree rooted at Chicago. Similarly, there is no need to search the right subtree of the tree rooted at Mobile (i.e., coordinate values  $(52, 10)$ ). Continuing our search, we find that only Miami, at coordinate values  $(90, 5)$ , satisfies our request. Thus, we need examine only three nodes during our search.

Similar techniques are applied when the search region is rectangular, making the query meaningful for both locational and nonlocational data. In general, the search cost depends on the type of query. Given  $N$  points, Lee and Wong [1132] have shown that, in the worst case, the cost of a range search of a complete k-d tree is  $O(d \cdot N^{1-1/d} + F)$ ,

Figure 1.41  
Example space partition for a  $k$ - $d$  tree that illustrates the worst-case behavior for the  $k$ - $d$  tree search procedure.

where  $F$  is the number of points found in the range. To see how this bound is obtained, we assume that  $d = 2$  and, without loss of generality, consider a rectangular search region (see Exercise 1), marked as hatched in Figure 1.41. Although not explicitly shown in the figure, nodes  $G$ ,  $H$ ,  $R$ , and  $V$  are roots of subtrees that may also be in the shaded region. Similarly, nodes  $E$ ,  $I$ ,  $S$ , and  $W$  are also roots of subtrees that may also contain just one node, in which case they are leaf nodes. We use the number of nodes visited while searching the tree as a measure of the amount of work that needs to be expended.

Since we are interested in the worst case, we assume that  $B$  and  $C$  (see Figure 1.41) partition the tree rooted at  $A$  in such a way that the search region is overlapped by the regions rooted at  $B$  and  $C$ . If  $B$  is within the search region, then the subtree rooted at  $D$  need not be searched further. If  $B$  is outside of the search region (as is the case here), then  $E$  and its subtrees (if any) need not be searched further. Similarly, if  $F$  is within the search region, then  $H$  and its subtrees (if any) need not be searched further. Finally, when  $F$  is outside of the search region (as is the case here), then  $I$  and its subtrees (if any) need not be searched further.  $G$  is chosen in such a way that both of its subtrees will have to be searched. Further partitioning of  $G$  is analogous to a recursive invocation of this analysis two levels deeper in the tree than the starting level (see the cross-hatched region in Figure 1.41).

The analysis of the remaining subtrees of  $B$  and  $F$  (i.e., rooted at  $D$  and  $H$ ) are equivalent to each other and enable the elimination of two subtrees from further consideration at every other level. For example, the children of the subtrees rooted at  $D$  are  $P$  and  $Q$ , with children rooted at  $R$  and  $S$ , and  $V$  and  $W$ , respectively. The subtrees (if any) rooted at  $S$  and  $W$  need no further processing.

We are now ready to analyze the worst case of the number of nodes that will be visited in performing a range search in a two-dimensional  $k$ - $d$  tree. Let  $t_i$  denote the number of nodes visited when dealing with a  $k$ - $d$  tree rooted at level  $i$  (where the deepest node in the tree is at level 0). Let  $u_j$  denote that number of nodes that are visited when dealing with a subtree of the form illustrated by the subtrees rooted at nodes  $D$  and  $H$  in Figure 1.41. This leads to the following recurrence relations:

$$\begin{aligned} t_i &= 1 + 1 + 1 + t_{i-2} + u_{i-2} + 1 + u_{i-3} \\ u_j &= 1 + 1 + 1 + 2 \cdot u_{j-2} \\ &\text{with initial conditions } t_0 = u_0 = 0 \text{ and } t_1 = u_1 = 1. \end{aligned}$$

$t_i$  and  $u_j$  can best be understood by referring to Figure 1.42, which is a treelike representation of the  $k$ - $d$  tree of Figure 1.41. The terms in  $t_i$  correspond to nodes or subtrees rooted at  $A$ ,  $B$ ,  $C$ ,  $G$ ,  $D$ ,  $F$ , and  $H$ , in order, while the terms in  $u_j$  correspond to nodes or subtrees rooted at  $D$ ,  $P$ ,  $Q$ ,  $R$ , and  $V$ , in order. The square nodes in Figure 1.42 (e.g.,  $E$ ,  $I$ ,  $S$ , and  $W$ ) correspond to leaf nodes or roots of subtrees that have been pruned; they do not have to be searched.

When these relations are solved, we find that, under the assumption of a complete binary tree (i.e.,  $N = 2^n - 1$ ),  $t_n$  is  $O(2 \cdot N^{1/2})$ . Note that, unlike the point quadtree, a complete binary  $k$ - $d$  tree can always be constructed (see the optimized  $k$ - $d$  tree of Bentley [164] discussed in Section 1.5.1.1). In general, for arbitrary  $d$ ,  $t_n$  is  $O(d \cdot N^{1-1/d})$ , and thus the worst-case cost of a range search for arbitrary  $d$  is  $O(d \cdot N^{1-1/d} + F)$ , where  $F$  is the number of points found in the range. The expected case is much better though and has been shown to be  $O(\log_2 N + F)$  using a balanced variant of a  $k$ - $d$  tree [181, 1767].

Partial range queries can be handled in the same way as range searching. Lee and Wong [1132] show that when ranges for  $s$  out of  $d$  keys are specified, the algorithm has a worst-case running time of  $O(s \cdot N^{1-1/d} + F)$ , where  $F$  is the number of points found in the partial range. For an alternative result, see Exercise 6.

As is the case for the point quadtree, the  $k$ - $d$  tree can be used to handle all three types of queries specified by Knuth [1046]. The range query is described above, while

Figure 1.42  
Tree representation of the space partition in Figure 1.41.

simple queries are a byproduct of the k-d tree insertion process. Boolean queries are straightforward. Range queries can be facilitated by use of a bounds array  $B[i]$  of  $2 \cdot d$  elements stored at each node. It contains the range of values for all of the coordinates of the points stored in the k-d tree rooted at the node.

### Exercises

1. Why was the search region in Figure 1.41 chosen to lie in the lower-left corner of the space instead of somewhere in the middle?
2. Write a procedure `KDREGIONSEARCH` to determine all the nodes in a given k-d tree that intersect a given rectangular region in  $d$ -dimensional space. Use a bounds array to facilitate your task. `KDREGIONSEARCH` should make use of a pair of auxiliary functions: one to determine if a subtree can be pruned, and the other to determine if a node is indeed in the search region.
3. Modify procedure `KDREGIONSEARCH` of Exercise 2 to handle a k-d tree node implementation that makes use of a superkey in its discriminator field.
4. Solve the recurrence relations for  $t_i$  and  $u_j$  used to analyze range searching in a k-d tree.
5. A partial range query is closely related to the range query. In this case, values are specified for  $s$  ( $s < d$ ) of the keys, and a search is made for all records having such values for the specified keys. Show how you would use procedure `KDREGIONSEARCH` of Exercise 2 to respond to a partial range query.
6. Given a complete k-d tree of  $N$  nodes, where  $N = 2^{d \cdot h} - 1$ , and all leaf nodes appear at depth  $d \cdot h - 1$ , prove Bentley's [164] result that, in the worst case,  $O(N^{(d-s)/d})$  nodes are visited in performing a partial range query with  $s$  out of  $d$  keys specified.
7. In Exercise 2 in Section 1.4.1.3, a *perfect point quadtree* was defined and used to analyze the expected number of nodes visited in performing a region query for a two-dimensional point quadtree. Define a *perfect k-d tree* in an analogous manner, and repeat this analysis.
8. Perform an average case analysis for region queries and partial range queries in a k-d tree.

#### 1.5.1.4 Point K-d Tree Variants

Our formulation of the k-d tree and its ancestral predecessors (i.e., the fixed-grid and the point quadtree) has the property that all partition lines at a given level of subdivision are parallel to the coordinate axes. When more than one axis is partitioned at a given level in the tree, then all partition lines at a given level of subdivision are orthogonal.

If there is just one partition at a given level of subdivision (e.g., a k-d tree), then all partition lines at all nodes at this subdivision level are along the same axis and are orthogonal to all partition lines at the immediately preceding and subsequent level of subdivision. Moreover, we have assumed that the partitions cycle through the various axes in a predefined and constant order and that the partition lines must pass through the data points (with the exception of the trie-based methods).

Building k-d trees to satisfy these properties can lead to trees that are unbalanced and hence not very good for search operations. In particular, the total path length (TPL) may be quite high. There are several techniques for relaxing these rules with the effect that the resulting trees will be more balanced. Sproull [1797] contains a brief discussion of several such techniques, some of which are elaborated in greater detail in this section. Use of such techniques will reduce the TPL and, thereby, make subsequent searching operations faster. There are two approaches to reduce the TPL, one static and the other dynamic. They are discussed below.

The static approach assumes that all the data points are known a priori. Bentley [164] proposes an optimized k-d tree that is constructed in the same manner as the optimized point quadtree of Section 1.4.1.1. In this case, the partition lines must pass through the data points and still cycle through the various axes in a fixed and constant order.

Alternative static data structures incorporating an “adaptive partitioning” are the *adaptive k-d tree* of Friedman, Bentley, and Finkel [650], the *fair-split tree* of Callahan and Kosaraju [297], the *VAMSplit k-d tree* of White and Jain [1989] (see Section 1.7.1.7 for more details), and the *minimum-ambiguity k-d tree* [1226, 1228]. Unlike the standard k-d tree, and in the spirit of the pseudo quadtree of Overmars and van Leeuwen [1444] (see Section 1.4.1.2), data is stored only in the leaf nodes. In other words, the partition lines need not pass through the data points.<sup>21</sup> Moreover, the partition lines need not cycle through the various axes.

These methods are differentiated by the way in which the discriminator key and value are chosen. In the case of the adaptive k-d tree, the fair-split tree, and the VAMSplit k-d tree, at each level of subdivision, the discriminator is chosen to be the key for which the spread of the values of the key is a maximum. This spread can be measured by any convenient statistic, such as the variance (e.g., the VAMSplit k-d tree [1989]), or by the distance from the minimum to the maximum value (e.g., the adaptive k-d tree [650] and the fair-split tree [297]) usually normalized with respect to the median value, and so on.

Once the discriminator key has been chosen, we must select the discriminator value. A common choice is to use the median so that approximately one-half of the records will be in each subtree and hence the structure will be balanced (e.g., the adaptive k-d tree [650]). An alternative is to use the value that splits the range spanned by the key in half (e.g., the fair-split tree [297]). All records with key values less than the discriminator value are added to the left subtree, and all records with key values greater than or equal to the discriminator value are added to the right subtree. This process is continued recursively until there are only a few nodes left in a set, at which point they are stored as a linked list. Note that since we no longer require a cyclical discriminator sequence, the same key may serve as the discriminator for a node and its father, as well as its child. Thus, the resulting structure could also be characterized as an instance of a *generalized pseudo k-d tree*. We use this term in the rest of our discussion whenever the partition lines need not pass through the data points while leaving open the method for choosing the discriminator at each level of subdivision, in contrast with a conventional pseudo k-d tree where the discriminators cycle through the attributes in a given order as in the k-d tree. We also make use of this term in Section 1.7.1.

---

<sup>21</sup> Bentley [168] uses the qualifier *homogeneous* when describing a k-d tree where data is stored in both nonleaf and leaf nodes and the qualifier *nonhomogeneous* when describing a k-d tree where data is stored only in the leaf nodes.

Figure 1.43 An adaptive k-d tree ( $d = 2$ ) corresponding to the data of Figure 1.1: (a) the resulting partition of space and (b) the tree representation.

Figure 1.43 shows the adaptive k-d tree corresponding to the data of Figure 1.1. Note that although Figure 1.43(b) leads to the impression that the adaptive k-d tree is balanced, this is not necessarily the case. For example, when several nodes have the same value for one of their keys, then a middle value is impossible to obtain. The concept of a superkey is of no use in such a case.

Figure 1.44 shows the fair-split tree corresponding to the data of Figure 1.1. Note that the fair-split tree will not usually be balanced. The actual implementation of the fair-split tree also stores the ranges of the discriminator values in the tree (i.e., minimum bounding hyperrectangles of the underlying data). It is used for  $k$ -nearest neighbor queries and solving the  $N$ -body problem (e.g., [126]), in contrast to a previous solution by Greengard and Rokhlin [754].

In contrast to the adaptive k-d tree, fair-split tree, and the VAMSplit k-d tree, the minimum-ambiguity k-d tree [1226, 1228] chooses the discriminator key and value on the basis of the query distribution rather than the data distribution. The minimum-ambiguity k-d tree is motivated by the fact that, in high dimensions, partitioning methods such as the k-d tree (as well as others) do not help much in differentiating between the data. In particular, queries such as finding the  $k$  nearest neighbors result in examining most of the data anyway, especially when the data is uniformly distributed. Thus, a linear scan

Figure 1.44  
A fair-split tree ( $d = 2$ ) corresponding to the data of Figure 1.1: (a) the resulting partition of space and (b) the tree representation.

of the data is often just as efficient as using an index, and there is no need to incur the cost of building the index (see Section 4.4.8 in Chapter 4). The minimum-ambiguity  $k$ - $d$  tree is designed to deal with the case that high-dimensional data is clustered (and hence of an inherently lower dimensionality) by adapting the decomposition to the distribution of the query points so that nearest neighbor finding can be performed efficiently. This is done by finding a partitioning method that minimizes the expected number of times that both subtrees of a node must be visited when finding the nearest neighbor to a query point.

Finding such a partitioning is difficult from a theoretical standpoint as the extent of the clustering may not be so well defined. On the other hand, from a practical standpoint, examining the distance to every possible query point is also not feasible. So, instead, a subset of the query points, termed a *training set*, is used, and the quantity that is minimized is the maximum number of candidate nearest neighbors to the query points in the training set. Formally, this is the sum over the two subtrees, each denoted by  $i$ , of the product of the number of data points in  $i$  and the number of query points for whom the region spanned by the distance from query point  $p$  to the nearest data point

$q$  has a nonempty intersection with  $i$ . This quantity is computed for every possible pair of subtrees along each of the keys, and the split is made along the key and value that minimize it. This process is repeated recursively until a block contains fewer than  $c$  points, where  $c$  is analogous to a bucket capacity.

The main drawback of the minimum-ambiguity k-d tree is the high number of training points that are needed for good performance (e.g., nine times the number of data points [1226, 1228]). This has a direct effect on the time needed to build it as the distance to the nearest neighbors must be computed for each of the elements of the training set. Moreover, the process of computing the discriminator key and value takes some time (see Exercise 7). The entire process of building the k-d tree with the training set is made faster by using the approximate nearest neighbor instead of the exact nearest neighbor [1226, 1228] (see Exercise 8). Experiments in terms of the number of nodes that are visited when finding approximate nearest neighbors with different approximation error tolerances for data of dimension 20 showed that the minimum-ambiguity k-d tree significantly outperformed the adaptive k-d tree for clustered data and query points from both a uniform distribution, as well as the same distribution as the data points [1226, 1228]. Nevertheless, due to the high cost of building it, the minimum-ambiguity k-d tree should only be used if the dataset is static, and the number of times it will be queried is far in excess of the number of training points needed for its construction.

It is interesting to observe that the manner in which the discriminator key and value are chosen in the minimum-ambiguity k-d tree is analogous to the way in which they are sometimes chosen for an R-tree when an R-tree node overflows (see Sections 2.1.5.2.1, 2.1.5.2.3, 2.1.5.2.4 of Chapter 2 and the related exercises). In particular, for the R-tree, we wish to partition the region in space containing bounding boxes (not necessarily disjoint) corresponding to the overflowing node into two parts so as to minimize the amount of overlap between the two parts. In this way, when subsequent search operations are performed (e.g., a variant of the point location query that finds the object that contains a given point when the R-tree is used to represent objects with extent, such as two-dimensional objects, or even the nearest neighbor query when the R-tree consists of bounding boxes of collections of points), the likelihood of visiting more than one subtree is reduced. The motivation in the minimum-ambiguity k-d tree is similar but with the difference that, in the minimum-ambiguity k-d tree representation of point data, the overlap is implicit since we do not actually store the search regions. Thus, the overlap is a property of the query instead of the data, which is the case in the R-tree, where it is also explicitly stored.

When the data volume becomes large, we may not want as fine a partition of the underlying space as is provided by the adaptive k-d tree and the other variants of the generalized pseudo k-d tree. In particular, it may be desirable for points to be grouped by proximity so that they can be processed together. The generalized pseudo k-d tree can be adapted to facilitate this, as well as to identify clusters of points, by grouping points by spatial proximity into buckets and using the generalized pseudo k-d tree decomposition rule (e.g., the one used for the adaptive k-d tree) to partition a bucket whenever it overflows its capacity. We term the result a *bucket generalized pseudo k-d tree*. We have already seen the use of bucketing in our definition of the bucket PR quadtree (see Section 1.4.2.2). However, in contrast to the bucket PR quadtree, in the bucket generalized pseudo k-d tree, the choice of both the key across which to split, as well as the positions of the partition lines, depends on the data. For example, consider Figure 1.45, the bucket generalized pseudo k-d tree corresponding to the data of Figure 1.1 when the bucket capacity is 2. The splitting rule uses as a discriminator the key whose values have the maximum range (i.e., the one used for the adaptive k-d tree, and hence the result can be described as an instance of the *bucket adaptive k-d tree*).

Henrich [825] discusses the general issue of bucket overflow in variants of k-d trees that make use of buckets. The examples and experiments are primarily in terms of bucket methods that employ a tree directory such as the LSD tree (see Section 1.7.1.3) where the nonleaf nodes are also bucketed. Nevertheless, the approach is much more general.

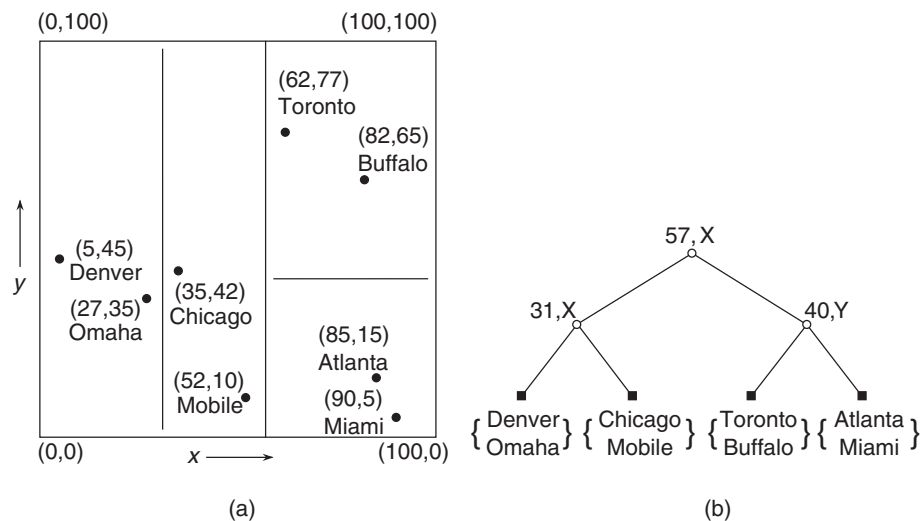

Figure 1.45  
A bucket generalized pseudo k-d tree and the records it represents corresponding to the data of Figure 1.1 for bucket size 2: (a) the resulting partition of space and (b) the tree representation.

In particular, Henrich proposes to make use of rotation operations similar to those used in B-trees so that data is redistributed from the overflowing bucket to a sibling bucket that is not too full. In the case of a k-d tree, once the data is redistributed, we may also have to adjust the partition line. The problem is that the sibling may also be too full, in which case the redistribution process must be applied recursively to the sibling. Experiments [825] revealed that general application of recursive redistribution resulted in worse performance due to the fact that the trees became deeper. Thus, Henrich [825] suggests that redistribution should be applied only in the following two instances:

1. Between sibling buckets.
2. Recursively if the overflowing bucket and corresponding ancestor subtree are heavier (i.e., deeper) than the subtree that is receiving the overflowing data. Moreover, the recursion should be attempted for a limited number of levels of the tree (usually one, as, otherwise, the price of the increase in execution time for the redistribution process dwarfs the relative increase in storage utilization and decrease in tree depth).

Matsuyama, Hao, and Nagao [1258] use the bucket generalized pseudo k-d tree in a geographic information system. In this case, even though the spatial objects have extent (i.e., they correspond to entries such as regions and lines in two dimensions), they are treated as points by storing a corresponding representative point such as the object's centroid. A variant of the bucket generalized pseudo k-d tree is also used by Ooi, McDonnell, and Sacks-Davis [1404, 1407]. In particular, they store the centroids of the objects and also associate with each node's partitioning line the maximum extent to the right (left), in terms of the coordinate  $j$  whose value is being tested, of all objects in the left (right) subtree. The result is termed a *spatial k-d tree* and is discussed further in Sections 1.7.1.2 and 3.3.2.5 of Chapter 3).

O'Rourke [1421, 1425] uses the bucket adaptive k-d tree, calling it a *Dynamically Quantized Space* (DQS), for cluster detection as well as for multidimensional histogramming to aid in focusing the Hough Transform (e.g., [514, 1122]). The *Dynamically Quantized Pyramid* (DQP) [1425, 1777] is closely related to the DQS in the sense that it is also used in the same application. Both the DQP and the DQS are instances of the bucket pseudo quadtree and the bucket generalized pseudo k-d tree, respectively, with the difference that in the DQP, the buckets are obtained by partitioning across all of the keys at each step while still varying the positions of the partition lines (the result is also

called an irregular cell-tree pyramid and is discussed in Section 2.1.5.1 of Chapter 2). Below, we briefly describe the Hough Transform in order to show an application of these bucket methods. This discussion is very specialized and thus may be skipped.

Techniques such as the Hough Transform facilitate the detection of arbitrary sparse patterns, such as curves, by mapping them into a space where they give rise to clusters. A DQS (i.e., a bucket generalized pseudo k-d tree) has  $k$  attributes or dimensions corresponding to a set of parameters that can be mapped by an appropriate function to yield image patterns. The buckets correspond to the parameter regions. Associated with each bucket is a count indicating the number of times that an element in its region appears in the data. The goal is to find evidence for the presence of clusters in parameter space.

The DQS is particularly useful in parameter spaces of high dimension (i.e.,  $\gg 2$ ). However, for the sake of this discussion, we just look at two-dimensional data. In particular, consider a large collection of short edges and try to determine if many of them are collinear. We do this by examining the values of their slopes and  $y$ -intercepts (recall that the equation of a line is  $y = m \cdot x + b$ ). It turns out that a high density of points (i.e., counts per unit volume) in the  $(m, b)$  plane is evidence that many collinear edges exist. We want to avoid wasting the space while finding the cluster (most of the space will be empty). To do this, we vary the sizes of the buckets (i.e., their parameter regions) in an attempt to keep the counts equal.

In two dimensions, the Hough Transform for detecting lines is quite messy unless each detected point has an associated slope. The same would be true in three dimensions, where we would want not only a position reading  $(x, y, z)$  but also the direction cosines of a surface normal  $(\alpha, \beta, \gamma)$ . We can then map each detection into the parameters of a plane, for example,  $(\rho, \alpha, \beta)$ , where  $\rho$  is the perpendicular distance from the plane to the origin. If there are many coplanar detectors, this should yield a cluster in the vicinity of some particular  $(\rho, \alpha, \beta)$ .

As the buckets overflow, new buckets (and corresponding parameter regions) are created by a splitting process. This splitting process is guided by the two independent goals of an equal count in each bucket and the maintenance of a uniform distribution in each bucket. This is aided by keeping a count and an imbalance vector with each bucket. When the need arises, buckets are split across the dimension of greatest imbalance. There is also a merging rule, which is applied when counts of adjacent neighbors (possibly more than two) are not too large, and the merges will not produce any highly unbalanced regions. This is especially useful if the data is dynamic.

The DQP addresses the same problem as the DQS with the aid of a complete bucket pseudo quadtree, which is known as a pyramid [1845] (see Section 2.1.5.1 of Chapter 2 for more details). Thus, for  $k$  attributes or dimensions, it is a full balanced tree where each nonleaf node has  $2^k$  children. In this case, the number of buckets (i.e., parameter regions), and the relationship between fathers and children are fixed. The DQP differs from the conventional pyramid in that the partition points (termed *cross-hairs*) at the various levels are variable rather than fixed.

The partition points of a DQP are initialized to the midpoints of the different attributes. They are adjusted as data is entered. This adjustment process occurs at all levels and is termed a *warping process*. One possible technique when inserting a new data point, say  $P$ , in a space rooted at  $Q$ , is to take a weighted average of the position of  $P$ , say  $\alpha$ , and of  $Q$ , say  $(1 - \alpha)$ . This changes the boundaries of all nodes in the subtree rooted at  $Q$ .  $P$  is recursively added to the appropriate bucket (associated with a leaf node), which causes other boundaries to change.

Figure 1.46 is an example of a two-dimensional DQP for three levels. It should be clear that regions grow smaller near inserted points and that the shape of the DQP depends on the insertion history, thereby providing an automatic focusing mechanism. The warping process is analogous to the splitting operation used in conjunction with a

Figure 1.46  
Example two-dimensional DQP for three levels.

DQS. The advantage of a DQP over the DQS is that it is easier to implement, and merging is considerably simpler. On the other hand, the DQP allocates equal resources for each dimension of the parameter space, whereas the DQS can ignore irrelevant dimensions, thereby yielding more precision in its focusing. Also, the DQS takes up less space than the DQP.

The drawback of methods such as the bucket generalized pseudo k-d tree (as exemplified by the DQS) and the DQP is that the result may not be aesthetically pleasing as the price of the balance is a bad aspect ratio. Intuitively, in two dimensions, this means that the lengths of the sides of a region differ greatly (such regions are characterized as *skinny* [516, 517], in contrast to others where the differences are not so great, which are characterized as *fat*). This makes them undesirable for applications such as drawing very large graphs using subgraphs (e.g., [516]). One way to define the *aspect ratio* in  $d$  dimensions is as the ratio of the smallest circumscribed hypersphere in  $R^d$  to the largest inscribed hypersphere in  $R^d$ , using any of the standard Minkowski distance metrics  $L_p$  (where, given the points  $(x_1, y_1)$  and  $(x_2, y_2)$ , the distance is defined as  $d_{L_p}((x_1, y_1), (x_2, y_2)) = ((x_1 - x_2)^p + (y_1 - y_2)^p)^{1/p}$  for integers  $p \geq 1$ ).

Duncan, Goodrich, and Kobourov [516, 517] address the issue of finding a representation where the shapes of all of the resulting regions have an aspect ratio, as defined above, less than a particular value  $\alpha$  (such regions are termed  $\alpha$ -balanced), while also ensuring that the resulting regions are not too unbalanced in terms of the number of points that they contain. The resulting representation is termed a *balanced aspect ratio tree* (BAR tree) and has the property that for a set of  $N$  points, the depth is  $O(\log N)$ . However, unlike the variants of the bucket generalized pseudo k-d tree, not all of the leaf nodes of the BAR tree need to be at the same depth; nor is the maximum difference in their depths bounded by one.

Note that the requirement that the regions be  $\alpha$ -balanced yields a structure that is very similar to the restricted quadtree [1453, 1771, 1772, 1940] and restricted bintree [513, 576, 651, 810, 1176, 1259, 1522, 1564, 1565] (see Section 2.2.4 of Chapter 2), where the widths of all adjacent blocks differ by at most a factor of 2. Other representations, such as the balanced box-decomposition tree (BBD-tree) of Arya, Mount, Netanyahu, Silverman, and Wu [100], which has  $O(\log N)$  depth for  $N$  points, may result in  $\alpha$ -balanced regions. However, the regions are not necessarily convex as some of the regions may have holes, making them unattractive for display purposes in applications such as graph drawing [516].

The basic structure of the BAR tree differs from that of the k-d tree by allowing an additional set of  $2^d$  possible partitions (aside from the  $d$  axis-parallel ones) that correspond to all of the possible combinations where the magnitude of the relative changes in each of the  $d$  directions is the same (e.g., 45-degree-angled partitions in two dimensions, of which there are four).<sup>22</sup> Such partitions are termed *canonical cuts*, and the resulting regions are termed *canonical regions*. These additional partitions, coupled with the above definition of the aspect ratio, enable dealing with the situation that all of the points lie in a corner of the region. In this case, without the 45-degree-angled partitions, we would have arbitrarily skinny regions.

It is also desirable, once all of the canonical cuts have been applied, that the number of points in the resulting regions not be too unbalanced. This condition does not necessarily hold when all of the resulting regions are  $\alpha$ -balanced. Thus, instead of requiring that the number of points in a region be cut roughly in half at every level, the BAR tree guarantees that the number of points is cut roughly in half every  $k$  levels ( $k = 2$  for  $d = 2$  and  $k = d + 2$  in general), which is not always possible with an arbitrary k-d tree or a

<sup>22</sup> This is more general than the  $g$ -degrees rotated  $x$ -range [1923], which is used as an object approximation (see Section 2.1.1 in Chapter 2) and allows two parallel extra partitions for two-dimensional data, although the angle is arbitrary rather than being restricted to 45 degrees as in the BAR tree.

$d$ -dimensional variant of the region quadtree (e.g., a region octree in three dimensions), while also guaranteeing that all of the resulting regions are  $\alpha$ -balanced.

In particular, given a value  $\beta$  ( $0.5 \leq \beta < 1$ ), termed a *reduction factor*, we say that when an  $\alpha$ -balanced region  $R$  (letting  $|R|$  denote the number of points in  $R$ ) is subdivided into two regions,  $R_1$  and  $R_2$ , the following properties hold:

1.  $R_1$  and  $R_2$  are  $\alpha$ -balanced.
2.  $|R_1| \leq \beta|R|$ , and  $|R_2| \leq \beta|R|$ .

The above is called a *one-cut*. A definition is also given for a *k-cut*, which divides an  $\alpha$ -balanced region  $R$  into two regions,  $R_1$  and  $R_2$ , such that

1.  $R_1$  and  $R_2$  are  $\alpha$ -balanced.
2.  $|R_2| \leq \beta|R|$ .
3. Either  $|R_1| \leq \beta|R|$ , or  $R_1$  is  $(k - 1)$ -cuttable with a reduction factor  $\beta$ .

The main motivation for this subdivision process is that the application of the sequence of  $k$  canonical cuts  $s_k, s_{k-1}, \dots, s_2, s_1$  to region  $R$  will result in  $k + 1$   $\alpha$ -balanced regions, each containing no more than  $\beta|R|$  points. In this case, we say that  $R$  is *k-cuttable*.

Duncan, et al. [517] prove that given a set of canonical cuts, if every possible  $\alpha$ -balanced canonical region is  $k$ -cuttable with a reduction factor  $\beta$ , then a BAR tree with maximum aspect ratio  $\alpha$  can be constructed with depth  $O(k \log_{1/\beta} N)$  for any set  $S$  of  $N$  points (see Exercise 11). More importantly, they also prove that for  $\alpha \geq 3d$  and  $\beta \geq d/(d + 1)$ , any  $\alpha$ -balanced canonical region  $R$  is  $(d + 2)$ -cuttable. Using these results and the fact that the maximum depth of the BAR tree is  $O(d^2 \log N)$  (see Exercise 12), they prove that a BAR tree with an appropriate maximum aspect ratio  $\alpha$  can be constructed in  $O(d^2 \cdot 2^d \log N)$  time, which for fixed dimensions is  $O(N \log N)$ . Thus, the BAR tree is balanced in two ways: clusters at the same level have approximately the same number of points, and each cluster region has a bounded aspect ratio.

Now, let us return to our more general discussion. Both the optimized and generalized pseudo k-d trees are static data structures, which means that we must know all of the data points a priori before we can build the tree. Thus, deletion of nodes is considerably more complex than for conventional k-d trees (see Section 1.5.1.2) since we must obtain new partitions for the remaining data. Searching in optimized and generalized pseudo k-d trees proceeds in an analogous manner to that in conventional k-d trees.

The dynamic approach to reducing the TPL in a k-d tree constructs the tree as the data points are inserted into it. The algorithm is similar to that used to build the conventional k-d tree, except that every time the tree fails to meet a predefined balance criterion, the tree is partially rebalanced. One radical approach, known as the *divided k-d tree* [1075], in the case of two-dimensional data, makes all subdivisions at the top of the tree along the first dimension value, and all subdivisions at the remaining levels on the dimension (of course, this idea can be generalized to higher dimensions). Thus, the result is somewhat similar to using a hierarchy of inverted lists (see Section 1.1). The actual implementation [1075] is based on a 2-3 tree [874] instead of a binary subdivision such as an AVL tree [15]. The key to this method is to make use of the ability to rebalance such a structure efficiently, thereby permitting it to have good dynamic behavior.

Overmars and van Leeuwen [1444] (see also Willard [1999]) rebalance the tree using techniques developed for constructing the optimized k-d tree. They present two variations: the first is analogous to the optimized point quadtree, and the second to the pseudo quadtree. One of the differences between these two approaches is that in the dynamic optimized k-d tree, the partition lines must pass through the data points, but this need not be the case for the dynamic pseudo k-d tree. This does not have an effect on searching. However, deletion will be considerably simpler in the dynamic pseudo k-d tree than in the dynamic optimized k-d tree.

Methods such as the dynamic optimized k-d tree and the dynamic pseudo k-d tree are characterized by Vaishnavi [1912] as yielding “severely” balanced trees in that they are generalizations of complete binary trees for one-dimensional data. As such, they can not be updated efficiently, and this has led Vaishnavi to propose a relaxation of the balancing criterion by generalizing the height-balancing constraint for a height-balanced binary search tree (also known as an AVL tree [15, 27]). This is done by storing data in a nested sequence of binary trees so that each nonleaf node  $P$  tests a particular key  $J$ . Each nonleaf node  $P$  has three children. The left and right children point to nodes with smaller and larger values, respectively, for the  $J$ th key. The third child is the root of a  $(k - 1)$ -dimensional tree containing all data nodes that have the same value for the  $J$ th key as the data point corresponding to  $P$ .<sup>23</sup> The “rotation” and “double rotation” restructuring operations of height-balanced trees are adapted to the new structure. For  $N$  points, their use is shown to yield  $O(\log_2 N + k)$  bounds on their search and update times (i.e., node insertion and deletion). Unfortunately, this data structure does not appear to be well suited for range queries.

The most drastic relaxation of the rule for the formation of the k-d tree is achieved by removing the requirements that the partition lines be orthogonal and parallel to the coordinate axes and that they pass through the data points. This means that the partition lines are arbitrary; thus, it is no longer meaningful to speak about the order in which the different coordinate axes are partitioned (e.g., [1797]). Also, the ancestral relationship (i.e., the common bond) between the k-d tree and the fixed-grid method is now meaningless as an array access structure to the results of the space partition is no longer possible.

Sproull [1797] suggests that the first partition line be obtained by computing the principal eigenvector of the covariance matrix of the data points. This axis, also known as the *principal axis*, points along the direction of the maximum variation in the data regardless of their orientation with respect to the coordinate axes.<sup>24</sup> This process is applied recursively to the resultant subsets. The same idea is used by McNames [1271] in his development of the principal axis tree (PAT). In this case, instead of a binary partition along the principal axis, the entire dataset is projected onto the principal axis, and the result is partitioned into  $m \geq 1$  distinct regions such that each region has approximately the same number of points. This process is recursively reapplied to each of the point subsets until each subset contains fewer than  $m$  points. Note that the principal axis tree is analogous to the multidimensional directory (MDD) [1183] discussed in Section 1.1, with the difference that the partition lines are no longer orthogonal (see Figure 1.5(b)). The idea of performing more than one partition along an axis is also used in the X-Y tree [1334] and the equivalent treemap [1758] and puzzletree [479] (see Section 2.1.2.9 of Chapter 2) with the difference that the partitions are only made along the coordinate axes, and the number of partitions is permitted to vary at each node.

The *Binary Space Partitioning tree* (BSP tree) of Fuchs, Kedem, and Naylor [658] is an example of a k-d tree where the subdivision lines are not necessarily orthogonal or parallel to the coordinate axes and do not necessarily pass through the data points. Each subdivision line is really a hyperplane, which is a line in two dimensions and a plane in three dimensions. Thus, in two dimensions, each node’s block is a convex polygon, while in three dimensions, it is a convex polyhedron.

The BSP tree is a binary tree where each child corresponds to a region. In order to be able to assign regions to the left and right subtrees, we need to associate a direction with each subdivision line. In particular, the subdivision lines are treated as separators

---

<sup>23</sup> The same principle is applied to the B-tree to yield the MDBT [1434, 1686] and the kB-tree [786, 787]. See Section 1.1 for more details.

<sup>24</sup> Singular Value Decomposition (SVD) (see Section 4.6.4.1 of Chapter 4) is also based on this principle.

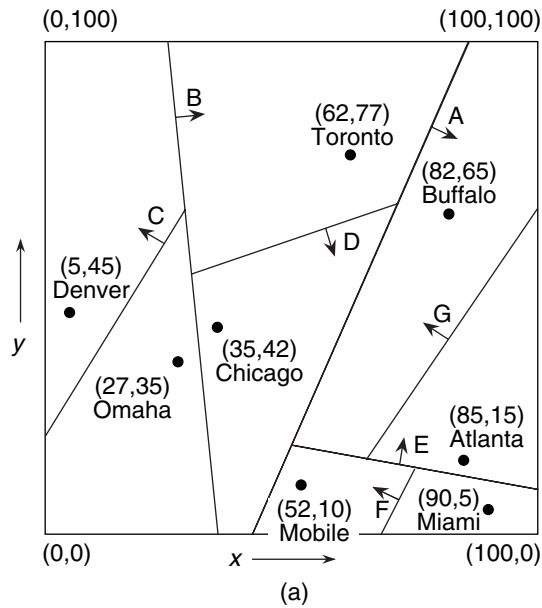

Figure 1.47  
An adaptation of the BSP tree to points and the records it represents corresponding to the data of Figure 1.1: (a) the resulting partition of space and (b) the tree representation.

between two halfspaces.<sup>25</sup> Let the subdivision line have the equation  $a \cdot x + b \cdot y + c = 0$ . We say that the right subtree is the “positive” side and contains all subdivision lines formed by separators that satisfy  $a \cdot x + b \cdot y + c \geq 0$ . Similarly, we say that the left subtree is “negative” and contains all subdivision lines formed by separators that satisfy  $a \cdot x + b \cdot y + c < 0$ . As an example, consider Figure 1.47(a), which is one of many possible adaptations of the BSP tree to store the point data in Figure 1.1. Notice the use of arrows to indicate the direction of the positive halfspaces. Although in this example the tree is balanced, this need not be the case. Similarly, the subdivision lines may pass through the data points themselves.

Although we have presented the BSP tree as a point representation in this section, the real motivation for the development of the BSP tree was to expedite the process of visibility determination in scenes composed of polyhedral objects where the faces are coincident with the partitioning planes (assuming three-dimensional data). This is discussed in Section 2.1.3.1 of Chapter 2. Nevertheless, the BSP tree has also been used

<sup>25</sup> A (linear) *halfspace* in  $d$ -dimensional space is defined by the inequality  $\sum_{i=0}^d a_i \cdot x_i \geq 0$  on the  $d + 1$  homogeneous coordinates ( $x_0 = 1$ ). The halfspace is represented by a column vector  $a$ . In vector notation, the inequality is written as  $a \cdot x \geq 0$ . In the case of equality, it defines a hyperplane with  $a$  as its normal. It is important to note that halfspaces are volume elements; they are not boundary elements.

by van Oosterom [1410, 1412] in the KD2-tree to represent objects as points in the same way that Ooi, McDonell, and Sacks-Davis used the bucket generalized pseudo k-d tree in their spatial k-d tree [1404, 1407]. In particular, the KD2-tree also stores the centroids of the objects and associates with each node  $P$ 's subdivision line  $I$  two lines,  $L$  and  $R$ , both of which are parallel to  $I$ .  $L$  ( $R$ ) is obtained by shifting  $I$  to the left (right), thereby expanding the space spanned by  $P$ 's right (left) subtree so that it defines the smallest subspace that covers all of the objects whose centroids are stored in  $a$ 's right (left) subtree. van Oosterom also defines a bucket variant of the KD2-tree, termed a *KD2B-tree* [1410, 1412], which is built using techniques similar to those employed in constructing an R-tree (see Section 2.1.5.2 of Chapter 2). In both the KD2-tree and the KD2B-tree, the leaf nodes also contain the minimum bounding spheres of the objects corresponding to the points stored therein as they provide a better approximation than the convex cells associated with the space that is spanned by the corresponding leaf nodes.

The BSP tree has also been used by Maneewongvatana and Mount [1229, 1230], who have adapted it to facilitate finding nearest neighbors in high dimensions by associating with each node  $a$  a bounding box in the form of a convex polyhedron, termed a *cover*, that contains every point in the  $d$ -dimensional space whose nearest data point is in the space spanned by  $a$ . The result is termed an *overlapped-split tree (os-tree)* (see Section 4.4.4 of Chapter 4 for more details) and is quite similar to an R-tree (see Section 2.1.5.2 in Chapter 2), except that the bounding boxes are not axis parallel. The resulting tree is formed in the same way as the KD2-tree of van Oosterom with the only difference being that, in the KD2-tree, the cover of a node corresponds to the extent of the objects whose centroids are associated with the node.

The *D-tree* of Xu, Zheng, Lee, and Lee [2035, 2036] is a generalization of the BSP tree where the subdivision lines are *polylines* (sequences of connected line segments of arbitrary orientation) instead of being restricted to be straight lines. In this case, the motivation of Xu et al. is to be able to represent an arbitrary partition of the underlying space instead of one that is based on a recursive halving of the underlying space, which is the case when using a k-d tree or a BSP tree. As an example, consider Figure 1.48(a), which is one of the many possible partitions of the underlying space spanned by the data points (i.e., cities) given in Figure 1.1 into regions so that there is one point per region, and Figure 1.48(b), one of the many possible D-trees for these eight regions. The

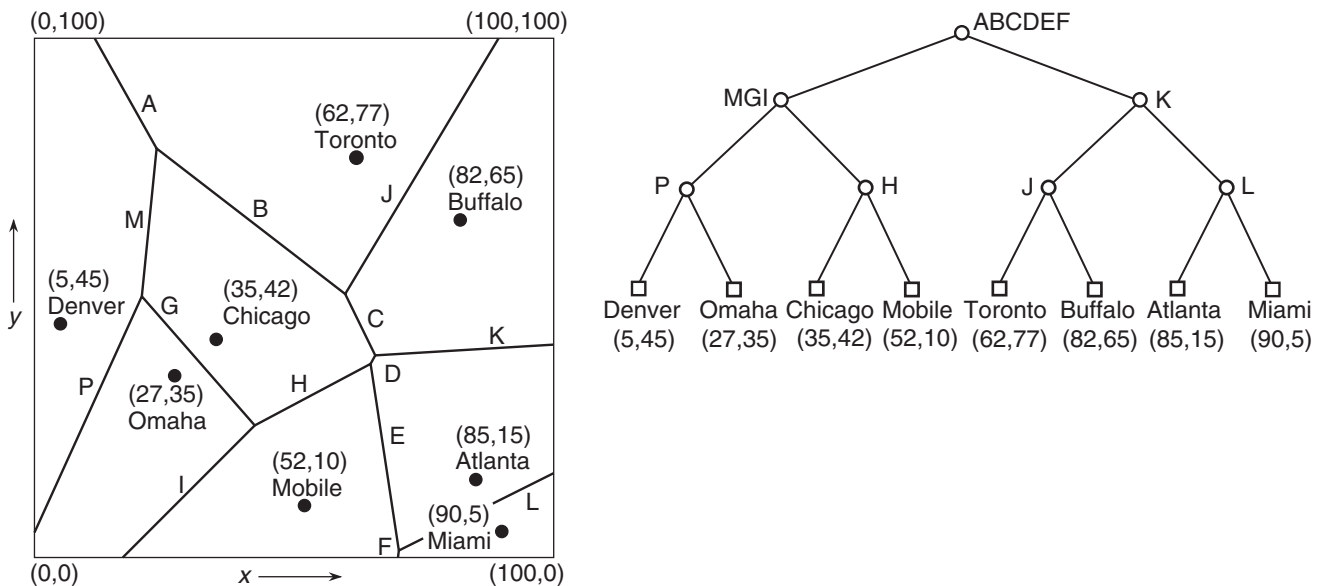

Figure 1.48  
(a) An example partition of the underlying space containing the data in Figure 1.1 into regions and (b) one of a number of its possible D-tree representations.

nonleaf nodes in Figure 1.48(b) represent the polylines that correspond to the boundaries of the regions or groups of regions in Figure 1.48(a), and they have been labeled with the vertices that make them up (i.e., using the letters A–P). For example, the root is labeled with ABCDEF as it separates the regions containing Denver, Omaha, Chicago, and Mobile in the left subtree and Toronto, Buffalo, Atlanta, and Miami in the right subtree.

The particular partition of the underlying space consisting of the locations of the eight cities given by Figure 1.1 that is depicted in Figure 1.48(a) is known as the *Voronoi diagram* [1941] and is discussed in much greater detail in Sections 2.2.1.4 and 2.2.2.6 of Chapter 2 and Sections 4.4.4 and 4.4.5 of Chapter 4. Briefly, given a distinguished set of points  $s_i$  (termed *sites*), the Voronoi diagram is a partition of the underlying space into regions  $r_i$ , one per site  $s_i$ , so that each point  $p$  in the space spanned by a region  $r_i$  is closer to the site  $s_i$  of  $r_i$  than to the site  $s_j$  ( $i \neq j$ ) of any other region  $r_j$ . It should be clear that the partition of the underlying space given in Figure 1.48(a) has this property.

The main drawback of using subdivision lines that are polylines (i.e., as in the D-tree) instead of straight lines is that it significantly complicates the determination of which side of a line contains a query point, which is the cornerstone of the efficient execution of a point location query. This query is usually implemented by constructing an arbitrary infinite line  $l$  through the query point  $q$  and counting the number  $n$  of boundaries of the containing region  $r$  crossed by  $l$  (e.g., [622]). An odd (even)  $n$  means that  $q$  is inside (outside)  $r$ . The implementation is simplified considerably when we can ensure that, without loss of generality, no vertical line can intersect the boundary of  $r$  more than twice (a partition of space that has this property is called a *y-monotone subdivision* and is discussed in greater detail in Section 2.1.3.3.1 of Chapter 2). Unfortunately, the partition of the underlying space induced by the D-tree is not necessarily a *y-monotone subdivision*, and thus we cannot make use of a simple test such as “above-and-below” (“left-and-right” or any other orientation). Instead, we must resort to imposing an additional hierarchy on the D-tree’s associated partition of the underlying space such as a hierarchy of triangulations as in the K-structure [1026] (see Section 2.1.3.2 of Chapter 2) or a hierarchy of “above-and-below” partitions consisting of groups of regions as in the separating chain method [1128] and the improved access structure for it known as the layered dag [541] (see Section 2.1.3.3 of Chapter 2). The problem is that these hierarchies invariably involve the addition of edges, thereby further partitioning the partition of the underlying space that is induced by the D-tree, and thus limiting its utility. In other words, the D-tree cannot be used effectively as an access structure on the original data without the imposition of an additional access structure on the D-tree itself.

### Exercises

1. Write a procedure BUILDOPTIMIZEDKDTREE to construct an optimized k-d tree.
2. In the text, we indicated that the optimized k-d tree can also be constructed dynamically. Given  $\delta$  ( $0 < \delta < 1$ ), show that there exists an algorithm to build such a tree so that its depth is always at most  $\log_{2-\delta} n + O(1)$  and that the average insertion time in an initially empty data structure is  $O(\frac{1}{\delta \log_2 N})$ . In this case,  $n$  denotes the number of nodes currently in the tree, and  $N$  is the total number of nodes in the final tree.
3. Write a procedure BUILDADAPTIVEKDTREE to construct an adaptive k-d tree.
4. Analyze the running time of procedure BUILDADAPTIVEKDTREE.
5. Show that the average search time for a hypercube range query (i.e., all sides are of equal length) in an adaptive k-d tree of  $N$  nodes is  $O(\log_2 N + F)$ , where  $F$  is the number of answers and is relatively small in comparison to  $N$ .
6. Define a pseudo k-d tree in an analogous manner to that used to define the pseudo quadtree in Section 1.4.1.2. Repeat Exercise 16 in Section 1.4.1.2 for the pseudo k-d tree. In other words, prove that the same result holds for  $N$  insertions and deletions in a  $d$ -dimensional pseudo k-d tree.

7. Consider the process of constructing a minimum-ambiguity k-d tree. Assume that you have  $n$  data points in  $d$ -dimensional space and that the training set has  $t$  points. How would you determine the discriminator key and value for a particular cell? What is the execution time complexity of this process for a particular cell? What is the total execution time for the entire process?
8. Suppose that you use the approximate nearest neighbor with approximation error tolerance  $\varepsilon$  in the construction of the minimum-ambiguity k-d tree. Explain how using the approximate nearest neighbor instead of the exact nearest neighbor affects the process of determining the discriminator key and value for a particular cell as the minimum-ambiguity k-d tree is built.
9. How would you use the Hough Transform to detect if some range data (i.e.,  $x$ ,  $y$ ,  $z$  readings) are coplanar?
10. Explain the rationale for the  $(k - 1)$ -cuttable condition in the definition of the BAR tree. In other words, how can the condition  $|R_1| \leq \beta R$  fail to hold?
11. Prove that given a set of  $N$  points and a set of canonical cuts, if every possible  $\alpha$ -balanced canonical region is  $k$ -cuttable with a reduction factor  $\beta$ , then a BAR tree with maximum aspect ratio  $\alpha$  can be constructed with depth  $O(k \log_{1/\beta} N)$ .
12. Prove that given  $N$  points and a maximum aspect ratio  $\alpha$ , the maximum depth of a BAR tree is  $O(d^2 \log N)$ .
13. Assume that you are given a BSP tree for a set of points  $S$  that yields a partition of space into  $m$  regions  $r_i$  with  $t_i$  ( $1 \leq i \leq m$ ) points in each region  $r_i$ . Can you prove that a space partition could also be obtained with orthogonal subdivision lines that are parallel to the axis so that we again have  $m$  regions  $u_j$ , where each  $u_j$  ( $1 \leq j \leq m$ ) contains the same points as one of the regions  $r_i$  ( $1 \leq i \leq m$ )? If this is true, then you have shown that the BSP tree does not yield a more general partition of space than the most general form of the adaptive k-d tree (i.e., the generalized pseudo k-d tree) in the sense that the space is partitioned into orthogonal blocks with faces that are parallel to the coordinate axes.
14. Does the result of Exercise 13 also hold for BSP trees for nonpoint objects (i.e., objects with extents such as line segments as discussed in Section 2.1.3.1 of Chapter 2, and, more generally, in Section 2.2.2 of Chapter 2)?

## 1.5.2 Trie-Based K-d Trees

The trie-based k-d tree is a binary tree adaptation of the PR quadtree and is obtained in the same way as the point k-d tree is obtained from the point quadtree. However, unlike the point k-d tree, in the trie-based k-d tree, the positions at which decomposition takes place do not have to coincide with data points. Trie-based k-d trees are closely related to the bintree representation of region data (see Section 2.1.2.6 of Chapter 2). In this case, we recursively decompose the underlying space from which the points are drawn into halves. The exact identity of the key or dimension that we partition depends on the partitioning scheme that is used.

In the rest of this section, we discuss a number of variants of the trie-based k-d tree. We start by presenting the basic structure called a PR k-d tree in Section 1.5.2.1. A shortcoming of the PR k-d tree is that it can get unbalanced when the data is clustered, thereby affecting query operations. The remaining subsections deal with methods of overcoming this shortcoming. Section 1.5.2.2 discusses one such method, which is based on changing the position of the partitions when they result in an empty node. Another solution is to make use of bucketing, albeit in a different manner from that in Section 1.7, described in Section 1.5.2.3. The remaining methods can be used with and without bucketing, although our description assumes a bucket capacity of 1. Two of them are distinguished from the PR k-d tree by the possibility of skipping the testing of some bits of the keys when their values do not help in distinguishing the data items in the dataset (Sections 1.5.2.4 and 1.5.2.5). A third method does not skip the testing of any of the bits but instead enables the simultaneous testing of one or more bits from several keys, as well as the specification of which results lead to the left and right children. This enables

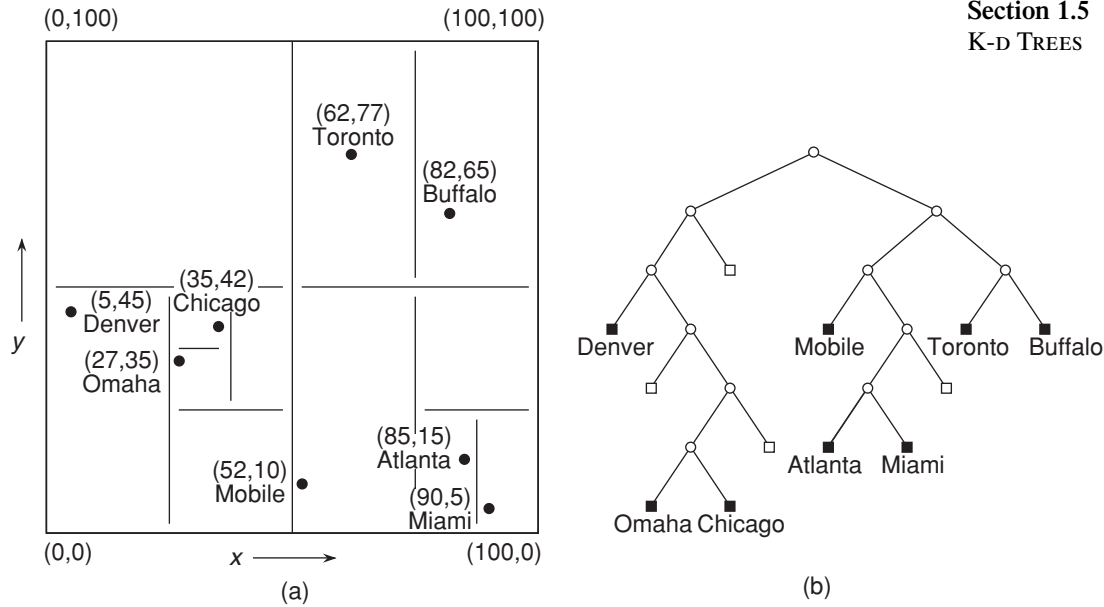

Figure 1.49 A PR k-d tree and the records it represents corresponding to the data of Figure 1.1: (a) the resulting partition of space and (b) the tree representation.

the creation of a more balanced structure (Section 1.5.2.6). The final method is designed to achieve logarithmic height as well as a bounded aspect ratio (Section 1.5.2.7).

### 1.5.2.1 PR K-d Tree

There are many partitioning options, although the most common, and the one we focus on in this and the remaining subsections, applies the halving process by cycling through the different axes in a predefined and constant order. Again, as in the point k-d tree, in our discussion we assume two-dimensional data, and we test  $x$  coordinate values at the root and at even depths (given that the root is at depth 0) and  $y$  coordinate values at odd depths. Such a tree is described by Orenstein [1413], who calls it a *k-d trie*. Using the terminology of Section 1.4.2, such a data structure would be called a *PR k-d tree* or a *PR bintree*. For the purpose of consistency with Section 1.4.2, we shall use the term *PR k-d tree*. For example, Figure 1.49 shows the PR k-d tree corresponding to the data of Figure 1.1.

The advantage of the cyclic partitioning is that there is no need to store the identity or value of the discriminating key. Of course, other partitioning options are also possible, although not as many as in the case of the point k-d tree since the positions through which the partition lines must pass are restricted. For example, we can vary the order in which we partition the various axes and employ rules similar to those used to construct the generalized pseudo k-d tree (e.g., the adaptive k-d tree), except that they can be used to choose only the partition axis rather than both the partition axis and the partition position. When there are absolutely no rules as to the order in which the axes corresponding to the keys are partitioned, then we term the result a *generalized k-d trie*. The generalized k-d trie represents point data in a manner analogous to that used for region data by the *Adaptive Hierarchical Coding* (AHC) [411] or *generalized bintree* described in Section 2.1.2.6 of Chapter 2.

One of the shortcomings of some trie-based representations such as the PR k-d tree (as well as the PR quadtree) is that when the data is not uniformly distributed (e.g.,

when the data is clustered),<sup>26</sup> the tree contains many empty nodes and, thereby, becomes unbalanced. For example, inserting Amherst at location (83,64) in the PR k-d tree (PR quadtree) given in Figure 1.49 (Figure 1.31) will result in much decomposition to separate it from Buffalo, which is at (82,65). This effect is shown explicitly by the amount of decomposition necessary to separate Omaha and Chicago in the PR k-d tree given in Figure 1.49.

### Exercises

1. Formulate a k-d tree variant of a matrix representation analogous to the MX quadtree (discussed in Section 1.4.2.1), and term it an *MX k-d tree* or an *MX bintree*. Give procedures `MXKDINSERT` and `MXKDDELETE` to insert and delete data points in an MX bintree.
2. Why would an MX k-d tree be a better matrix representation than the MX quadtree?
3. Each point in the MX k-d tree can be represented as a unique, one-dimensional number as a result of concatenating zeros and ones corresponding to left and right transitions in the tree while descending a path from the root to the point's leaf node. Such a representation is known as a *locational code*, which is discussed briefly in Section 1.8.5.1 and in much greater detail in Section 2.1.2.4 of Chapter 2. Assuming a  $2^n \times 2^n$  image, a set of  $N$  points is represented by  $N \cdot n$  bits. Devillers and Gandoin [483, 674] suggest that the space requirements can be reduced by using a method that encodes the set of  $N$  points using a string corresponding to a breadth-first traversal of the corresponding PR k-d tree, along with the cardinality of points in the subtrees. The first element of the output string is the number of points  $N$  encoded using  $2 \cdot n$  bits. Next, output the number of points in the left subtree of the PR k-d tree using  $\log_2(N + 1)$  bits. The number of points in the right subtree can be obtained by subtracting the number of points in the left subtree from the number of points in the father node. This process is repeated recursively for the nodes at the next level. The process ceases at each stage when a leaf node in the PR k-d tree is encountered. If the leaf node  $q$  corresponds to a point  $p$ , then the rest of the bits corresponding to the path from  $q$  to the corresponding node in the MX k-d tree are output. Assuming a uniform distribution data model so that when a nonleaf node (i.e., block) with  $c$  points is split, each of the children contains  $c/2$  points, what is the expected number of bits needed to encode the  $N$  points?
4. Write a pair of procedures `PRKDINSERT` and `PRKDDELETE` to insert and delete, respectively, data points in a PR k-d tree.
5. Assuming that key values are uniformly distributed real numbers in  $[0,1)$  represented in binary, prove that the average depth of a PR k-d tree is  $O(\log_2 N)$ . Can you extend this result to PR quadtrees?
6. Perform an average case analysis of the cost of a partial range query (a subset of the range query) for a point k-d tree and a PR k-d tree when the attributes are independent and uniformly distributed.

### 1.5.2.2 Sliding-Midpoint K-d Tree

The lack-of-balance shortcoming of the PR k-d tree is evident when one side of the splitting hyperplane contains no data (termed a *trivial split*). An easy way to overcome this shortcoming is to make use of the *sliding-midpoint rule* [1226, 1228, 1319]. This is done by first splitting along the midpoint as in the PR k-d tree. If there are data points along both sides of the splitting hyperplane, then the split is retained. However, if a trivial split results, then the splitting hyperplane is moved (i.e., “slid”) in the direction of the data until the first data point is encountered. The split is made so that one block contains this point while the other block contains the remaining points. This process is repeated recursively until each block contains just one point.<sup>27</sup> Thus, the sliding-midpoint k-d tree for  $N$  points has  $N$  leaf nodes, all of which are nonempty. For example, Figure 1.50

<sup>26</sup> See [1832] for an analysis of this situation.

<sup>27</sup> Actually, it is more common to halt the decomposition process whenever a block contains less than  $c$  points, where  $c$  is analogous to a bucket capacity. This is described below.

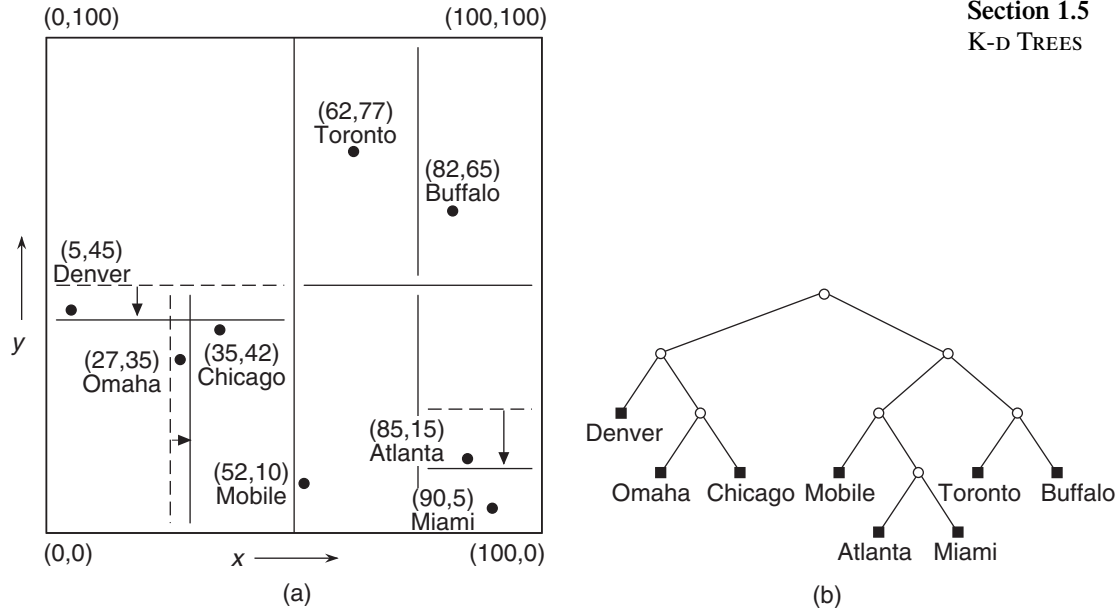

Figure 1.50  
A sliding-midpoint k-d tree and the records it represents corresponding to the data of Figure 1.1: (a) the resulting partition of space and (b) the tree representation. Broken lines indicate the original position of the partition plane before it has been slid to its final position, which is indicated by a solid line.

shows the sliding-midpoint k-d tree corresponding to the data of Figure 1.1. Notice the use of broken lines to indicate the original position of the partition plane before it has been slid to its final position, which is indicated by a solid line. Observe also that unlike the PR k-d tree, the sliding-midpoint k-d tree is a static structure as we must know all of the points before making a decision to slide a partition plane.

Given  $N$  points (assuming different values for each attribute), the complexity of building a sliding-midpoint k-d tree of height  $h$  is  $O(N \cdot h)$ , which is the same as that of building an adaptive k-d tree of the same height. However, unlike the adaptive k-d tree, where  $h$  is  $\log_2 N$ , for the sliding-midpoint k-d tree,  $h$  can be as bad as  $n$ . Nevertheless, using a method due to Vaidya [1908], it is possible to build the sliding-midpoint k-d tree in  $O(d \cdot N \cdot \log_2 N)$  time in dimension  $d$  (see Exercise 1).

The sliding-midpoint rule has a number of advantages over some other splitting rules. First of all, as mentioned above, it avoids the empty cells as is common in the PR k-d tree. It is interesting to observe that the real motivation for the sliding-midpoint rule is to slide the boundaries of the resulting cells toward the data clusters so that eventually, and ideally, the subsequent application of the recursive partitioning process will result in congruent cells with approximately the same number of data objects. In this respect, the sliding-midpoint rule can be said to be an adaptation of the adaptive k-d tree to an environment that makes use of regular decomposition.

The sliding-midpoint k-d tree helps overcome one of the drawbacks of the adaptive k-d tree. In particular, if the data points are highly clustered along some of the dimensions and vary greatly among the others, then the fact that the adaptive k-d tree repeatedly splits along the axis for which the points have the greatest spread means that the cells will be thin along some of the dimensions, thereby having a high aspect ratio. Therefore, in the adaptive k-d tree, a nearest neighbor query near the center of the data space may have to visit a large number of these thin cells. The sliding-midpoint k-d tree can also have cells with a high aspect ratio. However, in contrast to the adaptive k-d tree, a cell  $c$  in the sliding-midpoint k-d tree that has a high aspect ratio is adjacent to a cell  $c'$  that is fat along the same dimension  $i$  on which  $c$  is thin. This condition implies that in dimension

$i$ , the number of cells of diameter  $s$  that can overlap a ball of radius  $r$  can be bounded as a function of  $d$ ,  $s$ , and  $r$  (independent of the number of points in the data structure) [1226, 1227]. This property, called the *packing constraint*, is important for the efficiency of answering approximate nearest neighbor queries [100]. Thus, unlike the adaptive k-d tree, it is not possible to generate a long sequence of thin cells in the sliding-midpoint k-d tree, thereby lessening the effect of the high aspect ratio on nearest neighbor queries in the sliding-midpoint k-d tree.

### Exercises

1. Given  $N$   $d$ -dimensional points and assuming that a partitioning hyperplane for a k-d tree splitting rule in such a space can be obtained in  $O(d)$  time, show that a k-d tree (e.g., using the sliding-midpoint rule) can be built in  $O(d \cdot N \cdot \log_2 N)$  time.
2. The difference between the sliding-midpoint k-d tree and the PR k-d tree is that, whenever a split at a midpoint results in a trivial split, the splitting plane is moved (i.e., “slid”) in the direction of the data until encountering the first data point  $a$ . The split is made so that one block contains this point while the other block contains the remaining points. In this case, we end up with one relatively large block containing  $a$ , while the remaining points are in the other blocks, which are smaller. Thus, if  $a$  is part of a cluster of points, then the blocks that contain the points are not necessarily of similar size. For some applications, such as finding nearest neighbors, it may be desirable for the blocks to be of equal size. One way to achieve this is to halt the movement of the splitting plane in the case of a trivial split at a position so that we have as large an empty node as possible. Let us use the term *open-sliding midpoint k-d tree* to describe the result. It should be clear that the open-sliding midpoint k-d tree will require more space than the sliding-midpoint k-d tree as now we also have empty nodes. Determine the worst-case space requirements of the open-sliding midpoint k-d tree as a function of the number of points  $n$  and the dimensionality  $d$  of the underlying space, and give an example that attains it.

### 1.5.2.3 Bucket PR K-d Tree and PMR K-d Tree

A very simple method for overcoming the lack of balance in the PR k-d tree is to treat each block in the PR k-d tree as a bucket of capacity  $b$  and to stipulate that the block is split whenever it contains more than  $b$  points. We present two instances of this method that are differentiated on the basis of how many tests they apply at each step when encountering a full bucket.<sup>28</sup> Having buckets of capacity  $b$  ( $b > 1$ ) reduces the dependence of the maximum depth of the PR k-d tree on the minimum Euclidean distance separation of two distinct points to that of two sets of at most  $b$  points apiece. This is a good solution as long as the cluster contains  $b$  or fewer points as, otherwise, we still need to make many partitions. The result is termed a *bucket PR k-d tree* (also known as a *hybrid k-d trie* [1413]) and is shown in Figure 1.51 for the data of Figure 1.1 when the bucket capacity is 2. The bucket PR k-d tree assumes a cyclic partitioning. If we permit the order in which we partition the various axes to vary rather than cycling through them in a particular order, then the result is termed a *bucket generalized k-d trie*. It is referred to extensively in Section 1.7.1.

The PMR k-d tree [1360, 1361, 1362] for points<sup>29</sup> is another example of a bucketing method. It addresses the clustering problem by making use of a concept related to bucket

---

<sup>28</sup> At times, an additional restriction on the bucketing criterion is placed so that after a bucket with more than  $b$  items is split, most of the data is not in just one of the regions corresponding to the newly formed buckets. For example, in their presentation of the BD-tree (see Section 1.5.2.6), Ohsawa and Sakauchi [1386, 1387] suggest that a bucket with  $Nb$  items can be split until none of the regions corresponding to the newly formed buckets contains more than  $2N/3$  items. This splitting fraction is also used in the BBD-tree [100], where its use is justified from a theoretical standpoint (see Section 1.5.2.7 and Exercise 2 of that section).

<sup>29</sup> This structure was originally defined as a PMR quadtree, but its adaptation for k-d trees is straightforward: we vary the decomposition from  $2^d$  blocks at each level to just 2 blocks at each level.

Figure 1.51  
A bucket PR k-d tree and the records it represents corresponding to the data of Figure 1.1 for bucket size 2: (a) the resulting partition of space and (b) the tree representation.

capacity that we term a *splitting threshold*. Given a splitting threshold  $b$ , we say that if a block  $c$  contains more than  $b$  points, then it is split *once*, and only once. This is so even if one of the resulting blocks  $f$  still has more than  $b$  points. If, during the insertion of another point  $p$ , we find that  $p$  belongs in  $f$ , then  $f$  is split once, and only once. The idea is to avoid many splits when more than  $b$  points are clustered, and there are no other points in the neighborhood. The PMR k-d tree makes use of a cyclic partitioning.

On the other hand, a point is deleted from a PMR k-d tree by removing it from the node corresponding to the block that contains it. During this process, the occupancy of the node and its siblings is checked to see if the deletion causes the total number of points in them to be fewer than the predetermined splitting threshold. If the splitting threshold exceeds the occupancy of the node and its siblings, then they are merged, and the merging process is reapplied to the resulting node and its siblings. Notice the asymmetry between the splitting and merging rules. Also, observe that, unlike the bucket PR k-d tree, the shape of the PMR k-d tree does depend on the order in which the points were inserted.

### Exercises

1. Let the size of a data item be bounded by  $h$  (i.e., the maximum total number of bits in the  $k$  keys), and let the bucket capacity be  $c$ . Suppose that a bucket in a bucket PR k-d tree overflows. Assuming that each bit has an equal probability of being 0 or 1, find the expected number of bits that must be tested to resolve the overflow.
2. Write a pair of procedures `PMRKDINSERT` and `PMRKDDELETE` to insert and delete, respectively, data points in a PMR k-d tree.

### 1.5.2.4 Path-Compressed PR K-d Tree

In this section, as well as the next section (i.e., Section 1.5.2.5), we use techniques similar to those used in classical trie-based searching to avoid testing bits of the key value that make no difference in the result (i.e., they do not differentiate between the data items that

are present in the dataset).<sup>30</sup> Such a case arises when the key values have a common prefix. The Patricia trie [792, 1315], as used in digital searching [1046, p. 498], is one solution to this problem in the one-dimensional case. It makes use of the binary representation of the key values and replaces a sequence of two-way branches, where one result is always empty by a number that indicates which bit position should be tested next. In essence, we have compressed the sequence of tests. This technique is known as *path compression*. In some applications, knowing the results of the test enables us to reconstruct the values of the data items, which means that the leaf nodes of the tree need to store only the parts of the key values that have not been tested yet. In such a case, instead of storing the number of bits whose testing can be skipped, we often store their actual values. These values are represented by a binary bitstring (i.e., consisting of 1s and 0s) that indicates the values of the bits whose testing was skipped.

The application of path compression to a PR k-d tree involves taking parts of paths that consist of nonleaf nodes, all of whose siblings are empty (i.e., NIL), and compressing them so that all nonleaf nodes that have just one non-NIL child are eliminated. In particular, the nodes on these paths are replaced by one nonleaf node that indicates the results of the comparisons performed in accessing the first node in the path that has more than one non-NIL child. We term the result a *path-compressed PR k-d tree*. Path compression can also be applied to a PR quadtree and other related data structures. For example, Clarkson [396] suggests applying path compression to a multidimensional PR quadtree in one of a number of proposed solutions to the all nearest neighbors problem (i.e., given set  $A$  of multidimensional points, find the nearest neighbor in  $A$  of each point in  $A$ ).

Figure 1.52 is the path-compressed PR k-d tree resulting from the application of path compression to the PR k-d tree given in Figure 1.49. Notice that some nonleaf nodes in Figure 1.52(b) are labeled with a variable-length bitstring consisting of 0s and 1s, where 0 and 1 correspond to the test results “<” and “≥,” respectively. These bitstrings correspond to the tests that need not be performed (i.e., their corresponding path has been compressed). This information is necessary so that we know which bits to test at deeper levels of the tree.

For example, letting  $a$  correspond to the left child of the root of Figure 1.52(b), we have that  $a$  is equivalent to the left child of the root of Figure 1.49. Node  $a$  is labeled with 0, which indicates that the path from its equivalent in the original PR k-d tree in Figure 1.49 to its left child (i.e., 0) has been compressed by one level, as the right child of the left child of the root is empty in the original PR k-d tree in Figure 1.49. As another example, let  $b$  correspond to the right child of the left child of the root of Figure 1.52(b).  $b$  is equivalent to  $c$ , the right child of the left child of the left child of the root of Figure 1.49. From Figure 1.52(b), we find that  $b$  is labeled with 10, which indicates that the path from  $c$  (i.e., node  $b$ 's equivalent in the original PR k-d tree in Figure 1.49) to the left child (i.e., 0) of  $c$ 's right child (i.e., 1) has been compressed by two levels as both the left child of  $c$  and the right child of the right child of  $c$  are empty in the original PR k-d tree in Figure 1.49.

Path compression reduces the number of nodes in the tree by removing all empty leaf nodes and the tests that lead to them (represented by nonleaf nodes). This can be seen by examining Figure 1.52(a), which shows the blocks corresponding to the empty leaf nodes as shaded. Thus, given  $N$  records, the path-compressed PR k-d tree has  $N$  leaf nodes and  $N - 1$  nonleaf nodes for a total of  $2 \cdot N - 1$  nodes. However, the asymptotic expected average depth is not necessarily reduced. In this respect, the path-compressed PR k-d tree is analogous to the sliding-midpoint k-d tree—that is, they have the same number of nodes (but see Exercise 4). The difference is that, for the most part, the positions of

---

<sup>30</sup> If we are using bucketing, then the tests on the bits of the key values yield the address of a bucket that contains the data items present in the dataset. In the rest of the discussion in this and the remaining subsections, we speak of the actual data items rather than the bucket addresses.

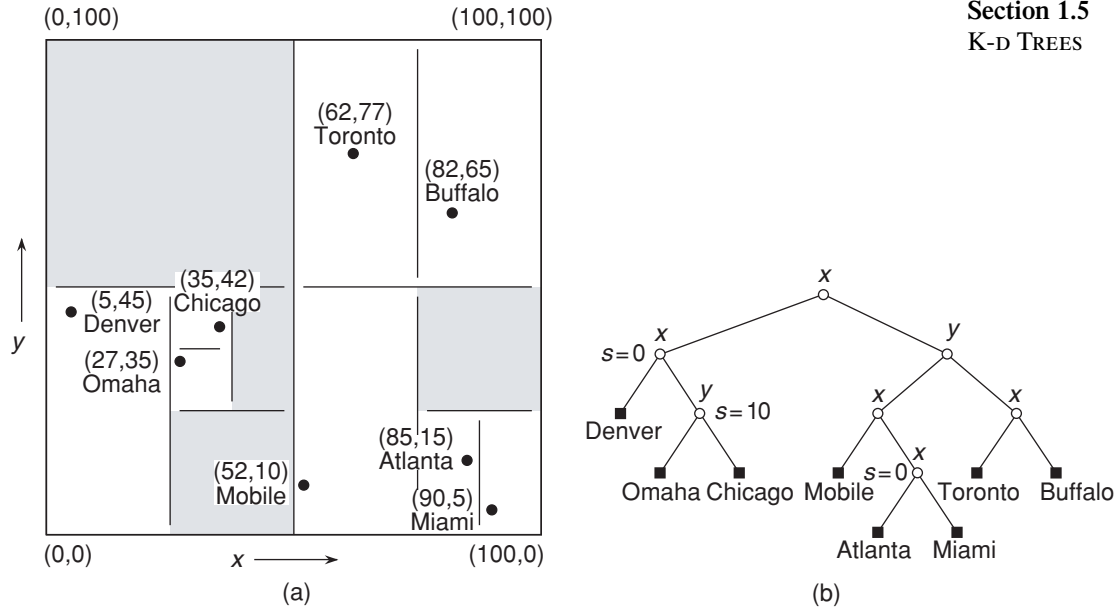

Figure 1.52  
A path-compressed PR k-d tree and the records it represents corresponding to the data of Figure 1.1: (a) the resulting partition of space (nonexisting blocks corresponding to empty leaf nodes are shown shaded) and (b) the tree representation.

the partitions in the sliding-midpoint k-d tree are determined by the data rather than by the embedding space from which the data is drawn. Moreover, when a midpoint split is not appropriate in a sliding-midpoint k-d tree (i.e., a trivial split results), then one of the two resulting blocks always contains just one point while the remaining points are in the other block. In contrast, a node split in the path-compressed PR k-d tree can result in both nodes having more than one point. Thus, the path-compressed PR k-d tree is not necessarily as deep as the sliding-midpoint k-d tree (see Exercises 2 and 3).

### Exercises

1. Write a pair of procedures PCPRKDINSERT and PCPRKDDELETE to insert and delete, respectively, data points in a path-compressed PR k-d tree.
2. Give an example where the path-compressed PR k-d tree is shallower than the corresponding sliding-midpoint k-d tree.
3. Is the maximum depth of the sliding-midpoint k-d tree always greater than or equal to that of the path-compressed PR k-d tree? Prove that this claim is true or give a counterexample.
4. Compare the space requirements of the path-compressed PR k-d tree and the sliding-midpoint k-d tree. Make sure to take into account the complexity of the nonleaf nodes.
5. Compare the open-sliding midpoint k-d tree described in Exercise 2 in Section 1.5.2.2 with the path-compressed PR k-d tree. Can you prove that the path-compressed PR k-d tree never has more nodes than the open-sliding midpoint k-d tree or never has a greater maximum depth? If not, give counterexamples for each case.

### 1.5.2.5 Path-Level Compressed PR K-d Tree

The depth of the path-compressed PR k-d tree can be reduced by applying level compression [51]. Operationally, we start at the root  $x$  of the path-compressed PR k-d tree and find the shortest path to a leaf node or a path-compressed node, say  $y$  at depth  $z$  relative to  $x$ , in the path-compressed PR k-d tree. An equivalent statement is that we are finding the largest complete subtree  $s$  rooted at  $x$  such that no element of  $s$  is a leaf or

path-compressed node (with the possible exception of  $x$ ) and compressing it. Now, all descendants of  $x$  at depth  $z$  are made children of  $x$ , which will now have  $2^z$  nonempty children. This process is applied recursively (i.e., in a top-down manner) to the  $2^z$  children of  $x$  at all levels. Of course, if  $z = 1$ , then no action takes place at  $x$ , and we reapply the process to the two children of  $x$ . The combination of level compression with path compression is termed *path-level compression*, and the result of the application of level compression to a path-compressed PR k-d tree is termed a *path-level compressed PR k-d tree*.

For example, Figure 1.53 is the path-level compressed PR k-d tree resulting from the application of level compression to the path-compressed PR k-d tree given in Figure 1.52. Notice that level compression was not applicable at the root of Figure 1.52(b) since the closest leaf or path-compressed nodes are children of the root. However, level compression was applicable at the right child of the root, say  $a$ , since the closest leaf or path-compressed nodes to  $a$  are at a depth of 2 relative to  $a$ .

Interestingly, path-level compression can be viewed as a single operation rather than treating path and level compression separately. In particular, if path compression can be applied over  $z$  levels, then path-level compression over  $z$  levels will result in two children. Furthermore, if perfect level compression can be applied over  $z$  levels (i.e., there are no leaf nodes, empty or not, at depth 1 through  $z - 1$ , and there are no empty leaf nodes at depth  $z$ ), then path-level compression over  $z$  levels results in  $2^z$  children.  $z$  is the maximum amount of level compression if all leaf nodes at depth  $z$  are nonempty, or there is at least one empty leaf node at depth  $z + 1$ . Our uniform treatment of path and level compression proceeds as follows. Starting at nonleaf node  $x$ , find the maximum depth  $w$  such that  $x$  has two sibling descendants at this and all shallower depths, where one of the descendants is a nonleaf node while the other sibling descendant is an empty leaf node. Let  $y$  be the nonleaf node descendant of  $x$  at depth  $w$ , and let  $z$  be the length of the shortest path from  $y$  to a nonempty leaf node descendant or 1 less than the length of the shortest path from  $y$  to an empty leaf node descendant, whichever is smaller. Path-level compression over  $w + z$  levels results in node  $x$  having  $2^z$  children corresponding to the  $2^z$  descendants of  $y$  at depth  $z$ .  $x$  is also labeled with a sequence of 1s and 0s corresponding to the path from  $x$  to  $y$ . Note that if  $w + z = 1$ , then no path-level compression is performed.

Figure 1.53  
A path-level compressed PR k-d tree and the records it represents corresponding to the data of Figure 1.1: (a) the resulting partition of space (nonexisting blocks corresponding to empty leaf nodes are shown shaded) and (b) the tree representation.

Our definition of the path-level compressed PR k-d tree is static in the sense that the path and level compression is performed once we have all of the data. This is fine if the data does not change too often. Updates may involve a considerable restructuring of the tree. This poses a problem in real-time applications where reduction in the search length is one of the main reasons for the use of path-level compression. Thus, the data structure must also be capable of being updated dynamically. It is clear that the insertion and deletion of a point may cause both path and level compression and decompression to take place. Path compression and decompression by themselves are fairly simple as they are local in nature and do not involve changing too many nodes. On the other hand, path compression and decompression in conjunction with level compression may result in the need for level compression and decompression, which is more costly.

Nilsson and Tikkanen [1379] describe a dynamic way of building the path-level compressed PR k-d tree that takes into account level compression by relaxing the formal requirements of when level compression and decompression must take place, thereby defining a dynamic variant of the data structure. Recall that in the formal definition of the path-level compressed PR k-d tree, a node of size  $2^z$  has exactly  $2^z$  nonempty children. In the dynamic variant of the data structure, some of the children of a node are allowed to be empty in order to reduce the frequency of level reorganizations that need to be performed in order to maintain the property that the shortest path to a leaf or path-compressed node in the path-level compressed PR k-d tree is of length  $z$ . Otherwise, the alternating action of deletion and insertion of nodes at the same level can cause repeated reorganizations.

It should be clear that level decompression (i.e., contraction or halving of the size of a nonleaf node in the path-level compressed PR k-d tree) should take place as soon as one of the children of a nonleaf node in the path-level compressed PR k-d tree becomes empty. This is equivalent to saying that the decompression should occur as soon as the shortest path from a nonleaf node to a leaf or path-compressed node in a path-compressed PR k-d tree decreases (say from  $z$  to  $z - 1$ ). Taking such an action in the path-level compressed PR k-d tree would result in much data movement, especially if nodes are deleted and inserted from the same level in alternating order. This situation is avoided by using a decompression threshold, say *low*, which sets a lower bound on the fraction of children that must be nonempty (equivalently, an upper bound on the fraction of children that can be empty). Thus, level decompression occurs only when the ratio of nonempty children to the total number of children of a node is less than *low*.

A similar principle is applied to level compression in the sense that it is performed in an anticipatory manner using a compression threshold, say *high*. Thus, given a nonleaf node  $x$  with  $2^z$  children in a path-level compressed PR k-d tree, instead of waiting for the situation that both of the  $2^z$  children of  $x$  are leaf or path-compressed nodes in the original path-compressed PR k-d tree, we perform level compression as soon as more than  $high \cdot 2^{z+1}$  of the grandchildren of  $x$  correspond to leaf or path-compressed nodes in a path-compressed PR k-d tree. Nilsson and Tikkanen [1379] found that values of 0.25 for *low* and 0.5 for *high* give good performance.

### Exercises

1. Write a pair of procedures `PLCPRKDINSERT` and `PLCPRKDDELETE` to insert and delete, respectively, data points in a path-level compressed PR k-d tree.
2. Implement the dynamic variant of the path-level compressed PR k-d tree.

#### 1.5.2.6 BD-Trees

The path-compressed PR k-d tree and the path-level compressed PR k-d tree (with perfect level compression) are unique. The price of this uniqueness is that these trees are not always balanced. In this section, we describe the BD-tree (denoting Binary Division) devised by Ohsawa and Sakauchi [1386, 1387]. It makes use of what we term *test-concatenation techniques* to test simultaneously bits from several keys, as well as several

bits from the same key, in a way that gives us freedom in choosing which data items appear in the left and right subtrees of the tree, thereby enabling the creation of a more balanced, as well as a more general, structure, but one that is not unique. The price of this freedom is that we must associate information with each nonleaf node that indicates which bit positions were tested and the value that each must have for the test to succeed, in which case the link to the left child is descended. Moreover, since the result of the test is binary (i.e., all bits must have the specified values for the test to hold), the test does not induce a partition of the underlying space into two congruent regions of space. In particular, only one of the two regions induced by the result of the test is guaranteed to be a hyperrectangle.

Although Ohsawa and Sakauchi describe the BD-tree as a bucket method for leaf nodes, in our initial discussion and example, we assume a bucket capacity of 1, which, in effect, leads to a structure that is similar to a path-compressed PR k-d tree. Nevertheless, the BD-tree in its full generality can represent a large range of block configurations and shapes, which, in fact, is far greater than that which can be obtained via the application of a PR k-d tree decomposition rule. Use of the PR k-d tree decomposition rule and the assumption of a bucket capacity of 1 means that the BD-tree can be formed in the same way as the path-compressed PR k-d tree—that is, paths in the PR k-d tree (also applicable to the PR quadtree) that consist of nonleaf nodes are compressed so that all nonleaf nodes with just one non-NIL child are eliminated. The compressed nonleaf nodes are replaced by one nonleaf node that indicates the results of the comparisons performed in accessing the first node in the path with more than one non-NIL child.

Even under these assumptions, there are still several important differences between the BD-tree and the path-compressed PR k-d tree. First of all, they differ in the format of the nonleaf nodes in the sense that, unlike the path-compressed PR k-d tree, the nonleaf nodes of the BD-tree contain more information than just the results of the comparisons that were eliminated by path compression. In particular, each nonleaf node  $a$  in the BD-tree contains a variable-length bitstring—termed a *discriminator zone expression* (DZE) by Ohsawa and Sakauchi—say  $s$ , consisting of 0s and 1s, that indicates the results of a sequence of tests involved in the formation of a PR k-d tree, starting at the root node, that lead to the formation of a region  $l$  deemed to be the left child of  $a$ .<sup>31</sup> The right child of  $a$  is accessed when the test result does not match the DZE of  $a$ . In other words, it corresponds to the part of the underlying space that remains if we do not descend to the left child of  $a$ . Thus, the right child actually corresponds to a region  $r$  that is not necessarily a hyperrectangle. This is the second important difference from the path-compressed PR k-d tree. In particular, like  $l$ ,  $r$  corresponds to a bucket or set of buckets, and, in fact, in the BD-tree, the points may lie anywhere in  $r$ . In contrast, when the BD-tree is formed in the same way as a path-compressed PR k-d tree,  $r$  is also a hyperrectangle corresponding to the minimum enclosing block for the remaining points in  $a$  (i.e., not spanned by  $l$ ) that can be generated by application of a PR k-d tree decomposition rule. Moreover, in this case, the right child of  $a$  is accessed by complementing the last binary digit of  $s$ . We say that 0 and 1 correspond to “<” and “≥,” respectively.

Figure 1.54 shows how a BD-tree is constructed in an incremental fashion for the data of Figure 1.1—that is, Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami are inserted in this order using a process that mimics the path-compressed PR k-d tree. All nonleaf nodes are labeled with their DZEs, assuming a sequence of alternating  $x, y, x, y, \dots$  tests, starting at the left end of the DZE. For example, in Figure 1.54(b), the root has a DZE of 0, which means that the left child corresponds to  $x < 50$  (i.e., the left half of the space spanned by the quadtree). As a more complicated example, the left child of the root in Figure 1.54(e) has a DZE of 000, which means that the left child of the left child of the root corresponds to  $x < 25$  and  $y < 50$ .

---

<sup>31</sup> We will see below in our more general definition of the BD-tree that the left child of  $a$  is sometimes a subset of  $l$ . More precisely, the left child of  $a$  is the intersection of the regions formed by  $a$  and  $l$ .

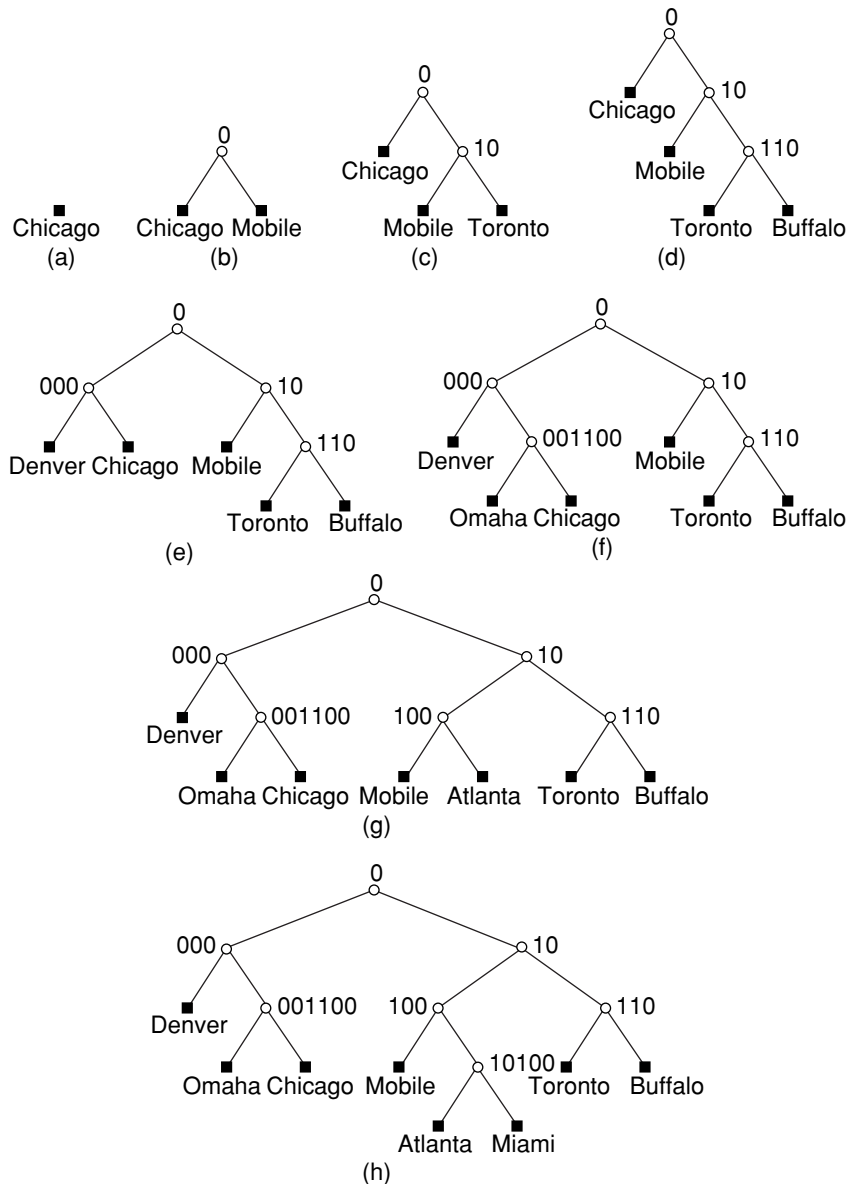

Figure 1.54 Sequence of partial BD-trees demonstrating the addition of (a) Chicago, (b) Mobile, (c) Toronto, (d) Buffalo, (e) Denver, (f) Omaha, (g) Atlanta, and (h) Miami, corresponding to the data of Figure 1.1.

Dandamudi and Sorenson [441] give a more precise and general definition of the BD-tree. They stipulate that if a node  $a$  represents a subset  $x$  of the space and is labeled with DZE  $s$ , then the left child of  $a$  corresponds to the region formed by the intersection of  $x$  and the space represented by  $s$ , while the right child of  $a$  corresponds to the region formed by the intersection of  $x$  and the complement of the space represented by  $s$ . Thus, unlike the case where the BD-tree and the path-compressed PR k-d tree were identical, we immediately see that the left child of  $a$  is not necessarily the same as the DZE  $s$  associated with  $a$  (e.g., block a in Figure 1.55(a) is a subset of the DZE 01). It is clear that using this more general definition means that there are many ways of forming a BD-tree since each region can be specified as the result of the intersection of more than one pair of regions. Thus, the BD-tree is not unique. In fact, rotation operations can be applied to reformulate the tests in the nonleaf nodes so that a greater degree of balancing is achieved. Such transformations are easy to express in terms of the DZEs [1387] and are

Figure 1.55  
(a) Example of a BD-tree with shorter DZEs at deeper levels in the tree.  
(b, c) Examples of a BD-tree and the corresponding decomposition of the underlying space that cannot be generated by a PR k-d tree splitting rule that cycles through the  $x$  and  $y$  coordinates in this order. In this example node  $c$  corresponds to a merge of (b) two nonsibling adjacent blocks and (c) two noncontiguous blocks.

often the same as the rotation operations used to preserve balance in conventional binary search trees (e.g., AVL trees [15]). Moreover, there are no restrictions on the DZEs that are used to label nodes, and, in fact, the same DZE  $s$  can be used to label more than one node since the region corresponding to the left child of  $a$  is the intersection of the space spanned by  $a$  and  $s$ , and different values of  $a$  will lead to different results unless the result is empty, in which case we have a meaningless test at  $a$ .

It should be clear that this labeling scheme includes the one that we used earlier in the analogy with the path-compressed PR k-d tree, as well as permits the generation of blocks that need not be hyperrectangles (e.g., block  $c$  in Figure 1.55(a)). It has a number of interesting features. First of all, the intersection operation enables the use of shorter DZEs at deeper levels in the tree (e.g., DZE 01 leading to block  $a$  in Figure 1.55(a)). Second, it permits the specification of block configurations that correspond to a decomposition of the underlying space that could not be generated by a PR k-d tree decomposition rule, even though all blocks are hyperrectangles (e.g., block  $c$  in Figure 1.55(b), which is the result of merging nonsibling adjacent blocks, assuming a decomposition based on alternating  $x, y, x, y, \dots$  tests starting at the left). Moreover, it permits the specification of block configurations where a node corresponds to two noncontiguous blocks (e.g., the node corresponding to block  $c$  in Figure 1.55(c)).

It is important to point out again that, unlike the variants of the PR k-d tree that we discussed (i.e., bucket, bucket PMR, path-compressed, and path-level compressed), the BD-tree does not result in the partitioning of the underlying space into a collection of hyperrectangles. In particular, the BD-tree always results in the decomposition of a region into two regions, only one of which is guaranteed to be a hyperrectangle. In this respect, the decomposition of the underlying space induced by the BD-tree is closely related to the BBD-tree [100] (see Section 1.5.2.7 for more details), the BANG file [640], and, to a lesser extent, the hB-tree [1201, 1613] and the BV-tree [643] as they do not require the use of regular decomposition (see Section 1.7.1 for more detail about these two structures). One of the differences between the BD-tree and BBD-tree is that, in the BBD-tree, the region that is not a hyperrectangle is the set difference of two hyperrectangles, while this is not necessarily the case for the BD-tree (see Section 1.5.2.7 for more on the differences between the BD-tree and the BBD-tree). Thus, the set of possible block configurations is greater for the BD-tree than the BBD-tree. We also observe that the DZE associated with node  $a$  indicates only which bit combinations of the key values should be tested in order to separate the data in the subtree rooted at  $a$ . However, it should be clear that they are not the only bits that are tested when deciding which child of  $a$  to descend as we are using the results of the tests to specify a region that is then intersected with the region corresponding to  $a$ , which may involve testing more bits. Interestingly, although the DZE has a similar format to the bitstring used in the path-compressed and path-level compressed PR k-d trees, there is really no compression taking place in the BD-tree as the DZE is only used to identify the block via the identity and values of the combinations of bits of keys when the tests are conducted starting at the root node.

It should be clear that the BD-tree can be used for data of arbitrary dimensionality. Dandamudi and Sorenson [441, 443] provide more details on how to implement basic operations on BD-trees such as insertion and deletion, as well as answer exact match, partial range, and range queries. For an empirical performance comparison of the BD-tree with some variations of the k-d tree, see Dandamudi and Sorenson [440, 442].

The or Generalized BD-tree (GBD-tree) [1388] extends the BD-tree by bucketing the nonleaf nodes as well as the leaf nodes. In particular, the number of DZEs in each nonleaf node is one less than the number of children. To accomplish traversal of the structure, the DZEs are sorted in ascending order within a node, with longer strings coming first. Search is performed by traversing the sorted list of DZEs and following the link associated with the first matching DZE (i.e., whose corresponding block contains the query point or object). In addition, each nonleaf node  $p$  contains the minimum bounding rectangles that span all of the minimum bounding rectangles associated with the children of  $p$ .

1. Write a procedure to insert a point into a two-dimensional BD-tree.
2. Write a procedure to delete a point from a two-dimensional BD-tree.
3. Write a procedure to perform a point search in a two-dimensional BD-tree.
4. Write a procedure to perform a range search for a rectangular region in a two-dimensional BD-tree.
5. Implement a BD-tree with a bucket capacity of  $c$ . In particular, write procedures to insert and delete nodes from it. The key issue is how to handle bucket overflow and underflow. Try to use techniques analogous to those used for B-trees, such as rotation of elements between adjacent buckets that are not completely full.

### 1.5.2.7 Balanced Box-Decomposition Tree (BBD-Tree)

The *balanced box-decomposition tree* (BBD-tree) [100] is closely related to the BD-tree. It differs, in part, from the BD-tree by the shapes of the underlying regions and also by always having a logarithmic depth that comes at the cost of a more complex index construction procedure. Thus, for  $N$  records, its height is always  $O(\log N)$ . The BBD-tree need not be used with bucketing, although satisfaction of the balance criterion assures that, starting with a region containing  $m$  points, after descent by a constant number of levels in the tree (at most 4, as can be seen in Exercise 1), the number of points contained within each of the subregions will be no greater than  $2m/3$  (see Exercise 2).<sup>32</sup> If this condition is not satisfied, then the offending region is split again. Unlike the BD-tree, each of the regions corresponding to a node has the shape of either a hyperrectangle or the set-theoretic difference of two hyperrectangles, one enclosed within the other. This shape condition also ensures that each of the regions is “fat”—in other words, each of the regions has an aspect ratio<sup>33</sup> less than some fixed constant. Clearly, using the Chessboard distance metric  $L_\infty$ , this ratio is at most 2 for any k-d trie, such as a PR k-d tree.

The BBD-tree is constructed as follows for a set of  $N$  points. First, a bounding hypercube that contains all these points is computed. This hypercube is the region associated with the root of the tree. The construction proceeds by recursively subdividing each region into smaller subregions and distributing the points among these regions. The points are distributed through two operations termed *split* and *shrink*. They correspond to two different ways of subdividing a region, and thus they are represented by two different types of nodes in the tree. A *split* partitions a region by a hyperplane that is parallel to the hyperplanes formed by one of the coordinate axes. A *shrink* partitions a region by a box (termed a *partitioning box*) that lies within the original region. It partitions a region into two children, one lying inside the partitioning box (termed the *inner box*) and one lying outside of it (termed the *outer box*). Figure 1.56(a) is an example of a split operation, and Figure 1.56(b) is an example of a shrink operation. If a split is performed on a region that contains an inner box, then the splitting hyperplane cannot intersect the interior of this box. If a shrink is performed on a region that has an inner box, then this inner box will lie entirely inside the partitioning box.

The BBD-tree construction algorithm is given a region and a subset of the points associated with this region. Each stage of the algorithm determines how to subdivide the current region, through the use of either a split or a shrink operation, and then distributes the points among the child nodes. We will see that the split and shrink operations each achieve a different and desirable goal. A split operation is guaranteed to decrease the geometric size of the child regions by virtue of the way in which the inner and outer

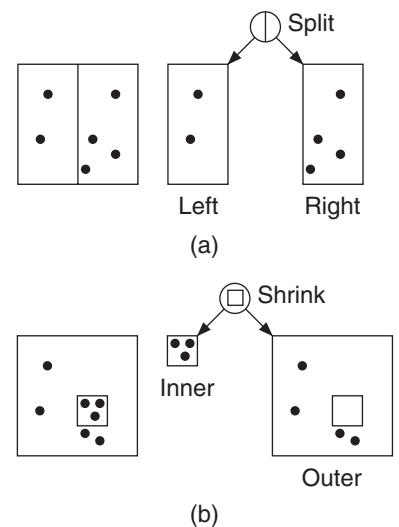

Figure 1.56 Example of (a) split and (b) shrink operations.

<sup>32</sup> Recall footnote 28 in this chapter.

<sup>33</sup> Recall from Section 1.5.1.4 that, using an appropriate distance metric, the aspect ratio of a cell is the radius of the smallest sphere that encloses the region to the radius of the largest sphere that is enclosed within the region.

Figure 1.57  
Examples of (a) midpoint split, (b) trial midpoint split, and (c) centroid shrink operations.

boxes are chosen (but after a shrink operation, only the inner child is smaller). A shrink operation is guaranteed to decrease, by a constant factor, the number of points in each of the child regions (although this may not necessarily occur as a result of a split operation unless the points are uniformly distributed), and this implies that the tree has logarithmic depth. However, a shrink operation is much more complex than a split operation. The simplest strategy is to apply split and shrink operations at alternate levels of the tree. A more practical approach is always to split (since it is a simpler operation) and to resort to shrinking only when needed to maintain logarithmic depth. This process is repeated until a region is obtained with at most one point (or at most as many points as the bucket capacity in case of the use of bucketing), after which a leaf node is generated.

A split operation is performed by a hyperplane that passes through the center of the cell and is orthogonal to its longest side (with ties broken arbitrarily). The operation is termed a *midpoint split*. If only midpoint split operations are performed, then the resulting structure is a PR k-d tree (see Figure 1.57(a)) and the regions are termed *midpoint boxes*. It is easy to see that each of the midpoint boxes will have bounded aspect ratios as the ratio of the longest to shortest side is at most 2.

Figure 1.58  
Centroid shrink with an inner box where the inner box  $i$  is separated from the region containing more than  $2m/3$  of the remaining points: (a) initial situation, (b) the corresponding BBD-tree, (c) the first midpoint split  $s$  that separates  $i$  from the region containing more than  $2m/3$  of the remaining points, and (d) the final BBD-tree.

A shrink is performed as part of a global operation, termed a *centroid shrink*, which will generally produce up to three new nodes in the tree (two shrink nodes and one split node). Let  $m$  denote the number of data points associated with the current region. Note that if the region being shrunk is an outer box of a shrink node, then  $m$  does not include the points lying within the corresponding inner box. The goal of a centroid shrink is to decompose this region into a constant number of fat subregions, each containing at most  $2m/3$  points.

The centroid shrink operation has two cases, depending on whether the current region has an inner box. We first consider the case in which the current region does not contain an inner box. A series of *trial midpoint split* operations is applied to the region (without altering the tree's structure). In each case, the recursion is applied only to the child having the greater number of points (see Figure 1.57(b)). This is repeated until the number of points in the current region is no more than  $2m/3$ . The inner box associated with this region serves as the partitioning box for the shrink operation, and thus the intermediate trial midpoint split operations are ignored. Observe that, just prior to the last split, there were at least  $2m/3$  data points, and since the recursion is applied to the subregion with the larger number of data points, the partitioning box contains at least  $m/3$  points. Thus, there are at most  $2m/3$  points either inside or outside the partitioning box (see Figure 1.57(c)).

We now consider the case in which the current region contains an inner box (see Figure 1.58(a) and the corresponding tree in Figure 1.58(b), where  $A$  corresponds to the shrink node and  $i$  is the inner box). In this case, the repeated application of the above procedure might create a region with two inner boxes, which is prohibited by our definition of a region. This situation is remedied by use of a decomposition process that has at most three stages corresponding to a shrink, a split, and a shrink operation, in that order. Recall that  $i$  is the current inner box. Perform the trial-splitting process as in the case described above, where the current region did not contain an inner box, until one of the following two situations arises:

- The first split  $s$  of the current region occurs that separates  $i$  from the region that contains more than  $2m/3$  of the remaining points (i.e., splits the region containing  $i$  from the region containing more than  $2m/3$  of the remaining points). Let  $b$  denote the region that was just split (see Figure 1.58(c)). Now, create a shrink node  $B$  whose partitioning box is  $b$ , and make node  $B$  the child corresponding to the outer box of  $A$ . Next, create a split node  $C$  corresponding to the split  $s$  that separates the majority of the points from  $i$ , and make  $C$  the child corresponding to the inner box of  $B$ . Now that the inner box  $i$  has been eliminated, we simply continue with the procedure described above for the case in which the current region does not contain an inner box, where a new shrink node  $D$  has been created with a partitioning box  $e$  (see Figure 1.58(d)).
- The current region contains  $i$  and has no more than  $2m/3$  of the points (where  $m$  does not include the points in  $i$ ). Therefore,  $i$  is nested within the partitioning box, which is fine. Let  $b$  denote the current region (see Figure 1.59(c)). Now, create a shrink node  $B$  whose partitioning box is  $b$ , and make node  $B$  the child corresponding to the outer box of  $A$ .

As a more complex example, consider Figure 1.60, which has 21 points. We start with a set of trial midpoint splits, always recursing on the side having more points (see Figure 1.60(a)). The first centroid shrink is obtained when we encounter a cell that contains 14 points, which is  $2m/3$  (see Figure 1.60(b) and the corresponding tree in

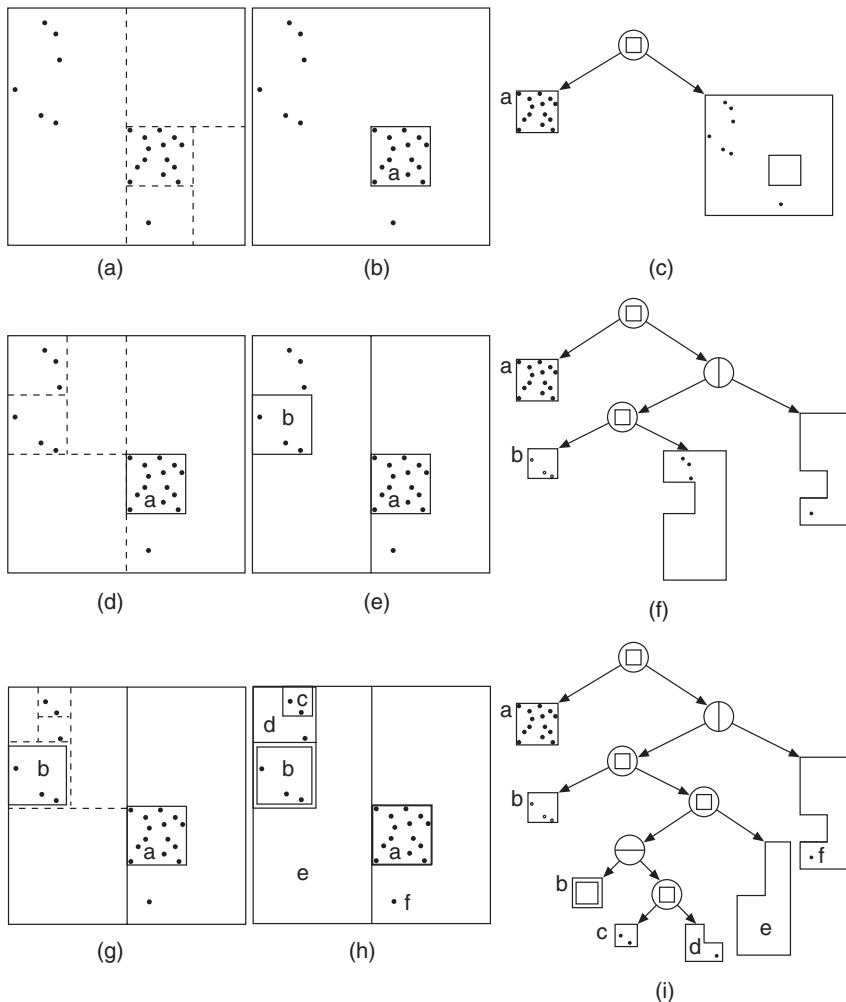

Figure 1.60  
Complex example of the construction of a BBD-tree for a set of 21 points: (a), (d), and (g) denote trial midpoint splits with (b), (e), and (h) denoting their corresponding centroid shrinks, with corresponding trees in (c), (f), and (i).

## Section 1.5 K-D TREES

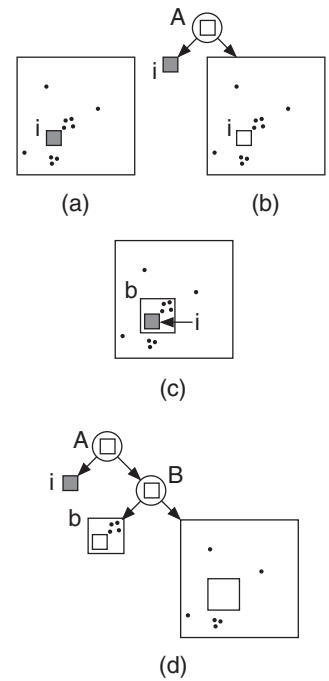

Figure 1.59  
Centroid shrink with an inner box where the inner box  $i$  is not separated from the region containing more than  $2m/3$  of the points. (a) Initial situation, (b) the corresponding BBD-tree, (c) the first midpoint split where neither of the regions contains more than  $2m/3$  of the points and one of the resulting regions  $b$  contains  $i$ , and (d) the final BBD-tree.

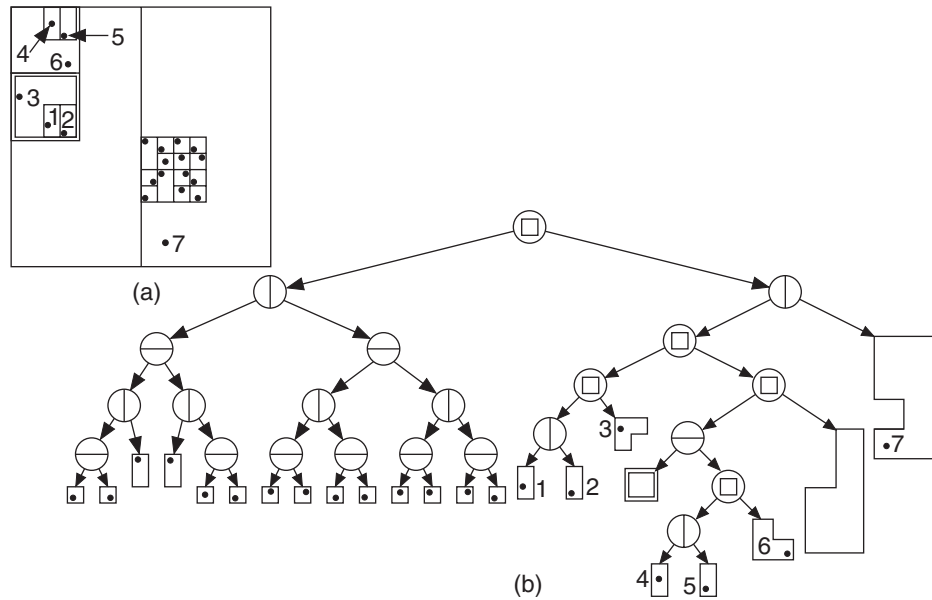

Figure 1.61  
(a) Final decomposition and (b) its corresponding BBD-tree for the complex example in Figure 1.60.

Figure 1.60(c)). This cell, labeled a in Figure 1.60(b), corresponds to the inner box that will be subsequently decomposed further, but this is easy because we will need only midpoint splits (see Figure 1.61) when using the more practical approach to the construction of a BBD-tree discussed earlier.

Next, we decompose the outer box, which contains the remaining seven points. Again, we perform trial midpoint splits until producing a cell that contains three points (see Figure 1.60(d)). We could use either the cell in the upper left or the one immediately below as the inner box to complete the centroid shrink operation. We use the one immediately below (i.e., the one labeled b in Figure 1.60(e)). We cannot apply a shrink operation immediately at this point since this would produce a cell having two inner boxes. Therefore, we introduce the center vertical split to separate these two inner boxes. On the left side of this split, we apply a shrink operation (see Figure 1.60(e), whose corresponding tree is given in Figure 1.60(f)). Note that, in this case, we applied only a midpoint split and shrink operation as there was no need for an initial shrink operation to yield a centroid shrink.

At this point, we want to decompose the region that lies to the left of the vertical split and outside the inner box labeled b in Figure 1.60(g). There are a total of three points. We perform trial midpoint splits until we succeed in separating two points from the third (see the upper left of Figure 1.60(g)). This is the inner box labeled c in Figure 1.60(h). However, again, we cannot apply a shrink at this point as we need to separate inner box b from inner box c in Figure 1.60(h). To do this, we perform a shrink to surround these two boxes, then separate them with a horizontal line via a midpoint split and conclude by applying a shrink to the desired box c (see Figure 1.60(h), whose corresponding tree is given in Figure 1.60(i)). Notice that the tree in Figure 1.60(i) has two nodes labeled b. The one at the shallower level corresponds to an inner box, and the one at the deeper level corresponds to an outer box that is empty as the inner box completely fills the cell.

Finally, we need to decompose the regions a, b, and c, although we do not explain it here (see Figure 1.61(a) and the corresponding tree in Figure 1.61(b)). Notice that in the decomposition of region a, shrinking was not necessary, and thus we used repeated split operations as in the more practical approach for the construction of the BBD-tree discussed earlier.

The fact that centroid shrink operations are performed at every other level of the BBD-tree implies that the total number of nodes in the tree is  $O(N)$  and that the BBD-tree has  $O(\log N)$  height. It is easy to verify that every region has a bounded aspect ratio (because the inner boxes are a result of repeated midpoint split operations, which produce regions with an aspect ratio of at most 2) and that each leaf of the BBD-tree contains only a constant number of points. The use of midpoint splits guarantees that the partitioning hyperplanes do not intersect the interior of inner boxes.

Since the height of the BBD-tree is  $O(\log N)$ , and as at each level we must examine the  $N$  points for distribution into the appropriate children, the BBD-tree can be constructed in  $O(dN \log N)$  time [100]. A direct implementation of the BBD-tree construction procedure given above is not efficient, however, because if the points in a cell are densely clustered in a very small region, then the number of midpoint splits needed to find the partitioning box cannot generally be bounded by a function of  $m$ . In particular, the number of necessary midpoint split operations depends on the minimum separation between the points. One way to remedy this problem is to compute the smallest midpoint box  $t$  that contains the data points prior to each split [396]. This remedy works because once  $t$  has been computed, the very next midpoint split operations will achieve a nontrivial partition of the points. Another implementation issue is how to partition the points after each split efficiently (see, e.g., [1908]).

As we pointed out before, it should be clear that the BBD-tree is somewhat similar to the BD-tree. Nevertheless, there are some differences. In particular, recall that one of the main differences is that the decomposition of space induced by a node in the BBD-tree is guaranteed to be either two hyperrectangles, or a hyperrectangle and the set difference of two hyperrectangles, while in the BD-tree the second region can be of arbitrary complexity. This increase in the complexity of the regions in the BD-tree makes it difficult to compute distances to the region, thereby complicating processes (such as nearest neighbor finding) that attempt to prune some regions from consideration.

Another difference between the BD-tree and the BBD-tree is that one usually knows all of the data points before building the BBD-tree (i.e., it is static using our characterizations), and the resulting height is always logarithmic, while the BD-tree is built one point at a time as the data points are encountered, and the attainability of the height bound is dependent on the number of rotations that are applied. However, see [207] for a variant of the BBD-tree that supports dynamic insertion and deletion.

Finally, the motivation for the BBD-tree is to support finding nearest neighbors efficiently by sometimes resorting to returning the approximate nearest neighbor (thereby looking at a predictable fraction of the data points rather than possibly having to look at all of the points in the worst case), which enables the attainment of an execution time bound that is inversely proportional to the approximation error tolerance  $\varepsilon$  [100] (see Section 4.3 of Chapter 4). The BBD-tree is used to support this purpose in the ANN library for approximate nearest neighbor searching [1319]. In contrast, the motivation for the BD-tree is to support good dynamic behavior as well as efficient exact match and partial range queries.

### Exercises

1. Suppose that split and shrink operations are applied at alternate levels of the BBD-tree. Show that, starting with a region containing  $m$  points, the number of points contained within each of the subregions will be no greater than  $2m/3$  after descent by at most four levels in the tree.
2. Consider a BBD-tree cell that has no inner box and contains  $b$  points. It was argued earlier that there exists a shrink operation that partitions this cell into an inner and outer box, each having no more than  $2b/3$  points. Assuming that shrinks are based on midpoint splits, is it possible to prove that for any  $x$ , where  $1/2 < x < 1$ , there exists a shrink operation so that neither box has more than  $b \cdot x$  points?

### 1.5.3 Conjugation Tree

The conjugation tree of Edelsbrunner and Welzl [546] (also termed the *Ham-Sandwich tree* [540]) is an interesting combination of a pseudo quadtree [1444] (Section 1.4.1.2), a pseudo k-d tree (Section 1.5.1.4), and a BSP tree [658] (Section 1.5.1.4) for points in the two-dimensional plane, while not being an instance of either of the structures. The motivation of the conjugation tree is to obtain a balanced structure where each quadrant contains approximately the same number of points.

The conjugation tree is formed as follows. Find a line  $L$  that bisects  $S$  into three subsets  $S_{left}(L)$ ,  $S_{right}(L)$ , and  $S_{on}(L)$ , which correspond to the points that are to the left of, to the right of, and on  $L$ , respectively. Moreover, the size of each of the subsets  $S_{left}(L)$  and  $S_{right}(L)$  is bounded by  $N/2$ . If  $N$  is odd, then  $S_{on}(L)$  cannot be empty, and in this case the bisecting line is unique if its direction is given. Next, find another line  $L'$ , termed the *conjugate* of  $L$ , which simultaneously splits each of the point sets evenly (i.e., bisects them). Willard [2000] has shown that such a line is guaranteed to exist (also known as the *Ham-Sandwich Theorem*).<sup>34</sup> Once  $L'$  has been found, the same process is applied to find a conjugate for  $L'$ , and so on. Each node in the conjugation tree contains the partitioning line segment  $L$ , pointers to the two subtrees, the number of points in the two subtrees, and the identity of the points that lie on  $L$ . The process halts when no points are left—that is, all points lie on some line, and thus  $S_{left}(i)$  and  $S_{right}(i)$  are empty for all lines  $i$ .

For example, Figure 1.62(a) is an example of the partition of the underlying space induced by a conjugation tree for the set of points given in Figure 1.1, augmented by eight additional points, P1–P8; Figure 1.62(b) shows the resulting tree, with the interior nodes labeled with the name of the partitioning line that caused its creation. It should be clear that the conjugation tree is a variant of a balanced pseudo quadtree and k-d tree, as well as a BSP tree. We use the characterization “pseudo” since the data is usually stored in the leaf nodes unless the partitioning lines coincide with some points. The structure is more like a BSP tree since the partitioning lines need not be axis-parallel; nor must they be orthogonal. The structure is neither a point quadtree nor a k-d tree since the partitions of the point sets that are induced by the conjugate lines are not carried out independently. In contrast, recall that in a point quadtree (k-d tree) each quadrant (half) is partitioned in a manner that is independent of its siblings, whereas this is not the case in the conjugation tree.

The conjugation tree is used by Edelsbrunner and Welzl to solve the halfplanar range search problem, which simply counts the number of points in a halfspace in  $O(N^{0.695})$  time and  $O(N)$  space (see Exercise 1). It is interesting to observe that the halfplanar range search problem is related to the point dominance problem that can be used to find the number of points in a hyperrectangular search region using an ECDF tree [180] (see Exercise 14 in Section 1.1). The conjugation tree can also be used to solve the line search problem that returns the number of points that lie on a given line segment. In this case, there is no need to keep track of the number of points in each subtree.

#### Exercises

1. Edelsbrunner and Welzl [543] use the following algorithm to perform a halfplanar range search (i.e., determine the number of points  $c$ ) in a halfspace  $h$  in two-dimensional space. Let  $g$  denote the line that bounds  $h$ . Let  $range(v)$  be the range of the space spanned by a node  $v$ , and let  $int(v)$  be the intersection of  $g$  and  $range(v)$ . Initialize  $c$ , the count of the number of points in  $h$ ,

<sup>34</sup> This theorem is really a discrete version of the Borsuk-Ulam Theorem [235, 540]. It is termed the *Ham-Sandwich Theorem* because of the analogy to the result of slicing a sandwich of ham so that there are two parts of equal amounts of bread and ham [540].

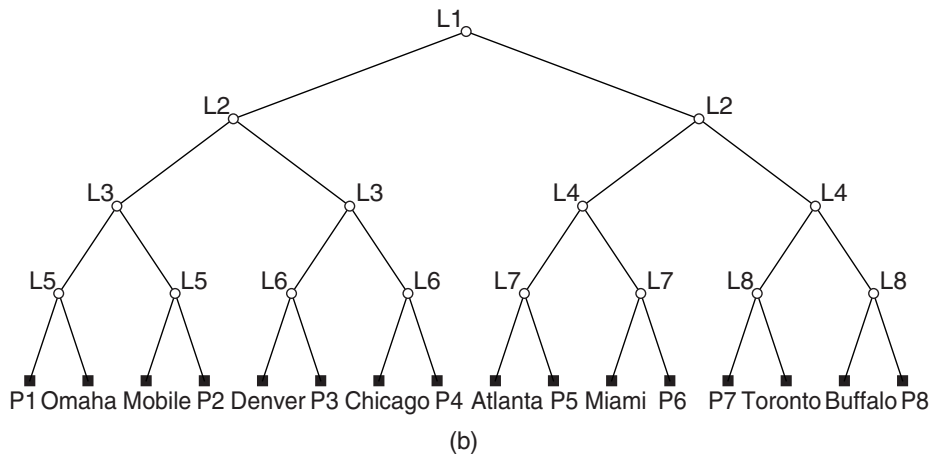

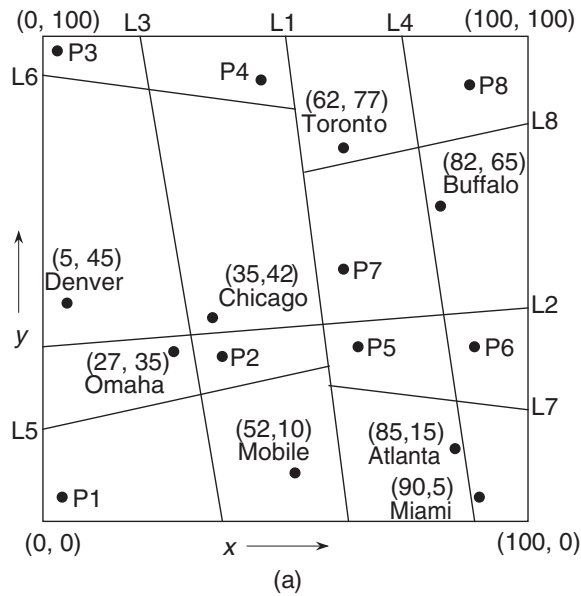

Figure 1.62  
A conjugation tree and the records it represents corresponding to the data of Figure 1.1 augmented by eight additional points, P1–P8: (a) the resulting partition of space and (b) the tree representation with the interior nodes labeled with the name of the partitioning line that caused its creation.

to 0. Perform a search starting at the root, and at each node  $v$ , check the value of  $int(v)$ . There are two cases. If  $int(v)$  is empty, then  $range(v)$  is either contained in  $h$ , or its intersection with  $h$  is empty. In the former case, all points in the subtrees of  $v$  are in  $h$ , and  $c$  is incremented accordingly. In the latter case, no action is taken. If  $int(v)$  is nonempty, then  $c$  is increased by the number of points in  $S_{on}(v)$  that belong to  $h$ , and the two children are visited recursively, if they exist. Prove that this algorithm can be executed in  $O(N^{0.695})$  time.

- The conjugation tree is used to obtain a balanced structure in two dimensions, where each quadrant contains approximately the same number of points. This is achieved by appealing to the Ham-Sandwich Theorem, which guarantees the existence of a line in two dimensions that splits two point sets evenly. In  $d$  dimensions, the same theorem means that there exists a  $D$ -dimensional hyperplane  $h$  that simultaneously bisects  $d$  point sets  $P_1, P_2, \dots, P_d$ .  $h$  is called a *Ham-Sandwich cut*. How can you obtain similar results in three dimensions and higher? In particular, can you construct an analog of the conjugation tree that would be balanced in a similar manner?

## 1.6 One-Dimensional Orderings

When point data is not uniformly distributed over the space from which it is drawn, then using the fixed-grid representation means that some of the grid cells have too much data associated with them. The result is that the grid must be refined by further partitions. Unfortunately, this leads to the creation of many empty grid cells, thereby wasting space. In Sections 1.4 and 1.5 we described how to eliminate some of the empty cells by aggregating spatially adjacent empty grid cells to form larger empty grid cells. However, not all spatially adjacent empty grid cells can be aggregated in this manner as the identities of the ones that can be aggregated are a function of the specific tree-based space decomposition process that was applied to generate them. In particular, recall that both the quadtree and the k-d tree are the result of a recursive decomposition process, and thus only empty grid cells that have the same parent can be aggregated.

In this section, we describe how to eliminate all empty grid cells by ordering all the grid cells (regardless of whether they are empty) and then imposing a tree access structure such as a balanced binary search tree, B-tree, and so forth, on the elements of the ordering that correspond to nonempty grid cells. The ordering is really a mapping from the  $d$ -dimensional space from which the data is drawn to one dimension. The mapping that is chosen should be invertible. This means that given the position of a grid cell in the ordering, it should be easy to determine its location. When the grid cells are not equal-sized but still result from a fixed grid, then we must also record the size of the nonempty grid cells.

There are many possible orderings with different properties (see Figure 2.5 and the accompanying discussion in Section 2.1 of Chapter 2). The result of drawing a curve through the various grid cells in the order in which they appear in the ordering is called a *space-filling curve* (e.g., [1603]). In this section, we elaborate further on two orderings: bit interleaving and bit concatenation. When all the attributes are either locational or numeric with identical ranges, then the orderings are applicable to the key values, as well as the locations of the grid cells. On the other hand, when some of the attributes are nonlocational, then the orderings are applicable only to the locations of the grid cells. In the latter case, we still need to make use of an additional mapping from the actual ranges of the nonlocational attribute values to the locations of the grid cells. We do not discuss this issue further here.

Bit interleaving consists of taking the bit representations of the values of the keys making up a record and forming a *code* consisting of alternating bits from each key value. For example, for  $d = 2$ , the code corresponding to data point  $A = (X, Y) = (x_m x_{m-1} \dots x_0, y_m y_{m-1} \dots y_0)$  is  $y_m x_m y_{m-1} x_{m-1} \dots y_0 x_0$ , where we arbitrarily deem key  $y$  to be the most significant. Figure 1.63 is an example of the bit interleaving mapping when  $d = 2$ . We have also labeled the codes corresponding to the cities of the example point set of Figure 1.1, which correspond to bit interleaving the result of applying the mapping  $f$  defined by  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$  to the values of the  $x$  and  $y$  keys, respectively. Recall that the same mapping was used to obtain the MX quadtree of Figure 1.29. The drawback of using bit interleaving is the fact that it is not performed efficiently on general computers. Its complexity depends on the total number of bits in the keys. Thus, in  $d$  dimensions, when the maximum depth is  $n$ , the work required is proportional to  $d \cdot n$ .

Bit concatenation consists of concatenating the key values (e.g., for data point  $A$ , the concatenated code would be  $y_m y_{m-1} \dots y_0 x_m x_{m-1} \dots x_0$ ). Bit concatenation is the same as row order or column order (depending on whether the  $y$  coordinate value or  $x$  coordinate value, respectively, is deemed the most significant). It is a classical ordering for storing images and is also known as *raster scan* or *scan order*.

Above, we have shown how to apply the orderings to the key values. Applying the orderings to the locations of the grid cells is easy. We simply identify one location in each grid cell  $c$  that serves as the representative of  $c$ . This location is in the same relative

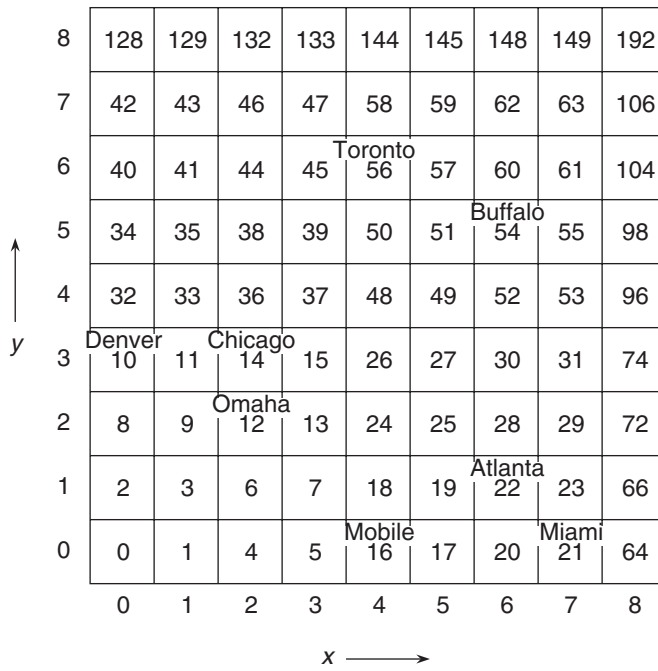

Figure 1.63  
Example of the result of applying the bit interleaving mapping to two keys ranging in values from 0 to 8. The city names correspond to the data of Figure 1.1, scaled by a factor of 12.5 to fall in this range.

position in all of the grid cells (e.g., in two dimensions, this could be the location in the lower-left corner of each grid cell). Once the location has been identified, we simply apply the ordering to its corresponding key values. Again, if the grid cells can vary in size, then we must also record their size.

It should be clear that, in light of our interest in range searching, bit interleaving is superior to bit concatenation since the latter results in long, narrow search ranges, whereas the former results in squarer search ranges. This argument leads to the conclusion that bit concatenation is analogous to the inverted list method, while bit interleaving is analogous to the fixed-grid method. In fact, bit concatenation results in the records' being sorted according to a primary key, secondary key, and so on.

Range searching using a tree-based representation of the result of applying a one-dimensional ordering is fairly straightforward. Below, we show how it is performed for a binary search tree by an algorithm proposed by Tropf and Herzog [1891]. We use Figure 1.64, which is the binary search tree corresponding to the key values of Figure 1.1, encoded using bit interleaving as in Figure 1.63. The range is specified by the minimum and maximum codes in the search area. For example, to find all the cities within the rectangular area defined by (25,25), (50,25), (50,63), and (25,63), represented by codes 12, 24, 50, and 38 (see Figure 1.65), respectively, we must examine the codes between 12 and 50. The simplest algorithm is recursive and traverses the binary search tree starting at its root. If the root lies between the minimum and maximum codes in the range, then both subtrees must be examined (e.g., code 21 in Figure 1.64). Otherwise, one subtree needs to be searched (e.g., the left subtree of code 54 in Figure 1.64).

This algorithm is inefficient because many codes lie in the range between the minimum and maximum codes without being within the query rectangle, as illustrated by the two staircases in Figure 1.65. Codes above the upper staircase are greater than the maximum search range code; codes below the lower staircase are less than the minimum search range code. All remaining codes are potential candidates; yet, most are not in the query rectangle.

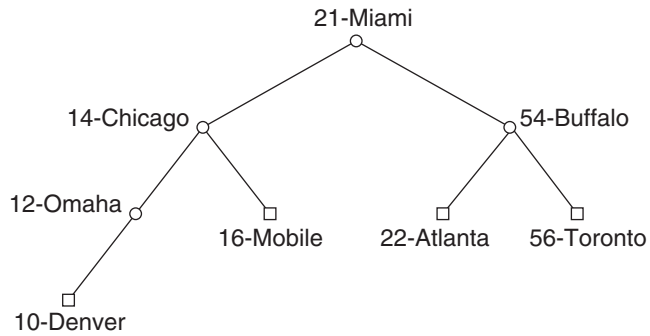

Figure 1.64  
A binary search tree corresponding to the data of Figure 1.1, encoded using bit interleaving as in Figure 1.63.

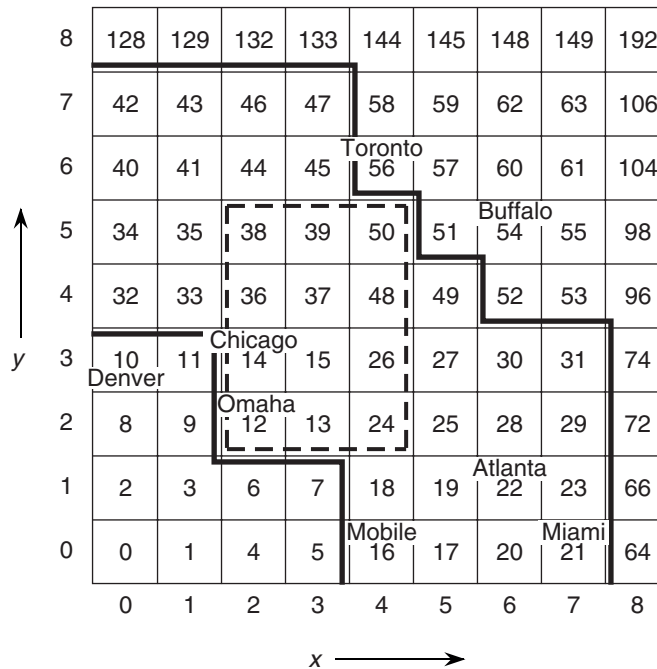

Figure 1.65  
Illustration of the range search process when using bit interleaving.

To prune the search range when the root lies within the search range (e.g., code 21 in Figure 1.64), Tropf and Herzog define two codes, termed LITMAX and BIGMIN, which correspond to the maximum code in the left child and the minimum code in the right child, respectively, that are in the query rectangle. The subsequent search of the left child uses LITMAX as the maximum code in the range (e.g., 15 in the left subtree of Figure 1.64), and the search of the right child uses BIGMIN as the minimum code in the range (e.g., 24 in the right subtree of Figure 1.64), with the result that many codes are eliminated from consideration (e.g., codes between 16 and 23 in Figure 1.64) after examination of the root for the query rectangle between 12 and 50.

Experiments reported by Tropf and Herzog [1891] show that, given  $N$  records, for small hypercube ranges, the average number of records inspected is  $O(d \cdot \log_2 N + F)$ , where  $F$  is the number of records found. White [1992] shows how to perform the same task when using a B-tree as the underlying representation with the same order of execution time.

As pointed out earlier, the ordering methods that we have described can be applied to any of the representations that make use of a recursive decomposition process to generate a set of grid cells of unequal size. In this case, recall that since the mapping is no longer onto, we also need to record some information to enable us to determine the size of the grid cell. A simple, and different, way to obtain an ordering is to traverse the underlying tree access structure and assign successively higher numbers to the grid cells. The problem with such an approach is that there is no simple correlation between the number that is assigned to the grid cell and its actual location in space (i.e., the mapping is not invertible).

An alternative, and preferable, solution is to assign a unique number to each grid cell  $c$  in the resulting space decomposition, based on the path from the root of the access structure to  $c$ , and to record some information about the size of the partition that takes place at each level of the tree. In fact, this approach is equivalent to the solution that we proposed at the start of this section, which represents each nonempty block consistently by some easily identifiable location in the block (e.g., the one in the lower-left corner of the block) and then applies the mapping (e.g., bit interleaving) to it. The result of the mapping is stored in the one-dimensional access structure, along with the size information. In fact, this is the basis of a linear index into a two-dimensional spatial database developed by Morton [1317] (frequently referred to as a *Morton order*, where the result of applying the mapping to a block is referred to as its *Morton number*) and refined later by several other researchers, including Gargantini [684] and Abel and Smith [8].

As we can see, bit interleaving is quite a powerful idea. In the rest of this section, we give a brief historical background of its development and mention an interesting application. It is difficult to determine the origin of the notion of bit interleaving. The first mention of it was by Peano [1478]. Bentley [164] attributes bit interleaving to McCreight as a way to use B-trees to represent multidimensional data. The resulting B-tree is called an *N-tree* by White [1992], while Orenstein and Merrett [1420] term it a *zkd Btree*. Note that the result is different from the k-d-B-tree of Robinson [1567] (see Section 1.7.1.1). It was proposed by Tropf and Herzog [1891] to give a linear order to multidimensional data and to access it via a binary search tree or balanced variant thereof. Orenstein and Merrett [1420] use the term *Z order* to denote the resulting ordering, while reviewing its use in several data structures in the context of range searching. They use the Z order to build a variant of a binary search tree that they term a *zkd tree*, while cautioning that it differs from the conventional k-d tree since an inorder traversal of a k-d tree does not necessarily yield the nodes in Z order.

An interesting twist on bit interleaving that is claimed to improve the efficiency of partial range queries, and potentially also of range queries, is reported by Faloutsos [581]. The idea is to ensure that the codes of successive points in the result of bit interleaving differ by just one bit. The rationale for this idea is based on the belief of Faloutsos that diagonal transitions between successive points  $a$  and  $b$  in the ordering, as is the case for the Z order that characterizes the result of the conventional use of bit interleaving, are undesirable because they result from the fact that at least two values of corresponding bit positions in the binary representations of the key values of  $a$  and  $b$  are not the same. This is most visible when performing a partial range (i.e., partial match) query.

An encoding where the codes of successive points differ by just one bit is known as a *Gray code* [745] (see, e.g., [1264]).<sup>35</sup> It can be achieved by making sure that the transitions between successive points in the ordering are either in the horizontal direction

---

<sup>35</sup> The Gray code is motivated by a desire to reduce errors in transitions between successive gray-level values. Its one-bit difference guarantee is achieved by the following encoding. Consider the binary representation of the integers from 0 to  $2^m - 1$ . This representation can be obtained by constructing a binary tree, say  $T$ , of height  $m$ , where each left branch is labeled 0 while each right branch is labeled 1. Each leaf node, say  $P$ , is given the label formed by concatenating the labels of the branches taken by the path from the root to  $P$ . Enumerating the leaf nodes from left to right yields the binary integers 0

Figure 1.66 Orderings induced on points from  $\{0, 1, 2, 3\}$  and the result of the partial range query  $x \geq 2$  shown shaded: (a) Gray-coded key values and Gray-coded result of bit interleaving (double Gray order), (b) bit interleaving without Gray codes (Z order), (c) Gray-coded result of bit interleaving (Gray order), and (d) bit concatenation with  $y$  being more significant than  $x$ .

or in the vertical direction (assuming two-dimensional data) but not in both directions. This property is guaranteed to hold if only one bit in the binary representation of just one of the values of the keys changes with each transition. Faloutsos [581] achieves this by using a Gray code to encode each of the keys, and then making horizontal and vertical transitions between the encoded key values. For example, Figure 1.66(a) is the result of using a Gray code to encode the set of two-dimensional points from  $\{0, 1, 2, 3\}$ , and the arrows show the resulting ordering on the Gray-encoded values of the keys of the points, which has also been subjected to a Gray code. The shape of the ordering resulting from this encoding should be compared with Figure 1.66(b), which illustrates the situation when bit interleaving is applied without the prior application of the Gray code. The effect is to replace the diagonal transitions in Figure 1.66(b) with horizontal or vertical transitions in Figure 1.66(a).

In fact, the same effect of guaranteeing that the codes of successive points in the result of bit interleaving differ by one bit can be achieved by making sure that only one bit in the binary representation of the values of just one of the keys changes with each transition between successive elements of the result of bit interleaving the binary representations of the key values. This can be seen by the ordering given in Figure 1.66(c) (termed a *Gray order*). Thus, we see that there is no need to use a Gray code to encode the individual keys. In essence, Faloutsos applies the Gray code twice, once for each of the key values and once to the result of bit interleaving the Gray-coded key values. We use the term *double Gray order* to describe such an order. It is also interesting to observe that encoding the individual keys with the Gray code, as in the double Gray order suggested by Faloutsos [581], results in increasing the average distance in the original space between two successive points to 2.00, in contrast to 1.50, when only the result of the bit interleaving is encoded with a Gray code (Gray order), and 1.67, when no Gray coding is applied at all to the result of bit interleaving (Z order). An even lower average distance of 1.43 is obtained by using the U order proposed by Schrack and Liu [1698, 1192], which is analogous to the Z order, where the basic recursive pattern is a “U” instead of a “Z.” For more detail on the derivation of this average distance, see Exercise 8 in Section 2.1.1.2 of Chapter 2.

In order to see the possible advantage using Gray code variants or the U order in a partial range query, suppose that  $k = 2$ , and the keys are  $x$  and  $y$  with ranges between 0 and 3. The query  $x \geq 2$  means that we need to examine only one cluster of points (e.g., the shaded portion of Figure 1.66(a)) when bit interleaving is applied after coding the keys with their Gray codes (but see Exercise 6)—that is, using the double Gray order. In contrast, for the same query, using bit interleaving without a Gray code, termed a *Gray order*, means that we must examine two clusters of points (e.g., the shaded portion of Figure 1.66(b)). The same result holds when we just use the U order. Using bit concatenation such that key  $y$  is more significant than  $x$ , the same query requires that we examine four clusters of points (e.g., the shaded portion of Figure 1.66(c)).

Depending on how the data is structured, a multiplicity of clusters may have a significant impact on the cost of retrieving the answer. Variants of the Gray code and the U orders increase the size of the clusters for some instances of partial range queries. Faloutsos [582] has shown that for a partial range query, using the double Gray order never increases the number of clusters and can reduce the number of clusters by at most 50%. Faloutsos further conjectures that the use of the double Gray order has a similar

---

to  $2^m - 1$ . The Gray codes of the integers are obtained by constructing a new binary tree, say  $TP$ , such that the labels of some of the branches in  $TP$  are the reverse of what they were in  $T$ . The algorithm is as follows. Initially,  $TP$  is a copy of  $T$ . Next, traverse  $T$  in preorder (i.e., visit the root node, followed by the left and right subtrees). For each branch in  $T$  labeled 1, exchange the labels of the two descendant branches of its corresponding branch in  $TP$ . No action is taken for descendants of branches in  $T$  labeled 0. Enumerating the leaf nodes in  $TP$  from left to right yields the Gray codes of the integers 0 to  $2^m - 1$ . For example, for 8 gray levels (i.e.,  $m = 3$ ), we have 000, 001, 011, 010, 110, 111, 101, 100.

effect on range queries, although, at the present, this is an open problem. Note that these properties should also hold for the Gray and U orders. The overhead cost incurred by using Gray codes is that of the conversion process from a binary representation, which is linear in the size of the codeword [1551].

### Exercises

1. Write an algorithm to perform bit interleaving of the  $x$  and  $y$  coordinate values of a point in an efficient manner.
2. Write a procedure `BiSEARCH` to perform a range search for a rectangular region in a two-dimensional database implemented as a binary search tree with bit interleaving as the mapping function.
3. Assume a  $d$ -dimensional database implemented as a B-tree with bit interleaving as the mapping function. Write a procedure `BTreeSEARCH` to perform a range search for a  $d$ -dimensional rectangular region.
4. Given a database of  $N$  records, prove that for a small, rectangular  $d$ -dimensional region, the range search in Exercise 3 takes  $O(d \cdot \log_2 N + F)$  time, where  $F$  is the number of records found.
5. Give an algorithm for converting between a binary representation and a Gray code and vice versa.
6. Give an example partial range query involving keys  $x$  and  $y$  with ranges between 0 and 3 such that the use of Gray codes on the result of interleaving (i.e., double Gray order), as well as Gray order and U order, does not result in a decrease in the number of clusters from the number of clusters that result from normal bit interleaving.
7. Prove that for partial range queries, using Gray codes prior to bit interleaving (i.e., double Gray order) never increases the number of clusters and can reduce them by a maximum of 50%.
8. Derive a method of enumerating all the possible partial range queries for two keys. Also, evaluate the expected number of clusters when using bit concatenation, bit interleaving, and bit interleaving using Gray codes.
9. What is the effect on range queries of bit interleaving using Gray codes (e.g., using a double Gray order, Gray order, and even a U order)?
10. One of the problems with the Gray code encoding is the existence of long horizontal and vertical transitions between successive elements in the order. Find an ordering that avoids this problem (see Section 2.1.1.2 of Chapter 2).

## 1.7 Bucket Methods

When the data volume becomes very large, much of the data resides in secondary storage (e.g., disk) rather than in main memory. This means that tree access structures such as the quadtree and k-d tree variants discussed in Sections 1.4 and 1.5, which are based on making between 1 and  $d$  tests at each level of the tree, become impractical due to the limited fanout at each node. The problem is that each time we have to follow a pointer, we may have to make a disk access. This is far costlier than indirect addressing, which is the case when the tree resides entirely in main memory. This has led to the development of what are termed *bucket methods*.

There are many different bucket methods, as well as ways to distinguish between them. One way to do so is by noting whether they organize the data to be stored or the embedding space from which the data is drawn. An alternative, and the one we follow in this section, is to subdivide them into two principal classes. The first class consists of aggregating the data objects in the underlying space. The second class consists

of decompositions of the underlying space with an appropriate access structure. It is important to note that not all of the methods can be classified so distinctly: some of them can be made to fit into both classes. We do not dwell on this issue further in this chapter.

The first class aggregates the actual data objects into sets (termed *buckets*), usually the size of a disk page in secondary memory so that the buckets are as full as possible. These methods still make use of a tree access structure, where each node in the tree is the size of a disk page, and all leaf nodes are at the same level. Thus, the fanout is much larger than in the quadtree (and, of course, the k-d tree). It should be clear that decomposing the underlying space is not a goal of these representations. Instead, they are more accurately classified as object hierarchies since they try to aggregate as many objects (points in our case) as possible into each node. When the nodes are too full, they are split, at which time some of the representations (e.g., the R-tree [791]) attempt to aggregate spatially proximate objects in the nodes resulting from the split. However, there is no guarantee that the space spanned by the collections of objects in the nodes (e.g., their convex hull, minimum bounding box, minimum bounding circle) is disjoint.

Nondisjointness is a problem for search algorithms because the path from the root of such structures (e.g., an R-tree) to a node that spans the space containing a given data point or object is not necessarily unique. In other words, the data point or object can be covered by several nodes of the R-tree; yet, it is found in only one of them. This results in more complex searches. No such problems exist when the decomposition of the space spanned by the collections of objects in the nodes is disjoint. Examples of such methods include the  $R^+$ -tree [593, 1718, 1803], which is really a k-d-B-tree [1567] with bounding boxes around the portions of space resulting from the decomposition. When the data objects have extent (e.g., nonpoint objects such as rectangles and lines), the disjointness requirement of these representations may result in decomposing the individual objects that make up the collection at the lowest level into several pieces. The disjointness requirement is usually expressed in the form of a stipulation that the minimum bounding boxes of the collection of objects at the lowest level of the tree (i.e., at the leaf nodes) be disjoint instead of that the minimum bounding boxes of the individual objects be disjoint.<sup>36</sup> The price that we pay for disjointness is that there is no longer a guarantee that each node will be as full as possible.

Neither the nondisjoint nor the disjoint object aggregation methods is discussed further in this chapter as each is covered in great detail in Sections 2.1.5.2 and 2.1.5.3, respectively, of Chapter 2, where their usage is discussed for nonpoint objects (e.g., region data). Of course, that discussion is also applicable for point data.

The above methods that are based on a disjoint decomposition of space can also be viewed as elements of the second class. The key property used to distinguish between the different elements of this class is whether the underlying space is decomposed into a grid of cells. When a grid is used, the access structure is usually an array (termed a *grid directory*). When a grid is not used, an access structure in the form of a tree is used (termed a *tree directory*). Such methods are the focus of the rest of this section. Tree directory methods are discussed in Section 1.7.1, and grid directory methods are discussed in Section 1.7.2. Section 1.7.3 concludes with a brief discussion of the analysis of the storage utilization of bucket methods.

## 1.7.1 Tree Directory Methods

The tree access structures that form the basis of bucket methods that make use of a tree directory differ from the quadtree and k-d tree access structures discussed in Sections 1.4

---

<sup>36</sup> Requiring the minimum bounding boxes of the individual objects to be disjoint may be impossible to satisfy, as is the case, for example, for a collection of line segments that all meet at a particular point.

and 1.5, respectively, in terms of the fanout of the nodes. As in the case of an R-tree, the data points are aggregated into sets (termed *point buckets* for the moment), where the sets correspond to subtrees  $S$  of the original access structure  $T$  (assuming variants of  $T$  with bucket size 1, where all data points are stored in the leaf nodes). They are made to look like the R-tree by also aggregating the internal (i.e., nonleaf) nodes of  $T$  into buckets (termed *region buckets* for the moment), thereby also forming a multiway tree (i.e., like a B-tree). This is in contrast to other bucket methods (e.g., the bucket PR quadtree, bucket PR k-d tree, bucket generalized k-d trie, and bucket PMR quadtree, discussed in Section 1.5.2), where only the contents of the leaf nodes are aggregated into buckets. The elements of the region buckets are regions. The tree access structures differ from the R-tree in the following respects:

1. The aggregation of the underlying space spanned by the nodes is often implicit to the structure.
2. All nodes at a given level are disjoint, and together they usually span the entire space.

In contrast, for the R-tree, the following must hold:

1. The spatial aggregation must be represented explicitly by storing the minimum bounding boxes that correspond to the space spanned by the underlying nodes making up the subtree.
2. The bounding boxes may overlap (i.e., they are not necessarily disjoint).

A region bucket  $R$ , whose contents are internal nodes of  $T$ , corresponds to a subtree of  $T$ , and its fanout value corresponds to the number of leaves in the subtree represented by  $R$ . Again, note that the leaves in the subtrees represented by the region bucket are internal nodes of the access structure  $T$ .

The use of a directory in the form of a tree to access the buckets was first proposed by Knott [1040]. The leaf nodes in a  $B^+$ -tree can also be used as buckets. Multidimensional point data can be stored in a  $B^+$ -tree by applying a linear ordering to it. In particular, such an ordering can be obtained by, for example, using bit interleaving, as mentioned in Section 1.6, and then storing the results in a B-tree (recall the zkd Btree). Unfortunately, in such a case, a B-tree node does not usually correspond to a  $k$ -dimensional rectangle. Thus, the representation is not particularly conducive to region searching.

Several different representations have been developed to overcome these deficiencies. They are the subject of the rest of this section, which is organized as follows. Section 1.7.1.1 describes the k-d-B-tree, which is the simplest tree directory method from a conceptual point of view. The drawback of the k-d-B-tree is the possible need to split many nodes when a node overflows. Section 1.7.1.2 outlines the hybrid tree, which is a variant of the k-d-B-tree that keeps track of some extra information so that the number of nodes that need to be split upon overflow is reduced at the expense of more costly search operations due to nondisjointness of the resulting regions. Section 1.7.1.3 presents the LSD tree, which is an alternative method of overcoming some of the drawbacks of the k-d-B-tree, although use of the LSD tree may lead to low storage utilization. Section 1.7.1.4 contains an overview of the hB-tree, which has better storage utilization than the LSD tree. This is achieved by removing the requirement that all blocks be hyperrectangles. Section 1.7.1.5 discusses methods where the underlying space from which the data is drawn is partitioned at fixed positions (i.e., based on a trie) rather than in a data-dependent manner as in the k-d-B-tree, LSD tree, and hB-tree. This includes the multilevel grid file, the buddy-tree, and the indextermBANG file. Section 1.7.1.6 explains the BV-tree, which is a novel method that has excellent performance guarantees for searching. All of the above techniques are dynamic. Section 1.7.1.7 describes a couple of static methods based on the generalized pseudo k-d tree.

### 1.7.1.1 K-d-B-Tree

A simple example of a method that makes use of a tree directory is the k-d-B-tree [1567]. It is best understood by pointing out that it is a bucket variant of a k-d tree similar in spirit to the bucket generalized pseudo k-d tree (see Section 1.5.1.4) in the following sense:

1. The partition lines need not pass through the data points.
2. There is no need to cycle through the keys.
3. All the data is in the leaf nodes.

The blocks corresponding to the leaf nodes of this variant are buckets of capacity  $b$  (termed *point pages*) where a bucket is split in two whenever it contains more than  $b$  points. What differentiates the k-d-B-tree from the bucket generalized pseudo k-d tree is that in order to form the k-d-B-tree, the nonleaf nodes making up subtrees of the bucket generalized pseudo k-d tree are also grouped into buckets of capacity  $c$  (termed *region pages*). In this case,  $c$  corresponds to the number of pointers in each subtree to point pages or other region pages. In other words,  $c$  is the number of leaf nodes in the extended binary tree<sup>37</sup> representation of the k-d tree corresponding to the space partition induced by the region page. Thus,  $c$  is the maximum number of regions that can make up a region page. Note that  $c$  does not have to be the same as  $b$ , and, in fact, it is usually smaller as the size of the individual entries in the region pages is usually larger since they represent the boundaries of regions.

As noted above, the nodes of the original bucket generalized pseudo k-d tree that make up each region page form a variant of a k-d tree  $T$  corresponding to the space partition induced by the region page.  $T$  stores region partitions in its nonleaf nodes and pointers to other region pages or point pages in its leaf nodes. Therefore,  $T$  is neither a generalized k-d tree since no actual data is stored in its nonleaf nodes; nor is  $T$  a generalized pseudo k-d tree as no actual data is stored in its leaf nodes. Thus, we term  $T$  a *generalized  $k^+$ -d tree* in recognition of its similarity in spirit to a  $B^+$ -tree since their nodes contain only partitions rather than actual data.

It is interesting to observe that obtaining a k-d-B-tree is equivalent to taking a bucket generalized pseudo k-d tree  $B$  and replacing it with a multiway tree  $B'$ , which is a variant of a  $B^+$ -tree<sup>38</sup> where the nodes of  $B'$  are aggregates of subtrees of  $B$  containing a maximum of  $c$  elements. One of the reasons for stating that the resulting structure is a *variant* of the  $B^+$ -tree is that, unlike the  $B^+$ -tree, we cannot guarantee that each bucket in the k-d-B-tree will be 50% full. However, as in a  $B^+$ -tree, all point pages (i.e., leaf nodes) in a k-d-B-tree are at the same depth.

Of course, the resulting structure of the k-d-B-tree has many of the same properties as the B-tree, although updates (i.e., insertion and deletion) cannot always be achieved in analogous ways. In particular, when new data values are inserted into (deleted from) a B-tree, an overflowing (underflowing) bucket is either split (merged with an adjoining bucket) and a middle partition value promoted to (demoted from) the father bucket. Alternatively, we could try to make use of what is termed *deferred splitting* to rotate values from adjacent buckets. Unfortunately, the latter is not generally possible in the case of multidimensional point data (i.e.,  $d > 1$ ) as the buckets are not split on the basis of an ordering—that is, partitions are made on the basis of the relative positions (i.e., locations) of the points in the underlying space that is spanned by the bucket.<sup>39</sup> Moreover, recall that only the leaf nodes contain actual data.

---

<sup>37</sup> In an *extended binary tree*, each node is either a leaf node or has two children.

<sup>38</sup> We have an analogy with a  $B^+$ -tree rather than a B-tree because in the k-d-B-tree all the data points are in the leaf nodes, while the nonleaf nodes contain only the boundaries of the partitions.

<sup>39</sup> But see the MD-tree of Nakamura, Abe, Ohsawa, and Sakauchi [1337], which is a k-d-B-tree with a fanout of 3, where deferred splitting is actually handled by reconfiguring the splitting lines when necessary. The MD-tree is also used as the basis of the RMD-tree [1337], which represents two-

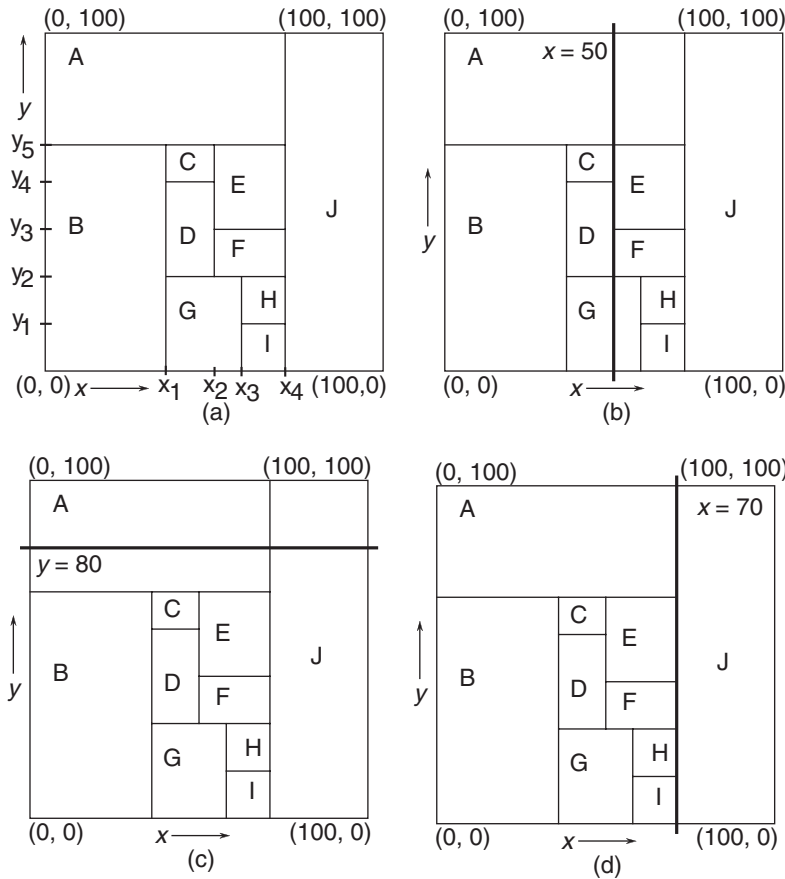

Figure 1.67  
 (a) A region page in a k-d-B-tree with capacity 9 that overflows.  $x_i$  ( $1 \leq i \leq 4$ ) and  $y_j$  ( $1 \leq j \leq 5$ ) denote the x-discriminator and y-discriminator values, respectively, of the corresponding k-d tree. The partitions are induced by splitting it into two region pages at (b)  $x = 50$ , (c)  $y = 80$ , and (d)  $x = 70$ .

If insertion of a point into the k-d-B-tree causes a point page  $p$  to overflow, then a partition line and axis are chosen and the corresponding bucket is split. This results in the creation of two new point pages  $s_1$  and  $s_2$ , and the data in  $p$  is inserted into the appropriate new point page based on its position relative to the partition line. Finally,  $p$  is deleted from the region page  $f$  that contains it, while  $s_1$  and  $s_2$  are added to  $f$ .

Adding  $s_1$  and  $s_2$  to  $f$  may also cause  $f$  to overflow. If this is the case, then we pick a partition line  $l$  and axis in the region corresponding to  $f$  and split  $f$  into region pages  $f_1$  and  $f_2$ . For example, consider the region page given in Figure 1.67(a) with  $x_i$  ( $1 \leq i \leq 4$ ) and  $y_j$  ( $1 \leq j \leq 5$ ) denoting the x-discriminator and y-discriminator values, respectively, of the corresponding k-d tree. Let the capacity of the region page be 9. As we can see, this page has ten regions and has overflowed. Suppose that we split it at  $x = 50$  as shown in Figure 1.67(b). This means that we must check the relative positions of all of the regions corresponding to the elements of  $f$  with respect to the partition line  $l$  (e.g.,  $x = 50$  in Figure 1.67(b)). In particular, we must determine if they lie entirely to the left (e.g., regions B, C, and D in Figure 1.67(b)) or entirely to the right (e.g., regions E, F, H, I, and J in Figure 1.67(b)) of  $l$  and insert them into  $f_1$  or  $f_2$  as is appropriate. All elements  $e$  of  $f$  whose regions are intersected by  $l$  (e.g., regions A and G in Figure 1.67(b)) must be split and new regions created that are inserted into  $f_1$  or  $f_2$ . This additional splitting process

dimensional objects as points in a four-dimensional space (see also Sections 3.3.2.2 and 3.3.2.3 of Chapter 3).

is applied recursively to the children of  $e$  and terminates upon reaching the appropriate point pages.

If a region page  $f$  has overflowed and  $f$  is not a root page of the k-d-B-tree, then  $f$  is deleted from its parent page  $g$ , the newly created region pages  $f_1$  and  $f_2$  are inserted into  $g$ , and the check for overflow is applied again (this time to  $g$ ). If  $f$  has overflowed and  $f$  is a root page of the k-d-B-tree, then a new region page  $h$  is created containing region pages  $f_1$  and  $f_2$  as its elements and  $l$  as the partition line. Thus, we see that the k-d-B-tree grows at the root (i.e., its height increases by one), which is the same way that the B<sup>+</sup>-tree grows.

Too many deletions may result in very low storage utilization. This can be overcome by either joining two or more adjacent point pages (i.e., catenating them), provided they are joinable (i.e., they have the same father region, their combined region forms a hyperrectangle, and the total number of points in the new page  $n$  does not cause  $n$  to overflow), or redistributing the contents of the adjacent point pages, which is the case when there is underflow in one of the point pages. If there is a reduction in the number of point pages, then this process is recursive in the sense that the parent region pages should be checked as well. For example, in Figure 1.67, region pages H and I are joinable. On the other hand, region page G is not joinable with region page H; nor is G joinable with region page I as neither of their combined regions forms a hyperrectangle. Note, however, that G is joinable with the combination H and I as their combined region does form a hyperrectangle. An alternative solution, which can also be applied in the case of overflow, is to reorganize the region pages by changing the positions (as well as the number) of partition lines. This will mean that descendant pages must be checked as well since this may cause the regions corresponding to the point pages to change, thereby necessitating the movement of points between pages, which may lead to overflow and creation of new partitions by going up the tree.

The drawback of the k-d-B-tree is that the insertion process is quite complex in the sense that we must be quite careful in our choice of a partition line  $l$  and partition axis when a region page  $f$  overflows. There are two problems. The first problem is that we must choose the new partition line so that the newly created region pages do not overflow. For example, suppose that we choose to partition region page  $f$  in Figure 1.67(a) at line  $l$  at  $y = 80$  as shown in Figure 1.67(c). Recall that this page has capacity 9. Let  $f_1$  and  $f_2$  represent the newly created region page corresponding to the areas below and above  $y = 80$ , respectively. Therefore, all elements of  $f$  that are below  $l$  (e.g., regions B, C, D, E, F, G, H, and I in Figure 1.67(c)) are inserted into  $f_1$ , while all elements of  $f$  that are above  $l$  (e.g., none in Figure 1.67(c)) are inserted into  $f_2$ . In addition, the elements of  $f$  whose regions are intersected by  $l$  (e.g., A and J) must be split and new regions created that are inserted into  $f_1$  and  $f_2$ . The result is that  $f_1$  contains ten regions and has overflowed, which means that it must also be split, thereby causing the k-d-B-tree to grow by an additional level. With the appropriate choice of partition lines, this process can be applied repeatedly to create much larger k-d-B-trees. Clearly, this is undesirable, and we should choose another partition line and axis. In fact, it is not difficult to construct another example where both of the newly created region pages have overflowed (see Exercise 1).

The second problem is that even if neither of the newly created region pages  $f_1$  and  $f_2$  overflows, then we may still have to apply the splitting process recursively to  $f_1$  and  $f_2$ , which may, in turn, cause a descent to the point pages. This recursive application of splitting can be avoided by choosing a partition line that is not intersected by any of the regions that make up the overflowing region page. For example, this is the case if we choose to partition the region page in Figure 1.67(a) at  $x = 70$  as shown in Figure 1.67(d). By the very nature of the k-d tree, such a partition line can always be found (see Exercise 2). The shortcoming of such a partitioning is that it may lead to very poor storage utilization in the region pages.

## Exercises

1. Consider a k-d-B-tree. Give an example partition line and axis whose use to split an overflowing region page  $f$  with a capacity  $c$  (i.e.,  $f$  has  $c + 1$  regions) yields two newly created region pages,  $f_1$  and  $f_2$ , that also overflow.
2. Why can we always find a partition line for a region page in a k-d-B-tree so that when a region page is split upon overflow, we do not have to apply the splitting process recursively to the child pages of the overflowing region page?
3. Write a procedure KDBINSERT to insert a point into a k-d-B-tree.
4. Write a procedure KDBDELETE to delete a point from a k-d-B-tree.
5. Write a procedure KDBPOINTQUERY to perform a point query in a k-d-B-tree.
6. Write a procedure KDBRANGEQUERY to perform a range query in a k-d-B-tree.

## 1.7.1.2 Hybrid Tree

It should be clear that in the k-d-B-tree the difficulty of choosing a partition line and axis that result in good space utilization without requiring further partitioning is a direct result of the requirement that the k-d-B-tree yield a disjoint decomposition of the underlying space. Chakrabarti and Mehrotra [317] suggest a modification of the k-d-B-tree, which they term a *hybrid tree* (see also Section 4.4.3 of Chapter 4), that avoids splitting the region and point pages that intersect the partition line  $l$  along partition axis  $a$  with value  $v$  by slightly relaxing the disjointness requirement. This is achieved by associating the intersecting pages with one of the two regions resulting from the partition, termed *low* and *high*, corresponding to the regions  $a \leq v$  and  $a > v$ , respectively. In addition, they replace the single partition line  $l$  by two partition lines  $l_{min}$  and  $l_{max}$ .  $l_{min}$  corresponds to the minimum value of coordinate  $a$  for all pages associated with region *high*, while  $l_{max}$  corresponds to the maximum value of coordinate  $a$  for all pages associated with region *low*. Of course, these changes may result in slower searches due to overlapping regions.

For example, if we partition the overflowing region page in the k-d-B-tree in Figure 1.67(a) at  $x = 50$  as shown in Figure 1.67(b), then we must decide with which partition to associate the pages A and G that intersect the partition line. One solution is to associate A with the left partition and G with the right partition. In this case, instead of one partition line at  $x = 50$ , we now have two partition lines at  $x = 70$  and  $x = 40$ , corresponding to the boundaries of regions *low* and *high*, respectively. Pages A, B, C, and D are associated with region *low*, while pages E, F, G, H, I, and J are associated with region *high*. An alternative is to retain the partition line at  $x = 50$  for region *high* and just add the partition line at  $x = 70$  for region *low*. In this case, the two regions have the same amount of data—that is, pages A, B, C, D, and G are associated with region *low*, while pages E, F, H, I, and J are associated with region *high*.

Recall from Section 1.5.1.4 that the same technique is used by Ooi, McDonell, and Sacks-Davis [1404, 1407] in their *spatial k-d tree* to represent a collection of objects with extent by storing their centroids in a k-d tree (see also Section 3.3.2.5 of Chapter 3). They keep track of the extent of the objects by associating with each nonleaf node, say  $P$  discriminating on coordinate  $a$ , information on the spatial extent of the objects stored in its two subtrees. In particular, they store the maximum value of coordinate  $a$  for the objects in the left child of  $P$  and the minimum value of coordinate  $a$  for the objects in the right child of  $P$ .

Associating two partition lines with each partitioned region is equivalent to associating a bounding box with each of the two regions *low* and *high*. The result is similar to an R-tree with the critical difference that the bounding box is not a minimum bounding box. In particular, if it were a minimum bounding box, then with each partition we would have to store the values of the partition line and axis, as well as  $4 \cdot d$  values for the boundaries of the two minimum bounding boxes in  $d$  dimensions. Instead, with each partition, the hybrid tree stores just three values: the partition axis and two partition lines.

Thus, the space requirements, especially in high dimensions, are considerably lower. Of course, the drawback of not using a minimum bounding box is that we cannot eliminate as effectively the dead space in a region.

Chakrabarti and Mehrotra [317] propose to eliminate some of the dead space by using an approximation of a bounding box obtained by quantizing the space spanned by the minimum bounding box using a small number of bits to represent the coordinate values of the two corners of the bounding box. Assuming the use of  $b$  bits per dimension, this is equivalent to imposing a  $2^b \times 2^b \times \dots \times 2^b$  grid on the space spanned by the partition and recording the corners of the grid cells that are partially covered by the minimum bounding box. For example, using 4 bits (which is shown to yield good results), instead of 64 bits (which is needed to store the floating-point representation of each coordinate value in the unquantized representation), results in lowering the space requirements for the bounding box by a factor of 16. This idea was first proposed by Henrich [826] in adapting the LSD tree (see Section 1.7.1.3) to handle high-dimensional data.

### Exercises

1. Write a procedure HYBRIDINSERT to insert a point into a hybrid tree.
2. Write a procedure HYBRIDDELETE to delete a point from a hybrid tree.
3. Write a procedure HYBRIDPOINTQUERY to perform a point query in a hybrid tree.
4. Write a procedure HYBRIDRANGEQUERY to perform a range query in a hybrid tree.

#### 1.7.1.3 LSD Tree

The *Local Split Decision tree* (LSD tree) [829] chooses a partition line that is not intersected by any of the regions that make up the overflowing region page in the k-d-B-tree, thereby avoiding the need for a recursive invocation of the splitting process. This is achieved by partitioning each region page of the k-d-B-tree at the root of the generalized  $k^+$ -d tree corresponding to the space partition induced by the overflowing region page. As mentioned above, such a partitioning may lead to poor storage utilization by creating region pages that could be almost empty. An extreme example of this situation results from repeated partitions, assuming a bucket capacity  $c$ , that create two region pages whose underlying space is spanned by two generalized  $k^+$ -d trees, having 1 and  $c$  leaf nodes, respectively. Recall that these newly created pages contain pointers to region pages at the next, deeper level of the k-d-B-tree. Observe that a generalized  $k^+$ -d tree containing  $n$  leaf nodes can have a height as large as  $n - 1$ , where we assume that a tree with one leaf node has a height of 0. Thus, the generalized  $k^+$ -d tree corresponding to the space partition induced by a region page with  $c$  leaf nodes may have a height as large as  $c - 1$ .

Clearly, if the bucket capacity  $c$  (the number of pointers to region or point pages here) is large, then the maximum height of the generalized  $k^+$ -d tree corresponding to the space partition induced by a region page could also be large, thereby requiring many tests in performing basic operations on the data, such as an exact match query. The LSD tree alleviates this problem, in part, by choosing the maximum height  $h$  of the extended binary tree representation of the generalized  $k^+$ -d tree corresponding to the space partition induced by the region page to be  $\lfloor \log_2 c \rfloor$ . In other words, for a given value of  $c$ ,  $h$  is chosen so that  $2^h \leq c < 2^{h+1}$ . Thus, the region page utilization is optimal when the generalized  $k^+$ -d tree corresponding to the space partition induced by the page is a complete binary tree (i.e.,  $2^h$  leaf nodes), while it is at its worst when the space partition is a linear binary tree (i.e.,  $h + 1$  leaf nodes). Notice also that when  $c$  is not a power of 2, then the region page utilization will never be 100%.

As in the k-d-B-tree, the LSD tree is best understood by assuming that we start with a variant of a bucket generalized pseudo k-d tree. Similarly, the key idea behind the LSD tree lies in distinguishing between the treatment of the nonleaf nodes of the tree (i.e.,

the bucket generalized pseudo k-d tree) from the treatment of leaf nodes that contain the actual data which are termed *data buckets* (i.e., point pages using the terminology of the k-d-B-tree). The nonleaf nodes are also grouped into pages of a finite capacity, termed *directory pages* (i.e., region pages using the terminology of the k-d-B-tree). The result is a variant of a  $B^+$ -tree where the root, termed an *internal directory page*, always resides in main memory and corresponds to the nonleaf nodes closest to the root of the bucket generalized pseudo k-d tree, while the nodes in the remaining levels, termed *external directory pages*, always reside in external storage. The root (i.e., the internal directory page) is a generalized  $k^+$ -d tree of finite size whose leaf nodes point to external directory pages or data buckets. Below, we first describe the external directory pages. This is followed by a description of the internal directory page. We use the LSD tree in Figure 1.68(a) to illustrate our explanation.

Each external directory page (as well as the internal directory page) is a generalized  $k^+$ -d tree implemented as an extended binary tree of a predefined maximum height  $h$ . The leaf nodes of each of the binary trees that make up an external directory page are either pointers to data buckets (i.e., point pages, using k-d-B-tree terminology) or other external directory pages (i.e., region pages using k-d-B-tree terminology). The internal nodes correspond to the partition values. The LSD tree definition stipulates that the lengths of the paths (in terms of the number of external directory pages that are traversed) from a particular leaf node in the internal directory to any data bucket are the same, while the lengths of the paths from different leaf nodes in the internal directory to any data bucket differ by at most one [829] (e.g., Figure 1.68(a)).

The pointer structure connecting the elements of the set of external directory pages and the data buckets yields a collection of trees (we are not speaking of the generalized  $k^+$ -d trees that make up each external directory page here). The internal nodes of these trees are external directory pages. Each internal node in each tree in this collection has a maximum fanout of  $2^h$ . In addition, in each tree, the paths from the root to the leaf nodes (i.e., the data buckets) have the same length, in terms of the number of external directory pages, which is analogous to a stipulation that the trees are “balanced” (although the individual internal nodes may have a different degree). Moreover, the heights of any two trees can differ by at most one.

When insertion of a data item into the LSD tree causes a data bucket (i.e., a point page using k-d-B-tree terminology) to overflow, the data bucket is split according to several possible rules that include a rule that ensures that the number of data items in the resulting data buckets is approximately the same and a rule that ensures that the size of the space spanned by the two data buckets is the same. These rules are examples of what are termed *data-dependent* and *distribution-dependent* strategies, respectively.<sup>40</sup> The latter is similar to the trie-based decomposition strategies. They differ from the generalized pseudo k-d tree as they are based on a local, rather than a global, view (i.e., there is no need to know the entire dataset). The split will cause the addition of a data bucket (i.e., point page using k-d-B-tree terminology), which will cause an additional node to be inserted into the corresponding ancestor external directory page  $p$ . For a discussion of some ways to avoid splitting a data bucket by rotating data from the overflowing bucket to a sibling bucket that is not too full, see [824, 825] (see also Section 1.5.1.4).

External directory pages are split if the addition of the new data bucket causes their height to exceed the predefined maximum value  $h$ . If a split occurs, then the directory page is split at the root of its corresponding generalized  $k^+$ -d tree, and the split is propagated farther up the tree, which may, in turn, eventually cause a node to be added to the internal directory page.

---

<sup>40</sup> See Section 3.3.2.4 of Chapter 3 for a more detailed explanation in the context of the use of an LSD tree to store a collection of rectangles where each rectangle is represented by the representative point method.

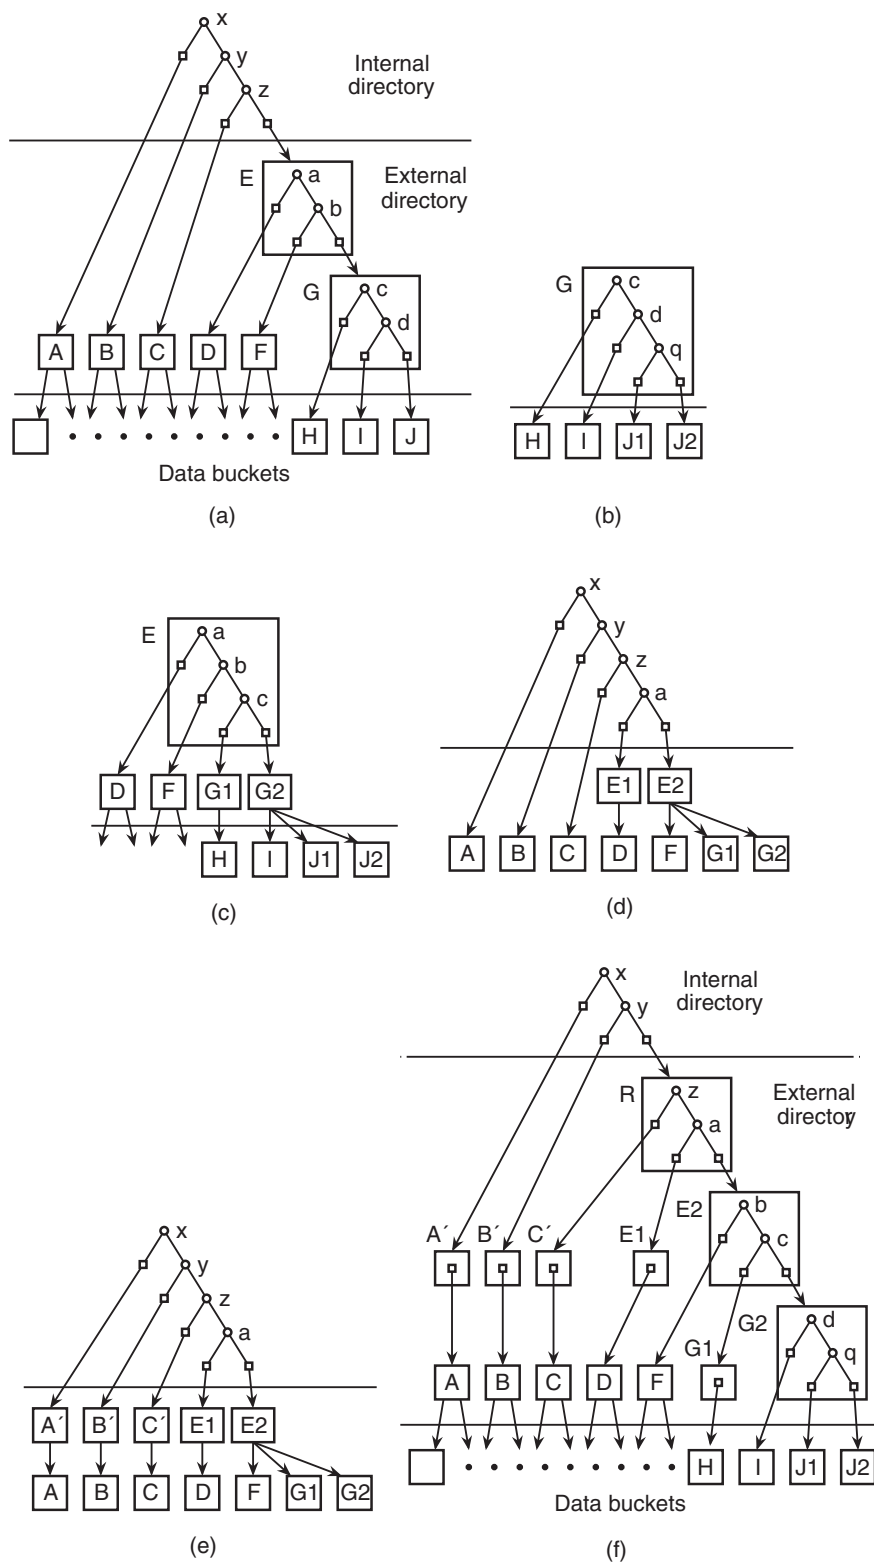

Figure 1.68  
Example LSD tree showing the result of inserting a point in data bucket J, which causes it to overflow. (a) Original tree, (b) effect of splitting data bucket J on external directory page G, (c) effect of splitting external directory page G on external directory page E, (d) effect of splitting directory page E on the internal directory page, (e) effect of making new external directory pages upon detecting overflow of the internal directory page so that the lengths of all paths from the root of the internal directory page to any of the data buckets are the same, (f) final tree.

The internal directory page has a finite capacity  $i$ , which is the maximum number of leaf nodes that it can contain. Note that the leaf nodes correspond to the regions induced by the generalized  $k^+$ -d tree partition of the underlying space.  $i$  is usually much larger than the capacity of the external directory pages. The internal directory page is kept in main memory. Again, as in the case of the external directory pages, the internal directory page is an extended binary tree. When the internal directory page is too full, one of its subtrees  $s$  is made into an external directory page  $p$ , and  $s$  is removed from the internal directory page (we say that  $s$  has been *paged*). In this case,  $s$  is replaced by a leaf node that points to  $p$ . Subtree  $s$  is chosen to be as large as possible, subject to the predefined maximum height of an external directory page and the “path length to a bucket” constraint. The latter constraint implies that the path lengths, in terms of the number of external directory pages that are traversed, of all paths from the root of the subtree  $s$  to a data bucket must be the same and that the path length is the minimum of the permitted path lengths (recall that the path lengths may differ by one). Satisfaction of these constraints ensures that the external directory pages are as large as possible and also prevents the internal directory page from overflowing too often.

If the subtree  $s$  that was chosen has just one node, which must be a leaf node, then the size of the internal directory page has not been reduced. Recall that leaf nodes are pointers to external directory pages or data buckets. Thus, after paging subtree  $s$  consisting of just a single leaf node, a pointer to  $s$  must be included in the internal directory page in a newly created leaf node  $t$ , which means that the internal directory page is still overflowing. However, we have created a new external directory page consisting of one leaf node, and thus the path length  $l$  from  $t$  to all of the data buckets  $\{B\}$  accessible from  $t$  has increased by one without violating our constraint that  $l$  be the same for all elements of  $\{B\}$  and that  $l$  differ by at most one from those of the remaining trees that make up the collection of external directory pages. In this case, the paging algorithm must be reapplied, but now the algorithm has the opportunity to choose another subtree to make into an external directory page that hopefully consists of more than one leaf node.

For example, letting  $i = 4$ ,  $h = 2$ , and  $c = 4$ , consider the situation when data bucket J overflows in the LSD tree whose directory map is given in Figure 1.68(a). Data bucket J is split into data buckets J1 and J2, with  $q$  serving as the new partitioning hyperplane that is promoted to the parent external directory page G (see Figure 1.68(b)). This causes G to have height 3, which is too large (as  $h = 2$ ). Therefore, G is split into external directory pages G1 and G2, with partitioning hyperplane  $c$  serving as the new partition value that is promoted to the parent external directory page E (see Figure 1.68(c)). Again, this causes E to have height 3, which is too large. Therefore, E is split into external directory pages E1 and E2, with partitioning hyperplane  $a$  serving as the new partition value that is promoted to the parent, who is the internal directory page (see Figure 1.68(d)). This causes the internal directory page to overflow as it has pointers to five external directory pages while there is room for only four since  $i = 4$ .

At this point, the definition of the LSD tree requires that we locate the largest subtree  $s$  in the internal directory page such that the length of the path from its root, in terms of the number of external directory pages that are traversed, to a data bucket is a minimum and that we make  $s$  into an external directory page. Continuing our example, this means that we make, in order, external directory pages  $A'$ ,  $B'$ , and  $C'$  out of the leaf nodes that are the left children of the internal nodes  $x$ ,  $y$ , and  $z$ , respectively, in Figure 1.68(d), yielding Figure 1.68(e). We now have the situation that the lengths of all paths from the internal directory page to any of the data buckets are the same. Of course, the internal directory page is still too full. Next, we convert the subtree rooted at internal node  $z$  in Figure 1.68(e), as it is the largest, into an external directory page as shown in Figure 1.68(f), and the insertion process is complete. Notice that the lengths of the paths to any data bucket are the same for any of the nodes in the resulting internal directory page, and they differ by just one for the different nodes in the resulting internal directory page.

It should be noted that the example we have described is a worst case in the sense that we had to make external directory pages that were essentially empty (i.e., did not correspond to a partition of the underlying space) when we created external directory pages  $A'$ ,  $B'$ , and  $C'$ , as well as  $E1$  and  $G1$  in Figure 1.68(e). This worst case is unlikely to arise in practice because the capacity  $i$  for the internal directory page is usually chosen to be quite large, while the external directory pages and the data buckets are usually the size of a page in the underlying operating system. For example, in experiments reported in [829], the internal directory contained 1,000 nodes, while the external directory pages and data buckets were 512 bytes. Assuming an extended binary tree representation for the internal directory page leads to a value of 500 for  $i$  as the number of leaf nodes is one greater than the number of nonleaf nodes. Moreover, using eight bytes per node, the maximum number of nodes that can be stored in an external directory page is 64, which corresponds to an extended binary tree of height  $h = 5$  as there are  $2^5 = 32$  leaf nodes and  $2^5 - 1 = 31$  nonleaf nodes. Thus, the page can hold as many as  $c = 32$  pointers to other external directory pages and data buckets.

If a cyclic partition order is used, then there is no need to keep track of the partition axes. In this case, the generalized  $k^+$ -d tree in each external directory page is simplified considerably, and its extended binary tree representation can be stored using the complete binary tree array representation (which is also often used to represent heaps and is sometimes called a *sequential heap*).

It is interesting to observe (as in the  $k$ -d-B-tree) that the structure of the LSD tree is similar to that which would be obtained by taking a binary search tree  $B$  of height  $mh$  and replacing it with a multiway tree  $B'$  of height  $m$ , where the nodes of  $B'$  correspond to aggregates of subtrees of  $B$  of height  $h$ . Again, this is analogous to the motivating idea for a B-tree with the exception that the fanout at each node of  $B'$  is at most  $2^h$ , whereas in a B-tree there is a predetermined minimum fanout, as well as a maximum fanout (usually related to the capacity of a page, which is also usually the case in the LSD tree [829]). The difference, of course, is that in the case of an LSD tree the binary search tree is a  $k$ -d tree, and each node in the resulting multiway tree represents a sequence of successive binary partitions of a hyperrectangular region.

Both the  $k$ -d-B-tree and the LSD tree result in the partitioning of the space corresponding to an overflowing region page into two region pages, each of which is a hyperrectangle. The  $k$ -d-B-tree permits quite a bit of latitude in the choice of the position of the partition line and identity of the partition axis at the expense of the possibility of further overflow on account of the need for further partitioning of the regions intersected by the partition line. In contrast, there is no further partitioning in the case of the LSD tree as each region page of the  $k$ -d-B-tree is partitioned at the root of the generalized  $k^+$ -d tree corresponding to the space partition induced by the overflowing region page. The drawback of this approach is that the storage utilization of the region pages resulting from the split may be quite poor.

### Exercises

1. Write a procedure `LSDINSERT` to insert a point into an LSD tree.
2. Write a procedure `LSDDELETE` to delete a point from an LSD tree.
3. Write a procedure `LSDPOINTQUERY` to perform a point query in an LSD tree.
4. Write a procedure `LSDRANGEQUERY` to perform a range query in an LSD tree.

#### 1.7.1.4 hB-Tree

The hB-tree [575, 1201] overcomes the low storage utilization drawback of the LSD tree by removing the requirement that the portions of the underlying space spanned by the region pages resulting from the split be hyperrectangles. Instead, the hB-tree splits each region page into two region pages so that each resulting region page is at least

Figure 1.69  
 The generalized  $k^+$ -d tree of the hB-tree node corresponding to the region page in Figure 1.67(a). The nonleaf nodes are labeled with the key that serves as the discriminator.

one-third full, thereby making the other region page no more than two-thirds full<sup>41</sup> (see Exercise 2). The portions of space spanned by the resulting region pages have the shapes of bricks with holes corresponding to region pages spanning a hyperrectangular space that has been extracted from the region page that has been split.<sup>42</sup> This analogy serves as the motivation for the name *holey brick tree* (hB-tree). Note that the one- to two-thirds balanced splitting property also holds for the point pages (see Exercise 3).

Each node corresponding to a region page in the hB-tree contains a generalized  $k^+$ -d tree<sup>43</sup> describing a partition of a corresponding hyperrectangular area. However, the space spanned by the node may not cover the entire hyperrectangle. In this case, some of the generalized  $k^+$ -d tree leaf nodes (corresponding to partitions of the hyperrectangle) are flagged as being external (denoted by *ext*) and thus spanned by other nodes of the hB-tree at the same level (such as its brothers). The best way to understand the hB-tree is to look at how it would deal with the overflowing region page, denoted by *P*, in Figure 1.67(a). It has 10 regions but its capacity is 9. Let Figure 1.69 be the generalized  $k^+$ -d tree corresponding to the region page *P* in Figure 1.67 that has overflowed. In this case, the space spanned by *P* is a rectangle and thus none of the nodes in the corresponding  $k^+$ -d tree are marked as being external. Notice that this example is quite simple as there are no external nodes in the generalized  $k^+$ -d trees of any of the child nodes of *P* since they are all also rectangles. We shall look at more complex examples later.

First, we must determine how to split the overflowing region page, say *P*. This is done by traversing its corresponding generalized  $k^+$ -d tree (i.e., Figure 1.69) in a top-down manner, descending at each step the subtree with the largest number of leaf nodes (i.e., regions). The descent ceases as soon as the number of regions in one of the subtrees, say

<sup>41</sup> This notion of minimum occupancy is also used in the BD-tree [1386, 1387] (see Section 1.5.2), the BANG file [640] (see Section 1.7.1.5), and the BV-tree (see Section 1.7.1.6).

<sup>42</sup> Note that subsequent splits may result in region pages that span areas that are not contiguous, but this is not a problem [1201].

<sup>43</sup> We characterize the structure using the qualifier *generalized* because the partitions need not be cyclic.

$S$ , lies between one-third and two-thirds of the total number of regions in the overflowing region page  $P$ . The space spanned by  $S$  corresponds to the brick that is being extracted from  $P$ .

In our example, the stopping condition is satisfied once we have made two left transitions, followed by two right transitions, in the generalized  $k^+$ -d tree of Figure 1.69. At this point, the brick that we will extract corresponds to the subtree of  $P$ 's generalized  $k^+$ -d tree, consisting of the child nodes C, D, E, and F (i.e., these are hB-tree nodes at the next deeper level in the hB-tree). We let  $S$  refer to a new hB-tree node, consisting of the subtree of  $P$ 's  $k^+$ -d tree, and let  $Q$  refer to the remaining portion of  $P^{44}$  (i.e., the result of extracting  $S$  from  $P$ ). The generalized  $k^+$ -d trees associated with  $Q$  and  $S$  are shown in Figure 1.70(a, b), respectively. Notice the use of the label *ext* in Figure 1.70(a) to mark the portions of the space covered by the generalized  $k^+$ -d tree (recall that this space is a hyperrectangle) that are spanned by another node in the hB-tree. This is needed because the underlying space spanned by its hB-tree node (i.e.,  $S$ ) is not a hyperrectangle. In contrast, no nodes are labeled *ext* in Figure 1.70(b) as the underlying space spanned by its hB-tree node (i.e.,  $Q$ ) is a hyperrectangle.

We must also propagate the result of the split to the father hB-tree node  $F$  of the node  $P$  corresponding to the overflowing region page (termed *posting* [1201]). In our example, after the split, we post a subtree that discriminates between  $Q$  and  $S$  to the father hB-tree node  $F$ . This results in merging the generalized  $k^+$ -d tree in Figure 1.71 into the generalized  $k^+$ -d tree for  $F$ . Of course, we must also check whether  $F$  has overflowed, which may cause further splitting and posting, eventually culminating in the growth of the hB-tree by one level.

From Figure 1.71, we see that the structure of the hB-tree is such that a particular region may appear more than once in the  $k$ -d tree that represents the node. Moreover, in the case of a node split as a result of node overflow, it is possible that some of the nodes in the hB-tree will have more than one parent (called the *multiple posting problem*). This means that the directory in the hB-tree is really a directed acyclic graph (i.e., there are no cycles, and the pointers are unidirectional), and thus is not actually a tree. As an example of this situation, consider the region page, say  $P$ , in Figure 1.72(a), whose generalized  $k^+$ -d tree is given in Figure 1.72(b). Suppose that  $P$  has overflowed. Of course, this example is too small to be realistic, but it is easy to obtain a more realistic example by introducing additional partition lines into the regions corresponding to A and B in the figure. In this case, we traverse  $P$ 's  $k$ -d tree in a top-down manner, descending at each step the subtree with the largest number of leaf nodes (i.e., regions) and stopping as soon as the number of regions in one of the subtrees, say  $S$ , lies between one-third and two-thirds of the total number of regions in the overflowing region page  $P$ . In this example, this is quite easy as all we need to do is descend to the left subtree of the right subtree of the root. The result is the creation of two hB-tree nodes (Figure 1.72(c, d), where region A is now split so that it has two parent hB-tree nodes, and the partition line between these two parent hB-tree nodes is posted to the father hB-tree node of  $P$ .<sup>45</sup>

If subsequent operations result in further splits of region A, then we may have to post the result of these splits to all of the parent hB-tree nodes of A. For example, suppose that region A in Figure 1.72(a) is subsequently split into regions A and C as shown in Figure 1.73(a). In this case, the resulting hB-tree nodes are given by Figure 1.73(b, c)

Figure 1.70  
The generalized  $k^+$ -d trees associated with the results of splitting the hB-tree node corresponding to the region page in Figure 1.67(a) with the generalized  $k^+$ -d tree given in Figure 1.69 into nodes (a)  $Q$  and (b)  $S$ . Each nonleaf node is labeled with the key that serves as the discriminator.

<sup>44</sup> In an actual implementation,  $Q$  can occupy the same disk page as  $P$  did.

<sup>45</sup> The splitting procedure for the hB-tree would actually truncate the generalized  $k^+$ -d tree in Figure 1.72(c) to yield a single leaf node pointing to A. In general, this is done by traversing the generalized  $k^+$ -d tree from the root and discarding nonleaf nodes until neither of the children are external markers. However, in the hB<sup>+</sup>-tree [575], which is an adaptation of the hB-tree designed to provide better support for recovery and concurrency, such a truncation is not performed. This is because in the hB<sup>+</sup>-tree the external markers are replaced by *sibling pointers* whose value provides useful information. In particular, for a node  $P$ , a sibling pointer in its generalized  $k^+$ -d tree points to the node that was extracted (as a result of splitting) from  $P$ , whose underlying space spans the corresponding area.

Figure 1.71  
The generalized  $k^+$ -d tree associated with the father of the hB-tree node corresponding to the region page in Figure 1.67(a) with the generalized  $k^+$ -d tree given in Figure 1.69, which has been split into nodes Q and S, whose generalized  $k^+$ -d trees are given by Figures 1.70(a) and (b), respectively. The nonleaf nodes are labeled with the key that serves as the discriminator.

Figure 1.72  
(a) Example region node where (b) is the generalized  $k^+$ -d tree of its hB-tree node and whose overflow is resolved by partitioning it, thereby creating two hB-tree nodes having (c) and (d) as their generalized  $k^+$ -d trees. The actual partition of the region page that is induced by the generalized  $k^+$ -d trees is shown by the broken line in (a). Each nonleaf node of the generalized  $k^+$ -d tree of the hB-tree nodes is labeled with the key that serves as the discriminator.

corresponding to Figure 1.72(c, d), respectively. Here we see that this could have possibly caused additional node splits to occur. The greater the number of such splits that take place, the more complicated the posting situation becomes. In fact, this complexity was later realized to cause a flaw in the original split and post algorithm for the hB-tree [574, 1614] and was subsequently corrected as part of the hB<sup>Π</sup>-tree [575].

**Exercises**

1. Give an example point set with  $4k$  points in two dimensions that cannot be partitioned by a vertical or a horizontal line into two sets, each of which has  $2k$  points.
2. Prove that it is always possible to split a region page in an hB-tree into two region pages so that each resulting region page is at least one-third full, thereby making the other region page

Figure 1.73  
(a) Result of splitting region A in Figure 1.72(a) into regions A and C, and the resulting two hB-tree nodes having (b) and (c) as their generalized  $k^+$ -d trees, which correspond to Figures 1.72(c) and (d), respectively. The actual partition of the region page that is induced by the generalized  $k^+$ -d trees is shown by the broken line in (a). Each nonleaf node of the generalized  $k^+$ -d tree of the hB-tree nodes is labeled with the key that serves as the discriminator.

no more than two-thirds full. Recall that the splitting of a region page is achieved by extracting a portion of the generalized  $k^+$ -d tree that describes the partitioning of the region page.

3. Prove that it is always possible to split a point page in an hB-tree into two point pages so that each resulting point page is at least one-third full, thereby making the other point page no more than two-thirds full.
4. Write a procedure HBINSERT to insert a point into an hB-tree.
5. Write a procedure HBDELETE to delete a point from an hB-tree.
6. Write a procedure HBPOINTQUERY to perform a point query in an hB-tree.
7. Write a procedure HBRANGEQUERY to perform a range query in an hB-tree.

### 1.7.1.5 K-d-B-Tries

Partitions in the k-d-B-tree (as well as the LSD tree and the hB-tree) are usually made in a data-dependent manner.<sup>46</sup> An alternative is to decompose recursively the underlying space from which the data is drawn into halves. The exact identity of the key being partitioned at each level of the decomposition process depends on the partitioning scheme that is used (e.g., whether we need to cycle through the keys). Such decompositions are characterized as being trie-based and have been used earlier in distinguishing between different forms of quadtrees (Sections 1.4.1 and 1.4.2) and k-d trees (Sections 1.5.1 and 1.5.2). Some examples of a trie-based decomposition are the PR k-d tree and the generalized k-d trie discussed in Section 1.5.2.

Trie-based decompositions have the obvious drawback of requiring many decomposition steps when the data is clustered, which results in empty subtrees. This is alleviated, in part, by making use of buckets, thereby leading to the bucket PR k-d tree and the bucket generalized k-d trie discussed in Section 1.5.2. The effects of clustering can be further mitigated by increasing the capacity of the buckets. Below, we discuss several extensions of the bucket generalized k-d trie (i.e., the multilevel grid file<sup>47</sup> [1087] and the buddy-tree [1710]) that have additional desirable characteristics. They differ from the bucket generalized k-d trie in that, as in the k-d-B-tree (and the LSD tree), they also aggregate the nonleaf nodes of the bucket generalized k-d trie. We use the term *k-d-B-trie* to refer to this general class of representations.

Our explanation of the k-d-B-trie is heavily influenced by the manner in which two of its variants, namely the multilevel grid file and the buddy-tree, are implemented. They yield a tighter decomposition of the underlying space in the sense that they eliminate some of the empty space that is inherent to the bucket generalized k-d trie. This is achieved by basing the overflow condition for an aggregated nonleaf node (i.e., a region page) on the number of nonempty regions or children that it comprises. Of course, other variants of the k-d-B-trie are also possible, and they often have different definitions. However, they all have in common the aggregation of the nonleaf nodes of a bucket generalized k-d trie and their organization using some variant of a k-d trie.

A k-d-B-trie has two types of pages: point pages (capacity  $b$ ), containing the actual data, and region pages (capacity  $c$ ) that contain pointers to point pages or to other region pages. Initially, we have one empty point page  $p$  and one region page  $r$  containing  $p$  that spans the entire underlying space  $U$ .<sup>48</sup> When  $p$  becomes full,  $p$  is split into two point pages,  $p_1$  and  $p_2$ , using a variant of a recursive decomposition process described below. We may think of the splitting of  $p$  as the result of applying a sequence of halving

---

<sup>46</sup> But see the discussion of distribution-dependent decompositions in LSD trees [829].

<sup>47</sup> Although the qualifier *grid file* is used in the name of the data structure, it has little connection with the grid file as described in Section 1.7.2.1.

<sup>48</sup> Actually, most implementations dispense with the initial region page. However, in our explanation, we find it useful to assume its existence so that we can see how the underlying space is decomposed once the initial point page, which covered no space at the start, becomes full.

operations on the underlying space  $U$ . The sequence terminates once the last halving operation results in two nonempty halves, spanning  $u_1$  and  $u_2$ . Since the k-d-B-trie is based on the bucket generalized k-d trie, the order in which the halving operations are applied to the domains of the different keys is permitted to vary. This leads to many possible different partitions of the underlying space and configurations of resulting point pages.

The result of the application of each halving operation to  $U$  is termed a *B-rectangle* [1710]. Thus, we see that  $u_1$  and  $u_2$  are B-rectangles. Depending on the configuration of the underlying space, we often find that  $p_i$  covers just a very small part of  $u_i$ . This will lead to inefficiencies in search, and thus we attempt to store a tighter approximation of the data in  $p_i$ . Let  $M(p_i)$  be the minimum bounding rectangle of  $p_i$ .<sup>49</sup> Each minimum bounding rectangle  $M(p_i)$  has a minimum bounding B-rectangle  $B(M(p_i))$ , termed the *B-region* of  $M(p_i)$ . The B-region of  $M(p_i)$  is obtained by continuing the application of recursive halving operations to  $u_i$ . With each entry for a point page  $p_i$  in the father  $r$ , we associate the B-region of  $M(p_i)$ . Thus, we can now see that  $u_1$  and  $u_2$  may be obtained by the application of just one halving operation on the B-region of  $M(p)$ . In the following, when we speak of the B-region of a node  $o$ , we mean the B-region of the minimum bounding rectangle of the data in the subtree at  $o$ .

As an example of the tighter approximation that can be obtained, assuming a bucket capacity of 4, consider the insertion of point X into the point page in Figure 1.74(a). Figure 1.74(b) is one possible result of splitting the overflowing page into two nonoverflowing halves; Figure 1.74(c) shows the B-regions and minimum bounding rectangles that will be stored in the newly created region page. Thus, we see that the k-d-B-trie obtained in Figure 1.74(c) has smaller point pages than would have been the case had we not used the B-regions. At a cursory glance, we might think that the use of B-regions leads to the creation of more regions by virtue of the presence of the empty regions (e.g., the upper-right quarter of Figure 1.74(c), which is marked with diagonal lines). However, this is not a problem because the overflow condition for a region page depends only on the nonempty regions that it comprises.

Each region page  $r$  consists of the B-regions of its constituent pages, which form a *B-partition* of  $r$ . The B-partition has the property that its constituent B-regions are pairwise disjoint. Note that requiring that the B-regions are pairwise disjoint is stronger than just requiring that the minimum bounding rectangles of the child pages (which are point or region pages) are disjoint. For example, although the two minimum bounding rectangles A and B in Figure 1.75 are disjoint, their B-regions are not disjoint as they are, in fact, the same. Empty B-rectangles (corresponding to empty point or region pages) are not represented explicitly in the region page, and thus they are not counted when determining if the capacity of  $r$  has been exceeded.

Once the initial point page has been split, insertion continues into the existing point pages, with splits made as necessary until the number of B-regions (i.e., point pages) exceeds the capacity  $c$  of the region page  $r$ . At this point, we split  $r$  into two region pages,  $r_1$  and  $r_2$ , by halving the B-region of  $r$ , and we propagate the split up the tree. If we are at the root of the tree, then we create a new region page,  $s$ , having  $r_1$  and  $r_2$  as its children. As this process of insertion is continued,  $s$  may eventually gain more children by virtue of splitting  $r_1$  and  $r_2$  until the number of region pages  $s$  comprises exceeds  $c$ , at which time another split operation is applied to  $s$ .

Of course, there are times when the newly inserted point  $q$  is not contained in any of the existing B-regions of the children of  $r$ . We have two options. The first is to extend the B-region of one of the children to cover  $q$ . The second is to create a new child with a B-region that covers  $q$ . Choosing the second option means that if we require the k-d-B-trie to be balanced (i.e., all point pages have to be at the same level), then we may have

<sup>49</sup> We assume that the sides of the minimum bounding rectangle are parallel to the axes corresponding to the keys.

## Section 1.7 BUCKET METHODS

Figure 1.74 Example showing the insertion of point X into a point page of capacity 4 in k-d-B-trie: (a) original point page, (b) one possible result of splitting the overflowing point page into two halves, and (c) the B-regions and bounding rectangles (shown shaded) that will be stored in the newly created region page; empty regions that have no corresponding entry in the region page are marked with diagonal lines.

Figure 1.75 Example pair of disjoint minimum bounding rectangles (shown shaded) whose B-regions are not disjoint.

Figure 1.76  
Example of a nonregular B-partition where each of the partitioning hyperplanes will pass through a B-region.

Figure 1.77  
(a) A region page and the generalized k-d tries corresponding to three possible partitions upon overflow given in (b), (c), and (d). Each non-leaf node is labeled with the name of the key that serves as the discriminator.

to create a chain of new region pages, each of which contains just one element, until reaching the leaf level of the k-d-B-trie. Note that some implementations of the k-d-B-trie, such as the buddy-tree, allow it to be unbalanced. We usually try the first option because it leads to better storage utilization and use the second option only if the first option is not possible.

When a region page is split, we want to avoid the problem that arose in the k-d-B-tree where the partition of a region page could cause the partitioning of some of its constituent region pages. This problem is avoided by requiring that the B-partition corresponding to each region page form a generalized k-d trie<sup>50</sup> (such a B-partition is termed *regular* [1710]). For example, assuming a region page capacity of 4, the partition into five regions (three of which are  $2 \times 1 \times 1$  hyperrectangles whose longest side is parallel to a different axis and two of which are  $1 \times 1 \times 1$  cubes) given in Figure 1.76 [1710] is not regular. In particular, no hyperplane exists that can partition it into two disjoint sets. The above problem can arise in the k-d-B-trie only when two child pages of a region page are merged, which means that the merging process must ensure that the result of the merge does not violate the regularity requirement (see Exercise 1).

Observe that the generalized k-d trie need not be unique, which means that the B-partition need not be unique. For example, consider Figure 1.77(b–d), which shows three possible generalized k-d tries for the region page in Figure 1.77(a). Observe that in this figure, and for the purposes of facilitating the process of determining whether a B-partition is regular, each leaf node in the generalized k-d trie represents the largest possible bounding B-rectangle for the B-region corresponding to the node, thereby obviating the need for empty nodes.

It should be clear that each region page  $r$  in a k-d-B-trie is a collection of disjoint B-regions whose union (in terms of the portions of the underlying space that they span) is a subset of the underlying space spanned by  $r$ . This property is useful in making the k-d-B-trie a good structure for the execution of search queries (e.g., range queries) because we can avoid examining regions that cannot possibly contain data (e.g., notice the empty region in the upper-right corner of Figure 1.74(c)). Thus, the B-regions have similar properties to the minimum bounding boxes that form the basis of the R-tree. B-regions differ from minimum bounding boxes by virtue of the fact that their sizes and positions are restricted to being a result of the application of a recursive halving process to the underlying space.

Since each B-partition can be represented by a generalized k-d trie, we can represent the B-regions making up both the point and region pages of the k-d-B-trie compactly by just recording the minimum number of bits (i.e., the paths in the generalized k-d trie, one per key, to the B-region, with left and right transitions being represented by 0 and 1, respectively<sup>51</sup>) necessary to differentiate them from the remaining B-regions. Note that in this case we are representing the full generalized k-d trie in contrast to the one depicted in Figure 1.77, which employs just enough partitions to distinguish the different minimum bounding B-rectangles for the pages making up the B-partition. In contrast, in the k-d-B-tree, we need to store the whole partition value for each key.<sup>52</sup>

The k-d-B-trie has great flexibility in determining which nonfull point and region pages are to be merged when deletions take place, as well as when page splitting results in pages that are underfull. This permits the k-d-B-trie to have good dynamic behavior. In particular, assuming  $d$ -dimensional data, if we used a PR k-d tree instead of a generalized

<sup>50</sup> We could have also used the term *generalized  $k^+$ -d trie* to describe this k-d trie to reinforce the similarity of the representation of the nodes of the k-d-B-trie to those of the k-d-B-tree.

<sup>51</sup> A separate path for each key is needed instead of just one sequence of interleaved 0s and 1s because the attributes are not being tested in cyclic order and thus the correspondence between the identity of the tested attribute and the result of the test must be recorded.

<sup>52</sup> In fact, for some implementations of the k-d-B-tree, associated with each region entry in a region page is a rectangle, requiring two values for each key, representing the region.

k-d trie, then a page  $a$  could be merged with just one page (i.e., the brother of  $a$ ). In contrast, in the k-d-B-trie,  $a$  can be merged with up to  $d$  pages corresponding to the  $d$  possible keys whose domain axes could have been split in half when  $a$  was created (i.e., as a result of a split). The pages with whom  $a$  can be merged are termed its *buddies*. In fact, the definition of a buddy could be made less restrictive by stipulating that two child pages,  $g$  and  $h$ , in region page  $p$  are buddies if the intersection of the B-region of their union with the B-regions of all remaining pages in  $p$  is empty. This means that the maximum number of pages with which  $a$  can be merged (i.e., buddies) is even greater than  $d$  (see [1706, 1710]). To see why this is true, recall that the B-regions of the child pages of a region page  $p$  can be represented by several different generalized k-d tries (whereas there is only one way to do so with a PR k-d tree). Therefore, a page  $b_i$  is a *buddy* of page  $a$  if  $a$  and  $b_i$  occur in sibling leaf nodes in some generalized k-d trie representing the partition of  $p$ . For example, in Figure 1.77,  $a$  can be merged with  $b_1$ ,  $b_2$ , or  $b_3$ .

There are several variants of the k-d-B-trie. The most notable are the multilevel grid file [1087] and the buddy-tree [1710]. The key difference between the multilevel grid file and the buddy-tree is the fact that in the buddy-tree a minimum bounding rectangle is stored for each of the child pages (instead of their B-regions, which may be computed from the minimum bounding rectangles as needed), while the multilevel grid file just stores the B-regions with the bitstring approach described above (see Figure 1.78). Another difference is that the buddy-tree exploits the less restrictive definition of a buddy, thereby permitting a page to be merged with a larger range of pages. In addition, the buddy-tree is not always balanced in order to prevent the existence of region pages with only one child page (see below for more details). Finally, the multilevel grid file employs a hashing function that is applied to the various keys prior to the application of the trielike decomposition process. This enables indexing on a wider variety of key types, such as strings of characters, and so on.

The fact that empty B-rectangles are not represented in a region page  $r$  leads to an interesting situation when a point  $q$  being inserted into  $r$  does not lie in the B-regions of any of the child pages of  $r$ . In other words,  $q$  is in an empty B-rectangle. Recall that the point insertion procedure is top-down in the sense that we start at the root of the k-d-B-trie and search for the point page containing  $q$ . The search ceases once we encounter such a point page or if we encounter an empty B-rectangle  $e$  in a region page  $r$ . In the latter case, we have two options. The first option is to attempt to enlarge one of the existing B-regions to accommodate the point. If this is not possible, then the second option is to create a new page for  $q$ . Let us look more closely at how we attempt to enlarge one of the existing B-regions. This is achieved by checking whether the B-region of  $q$  (i.e., the B-region of the minimum bounding rectangle of  $q$ ) can be merged with the B-region of one of its buddies in  $r$ . If such a buddy  $a$  exists, and if  $a$  is not already filled to capacity, then we enlarge the B-region of  $a$  to accommodate  $q$  in the corresponding entry of region page  $r$  and continue by inserting  $q$  into  $a$ . If no nonfull buddy exists, then we resort to the second option and create a new point page  $v$  of one point.

The newly created point page should be at the deepest level of the k-d-B-trie. However, this would lead to a long sequence of region pages with just one nonempty entry. This is quite inefficient, and thus in some implementations of the k-d-B-trie (e.g., in the buddy-tree but not in the multilevel grid file), an unbalanced structure is used where the new point page  $v$  is added at the depth  $i$  of the empty B-rectangle  $t$  in which  $q$  fell. However, if this new point page  $v$  at depth  $i$  overflows at some later time, then  $v$  is pushed one level down in the k-d-B-trie to depth  $i + 1$  and then split. This action is taken instead of splitting  $v$  at depth  $i$  and possibly having to split the region page  $w$  at depth  $i - 1$  when  $w$  overflows as a result of the split at depth  $i$ .

Note that when the keys are clustered, methods such as the k-d-B-trie do not yield a very good partition of the underlying space. However, results of experiments with the buddy-tree [1710] show that the fact that empty B-rectangles are not represented explicitly ameliorates this drawback to such an extent that it is no longer significant.

Figure 1.78  
Example illustrating the difference between (a) a multilevel grid file and (b) a buddy-tree. Notice the use of minimum bounding rectangles (shown shaded) in (b).

(a)

(b)

Figure 1.79  
(a) Example illustrating a region page in the BANG file and (b) its corresponding PR k-d tree.

Nevertheless, the definition of the multilevel grid file does take this into consideration by virtue of the hashing functions that, we recall, are applied to the various keys prior to the application of the trielike decomposition process. However, it should be noted that, in general, it is quite difficult to devise an order-preserving hashing function that significantly reduces clustering. Moreover, the use of a non-order-preserving hashing function (which can be devised to spread the hash values virtually uniformly) is a drawback for range queries.

The BANG file [640, 641, 645, 646] is a variant of the k-d-B-trie that requires that the underlying space be decomposed by a sequence of partitions that cycle through the keys in a fixed order. Moreover, unlike other variants of the k-d-B-trie (such as the buddy tree and multilevel grid file), the BANG file removes the requirement that the portions of the underlying space that are spanned by the region pages be hyperrectangles. Instead, the BANG file requires only that the space spanned by the set of regions that make up each region page be describable by a PR k-d tree where the individual regions are unions of the blocks corresponding to collections of leaf nodes of the PR k-d tree. In this sense, the region pages are similar to those in the hB-tree except that the BANG file makes use of regular decomposition. In particular, as mentioned above, in the BANG file, the underlying space is decomposed by cycling through the various keys in a fixed and predetermined cyclic order (e.g.,  $xyxyx\dots$ ). Thus, the BANG file is a variant of the k-d-B-trie in a similar way as the hB-tree is a variant of the k-d-B-tree.

As an example of the type of space decomposition permitted by the BANG file, consider the region page in Figure 1.79(a) and its corresponding PR k-d tree in Figure 1.79(b), which consists of the four regions, A, B, C, and D. Observe that, using the parlance of hB-trees, regions A and B play the role of holey bricks, regions B and D play the role of the bricks that are removed from A, and region C plays the role of the brick that is removed from B. In the BANG file, each of the various regions prior to the removal of the bricks is represented by a bitstring corresponding to the path from the root of the PR k-d tree of the region page to the nearest common ancestor of all leaf nodes belonging to the same region (i.e., the outer boundary of the original hyperrectangle before extraction of any bricks). For example, letting 0 correspond to branches to the left and below the partition line, while letting 1 correspond to branches to the right and above a partition line, we have that A is represented by the empty bitstring (as the nearest common ancestor is the root of the PR k-d tree), while B is represented by 10. The actual regions (i.e., their bit strings) are stored in a B-tree-like structure where, upon a split of a region page, each of the resulting region pages is at least one-third full, thereby making the other page no more than two-thirds full, as in the hB-tree (see Section 1.7.1.4). Another difference between the BANG file and the hB-tree (i.e., besides the BANG file's being based on a regular decomposition instead of allowing splits at arbitrary positions) is that this B-tree-like structure is a tree rather than a directed acyclic graph, as is the case for the hB-tree, since each region is only represented once in the BANG file.

The execution of operations, such as an exact match query, using the BANG file is facilitated by sorting the regions corresponding to each region page in the BANG file in order of increasing size of their blocks (i.e., prior to the removal of the bricks). The exact match query is performed by testing the regions for containment of the query point  $p$  in this order and stopping the search as soon as a region is found to contain  $p$ . This will guarantee that the smallest region enclosing  $p$  is selected. The process of searching for the block containing  $p$  can be implemented by sorting the bitstrings in lexical order (e.g., empty, 0, 011, 1, 101). Notice that this will order the bitstrings of larger blocks before the bitstrings of small blocks contained in them. The search itself is done by performing a prefix bit matching in the resulting list in reverse order (i.e., starting from the end) for the bitstring describing  $p$ . Unfortunately, this search process may take as much as  $O(N)$  time when the  $N$  blocks are all nested within each other (i.e., the blocks are numbered  $b_i$ ,  $1 \leq i \leq N$ , where  $b_i$  contains  $N - i$  blocks). Thus, we see that, even though the original intent of the BANG file is to have a disjoint decomposition of the underlying space,

the actual representation used here makes use of nondisjoint blocks and hence the more complex search time for the exact match query.

Freeston [645] overcomes the worst-case  $O(N)$  execution time of the exact match query by modifying the BANG file so that the search paths are unique but at the loss of the minimal page occupancy guarantee. Ouksel and Mayer [1438] take an alternative approach to reducing the worst-case execution time of the exact match query. In particular, they reduce it to a function of the product of the logarithms of the number of nesting levels and the number of blocks by using a different implementation than Freeston [640] of the BANG file as the set of blocks prior to the removal of the bricks. They use a slightly modified form of the bitstring. In particular, all of the bitstrings have the same length, which is equal to the maximum possible level of decomposition, by padding them with zeros on the right and also by recording the length of the original unpadded bitstring. The resulting padded bitstrings are stored in a structure such as a B-tree and sorted in increasing order, with the length of the original unpadded bitstring serving as a secondary key to break ties. The padded bitstring is equivalent to a locational code, which is discussed briefly in Section 1.8.5.1 and in much greater detail in Section 2.1.2.4 of Chapter 2.

The key to Ouksel and Mayer's method is to partition the blocks into subsets where all members of a subset have the same nesting level (i.e., the number of containing ancestor blocks). Each of these subsets can be stored in a separate B-tree, and the result is called a *nested interpolation-based grid file* (NIBGF) [1438]. Note that the use of the term *grid file* is somewhat misleading as the NIBGF bears little resemblance to a grid file, being really a pointerless representation for the BANG file. In particular, the search is now a binary search through the various nesting levels. At each nesting level  $l$  that is tested, determine if the query point is covered by one of the blocks in the B-tree corresponding to the level. If it is, then the search proceeds at deeper nesting levels. If it is not, then the search proceeds at shallower nesting levels.

The worst-case execution time of this process is the product of the log of the number of nesting levels  $h$  and the cost of a B-tree lookup. A more precise analysis takes into account the fact that the B-trees at the different levels will differ in size, and thus the analysis is in terms of the number of B-tree nodes that must be examined. Letting  $h$  denote the number of nesting levels, Ouksel and Mayer show that the worst-case execution time is  $O(\log_2 h \cdot \log_{\lfloor b/2 \rfloor} N)$  for a B-tree of order  $b$  (see Exercise 3). Special cases can yield tighter bounds. For example, if there are  $N$  nesting levels, then the cost is  $O(\log_2 N)$  comparisons and corresponding B-tree node lookups. If there is just one nesting level, then only one B-tree node lookup is needed, and the cost is  $O(\log_{\lfloor b/2 \rfloor} N)$  B-tree node lookup operations.

Ouksel and Mayer's solution is not just applicable to the BANG file. It is applicable to any representation that makes use of nondisjoint nested blocks, such as those resulting from the association of objects with their minimum enclosing quadtree or k-d tree blocks. Some examples include the MX-CIF quadtree [1009], R-file [909], and filter tree [1720] (see the discussion in Section 2.1.4.1 of Chapter 2 and Sections 3.4.1 and 3.4.2 of Chapter 3).

The use of bitstrings to represent the various regions in the BANG file is similar to that used in the BD-tree [1386, 1387]<sup>53</sup> but quite different from the one used in the multilevel grid file [1087].<sup>54</sup> Nevertheless, a key difference between the BANG file and the BD-tree is the fact that the BD-tree does not aggregate the nonleaf nodes of the

---

<sup>53</sup> The difference is that in the BANG file the bitstrings corresponding to the regions are kept in a sorted list according to their size, while in the BD-tree they are kept in a binary tree. This results in a different search process, possibly visiting different regions, although, of course, the end result for both representations is the same!

<sup>54</sup> Recall that in the multilevel grid file, a set of bitstrings, one per key, is associated with each page since the keys are partitioned in arbitrary order rather than in a cyclic order as in the BANG file, thereby precluding the possibility of using just one bitstring, which is what is done in the BANG file. However, more importantly, in the multilevel grid file, the bitstrings represent rectangular regions, as in the BANG

structure into buckets. In particular, in the BD-tree, only the leaf nodes are aggregated into buckets. Therefore, the BANG file is related to the BD-tree in a way similar to how the k-d-B-tree is related to the bucket generalized pseudo k-d tree. An even more precise analogy is that the BANG file is related to the BD-tree in the same way as the k-d-B-trie (e.g., the buddy-tree or the multilevel grid file) is related to the bucket PR k-d tree as they all also make use of regular decomposition.

### Exercises

1. Give an algorithm to test whether two pages in a k-d-B-trie can be merged. Recall that two pages can be merged only if the resulting page is not too full and if the result is a B-partition.
2. Do we need to test if the result of a page split in a k-d-B-trie is a B-partition?
3. Letting  $N$  denote the number of blocks,  $h$  the number of nesting levels, and  $b$  the bucket capacity of a B-tree node, show that the worst-case cost, in terms of B-tree node accesses, of an exact match query in a nested interpolation-based grid file (NIBGF) with  $N$  blocks is  $O(\log_2 h \cdot \log_{\lfloor b/2 \rfloor} N)$ .
4. Write a procedure BUDDYINSERT to insert a point into a buddy-tree.
5. Write a procedure BUDDYDELETE to delete a point from a buddy-tree.
6. Write a procedure BUDDYPOINTQUERY to perform a point query in a buddy-tree.
7. Write a procedure BUDDYRANGEQUERY to perform a range query in a buddy-tree.
8. What is the maximum number of possible buddies in a buddy-tree?

### 1.7.1.6 BV-Tree

The lifting of the requirement that the portions of the underlying space spanned by the region pages be hyperrectangles is a central principle behind the development of both the hB-tree and the BANG file. Recall that both the hB-tree and the BANG file are designed to overcome the cascading split problem that is common to the k-d-B-tree: the insertion of a split line may cause a recursive application of the splitting process all the way to the point pages. This means that we do not have a bound on the number of nodes in the directory structure as a function of the number of data points. Moreover, as we saw, the directory of the hB-tree is not a tree (recall that it is a directed acyclic graph) since it may be impossible to avoid the situation that some of the regions in the region page (i.e., directory node) that is being split will fall partially into both of the region pages resulting from the split.

The occurrence of this problem is addressed by Freeston [643] by use of a clever innovation. The innovation is to decouple [1640] the hierarchy inherent in the tree structure of the directory (where the node entries consist of point and region pages) from the containment hierarchy associated with the recursive partitioning process of the underlying space from which the data is drawn. Below, we use the term *BV-tree* to denote the tree structure of the directory obtained from applying the technique described in [643]. The goal is for the BV-tree to have properties similar to the desirable properties of the B-tree while avoiding the problems described above. In particular, a bounded range of depths (and hence a maximum) can be guaranteed for the BV-tree based on the maximum number of data points and capacity (i.e., fanout) of the point and region pages (they may differ). These bounds are based on the assumption that each point page is at least one-third full [643]. Moreover, in spite of the fact that the BV-tree is not quite balanced, search procedures always proceed level to level in the containment hierarchy. For exact match point search, this means that the number of steps to reach a point page is equal to the depth of the containment hierarchy. Note that in this section we use the

---

file, but all the regions in a given page are disjoint rather than being allowed to be nested, as is the case for the BANG file.

term *containment hierarchy* instead of *decomposition hierarchy* because it provides a more accurate description of the constraints on the decomposition process imposed by the BV-tree. We also use the term *directory node*, instead of the term *region page*, in order to reinforce the meaning that these pages are part of the directory and also to make the connection to the PK-tree [1952, 2043] (see Section 1.8), which is another representation that makes use of decoupling [1640] (now it is the grouping and partitioning processes that are decoupled). On the other hand, we continue to use the term *point page*, but in the PK-tree presentation, we use the term *point node* as the number of points in the node may be quite small.

This section is organized as follows. Section 1.7.1.6.1 defines the BV-tree. Section 1.7.1.6.2 describes how to build a BV-tree with the aid of a detailed example. Section 1.7.1.6.3 shows how to search a BV-tree for a region that contains a given point. Section 1.7.1.6.4 discusses the performance of the BV-tree in terms of its storage requirements. Section 1.7.1.6.5 concludes the presentation by reviewing some of the key properties of the BV-tree and compares it with some other representations, including the R-tree.

### 1.7.1.6.1 Definition

In order for the BV-tree technique to be applicable, the regions in the containment hierarchy are required to be disjoint within each level. Furthermore, the boundaries of regions at different levels of the containment hierarchy are also required to be nonintersecting. These requirements hold when the decomposition rules of both the BANG file and the hB-tree are used for the containment hierarchy. However, in the case of the BANG file, their satisfaction when splitting and merging nodes is almost automatic due to the use of regular decomposition; in the case of the hB-tree, we need to make use of an explicit k-d tree to represent the history of how the regions were split. In contrast, in the case of the BANG file, the splitting history is implicitly represented by the bitstring corresponding to each region.

As in the BANG file and in the hB-tree, there are two ways in which regions in the BV-tree are created that satisfy these properties. In particular, upon node overflow, the underlying space (e.g., Figure 1.80(a)) is recursively decomposed into disjoint regions either by splitting them into what we term *distinct regions* (e.g., Figure 1.80(b)) or *contained regions* (e.g., Figure 1.80(c)). Splitting into contained regions is achieved via the extraction of smaller-sized regions, thereby creating one region with holes. The disjointness of the regions at a particular level in the containment hierarchy ensures that the outer boundaries of the regions do not intersect (although they may touch or partially coincide). It can be shown that such partitions can be made so that each of the resulting partitions is at least one-third full (see Exercise 1). The BV-tree is built in a bottom-up manner so that data is inserted in point pages (of course, the search for the point page to insert into is done in a top-down manner). Overflow occurs when the point page is too full, at which time the point page is split, thereby leading to the addition of entries to the directory node that points to it, which may eventually need to be split when it points to more point pages than its capacity allows.

Before proceeding further, let us define some of the naming and numbering conventions that we use in our presentation. For a BV-tree of height  $h$  (i.e., with  $h$  levels of decomposition or containment), the levels in the containment hierarchy are numbered from 0 to  $h$ , where 0 is the deepest level (i.e., corresponding to point pages). Each level in the containment hierarchy has several regions associated with it that span the regions spanned by every point page or directory node in the immediately deeper level in the containment hierarchy. The levels in the directory hierarchy are numbered from 1 to  $h$ , with level 1 containing the leaf nodes whose entries are point pages. This convention enables a node at level  $v$  in the directory hierarchy to be (normally) associated with a region at level  $v$  in the containment hierarchy. For example, we can view the region representing the entire data space as being at level  $h$  in the decomposition hierarchy, and

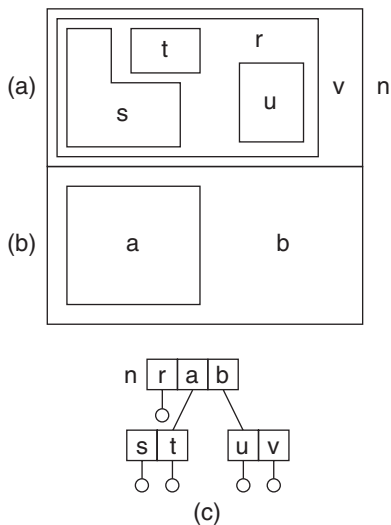

Figure 1.80  
(a) Example region and the result of splitting it into (b) distinct regions or (c) contained regions.

the root node (at directory level  $h$ ) also represents the entire data space. It is important to distinguish between a level in the containment hierarchy and a level in the directory hierarchy, since these two hierarchies are decoupled in the BV-tree. In fact, the result of decoupling these two hierarchies is that a node at level  $v$  of the containment hierarchy appears as an entry of a node at directory level  $v + 1$  or shallower.

Nevertheless, the use of the term *level* can be quite confusing. Therefore, in order to differentiate between levels in the containment and directory hierarchies, as well as to reduce the potential for confusion, we frequently distinguish between them by using the terms *clevel* and *dlevel*, respectively. However, we do not use these terms when the term *level* is explicitly qualified by using the full expression *directory level* or *level of the containment hierarchy*.

Note that the nonintersection of the outer boundaries described above holds for all pairs of regions and not just for those at the same level of decomposition. However, the containment relationship does not require that regions at deeper levels of decomposition (i.e., smaller level numbers) be contained in regions at shallower levels of decomposition (i.e., larger level numbers).

The containment condition can be restated as stipulating that the interiors of any two regions  $a$  and  $b$  (regardless of whether their holes are taken into account) are either disjoint (with boundaries that are permitted to coincide partially) or one region is completely contained within the other region (i.e.,  $a$  is in  $b$ , or  $b$  is in  $a$ ). From the standpoint of the structure of the directory hierarchy, the containment condition implies that if the region corresponding to directory node  $n$  is split on account of  $n$  having overflowed into regions  $a$  and  $b$  such that the area spanned by one of the regions corresponding to a child  $r$  of  $n$  (which must be redistributed into the directory nodes corresponding to  $a$  and  $b$ ) intersects (i.e., overlaps) both  $a$  and  $b$ , then the region corresponding to  $r$  must completely contain either  $a$  or  $b$ .

Figure 1.81  
Example illustrating the containment condition when (a) the directory node  $n$  overflows, (b) the result of splitting it into two directory nodes  $a$  and  $b$ , and (c) the resulting directory hierarchy.

For example, consider the region corresponding to directory node  $n$  in Figure 1.81(a), which has overflowed on account of containing five items while its capacity is 4. The region corresponding to  $n$  has been split into two regions  $a$  and  $b$ , shown in Figure 1.81(b), which are not disjoint and thus have the property that each of their children is either entirely contained within one of them (i.e.,  $s$  and  $t$  are contained within  $a$ , and  $u$  and  $v$  are contained within  $b$ ), while  $r$  (which overlaps both  $a$  and  $b$ ) in fact contains  $a$  in its entirety. In the BV-tree, when this happens,  $r$  (and most importantly its corresponding region) will be “associated” with the resulting directory node (termed its *guard*), whose corresponding region it completely contains (see below for more detail about the mechanics of this process). Formally, a region  $r$  at level  $l$  in the containment hierarchy is said to be a *guard* of region  $a$  at level  $m$  in the containment hierarchy if and only if  $r$  is at a deeper level in the containment hierarchy than  $a$  (i.e.,  $l < m$ ), and  $r$  is the smallest of all regions at level  $l$  that enclose  $a$ . This is shown in our example by associating  $r$  with the entry corresponding to  $a$  in the replacement directory node  $n$  in Figure 1.81(c), where it is placed in front of  $a$ .

The BV-tree definition does not stipulate how the underlying space spanned by the elements of the directory structure (i.e., directory nodes) is to be decomposed; nor does it restrict the shapes of the resulting regions, provided that their outer boundaries do not intersect. In particular, the underlying space may be decomposed into regions of arbitrary shape and size—that is, neither the space spanned by the regions need be hyperrectangular; nor, as is the case for the hB-tree and BANG file, must the faces of the regions be parallel to the coordinate axes. However, since the space decomposition generated by the BANG file satisfies the nonintersecting outer boundary requirement, the BV-tree method may be used to obtain a variant of the BANG file (i.e., a regular decomposition of the underlying space) that does not suffer from either a nonunique search path or the lack of a minimum storage occupancy.

The fact that regions created at certain levels (i.e., clevels) of decomposition of the underlying space may be associated with directory nodes at shallower directory levels in the directory hierarchy means that the union of the regions associated with all of the directory nodes found at directory level  $i$  of the directory hierarchy of the BV-tree does not necessarily contain all of the data points. This is not a problem for searching operations because, in such a case, each directory node also contains entries that correspond to regions that were not split at deeper levels of the containment hierarchy. These node entries are present at the shallower directory level because, otherwise, they and their corresponding regions would have had to be split when the directory node corresponding to the region in which they were contained was split. Instead, they were promoted to the next shallower directory level, along with the region corresponding to the newly created directory node that they contained. The directory hierarchy entries whose corresponding regions were created at deeper levels of the containment hierarchy (i.e., the ones that were promoted) serve as guards of the shallower directory-level directory nodes and are carried down the directory hierarchy as the search takes place.

Since promotion can take place at each directory level, a situation could arise where guards are promoted from  $d$ level to  $d$ level. For example, suppose that directory node  $a$  has been promoted from being an entry in a node at directory level  $i$  to being an entry in directory node  $x$  at directory level  $i + 1$ , where  $a$  serves as a guard of an entry  $b$  that is a directory node. Next, suppose that  $x$  overflows, such that its region  $c$  is split into two regions whose corresponding directory nodes are  $d$  and  $e$ , which replace  $x$  in the parent node  $y$  of  $x$ . Now, it is possible that the region corresponding to  $b$  contains the regions corresponding to either  $d$  or  $e$ , say  $e$ . In this case,  $b$  is promoted to  $y$  at directory level  $i + 2$ , where it serves as a guard of  $e$ , and thus  $a$  must also be promoted to  $y$  as  $a$  is a guard of  $b$ . Subsequent splits can result in even more promotion for  $a$ . Thus, we see that every unpromoted entry in a directory node at directory level  $i$  can have as many as  $i - 1$  guards, where we once again assume that the deepest directory nodes are at  $d$ level 1 (but they contain entries that correspond to point pages at  $c$ level 0).

### Exercise

1. Suppose that we formally define the concept of a containment hierarchy as follows. Let the *dataspace* be the set  $D$  from which all data objects are drawn. That is, for any possible data object  $d$ , we have  $d \in D$ . A *region*  $R$  is any subset of  $D$ . A *nontrivial region*  $R$  is a region such that  $R \neq \emptyset$ . The *complement* of region  $R$ , denoted by  $R'$ , is the region  $R' = D \setminus R$ . Region  $R$  *contains* region  $P$  if and only if  $P \subseteq R$ . Region  $R$  *properly contains* region  $P$  if and only if  $P$  contains  $R$  and  $P \neq R$ . Regions  $R$  and  $P$  are *coherent* if and only if either  $R$  contains  $P$  or  $P$  contains  $R$ . Regions  $R$  and  $P$  are *disjoint* if and only if  $R \cap P = \emptyset$ . Regions  $R$  and  $P$  are *cordial* if and only if they are either disjoint or coherent. A set of nontrivial regions  $S$  forms a *containment hierarchy* if and only if all regions in  $S$  are cordial to other regions in  $S$ . A *bottom* of a containment hierarchy  $S$  is a region  $B$  in  $S$  that properly contains no region of  $S$ . A *top* of a containment hierarchy  $S$  is a region  $B$  in  $S$ , such that no region of  $S$  properly contains  $B$ .

Notice that any containment hierarchy  $S$  can be viewed as a directed forest  $F$  with elements of  $S$  as its vertices, such that for any two regions  $R$  and  $P$ ,  $R$  is a proper ancestor of  $P$  in  $F(S)$  if and only if  $R$  properly contains  $P$ . Notice also that the leaves of  $F(S)$  are the bottoms of  $S$  and the roots of  $F(S)$  are the tops of  $S$ . For each region  $s$  of  $S$ , let  $h_S(s)$  be the height of  $s$  in  $F(S)$  and  $n_S(s)$  be the number of regions in  $S$  that are contained by  $s$  including  $s$ .

Containment hierarchies  $S$  and  $U$  are *disjoint* if and only if, for all  $s \in S$  and  $u \in U$ ,  $s$  and  $u$  are disjoint. Containment hierarchies  $S$  and  $U$  are said to form a *split* of containment hierarchy  $V$  if and only if  $V = S \cup U$  and either  $S$  and  $U$  are disjoint or all tops of  $U$  are properly contained by exactly one bottom of  $S$ . It is easy to see that if containment hierarchies  $S$  and  $U$  are a *split* of containment hierarchy  $V$ , then  $S \cap U = \emptyset$ .

Using the above definitions, prove that any containment hierarchy  $V$  with  $|V| > 1$  can be split into two containment hierarchies  $S$  and  $U$  such that  $\lceil \frac{1}{3}|V| \rceil \leq |U| \leq \lfloor \frac{2}{3}|V| \rfloor$ .

Figure 1.82 Initial step in creating a BV-tree: (a) containment hierarchy and (b) directory hierarchy.

### 1.7.1.6.2 Building a BV-Tree

The best way to see how the BV-tree works is to consider an example of how it is built. As mentioned above, each directory node  $a$  corresponds to a region in the underlying space. The entries in  $a$  contain regions and pointers to their corresponding point page or directory node (i.e., entries with regions at level 0 correspond to point pages, but regions at shallower levels correspond to directory nodes). When  $a$  is at level  $i$  of the directory hierarchy, its entries may be at levels 0 to  $i - 1$  of the containment hierarchy. The entries whose corresponding regions are at levels deeper than  $i - 1$  have been *promoted* to the node  $a$ , which is at a shallower level in the directory, where they serve as *guards* of some of the entries in  $a$ . Each entry in  $a$  also contains information about the level of the region it contains, so we may distinguish between promoted and unpromoted entries.

Node  $a$  contains a maximum of  $m$  entries, where  $m$  is the fanout of  $a$ . Node  $a$  is split if it overflows—that is, if the total number of entries in  $a$  (not distinguishing between promoted and unpromoted entries) exceeds  $m$ . In our example, we assume a fanout value of 7 for the point pages and 4 for the directory nodes. When a directory node is split, the BV-tree definition [643] claims that it should be possible to distribute its entries in the newly created directory nodes  $a$  and  $b$  so that each of  $a$  and  $b$  is at least one-third full because this is one of the properties of the BV-tree that enables it to guarantee an upper bound on the maximum depth of the directory hierarchy. As we will see below, this may not always be possible for all fanout values, thereby requiring some adjustments in the definition of the fanout (see Section 1.7.1.6.4).

Let us start with a set of eight points, labeled 1–8. This means that the capacity (i.e., fanout) of the corresponding point page is exceeded, and thus it is split into two regions, thereby creating  $a_0$  and  $b_0$ , containing points 1–4 and 5–8, respectively, and having a containment and directory hierarchy given in Figures 1.82(a, b), respectively.

Next, we add points 9–12, which cause  $a_0$  to be split into  $a_0$  and  $c_0$ , points 13–16, which cause  $a_0$  to be split into  $a_0$  and  $d_0$ , and points 17–20, which cause  $a_0$  to be split into  $a_0$  and  $e_0$ , as shown in Figure 1.83(a). However, this causes the single directory node to overflow, and it is split into two nodes whose corresponding regions are  $a_1$  and  $b_1$ , as shown in Figure 1.83(b). Since region  $a_0$  intersects both  $a_1$  and  $b_1$ , while completely containing  $a_1$ ,  $a_0$  is promoted to the newly created directory node where it serves as a guard on region  $a_1$ . The resulting directory hierarchy is shown in Figure 1.83(c). Note that  $a_0$  is the region that, if it were not promoted, we would have to split along the boundary of  $a_1$ . By avoiding this split, we also avoid the possibility of further splits at deeper levels of the directory hierarchy. Thus, the fact that  $a_0$  appears at this shallower level in the directory hierarchy ensures that  $a_0$  will be visited during any search of the BV-tree for a point on either side of the branch that would have been made if we would have split  $a_0$ , which we would have had to do if we did not promote it.

Figure 1.83  
Second step in creating a BV-tree: (a) containment hierarchy at the deepest level ( $clevel = 0$ ), (b) containment hierarchy at the shallowest level ( $clevel = 1$ ), and (c) directory hierarchy.

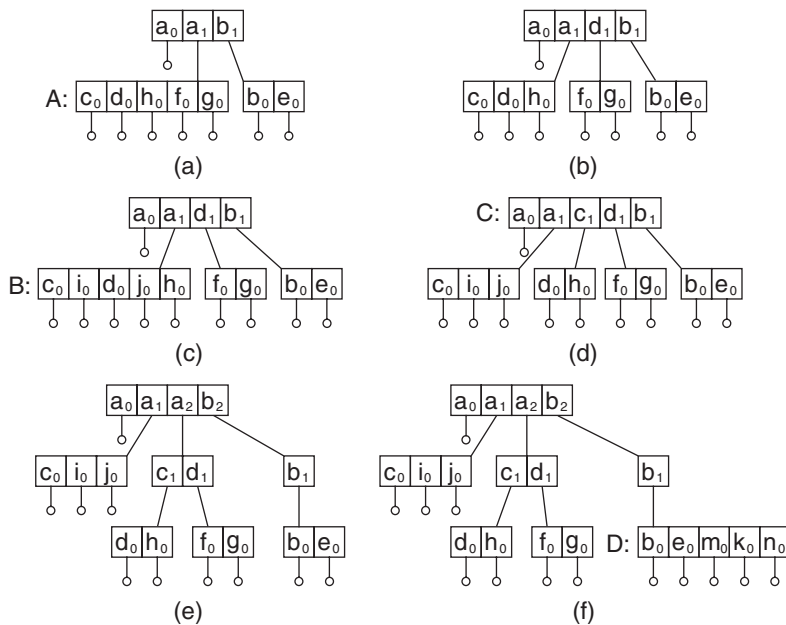

Figure 1.84  
Sequence of intermediate directory hierarchies illustrating the node-splitting operations taking place when points are added to the BV-tree of Figure 1.82 until obtaining the BV-tree of Figure 1.85.

Now, suppose that more points are added so that the underlying space is split several times. We do not go into as much detail as before in our explanation, except to indicate one possible sequence of splits. We also no longer show the points in the point pages.

1. Split  $d_0$  into  $d_0$ ,  $f_0$ , and  $g_0$ , which is followed by splitting  $d_0$  into  $d_0$  and  $h_0$ . This results in the directory hierarchy given in Figure 1.84(a), where the directory node corresponding to  $a_1$ , labeled A, must be split as it overflows. Node A is split into two directory nodes whose corresponding regions are  $a_1$  and  $d_1$ , resulting in the directory hierarchy given in Figure 1.84(b).

Figure 1.85  
Final step in creating a BV-tree: (a) containment hierarchy at the deepest level ( $clevel = 0$ ), (b) containment hierarchy at the intermediate level ( $clevel = 2$ ), (c) containment hierarchy at the shallowest level ( $clevel = 3$ ), and (d) BV-tree.

2. Split  $c_0$  into  $c_0$  and  $i_0$ , which is followed by splitting  $d_0$  into  $d_0$  and  $j_0$ . This results in the directory hierarchy given in Figure 1.84(c), where the directory node corresponding to  $a_1$ , labeled B, must be split as it overflows. Node B is split into two directory nodes whose corresponding regions are  $a_1$  and  $c_1$ , resulting in the directory hierarchy given in Figure 1.84(d), where the directory node corresponding to the root, labeled C, must be split as it overflows.
3. Node C is split into two directory nodes whose corresponding regions are  $a_2$  and  $b_2$ , resulting in the directory hierarchy given in Figure 1.84(e). Several items are worthy of note:
  - (a) The directory node corresponding to the root also contains an entry corresponding to region  $a_1$  because  $a_1$  intersects both  $a_2$  and  $b_2$ , while completely containing  $a_2$ . Thus,  $a_1$  becomes a guard of  $a_2$ .
  - (b) Since  $a_0$  originally guarded  $a_1$ ,  $a_0$  continues to do so, and we find that  $a_0$  is also promoted to the root of the directory hierarchy.
  - (c) The directory node corresponding to region  $b_2$  contains only the single region  $b_1$ . This means that our requirement that each directory node be at least one-third full is violated. This cannot be avoided in this example and is a direct result of the promotion of guards. This situation arises primarily at shallow dlevels when the fanout value is low compared to the height of the directory hierarchy. It is usually avoided by increasing the value of the fanout as described in Section 1.7.1.6.4.
4. Split  $e_0$  into  $e_0$ ,  $k_0$ , and  $m_0$ , which is followed by splitting  $a_0$  into  $a_0$  and  $n_0$ . This results in the directory hierarchy given in Figure 1.84(f), where the directory node corresponding to  $b_1$ , labeled D, must be split as it overflows. There are several ways to split D. One possibility, and the one we describe, is to split D into two directory nodes whose corresponding regions are  $b_1$  and  $e_1$ , resulting in the directory hierarchy given in Figure 1.85(d). Since region  $e_0$  intersects both  $e_1$  and  $b_1$ , while completely containing  $e_1$ ,  $e_0$  is promoted to the directory node containing entries corresponding to  $b_1$  and  $e_1$ , where  $e_0$  serves as a guard on region  $e_1$ . The three levels that make up the final containment hierarchy are shown in Figure 1.85(a–c). Notice that we could have also split D so that the region  $e_1$  contained regions  $e_0$ ,  $k_0$ , and  $m_0$ . In this case,  $e_0$  would not be needed as a guard in the directory node containing entries corresponding to regions  $b_1$  and  $e_1$ .

### Exercises

1. Suppose that a region  $r$  at level  $v$  in the containment hierarchy serves as a guard  $g$  for a region at level  $v + 1$  in the containment hierarchy, and the directory node whose corresponding region is  $r$  overflows. How would you handle the situation? In particular, what are the ramifications of splitting  $r$  into two disjoint regions in contrast to one where one region contains the other?
2. How would you deal with deletion in a BV-tree?

### 1.7.1.6.3 Searching a BV-Tree

Having shown how to construct the BV-tree, we now examine the process of searching a BV-tree for the region that contains a point  $p$  (termed an *exact match search* here). The key idea behind the implementation of searching in the BV-tree is to perform the search on the containment hierarchy rather than on the directory hierarchy. At a first glance, this appears to be problematic because the BV-tree represents only the directory hierarchy explicitly, while the containment hierarchy is represented only implicitly. However, this is not a problem at all because the containment hierarchy can be, and is, reconstructed on the fly, as necessary, with the aid of the guards when performing the search. In particular, at each stage of the search, the relevant guards are determined, and they are carried down the directory hierarchy as the search proceeds. Note that, as we show below, all exact

match searches are of the same length and always visit every level in the containment hierarchy (see Exercise 1).

We explain the search process in greater detail below. Initially, we differentiate between the searches depending on whether the directory node being searched is the root of the directory hierarchy, assumed to be at dlevel  $v$ . Recall that all unpromoted entries in the root correspond to regions at level  $v - 1$  in the containment hierarchy. The search starts at the root of the directory hierarchy at dlevel  $v$  (assuming that the deepest directory node is at dlevel 1 and describes regions at level 0 in the containment hierarchy). It examines the regions corresponding to all of the entries (i.e., including the guards) and selects the smallest region  $r$  (corresponding to entry  $e_r$ ) that contains the query point  $p$ . Entry  $e_r$  is termed the *best match*. The level  $v - 1$  directory node at which the search is continued depends on whether  $e_r$  is a guard:

1. Entry  $e_r$  is not a guard: Continue the search at the directory node pointed at by  $e_r$  with a guard set formed by the current set of guards of  $e_r$  (as many as  $v - 1$  guards, one for each of levels 0 through  $v - 2$  in the containment hierarchy).
2. Entry  $e_r$  is a guard: Find the smallest region  $s$  containing  $r$  whose corresponding entry  $e_s$  is not a guard. It is easy to show that  $e_s$  must exist. The area spanned by  $s$  may also contain other regions, say the set  $O$ , corresponding to guards whose regions contain  $r$ . Continue the search at the directory node pointed at by  $e_s$  with a guard set consisting of  $e_r$ , the set of entries corresponding to the regions that make up  $O$ , and the guards that correspond to regions that contain  $s$ . The guards that correspond to regions that contain  $s$  are from levels in the containment hierarchy for which  $O$  does not contain guards. For each of these clevels, choose the guard that has the smallest region that contains  $p$ . In other words, the guard set can contain at most one guard for each of levels 0 through  $v - 2$  in the containment hierarchy, for a maximum of  $v - 1$  guards.

Searching at directory node  $a$  at dlevel  $u$  other than the root uses a similar procedure as at the root. Again, we wish to determine the level  $u - 1$  directory node at which the search is to be continued. This is done by finding the smallest region  $r$  (termed the *best match*) containing  $p$ . The difference is that the best match is obtained by examining the guard  $g$  at clevel  $u - 1$  (if it exists) of the  $u$  guards at clevels 0 through  $u - 1$  that make up the guard set that was brought down from the previous search (i.e., from dlevel  $u + 1$ ) and the entries in  $a$  that are not guards (note that it may be the case that none of the entries in  $a$  are guards, as can be seen by examining point  $w$  and the directory node whose corresponding region is  $a_2$  in Figure 1.85(a)). There are two options:

1. If the best match is the region corresponding to  $g$ , then continue the search at the level  $u - 1$  directory node pointed at by  $g$ . The guard set must also be updated as described below.
2. Otherwise, the best match is  $r$ , which corresponds to an entry in  $a$  (say  $e_r$ ), and continue the search at dlevel  $u - 1$  at the directory node pointed at by  $e_r$ . Use a guard set obtained by merging the matching guards found at dlevel  $u$  with those brought down from dlevel  $u + 1$ . Discard  $g$ , the clevel  $u - 1$  guard brought down from dlevel  $u + 1$  (if it exists), as  $g$  cannot be a part of a directory node at dlevel  $u - 1$  since each entry at dlevel  $i$  of the directory hierarchy can contain at most  $i - 1$  guards, and the search will next be on regions at clevel  $u - 2$ . Note that two guards at a given dlevel are merged by discarding the one that provides the poorer match.

Interestingly, there is really no need to differentiate the treatment of root nodes from that of nonroot nodes. In particular, in both cases, only the unpromoted nodes (i.e., entries whose corresponding regions are not guards) need to be examined. In the case of the root node, initially no guard set is brought down from the previous dlevel. Thus, it is initially empty. In this case, the new guard set is formed by finding the guard for each clevel that has the smallest region that contains  $p$ .

In order to understand the exact match search algorithm better, let us see how we find the regions in the BV-tree of Figure 1.85(a) that contain the points  $w$ ,  $x$ ,  $y$ , and  $z$ , which are  $a_0$ ,  $a_0$ ,  $a_0$ , and  $e_0$ , respectively. Notice that each region has been labeled with subscripts denoting its level in the containment hierarchy. This is also two less than the deepest level in the directory hierarchy at which it can serve as a guard, and one less than the deepest level in the directory hierarchy at which it will get carried down in the guard set.

1. The search for  $w$  first examines the root, at dlevel 3, and determines  $a_2$  to be the best match. The search continues at the dlevel 2 directory node whose corresponding region is  $a_2$  (i.e., containing  $c_1$  and  $d_1$ ) with a guard set consisting of  $a_0$  and  $a_1$ . There is no match in the entries in  $a_2$  (i.e., neither  $c_1$  nor  $d_1$  contains  $w$ ), and thus we use the guard  $a_1$  brought down from dlevel 3 as the best match. The search continues at the dlevel 1 directory node whose corresponding region is  $a_1$  (i.e., containing  $c_0$ ,  $i_0$ , and  $j_0$ ) with a guard set consisting of  $a_0$ . Again, there is no best match in the entries in  $a_1$  (i.e., neither  $c_0$  nor  $i_0$  nor  $j_0$  contains  $w$ ), but the guard  $a_0$  contains  $w$ , and since the region corresponding to  $a_0$  is at level 0 of the containment hierarchy, we are done. Therefore,  $w$  is in  $a_0$ .
2. The search for  $x$  first examines the root, at dlevel 3, and determines  $a_1$  to be the best match. However,  $a_1$  is a guard, and thus it finds the smallest nonguard region containing  $a_1$ , which is  $b_2$ . The search continues at the dlevel 2 directory node whose corresponding region is  $b_2$  (i.e., containing  $b_1$ ,  $e_0$ , and  $e_1$ ) with a guard set consisting of  $a_0$  and  $a_1$ . The best match in this node is  $b_1$ . However, the clevel 1 guard in the guard set is  $a_1$ , and its corresponding region is a better match. The search continues in the dlevel 1 directory node whose corresponding region is  $a_1$  (i.e., containing  $c_0$ ,  $i_0$ , and  $j_0$ ) with a guard set consisting of  $a_0$ . There is no best match in this node, but the guard  $a_0$  contains  $x$ , and since the region corresponding to  $a_0$  is at level 0 of the containment hierarchy, we are done. Therefore,  $x$  is in  $a_0$ .
3. The search for  $y$  first examines the root, at dlevel 3, and determines  $a_0$  to be the best match. However,  $a_0$  is a guard, and thus it finds the smallest nonguard region containing  $a_0$ , which is  $b_2$ . The search continues at the dlevel 2 directory node whose corresponding region is  $b_2$  (i.e., containing  $b_1$ ,  $e_0$ , and  $e_1$ ) with a guard set consisting of  $a_0$ . The best match in this node is  $b_1$ . There is no clevel 1 guard in the guard set, and the search continues at the dlevel 1 directory node whose corresponding region is  $b_1$  (i.e., containing  $b_0$  and  $n_0$ ) with a guard set consisting of  $a_0$  (we ignore  $e_0$  as it does not contain  $y$ ). There is no best match in  $b_1$ , but the guard  $a_0$  contains  $y$ , and since the region corresponding to  $a_0$  is at level 0 of the containment hierarchy, we are done. Therefore,  $y$  is in  $a_0$ .
4. The only difference in searching for  $z$  from searching for  $y$  is that the search is continued at the directory node whose corresponding region is  $b_1$  (i.e., containing  $b_0$  and  $n_0$ ) with a guard set consisting of  $e_0$ , as it provides the better match (i.e., both  $e_0$  and  $a_0$  contain  $z$ , but  $a_0$  contains  $e_0$ ). Therefore,  $z$  is in  $e_0$ .

### Exercises

1. Prove that all exact match searches in a BV-tree have the same length and always visit every level in the containment hierarchy.
2. Consider an exact match search for a point  $p$  in a BV-tree. This requires traversing the directory hierarchy of the tree while applying a process that finds the best match entry in a particular directory node  $a$ . When processing the root node, if the best match  $e_r$  corresponding to region  $r$  is a guard, then we need to find the smallest region  $s$  containing  $r$  whose corresponding entry  $e_s$  is not a guard. Prove that  $e_s$  exists.
3. Continuing Exercise 2, prove that any matching guards enclosed by region  $s$  also enclose  $r$ .
4. Let us try to generalize Exercise 2 to nodes other than the root. In particular, suppose that, during the search for a point  $p$  in a BV-tree, we have reached a nonroot node  $a$  at directory

level  $v$ . Note that this means that the nonguard entries in  $a$  correspond to regions at level  $v - 1$  in the containment hierarchy. Let  $e_r$ , corresponding to region  $r$ , be the best match among the entries in  $a$  plus the level  $v - 1$  entry in the guard set brought down from shallower levels. If  $e_r$  is a guard in  $a$ , then we need to find a region  $s$  containing  $r$  whose corresponding entry  $e_s$  is either a nonguard entry in  $a$  or is the level  $v - 1$  member of the guard set (to see that  $e_s$  can be a nonguard, consider the search for  $z$  in Figure 1.85 where  $e_0$  is the best match in the directory node whose corresponding region is  $b_2$ , although  $e_0$  is enclosed by  $b_1$  which is not a guard). Prove that  $e_s$  exists.

5. Suppose that you modify the exact match search procedure in a BV-tree so that when a search of a directory node  $a$  at level  $v$  finds that the best match is a guard  $g$  at level  $v - 2$ , then the search is continued in the level  $v - 2$  directory node corresponding to  $g$ . This is instead of the regular search process, which leads to the following actions:
  - (a) Finding the best match  $d$  in the entries in  $a$  that are not guards and applying the same process to the level  $v - 2$  entries in  $d$ , obtaining  $e$  as the best match.
  - (b) Checking if  $e$  is a better match than the guard  $g$  at level  $v - 2$  (if one exists) in the guard set that was brought down from the previous search (i.e., from level  $v$ )

In other words, if this modification is valid, then it would appear that there is no need to perform the search at the level  $v - 1$  directory node once we have found that the best match at level  $v$  is a guard. Prove or disprove the validity of this modification. If it is not valid, then construct a counterexample using the BV-tree of Figure 1.85.

#### 1.7.1.6.4 Performance

Among the main reasons for the attractiveness of the BV-tree are its guaranteed performance for executing exact match queries, its space requirements in terms of the maximum number of point pages and directory nodes, and the maximum level of the directory structure necessary for a particular volume of data given the fanout of each directory node. The fanout is equal to the quotient of the number of bits in each node (i.e., page size) and the number of bits needed for each directory entry. The reason that these bounds exist for the BV-tree while they may not exist for the hB-tree is that in the BV-tree there is no need to worry about the multiple posting problem. Thus, each region is pointed at just once in the BV-tree.

The BV-tree performance guarantees are based in part on the assumption that each point page is at least one-third full [643]. This is justified by appealing to the proof given for the hB-tree's satisfaction of this property [1201] (and likewise for the BANG file). The presence of the guards complicates the use of the assumption that each directory node is at least one-third full (which holds for the hB-tree and the BANG file). For example, while illustrating the mechanics of the BV-tree insertion process, we saw an instance of a directory node split operation where the nodes resulting from the split were not at least one-third full (recall Figure 1.84(e)). This situation arose because of the presence of guards whose number was taken into account in the node occupancy when determining if a directory node had overflowed. However, the guards are not necessarily redistributed among the nodes resulting from the split. Instead, they are often promoted, thereby precipitating the overflow of directory nodes at shallower levels of the directory hierarchy.

At this point, let us reexamine the situation that arises when a directory node overflows. There are two cases, depending on whether the overflowing directory node is a guard node. We first deal with the case that the overflowing directory node is not a guard node. As mentioned earlier, a directory node at level  $v$  (assuming that the deepest directory node is at level 1) may have a maximum of  $v - 1$  guards for each entry in it that is not a guard. An overflowing directory node  $a$  at level  $v$  has  $F + 1$  entries. Let  $a$  be split into directory nodes  $b$  and  $c$ . Now suppose that, after the split, entry  $d$  in  $a$  serves as a guard for directory node  $c$  and that  $d$  has  $v - 1$  guards in  $a$ . Therefore,  $d$  will be promoted as a guard to the directory node  $e$  at level  $v + 1$  that serves as the father of  $a$ . In addition, we have to promote all of the  $v - 1$  guards of  $d$  in  $a$ . This means that we

have only  $F + 1 - v$  entries to distribute into  $b$  and  $c$ , which must each be at least one-third full (i.e., contain at least  $F/3$  entries each). Thus, we must be careful in our choice of  $F$ . In particular, if  $F < 3v - 3$ , then it is not possible to guarantee the one-third-full condition (e.g., when the promoted node has  $v - 1$  guards so that a total of  $v$  nodes get promoted to dlevel  $v + 1$ ).

Clearly, choosing  $F$  to be large is one way to increase the likelihood of avoiding such problems. An alternative method of avoiding this problem altogether is to permit the directory nodes to be of variable size and to take only the number of unpromoted entries into account when determining how to split an overflowing node. In this case, we can avoid most problems by increasing the capacity of a directory node at dlevel  $v$  to be  $F \cdot v$ , thereby guaranteeing enough space to store the maximum number of guards (i.e.,  $v - 1$ ) for each unpromoted entry in the directory node (see Exercises 5–7). Interestingly, this has little effect on the overall size of the directory since it can be shown that so few of the directory nodes are at the shallowest level [643]. An added benefit of permitting the directory nodes to vary in size and taking only the number of unpromoted entries into account is that now the execution time for the search query is the same as it would be for a balanced tree with the same number of point pages (assuming the same fullness-percentage guarantee).

We now deal with the case that the overflowing directory node is a guard node. This means that we must take into account the question of whether the two resulting nodes satisfy the same criteria for promotion as the original overflowing node [644]. If yes, then the situation is quite simple: the corresponding entry in the directory node at the next shallower level is replaced by entries for the two new guard nodes, and the overflow continues to be propagated if necessary. Otherwise, the situation is more complex as it may involve demotion, which may have an effect on the rest of the structure. Freeston [644] suggests that the demotion be postponed at the cost of requiring larger directory nodes. The exact details of this process are beyond the scope of our discussion.

The number of guards present also has a direct effect on the number of point pages and directory nodes in the BV-tree of dlevel  $v$ . It can be shown that regardless of the number of guards present, given the same fanout value  $F$  for both point pages and directory nodes, the ratio of directory nodes to point pages is  $1/F$  [643] (see Exercise 4). Assuming that the deepest directory nodes are at level 1, the maximum number of point pages in a BV-tree of height  $v$  is  $F^v$  and arises when there are no guards (see Exercise 1 for a related result). This is the case when each directory node split results in two disjoint halves as no guards need to be promoted. The minimum number of point pages for a BV-tree of height  $v$  and fanout  $F$  is  $F^v/v!$ , where  $F \gg v$ , and arises when each directory node at level  $i$  contains  $i - 1$  guards for each unpromoted entry in the node (see Exercises 2 and 3). From a practical standpoint, in order to accommodate the same number of point pages, for a fanout value of 24, a BV-tree of height 3 will have to grow to height 4. Similarly, BV-trees of heights 4 and 5 will have to grow to heights 6 and 10, respectively. For a fanout value of 120, the effect is even less pronounced. In particular, for this fanout value, BV-trees of heights 4 and 6 will have to grow to heights 5 and between 8 and 9, respectively. Thus, when the data pages are of size 1,024 bytes, a 200 GB file will contain about 200 M pages. These 200 M pages will fill up a BV-tree of height 4, and, in the worst case, will require the height of the BV-tree to grow by 1 to be of height 5.

### Exercises

1. Prove that the maximum number of directory nodes in a BV-tree of height  $v$  and fanout  $F$  is approximately  $F^{v-1}$  for  $F \gg 1$ .
2. Prove that the minimum number of point pages in a BV-tree of height  $v$  and fanout  $F$  is approximately  $F^v/v!$  for  $F \gg v$ .
3. Prove that the maximum number of directory nodes in the BV-tree of height  $v$  and fanout  $F$  for which the number of point pages is a minimum is approximately  $F^{v-1}/v!$  for  $F \gg v$ .

4. Prove that the ratio of directory nodes to point pages in a BV-tree is  $1/F$  regardless of whether a minimum or maximum number of guards is present.
5. Suppose that the directory nodes in the BV-tree are of varying size. In particular, assume that a directory node at level  $i$  of a BV-tree with fanout  $F$  is large enough to contain  $F$  unpromoted entries and  $F \cdot (i - 1)$  guards (i.e., unpromoted entries). Show that the total number of point pages we can now have in the worst case of a BV-tree of height  $v$  and fanout  $F$  is  $\approx F^v$  for  $F \gg 1$ .
6. Using the variable BV-tree node size assumption of Exercise 5, show that the total number of directory nodes we can now have in the worst case of a BV-tree of height  $v$  and fanout  $F$  is  $\approx F^{v-1}$  for  $F \gg 1$ .
7. Using the variable BV-tree node size assumption of Exercises 5 and 6, prove that the ratio of directory nodes to point pages in a BV-tree is  $1/F$  when the maximum number of guards is present.
8. Suppose that you use the variable BV-tree node size assumption of Exercises 5 and 6. This means that the directory nodes are not all the same size. Assuming that each directory node at level  $v$  originally required  $B$  bytes, the variable node size means that each node will be of size  $Bv$  bytes. Show that this modification leads to a very nominal growth in the number of bytes needed to represent the index nodes. In particular, given a BV-tree of height  $v$  and fanout  $F$ , prove that the space requirements for the index nodes is approximately  $BF^{v-1}$ —that is,  $B$  times the number of directory nodes as derived in Exercise 6. Thus, the increased size of the nodes close to the root has a negligible effect on the total size of the directory in that, when we use  $B$  bytes for each directory node, we also obtain an index size of  $BF^{v-1}$  in the best case.

### 1.7.1.6.5 Summary

The implementation of the searching process demonstrates the utility of the innovation in the design of the BV-tree. The directory is stored economically by reducing the number of nodes necessary due to the avoidance of needless splitting of regions. Recall that this was achieved by decoupling the directory hierarchy from the decomposition hierarchy.<sup>55</sup> Nevertheless, in order to perform searching efficiently (i.e., to avoid descending nodes needlessly, as is the case in the R-tree where the space containing the desired data can be covered by several nodes due to the nondisjoint decomposition of the underlying space), the regions must be split or at least examined in a way that simulates the result of the split, thereby posing apparently contradictory requirements on the data structure. In the BV-tree, this is avoided by the presence of the guards that are associated with the relevant nodes of the directory hierarchy. In fact, the guards are always associated with the directory node that corresponds to the nearest common ancestor of the directory nodes with whom they span some common portion of the underlying space. This is very similar to the notion of fractional cascading [339, 340], which is used in many computational geometry applications, such as the point location query (see Section 2.1.3.3.2 of Chapter 2).

Although up to now we have looked at the BV-tree as an attempt to overcome the problems associated with variants of the k-d-B-tree, the BV-tree can also be viewed as a special case of the R-tree that tries to overcome the shortcomings of the R-tree. In this case, the BV-tree is not used in its full generality since, in order for the analogy to the R-tree to hold, all regions must be hyperrectangles. Of course, although these analogies and comparisons are matters of interpretation, closer scrutiny does reveal some interesting insights.

---

<sup>55</sup> The decoupling idea is also used in the PK-tree (see Section 1.8), where the motivation is the decoupling of the tree structure of the partition process of the underlying space from that of the node hierarchy (i.e., the grouping process of the nodes resulting from the partition process) that makes up the tree directory. See also [462] for a related approach to triangular decompositions of surfaces, such as terrain data.

The main drawback of the k-d-B-tree and its variants is the fact that region splits may be propagated downwards. This is a direct result of the fact that regions must be split into disjoint subregions where one subregion cannot contain another subregion. The hB-tree attempts to overcome this problem, but it still suffers from the multiple posting problem. In this case, instead of splitting point pages into several pieces, directory nodes are referenced several times. In terms of efficiency of the search process, the multiple posting problem in the hB-tree is analogous to the multiple coverage problem of the R-tree. In particular, the multiple coverage problem of the R-tree is that the area containing a specific point may be spanned by several R-tree nodes since the decomposition of the underlying space is not disjoint. Thus, just because a point was not found in the search of one path in the tree does not mean that it would not be found in the search of another path in the tree. This makes search in an R-tree somewhat inefficient.

At a first glance, the BV-tree suffers from the same multiple coverage problem as the R-tree. This is true when we examine the directory hierarchy of the BV-tree. However, the fact that the search process in the BV-tree carries the guards with it as the tree is descended ensures that only one path is followed in any search, thereby compensating for the multiple coverage. Notice that what is really taking place is that the search proceeds by levels in the containment hierarchy, even though it may appear to be backtracking in the directory hierarchy. For example, when searching for point  $x$  in the BV-tree of Figure 1.85(a), we immediately make use of the guards  $a_0$  and  $a_1$  in our search of region  $b_2$ . We see that these three regions have quite a bit in common. However, as we descend the BV-tree, we find that some of the regions are eliminated from consideration, resulting in the pursuit of just one path. One way to speed the searches in the BV-tree is to organize each directory node into a collection of trees corresponding to the containment hierarchy represented by the node.

The use of the containment hierarchy in the BV-tree can be thought of as leading to a special case of an R-tree in the sense that the containment hierarchy serves as a constraint on the relationship between the regions that form the directory structure. For example, in the R-tree, the regions are usually hyperrectangles (termed *bounding hyperrectangles*), whereas in the BV-tree they can be of any shape. In particular, the constraint is that any pair of bounding hyperrectangles of two children  $a$  and  $b$  of an R-tree node  $r$  must be either disjoint, or one child must be completely contained within the other child (i.e.,  $a$  is in  $b$ , or  $b$  is in  $a$ ). In addition, if we were to build an R-tree using the BV-tree rules, then we would have to modify the rules as to the action to take when inserting a point (or, more generally, an object) that does not lie in the areas spanned by any of the existing bounding hyperrectangles. In particular, we must make sure that the expanded region does not violate the containment hierarchy requirements. Overflow must also be handled somewhat differently to ensure the promotion of guards so that we can avoid the multiple coverage problem. Of course, once this is done, the structure no longer satisfies the property that all leaf nodes be at the same level. Thus, the result is somewhat like the S-tree [22] (see Section 2.1.5.2 of Chapter 2), which is a variant of the R-tree designed to deal with skewed data.

It is interesting to note that when the underlying objects are not points, it may be impossible to guarantee satisfaction of the containment hierarchy requirements when the regions that form the elements of the directory structure are bounding hyperrectangles. In fact, an example of such an impossible case can be constructed when the minimum bounding objects of the underlying objects are hyperrectangles [36], as shown in Figure 1.86. In particular, the figure demonstrates a situation where it is not possible to split the boxes in the figure into two or more groups such that

1. each group is represented by a minimum bounding hyperrectangle, and
2. each group contains at least two of the rectangles in the figure, and
3. the minimum bounding hyperrectangles corresponding to the groups form a containment hierarchy (i.e., they are either pairwise disjoint, or one is contained within the other).

In this case, we may need to use more general and application-specific bounding structures and, most likely, also to require that the objects not overlap. The investigation of the exact relationship between the R-tree and the BV-tree is an issue for further study.

### Exercises

- Figure 1.86 shows a dataset with 12 rectangles that cannot be properly split into two sets that satisfy the containment hierarchy requirements. Can you find a generalized pattern for a set containing an arbitrarily large number of rectangles?
- Investigate the relationship between the BV-tree and the R-tree. In particular, as outlined in the text, define an R-tree node-splitting rule that satisfies the containment hierarchy rules.
- Suppose that the objects under consideration are not points and, instead, have extent (e.g., line segments and rectangles). What restrictions on the shape objects are necessary so that the BV-tree rules can be adapted for use with an R-tree or one of its variants?

Figure 1.86 Example of a collection of hyperrectangle minimum bounding objects for which it is impossible to guarantee satisfaction of the containment hierarchy requirements—that is, the collection cannot be subdivided into two sets that both have at least two members and where the minimum bounding hyperrectangles of the sets are either disjoint or one is contained in the other.

### 1.7.1.7 Static Methods

The LSD tree, k-d-B-tree, hB-tree, k-d-B-trie, BANG file, and BV-tree are all dynamic structures where data is inserted at the leaf nodes, and splits are propagated upwards. Thus, they are often characterized as bottom-up data structures. A pair of related data structures are the VAMSplit (variance approximate median split) k-d tree [1989] and the VAMSplit R-tree [1989]. They differ from the LSD tree, k-d-B-tree, hB-tree, and BANG file in that they are static structures where the partitions (i.e., splits) are made in a top-down manner on the basis of knowledge of the entire dataset.

The *VAMSplit k-d tree* [1989] is really a bucket variant of the generalized pseudo k-d tree (e.g., the adaptive k-d tree) in the sense that each leaf node corresponds to a disk bucket or block of capacity  $b$  and thus we split a set of elements only if its cardinality exceeds  $b$ . Notice that the tree need not be complete. However, the depths of any two leaf nodes differ by at most one. The partitioning axis is chosen corresponding to the dimension with the maximum variance. The partitioning position is chosen with the goal that the leaf nodes (i.e., buckets) will be as full as possible. Thus, the partitioning position is not necessarily the median value along the partitioning axis (as in the adaptive k-d tree described in Section 1.5.1.4), although it is usually within a relatively close range of the median (hence the use of the qualifier *approximate median split*) [1989].

In particular, assuming a set of  $N$  nodes, if  $N \leq 2b$ , then we choose the median value as the partitioning position so that the left child has  $\lfloor N/2 \rfloor$  elements, and the right child has  $N - \lfloor N/2 \rfloor$  elements. Otherwise,  $N > 2b$ , and we choose a partitioning position so that the left child contains  $mb$  elements, where  $mb$  is the largest multiple of  $b$  that is less than  $N/2$ , and the right child contains the remaining elements. Such an action will minimize the number of leaf nodes in the final k-d tree by maximizing the number of completely full nodes so that at most two will not be full (see Exercise 3).

As an example, suppose that we have a set with 22 elements and bucket capacity of 5 for which we want to build a VAMSplit k-d tree. There are many ways to partition this set. Below, we consider only the way in which the partitioning positions are chosen, thereby assuming that the partitioning axes have already been determined. Figure 1.87(a) shows the size of the subtrees in the resulting k-d tree when the partitioning position is the median with six leaf nodes (i.e., buckets), and Figure 1.87(b) shows the resulting VAMSplit k-d tree when the partitioning position is chosen so as to minimize the total number of leaf nodes, which is five here. Note that although the difference in the number of leaf nodes is just one in this case, examples can be constructed with more elements where the difference in the number of leaf nodes is considerably higher.

Once the partitioning positions have been chosen, the internal nodes of the tree are aggregated into buckets of capacity  $c$  proceeding from the root downwards in a breadth-first traversal of the subtrees until enough nodes have been accumulated to

Figure 1.87 K-d trees with 22 elements and a bucket capacity of 5 that are built by using a partitioning position (a) at the median of the elements in the subtree and (b) at the position that minimizes the total number of leaf nodes (i.e., a VAMSplit k-d tree with no aggregation of the internal nodes). Each nonleaf node indicates the number of elements in the corresponding subtree.

fill the bucket (i.e.,  $c$ ). This process is applied recursively to the rest of the tree until the leaf nodes are encountered. The similarity to a top-down LSD tree and a top-down k-d-B-tree should be clear. The search performance of the VAMSplit k-d tree is enhanced by associating with each node  $i$  in the VAMSplit k-d tree a minimum bounding box of the part of the underlying space that is spanned by the internal nodes that have been merged into  $i$ . The result is termed a *VAMSplit R-tree* [1989]. However, unlike the real R-tree, minimization of overlap or coverage plays no role in deciding which internal nodes should be aggregated. This decision is based purely on the k-d tree splits. Thus, we see that the VAMSplit R-tree is related to the VAMSplit k-d tree in the same way that the R<sup>+</sup>-tree [593, 1718, 1803] is related to the k-d-B-tree (see Section 2.1.5.3 of Chapter 2). In fact, a more appropriate name for the VAMSplit R-tree is a VAMSplit R<sup>+</sup>-tree.

### Exercises

1. Assuming a bucket size of 5, can you come up with a simpler example than that given in Figure 1.87 to illustrate the advantage of not using a partitioning position at the median of the set of elements in an adaptive k-d tree such as the VAMSplit k-d tree?
2. Give an algorithm to build a VAMSplit k-d tree.
3. Prove that the number of nonfull leaf nodes in a VAMSplit k-d tree is at most two.
4. Give an algorithm to build a VAMSplit R-tree.

## 1.7.2 Grid Directory Methods

There are several methods of decomposing the underlying space into a grid of cells, termed *grid cells*. The contents of the grid cells are stored in pages (termed *buckets*) in secondary memory. Some of the methods (e.g., grid file and EXCELL) permit a bucket to contain the contents of several grid cells but do not permit a grid cell to be associated with more than one bucket. Other methods (e.g., linear hashing and spiral hashing, also known as spiral storage) do not permit a bucket to contain the contents of more than one grid cell but do permit a grid cell to be associated with more than one bucket, in which case the additional buckets are known as *overflow buckets*. When more than one grid cell is associated with a bucket, then the union of these grid cells must form a  $d$ -dimensional hyperrectangle. The actual buckets associated with the grid cells are usually accessed with the aid of a directory in the form of an array (termed a *grid directory*) that can change as the data volume grows or contracts.

Below, we focus on what to do if the data volume grows to such an extent that either one of the grid cells or buckets is too full. There are several possible solutions. When a bucket is too full, we just split it. When a grid cell is too full, we usually need to make a new grid partition. In this case, the most extreme solution is to make a new grid by refining the entire grid of  $g$   $d$ -dimensional grid cells by doubling it along all keys (i.e., halving the width of each side of a grid cell), thereby resulting in  $2^d \cdot g$  grid cells. This is quite wasteful of space and is not discussed further here.

Whatever action we take, we must maintain the grid while also resolving the issue of the overflowing grid cell (usually by splitting it). This can be achieved by refining the partition along just one of the keys through the introduction of one additional partition. The drawback of such an action is that the grid cells are no longer equal sized. This means that, given a point, we cannot determine the grid cell in which it is contained without the aid of an additional data structure (termed a *linear scale* and discussed briefly in Section 1.1) to indicate the positions of the partitions. If there are originally  $\prod_{i=1}^d g_i$  grid cells with  $g_i - 1$  partition positions along key  $i$ , then, without loss of generality, refining key  $d$  results in  $(g_d + 1) \cdot \prod_{i=1}^{d-1} g_i$  grid cells. This is the basis of multipaging [1287, 1288]) and the grid file [839, 840, 1376].

We can avoid the need for the linear scales by uniformly partitioning all grid cells in the same way, rather than just the cells in the  $(d - 1)$ -dimensional hyperplane that passes through the overflowing grid cell. In essence, we halve the width of just one of the sides of each grid cell, thereby doubling the granularity of the decomposition along one of the axes. This results in doubling the total number of grid cells to yield  $2 \cdot g$  grid cells. This is the basis of the EXCELL method [1822].

An alternative approach is to order the grid cells according to one of a subset of the one-dimensional orderings of the underlying space described in Section 1.6 and to use linear hashing to resolve an overflowing grid cell. In this case, we start with a grid of equal-sized grid cells (initially containing just one grid cell) that are split into two halves in succession in a consistent manner (i.e., along the same key), according to the particular one-dimensional ordering that is used, until all grid cells have been split, at which point the process is restarted with a split across the same or another key. The drawback of this method is that the grid cell that is split is not necessarily the one that has become too full. This is resolved by making use of what are termed *overflow buckets*.

It is important to observe that for linear hashing the grid directory is a one-dimensional array instead of a  $d$ -dimensional array as for the grid file and EXCELL. This is because the result of the hashing function is just an address in one dimension, although the underlying space is partitioned into sets of ranges of values that for most variants of linear hashing (with the notable exception of spiral hashing) correspond to grid cells in  $d$  dimensions. For most variants of linear hashing, the ranges have a limited set of possible sizes. In fact, if there is a one-to-one correlation between the numbering of the grid cells and the bucket labels, then there is no need for a grid directory in linear hashing.

The rest of this section is organized as follows. Section 1.7.2.1 describes the grid file. Section 1.7.2.2 presents EXCELL. Section 1.7.2.3 reviews linear hashing and explains how it can be adapted to handle multidimensional point data. Section 1.7.2.4 discusses some alternative implementations of linear hashing that address the drawback that the grid cell that has been split most recently is not necessarily the one that is full. This discussion also includes an explanation of how to adapt the related method of spiral hashing to multidimensional point data. Section 1.7.2.5 contains a brief comparison of the various bucket methods that make use of a grid directory.

### 1.7.2.1 Grid File

The *grid file* of Nievergelt, Hinterberger, and Sevcik [839, 840, 1376] is a variation of the fixed-grid method that relaxes the requirement that grid subdivision lines be equidistant. Its goals are to retrieve records with at most two disk accesses and to handle range queries efficiently. This is done by using a grid directory in the form of an array to the grid cells. All records in one grid cell are stored in the same bucket. However, several grid cells can share a bucket as long as the union of these grid cells forms a  $d$ -dimensional hyperrectangle in the space of the data. Although the regions of the buckets are piecewise disjoint, together they span the entire underlying space.

The purpose of the grid directory is to maintain a dynamic correspondence between the grid cells and the buckets. The grid directory consists of two parts. The first is a dynamic  $d$ -dimensional array, containing one entry for each grid cell. The values of the elements are pointers to the relevant buckets. Usually buckets will have a capacity of 10 to 1,000 points. Thus, the entry in the grid directory is small in comparison to a bucket. We are not concerned with how the points are organized within a bucket (e.g., linked list, tree). The grid directory is usually stored on disk as it may be quite large, especially when  $d$  is large.

The second part of the grid directory is a set of  $d$  one-dimensional arrays called *linear scales*. These scales define a partition of the domain of each key. They enable access to the appropriate grid cells by aiding the computation of their address based on the value

Figure 1.88  
Grid file partition for the data corresponding to Figure 1.1.

of the relevant keys. The linear scales are kept in main memory. It should be noted that the linear scales are useful in guiding a range query, by indicating the grid cells that overlap the query range. The linear scales can also be implemented using binary trees (see Sections 1.7.2.3, 1.7.2.4.1, and 1.7.2.4.2, as well as Exercise 1).

Thus, we see that the two goals of the grid file are met. Any record is retrieved with two disk accesses: one disk access for the grid cell and one for the bucket. Of course, a variant of the grid file could also be formulated that guarantees that any record can be retrieved with  $i$  disk accesses by making use of a hierarchy of  $i - 2$  grid files to organize the grid directory, each of which would be stored on disk. In fact, Hinrichs [840] describes such an approach, which he terms a *two-level grid file*, where the additional grid file is used to manage the grid directory. However, in order to obviate the need for a third disk access, Hinrichs proposes to store the first grid directory in main memory as well. Range queries are efficient, although, since the sizes of the grid cells (i.e., the ranges of their intervals) are not related to the query range, it is difficult to analyze the amount of time necessary to execute a range query.

As an example, consider Figure 1.88, which shows the grid file representation for the data of Figure 1.1. Once again, we adopt the convention that a grid cell is open with respect to its upper and right boundaries and closed with respect to its lower and left boundaries. The bucket capacity is two records. There are  $d = 2$  different keys. The grid directory consists of nine grid cells and six buckets labeled A–F. We refer to grid cells as if they are array elements: grid cell  $(i, j)$  is the element in column  $i$  (starting at the left with column 1) and row  $j$  (starting at the bottom with row 1) of the grid directory.

Grid cells  $(1,3)$ ,  $(2,2)$ , and  $(3,3)$  are empty; however, they do share buckets with other grid cells. In particular, grid cell  $(1,3)$  shares bucket B with grid cells  $(2,3)$  and  $(3,3)$ , while grid cells  $(2,2)$  and  $(3,2)$  share bucket E. The sharing is indicated by the broken lines. Figure 1.89 contains the linear scales for the two keys (i.e., the  $x$  and  $y$  coordinates). For example, executing an exact match query with  $x = 80$  and  $y = 62$  causes the access of the bucket associated with the grid cell in row 2 and column 3 of the grid directory of Figure 1.88.

The grid file is attractive, in part, because of its graceful growth as more and more records are inserted. As the buckets overflow, we apply a splitting process, which results in the creation of new buckets and a movement of records. To explain the splitting process, let us examine more closely how the grid file copes with a sequence of insertion

Figure 1.89  
Linear scales for (a)  $x$  and (b)  $y$  corresponding to Figure 1.88.

operations. Again, we assume a bucket capacity of 2 and observe how a grid file is constructed for the records of Figure 1.1 in the order in which they appear there: Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami.

The insertion of Chicago and Mobile results in bucket A being full. Insertion of Toronto leads to an overflow of bucket A, causing a split. We arbitrarily split along the  $y$  axis at  $y = 70$  and modify the linear scale for key  $y$  accordingly. Toronto is inserted into B, the newly allocated bucket (see Figure 1.90(a)).

Next, we try to insert Buffalo and find that the bucket in which it belongs (i.e., A) is full. We split the  $x$  axis at  $x = 45$  and modify the linear scale for key  $x$ . This results in the insertion of Buffalo in bucket C and the movement of Mobile from bucket A to bucket C (see Figure 1.90(b)). Note that, as a result of this split, both grid cells (1,2) and (2,2) share bucket B, although grid cell (1,2) is empty. Alternatively, we could have marked grid cell (1,2) as empty when the  $x$  axis was split. This has the disadvantage that, should

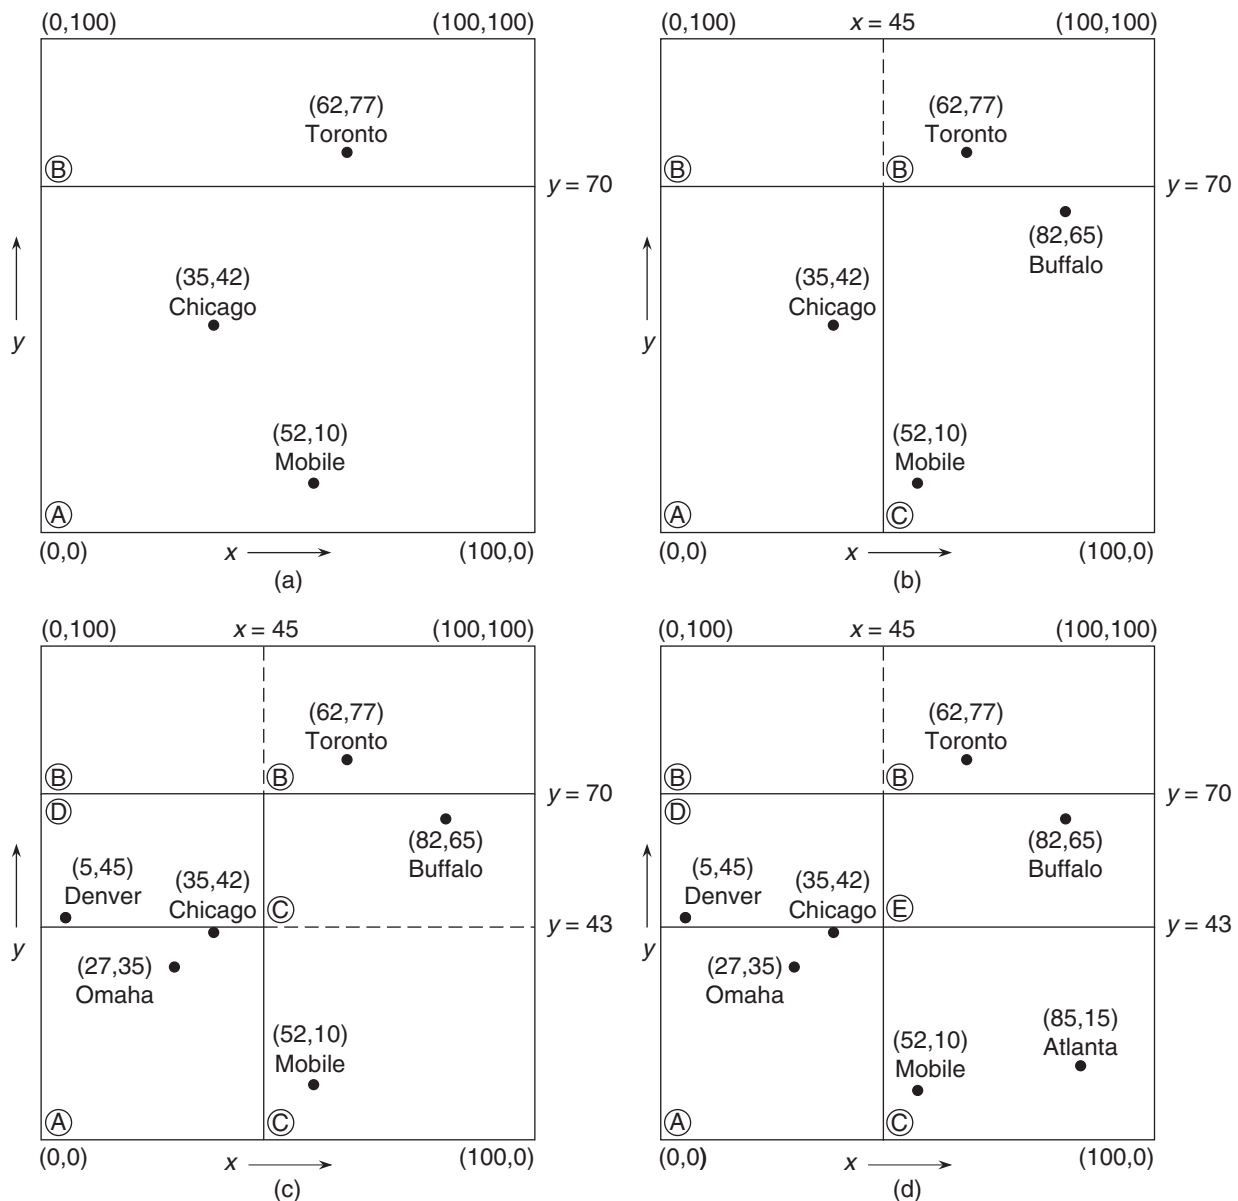

Figure 1.90 Sequence of partial grid partitions demonstrating the result of the insertion of (a) Chicago, Mobile, and Toronto, (b) Buffalo, (c) Denver and Omaha, and (d) Atlanta.

we later wish to insert a record into grid cell (1,2), we would either have to allocate a new bucket or search for a neighboring bucket that was not full and whose grid cells formed a convex region with grid cell (1,2).

The insertion of Denver proceeds smoothly. It is placed in bucket A. Omaha also belongs in bucket A, which means that it must be split again. We split the  $y$  axis at  $y = 43$  and modify the linear scale for key  $y$ . In addition, we create a new bucket, D, to which Denver is moved, while Omaha and Chicago remain in bucket A (see Figure 1.90(c)). Note that as a result of this split, both grid cells (2,1) and (2,2) share bucket C, contributing Buffalo and Mobile, respectively.

Attempting to insert Atlanta finds it belonging in bucket C, which is full; yet, grid cell (2,1) is not full. This leads to splitting bucket C and the creation of bucket E. Bucket C now contains Mobile and Atlanta and corresponds to grid cell (2,1), while bucket E now contains Buffalo and corresponds to grid cell (2,2) (see Figure 1.90(d)). Note that we did not have to partition the grid in this case. Thus, no change needs to be made to the linear scales; however, the grid directory must be updated to reflect the association of grid cell (2,2) with bucket E instead of bucket C.

Finally, insertion of Miami finds it belonging to bucket C, which is full. We split the  $x$  axis at  $x = 70$  and modify the linear scale for key  $x$ . A new bucket, F, is created to which Atlanta and Miami are moved (see Figure 1.88). Once again, we observe that as a result of this split, grid cells (2,3) and (3,3) share bucket B, although grid cell (3,3) is empty. Similarly, grid cells (2,2) and (3,2) share bucket E, although grid cell (2,2) is empty.

At this point, we are ready to elaborate further on the splitting process. From the above, we see that two types of bucket splits are possible. The first, and most common, arises when several grid cells share a bucket that has overflowed (e.g., the transition between Figure 1.90(c, d) upon the insertion of Atlanta).

In this case, we merely need to allocate a new bucket and adjust the mapping between grid cells and buckets.

The second type of a split arises when we must refine a grid partition. It is triggered by an overflowing bucket, all of whose records lie in a single grid cell (e.g., the overflow of bucket A upon insertion of Toronto in Figure 1.90(a)). In this case, we have a choice with respect to the dimension (i.e., axis) and location of the splitting point (i.e., we do not need to split at the midpoint of an interval). Without any external knowledge or motivation, a reasonable splitting policy is one that cycles through the various keys (e.g., first split on key  $x$ , then key  $y$ , key  $x$ , ..., as was done in Figure 1.90) and uses interval midpoints. This is the approach used in the grid file implementation [1376].

An alternative splitting policy is an adaptive one favoring one key over others. This is akin to a favored key in an inverted file. It results in an increase in the precision of answers to partially specified queries (i.e., partial range) where the favored key is specified. Such a policy is triggered by keeping track of the most frequently queried key (in the case of partial range queries) and by monitoring dynamic file content, thereby increasing the granularity of the key scales. Splitting at locations other than interval midpoints is also an adaptive policy.

The grid refinement operation is common at the initial stage of constructing a grid file. However, as the grid file grows, it becomes relatively rare in comparison with the overflowing bucket that is shared among several grid cells. Nevertheless, the frequency of grid refinement can be reduced by varying the grid directory as follows: Implement the grid directory as a  $d$ -dimensional array whose size in each dimension is determined by the shortest interval in each linear scale (i.e., if the linear scale for key  $x$  spans the range 0 through 64 and the shortest interval is 4, then the grid directory has 16 entries for dimension  $x$ ).

This variation is a multidimensional counterpart of the directory used in extendible hashing [579] and is the basis of EXCELL [1822] (see Section 1.7.2.2). Its advantage is that a refinement of the grid partition will cause a change in the structure of the directory only if the shortest interval is split, in which case the grid directory will double in size. Such a representation anticipates small structural updates and replaces them by a large one. It is fine as long as the data is uniformly distributed. Otherwise, many empty grid cells will arise.

The counterpart of splitting is merging. There are two possible instances where merging is appropriate: bucket merging and directory merging. Bucket merging, the more common of the two, arises when a bucket is empty or nearly empty. Bucket-merging policy is influenced by three factors. First, we must decide which bucket pairs are candidates for merging. This decision can be based on a *buddy system* or a *neighbor system*.

In a *buddy system* [1042, 1044], each bucket, say  $X$ , can be merged with exactly one bucket, say  $B_j$ , in each of the  $d$  dimensions. Ideally, the chosen bucket, say  $B_j$ , should have the property that, at some earlier point, it was split to yield buckets  $X$  and  $B_j$ . We call this buddy the “true” buddy. For example, consider the grid directory of Figure 1.91, which contains buckets A–K and X. Assume that when a bucket is split, it is split into two buckets of equal size. Since  $d = 2$ , the only potential buddies of bucket X are I and J. We can keep track of the true buddies by representing the splitting process as a binary tree, thereby maintaining the buddy relationships.

In a *neighbor system*, each bucket can be merged with either of its two adjacent neighbors in each of the  $d$  dimensions (the resulting bucket region must be convex). For example, in the grid directory of Figure 1.91, bucket X can be merged with any one of its neighbors, buckets C, I, or J. Note that X cannot be merged with neighbor bucket G since the resulting bucket region would not be convex.

The second factor influencing bucket-merging policy deals with the ordering among possible choices should there be more than one candidate. In the case of the buddy system, we give priority to the true buddy. Otherwise, this factor is relevant only if it is desired to have varying granularity among keys. In particular, if the splitting policy favors some keys over others, the merging policy should not undo it.

The third factor is the merging threshold: when should a candidate pair of buckets actually be merged? It should be clear that the sum of the bucket occupancy percentages for the contents of the merged bucket should not be too large because, otherwise, it will soon have to be split. Nievergelt, Hinterberger, and Sevcik [1376] conducted simulation studies showing the average bucket occupancy to be 70% and suggest that this is an appropriate merging threshold for the occupancy of the resulting bucket.

Directory merging arises when all the grid cells in two adjacent cross sections (i.e., slices along one axis) in the grid directory are associated with the same bucket. For example, consider the two-dimensional grid directory of Figure 1.92, where all grid cells in column 2 are in bucket C, and all grid cells in column 3 are in bucket D. In such a case, if the merging threshold is satisfied, then buckets C and D can be merged, and the linear scales modified to reflect this change.

Generally, directory merging is of little practical interest since, even if merging is allowed to occur, it is probable that splitting will soon have to take place. Nevertheless, there are occasions when directory merging is of use. First, directory merging is necessary in the case of a shrinking file. Second, it is appropriate when the granularity of certain keys is being changed to comply with the access frequency of the key. Third, it is a useful technique when attempting to get rid of inactive keys. In such a case, the key could be set to a “merge only” state. Eventually, the partition will be reduced to one interval, and the corresponding dimension in the grid directory can be removed or assigned to another key.

Figure 1.91  
Example grid directory illustrating bucket merging when using the grid file.

Figure 1.92  
Example grid directory illustrating directory merging when using the grid file.

At times, it is desired to update an existing grid file with a large number of points at once. This is more efficient than updating the grid file one point at a time. This technique is known as *bulk insertion*. It can also be used to build the grid file from scratch, in which case it is also known as *bulk loading*. In the case of the grid file, the goal is to minimize the size of the grid file needed to ensure the absence of bucket overflow for a given dataset. This problem was first addressed by Li, Rotem, and Srivastava [1160], who were concerned with the bulk loading of grid files for two-dimensional data distributed across multiple sites in a “shared nothing” environment. They show how to partition the data among several processors and have each processor build its own grid file. Their method assumes an existing partition along one dimension and a fixed number of partitions along the remaining dimension. Given this assumption, they partition the remaining dimension optimally using a dynamic programming approach. Leutenegger and Nicol [1154] show that the dynamic programming approach is inefficient for large grid files and, instead, reformulate the problem as one of finding the smallest number of partitions in the remaining dimension for which the total overflow is zero. This enables them to use a fast heuristic algorithm instead of a slow and expensive dynamic programming algorithm.

As we pointed out, the grid file guarantees that any record can be retrieved with two disk accesses. This is fine for point queries (exact match); however, range queries require considerably more disk accesses. Kriegel [1078] reports on an empirical comparison of the grid file and a pair of versions of a multidimensional B-tree termed the *kB-tree* [786, 787] and the *MDBT* [1686] (see Section 1.1 for a brief description), as well as the inverted file. Kriegel’s data [1078] show that when the keys are correlated and nonuniformly distributed, the grid file is superior with respect to insertions, deletions, and exact match queries, but the structures that are based on the B-tree variants are superior with respect to partial range queries. For range queries, the performance of the grid file is at best comparable to the B-tree variants and often worse. The performance of the inverted file is always worse than the alternatives. On the other hand, when the keys are independent and uniformly distributed, Kriegel [1078] points out that the grid file is expected to be superior on all counts. In all cases, the space requirements of the grid file are always lower than those of the B-tree variants. The relative performance of the kB-tree and the MDBT is comparable.

The grid file is similar to the multipaging method of Merrett and Otoo [1287, 1288]. Multipaging also uses a directory in the form of linear scales called *axial arrays*. However, instead of using a grid directory to access the data pages, multipaging accesses a data page and its potential overflow chain using an address that is computed directly from the linear scales. There are two variants of multipaging: static and dynamic. In static multipaging [1287], both the expected number of probes needed to access any record and the storage utilization are bounded. The result is similar to the fixed-grid method (recall Section 1.1) in that these values are used to determine the optimal partitioning of the grid. Thus, the method is designed to work when the data is known in advance. Dynamic multipaging [1288] is designed to work when the data is constantly changing and thus can deal with the case that the data pages grow and split at will. In this case, only the expected number of probes to access any record is bounded.

Comparing the grid file and multipaging, we find that the grid file uses multipaging as an index to the grid directory. Therefore, multipaging saves space by not requiring a grid directory, but this is at a cost of requiring bucket (i.e., data page) overflow areas. This means that multipaging can obtain good average-case performance, but it cannot guarantee record retrieval with two disk accesses. In addition, insertion and deletion in multipaging involves whole rows or columns (in the two-dimensional case) of data pages when splitting or merging data pages, while the grid file can split one data page at a time and localize more global operations in the grid directory. The absence of the grid directory in multipaging means that, in the case of dynamic multipaging, some attention must also be paid to how the resulting multipaging space is to be addressed. In this

case, dynamic multipaging resembles some of the more sophisticated variants of linear hashing (see Section 1.7.2.4), and the issue is dealt with in a similar manner.

### Exercises

1. The linear scales are implemented as one-dimensional arrays. They could also be implemented as binary trees. What would be the advantage of doing so?
2. Implement a database that uses the grid file to organize two-dimensional data.
3. The grid file is considered to be an instance of a bucket method with fanout 2 (i.e., the number of buckets into which an overflowing bucket is split, which also includes the B-tree, EXCELL, and EXHASH) and 0.69 average storage utilization [1376] (see the general discussion in Section 1.7.3). The *twin grid file* [907, 908] is a representation that makes use of two grid files and has been observed to result in improving the average storage utilization of the grid file to 90%. Give an intuitive explanation of why this is so.
4. How can you improve the performance of the twin grid file discussed in Exercise 3?
5. Calculate the expected size of the grid directory for uniformly distributed data.

### 1.7.2.2 EXCELL

The EXCELL method of Tamminen [1822] is similar in spirit to the grid file in that it also makes use of a grid directory and retrieves all records with at most two disk accesses. The principal difference between them is that grid refinement for the grid file splits only one interval in two and results in the insertion of a  $(d-1)$ -dimensional cross section. In contrast, a grid refinement for the EXCELL method splits all intervals in two (the partition points are fixed) for the particular dimension and results in doubling the size of the grid directory. This means that all grid cells are of the same size in EXCELL, but this is not the case for the grid file.

The result is that the grid directory grows more gradually when the grid file is used, whereas use of EXCELL reduces the need for grid refinement operations at the expense of larger directories, in general, due to a sensitivity to the distribution of the data. However, a large bucket size reduces the effect of nonuniformity unless the data consists entirely of a few clusters. The fact that all grid cells define equal-sized (and convex) regions has two important ramifications. First, it means that EXCELL does not require a set of linear scales to access the grid directory and retrieve a record with at most two disk accesses, as is needed for the grid file. Thus, grid directory access operations are considerably faster for EXCELL. Second, it means that the partition points are fixed and are not chosen on the basis of the data, as is the case for the grid file. Therefore, range queries are efficient with an execution time that is proportional to the number of buckets corresponding to the grid cells that make up the range being searched (i.e., to the size of the range). In contrast, the number of grid cells that make up a range in the grid file is not proportional to the size of the range.

An example of the EXCELL method is given in Figure 1.93, which shows the representation for the data in Figure 1.1. Here the  $x$  axis is split before the  $y$  axis. Again, the convention is adopted that a rectangle is open with respect to its upper and right boundaries and closed with respect to its lower and left boundaries. The capacity of the bucket is two records. There are  $d = 2$  different keys. The grid directory is implemented as an array; in this case, it consists of eight grid cells (labeled in the same way as for the grid file) and six buckets labeled A–F. Note that grid cells (3,2) and (4,2) share bucket C, while grid cells (1,2) and (2,2), despite being empty, share bucket D. The sharing is indicated by the broken lines. Furthermore, when a bucket size of 1 is used, the partition of space induced by EXCELL is equivalent to that induced by a PR  $k$ - $d$  tree [1413], although the two structures differ by virtue of the presence of a directory in the case of EXCELL.

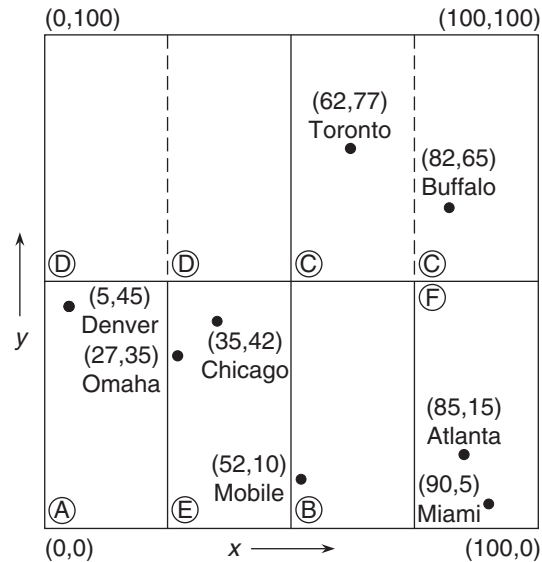

Figure 1.93  
EXCELL representation for the data corresponding to Figure 1.1 when the  $x$  axis is split before the  $y$  axis.

As a database represented by the EXCELL method grows, buckets will overflow. This leads to the application of a splitting process, which results in the creation of new buckets and a movement of records. To explain the splitting process, we examine how EXCELL copes with a sequence of insertion operations corresponding to the data of Figure 1.1. Again, we assume a bucket capacity of 2 and that the records are inserted in the order in which they appear in Figure 1.1—that is, Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami.

The insertion of Chicago and Mobile results in bucket A being full. Insertion of Toronto leads to an overflow of bucket A, which compels us to double the directory by splitting along key  $x$ . We split bucket A and move Mobile and Toronto to B, the newly allocated bucket (see Figure 1.94(a)). Next, we insert Buffalo and find that the bucket in which it belongs (i.e., B) is full. This causes us to double the directory by splitting along key  $y$ . We now split bucket B and move Toronto and Buffalo to C, the newly allocated bucket (see Figure 1.94(b)). Note that bucket A still contains Chicago and overlaps grid cells (1,1) and (1,2).

The insertion of Denver proceeds smoothly, and it is placed in bucket A. Omaha also belongs in bucket A, which has now overflowed. Since bucket A overlaps grid cells (1,1) and (1,2), we split it, thereby allocating a new bucket, D, such that buckets A and D correspond to grid cells (1,1) and (1,2), respectively (see Figure 1.94(c)). However, neither Denver, Chicago, nor Omaha can be moved to D, thereby necessitating a directory doubling along key  $x$ . We now split bucket A and move Chicago and Omaha to E, the newly allocated bucket (see Figure 1.94(d)). Note that buckets B, C, and D retain their contents, except that now each bucket overlaps two grid cells.

Next, Atlanta is inserted into bucket B. Insertion of Miami causes bucket B to overflow. Since B overlaps grid cells (3,1) and (4,1), we split it, thereby allocating a new cell, F, such that buckets B and F correspond to grid cells (3,1) and (4,1), respectively. Atlanta and Miami are moved to F (see Figure 1.93).

From the discussion, we see that two types of bucket splits are possible. The first, and most common, is when several grid cells share a bucket that has overflowed (e.g., the transition between Figures 1.94(d) and 1.93 caused by the overflow of bucket B as

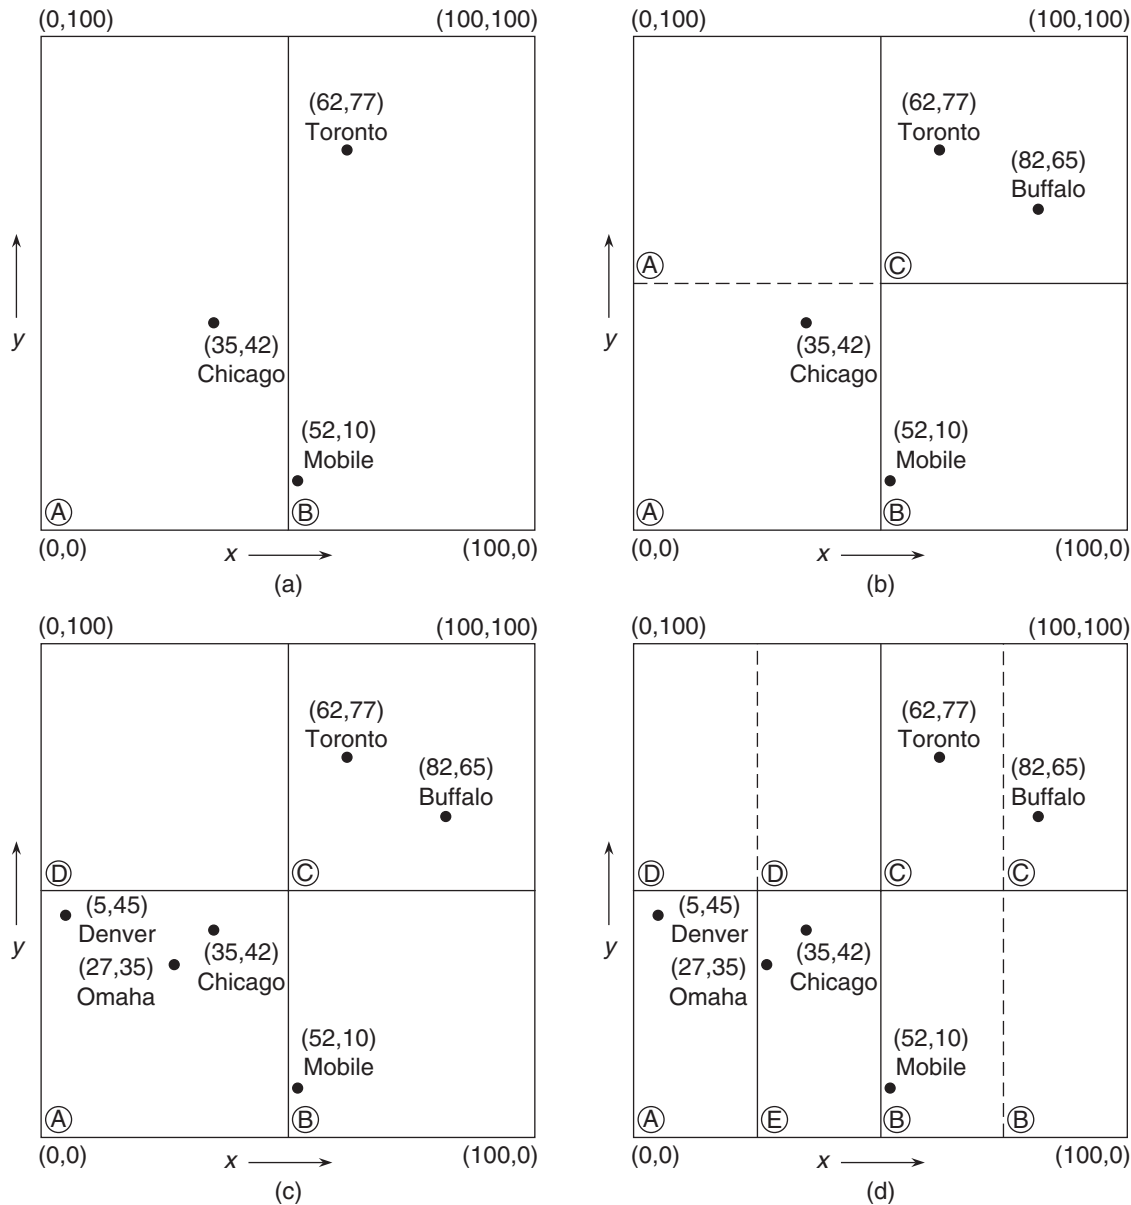

Figure 1.94  
 Sequence of partial EXCELL partitions demonstrating the result of the insertion of (a) Toronto, (b) Buffalo, and (c, d) Omaha.

Atlanta and Miami are inserted in sequence). In this case, we allocate a new bucket and adjust the mapping between grid cells and buckets.

The second type of a split causes a doubling of the directory and arises when we must refine a grid partition. It is triggered by an overflowing bucket that is not shared among several grid cells (e.g., the overflow of bucket A upon insertion of Toronto in Figure 1.94(a)). The split occurs along the different keys in a cyclic fashion (i.e., first split along key  $x$ , then  $y$ , then  $x$ , etc.).

For both types of bucket splits, the situation may arise that none of the elements in the overflowing bucket belongs to the newly created bucket, with the result that the directory will have to be doubled more than once. This is because the splitting points are fixed for EXCELL. For example, consider bucket A in Figure 1.95(a) with bucket capacity 2 and containing points X and Y. Insertion of point Z (see Figure 1.95(b)) leads

(a)

(b)

(c)

Figure 1.95 Example showing the need for three directory doubling operations using EXCELL when inserting point Z, assuming a bucket capacity of 2.

Figure 1.96 Example demonstrating the possibility of directory merging when using EXCELL.

to overflow of A and causes three directory doublings (see Figure 1.95(c)). In contrast, the fact that the splitting point is not fixed for the grid file means that it can be chosen so that only one grid refinement is necessary. Thus, we see that the size of the EXCELL grid directory is sensitive to the distribution of the data. However, a large bucket size reduces the effect of nonuniformity unless the data consists entirely of a few clusters.

The counterpart of splitting is merging. However, it is considerably more limited in scope for EXCELL than for the grid file. Also, it is less likely to arise because EXCELL has been designed primarily for use in geometrical applications where deletion of records is not so prevalent. There are two cases where merging is appropriate.

The first, and most common, is bucket merging, which arises when a pair of buckets is empty or nearly empty. The buckets that are candidates for merging, say X and Y, must be buddies in the sense that, at some earlier time, one of them was split, say X, to yield X and Y (e.g., A and E in Figure 1.93 but not A and C). Once such a bucket pair has been identified, we must see if its elements satisfy the merging threshold. In essence, the sum of the bucket occupancy percentages for the contents of the merged bucket should not be too large because, otherwise, it might soon have to be split.

The second instance where merging is possible is directory merging. It arises when either each bucket buddy pair in the grid directory meets the merging threshold (e.g., B and C, D, and E in Figure 1.96) or the bucket overlaps more than one grid cell (e.g., bucket A overlaps grid cells (1,2) and (2,2), and bucket F overlaps grid cells (3,1) and (4,1) in Figure 1.96). This is quite rare.

*Exercise*

1. Implement a database that uses EXCELL to organize two-dimensional data.

**1.7.2.3 Linear Hashing**

Linear hashing [1106, 1187] is a technique for avoiding drastic growth in the size of a hash table when it becomes too full (i.e., when a hash bucket overflows). In essence, use of linear hashing enables the hash table to grow by just one hash bucket, instead of doubling the number of hash buckets, as is the case with some hashing methods such as EXHASH [579], the extendible hashing function that forms the basis of EXCELL [1823].

This section is organized as follows. We first review the basic principles of linear hashing and show how to adapt it to handle multidimensional data (Section 1.7.2.3.1). This adaptation makes use of reversed bit interleaving as the hashing function. Next, we show how to implement linear hashing with multidimensional extendible hashing (MDEH) as the hashing function where the order in which overflowing buckets are split is more natural (Section 1.7.2.3.2). This is followed by an explanation of dynamic z hashing, which ensures that the newly created buckets are stored near each other (Section 1.7.2.3.3). We conclude with a brief discussion of linear hashing with partial expansions (LHPE), which addresses the issue that the load factors of the buckets that have just been split are much smaller than those of buckets that have not. In particular LHPE addresses this issue by splitting  $q$  buckets into  $q + 1$  buckets, as done in some implementations of the B-tree (Section 1.7.2.3.4).

As the primary focus of this section is the adaptation of linear hashing to multidimensional data, the explanation of linear hashing is somewhat brief. Appendix B contains a more detailed explanation of linear hashing and how it is related to other methods, such as extendible hashing. Readers who are not familiar with linear hashing are encouraged to consult it first before continuing further in this section.

**1.7.2.3.1 Adapting Linear Hashing to Multidimensional Data**

Our adaptation is based on starting with a grid of equal-sized grid cells, ordering the grid cells using a mapping from  $d$  dimensions to one dimension (perhaps one of the orderings

discussed in Section 1.6), and then, if necessary, splitting the grid cells one at a time in a manner consistent with the chosen order until all grid cells have been split. This results in creating a new grid of equal-sized grid cells, at which time the process is reapplied. Each bucket is associated with just one grid cell.

The key idea behind linear hashing is the decoupling of the decision as to which grid cell is to be split from the identity of the grid cell whose bucket has overflowed. This is a direct result of the predetermined order in which the grid cells are split. Since we must still deal with the fact that a bucket is too full, we have two types of buckets: primary and overflow. Each grid cell has a different primary bucket. When attempting to insert a data point  $p$  whose grid cell  $c$ 's primary bucket  $b$  is full, then  $p$  is inserted into an overflow bucket associated with  $c$ . Generally, the overflow buckets are chained to the primary buckets. Assuming that there are  $m$  grid cells, we use a one-dimensional directory addressed from 0 to  $m - 1$  to access the primary buckets associated with the grid cells. However, if there is a one-to-one correlation between the numbering of the grid cells and the primary bucket labels (as we will assume in our example), then there is no need for a grid directory.

Formally, we treat the underlying space as having a complete grid  $T$  imposed on it, said to be at *level*  $n$ , and a partial grid,  $T'$ , said to be at level  $n + 1$ , where some of the grid cells in  $T$  have been split into two equal-sized parts.<sup>56</sup>  $n$  denotes the number of total grid partitions that have been applied, where a *total grid partition* means that the number of grid cells has doubled in size. Given a complete grid at level  $n$ , we have  $m$  ( $2^n \leq m \leq 2^{n+1} - 1$ ) disjoint grid cells that span the entire underlying space:  $2^{n+1} - m$  of the grid cells are  $d$ -dimensional hyperrectangles of size  $v$  (both in volume and orientation), while the remaining  $2 \cdot (m - 2^n)$  grid cells are  $d$ -dimensional hyperrectangles of size  $v/2$ . The set of grid cells of size  $v$  are the ones that have not been split yet.

In order to make this method work, we need an ordering for the grid cells. In addition, we need a way to determine the grid cell associated with each data point. Moreover, if we do not assume a one-to-one correlation between the numbering of the grid cells and the primary bucket labels, then we also need a way to determine the directory element associated with each grid cell so that the relevant bucket can be accessed. Since we are using an ordering, we will need to make use of at least one mapping from  $d$  dimensions to one dimension.

In the following, we describe the approach that we use. Identify each grid cell  $c$  by the location of the point in the underlying space at the corner of  $c$  that is closest to the origin (e.g., the lower-leftmost corner for two-dimensional data with an origin at the lower-leftmost corner of the underlying space) and denote it as  $l(c)$ . Also, let  $u(c)$  be the location of the point in the underlying space at the corner of  $c$  that is farthest from the origin (e.g., the upper-rightmost corner for two-dimensional data with an origin at the lower-leftmost corner of the underlying space).

We need two mappings. First, we need a mapping  $g$  from  $d$  dimensions to one dimension that assigns a unique number to each data point in  $d$  dimensions (i.e., an ordering). For this mapping, we use one of the orderings discussed in Section 1.6 that satisfies the properties given below. The ordering is implemented in such a way that the first element in the ordering corresponds to the point closest to the origin.

1. The position in the ordering of each data point  $p$  in grid cell  $c$  is greater than or equal to that of  $l(c)$  (i.e., after)—that is,  $g(p) \geq g(l(c))$ .
2. The position in the ordering of each data point  $p$  in grid cell  $c$  is less than or equal to that of  $u(c)$  (i.e., before)—that is,  $g(p) \leq g(u(c))$ .

---

<sup>56</sup> Note that, in this case, the term *level* has the same meaning as *depth* for representations that make use of a tree or trie access structure. As we will see, in many other applications (e.g., the region quadtree, as well as the BV-tree in Section 1.7.1.6), the term *level* has a different meaning in the sense that it indicates the number of aggregation steps that have been performed.

3. The position in the ordering of any data point not in grid cell  $c$  is either before that of  $l(c)$  or after that of  $u(c)$ .

All of these properties are satisfied for both bit interleaving and bit concatenation. Observe that these properties ensure that the ordering also applies to the grid cells. For both bit interleaving and bit concatenation, the ordering also indicates the order in which the grid cells are partitioned. In particular, the partition order is equal to the order from left to right in which the bits of the binary representation of the keys are combined to form the position of the point in the ordering.

Second, we need a mapping  $h$  from the one-dimensional representative  $k$  of each point  $p$  and grid cell  $c$  in a complete grid at level  $n$  (i.e.,  $k = g(p)$  and  $k = g(l(c))$ , respectively) to a number  $a$  in the range 0 to  $m - 1$ . The result of this mapping  $a = h(k)$  serves as an index in the directory to access the buckets and is a one-dimensional array. The mapping  $h$  is such that the  $2^{n+1} - m$  grid cells of size  $v$  are associated with directory addresses  $m - 2^n$  through  $2^n - 1$ , and the remaining  $2 \cdot (m - 2^n)$  grid cells of size  $v/2$  are associated with directory addresses 0 through  $m - 2^n - 1$  and  $2^n$  through  $m - 1$ . Each directory element at address  $a$  contains the identity of the bucket corresponding to the grid cell associated with  $a$ .

Linear hashing implements the function  $h$  as two hash functions,  $h_n$  and  $h_{n+1}$ . The function  $h_n(k) = k \bmod 2^n$  is used to access the buckets associated with the grid cells at directory addresses  $m - 2^n$  through  $2^n - 1$ ;  $h_{n+1}(k) = k \bmod 2^{n+1}$  is used to access the buckets associated with the grid cells at directory addresses 0 through  $m - 2^n - 1$  and those at directory addresses  $2^n$  through  $m - 1$ . Such a file is said to be of level  $n, n + 1$  so that the grid cells accessed by  $h_n$  are at level  $n$  and those accessed by  $h_{n+1}$  are at level  $n + 1$ . Note that when  $m = 2^n$ , no grid cells are accessed by  $h_{n+1}$ .

Our adaptation of linear hashing to multidimensional data requires a function  $g$  that has the property that all of the data points associated with a particular directory element (i.e., grid cell) are within a given range (recall properties 1–3). Unfortunately, this is not the case when we use the hash function  $h_n(k) = k \bmod 2^n$ , where  $k = g(p)$ . In particular, for any binding of  $k$ ,  $h_n(k)$  has the property that all of the points in a given directory element agree in the  $n$  least significant bits of  $k$ . Such a hash function is used to explain linear hashing in Appendix B. This is fine for random access; however, it does not support efficient sequential file access (in terms of spatial proximity) since different directory elements, and hence different buckets, must be accessed. On the other hand, if  $h_n$  would discriminate on the most significant bits of  $k$ , then all of the points mapped to a given directory element would be within a given range and hence in the same grid cell, thereby satisfying properties 1–3 of the mapping. Assuming  $k$  is of fixed length (i.e., the number of bits is fixed), this can be achieved by redefining the hashing function  $h_n$  to be  $h_n(k) = \text{reverse}(k) \bmod 2^n$ . An implementation of linear hashing that satisfies this property is termed *order preserving linear hashing* (OPLH).

In one dimension, OPLH is analogous to a trie. For multidimensional data (e.g.,  $d$  dimensions), the same effect is obtained by combining the bits from the various keys (e.g., via interleaving, concatenation), reversing the result, and then performing a modulo operation. When the combination is based on bit interleaving, the result is analogous to a  $k$ - $d$  trie, and its behavior for range searching is discussed in some detail in Section 1.6. In the rest of this section, we use the combination of bit interleaving as the function  $g$  whose result is reversed to form a hashing function that we term *reversed bit interleaving*, which we use in conjunction with linear hashing. We refer to this combination as *linear hashing with reversed bit interleaving* (LHRBI).

Reversed bit interleaving results in partitioning the underlying space in a cyclic manner. For example, assuming a bit interleaving order of  $yxyxy \dots$  (i.e., the  $y$  coordinate is the most significant), then the first partition splits every grid cell in two using the  $y$  coordinate, the second partition splits every grid cell in two using the  $x$  coordinate, the third partition splits every grid cell in two using the  $y$  coordinate, and so on. After each partition, the number of grid cells doubles. After each cycle of partitions (i.e., one

partition per key), the number of grid cells grows by a factor of  $2^d$ . Of course, a different partitioning order could be obtained by combining the keys in a different order. For example, we could have defined a similar function, termed *reversed bit concatenation*, that would complete all partitions along one key before starting a partition on another key. We refer to this combination as *linear hashing with reversed bit concatenation* (LHRBC). However, reversed bit concatenation has the drawback of favoring some of the keys over the others, and thus we do not discuss its use further here.

It is interesting to note that the use of reversed bit interleaving with linear hashing seems to have been proposed independently by Burkhard [282] (who terms it *shuffle order*), Orenstein [1414], and Ouksel and Scheuermann [1435] (see also [1829]). This combination is applied to range searching by Burkhard [282] and Orenstein and Merrett [1420], although they each used different search algorithms.

Now, let us briefly review the mechanics of linear hashing and then give an example of its use with multidimensional data. Recall that a file implemented using linear hashing has both primary and overflow buckets. One primary bucket is associated with each grid cell. The storage utilization factor,  $\tau$ , is defined to be the ratio of the number of records (i.e., points) in the file to the number of positions available in the existing primary and overflow buckets.

When the storage utilization factor exceeds a predetermined value, say  $\alpha$ , then one of the grid cells is split. When grid cell  $c$  associated with the directory element at address  $b$  is split, its records are rehashed using  $h_{n+1}$  and distributed into the buckets of the grid cells associated with directory elements at addresses  $b$  and  $b + 2^n$ . The identity of the directory element corresponding to the next grid cell to be split is maintained by the pointer  $s$  that cycles through the values 0 to  $2^n - 1$ . When  $s$  reaches  $2^n$ , all of the grid cells at level  $n$  have been split, which causes  $n$  to be incremented and  $s$  to be reset to 0.

It is important to observe that a grid cell split does not necessarily occur when a point is inserted that lies in a grid cell whose primary bucket is full; nor does the primary bucket of the grid cell that is split have to be full. Nevertheless, the justification for using linear hashing is that eventually every bucket will be split, and, ideally, all of the overflow buckets will be emptied and reclaimed. This is similar to the rationale for analyzing algorithms using the amortization method [163].

As an example of the partitioning that results when  $g$  is bit interleaving, consider, again, the point set of Figure 1.1 after the application of the mapping  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$  to the values of the  $x$  and  $y$  coordinates, respectively. The result of this mapping is given in columns 4 and 5 of Figure 1.97. Next, apply reversed bit interleaving to its keys to yield the mappings given in columns 6 and 7 of the figure, depending on whether we take the  $x$  coordinate as the most significant (column 6 and

NAME	X	Y	$f(X)$	$f(Y)$	CODEX	CODEY

Figure 1.97  
 Reversed bit interleaving applied to the result of applying  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$  to the values of the  $x$  and  $y$  coordinates, respectively, of the point set in Figure 1.1.

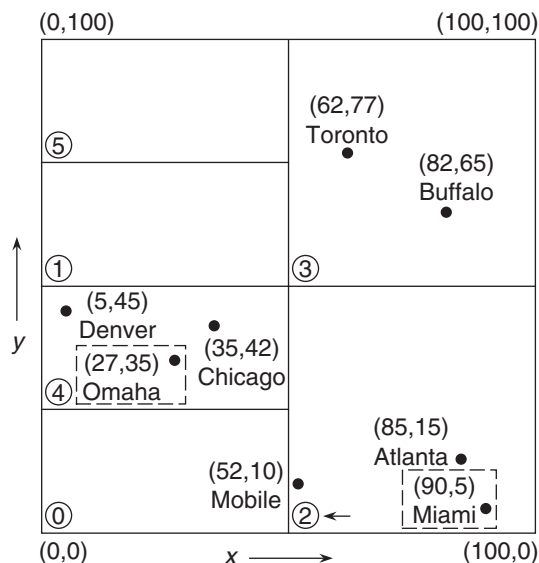

Figure 1.98  
The representation resulting from applying linear hashing with reversed bit interleaving (LHRBI) corresponding to Figure 1.1. The  $y$  coordinate is assumed to be the most significant. Overflow bucket contents are enclosed by broken lines. A leftward-pointing arrow indicates the next bucket to be split.

labeled CODEX) or the  $y$  coordinate (column 7 and labeled CODEY). In our example, we treat the  $y$  coordinate as the most significant and thus make use of the values in column 7.

Assume that the primary and overflow buckets are both of size 2 and that a bucket will be split whenever  $\tau$ , the storage utilization factor, is greater than or equal to 0.66 (i.e.,  $\alpha = 0.66$ ). We also assume that there is a one-to-one correlation between the numbering of the grid cells and the primary bucket labels and thus there is no need for a grid directory. Therefore, we use numbers to refer to both the grid cells and the primary buckets associated with them. Inserting the cities in the order Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami yields the partition of the database shown in Figure 1.98, which has six primary buckets, labeled 0–5, and two overflow buckets. To explain the splitting process, we examine more closely how Figure 1.98 was obtained.

Initially, the file consists of just grid cell 0 and bucket 0, which is empty. The file is of level 0,1. The pointer to the next grid cell to be split,  $s$ , is initialized to 0. Chicago and Mobile, which lie in grid cell 0, are inserted in bucket 0, which yields  $\tau = 1.00$ . This causes grid cell 0 to be split and bucket 1 to be allocated.  $s$  retains its value of 0, and both Chicago and Mobile remain in bucket 0 (see Figure 1.99(a)).

Toronto lies in grid cell 1 and is inserted into bucket 1. However, now  $\tau = 0.75$ , thereby causing grid cell 0 to be split,  $s$  to be set to 1, bucket 2 to be allocated, and Mobile to be placed in it (see Figure 1.99(b)). Our file is now of level 1,2.

Next, we try to insert Buffalo, which lies in grid cell 1 and hence is inserted in bucket 1. However, now  $\tau = 0.67$ , thereby causing grid cell 1 to be split,  $s$  to be reset to 0, bucket 3 to be allocated, and Toronto and Buffalo to be placed in it (see Figure 1.99(c)).

Denver lies in grid cell 0 and is inserted into bucket 0. Omaha lies in grid cell 0, and hence it is inserted into bucket 0. However, now  $\tau = 0.75$ , thereby causing grid cell 0 to be split,  $s$  to be set to 1, bucket 4 to be allocated and and Denver and Chicago to be moved into it. Our file is now of level 2,3. Unfortunately, Omaha also lies in grid cell 4, but bucket 4 is full and thus an overflow bucket must be allocated and attached to grid cell 4, and Omaha is placed in it (see Figure 1.99(d)).

Atlanta lies in grid cell 2 and is placed in bucket 2. Miami also lies in grid cell 2 and is placed in bucket 2. However, now  $\tau = 0.67$ , thereby causing grid cell 1 to be split,  $s$  to be set to 2, and bucket 5 to be allocated. After the grid cell split, we still have too many items in bucket 2, and thus an overflow bucket must be allocated and attached to grid cell 2, and Miami is placed in it (see Figure 1.98).

- Write a procedure LINRANGESearch to perform a range search for a rectangular region in a two-dimensional database implemented with linear hashing using reversed bit interleaving as the hashing function.

### 1.7.2.3.2 Multidimensional Extendible Hashing (MDEH)

The drawback of using linear hashing with reversed bit interleaving as the hashing function  $h$  is that the order in which the grid cells are split is not consistent with a splitting policy that introduces a  $(d - 1)$ -dimensional partitioning hyperplane  $l$  (as in the grid file), and then splits the group of grid cells intersected by  $l$  (termed a *slice*), thereby creating an additional slice, before attempting to split other grid cells.<sup>57</sup> Such a splitting order is more in line with the manner in which the grid file grows and is frequently desired as it preserves some locality, at least across the key  $k$  that is being split. In particular, these grid cells are spatially contiguous within the range of  $k$  that has been split and hence are more likely to be full when the split is made (this is especially true when we use the PLOP hashing variant of linear hashing described in Section 1.7.2.4.2). Thus, we need another hashing function  $f$ .  $f$  must also stipulate the order in which the grid cells in the slice intersected by  $l$  are to be split and buckets allocated for them (as well as deallocated, if necessary, should there have been overflow buckets associated with some of the corresponding grid cells in  $l$ ).

Figure 1.100 (a–f) The order in which the underlying space is partitioned during creation of the first 16 grid cells when applying linear hashing with reversed bit interleaving (LHRBI) (i.e.,  $h$ ), where the  $y$  coordinate is the most significant. The grid cells are numbered in the order in which they were created.

$f$  results in partitioning the axes corresponding to the  $d$  keys in a cyclic manner, starting with one partition for each of the keys, thereby resulting in  $2^d$  grid cells after completing the first cycle of partitions. Next,  $f$  cycles through the keys partitioning each key’s axis twice, each key’s axis four times on the next cycle, and so on.<sup>58</sup> As grid cells are partitioned, new ones are created and assigned numbers in increasing order, assuming that initially the entire set of data is in grid cell 0. The central property of  $f$  is that all the grid cells in slice  $a$  are split in two before any grid cells in any of the other slices are split, and the grid cells in  $a$  are split in the order in which they were created.<sup>59</sup> In contrast, the reversed bit interleaving hashing function  $h$  uses a different split policy in that it does not introduce a  $(d - 1)$ -dimensional partitioning hyperplane. Instead,  $h$  results in splitting the grid cells in the order in which they were created, regardless of the identities of the slices in which they are contained.

In order to see this distinction between  $f$  and  $h$ , assume that the partitions are made on a cyclic basis  $yxyxy \dots$  (i.e., the  $y$  coordinate is more significant than the  $x$  coordinate). Figures 1.100 and 1.101 show the order in which the first 16 grid cells (starting with the initial grid cell 0) are partitioned for both  $h$  and  $f$  (also known as *MDEH*, as described below), respectively. The numbers associated with the cells correspond to the order in which they were created. Assume that the underlying space is a unit-sized square with an origin at the lower-left corner and that it is partitioned by a recursive halving process along the range of the corresponding key so that, after each cycle of partitions through all of the keys, the result is a grid of cells having a uniform width across all keys. The labels along the axes in Figure 1.101 indicate the relative time at which the partition was performed along the axis (subsequently referred to as the *partition number*).

Note that in the transition between Figure 1.100(b, c), grid cells 0 and 1 are split, thereby creating grid cells 4 and 5. However, these grid cells (i.e., 0 and 1) are not

<sup>57</sup> This problem also holds for using linear hashing with reversed bit concatenation. We do not discuss it here as it favors some keys over others.

<sup>58</sup> We shall see later that the cyclic partitioning order is not a requirement of the definition of  $f$ . In other words, other partition orders are also possible as long as the number of partitions along the axis of each key doubles for each subsequent partitioning along that key. However, for the present, we assume a cyclic partition order.

<sup>59</sup> The grid cells in  $a$  that are being split were not necessarily created in immediate succession (i.e., they are not necessarily numbered in consecutive order). In other words, grid cell  $c_i$  in  $a$  is split before grid cell  $c_j$  in  $a$  if grid cell  $c_i$  was created earlier than grid cell  $c_j$ , although, of course, other grid cells in different slices than  $a$  could have been created in the time between the creation of  $c_i$  and  $c_j$ .

partitioned by the same one-dimensional hyperplane (which would be a line in two dimensions as is the case here). In contrast, the transition between Figure 1.101(b, c) does proceed by completely partitioning one slice before partitioning another slice. Thus, we find that the first two grid cells that are split (i.e., 0 and 2) are partitioned by the same hyperplane (i.e., the line  $y = 0.25$ ), thereby creating grid cells 4 and 5.

Figure 1.102 shows the correspondence between the partition numbers in Figure 1.101 (i.e., the labels along the axes) and the numbers of the grid cells that are created by the first three partitions along each key (i.e., two cycles for each key) when  $d = 2$ . This correspondence can be calculated by using MDEH (*multidimensional extendible hashing*) [1428]<sup>60</sup>, which serves as the desired hashing function  $f$ , thereby obviating the need for the directory shown in Figure 1.102.

To convince ourselves that the MDEH function really does what it is supposed to do, let us determine the grid cell that contains the point  $(x = 0.3, y = 0.6)$ . Once again, we assume that the underlying space of Figure 1.101 is a unit-sized square with an origin at the lower-left corner that is partitioned by a recursive halving process along the range of the corresponding key so that, after each cycle of partitions through all of the keys, the result is a grid of cells having a uniform width across all keys. The labels,  $S_x$  and  $S_y$ , along the axes in Figure 1.101 indicate the partition number that causes the creation of the  $(d - 1)$ -dimensional region of grid cells immediately to its right (for the  $x$  coordinate) or above (for the  $y$  coordinate). We also assume that the partitioning process has cycled through both keys twice, thereby resulting in Figure 1.101(f). This information is used to determine from Figure 1.101(f) that our query point is in the grid cell created by the second partition along the  $x$  axis and the first partition along the  $y$  axis. Looking up the entry in Figure 1.102 corresponding to  $S_x = 2$  and  $S_y = 1$  yields grid cell number 9, which is indeed the number associated with the grid cell containing the point in Figure 1.101(f).

Our explanation of how to determine the grid cell  $c$  that contains a point  $p$  at location  $r$ , with  $r_i$  ( $1 \leq i \leq d$ ) as the values for key  $i$ , omitted one crucial step. In particular, we need to find a way to compute the partition numbers corresponding to the different partitioning hyperplanes for the keys so that they can be used as parameters to MDEH. In our explanation, the existence of  $d$  one-dimensional directories, such as those found along the axes of Figure 1.101(f), that correlate the locations of the partitioning hyperplanes with the partition numbers was implicitly assumed, when in fact such directories do not exist. When the partitions are obtained by a recursive halving process of the range of the keys that make up the underlying space (as is the case in this example), the equivalent effect of these one-dimensional directories can be achieved by applying the following five-step process to each key value  $r_k$ . Assume that key  $k$  has been partitioned  $q_k$  times such that  $2^n \leq q_k < 2^{n+1}$ , where  $n$  is the number of times a full cycle of partitions has been made through  $k$ .

1. Determine the range  $t_k$  of values for key  $k$ .
2. Calculate the width  $w_k$  of a grid cell for key  $k$  (i.e.,  $w_k = t_k / 2^{n+1}$ ).
3. Compute the position  $u_k$  ( $0 \leq u_k < 2^{n+1}$ ) of the grid cell containing  $r_k$  (i.e.,  $u_k = t_k \div w_k$ ).
4. Reverse the  $n + 1$  least-significant bits of the binary representation of  $u_k$  to obtain  $v_k$ , which is the desired partition number.
5. If  $v_k > q_k$ , then recalculate  $v_k$  using steps 2–4 with  $2^n$  instead of  $2^{n+1}$  in steps 2 and 3.

An alternative to the five-step process described above is to use a set of  $d$  one-dimensional directories in the form of linear scales (as in the grid file), one per key,

<sup>60</sup> Also referred to as the access function for a uniform extendible array of exponential varying order (UXAE). MDEH was first presented by Merrett and Otoo [1288] as the cornerstone of dynamic multipaging (see Section 1.7.2.1), which enables mapping the grid cells into a linear sequence in memory while permitting the dataset to grow dynamically.

## Section 1.7 BUCKET METHODS

Figure 1.101  
(a–f) The order in which the underlying space is partitioned during creation of the first 16 grid cells when using a hashing function that splits all grid cells within a slice before splitting other grid cells (i.e.,  $f$ , which is also MDEH), where the  $y$  coordinate is the most significant. The grid cells are numbered in the order in which they were created. The labels along the axes indicate the relative time at which the partition was performed along the axis.

Figure 1.102  
Correspondence between partition numbers (shown as horizontal and vertical axes of the table) and the number of the grid cells that are created by the first three partitions of the keys when all grid cells in one slice are split before splitting other grid cells. Assume that  $d = 2$ , where the  $y$  coordinate is the most significant. This table is the same as the function MDEH.

Figure 1.103  
Linear scales showing the correspondence between coordinate values and partition numbers for the (a)  $x$  and (b)  $y$  axes, corresponding to the partition of the underlying space given in Figure 1.101(f). This can also be obtained by use of a five-step process outlined in the text.

implemented as binary trees (see Exercise 1). Each nonleaf node of the binary trees indicates the key value corresponding to the partition,<sup>61</sup> and the leaf nodes indicate the partition number. For example, Figure 1.103 shows the linear scales for the  $x$  and  $y$  axes corresponding to the partition of the underlying space given in Figure 1.101(f). Note that after each full cycle of partitions through the  $d$  keys, the linear scales are identical (as is the case in our example).

The method outlined above for determining the grid cell  $c$  that contains a point  $p$  given its location  $r$  demonstrates the second principal way in which  $f$  (i.e., MDEH) differs from the hashing functions used with linear hashing. In particular,  $c$  is not obtained by directly applying  $f$  to  $r$  (or to the result of reversing the bit interleaved or bit concatenated representation of the key values that make up  $r$ , as in linear hashing). Instead,  $c$  is determined by applying  $f$  to the partition numbers along the axes corresponding to the values of its keys that caused  $c$  to be created. The actual correspondence between partition numbers and key values is obtained by use of either the linear scales or the five-step process outlined above, given the number of times each key has been partitioned.

Upon some reflection, it should be apparent that  $f$ , in conjunction with the partition numbers, plays the same role as the table given in Figure 1.101(f) to indicate the two-dimensional correspondence between key values and grid cell numbers. Unfortunately, we do not have the luxury of having space to store this table, which is why we make use of  $f$ . It should be clear that the lack of this table is what sets linear hashing apart from the grid file (for which the table exists), which, after all, is the point of this discussion (i.e., how to avoid the table). Note that the use of the linear scales or the five-step process to calculate the partition numbers, which are then supplied as parameters to the hash function  $f$  to determine the grid cell containing the query point, obviates the need for the hashing function  $f$  to satisfy ordering properties 1–3 outlined in Section 1.7.2.3.1. In contrast, when using a hashing function that satisfies OPLH, we usually apply the hash function directly to the result of interleaving or concatenating the bits of the query point rather than computing the partition numbers corresponding to the coordinate values of the query point, as is the case when using MDEH.

Grid cells are split whenever the storage utilization factor  $\tau$  exceeds a predetermined value, say  $\alpha$ . We use a split index (termed an *expansion index* [1085]) in the form  $E = (e_1, e_2, \dots, e_d)$  to indicate which grid cell  $c$  is to be split next. The identity of  $c$  is determined by applying the MDEH hash function to the  $d$  values of  $e_i$ , where  $e_i$  is the partition number corresponding to key  $i$ . The actual split occurs by passing the  $(d - 1)$ -dimensional hyperplane corresponding to partition  $e_k$  through  $c$ . The split procedure is as follows. Assume that we are in the  $j$ th split cycle (meaning that we have cycled through the  $d$  keys  $j - 1$  times) for key  $k$ . Thus, we must now apply  $2^{j-1}$  partitions to  $k$ . We first determine the slice that is being partitioned (i.e.,  $e_k$ , termed the *expansion slice*). Next, we check if we are splitting the first cell in slice  $e_k$  (i.e.,  $e_i = 0$  for all  $i$ , where  $1 \leq i \leq d$  and  $i \neq k$ ). In this case, we compute a partition point along key  $k$  that partitions the slice in two. Next, we split the cell.

Once a cell has been split, we check if all of the grid cells intersected by the current partition (i.e., in the expansion slice) have been split. If they have not, then we determine the next cell to be split, which is done in increasing lexicographic order of  $E$ , while holding  $e_k$  fixed. If they have, then, assuming that linear scales are used,<sup>62</sup> we update the linear scale of  $k$  to contain the partition value, as well as the new partition numbers, and reset the expansion index. We then proceed to the next partition on key  $k$  by incrementing  $e_k$  by 1, unless we are processing the final slice (i.e., the  $2^{j-1}$ th slice in the current split

<sup>61</sup> There is no need to store the key value in the nonleaf nodes because they can always be determined from knowledge of their ranges and the path followed when descending from the root of the binary tree corresponding to the linear scale to the appropriate leaf node.

<sup>62</sup> In the rest of this discussion, we assume that linear scales are used as this will make the process general and enables it to be used with quantile hashing and PLOP hashing as described in Section 1.7.2.4.

cycle), in which case we proceed to the next key in cyclic order and possibly increase the cycle number  $j$  if  $k = d$ .

At this point, let us describe the process of determining the grid cell  $c$  associated with a query point  $p = (p_1, p_2, \dots, p_d)$  in more detail. As mentioned above, we look up the coordinate values of  $p$  in the linear scales (or use our five-step procedure) and obtain the partition numbers for the different keys, say  $s_i$  ( $1 \leq i \leq d$ ). We must now determine if  $c$  lies inside or outside the expansion slice as this indicates whether we can apply  $f$  directly to  $s_i$  to obtain the value of  $c$ . Assume that we are currently partitioning on key  $k$ . Therefore, from the expansion index  $E$ , we know that  $e_k$  denotes the partition number, thereby enabling the identification of the expansion slice for key  $k$ . We can determine whether  $c$  will be inside or outside the expansion slice by examining the values of  $s_i$  ( $1 \leq i \leq d$ ).

1. If  $s_k = e_k$  and if the sequence  $s_i$  ( $1 \leq i \leq d$ ) is lexicographically less than  $E$ , then the grid cell containing  $p$  has already been expanded. This means that we have to recompute the partition number  $s_k$ , say  $q$ , for key  $k$  by including the expansion partition in the lookup process that uses the linear scales of key  $k$  (or use our five-step procedure). The function  $f$  is now applied to  $s_i$  ( $1 \leq i \leq d$ ) with  $q$  replacing  $s_k$  to yield the grid cell corresponding to  $c$ .
2. If  $c$  is outside the expansion slice, then we apply  $f$  to  $s_i$  ( $1 \leq i \leq d$ ) to yield the grid cell corresponding to  $c$ .

For example, consider the grid partition given in Figure 1.104(a) where the  $x$  coordinate is currently being partitioned (again assuming a cyclic order  $yxyx\dots$ ). In particular, we have cycled through the  $y$  axis twice and through the  $x$  axis once. We are currently in the second partition on the second cycle of the  $x$  axis with an expansion index value of  $E = (2, 1)$  (denoting that the next grid cell to be split is the one formed by the second partition on  $y$  and the first partition on  $x$ ). The corresponding linear scales are given to the left of the  $y$  axis and below the  $x$  axis. Let us first search for the point  $(x = 0.3, y = 0.8)$ . From the linear scales, we have that  $S_y = 3$  and  $S_x = 2$ . Since  $S_x \neq 1$ , the grid cell containing  $(x = 0.3, y = 0.8)$  is not in the expansion slice and thus the grid cell is obtained by applying MDEH (i.e., grid cell 11).

As another example, suppose that we search for the point  $(x = 0.8, y = 0.6)$ . From the linear scales, we have that  $S_y = 1$  and  $S_x = 1$ . Since  $S_x = 1$ , the grid cell containing  $(x = 0.8, y = 0.6)$  is in the expansion slice. Moreover, since  $(S_y, S_x) = (1, 1) <^L (2, 1) = E$  (where  $<^L$  denotes the lexicographic ordering), the grid cell containing  $(x = 0.8, y = 0.6)$

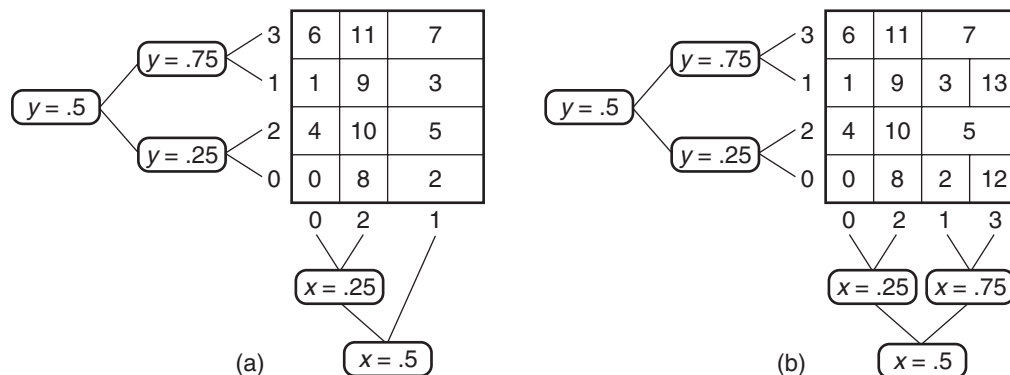

Figure 1.104  
(a) Example grid partition illustrating the use of MDEH with the  $y$  coordinate being the most significant. Linear scales are given to the left of the  $y$  axis and below the  $x$  axis. The expansion index has a value  $E = (2, 1)$ . (b) The modified linear scale for  $x$  to reflect the fact that the third partition on the  $x$  axis has not yet been completed but is used when the query point is in a grid cell in the expansion slice that has already been expanded.

Correlation of grid cell addresses to the underlying space for (a) linear hashing with reversed bit interleaving (LHRBI), (b) MDEH, and (c) Morton order (i.e., conventional bit interleaving), where the  $y$  coordinate is the most significant after two complete cycles of splitting along the two keys. The heavy lines denote the boundaries of a  $2 \times 2$  search window in the upper half of the underlying space.

has already been expanded. Therefore, we have to include this expansion in the linear scales (see Figure 1.104(b)) when looking up the value of  $S_x$ , which is now 3. Applying MDEH to  $S_y = 1$  and  $S_x = 3$  yields grid cell 13. Note that had we looked for the point  $(x = 0.8, y = 0.8)$ , we would have  $S_y = 3$  and  $S_x = 1$ , which is also in the expansion slice. However,  $(S_y, S_x) = (3, 1)$  is not lexicographically less than  $E = (2, 1)$ , and thus we can apply MDEH directly to obtain grid cell 5.

### Exercises

1. What is the drawback of implementing the linear scales as one-dimensional arrays?
2. Give an algorithm for computing the value of MDEH for a set of partition numbers  $s_i$  ( $1 \leq i \leq d$ ), where we have made  $j$  cycles through each key.
3. Write a procedure MDEHPOINTSEARCH to perform a point search (i.e., exact match query) in a two-dimensional database implemented with MDEH as the hashing function.
4. Write a procedure MDEHRANGESEARCH to perform a range search for a rectangular region in a two-dimensional database implemented with MDEH as the hashing function.

### 1.7.2.3.3 Dynamic Z Hashing

Hashing functions that satisfies OPLH (i.e., both LHRBI and LHRBC) and MDEH have the shortcoming that grid cells at consecutive addresses (i.e., buckets) are not usually in spatial proximity. Equivalently, grid cells that are in spatial proximity are not usually in consecutive addresses (i.e., buckets). If the numbers of the grid cells correspond to disk addresses (not an unreasonable assumption), then execution of queries such as multidimensional range queries (e.g., a hyperrectangular window query) usually results in a large number of seek operations. In order to see this, consider Figure 1.105, which shows the correlation of grid cells to the underlying space for linear hashing with reversed bit interleaving (Figure 1.105(a)), MDEH (Figure 1.105(b)), and the Morton order, which is the same as conventional bit interleaving (Figure 1.105(c)), where the  $y$  coordinate is the most significant after two complete cycles of splitting along the two keys. In particular, let us examine the grid cells that overlap the  $2 \times 2$  search window in the upper half of each part of the figure (shown with a heavy line). Notice that only for conventional bit interleaving (i.e., the Morton order) are any of the covering grid cells at consecutive addresses. The goal is to make this number as large as possible.

The problem lies in the order in which the newly created grid cells are created. In particular, for a hashing function that satisfies OPLH (i.e., both LHRBI and LHRBC) and MDEH, when a grid cell is split, the grid cells resulting from the split are not stored in consecutive addresses. Thus, we need a method that preserves proximity by having the property that whenever a grid cell at address  $c$  is split, it must result in the creation of two grid cells at consecutive addresses, say at  $a$  and  $a + 1$ . Since the grid cell at address  $c + 1$  is usually occupied, we cannot split  $c$  to create  $c$  and  $c + 1$ . Moreover, when the grid cell at address  $c + 1$  is split, we would like its result to be near the result of splitting the grid cell at address  $c$  (i.e.,  $a$  and  $a + 1$ ). Interestingly, the Morton order does satisfy these requirements in that it has the property that a grid cell at address  $c$  is split into two grid cells at addresses  $2c$  and  $2c + 1$  (see Exercise 3). The Morton order is the basis of the  $z^+$ -order [906]. The difference from the Morton order is that the  $z^+$ -order enables the representation of the partition at times other than when a key is fully expanded (i.e., when we have doubled the number of grid cells as a result of splitting all of the grid cells for a particular key). When a key is fully expanded, the  $z^+$ -order is equivalent to the Morton order.

The central idea behind the  $z^+$ -order is to determine a sequence in which the grid cells are to be split so that the ordering is preserved. Assume that we have just completed  $L$  expansions, thereby having  $2^L$  grid cells with addresses  $0, 1, \dots, 2^L - 1$ , and we are now ready to start on the  $L + 1$ st expansion. Clearly, when we split the grid cell at address  $c$  to yield grid cells at addresses  $2c$  and  $2c + 1$ , these grid cells must not be occupied.

This property does not hold if we try to split the grid cell at address 0. One way to ensure that this does not occur is to split the grid cells in decreasing order, starting with the grid cell at address  $2^L - 1$ , thereby creating grid cells at addresses  $2^{L+1} - 2$  and  $2^{L+1} - 1$ . The problem with this approach is that it creates a large gap of unused grid cells, which contradicts the purpose of linear hashing—to extend the range of addresses in an incremental manner as needed. Moreover, it results in low storage utilization.

Ideally, if there are currently  $4t$  grid cells in use (at addresses  $0, 1, \dots, 4t - 1$ ), then we want to place the newly created grid cells at addresses  $4t$  and  $4t + 1$ . This means that we split the grid cell at address  $2t$ , thereby creating a gap (i.e., an unused grid cell) at  $2t$ . This is fine as long as we do not create too many gaps and if the gaps are small. Thus, any technique that we use must fill up the gaps as soon as possible, as well as minimize their number. The gaps are filled by splitting the predecessor grid cells. For example, suppose that after splitting the grid cell at address  $2t$ , we split the grid cell at address  $2t + 1$ , thereby creating grid cells at addresses  $4t + 2$  and  $4t + 3$ . This means that we now have a gap at addresses  $2t$  and  $2t + 1$ , which means that the next grid cell to be split is the one at address  $t$ . This process is continued recursively until all grid cells have been split, and we have  $2^{L+1}$  grid cells at addresses  $0, 1, \dots, 2^{L+1} - 1$ . This splitting method is termed *dynamic z hashing* [906].

As an example of dynamic z hashing, consider Figure 1.105(c), which corresponds to the mapping of grid cells and addresses when using the Morton order for the fourth expansion (i.e.,  $L = 4$ ). During the fifth expansion (i.e.,  $L = 5$ ), the grid cells are split in the following order, where we use the notation  $(a:bc)$  to denote that the grid cell at address  $a$  has been split to create grid cells at addresses  $b$  and  $c$ : (8:16 17), (9:18 19), (4:8 9), (10:20 21), (11:22 23), (5:10 11), (2:4 5), (12:24 25), (13:26 27), (6:12 13), (14:28 29), (15:30 31), (7:14 15), (3:6 7), (1:2 3), (0:0 1).

As mentioned above, the cost of using the  $z^+$ -order is a lower storage utilization due to the existence of unused grid cells (i.e., gaps). The storage efficiency can be obtained by calculating the average number of gaps during a full expansion. Assuming that  $L$  full expansions have been carried out, it can be shown that the  $L + 1$ st expansion has an average of  $L/2$  gaps (see Exercise 2) [906]. Experiments comparing the  $z^+$ -order with a variant of MDEH have shown that use of  $z^+$ -order for hyperrectangular range queries results in a significant reduction in the number of sequences of consecutive grid cells that need to be examined, thereby lowering the number of disk seek operations that will be needed and thus yielding faster execution times.

### Exercises

1. Give an algorithm to implement dynamic z hashing.
2. Show that the average number of unused grid cells (i.e., the sizes of the gaps) during the  $L + 1$ st expansion when using the  $z^+$ -order is  $L/2$ .
3. One of the main properties that enables the Morton order to be used as the basis of dynamic z hashing is that a grid cell at address  $c$  is split into two grid cells at addresses  $2c$  and  $2c + 1$ . Does this property also hold for the Peano-Hilbert order? If it does not hold, can you state and prove how often it does hold? Also, if it does not hold, can you find a similar property that does hold for the Peano-Hilbert order?
4. The  $z^+$ -order [906] was devised in order to ensure that when a grid cell is split in linear hashing, the newly created grid cells are in spatial proximity. The  $z^+$ -order makes use of a Morton order. Can you define a similar ordering, termed  $p^+$ -order, that makes use of a Peano-Hilbert order instead of a Morton order? If yes, give an algorithm for the splitting method that is analogous to dynamic z hashing (i.e., *dynamic p hashing*).
5. Compare the  $z^+$ -order and the  $p^+$ -order (i.e., the Morton and Peano-Hilbert orders as described in Exercise 4) in terms of their storage efficiency by examining the average number of gaps. The comparison should be analytic. If this is not possible, then use an experimental comparison.

6. Compare the  $z^+$ -order and the  $p^+$ -order (i.e., the Morton and Peano-Hilbert orders as described in Exercise 4) in terms of their efficiency in answering range queries by examining the average number of sequences of consecutive grid cells that are examined. The comparison should be analytic. If this is not possible, then use an experimental comparison. Do the results match the general comparison of the efficiency of the Morton and Peano-Hilbert orders described in [983]?

#### 1.7.2.3.4 Linear Hashing with Partial Expansions (LHPE)

A general drawback of linear hashing is that, during each expansion cycle, the load factor of the buckets corresponding to the grid cells that have been split is only one-half of the load factors of the buckets corresponding to the grid cells that have not yet been split in the cycle. Thus, the records are not uniformly distributed over all of the buckets, thereby leading to worse query performance (e.g., search). The performance is worse because there are more overflow buckets to be searched. Larson [1105] proposes a variant of linear hashing termed *linear hashing with partial expansions* (LHPE) to overcome this problem. The key idea is that the number of grid cells is doubled in a more gradual manner through the application of a sequence of partial expansions.

For example, assuming that a file contains  $2N$  buckets, the doubling can be achieved in a sequence of two partial expansions, where the first expansion increases the file size to 1.5 times the original size and the second expansion increases it to twice the original size. In particular, the original file is subdivided into  $N$  pairs of buckets, say 0 and  $N$ , 1 and  $N + 1$ , ...,  $N - 1$  and  $2N - 1$ . Now, instead of splitting a bucket as in linear hashing, the first partial expansion creates a new bucket,  $2N$ , corresponding to the first pair 0 and  $N$  and rehashes their contents into buckets 0,  $N$ , and  $2N$ . This process is repeated until we have  $3N$  buckets, at which time a similar second partial expansion is applied to  $N$  trios of buckets, where a new bucket is created for each trio of buckets until we have  $4N$  buckets. The next time we need to allocate a new bucket, we start a new sequence of two partial expansions, resulting in the file growing to  $6N$  and  $8N$  buckets after each partial expansion.

It should be clear that we could use more than two partial expansions, say  $q$ , in which case each partial expansion would result in the number of buckets being increased by a factor of  $1/q$  times the number of buckets at the beginning of each full expansion cycle. Interestingly, the choice of  $q = 2$  seems to be the best from a performance standpoint since the more uniform load factor resulting from the larger number of partial expansions (thereby leading to a lower search cost due to the reduction in the number of overflow buckets) is not worth the higher bucket-splitting costs [1105].

Partial expansions can be easily used with a hashing function that satisfies OPLH (regardless of whether bit interleaving or bit concatenation is used). Using partial expansions with MDEH is a bit trickier because the expansion unit is a slice rather than a grid cell. This means that instead of expanding groups of individual grid cells, we must expand groups of slices. Kriegel and Seeger [1084] take this into consideration by proposing to split two adjacent slices into three on the first partial expansion for key  $k$ , followed by a split of three adjacent slices into four on the second partial expansion for  $k$ . They term the result *multidimensional order-preserving linear hashing with partial expansion* (MOLHPE) and give a function for its computation.

#### Exercise

1. Give an algorithm for computing the value of MDEH for a set of partition numbers  $s_i$  ( $1 \leq i \leq d$ ) where we have made  $j$  cycles through each key and that uses two partial expansions (i.e., MOLHPE).

#### 1.7.2.4 Alternative Implementations of Linear Hashing

Both linear hashing (regardless of whether the variant used is order preserving) and MDEH have the drawback that the grid cell that has been split most recently is not

necessarily the one that is full. Three approaches, quantile hashing [1084, 1086], PLOP (denoting *piecewise linear order preserving*) hashing [1085], and spiral hashing [1106, 1247, 1324], discussed below, try to overcome this drawback by, in part, varying the range of values (i.e., in the underlying data domain) that can be associated with some of the grid cells (true for all three approaches) and by allowing some flexibility in choosing the next grid cells to be partitioned (true for PLOP hashing). Two of the approaches (i.e., quantile hashing and PLOP hashing) make use of MDEH as the underlying hashing function, while spiral hashing makes use of a hashing function that has similar properties to those used in OPLH as discussed in Section 1.7.2.3.1.

These approaches have the effect of permitting greater variability in the size of some of the grid cells, thereby differing from conventional linear hashing, as described in Section 1.7.2.3, where the number of possible sizes of the grid cells is quite limited.<sup>63</sup> Moreover, in both quantile and PLOP hashing, the space  $U$  spanned by the grid cell is still a hyperrectangle, although subsets of the individual grid cells no longer need to be similar. In contrast, in spiral hashing,  $U$  can have an arbitrary shape and, in fact, need not always be spatially contiguous.

A central difference between these three approaches is the action taken when the storage utilization factor is exceeded (i.e., the determination of which cell or group of cells is to be partitioned or, if there is no choice, where to place the partition).

1. Quantile hashing partitions a group of grid cells on the basis of a stochastic approximation of what the future distribution of the incoming data might look like for the associated quantile, which is always a power of  $1/2$ .
2. PLOP hashing partitions a group of grid cells on the basis of which one contains the maximum number of data items.
3. Spiral hashing partitions the grid cell for which  $U$  is a maximum.

#### 1.7.2.4.1 Quantile Hashing

Quantile hashing [1084, 1086] is just an implementation of the MDEH hashing function where, instead of partitioning each expansion slice of key  $k$  in half, we compute a partition point along key  $k$  that partitions the quantile associated with the slice so that approximately one-half of the incoming values that are in the range of the expansion slice will fall in each of the two resulting slices. For example, for the partition associated with the  $1/2$  quantile, its position is based on the estimate of the median along the key. Linear scales in the form of binary trees described in Section 1.7.2.3 are used to keep track of the actual partition points for each key, thereby enabling the correlation of the partitioning hyperplane with the partition numbers that are used as parameters to MDEH so that we can determine the grid cell associated with a particular point. The grid cell split procedure is the same as that used for the implementation of linear hashing with the MDEH hashing function (i.e., it makes use of the expansion index).

Figure 1.106 is an example of the type of partitioning of the underlying grid that is supported by quantile hashing. In essence, we have taken the partition of the underlying space given by Figure 1.101(f) and varied the positions of the partition lines from being the result of a recursive halving process. The actual partition points are recorded by the linear scales, which are given to the left of the  $y$  axis and below the  $x$  axis. Notice that, in the figure, we have also identified the quantiles in the nonleaf nodes by use of the

---

<sup>63</sup> In particular, when using linear hashing with a hashing function that satisfies order preserving linear hashing (OPLH) (as well as in EXCELL), there are two possible sizes for the grid cell, depending on whether the cell has been split in the current cycle of splits across the different keys. When MDEH is the hashing function, the range of grid cell sizes is larger as it depends on the number of times a particular slice has been split in the current cycle of splits across the different keys. However, the sizes of the grid cells differ only by factors that are powers of 2. Note that no matter which hashing function is used, for linear hashing, at any time after a complete cycle through all of the keys, all grid cells are of equal size.

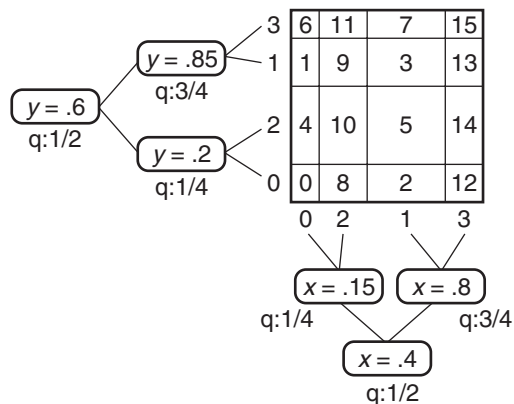

Figure 1.106  
Example grid partition illustrating quantile hashing with the  $y$  coordinate being the most significant. Linear scales are given to the left of the  $y$  axis and below the  $x$  axis. The quantiles are also identified in the nonleaf nodes of the linear scales in the form of “ $q$ : quantile number.”

notation “ $q$ : quantile value,” although this is not necessary if we always use quantiles that are powers of 2. In particular, we can determine the quantile by noting the path followed when descending from the root of the linear scale to the appropriate leaf node.

The drawback of quantile hashing is that it assumes that the distribution of the incoming data does not change over time (i.e., it is stable). For example, if the data comes in a sorted order, say increasing without loss of generality, for a particular key (or lexicographically for all keys), then we have a problem as soon as we perform the first partition. In particular, the partition associated with the  $1/2$  quantile results in the first slice being repeatedly partitioned in future cycles, while no future data will ever be encountered that falls into its range. Another problem arises when the data tends to cluster around a few points in the underlying space (e.g., areas of dense population). If the cluster centers suddenly change, then quantile hashing will perform poorly (at least for a while) as it had adjusted the positions of its partitions according to the old and known cluster centers.

### Exercises

1. Write a procedure `QUANTILEPOINTSEARCH` to perform a point search in a two-dimensional database implemented with quantile hashing.
2. Write a procedure `QUANTILERANGESEARCH` to perform a range search for a rectangular region in a two-dimensional database implemented with quantile hashing.
3. Give an algorithm for merging grid cells in a two-dimensional database of points implemented with quantile hashing.

#### 1.7.2.4.2 Piecewise Linear Order Preserving (PLOP) Hashing

One way to overcome the drawbacks of quantile hashing that were pointed out in Section 1.7.2.4.1 is to apply repartitioning. Unfortunately, this is a costly process as it involves moving the positions of the partitions and, more importantly, moving the data in the corresponding grid cells. The alternative is to base the partitioning on the known data and to split the slices that contain the most data points. This is the basis of PLOP hashing [1085], which is a special case of dynamic multipaging [1288] (see Section 1.7.2.1). PLOP hashing is similar to quantile hashing in the sense that it cycles through the keys and doubles the number of partitions along each key’s axis for each key

on successive cycles.<sup>64</sup> However, the difference is that where in each cycle for a given key, quantile hashing splits each slice into two new slices, PLOP hashing may repeatedly split the same slice during the cycle if it turns out that it is the one that contains the most data points. Thus, PLOP hashing is much more suited to a dynamically changing distribution of data. Of course, both methods create the same number of new slices for key  $k$  during each cycle (i.e., they are doubled, thereby also doubling the number of grid cells). However, whereas in quantile hashing each grid cell is split during each cycle, in PLOP hashing some grid cells may never be split during a cycle, while other grid cells may be split many times by virtue of the fact that their containing slice is split many times during the cycle.

PLOP hashing is implemented by modifying the binary trees corresponding to the linear scales associated with the axes of the keys in quantile hashing, as well as the implementation of the MDEH hashing function. Once again, the nonleaf nodes record the positions of the partitions. However, the fact that the partitions may be applied to the same slice several times during a cycle means that the resulting binary tree is no longer “almost complete” in the sense that there is no longer a difference of at most one between the depths of all the leaf nodes, as is the case with quantile hashing. Each leaf node corresponds to a slice  $i$  and contains the number of the partition along the axis of key  $k$  that resulted in the creation of  $i$ . This number is used as the parameter to the MDEH function when attempting to determine the grid cell that contains a particular query point  $p$  at location  $l$ . In addition, each leaf node contains the number of data points in the corresponding slice. This number is used to determine which slice to partition next for key  $k$  when the storage utilization factor  $\tau$  exceeds  $\alpha$  and all grid cells in the slice that is currently being partitioned have already been expanded. Of course, whenever a slice is partitioned, a new nonleaf node  $t$  is created in the binary tree for the new partition, a new slice is allocated (with a partition number one higher than the current maximum for key  $k$ ), and the count fields of the children of  $t$  are set. Note that the grid cell  $c$  associated with a particular point is determined in the same manner as with quantile hashing in the sense that the linear scales, in conjunction with the expansion index, are used to determine the appropriate partition numbers, which are then used as arguments to the MDEH function.

Figure 1.107(a) is an example of the type of partitioning of the underlying grid that is supported by PLOP hashing. The actual partition points are recorded by the linear scales, which are given to the left of the  $y$  axis and below the  $x$  axis. In essence, we have taken the partition of the underlying space given by Figure 1.101(f) and varied the positions of the partition lines from being the result of a recursive halving process. The linear scales in our figure are somewhat incomplete as their leaf nodes should also contain the number of data points in the corresponding slice. We have omitted this information here in the interest of reducing the complexity of the figure.

A number of interesting observations can be made by looking at this example (i.e., Figure 1.107(a)). First, note that some slices have been partitioned several times in a cycle, but others have not been partitioned at all during some cycles. Here we see that, on the first cycle, we partitioned the  $y$  axis at  $y = 0.7$  and the  $x$  axis at  $x = 0.3$ . Second, notice that during the second cycle, slice 0 along the  $y$  axis was partitioned twice and likewise for slice 1 along the  $x$  axis. Third, we observe that when slice 0 along the  $x$  axis was split in the first cycle, the newly created slice 1 was associated with the right half of the underlying space. However, we could have also associated the newly created slice with the left half of the underlying space, as shown in Figure 1.107(b). Clearly, this is permissible as the linear scales provide the association of partition numbers with regions of the grid.

---

<sup>64</sup> As mentioned in the original definition of  $f$  (and MDEH), the requirement that we cycle through the axes is not necessary. Thus, both quantile hashing and PLOP hashing can be implemented without this requirement; this is pointed out at the end of this section.

Locating the grid cell containing a particular point with PLOP hashing is accomplished in the same way as for linear hashing with the MDEH hashing function. Once again, we find the leaf nodes in the binary trees of the linear scales that contain the region corresponding to the values of the keys, and then use the partition numbers recorded in the leaf nodes as arguments to MDEH. For example, let us first search for the point  $(x = 0.4, y = 0.6)$ . Using Figure 1.107(a), from the linear scales we have that  $S_x = 1$  and  $S_y = 2$ . There is no expansion index here as we have completed two full cycles. Applying MDEH yields the grid cell 5. Using Figure 1.107(b), from the linear scales we have that  $S_x = 0$  and  $S_y = 2$ . There is no expansion index here as we have completed two full cycles. Applying MDEH yields the grid cell 4.

**Exercises**

1. Why could you not implement the linear scales for PLOP hashing as one-dimensional arrays? In other words, why must they be implemented as binary trees?
2. Write a procedure PLOPPPOINTSEARCH to perform a point search in a two-dimensional database implemented with quantile hashing.
3. Write a procedure PLOPRANGESEARCH to perform a range search for a rectangular region in a two-dimensional database implemented with PLOP hashing.

**1.7.2.4.3 Spiral Hashing**

Spiral hashing is the third approach that we discuss. Our presentation is quite brief and assumes that readers are familiar with it. Appendix C contains a more detailed explanation of spiral hashing. Readers who are not familiar with spiral hashing are encouraged to consult it first before continuing further in this section.

In this approach, we apply the same mapping  $g$  to a point  $p$  in  $d$  dimensions to yield a value  $k$  in one dimension, as in linear hashing. The difference is that the range of the mapping must be in  $[0, 1)$ . This is achieved by dividing the result  $k = g(p)$  of the mapping by  $2^s$ , where  $s$  is the total number of bits that make up the bit-interleaved or bit-concatenated value. Such an action has the same effect as the function  $h_n(k) = reverse(k) \bmod 2^n$ , where *reverse* corresponds to reversed bit interleaving or reversed bit concatenation. Recall that this definition of  $h_n(k)$  ensures that all records in the same

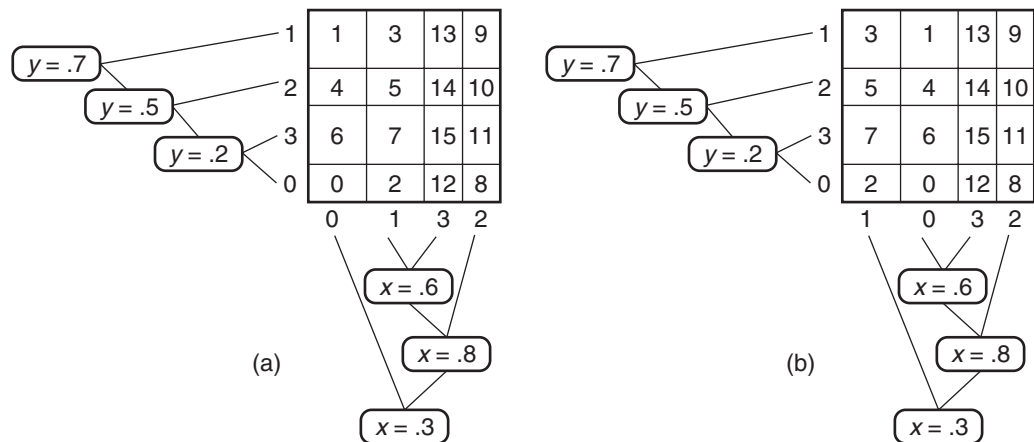

Figure 1.107 Example grid partition illustrating PLOP hashing with the  $y$  coordinate being the most significant. Linear scales are given to the left of the  $y$  axis and below the  $x$  axis. When slice 0 along the  $x$  axis is split in the first cycle, (a) the newly created slice 1 is associated with the right half of the underlying space, while in (b) it is associated with the left half of the underlying space. The leaf nodes of the linear scales should also contain the number of data points in the corresponding slice, although this is not shown here.

grid cell or bucket agree on the values of the  $n$  most-significant bits of  $k$  and hence they are within the same range.

Spiral hashing also decomposes the underlying values into disjoint ranges of  $k$  so that all points within a given range are stored in the same bucket (and possibly overflow buckets). Thus, the extent of the range is analogous to the concept of a grid cell in linear hashing. Moreover, as in linear hashing, a primary bucket of finite capacity is associated with each range, as are overflow buckets. The difference from linear hashing is that in spiral hashing, the ranges are not equal sized after a full cycle of splits for all keys. Again, as in linear hashing, buckets are split when the storage utilization factor  $\tau$  exceeds a predetermined value  $\alpha$ . Another difference from linear hashing is that the bucket  $b$  that is split is the one that corresponds to the largest-sized range.  $b$ 's range is split into  $r$  ( $r \geq 2$ ) unequal-sized ranges that are smaller than any of the existing ranges. As with linear hashing, establishing a one-to-one correlation between the values of the spiral hashing function  $y(k) = \lfloor r^{-x(k)} \rfloor$  and the primary bucket labels obviates the need for the one-dimensional array analog of the grid directory.

Using such a splitting policy, assuming a uniform distribution of data, the bucket corresponding to the range of values that is split is said to be more likely to have been full than the buckets that correspond to the smaller-sized ranges. Unfortunately, since the result of the one-dimensional mapping of the underlying space is no longer partitioned into equal-sized ranges (or a limited set of possible sizes at an instance that does not immediately follow a full cycle of splits for all keys) of values, there is less likelihood that the one-dimensional ranges correspond to a grid cell in  $d$  dimensions. This has the undesirable effect that the ranges of values in each partition are not always spatially contiguous, as is the case for linear hashing. This limits the utility of this technique.

For example, Figure 1.108 shows the result of applying spiral hashing to the points of Figure 1.1 under the same conditions that were used to construct Figure 1.98 for linear hashing. Once again, we assume a bit-interleaving ordering with the  $y$  coordinate being the most significant after application of the mapping  $f$  to the  $x$  and  $y$  coordinate values, where  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$ , respectively. However, as we divide the result of the interleaving by  $2^s$ , where  $s$  is the number of bits (six in our example), there is no need for reversing the bits, as was done in the linear hashing example. The

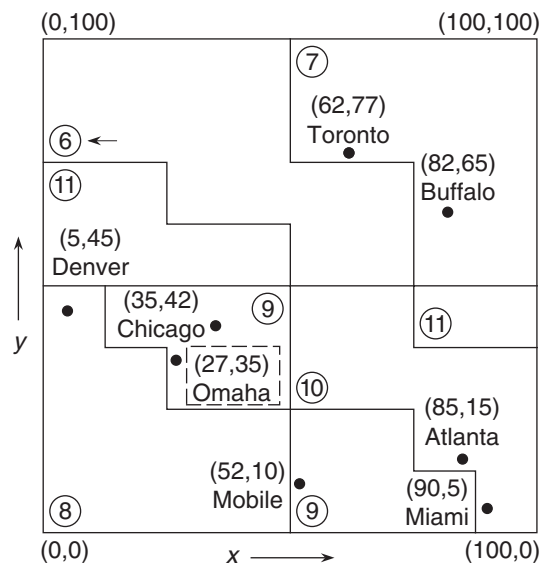

Figure 1.108  
Spiral hashing representation using bit interleaving for the data of Figure 1.1. The  $y$  coordinate is assumed to be the most significant. Overflow bucket contents are enclosed by broken lines. A leftward-pointing arrow indicates the next bucket to be split.

primary and overflow bucket capacities are 2, and a bucket is split whenever  $\tau$ , the storage utilization factor, is greater than or equal to 0.66 (i.e.,  $\alpha = 0.66$ ). The cities are inserted in the order Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami.

Figure 1.109, in conjunction with Figure 1.108, shows the contents of the buckets and their corresponding spatial regions after the insertion of Chicago and Mobile (Figure 1.109(a)); Toronto (Figure 1.109(b)); Buffalo, Denver, and Omaha (Figure 1.109(c)); Atlanta (Figure 1.109(d)); and Miami (Figure 1.108). The steps in the insertion process are the same as those for the example in Appendix C shown in Figures C.6 and C.7. The only difference is that Figures 1.108 and 1.109 also show the spatial correspondence between the buckets and the corresponding regions of space. Notice that the spatial regions associated with bucket 11 are not spatially contiguous.

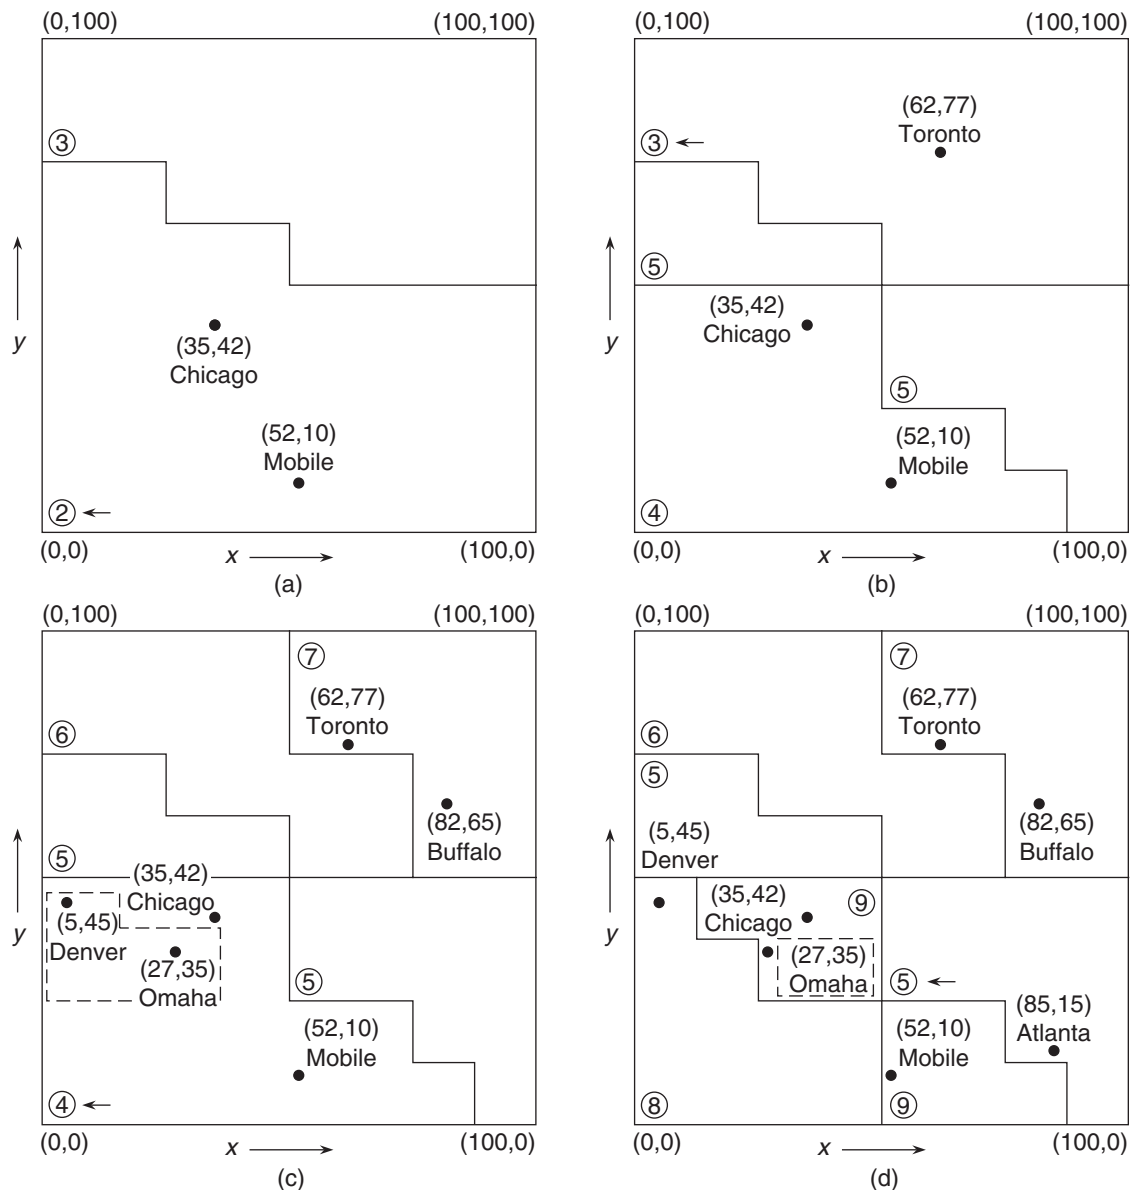

Figure 1.109 Sequence of spatial correspondences between the regions of space and the buckets created by spiral hashing using bit interleaving for the data of Figure 1.1, demonstrating the result of the insertion of (a) Chicago and Mobile, (b) Toronto, (c) Buffalo, Denver, and Omaha, and (d) Atlanta. Overflow bucket contents are enclosed by broken lines.

*Exercises*

See also the exercises in Appendix C.

1. Suppose that spiral hashing is used to store two-dimensional point data, and each point is mapped to a value by use of bit interleaving. Prove that each bucket will span at most two spatially noncontiguous regions.
2. Suppose that spiral hashing is used to store point data of arbitrary dimension, and each point is mapped to a value by use of bit interleaving. What is the maximum number of spatially noncontiguous regions that can be spanned by a bucket?
3. Can you come up with a mapping for multidimensional point data to a value so that when it is used in conjunction with spiral hashing, each bucket will span just one spatially contiguous region?
4. Show the result of applying spiral hashing to the database of Figure 1.1 using reversed bit interleaving. Thus, instead of using the hashing function  $h(k) = k/2^s$ , where  $s$  is the total number of bits that make up the interleaved key value, use the function  $h''(k) = \text{reverse}(k)/2^s$ , in which *reverse* reverses the value of key  $k$  prior to the application of the hashing function. Again, assume that the cities are inserted in the order Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami. Also, assume that the primary and overflow buckets are both of size 2,  $r = 2$ , and that a bucket will be split when  $\tau$ , the storage utilization factor, is greater than or equal to 0.66. Is there a difference in this example between using the  $x$  coordinate as the most significant or the  $y$  coordinate?
5. Is there any advantage to using reversed bit interleaving with spiral hashing?

**1.7.2.4.4 Summary**

Our presentation of quantile hashing, PLOP hashing, and spiral hashing, assumed a cyclic partitioning order. This is not absolutely necessary. In other words, we can use a variant of MDEH that permits the partitions for the different keys to proceed in arbitrary order. For example, assuming three-dimensional data, one possible key partition order would be  $zzyyzxxxxyy\dots$ . Such an ordering is achieved by modifying the MDEH function [1288, 1428] to keep track of the order in which the keys were partitioned. This is not needed when using a cyclic order because, given the partition number and the cyclic order of the keys, we know the identity of the corresponding partitioning key. Of course, we still have the requirement that the number of partitions along each key's axis must double for each subsequent partitioning along that key. In fact, this partition-doubling requirement can also be dispensed with, as is the case in dynamic multipaging [1288], by also keeping track of the number of existing partitions at each application of a partition step for a key. Notice that the above variation of the partitioning order is also possible for spiral hashing, although, once again, we need to keep track of the order in which the keys are partitioned instead of via bit interleaving or bit concatenation, as is usually the case.

*Exercises*

1. Give an algorithm for computing the value of MDEH for an arbitrary partition order rather than a cyclic one. In other words, we do not have to cycle through the keys. For example, for three-dimensional data, a cyclic partitioning order is  $zyxzyxzyx\dots zyx$ , while  $zzyyzxxxxyy\dots$  is an example of an arbitrary order. Of course, we still have the requirement that the number of partitions along each key's axis must double for each subsequent partitioning along that key.
2. Give an algorithm for computing the value of MDEH for an arbitrary partition order rather than a cyclic one, as in Exercise 1, that permits partial expansions.
3. How would you completely generalize the implementation of PLOP hashing so that there is no need to complete a set of partitions along a key before starting to partition another key. In other words, the partitions on the keys can be sequenced arbitrarily without requiring that the number of grid cells be doubled for a key before a partition can be made on a different key. Moreover, there is no need to cycle through the keys.

4. One possible rationale for splitting all grid cells from one slice before splitting grid cells from another slice (as is the case when using the MDEH function) is that the grid cells in the slice are split in such an order that if grid cell  $c_i$  is split immediately before grid cell  $c_{i+1}$ , then  $c_i$  and  $c_{i+1}$  are spatially contiguous and hence more likely to be full. Does the spatial contiguity property always hold for successive splits of grid cells within a slice?

### 1.7.2.5 Comparison

Both the grid file and EXCELL guarantee that a record can be retrieved with two disk accesses: one for the  $d$ -dimensional grid directory element that spans the record (i.e., the grid cell in which its corresponding point lies) and one for the bucket in which it is stored. This is not necessarily the case for linear hashing methods (as well as their variants, including spiral hashing). The problem is that, although linear hashing methods often dispense with the need for a directory,<sup>65</sup> the possible presence of an unbounded number of overflow buckets means that each one must be accessed during an unsuccessful search for a record corresponding to a point that is spanned by a particular grid cell.

Although, for pedagogical purposes, the grid directories of Figures 1.88 and 1.93 were constructed in such a way that EXCELL required less grid cells than the grid file (8 versus 9), this is not generally the case. In fact, splitting points can always be chosen so that the number of grid cells and buckets required by the grid file is less than or equal to the number required by EXCELL. For example, if the space of Figure 1.88 were split at  $x = 55$  and  $y = 37$ , then only four grid cells and buckets would be necessary.

Regnier [1550] has performed an analytical study of the directory size for the grid file under a uniform distribution. Comparison with similar studies for EXCELL [617, 1549] finds that the grid file appears to be asymptotically better than EXCELL, especially for nonuniform data distributions [1550]. However, for uniformly distributed data and large bucket sizes (e.g., larger than 50), EXCELL is preferred because it is easier to implement.

Interestingly, EXCELL can be characterized as a method that decomposes the underlying space into buckets of grid cells, where the space spanned by the buckets corresponds to blocks in a bintree decomposition of space (see Section 2.1.2.6 of Chapter 2), while the buckets corresponding to the individual grid cells are accessed by a directory in the form of an array. This decomposition of space is also identical to what is obtained by the bucket PR k-d tree. This close relationship between these methods causes EXCELL to be classified as a representation that employs regular decomposition. In particular, the buckets in EXCELL are created by a halving process.

The main difference between EXCELL and these representations is that the directory of EXCELL corresponds to the deepest level of a complete bintree or bucket PR k-d tree. Alternatively, we can say that EXCELL provides a directory to a space decomposition that is implemented as a bintree or bucket PR k-d tree. In particular, EXCELL results in faster access to the buckets since the k-d trie search step (i.e., following pointers in the tree) is avoided. However, if the longest search path in the tree has length  $s$ , then the EXCELL directory has  $2^s$  entries.

From a superficial glance, EXCELL appears to be closely related to linear hashing with reversed bit interleaving as the hashing function. The reason for this observation is the fact that the space spanned by the buckets in the two methods resembles blocks in a bintree decomposition of space. For example, compare the decomposition induced by EXCELL when the  $x$  coordinate is split before the  $y$  coordinate (shown in Figure 1.93) with the result of applying linear hashing to the data of Figure 1.1 when the  $x$  coordinate is the most significant (shown in Figure 1.110).

---

<sup>65</sup> We use the qualifier *often* because, although linear hashing methods dispense with the need for a  $d$ -dimensional grid directory, a one-dimensional grid directory  $O$  may be needed to access the buckets associated with the grid cells unless there is a one-to-one correspondence between the numbering of the grid cells and the bucket labels, in which case there is no need for  $O$ .

Figure 1.110  
The representation resulting from applying linear hashing with reversed bit interleaving (LHRBI) corresponding to the data of Figure 1.1 when the  $x$  coordinate is taken as the most significant.

Figure 1.111  
EXCELL representation corresponding to the data of Figure 1.1 when the  $y$  axis is split before the  $x$  axis.

Unfortunately, this similarity exists only when the buckets in EXCELL span no more than two grid cells. Recall that there is a one-to-one correspondence between primary buckets and grid cells in linear hashing, and for linear hashing with reversed bit interleaving (LHRBI) all grid cells are either of volume  $v$  or  $v/2$ . Greater variance in the volume of grid cells is not permitted for LHRBI (but see linear hashing with MDEH, as well as quantile hashing and PLOP hashing). For example, compare the decomposition induced by EXCELL when the  $y$  axis is split before the  $x$  axis (see Figure 1.111) with the result of applying LHRBI to the data of Figure 1.1 when the  $y$  coordinate is the most significant (see Figure 1.98). Letting  $v$  be the size of the next grid cell to be split in the linear hashing example (i.e., Figure 1.98), we see that, in the space decomposition

induced by linear hashing, all buckets span regions (i.e., grid cells) of size  $v$  or  $v/2$ , while in the space decomposition induced by EXCELL (i.e., Figure 1.111), we have buckets that span regions of size  $2v$  (e.g., bucket B),  $v/2$  (e.g., A and F), and  $v/4$  (e.g., C, D, E, and G). Thus, we see a bintree of four levels in the case of EXCELL but a bintree of just two levels in the case of LHRBI.

Other differences are that, in EXCELL, a bucket overflow may trigger a bucket split or a doubling of the directory, whereas, in linear hashing, at most two new buckets are allocated (one for a bucket split and one for an overflow bucket—recall the insertion of Omaha in the transition between Figure 1.99(c, d) in Section 1.7.2.3). In essence, using linear hashing, there is a more gradual growth in the size of the directory at the expense of the loss of the guarantee of record retrieval with two disk accesses. In addition, assuming equal bucket sizes and ignoring the situation of a directory split, linear hashing usually requires additional buckets since the bucket that is split is not necessarily the one that has overflowed.

Nevertheless, the relationship between EXCELL and LHRBI and MDEH is worthy of further comment. Disregarding our observations about the differing bucket sizes and just dealing with the grid cells that result from using EXCELL, a relationship does indeed exist. In particular, assuming an instance where linear hashing has applied all of the possible partitions for a specific key, and no key is partially partitioned, we find that both LHRBI and MDEH yield a decomposition of the underlying space  $U$  into grid cells, which is equivalent to EXCELL without requiring a  $d$ -dimensional grid directory.

At a first glance, a similar statement can be made about the relationship of PLOP hashing to the grid file. In particular, PLOP hashing appears to yield a partition of the underlying space  $U$  into grid cells, which is similar to that of the grid file without requiring a  $d$ -dimensional grid directory. Unfortunately, this statement is not quite true as PLOP hashing requires that the number of partitions along each key's axis double for each subsequent partitioning along that key and that, during the time at which we partition along a particular key, we cannot intersperse a partition along a different key. Thus, even though we do not have to cycle through the different keys, we must perform a complete partition along the key. In contrast, the grid file permits the partitions along the various keys to proceed in arbitrary order and allows an arbitrary number of partitions along each key's axis. In other words, key  $i$  may be partitioned once, followed by two partitions along key  $j$ , in turn followed by five partitions along key  $i$ , and so on.

A general problem that afflicts linear hashing (whether or not it is order preserving) is that the records may not be well distributed in the buckets when the data is not uniformly distributed. This means that overflow will be more common than with traditional hashing methods. It also has the effect of possibly creating a large number of sparsely filled buckets. Consequently, random access is slower since, in the case of overflow, several buckets may have to be examined. Similarly, sequential access will also take longer as several buckets will have to be retrieved without finding too many records. The problem is that all of the variants of linear hashing require that all buckets be stored at one or two levels. This has the advantage that at most two hash operations are required to determine the primary bucket to be accessed (see Exercise 1 in Appendix B).

Orenstein [1414] proposes a technique he terms *multi-level order preserving linear hashing* (MLOPLH) to be used with OPLH to deal with these problems. In particular, MLOPLH alleviates the sparseness problem by storing parts of the file in buckets at lower levels than  $n$ . Such buckets result from the combination of a sparse bucket with its brother(s). The major problem with MLOPLH is that now we may require  $n + 1$  disk read operations (equal to the number of bucket accesses) to locate a bucket, whereas, previously, at most two hash operations were necessary.

The reason so many buckets may have to be accessed in MLOPLH is that linear hashing methods do not make use of a directory. Thus, encountering an empty bucket is the only way to detect that records of one bucket have been merged with those of another bucket at a lower level (see Exercise 3). Even more buckets will have to be accessed when

deletion of a record causes a sparse bucket to be combined with its brother. In contrast, methods such as the grid file and EXCELL, which use a directory, do not suffer from such a problem to the same extent. The reason the sparseness issue can be avoided is that the directory indicates the buckets associated with each grid cell, and several grid cells can share a bucket.

### Exercises

1. Why does linear hashing usually require at least as many buckets as EXCELL?
2. Given a large set of multidimensional point data, which of the bucket methods would you use? Take the volume of the data and its distribution into account. Can you support your choice using analytic methods?
3. Explain how MLOPLH [1414] looks up a value  $v$ .
4. Explain how MLOPLH splits a bucket.
5. Explain how MLOPLH merges two buckets.

### 1.7.3 Storage Utilization

In our discussion of the different bucketing methods, we often mentioned their storage utilization. In this case, we were referring to the extent that the buckets are full, given that they are split whenever they contain more elements than the bucket capacity. In particular, when a bucket of capacity  $b$  is full, it is split into  $n$  buckets, where  $n$  is the *fanout*. This is primarily of interest for methods that are based on a disjoint decomposition of the underlying space. These methods differ on the basis of whether they use a directory, the nature of the redistribution strategy, as well as the value of the fanout.

The storage utilization  $u$  of bucket method  $R$  that uses  $J$  buckets of capacity  $m$  to provide a total capacity of  $a = Jm$  slots for storing  $v$  records has a value of  $v/a$ , where  $u$  ranges between 0 and 1. The fuller each bucket is (i.e., the closer the number of records that each bucket contains is to  $m$ ), the smaller the value of  $J$ , and hence the larger the value of  $u$ . Thus, the greater the value of  $u$ , the more efficient  $R$  is in terms of storage utilization. Ang and Samet [53, 57] have shown that  $U$ , the average of  $u$ , under appropriate data distribution models, is  $\frac{\ln n}{n-1}$  for a large number of bucketing methods subject to some constraints discussed below. Thus, it only depends on the fanout value  $n$  (i.e., how many buckets are needed when a full bucket is split), thereby enabling them to ignore the implementation details of the different bucket methods. This analysis assumes that the data is uniformly distributed. Of course, it should be clear that regardless of the nature of the bucket method used, it is often the case that  $U$  oscillates as the number of points increases since it is impossible for all buckets to be full always.

We note that the analysis of the average storage utilization has been carried out by a number of researchers for particular bucket methods. For example, EXHASH [579], B-trees [1151, 2046], and EXCELL [1827] are all instances of a bucket method of fanout 2, whose average storage utilization has been independently shown to be 0.69. Similarly, the PR quadtree (or, more appropriately, the PR quadtree) is an instance of a bucket method of fanout 4, and its average storage utilization has been shown to be 0.46 [1827]. Most of these analyses assume that the data is drawn from a uniform distribution. However, these analyses were for the individual bucket methods rather than a general one. Ang and Samet's analysis is of interest because it is a unification of these results in a manner that is only dependent on the fanout and independent of the nature of the directory. In fact, Ang and Samet's analysis is a generalization from  $n = 2$  to arbitrary values of  $n$  (thus applicable to any other trie-based bucketing method) of the analysis performed by Fagin, Nievergelt, Pippenger, and Strong [579] for EXHASH, which is based on an analysis by Knuth [1046, pp. 128–134]. The same generalization was also applied by

Ang and Samet to the analysis of Leung [1151] to obtain an approximate average storage utilization, which is equivalent to the mean of the average storage utilization.<sup>66</sup>

It is important to note that the analysis of Ang and Samet assumes that if a record is in a particular bucket, then it is equally likely to be in any of the children of the bucket in the case of a split. This assumption usually leads to a balanced structure and is thus useful for data structures based on digital searching (i.e., trie-based methods) or on the use of balancing (e.g., AVL trees [15] and balanced B-trees [2046]). In contrast, in the case of tree-based methods (e.g., binary search trees and point quadtrees), the order in which the data is encountered is important. Their analyses complement the above results. In particular, they are based on the use of generating functions (e.g., [880]) and, of course, yield different results (e.g., 0.33 for a point quadtree [880]).

## 1.8 PK-Trees

Wang, Yang, and Muntz [1952, 2043] use the term *PK-tree* to describe a family of data structures that are based on the application of a grouping technique whose effect, at a first glance, seems to be similar to bucketing; yet, is quite different in philosophy and result. In particular, the similarity lies in the fact that the basis of the decomposition process appears to be equivalent to a straightforward bucket method, such as the bucket PR quadtree and the bucket PR k-d tree. The key principle in the PK-tree is the use of a parameter  $k$  (known as a *k-instantiation value*) to stipulate the minimum number of objects or nodes that are grouped to form a node. In contrast, bucket methods use the parameter *bucket capacity* to stipulate a maximum number of objects or nodes that can be grouped together.

The PK-tree was originally developed as a means of representing high-dimensional point data in applications such as similarity searching, data mining, and bioinformatics databases. In particular, the originators of the PK-tree describe it as a spatial index and evaluate its performance with respect to conventional techniques, such as the X-tree [190] (see Section 4.4.1 in Chapter 4) and the SR-tree [999] (see Section 4.4.2 in Chapter 4). Unfortunately, as we will see in Sections 4.4.6 and 4.4.8 of Chapter 4, for most access methods that rely on the decomposition of the underlying space, performance for high-dimensional data is often unsatisfactory when compared with not using an index at all (e.g., [212]). Thus, the PK-tree is little known. However, it does have some very interesting properties whose utility extends beyond the domain of high-dimensional data, and it is in this context that we describe it here. In particular, it is useful for low-dimensional data like that found in applications such as spatial databases and geographic information systems (GIS).

This section is organized as follows. Section 1.8.1 motivates the development of the PK tree by reviewing the properties that it shares with bucket methods. Section 1.8.2 gives an overview of the PK-tree, and Section 1.8.3 presents a formal definition of the PK-tree. Section 1.8.4 compares the PK-tree with bucket methods. Section 1.8.5 describes how searching, insertion, and deletion are implemented in a PK-tree, as well as provides an outline of the underlying representation. Section 1.8.6 concludes the presentation by discussing some of the key properties of the PK-tree and continues the comparison with other methods.

---

<sup>66</sup> More precisely, the analysis of Fagin et al. was used by Ang and Samet to obtain the mean of the average storage utilization value. Note the distinction between “average,” which corresponds to all trees with  $v$  points, and the “mean of the average,” which deals with different values of  $v$ , the number of points. This is in contrast to the term *approximate average*, which is what Leung really derived in [1151].

### 1.8.1 Motivation

Recall that in the bucket method we recursively decompose the underlying space into disjoint blocks until the number of items in each block is less than or equal to the bucket capacity. The buckets are often the size of a disk page, and the bucket capacity is the maximum number of spatial objects that can be stored in the page. Once the underlying space has been decomposed into buckets, we usually make use of a directory to facilitate access (often referred to as an *access structure*). This directory is usually in the form of a tree and closely mimics the recursive decomposition (i.e., partitioning process). Without loss of generality, assuming two-dimensional data, in the case of a quadtree, each node in the tree has four children. Thus, we see that the leaf nodes correspond to buckets with a large capacity, while nonleaf nodes are generally small. A somewhat similar way to express this is that the fanout of the leaf nodes is high, while the fanout of the nonleaf nodes is generally small and, in the case of a quadtree, is a function of the dimensionality of the underlying space.

Ideally, we would also like to have a large fanout for the nonleaf nodes. This is the motivation for the development of the R-tree (see Section 2.1.5.2 in Chapter 2) and the bucket methods that make use of a tree directory (see Section 1.7.1). However, the R-tree results in a nondisjoint decomposition of the underlying space as it is based on the aggregation of the objects in the underlying space (actually the minimum bounding boxes or spheres of the objects). Instead, as we pointed out earlier, in this chapter we are interested in alternative methods based on a disjoint decomposition of the underlying space. Section 1.7.1 describes several such alternative methods that aggregate the nonleaf nodes to form larger nodes, thereby obtaining a larger fanout for the nonleaf nodes. In this section, we will see some of the ways in which the PK-tree differs from these methods.

One obvious way to increase the fanout in the nonleaf nodes is to aggregate the nonleaf nodes at several successive levels of decomposition into one nonleaf node. For example, in the case of a quadtree in two dimensions, instead of stipulating that each nonleaf node corresponds to a recursive aggregation of four children, we could stipulate that each nonleaf node corresponds to a recursive aggregation of  $4^i$  children, where  $i$  is permitted to vary across nonleaf nodes at the same level, as well as at different levels. We use the term *quadgrid* to describe this technique; the “grid” suffix serves to remind us that the decomposition of the underlying two-dimensional space that is induced by the nonleaf node is analogous to that obtained by a grid of side length  $2^i$ . The quadgrid is a form of level compression (recall the discussion of the path-level compressed PR k-d tree in Section 1.5.2). The problem with the quadgrid is the inflexibility of the adaptive nature. Notice that all children of a nonleaf node in the quadgrid are of the same size in the sense that their corresponding blocks span regions of the underlying space that have the same size. Ideally, we would like to have a bit more flexibility.

Using the above description of the quadgrid as a starting point, we point out that one of the key innovations of the PK-tree is the realization that all of the nodes at the same level of the hierarchy represented by the tree need not span identically sized regions in the underlying space. In other words, the principal idea behind the PK-tree is the decoupling of the tree structure of the partition process of the underlying space from that of the node hierarchy (i.e., the grouping process of the nodes resulting from the partition process) that makes up the tree directory. The PK-tree is a grouping technique and thus can be adapted to a number of different partitioning techniques. To understand what we mean by “decoupling,” observe that the access structure for the blocks that correspond to the leaf nodes that result from the partitioning process may be different from the customary tree that caused the creation of the blocks. This decoupling idea also forms the basis of several bucket methods that make use of a tree directory described in Section 1.7.1. Note that the term *decoupling* could also be used to describe the differentiation of the construction of a spatial index with the aid of bulk loading (e.g., [87, 194, 1160]) from the

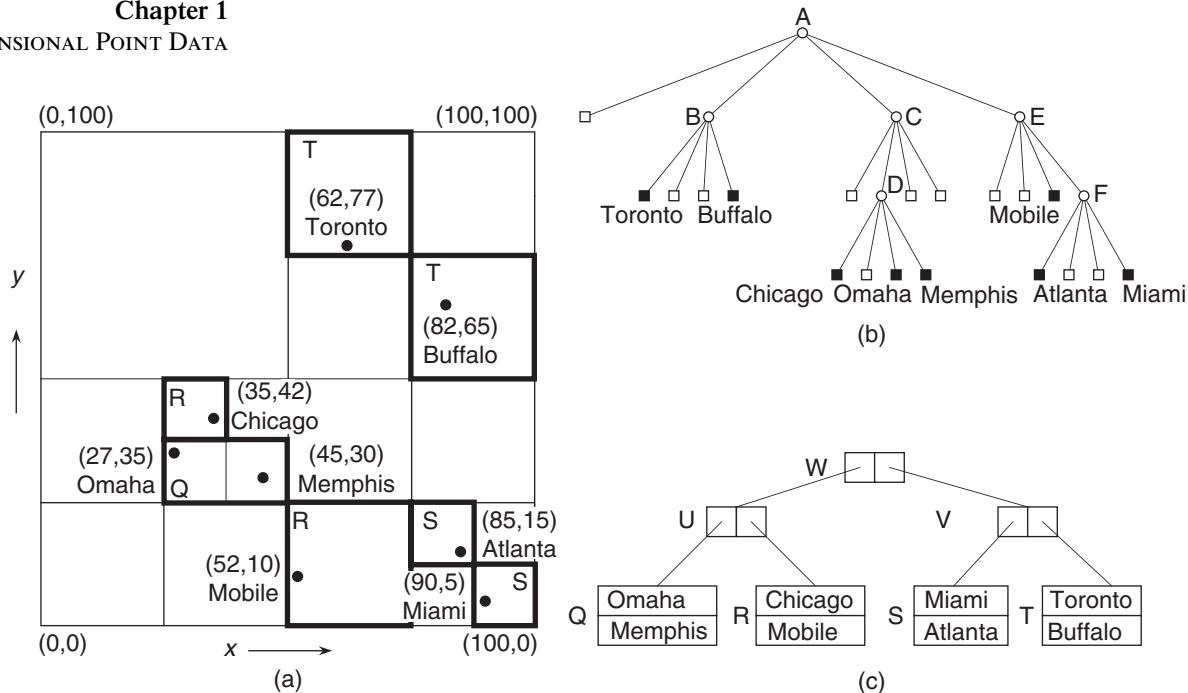

Figure 1.112  
A PR quadtree and the records it represents: (a) the resulting partition of space, (b) the tree representation, and (c) one possible B<sup>+</sup>-tree for the leaf blocks where each node has a minimum of two and a maximum of three entries. Each nonempty block in (a) has been labeled with the name of the B<sup>+</sup>-tree leaf node in which it is a member.

process of building it incrementally (see Section 2.1.5.2.6 of Chapter 2). In other words, the term *decoupling* could be applied to many other processes used in the construction of spatial indexes besides the partitioning and grouping processes. Therefore, whenever we use the term, we make sure to qualify it appropriately unless there is no potential for confusion.

As an example of decoupling, we find that in many applications the blocks resulting from a region quadtree decomposition of the underlying space are represented by unique numbers (known as *locational codes* and discussed briefly below in Section 1.8.5.1), which are then aggregated into groups and stored in the leaf nodes of a B<sup>+</sup>-tree (see the discussion in Section 2.1.2.4 in Chapter 2), which serves as the access structure (e.g., [2, 1577]). In the case of regular decompositions, such as the PR quadtree, we can reconstruct the PR quadtree just from knowledge of the locational codes of the nonempty leaf blocks, and thus the B<sup>+</sup>-tree only needs to store the locational codes of these blocks—that is, we ignore the empty and nonleaf blocks. For example, Figure 1.112(c) is one possible B<sup>+</sup>-tree corresponding to the leaf blocks of the PR quadtree whose block decomposition and corresponding tree representation are given in Figure 1.112(a, b), respectively. This PR quadtree is almost the same as the PR quadtree in Figure 1.31 except that Denver at (5,45) has been replaced by Memphis at (45,30). Each node of the B<sup>+</sup>-tree in our example has a minimum of two and a maximum of three entries. We do not show the values of the locational codes of the contents of the leaf nodes of the B<sup>+</sup>-tree. We also do not show the discriminator values that are stored in the nonleaf nodes of the B<sup>+</sup>-tree. We have marked the leaf blocks of the PR quadtree in Figure 1.112(a) with the label of the leaf node of the B<sup>+</sup>-tree of which it is a member (e.g., the block containing Chicago is in leaf node R of the B<sup>+</sup>-tree).

It should be clear that the above combination of the PR quadtree and the B<sup>+</sup>-tree has decoupled the tree structure of the partition process of the underlying space from the tree structure resulting from the grouping process. More precisely, the grouping process

is based on proximity in the ordering of the locational codes and on the minimum and maximum capacity of the nodes of the  $B^+$ -tree. However, as we will see, in this, as well as in many of the bucket methods (including those described in Section 1.7.1), the region of space  $s$  spanned by node  $p$  of the  $B^+$ -tree does not necessarily have the same shape as the blocks that have been aggregated in  $p$ , whereas such a property holds for the PK-tree. In particular, in our example, in the case of a quadtree-like decomposition that makes use of regular decomposition, there is no guarantee that  $s$  is a square; this is the case, however, in the PK-tree when the PK-tree is based on a quadtree-like partitioning process that makes use of regular decomposition.

In fact, in our example, the resulting structure has the property that the space that is spanned by a leaf node of the  $B^+$ -tree (i.e., the blocks spanned by it) has a number of shapes, including a staircase (e.g., the leaf blocks in Figure 1.112(a), that make up leaf nodes S and T of the  $B^+$ -tree in Figure 1.112(c)), as well as noncontiguous regions (e.g., the leaf blocks in Figure 1.112(a) that make up leaf node R of the  $B^+$ -tree in Figure 1.112(c)). Of course, we could take the minimum bounding box of each node; however, now the problem is that the boxes will do a poor job of filtering due to a poor fit and also will not usually be disjoint. Similar problems arise for the minimum bounding boxes of the space aggregates corresponding to the nonleaf nodes of the  $B^+$ -tree. The problem is even more acute if we restrict the minimum bounding box to being one formed by the same rule as the partition process. In this case, the minimum bounding box can be as large as the underlying space (e.g., the minimum bounding quadtree block of leaf node R and nonleaf nodes U, V, and W of the  $B^+$ -tree in Figure 1.112(c)).

Interestingly, the same decoupling idea has also been used, albeit in a very different way, in the BV-tree [643] (see Section 1.7.1.6). However, the motivation for the decoupling in the BV-tree was different: to overcome a complication in disjoint space partitioning methods that lead to balanced trees (e.g., the BANG file [640, 641, 645, 646] and the hB-tree [1201, 1613] as discussed in Sections 1.7.1.5 and 1.7.1.4, respectively). In particular, the complication is that a node split may be such that one of the children of the split node becomes a child of both of the nodes resulting from the split.

## 1.8.2 Overview

The PK-tree can best be understood by examining an operational definition of its construction given the result of an existing partitioning process. If we view the partitioning process as forming a tree structure (termed a *partition tree*), then, in essence, each PK-tree node represents a subset of the nodes in the partition tree. The PK-tree is constructed by applying a bottom-up grouping process to the nodes of the corresponding partition tree where the partition tree nodes are merged into supernodes until a minimum occupancy, say  $k$ , has been attained.

The process starts by creating a PK-tree node for each node in the partition tree. We distinguish between the nodes that are formed for the points (i.e., the leaf blocks of the partition tree, some of which are empty) and the nodes formed for the blocks of the partition tree at higher levels (i.e., the nonleaf blocks), calling them *point nodes* and *directory nodes*, respectively. Next, we start grouping the nodes in bottom-up fashion, using the  $k$ -instantiation parameter  $k$  to decide how many and which nodes to group. At the deepest level, we eliminate all point nodes whose blocks do not contain a point (i.e., the empty ones) and remove them from their parents (i.e., the links to them). For a directory node  $a$ , we check the number of child nodes (which are nonempty), and if  $a$  has less than  $k$  child nodes, then we remove  $a$  and link its children to the parent of  $a$ .<sup>67</sup> This process is terminated at the root, which means that the root can have less than  $k$

<sup>67</sup> Note that, as a result of this relinking process, the number of entries in a node is almost always greater than  $k$ . In Section 1.8.5.2, we show that there is indeed an upper bound on the number of entries in a node, which depends on  $k$  and the branching factor  $F$  of the underlying partitioning process.

children. The nodes of the partition tree that remain become nodes of the PK-tree and are said to be *k-instantiated*, and likewise for the blocks that correspond to them.

As an example, suppose that the partition tree is the PR quadtree given in Figure 1.112. We now show how to form the corresponding PK-tree, which we call a *PK PR quadtree*. Similar techniques could have been applied to other partition trees, such as a PR *k-d tree*, in which case we would have a *PK PR k-d tree*. We first find that node B in the PR quadtree has just two nonempty point node children, Toronto and Buffalo. Therefore, node B is removed and its children, Toronto and Buffalo, are linked to B's parent, A. Next, we find that directory node D in the PR quadtree has three nonempty point node children, Chicago, Omaha, and Memphis, which means that it is *k-instantiated*, and thus D is made a node of the PK-tree. However, D is the only nonempty child of its parent, directory node C of the PR quadtree. Therefore, C is removed, and its child, D, is linked to C's parent, A. Checking directory node F in the PR quadtree, we find that F has just two nonempty point node children, Atlanta and Miami. Therefore, node F is removed, and its children, Atlanta and Miami, are linked to F's parent, E. At this point, we have that directory node E in the PR quadtree has three point node children, Mobile, Atlanta, and Miami, which means that it is *k-instantiated*, and thus E is made a node of the PK-tree. Note that during this process we removed nodes B, C, and F of the partition tree, while only nodes A, E, and D of the partition tree are also in the PK-tree, besides the nodes corresponding to the data points. The result is that root node A of the PK-tree has four children corresponding to Toronto, Buffalo, and nodes D and E, which are the results of the *k-instantiation* of Chicago, Omaha, and Memphis, and of Mobile, Atlanta, and Miami, respectively. Figure 1.113(a) shows the decomposition of the underlying space, and Figure 1.113(b) is the corresponding tree structure. The boundaries of the blocks in Figure 1.113(a) that correspond to the nonleaf nodes in Figure 1.113(b) are drawn using heavy lines. The empty blocks in the first level of the decomposition of the underlying space induced by the PK PR quadtree in Figure 1.113(a) are shown shaded. Notice that all of the child blocks are similar but need not be congruent (i.e., they can be of different size, as is the case for blocks D and E); nor must the space spanned by their union equal

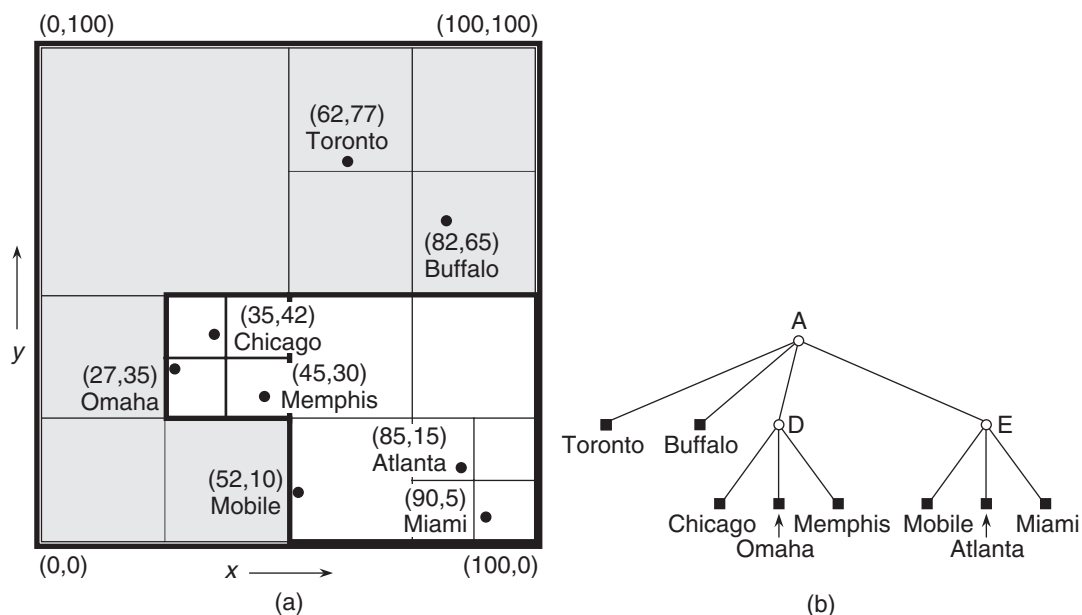

Figure 1.113  
A PK PR quadtree with  $k = 3$  corresponding to the data in Figure 1.112: (a) the resulting partition of space and (b) the tree representation. The heavy lines indicate the boundaries of the blocks corresponding to the nonleaf nodes in the tree structure. Empty blocks in the first level of decomposition of the underlying space induced by the PK PR quadtree are shown shaded and are not represented in the tree structure.

the space spanned by their parent (as is the case for blocks D and E, whose union is not equal to that of their parent, A).

When  $k = 2$ , application of the above process to the PR quadtree yields the same result as applying path compression, which is discussed in Section 1.5.2 in the context of the path-compressed PR k-d tree, path-level compressed PR k-d tree, and the BD-tree. In particular, path compression occurs in the PK-tree because empty nodes in the original PR quadtree are not included in the PK-tree, and thus are not counted among the  $k$  or more children that make up each PK-tree nonleaf node. Of course, letting  $k = 2$  when the partition tree is a PR k-d tree yields a PK PR k-d tree which is the same as a path-compressed PR k-d tree. However, notice that when  $k > 4$  ( $k > 2$ ), application of the above process to a partition tree that is a PR quadtree (PR k-d tree) yields a result similar to, but not the same as, applying level compression. The reason for the absence of equivalence here is that use of level compression aggregates all descendants of a node down to a fixed depth, whereas this is not a necessary condition in the case of a PK-tree. Thus, using a value of  $k$  that is greater than the branching factor of the underlying partitioning process yields a more flexible result than level compression.

The PK PR quadtree appears similar to a bucket PR quadtree, but unlike the bucket PR quadtree, each node in the PK PR quadtree has a minimum number of children instead of a maximum. This also applies to a PK-tree when the partition tree is not a PR quadtree.<sup>68</sup> Note that although all of the blocks that correspond to the children of a PK PR quadtree nonleaf node are squares, they are not all the same size, even though the space spanned by a nonleaf node in a PK PR quadtree is still a square. Observe also that when the partition tree is a variant of a quadtree, and  $k$  is larger than 4, then all nonleaf nodes, all of whose children are leaf nodes, in the partition tree are removed and do not appear in the PK-tree.

### 1.8.3 Definition

Given that the PK-tree really addresses the grouping process once a partitioning process yielding a partition tree has been chosen, it is not surprising that the actual, and formal, definition of the PK-tree is bottom up. In particular, given a value of  $k$ , where  $k > 1$ , the definition of the PK-tree is in terms of the concept of *k-instantiation*, where we say that a node or block in the partition tree is *k-instantiated* if it has a corresponding node or block in the PK-tree. We also say that a node or block  $a$  in the partition tree *directly contains* a *k-instantiated* node or block  $b$  if  $b$  is not contained by any *k-instantiated* node or block smaller than  $a$ . The PK-tree is the hierarchy that consists of just the *k-instantiated* nodes of the partition tree.

1. A nonempty leaf node (i.e., a point node) in the partition tree is *k-instantiated*.
2. A nonleaf node (i.e., a directory node)  $a$  in the partition tree is *k-instantiated* if  $a$  directly contains at least  $k$  *k-instantiated* nodes or blocks. In other words, if  $a$ 's corresponding node  $b$  in the PK-tree has  $j$  ( $j \geq k$ ) children  $c_i$  ( $1 \leq i \leq j$ ), then each node in the partition tree that corresponds to one of  $c_i$  is both a descendant of  $a$  and is *k-instantiated*. Furthermore, there are no other *k-instantiated* nodes in the partition tree on the path from  $a$  to  $c_i$ .
3. The root node of the partition tree is *k-instantiated* (i.e., regardless of how many children its corresponding node in the PK-tree has).

<sup>68</sup> This statement is a bit loose in the sense that we will see that the nodes in both PK-tree and bucket methods have a minimum and maximum number of children. The real difference lies in the condition behind the node-formation process, which is a minimum in the case of the PK-tree and a maximum in the case of a bucket method.

In other words, unlike most tree definitions, which are often inductive, and where the base case is in terms of the root node of the partition tree (i.e., a tree with just one node) or an empty tree, in the PK-tree, the base case is in terms of the leaf nodes of the partition tree. Note that the above definition is rather cumbersome in light of the need to make a distinction between the nodes in the partition tree and the PK-tree. Nevertheless, it is necessary as there is a potential for confusion since we often use the term *node*. We will adopt the convention that whenever we speak of a node, we mean either a node of the PK-tree or a node of the partition tree. Usually, it will be clear from the context of the discussion which one is meant, but when it is not, we specify explicitly which type is meant.

The definition of the PK-tree is somewhat hard to understand as much of its significance lies in what is *not*  $k$ -instantiated. In particular, we have defined only whether a node in the original partition tree is  $k$ -instantiated. In addition, we must specify what is to become of nodes in the partition tree that are not  $k$ -instantiated. Notice also that our definition implies that empty children are not  $k$ -instantiated. A more explicit definition is that a nonleaf node  $a$  in the partition tree is  *$k$ -instantiated* (or equivalently  *$k$ -instantiable*) if  $a$  has at least  $k$  descendants  $c_i$  that are  $k$ -instantiated, and there are no other  $k$ -instantiated nodes between  $a$  and  $c_i$ . If a node  $q$  in the partition tree is not  $k$ -instantiated, then its children become children of the PK-tree node corresponding to the deepest ancestor  $a$  of  $q$  (i.e.,  $a$  is the  $k$ -instantiated ancestor of  $q$  that is farthest from the root). Similarly, a  $k$ -instantiated node  $q$ , which is not a root node in the partition tree, is said to become  *$k$ -deinstantiated* when the number of nonempty children of its corresponding PK-tree node  $a$ , which is therefore also not a root node, falls below  $k$ . In this case, the fewer than  $k$  children of  $q$ 's corresponding PK-tree node  $a$  are delinked from  $a$  and made children of  $g$ , the father of  $a$ , which must exist because  $q$  is not a root node, and  $a$  is returned to available storage to be reused again in the case of dynamic storage allocation. This definition of the PK-tree is a bit hard to visualize, which is why we also give the operational definition of the construction of the PK tree above.

What makes the PK-tree so attractive is that it is possible to make the internal nodes sufficiently large (i.e., by increasing their maximum capacity) so that each node can be stored efficiently in a disk page. The number of elements making up a PK-tree node differs on the basis of the underlying partition tree. For example, when the partition tree is a two-dimensional PR quadtree, then each node in the corresponding PK PR quadtree has a minimum of  $k$  children and a maximum of  $4 \cdot (k - 1)$  children. Similarly, when the partition tree is a three-dimensional PR quadtree (i.e., a PR octree), then each node in the corresponding PK PR octree has a minimum of  $k$  children and a maximum of  $8 \cdot (k - 1)$  children. Interestingly, when the partition tree is a PR  $k$ -d tree, then each node in the corresponding PK PR  $k$ -d tree has a minimum of  $k$  children and a maximum of  $2 \cdot (k - 1)$  children, regardless of the dimensionality of the underlying space.

Of course, in order for the internal nodes of the PK-tree to have a large capacity, we must choose values of  $k$  larger than the branching factor of the corresponding partitioning process (i.e., 4 and 8, for the PR quadtree and PR octree, respectively). However, this is not really a problem as it simply means that we aggregate a larger number of nodes at each level of the tree. In fact, making  $k$  larger appears to increase the resemblance of the PK-tree to a quadgrid. However, the important difference is that, although in the case of a PK-tree with a quadtree partition tree, the  $k$  elements that are aggregated to form a node are squarelike, unlike the quadgrid, the blocks in the underlying space spanned by the individual aggregated elements need not necessarily be congruent (i.e., their corresponding sides do not have to have the same length).

## 1.8.4 Comparison with Bucket Methods

Earlier we mentioned that the PK PR quadtree (and, more generally, the PK-tree based on any partitioning process) resembles the bucket PR quadtree (or any variant of a bucket

partitioning process, such as a bucket PR k-d tree). This was based on the apparent similarity of  $k$ -instantiation and bucketing. In fact, these two concepts are very different, although their effects are very similar. The most obvious difference, which was already pointed out, is that each node in the PK-tree is defined in terms of a minimum number of children, while in the bucket variants, each node is defined in terms of a maximum number of children. Another important difference is that bucketing is a top-down process, which means that for a bucket capacity  $k$ , the decomposition halts as soon as we encounter a block with  $k$  or fewer objects. Thus, we are seeking a maximum enclosing quadtree (or k-d tree) block for the  $k$  or fewer objects. In contrast, the  $k$ -instantiation in the PK-tree (as well as path compression) are bottom-up processes, and we are seeking the minimum enclosing quadtree (or k-d tree) block for the group of at least  $k$  objects.

This difference can be seen by observing that if a group of  $k$  objects exists in a block  $i$  of size  $2^a \times 2^a$  that is embedded in a larger block  $j$  of size  $2^b \times 2^b$  such that  $j$  contains no other objects, then a bucket method would use block  $j$ , while a PK-tree would use block  $i$ . Interestingly, the similarity between the two processes lies in the time at which they halt (i.e., as soon as possible!). In particular, the bottom-up process halts as soon as a block contains at least  $k$  objects, and the top-down process halts as soon as a block contains at most  $k$  objects.

$K$ -instantiation, which is the principal idea behind the PK-tree, can be applied to other partitioning processes that are based on a disjoint decomposition of space (preferably a regular decomposition but not required) besides the PR quadtree (see Exercise 1 in Section 1.8.6). In particular, adapting the PK-tree to a two-dimensional PR k-d tree, yielding a PK PR k-d tree, we find that each node has a minimum of  $k$  children and a maximum of  $2 \cdot (k - 1)$  children. This resembles the classical  $B^+$ -tree definition (as well as an R-tree and other bucket variants discussed in Section 1.7.1) in terms of having nodes with a variable capacity; yet, each node is guaranteed to be at least half-full.

Of course, there are some important differences between the PK-tree and these bucket variants. In particular, the main difference is that, unlike the  $B^+$ -tree (and R-tree), the PK-tree is not necessarily balanced. The PK PR k-d tree is somewhat similar to the BD-tree (see Section 1.5.2.6), which is also a bucket method, but the PK-tree has the advantage that it is uniquely defined while the BD-tree is not. However, the nonuniqueness of the BD-tree does enable the BD-tree to be varied so that a more balanced structure can be achieved. The price of the balance is that the BD-tree does not decompose the underlying space into squares. Instead, the decomposition is into a collection of “holey bricks” (i.e., squares that possibly have smaller squares cut out) similar to that resulting from use of other bucket methods, such as the hB-tree (see Section 1.7.1.4) and the BANG file (see Section 1.7.1.5). This makes subsequent processing a bit difficult. Also, all but the leaf nodes in the BD-tree have a fanout of 2, whereas the fanout of all of the PK PR k-d tree nodes is much higher. The limited fanout of the nonleaf nodes in the BD-tree reduces the motivation for using it as a disk-resident data structure.

## 1.8.5 Operations

The PK-tree is a dynamic structure, which means that items can be inserted and deleted from an existing PK-tree without having to rebuild the structure for the entire dataset. Updating a PK-tree to add or remove a point  $p$  is a two-step process. The first step corresponds to a search for  $p$ . It starts at the root and proceeds in a top-down manner, guided by the decomposition rules for the specific partitioning process that has been chosen (e.g., PR quadtree, PR k-d tree). In essence, we are searching the blocks induced by the decomposition for the block  $b$  containing  $p$ . Once  $b$  has been found, the actual operation is performed, if possible (i.e.,  $b$  is empty or does not contain  $p$  in the case of insertion, or  $b$  contains  $p$  in the case of deletion), and the grouping process is applied in a bottom-up manner, as necessary, to ensure that the result is a PK-tree. In the rest of this

section, we discuss the representation of the PK-tree, as well as elaborate further on the searching process (Section 1.8.5.1) and the implementation of insertion (Section 1.8.5.2) and deletion (Section 1.8.5.3).

### 1.8.5.1 Representation and Searching

The mechanics of the search process are heavily dependent on the representation of the points and the nodes. The search for point  $p$  starts at the root and looks for the node whose corresponding block contains  $p$ . This is not so simple for the following reasons:

1. The blocks corresponding to the children of a node in the PK-tree are not necessarily the same size.
2. The union of the blocks corresponding to the elements of  $q$  is not necessarily equal to the block corresponding to  $q$  on account of the elimination of the empty children via a process analogous to path compression.

The child blocks (i.e., both point nodes and directory nodes) of each node  $a$  are represented by a unique number known as a locational code (see Section 2.1.2.4 of Chapter 2 for more detail). For example, such a number can be formed by applying bit interleaving to the binary representations of the coordinate values of an easily identifiable point in each block (e.g., its lower-left corner when the origin is in the lower-left corner of the underlying space as in Figure 1.112(a)) and concatenating this number with the base 2 logarithm of its block size—that is,  $i$  for a block of size  $2^i$ . These locational codes are sorted in increasing order, thereby yielding an ordering (called a Morton order [1317] or Z order [1420]) equivalent to that which would be obtained by traversing the nonempty leaf nodes (i.e., blocks) of the tree representation of the decomposition of the embedding space from which the data is drawn in the order SW, SE, NW, and NE for a quadtree (or bottom, top, left, and right for a k-d tree). Of course, other orders, such as the Peano-Hilbert order [835], have also been used (e.g., [591, 937]).

Ordering the locational codes in increasing order facilitates searching for a particular point  $p$  as we can make use of a binary search for the block in  $a$  that contains  $p$ . This implementation poses a problem when  $a$  is a point node because the coordinate values of the points are usually specified with greater precision than is permitted by the resolution of the underlying space. Thus, it is usually stipulated that the underlying space has some finite resolution, and, therefore, the locational code of the point node is really the locational code of the  $1 \times 1$  block that contains the point. In addition, besides the locational code, associated with each entry corresponding to child block  $b$  is a pointer to either the actual node in the PK-tree corresponding to  $b$  when  $b$  is a directory node in the partition tree, or a pointer to a record containing the rest of the information about the point (i.e., its coordinate values and any other relevant information). Of course, if two points fall into the same  $1 \times 1$  cell, then they have the same locational code. However, they can still be distinguished because the combination of the locational code and pointer to the rest of the information about the point is unique. It is interesting to observe that the stipulation that the points are represented by  $1 \times 1$  blocks means that the partition tree is actually an MX quadtree (e.g., [1637]), and the corresponding PK-tree is really a PK MX quadtree (see Figure 1.114). Now we see that every node in the PK MX quadtree is a minimum enclosing quadtree block of the points in the space spanned by its corresponding block (whereas this was not quite true for the blocks corresponding to the point nodes when the partition tree is a PR quadtree).

### 1.8.5.2 Insertion

Although our operational definition of the PK-tree has implied that we know all of the data items before building it (i.e., it is static), as we pointed out above, the PK-tree is a dynamic structure in the sense that data can be inserted and removed one at a time without our having to rebuild the structure from scratch. However, checks for  $k$ -instantiation

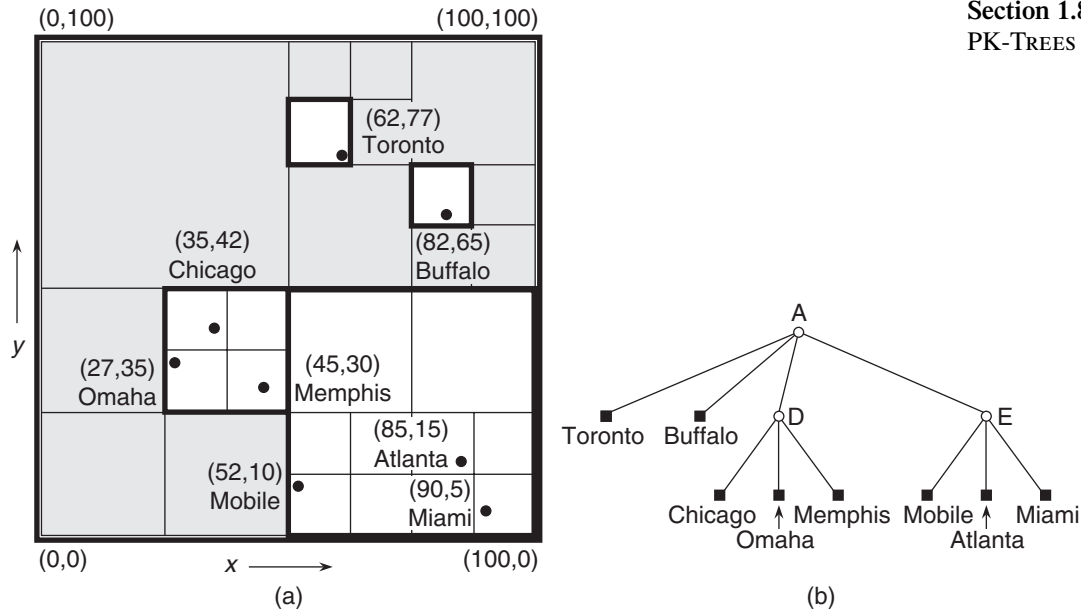

Figure 1.114  
A PK MX quadtree with  $k = 3$  corresponding to the data of Figure 1.112: (a) the resulting partition of space and (b) the tree representation. The heavy lines indicate the boundaries of the blocks corresponding to the nodes (leaf and nonleaf) in the first level of the tree structure. Empty blocks in the first level of decomposition of the underlying space induced by the PK MX quadtree are shown shaded and are not represented in the tree structure.

and  $k$ -deinstantiation may have to be applied at each level of the PK-tree during the grouping process. In particular, once the position where the point to be inserted or the point to be deleted has been found, we continuously check in a bottom-up manner for the applicability of  $k$ -instantiation or  $k$ -deinstantiation until it is no longer applicable, or we have reached the root of the structure. This is a direct consequence of the fact that the PK-tree is defined in a bottom-up manner (i.e., recall that the nodes of the PK-tree are always defined in terms of their descendants). The details of the insertion and deletion processes are given in the rest of this section and in Section 1.8.5.3, which follows immediately.

The insertion of a point  $p$ , which belongs in a block  $b$  of the partition tree, which is in turn contained in block  $c$  corresponding to nonleaf node  $q$  in the PK-tree, may result in the  $k$ -instantiation of an ancestor block  $b'$  of  $b$  in  $q$ . In this case, a new node  $t$  is created that corresponds to  $b'$ , whose elements are  $p$  and  $k - 1$  other elements of  $q$ . Observe that  $b'$  corresponds to the minimum enclosing block of  $p$  and the  $k - 1$  elements of  $q$  that form  $t$ . Note also that  $t$  cannot contain more than  $k$  elements as, otherwise,  $t$  would have already existed since the block in the partition tree corresponding to  $t$  was not  $k$ -instantiated prior to the insertion of  $p$ . Node  $t$  is made an element of  $q$ , and  $t$ 's  $k - 1$  elements, excluding  $p$ , are removed from  $q$ . This action may cause the block in the partition tree corresponding to  $q$  (i.e.,  $c$ ) to cease being  $k$ -instantiated as fewer than  $k$  elements may be left in it (i.e.,  $c$  is  $k$ -deinstantiated). This means that the elements of  $q$  must be made elements of the father  $f$  of  $q$  in the PK-tree. This process is applied recursively on  $f$ , with  $t$  taking on the role of  $p$ , as long as we end up with a node that contains fewer than  $k$  elements or encounter the root, at which time we halt. Recall that according to the definition of the PK-tree, the root's corresponding block in the partition tree is always  $k$ -instantiated, regardless of the number of nonempty children.

For example, consider the PK PR quadtree with  $k = 5$  with points 1–4 and A–O and nonleaf nodes W–Z given in Figure 1.115(a). Figure 1.115(b) is the block decomposition of the underlying space of size  $2^9 \times 2^9$  induced by the corresponding PR quadtree (i.e., the partition tree) where these points (and an additional point P that will be subsequently

Figure 1.115  
 (a) Tree representation of an example PK PR quadtree for  $k = 5$ ; (b) a block decomposition of the underlying space (at logarithmic scale but all blocks are square and of a width that is a power of 2), where the labeled points can lie so that the tree representation in (a) would be physically realizable; and (c) the result of inserting point P into the PK PR quadtree in (a).

inserted) lie. All blocks in Figure 1.115(b) are square, and the points can lie in any location in the square in which they are found. Note that the block decomposition in Figure 1.115(b) does not correspond to an MX quadtree since as soon as a block contains just one point, we halt the decomposition, whereas in the MX quadtree we would descend to the final level where each point is a  $1 \times 1$  block. Of course, since the PK-tree effectively “path-compresses” all of the extra decomposition, there is no point in using the MX quadtree. Observe also that the example in Figure 1.115(b) is drawn using a logarithmic scale as the widths of the blocks at each successive level of decomposition are one half the widths of the blocks at the immediately preceding level. Figure 1.115(c) shows the result of inserting point P into the PK PR quadtree of Figure 1.115(a), given the physical interpretation of Figure 1.115(b). Nonleaf nodes  $V' - Y'$  have been added during the insertion process, while nodes  $W - Y$  (see Figure 1.115(a)) have been removed.

Notice that the insertion of  $P$  has led to the  $k$ -instantiation of the partition tree node corresponding to the minimum enclosing block of it and points 1–4, thereby causing the creation of node  $V'$  in Figure 1.115(c). In fact, this act of  $k$ -instantiation has caused the  $k$ -deinstantiation of the block in the partition tree corresponding to node  $W$ , as now it contains only four elements (i.e.,  $A$ – $C$  and  $V'$ ), thereby causing the promotion of the partition tree blocks corresponding to points  $A$ – $C$  and node  $V'$  to node  $X$ . This causes the  $k$ -instantiation of the minimum enclosing partition tree block of points  $A$ – $D$  and node  $V'$  and the formation of a new node  $W'$ . This action results in the  $k$ -deinstantiation of the block in the partition tree corresponding to node  $X$  as now it contains only four elements (i.e., points  $E$ – $G$  and node  $W'$ ), thereby causing the promotion of the partition tree blocks corresponding to points  $E$ – $G$  and node  $W'$  to node  $Y$ . This causes the  $k$ -instantiation of the minimum enclosing partition tree block of points  $E$ – $H$  and node  $W'$  and the formation of a new node  $X'$ . Once again, this action results in the  $k$ -deinstantiation of the block in the partition corresponding to node  $Y$ , as now it contains only four elements (i.e., points  $I$ – $K$  and node  $X'$ ), thereby causing the promotion of the partition tree blocks corresponding to points  $I$ – $K$  and node  $X'$  to node  $Z$ . This causes the  $k$ -instantiation of the minimum enclosing partition tree block of points  $I$ – $L$  and node  $X'$  and the formation of a new node  $Y'$ . At this point, node  $Z$  remains with just four elements corresponding to points  $M$ – $O$  and node  $Y'$ , but, as  $Z$  is the root of the tree,  $Z$ 's corresponding block in the partition tree is  $k$ -instantiated by definition. Thus, we are done, and there is no need to be concerned about whether  $Z$  has fewer than  $k$  elements.

It is important to note that this example does not represent typical data because it corresponds to data that is extremely skewed. It was chosen because it represents the worst possible case for the insertion algorithm in the sense that it results in a  $k$ -instantiation and  $k$ -deinstantiation at each level of the PK-tree (for more details, see Section 1.8.6).

The actual insertion of a point  $p$  in a PK-tree rooted at node  $q$  with instantiation parameter  $k$  is given by procedure PKINSERT. PKINSERT is recursive and is invoked with the point to be inserted, pointers to the root of the subtree currently being processed (initially, the root of the entire PK-tree) and its father (initially NIL for the initial invocation), and the instantiation parameter  $k$ . We assume that nodes in the PK-tree are of type *node*. PKINSERT accounts for the possibility that  $k$ -instantiation and  $k$ -deinstantiation could take place at all levels. This is achieved via the use of recursion. However, PKINSERT is not efficient if  $k$ -instantiation and  $k$ -deinstantiation do not take place at all levels. In particular, we know that as soon as we have found a step at which  $k$ -instantiation cannot take place, we no longer have to check for it and can safely exit the procedure. Thus, a more efficient algorithm would not use recursion; however, we would still need to capture a history of the manner in which we descended to the current node from the root so that the equivalent of recursion unwinding could be executed. Alternatively, we could also benefit from a programming construct that enabled us to exit from a recursive instantiation of the procedure and from all remaining levels of recursion. Locations in the code where this feature would be useful are accompanied by a suitably phrased comment.

Procedure PKINSERT makes use of the following auxiliary procedures: FINDCHILD, MAKENODEANDADDASCHILD, FORMNODEFORMINENCLOSINGBLOCKWITHKITEMS, REMOVECHILDSOFNEWNODEFROMFATHER, INSERTNODE, COUNTCHILDS, and INSERTCHILDSOFNODE. These procedures are important as they correspond to the decomposition rules of the partition tree. Recall that the key idea in the PK-tree is the decoupling of the partition process from the grouping process. Thus, we should have one set of procedure implementations for a PR quadtree, another different set for an MX quadtree, and so on.

Procedure FINDCHILD( $P, Q$ ) finds the child of node  $Q$  that contains point  $P$ . MAKENODEANDADDASCHILD( $P, Q$ ) creates a new node  $t$  for point  $P$ , adds  $t$  as a child of node  $Q$ , and returns  $t$  as its value. FORMNODEFORMINENCLOSINGBLOCKWITHKITEMS( $D, Q, K$ ) finds the minimum enclosing block in the partition tree of

element  $D$  in node  $Q$  with at least  $K$  elements and forms a new PK-tree node  $t$  corresponding to it that is returned as its value. In other words, it performs  $k$ -instantiation, if possible. Note that if  $Q$  is a root node with fewer than  $K$  elements and FORMNODEFORMINENCLOSINGBLOCKWITHKITEMS cannot find a block with  $K$  elements, then it returns  $Q$  as the value. Procedure REMOVECHILDSONEWNODEFROMFATHER( $T, Q$ ) removes the children of node  $T$  from node  $Q$ . INSERTNODE( $T, Q$ ) makes node  $T$  a child of node  $Q$ . COUNTCHILDS( $Q$ ) counts the number of elements (i.e., corresponding to nonempty children) in node  $Q$ . INSERTCHILDSONODE( $Q, F$ ) makes the children of node  $Q$  be children of node  $F$ , while REMOVENODEFROMFATHER( $Q, F$ ) removes the entry for node  $Q$  in node  $F$ , which is  $Q$ 's father.

```

1  recursive node procedure PKINSERT( $P, Q, F, K$ )
2  /* Attempt to insert point  $P$  in the PK-tree with parameter  $K$  rooted at node
    $Q$  whose father is  $F$ . An empty PK-tree still has a nonempty root node
   with no entries in it. */
3  value pointer point  $P$ 
4  value pointer node  $Q, F$ 
5  value integer  $K$ 
6  pointer node  $D, S, T$ 
7   $S \leftarrow$  FINDCHILD( $P, Q$ )
8   $D \leftarrow$  if ISNULL( $S$ ) then MAKENODEANDADDASCHILD( $P, Q$ )
9      else PKINSERT( $P, S, Q, K$ )
10     endif
11   $T \leftarrow$  FORMNODEFORMINENCLOSINGBLOCKWITHKITEMS( $D, Q, K$ )
12  if  $T = Q$  then
13     return  $Q$  /* Can exit completely as no  $k$ -instantiation has occurred */
14  else /* Propagate  $k$ -instantiation */
15     REMOVECHILDSONEWNODEFROMFATHER( $T, Q$ )
16     INSERTNODE( $T, Q$ )
17     if not ISNULL( $F$ ) and COUNTCHILDS( $Q$ )  $< K$  then
18         /* propagate  $k$ -deinstantiation */
19         INSERTCHILDSONODE( $Q, F$ )
20         REMOVENODEFROMFATHER( $Q, F$ )
21         RETURNTOAVAIL( $Q$ )
22     return  $T$ 
23  else return  $Q$  /* Can exit completely as no further  $k$ -instantiation can */
24  endif /* take place since no  $k$ -deinstantiation has occurred */
25  endif

```

It is interesting to observe that, at times, a node may temporarily contain more than the maximum possible number of elements, which is  $F \cdot (k - 1)$  for a partition tree with a branching factor  $F$ . This is the case when  $k$ -deinstantiation takes place (i.e., right after  $k$ -instantiation, which, as we will see in Section 1.8.5.3, also occurs when a point is deleted rather than limited to occurring when a point is inserted) or when an insertion is made into a PK-tree node that is full. Suppose that node  $n$  contains  $F \cdot (k - 1)$  elements. If we insert a new element into  $n$ , then  $n$  will momentarily contain  $F \cdot (k - 1) + 1$  elements. Similarly, a  $k$ -deinstantiation involving  $n$  that replaces one of the elements in  $n$  by  $k - 1$  elements from a child node results in  $n$  containing  $F \cdot (k - 1) - 1 + (k - 1) = F \cdot (k - 1) + k - 2 = (F + 1) \cdot (k - 1) - 1$  elements. Of course, in both cases, the newly added elements of  $n$  will be immediately  $k$ -instantiated with other element(s) of  $n$ , and the node will once again contain a maximum of  $F \cdot (k - 1)$  elements.<sup>69</sup>

<sup>69</sup> A more detailed explanation is as follows. Suppose that a block  $b'$  in node  $q$  becomes  $k$ -instantiated (via the insertion of a point, the promotion of  $k - 1$  elements of the partition tree due to  $k$ -deinstantiation, or the invocation of procedure FORMNODEFORMINENCLOSINGBLOCKWITHKITEMS). In this case, a new node  $t$  will be created corresponding to  $b'$  that has  $k$  elements. Node  $t$  is made an element of  $q$ , and  $t$ 's  $k$  elements (or  $k - 1$  elements if the  $k$ -instantiation has resulted from the

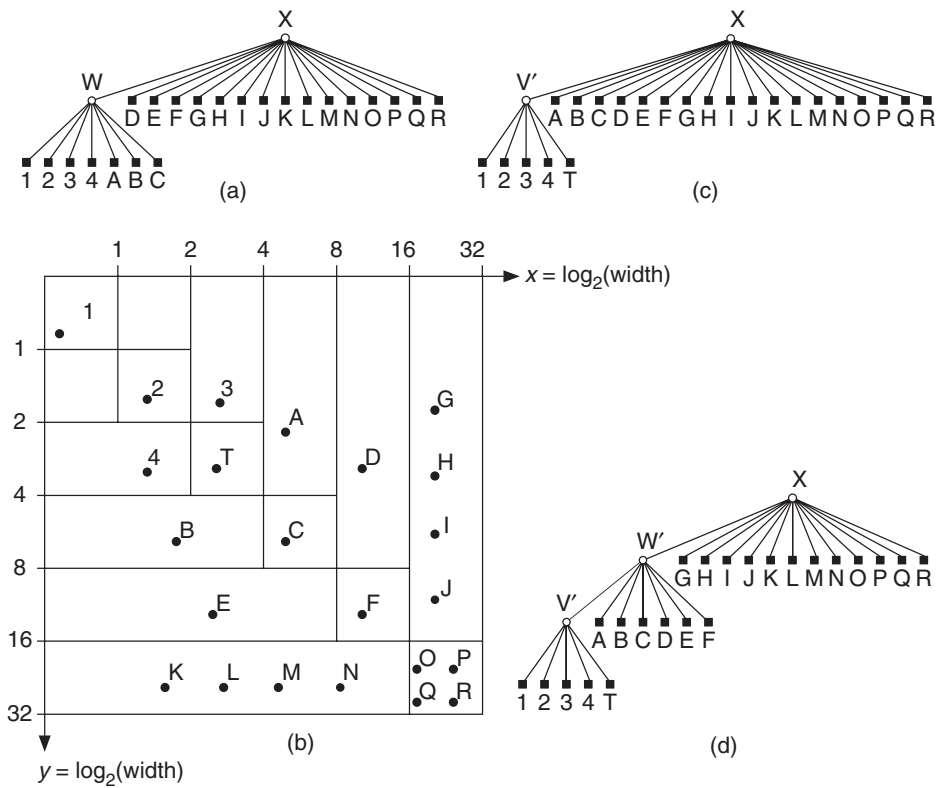

Figure 1.116  
 (a) Tree representation of an example PK PR quadtree for  $k = 5$ ; (b) a block decomposition of the underlying space (at logarithmic scale but all blocks are square and of width that is a power of 2), where the labeled points can lie so that the tree representation in (a) would be physically realizable; (c) the tree representation after the combination of  $k$ -instantiation and  $k$ -deinstantiation resulting from inserting point T into the PK PR quadtree in (a); and (d) the final tree representation.

As an example of how this situation can arise, consider the PK PR quadtree with  $k = 5$  with points 1–4 and A–R and nonleaf nodes W and X given in Figure 1.116(a). Figure 1.116(b) is a block decomposition of the underlying space of size  $2^5 \times 2^5$ , where these points (and an additional point T that will be subsequently inserted) lie. All blocks in Figure 1.116(b) are square, and the points can lie in any location in the square in which they are found. Observe also that Figure 1.116(b) is drawn using a logarithmic scale as the widths of the blocks at each successive level of decomposition are one-half the widths of the blocks at the immediately preceding level.

Inserting T into the PK PR quadtree of Figure 1.116(a), given the physical interpretation of Figure 1.116(b), has led to the  $k$ -instantiation of the partition tree node corresponding to the minimum enclosing block of it and points 1–4, causing the creation of node  $V'$ , as shown in Figure 1.116(c). In fact, this act of  $k$ -instantiation has caused the  $k$ -deinstantiation of the block in the partition tree corresponding to node W,

addition of a new point) are removed from  $q$ . This action may cause the block  $c$  in the partition tree corresponding to  $q$  to cease being  $k$ -instantiated, as fewer than  $k$  elements may be left in it (i.e.,  $c$  is  $k$ -deinstantiated). The maximum number of elements remaining in  $q$  (including  $t$ ) is  $k - 1$ . This means that the elements of  $q$  must be made elements of the father  $f$  of  $q$ . Thus, the number of elements in  $f$  grows by at most  $k - 2$  as one of its elements (i.e.,  $q$ ), which has become  $k$ -deinstantiated, is replaced by  $k - 1$  additional elements for a net gain of  $k - 2$ . Thus, if  $f$  already has the maximum number of elements (i.e.,  $F \cdot (k - 1)$ ), then the maximum number of elements in a node is really  $(F + 1) \cdot (k - 1) - 1$ . Of course, if this is the case, the newly added elements of  $f$  will be immediately  $k$ -instantiated with an element of  $f$ , and the maximum number of elements in the node will once again be  $F \cdot (k - 1)$ .

as now it contains only four elements (i.e., points A–C and node  $V'$ ), thereby causing the promotion of the partition tree blocks corresponding to points A–C and node  $V'$  to node  $X$ , as shown in Figure 1.116(c). At this point, node  $X$  contains 19 elements, which is 3 more ( $=k - 2$  when  $k$  is 5) than the possible maximum number of elements. However, this causes the  $k$ -instantiation of the minimum enclosing partition tree block of points A–F and node  $V'$ , and a new node  $W'$  is formed, as shown in Figure 1.116(d). At this point, node  $X$  has 13 elements, and we are below the possible maximum number of elements.

Note that the physical size of a node (in bytes) is dictated by the chosen page size of the disk-resident tree file (often 4 kB). Thus, it is undesirable for the node to become larger than the physical size. There are essentially two ways to overcome this problem. The first is to allow the size of the nodes to exceed the physical size (i.e., the page size) when in memory (e.g., by allocating a larger memory block or by maintaining an overflow buffer of  $k - 2$  elements, which is used only when a node overflows in the described manner). The second is to modify the code for the PK-tree update operations (i.e., both insertion and deletion algorithms) so that they avoid the overflow problem. In particular, before adding  $m$  elements to a node  $n$  (either through insertion or  $k$ -deinstantiation), we check whether we can  $k$ -instantiate these  $m$  new elements together with  $k - m$  existing elements in  $n$ . If this is possible, then we perform the  $k$ -instantiation without adding the  $m$  elements to  $n$ ; otherwise, it is safe to add the new elements without exceeding the maximum size.

### Exercise

1. Write an iterative version of the PK-tree insertion algorithm, procedure PKINSERT, that does not perform unnecessary  $k$ -instantiation tests (i.e., the calls to procedure FORMNODE-FORMINENCLOSINGBLOCKWITHKITEMS) once we know that no more occurrences of  $k$ -instantiation are possible.

### 1.8.5.3 Deletion

Deletion of a point  $p$  that is an element of nonleaf node  $q$  in the PK-tree is handled in a similar manner to insertion. The difference from insertion is that deletion may result in the removal of nodes from the PK-tree whose corresponding blocks in the partition tree were formerly  $k$ -instantiated. If the block in the partition tree corresponding to  $q$  is still  $k$ -instantiated after the deletion, then no further action must be taken. Otherwise,  $q$  must be deallocated, and its remaining  $k - 1$  elements are made elements of the father  $f$  of  $q$  in the PK-tree (i.e., the block in the partition tree corresponding to  $q$  is  $k$ -deinstantiated). The insertion of additional elements in  $f$  may mean that one of the subblocks, say  $b'$ , of the partition tree block  $b$  corresponding to  $f$  that contains the newly inserted  $k - 1$  elements, plus at least one other element, may become  $k$ -instantiated. In this case, a new node  $t$  will be created that corresponds to  $b'$ . Note that  $t$  can contain more than  $k$  elements. Node  $t$  is made an element of  $f$ , and  $t$ 's elements are removed from  $f$ . This action may cause the block in the partition tree corresponding to  $f$  (i.e.,  $b$ ) to cease being  $k$ -instantiated, as fewer than  $k$  elements may be left in it (i.e.,  $b$  is  $k$ -deinstantiated). This means that the elements of  $f$  must be made elements of the father  $g$  of  $f$ . This process is applied recursively on  $g$ , with  $t$  taking on the same role as  $p$  in the insertion process, as long as we end up with a node that contains fewer than  $k$  elements or encounter the root, at which time we halt. Recall that, according to the definition of the PK-tree, the root's corresponding block in the partition tree is always  $k$ -instantiated, regardless of the number of nonempty children.

For example, consider the PK PR quadtree with  $k = 5$  with points 1–4, A–M, and P and nonleaf nodes V–Z in Figure 1.117(a). Figure 1.117(b) is the block decomposition of the underlying space of size  $2^9 \times 2^9$  induced by the corresponding PR quadtree (i.e., the partition tree) where these points lie. All blocks in Figure 1.117(b) are square, and the points can lie in any location in the square in which they are found. Observe that the example in Figure 1.117(b) is drawn using a logarithmic scale as the widths of the

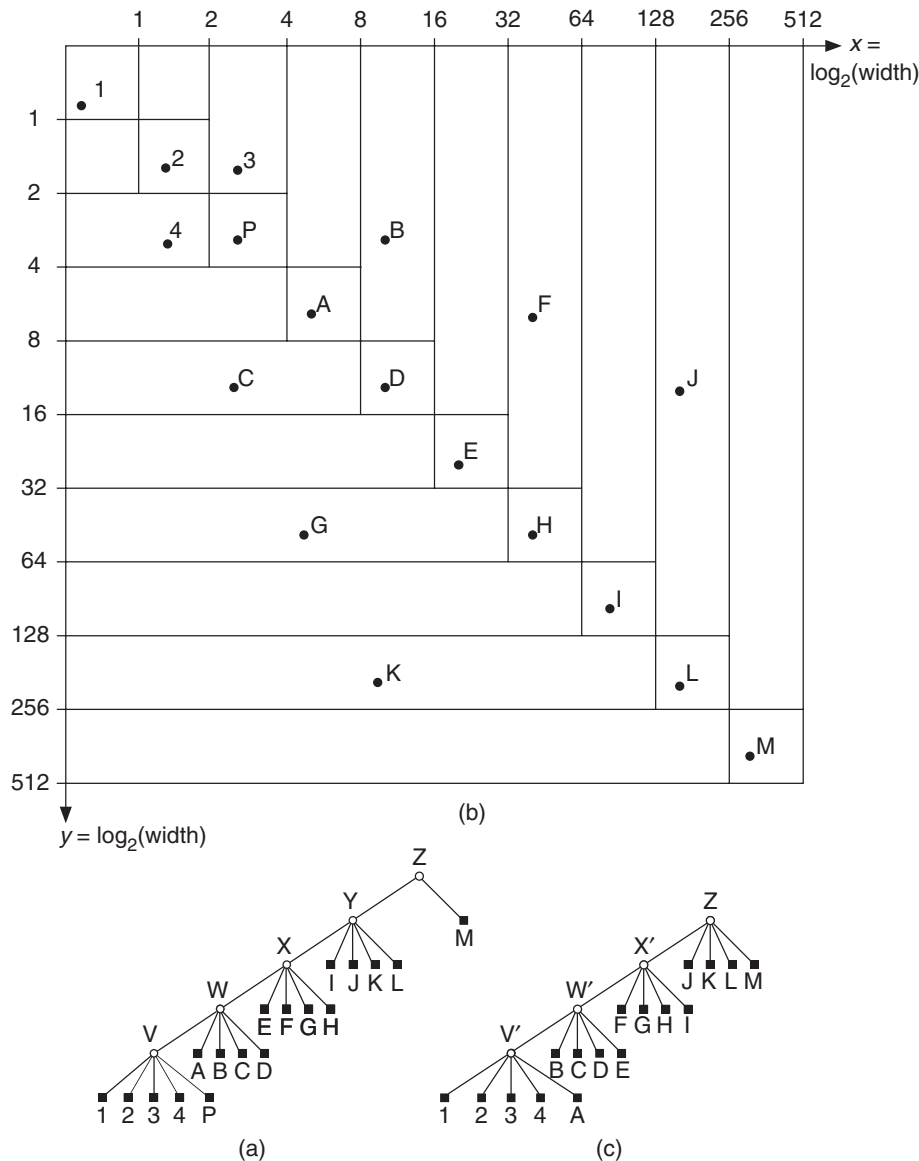

Figure 1.117  
 (a) Tree representation of an example PK PR quadtree for  $k = 5$ ; (b) a block decomposition of the underlying space (at logarithmic scale but all blocks are square and of width that is a power of 2), where the labeled points can lie so that the tree representation in (a) would be physically realizable; and (c) the result of deleting point P from the PK PR quadtree in (a).

blocks at each successive level of decomposition are one-half the widths of the blocks at the immediately preceding level. Figure 1.117(c) shows the result of deleting point P from the PK PR quadtree of Figure 1.117(a), given the physical interpretation of Figure 1.117(b). Nonleaf nodes V–Z are the nonleaf nodes in the original PK-tree. Nodes V'–X' have been added during the deletion process, while nodes V–Y have been removed.

Notice that the deletion of P has led to the  $k$ -deinstantiation of the partition tree node corresponding to V (as it has just four elements corresponding to points 1–4). This action results in the removal of node V in Figure 1.117(c) and the promotion of points 1–4 to node W. This causes the  $k$ -instantiation of the minimum enclosing partition tree block of the points 1–4 and the block corresponding to point A, and a new node V' is formed that is made an element of node W. This action results in the  $k$ -deinstantiation of the block in the partition tree corresponding to node W, as now it contains only four elements

(i.e., points B–D and node  $V'$ ), thereby causing the promotion of the partition tree blocks corresponding to points B–D and node  $V'$  to node X. This causes the  $k$ -instantiation of the minimum enclosing partition tree block of points B–E and node  $V'$  and the formation of a new node  $W'$  that is made an element of node X. This results in the  $k$ -deinstantiation of the block in the partition tree corresponding to node X, as now it contains only four elements (i.e., points F–H and node  $W'$ ), thereby causing the promotion of partition tree blocks corresponding to points F–H and node  $W'$  to node Y. This causes the  $k$ -instantiation of the minimum enclosing partition tree block of points F–I and node  $W'$  and the formation of a new node  $X'$  that is made an element of node Y. This results in the  $k$ -deinstantiation of the block in the partition tree corresponding to node Y, as now it contains only four elements (i.e., points J–L and node  $X'$ ), thereby causing the promotion of the partition tree blocks corresponding to points J–L and node  $X'$  to node Z, which is the root node with just one other element (i.e., M). At this point, node Z has five elements, but, as Z is the root of the tree, Z's corresponding block in the partition tree is  $k$ -instantiated by definition. Thus, we are done, and there is no need to be concerned about whether Z has fewer than  $k$  elements.

It is important to note that this example does not represent typical data but corresponds to data that is extremely skewed. It was chosen because it represents the worst possible case for the deletion algorithm in the sense that it results in a  $k$ -instantiation and  $k$ -deinstantiation at each level of the PK-tree (for more details, see Section 1.8.6).

The actual deletion of a point  $p$  in a PK-tree rooted at node  $q$  with instantiation parameter  $k$  is given by procedure PKDELETE. PKDELETE is recursive and is very similar to PKINSERT. PKDELETE is invoked with the point to be deleted, pointers to the root of the subtree currently being processed (initially the root of the entire PK-tree) and its father (initially NIL for the initial invocation), and the instantiation parameter  $k$ . PKDELETE accounts for the possibility that  $k$ -instantiation and  $k$ -deinstantiation could take place at all levels. This is achieved via the use of recursion. However, as we remark in our discussion of PKINSERT, PKDELETE is not efficient if  $k$ -instantiation and  $k$ -deinstantiation do not take place at all levels. In particular, we know that as soon as we have found a step at which  $k$ -instantiation can no longer take place, we no longer have to check for it and can safely exit the procedure. Thus, a more efficient algorithm would not use recursion; however, we would still need to capture a history of the manner in which we descended to the current node from the root so that the equivalent of recursion unwinding could be executed. Alternatively, we could also benefit from a programming construct that enabled us to exit from a recursive instantiation of the procedure and from all remaining levels of recursion. Locations in the code where this feature would be useful are accompanied by a suitably phrased comment.

Procedure PKDELETE makes use of the same auxiliary procedures as PKINSERT with the addition of ISPOINT and CHOOSECHILD. Recall from our discussion of PKINSERT that these procedures are important as they correspond to the decomposition rules of the partition tree, and there is one set of procedure implementations for the PR quadtree, another set for the MX quadtree, and so on. Procedure ISPOINT( $S$ ) determines if node  $S$  corresponds to a single point. CHOOSECHILD( $Q$ ) returns a pointer to one of the children of  $Q$ . This is useful in case any  $k$ -deinstantiation takes place at the level of the tree at which the deleted point was found.

```

1  recursive node procedure PKDELETE( $P, Q, F, K$ )
2  /* Attempt to delete node  $P$  from the PK-tree with parameter  $K$  rooted at
   node  $Q$  whose father is  $F$ . An empty PK-tree still has a nonempty root
   node with no entries in it. */
3  value pointer point  $P$ 
4  value pointer node  $Q, F$ 
5  value integer  $K$ 
6  pointer node  $D, S, T$ 
7   $S \leftarrow \text{FINDCHILD}(P, Q)$ 

```

```

8  if ISNULL( $S$ ) then
9    return  $Q$  /*  $P$  is not in the PK-tree and can exit completely */
10 elseif ISPOINT( $S$ ) then
11   /*  $S$  must be point  $P$  as, otherwise, FINDCHILD is NIL */
12   REMOVENODEFROMFATHER( $S, Q$ )
13   RETURNTOAVAIL( $S$ )
14    $T \leftarrow$  CHOOSECHILD( $Q$ )
15 else
16    $D \leftarrow$  PKDELETE( $P, S, Q$ )
17    $T \leftarrow$  FORMNODEFORMINENCLOSINGBLOCKWITHKITEMS( $D, Q, K$ )
18   if  $T = Q$  then
19     return  $Q$  /* Can exit completely as no  $k$ -instantiation has occurred */
20   else /* Propagate  $k$ -instantiation */
21     REMOVECHILDSONEWNODEFROMFATHER( $T, Q$ )
22     INSERTNODE( $T, Q$ )
23   endif
24 endif
25 if not ISNULL( $F$ ) and COUNTCHILDS( $Q$ ) <  $K$  then
26   /* propagate  $k$ -deinstantiation */
27   INSERTCHILDSOFNODE( $Q, F$ )
28   REMOVENODEFROMFATHER( $Q, F$ )
29   RETURNTOAVAIL( $Q$ )
30   return  $T$ 
31 else /* Can exit completely as no further  $k$ -instantiation can */
32   return  $Q$  /* take place since no  $k$ -deinstantiation has occurred */
33 endif

```

### Exercises

1. Write an iterative version of the PK-tree deletion algorithm, procedure PKDELETE, that does not perform unnecessary  $k$ -instantiation tests (i.e., the calls to procedure FORMNODEFORMINENCLOSINGBLOCKWITHKITEMS) once we know that no more occurrences of  $k$ -instantiation are possible.
2. Suppose that after deletion we have the situation that a root node  $r$  has just one child  $s$  that is a nonleaf node. Should we make the children of  $s$  be children of  $r$  and delete  $s$ ? An example of such a situation would arise after deleting point  $M$  from the PK PR quadtree in Figure 1.117(a).

## 1.8.6 Discussion

The examples in Figures 1.115 and 1.117 point out how and when the process of  $k$ -instantiation and  $k$ -deinstantiation can take place at all levels of the PK-tree. Notice that the particular configuration of data in our examples starts with (results in) each nonleaf node, save the root (which is always  $k$ -instantiated regardless of how many entries it has) at the end (start) of the insertion (deletion) process, being completely full (i.e., truly  $k$ -instantiated) with respect to the given value of  $k$  (i.e.,  $k = 5$  in our example). They represent the worst case of the PK-tree in the sense that insertion (deletion) of one point has caused the depth of the PK-tree to increase (decrease) by one level. However, it is the maximum possible increase (decrease) in depth due to the insertion (deletion) of a point. This is in contrast to the conventional PR quadtree, where the increase (decrease) in depth depends on the minimum separation between the newly added (deleted) point and the closest existing point to it in the tree. Similar examples of the worst case can be constructed for any value of  $k$ .

An additional important observation from these examples is that the maximum depth of a PK-tree with  $N$  nodes is  $O(N)$ , and thus the worst-case input/output time complexity to search (as well as update) is  $O(N)$ . Thus, we see that the PK-tree does not behave well (from the perspective of being a balanced structure) for skewed distributions of data as in our example, although Wang, Yang, and Muntz [1952] have shown that, under certain assumptions on the probability distribution of the data (including uniformly distributed data [2043]), the expected search cost is  $O(\log N)$ .

It is interesting to observe that, as in all methods based on the conventional application of regular decomposition, insertion and deletion of a point in a PK-tree may cause a substantial number of operations analogous to node splitting and merging, respectively, to take place. However, the process is not so clearly identifiable as one of pure merging (in the case of deletion, e.g., in a PR quadtree, a PR k-d tree, or an MX quadtree) and pure splitting (in the case of insertion, e.g., in a PR quadtree, a PR k-d tree, or an MX quadtree). The analogs of splitting and merging are the processes of  $k$ -instantiation and  $k$ -deinstantiation, respectively. However, both of these processes may take place in a PK-tree when inserting, as well as deleting, a point, whereas in the methods based on conventional application of regular decomposition, nodes are either split or merged but not both.

In fact, as we have seen, the amount of splitting and merging that is needed in a PK-tree may be as large as the maximum depth of the tree. This occurs because  $k$ -instantiation is defined in a bottom-up manner, resulting in the possible propagation of the effects of updates as high as the root. In contrast, in the methods that are based on pure path compression (i.e., path-compressed PR k-d tree, path-level compressed PR k-d tree, and the BD-tree), a node split or merge takes place just once rather than multiple times, as is the case for the structures from which they are derived (i.e., the PR and MX quadtrees and their corresponding k-d tree variants) as there are no empty nodes to merge. Notice that the PMR k-d tree and PMR quadtree (see Section 1.5.2) are somewhat anomalous in that the splits take place just once (assuming point objects), while the merges can happen across several levels.

The PK-tree still suffers from a sensitivity to skewness despite some claims to the contrary [1952, 2043]. This can be seen by the worst-case examples for  $k = 5$  shown in Figures 1.115 and 1.117. The linear nature of the worst case of tree structures resulting from the use of a regular decomposition process that plagues all decomposition methods that are insensitive to the order of insertion can never be completely avoided. In contrast, the linear nature of the worst case of tree structures resulting from the use of methods that are not based on a regular decomposition process (e.g., the worst case of a binary search tree when the data is processed in sorted order and, likewise, for the worst case of the point quadtree) can be avoided by changing the order of insertion. Nevertheless, for the tree structures that result from the use of a regular decomposition process, we at least can avoid the tests that do not lead to differentiation between data. This is the effect of path compression in the path-compressed PR k-d tree, path-level compressed PR k-d tree, and the BD-tree. Moreover, the skewed data distributions are quite rare, and, in addition, the relatively large values of  $k$  ensure that the resulting trees are relatively shallow.

Interestingly, recalling Section 1.5.2, the PMR approach (both the PMR quadtree and the PMR k-d tree) is also motivated by a desire to avoid too many split operations. While the PMR approach does not employ path compression explicitly, it has the same effect when we recall that, with each newly added data item, we split the block containing it once, and only once. This can be viewed as a form of an inverse of path compression. In particular, in the bucket PR quadtree, the alternative to the PMR quadtree, we always split blocks whose occupancy is greater than the bucket capacity. The effect is that a block may be split and resplit repeatedly for the same insertion. In contrast, in the PMR quadtree, we protract the splitting process by performing it at most once for each insertion. We say that the effect is like the inverse of path compression because the fact that initially we perform only one split is analogous to performing path compression on all but one

level. As more data items are added, we slowly undo the path compression by splitting the block each time it gains a member. Recall that this test elimination is what makes these representations similar in spirit to the Patricia trie [792, 1315].

In some sense, what we have achieved with structures such as the PK tree and those involving path and level compression that were discussed in Section 1.5.2, and, to a lesser degree, in the PMR k-d tree and PMR quadtree, is to make these structures more similar to the point quadtree and k-d tree in that each test leads to the differentiation between at least two data items. The result is that the space requirements are proportional to the number of data items instead of the inverse of the minimum separation between two data items. Thus, using the PK-tree and the related methods based on path and level compression has enabled us to achieve the best of both worlds in the sense that we have the benefits of regular decomposition while requiring  $O(N)$  space, thereby avoiding the customary dependence on the resolution of the underlying space (i.e., the maximum number of decomposition steps).

An alternative characterization of what we have been able to achieve is that, in terms of the space requirements, we have the best of the image-space (i.e., regularity of the decomposition process, thereby enabling us to take advantage of the fact that the data is in registration, which facilitates set-theoretic operations) and object-space (i.e.,  $O(N)$  space requirements) representations. The latter is achieved primarily by virtue of the almost total elimination of empty children when a k-d tree variant is used (with the exception of the PMR k-d tree). This reduction in the space requirements has a direct impact on reducing the heights of the trees and hence the search time as tests are eliminated. However, it is important that we still do not have  $O(\log N)$  guaranteed tree heights and searches, as is possible with object-space representations when data is moved in the structure after insertion to achieve balance. The possible downside of such an approach is that the resulting representation is not unique, whereas this is usually the case for most image-space methods.

Although we have stressed the differences between  $k$ -instantiation and bucketing, the concepts are related in that they both aggregate partition tree nodes into “supernodes” via the application of methods similar to level compression and, to a lesser extent, path compression. In particular, it should be clear that  $k$ -instantiation could also be defined in terms of the maximum enclosing quadtree (or k-d tree) block instead of the minimum enclosing quadtree block, but the insertion and deletion algorithms would be more complex (see Exercise 2). As we pointed out earlier, bucketing can be applied to most of the methods that involve path and level compression. The key advantage of the PK-tree is that bucketing (in the form of  $k$ -instantiation) is applied not just to the leaf nodes but also to the nonleaf nodes. The result, in the case of coupling the PK-tree with a PR k-d tree decomposition process, is a bucketing criterion that stipulates that each node has between  $k$  and  $2 \cdot (k - 1)$  elements. Thus, instead of having just a maximum bucket occupancy, we also have a minimum bucket occupancy. This resembles the classical B-tree definition, which is the result of applying a variation of bucketing to a binary search tree. The advantage of using the PK-tree over the method described in Section 1.8.1, where the PR quadtree (as well as a PR k-d tree) was combined with a  $B^+$ -tree, is that in the PK PR k-d tree, the blocks corresponding to the area spanned by the data in the nodes (both leaf and nonleaf) are always similar in the sense that for  $d$ -dimensional data there are  $d$  possible hyperrectangular block shapes. Recall from the discussion of Figure 1.112 in Section 1.8.1 that this was not the case for the combination of the PR quadtree (or any other space decomposition method where the blocks are represented by locational codes) and a  $B^+$ -tree. Another advantage of the PK-tree is that, in the case of nonleaf nodes, the bucket elements can be points (i.e., objects) or pointers to child nodes, rather than having to be just one type. This was seen to yield greater flexibility.

The PK-tree appears to be similar to bucket methods based on regular decomposition, such as the k-d-B-trie discussed in Section 1.7.1. In particular, the bucketing condition is only in terms of the nonempty regions resulting from the application of regular

decomposition of the underlying space. Similarly,  $k$ -instantiation is also only in terms of these nonempty regions. Nevertheless, there are some very important differences.

The most important difference is that in the PK-tree no distinction is made between data and directory nodes—that is, the PK-tree consists of the  $k$ -instantiated nodes of the corresponding partition tree (which may be data or directory nodes). Thus, points (or other objects) can appear in both leaf and nonleaf nodes of the PK-tree. This has the ramification that groups of points can stay grouped together in the same node for a much longer time than if bucketing was used. In particular, when using a bucket method, once two points are placed in the same bucket, they remain in the same bucket until it overflows, at which time they may be separated, whereas in the PK-tree these points are often moved between nodes as dictated by  $k$ -instantiation considerations. A drawback of having the points in both leaf and nonleaf nodes is that the fanout of the nonleaf nodes is potentially reduced, thereby leading to longer search paths since the height of the tree is longer. On the other hand, a drawback of storing only points in leaf nodes, as in the  $k$ -d-B-trie, is that the storage utilization of the leaf nodes may be low.

Another difference is that the PK-tree is defined in terms of a particular decomposition rule (i.e., the order in which the axes forming the underlying space are split is fixed). In contrast, the order is permitted to vary in the  $k$ -d-B-trie, thereby allowing a more compact representation of the regions that make up a nonleaf node and yielding a greater flexibility in splitting and merging of regions when updates take place. Of course, we could also use a variable splitting rule with the PK-tree, but this would complicate the process of detecting  $k$ -instantiation.

### Exercises

1. How would you adapt the PK-tree to a partitioning process that is not based on a regular decomposition of the underlying space? In particular, can you adapt it to a conventional point quadtree or a  $k$ -d tree?
2. Rewrite procedures PKINSERT and PKDELETE for a PK-quadtrees where the nonleaf nodes are defined in terms of a maximum enclosing quadtree block rather than a minimum enclosing quadtree block.
3. Write a procedure PKPOINTQUERY to perform a point query in a PK-tree.
4. Write a procedure PKRANGEQUERY to perform a range query in a PK-tree.

## 1.9 Conclusion

A principal motivation for our discussion of the representation of collections of multidimensional point data is the desire to be able to distinguish between the individual elements of the collections so that they can be retrieved efficiently on the basis of the values of their attributes. The key to the retrieval process is the fact that the values of the attributes can be ordered (i.e., a sort sequence exists for them). We are not concerned with retrieval on the basis of values that cannot be ordered. Much of our presentation (for both one-dimensional and multidimensional point data) has differentiated the representations on the basis of whether they organize the data to be stored according to its value (termed *tree-based* earlier) or whether they organize the values of the embedding space from which the data is drawn (termed *trie-based* earlier). In either case, the effect is to decompose the space (i.e., domain) from which the data is drawn into groups. The representations are further differentiated on the basis of how the ranges of the boundaries of the spatial units corresponding to the groups are determined, the nature of the grouping process, and how the groups are accessed.

In this section we present a taxonomy that includes many of the representations that were described in this chapter. Some of those that are not explicitly discussed here are

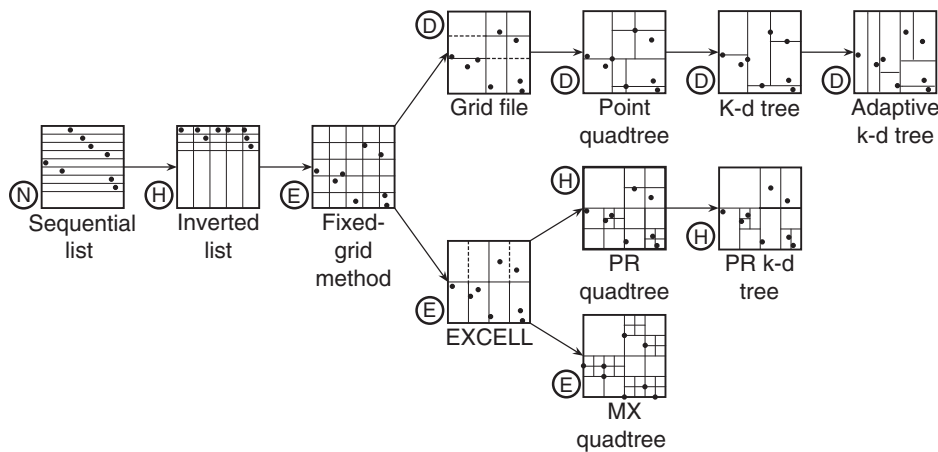

Figure 1.118  
Tree representation of the interrelationship among the different data structures discussed in this chapter using the data in Figure 1.1.

a subject of Exercises 1–5. To understand their interrelationship better, we make use of Figure 1.118, a tree whose nodes are different representations. Each node in the tree is labeled with the name of the corresponding representation and contains a drawing that is an approximation of how it represents the two-dimensional data of Figure 1.1. The nodes of the tree are also labeled with a classification indicating whether they organize the data based on its values (denoted by D), organize the embedding space from which the data is drawn (denoted by E), or neither organize the data nor the embedding space from which it is drawn (denoted by N). We also makes use of an additional classification denoted by H indicating that the representation exhibits behavior that we associate with at least two of D, E, and N.

The depths of the nodes in the tree also convey important information on the relationship between the various data structures. We assume that the root of the tree is at depth 0. Our taxonomy reflects the fact that all of the representations are based on a decomposition of the underlying space into spatial elements termed *cells*. The tree reflects a progression from representations based on a fixed grid to ones based on an adaptive grid. The latter means that we have flexibility with respect to the size and shape of the cells. This progression also mirrors closely the transition from the use of access structures (i.e., directories) in the form of fixed grids (i.e., arrays) to trees in the sense that an adaptive grid usually requires some variant of a tree access structure. We make no special provision for the bucket methods that make use of a tree directory. Similarly, we make no special provisions for the methods that are used with the PK-tree. In particular, we view them as natural methods of grouping more than one item in a cell. This is not the case for some of the bucket methods that make use of a grid directory that are shown in the tree, in which case we use a bucket capacity of 2. When the access methods are trees, there are many choices for the type of the tree. We do not assume a particular choice for the tree.

Note that our characterizations are not necessarily unique. Other characterizations are undoubtedly equally valid (see Exercise 8), and we may have omitted some characterizations or data structures (see Exercise 5). Nevertheless, we have tried to place each of the data structures discussed in the previous sections in an appropriate position relative to the other representations.

Depth 0 represents no identifiable organization of the data. The data is maintained in a sequential list that usually corresponds to the order in which it was inserted into the database. In the example in Figure 1.118, we have drawn the sequential list so that the elements are in the same order from top to bottom as they appear in Figure 1.1. The position of the point in each row corresponds to the value of its  $x$  coordinate.

Depth 1 corresponds to a partition of space that takes only one key into consideration. The inverted list appears at this depth and is characterized as hybrid. The key governing the partition exhibits behavior of type D. In contrast, the data values of the remaining keys have no influence on the way the space is organized and hence exhibit behavior of type N. In the example in Figure 1.118, we have assumed an inverted list for the key corresponding to the  $x$  coordinate. The position of the point in each entry corresponds to the value of its  $x$  coordinate. At this depth, we find the simplest types of cells.

At depth 2, all keys are taken into account, resulting in a partition that yields a decomposition into a fixed number of cells. Although we do not do so here, we could distinguish between cells of equal size and of varying size. The fixed-grid method, type E, is an example of the former. There are several ways of realizing cells of varying size, although they are not discussed in this chapter. For example, we could have a grid of cells of unequal size, which would require an additional data structure, such as linear scales, to locate the partition lines. Such a data structure would be of type D. Both this and the fixed-grid methods make use of a directory in the form of an array. An alternative is to use a recursive decomposition process to generate the partition into a fixed number of cells. An example of such a representation is the Dynamically Quantized Pyramid (DQP) [1777, 1425], which is a recursive decomposition into  $2^d$  hyperrectangular cells that need not be of equal size. The DQP requires a directory in the form of a tree and would also be of type D.

Depth 3 is a generalization of depth 2. It permits the cells of the representations at depth 2 to vary in number. The amount of variation depends on the volume of the data. The goal is not to fill a cell beyond its capacity. Thus, the decomposition is adaptive. The fixed-grid method is refined to yield the grid file, type D, with cell boundaries that are allowed to vary, and EXCELL, type E, with cell boundaries at predetermined positions. Notice that the representations at this level (as well as most of the ones at depth 2) use directories in the form of arrays to access the data. However, in the case of the grid file, an additional access structure in the form of a tree is needed to determine the cell of the array that corresponds to a given point since the boundaries of the cells are free to vary. In addition, the representations at depth 3 enable the retrieval of a record in constant time.

The representations at depth 4 differ from those at depth 3 in that when a cell becomes too full (i.e., it overflows), only that particular cell is partitioned. In contrast, assuming  $d$ -dimensional data, at depth 3, a partition is made over a  $(d - 1)$ -dimensional cross section. This means that we can no longer make use of a directory in the form of an array. Instead, we make use of directories in the form of a tree. The partition in the representations at depth 4 results in a cell's being decomposed into  $2^d$  cells. At this depth, we find that the grid file is refined to yield the point quadtree of type D. EXCELL is refined to yield an MX quadtree of type E and a PR quadtree of type H. The PR quadtree is of type H because the partition points are fixed; however, the number of partition points depends on the relative position of the data points.

When a cell in one of the representations at depth 5 overflows, it is partitioned but decomposed into only two cells in contrast with  $2^d$  for depth 4. The partitions that are made at the different levels in the relevant data structures cycle through the keys. At this depth, we find that the point quadtree is refined to yield a k-d tree of type D, and the PR quadtree is refined to yield a PR k-d tree of type H.

When a cell in one of the representations at depth 6 overflows, a partition is made using the key that has the greatest spread in values across the cell. Thus, we no longer need to cycle through the various keys as was done for the representations at depth 5. The adaptive k-d tree of type D (as well as the fair-split tree and the VAMSplit k-d tree) is an example of this class of data structure (also characterized as a generalized pseudo k-d tree in Section 1.5.1.4).

The representations at depth 4 to 6 are usually implemented using access structures in the form of a tree with fanout  $2^d$  for depth 4 and fanout 2 for depths 5 and 6. However,

they can also be implemented by representing each of the cells by a unique number  $n$  that corresponds to the location of some easily identifiable point in the block (i.e., its lower-right corner) and its size, also known as a locational code.  $n$  is stored in one of the one-dimensional access structures, such as a binary search tree or B-tree, along with the actual point that is associated with the cell. Such representations are discussed in greater detail in Sections 2.1.1.4 and 2.1.2.4 of Chapter 2. Observe that use of the tree access structure results in an implicit aggregation of the space spanned by the cells that are being aggregated. This is in contrast to representations that aggregate the objects (i.e., points) that are stored in the cells, in which case the space occupied by the points must be aggregated explicitly (e.g., by use of minimum bounding boxes as is done in the R-tree).

At this point, let us examine how some of the other representations that we discussed fit into our taxonomy. Representations such as the range tree and the priority search tree (as well as the range priority tree), although not shown explicitly in Figure 1.118, belong at depth 1 because they correspond to the result of the imposition of an access structure on the inverted list. Recall that the inverted list is nothing more than a decomposition of the underlying space into one-dimensional cells. The one-dimensional range tree provides an access structure on just one attribute, while the multidimensional range tree corresponds to the result of the recursive application of range trees of one fewer attribute to range trees. The drawback of the multidimensional range tree is the high space requirements since the data must be replicated. The priority search tree is like a range tree on one attribute (i.e., the one for which we have the inverted list) with the addition of a heap on the remaining attribute.

Notice that, with the exception of the grid file and EXCELL, we did not include the bucket methods that make use of a tree directory in our taxonomy. The reason is that the basic idea behind these bucket methods is the grouping of several items in a cell (e.g., the bucket PR quadtree), as well as the application of the grouping to the cells (e.g., the k-d-B-tree, k-d-B-trie, LSD tree, hB-tree, BV-tree, VAMSplit tree). However, the basic idea is still the same in the sense that the principle behind the underlying organization is one of the representations at depths 4–6. Of course, the difference is that the internal nodes of the tree have a higher fanout.

It is important to observe that our classification (i.e., Figure 1.118) has not included any of the data structures that are used to support the one-dimensional orderings. This is to be expected as once the data has been ordered in this way (regardless of whether the attributes are locational or nonlocational), we are representing the ordering rather than the actual data. The elements of the ordering are not multidimensional points in a true sense. Nevertheless, they can be viewed as multidimensional points of dimension 1. In this case, their representation fits into some of the categories that we have defined. For example, the binary search tree and B-tree would fit into the same classification as the point quadtree.

Notice also that our classification system did not contain any of the grid directory representations, such as linear hashing, quantile hashing, PLOP hashing, and spiral hashing, as they do not generally result in a new method of decomposing the underlying space. They are primarily implementations of the grid directory methods that provide an alternative in the form of a one-dimensional directory to the use of a  $d$ -dimensional directory, as in the grid file and EXCELL. In addition, they have the important property that, since the directory is one-dimensional, the directory can grow in a more gradual manner. In particular, the directory grows by one directory element (referred to as a *grid cell*) at a time instead of by doubling (as in EXCELL) or by the volume (in terms of the number of grid cells) of the  $(d - 1)$ -dimensional cross section perpendicular to the key whose axis is being partitioned (as in the grid file).

Actually, the above statement that the one-dimensional grid directory methods do not result in a different decomposition of the underlying space is true only for linear hashing (with reversed bit interleaving as the hashing function), where the underlying

space is decomposed as in EXCELL, and for quantile hashing and PLOP hashing, which decompose the underlying space as in the grid file. On the other hand, this statement is not true for spiral hashing, which is probably the most radically different of these one-dimensional directory methods as it is the only method whose use does not result in decomposing the underlying space into hyperrectangular  $d$ -dimensional cells. Moreover, not all of the regions resulting from the decomposition are spatially contiguous.

Thus, our failure to include linear hashing, quantile hashing, and PLOP hashing is justified, while spiral hashing does not seem to have any place in our classification, as our entire discussion has been predicated on the fact that the underlying space is decomposed into hyperrectangular  $d$ -dimensional cells. In retrospect, perhaps the right place to insert a family of methods that include spiral hashing is at a depth between 1 and 2, which would distinguish between methods on the basis of the shape of the underlying cell (see also Exercise 6), as well as on whether the cells need to be spatially contiguous. It should be clear that, at this point, we have really only scratched the surface in our attempt at a classification. Many other methods are possible and desirable.

A taxonomy similar to the one that we discussed is used by Aref and Ilyas [70] in their development of the *spatial partitioning generalized search tree* (SP-GiST), an extensible index structure that can be made to behave in the same way as many of the data structures described in this chapter, as well as those described in the remaining chapters. In particular, Aref and Ilyas present a class of primitives that support the class of space partitioning unbalanced trees. As in our taxonomy, the data structures that they support are differentiated on the basis of whether they organize the data based on its values or organize the embedding space from which it is drawn. Their structure depends on the following parameters:

1. The type of data (e.g., points, lines, rectangles, regions, surfaces, volumes, words, etc.),
2. The decomposition fanout (e.g., the number of partitions at each level),
3. A halting rule for the decomposition process, which could be a function of the size of the underlying space,
4. Whether or not single-arc nodes are allowed (i.e., a node can have just one child as is the case in the path-compressed PR k-d tree),
5. Bucket size.

The above parameters give a rough specification of the data structure. The actual implementation requires more detailed primitives. Aref and Ilyas decompose these additional primitives into two sets. The first set contains *interface parameters*, which enable a more precise definition of the structure. They are an expansion of the above parameters. For example, an interesting primitive is *PathShrink*, which describes the structure of the internal nodes of the tree. It has three possible values:

1. Never Shrink: The data is inserted in the node at the maximum possible level of decomposition (e.g., an MX quadtree for point data).
2. Leaf Shrink: The data is inserted into the first candidate leaf node encountered in the search process (e.g., a PR quadtree for point data).
3. Tree Shrink: Internal nodes are merged in order to eliminate all internal nodes with just one child (e.g., a path-compressed PR k-d tree, as well as the Patricia trie).

A related primitive is *NodeShrink*, which determines if empty partitions should be retained in the tree (e.g., empty nodes in trees such as the point, MX, PR quadtrees).

The second set of primitives contains *external methods*, which enable the user to specify the basic actions used in searching and building the tree:

1. Consistent: This enables navigating the tree during a search.

2. PickSplit: This defines how to split a node when building the structure and adding data.
3. Cluster: This defines how nodes are clustered into disk pages.

Note that if deletion is allowed, then an additional primitive is needed to deal with merging or removal of nodes.

The SP-GiST is similar in spirit to the *Generalized Search Tree* (GiST) [66 817], but with some very important differences. In particular, the goal of GiST is to provide a single implementation for indexes based on the B-tree, such as the R-tree in the spatial domain. GiST is designed to deal with indexes that are based on object hierarchies, which means that the key principle is one of object aggregation and the maintenance of a balanced structure. The fact that the objects occupy space is used in deciding the composition of the aggregates, but the underlying space is never decomposed, although the space occupied by the objects is aggregated. In contrast, SP-GiST is designed to deal with indexes that are based on space hierarchies that are a direct result of a recursive disjoint decomposition of the space in which the objects are embedded or drawn from (i.e., domain). This decomposition may be based on the space or on the values of the data in the space. Thus, there is no guarantee of balance. Note also that the domain need not be spatial (e.g., it can be text or any other type on which a linear ordering can be imposed). Therefore, the distinction between GiST and SP-GiST is that the former is designed to deal with object hierarchies while the latter is designed to deal with space hierarchies. This distinction is explored in much greater detail in Section 2.1 of Chapter 2.

At this point, let us briefly comment on the generality of the representations that we have described. Our presentation and examples have been in terms of records, all of whose attribute values were locational or numeric. As stated in the opening remarks of the chapter, most of these representations can be generalized so that they are also applicable to records that contain additional nonlocational attributes, as well as only nonlocational attributes. Below, we briefly discuss how to achieve this generalization.

The tree-based methods are easily extended to deal with nonlocational attributes. In this case, the partitions are made on the basis of the values of the attributes and make use of the ordering that is used for each attribute's value. Thus, representations such as the point quadtree, k-d tree, and adaptive k-d tree, as well as the range tree and the priority search tree, can be used. This ordering can also serve as the basis of an inverted list as well as a grid file.

Extension of the trie-based methods to deal with nonlocational attributes is a bit more complex. The main issue is that many of the representations that we have discussed are based on a binary subdivision of the underlying domain of the attributes, thereby resulting in trees with two-way branches. In the case of the locational attributes, which are always numbers, this is quite simple as we use the representation of the values of the numeric attributes as binary digits. When the nonlocational attribute values can be treated as sequences of characters with  $M$  possible values, then we have  $M$ -way branches instead of two-way branches. Thus, representations such as the PR quadtree and PR k-d tree are easily adapted to nonlocational attributes. Similarly, we can also adapt the fixed-grid method as well as EXCELL. In fact, the  $M$  possible values of each of the characters can also be viewed as being composed of  $\lceil \log_2 M \rceil$  binary digits, and thus we can still use a two-way branch on the ordering of the individual characters making up the attribute's value.

Note that the MX quadtree cannot be adapted to the general situation where we have locational and nonlocational attributes. The problem is that the MX quadtree is appropriate only for the case that all of the attribute values have the same type and range. Moreover, the domain of the attribute values must be discrete. Of course, if these criteria are satisfied, then an appropriate variant of the MX quadtree can be used for nonlocational attributes.

1. How does the pseudo quadtree fit into the taxonomy of Figure 1.118?
2. How does the optimized point quadtree fit into the taxonomy of Figure 1.118?
3. How does the BD-tree fit into the taxonomy of Figure 1.118?
4. How do the range tree, priority search tree, inverse priority search tree, and multidimensional range tree fit into the taxonomy of Figure 1.118?
5. The taxonomy shown in Figure 1.118 could be formulated differently. First, we qualify the E and D categories as being of type 1 or  $d$ , depending on whether they take one or  $d$  dimensions into account. Also, let depth 3 be characterized as a refinement of depth 2 with overflow handling. Add another data structure, termed a *pyramid*, that yields a  $2^d$  growth in the directory upon a bucket overflow. Now, depth 4 can be recast as replacing a directory in the form of an array by a directory in the form of a tree. How would you rebuild depths 3–6 of Figure 1.118 using this new taxonomy?
6. How would you revise the taxonomy of Figure 1.118 to account for the fact that the shape of the cells into which the underlying space is decomposed need not be hyperrectangular (e.g., triangles)? In other words, include some decompositions that use these shapes. How does this generalize to dimensions higher than 2?
7. How would you revise the taxonomy of Figure 1.118 to account for the fact that the shape of the cells into which the underlying space is decomposed need not be hyperrectangular or spatially contiguous (e.g., spiral hashing)?
8. (Markku Tamminen) In the opening section of this chapter, several issues were raised with respect to choosing an appropriate representation for point data. Can you devise a taxonomy in the same spirit as Figure 1.118 using them? For example, let each depth of the tree correspond to a different property. At depth 0, distinguish between an organization of the data and an organization of the embedding space from which the data is drawn. At depth 1, distinguish between dynamic and static methods. At depth 2, distinguish between the number of keys on which the partition is being made. At depth 3, distinguish between the presence and absence of a directory. At depth 4, distinguish between the types of directories (e.g., arrays, trees). At depth 5, distinguish between bucket and nonbucket methods.
9. How would you adapt SP-GiST to deal with the PK-tree? Recall that the PK-tree decouples the partition process from the grouping process. Is it enough to modify the *PathShrink* and *NodeShrink* primitives?
10. The Euclidean matching problem consists of taking a set of  $2 \cdot N$  points in the plane and decomposing it into the set of disjoint pairs of points so that the sum of the Euclidean distances between the components of each pair is a minimum. Would any of the representations discussed in this chapter facilitate the solution of this problem? Can you solve this problem by building a set of pairs, finding the closest pair of points, discarding it, and then applying the same procedure to the remaining set of points? Can you give an example that demonstrates that this solution is not optimal?
11. Exercise 10 proposes one solution to the Euclidean matching problem. An alternative solution proceeds in a manner analogous to that used in constructing the adaptive k-d tree in Section 1.5.1.4. In essence, we sort the points by increasing  $x$  and  $y$  coordinate values and then split them into two sets by splitting across the coordinate with the largest range. This process is applied recursively. Implement this method and run some experiments to show how close it comes to achieving optimality. Can you construct a simple example where the method of Exercise 10 is superior?
12. Suppose that you are given  $N$  points in a two-dimensional space and a rectangular window, say  $R$ , whose sides are parallel to the coordinate axes. Find a point in the plane at which the window can be centered so that it contains a maximum number of points in its interior. The window is not permitted to be rotated—it can be translated only to the point. Would any of the representations discussed in this chapter facilitate the solution of this problem?

---

# Object-Based and Image-Based Image Representations

---

The representation of spatial objects and their environment is an important issue in applications of computer graphics, game programming, computer vision, image processing, robotics, pattern recognition, and computational geometry (e.g., [91, 1636, 1637, 1811]). The problem also arises in building databases to support them (e.g., [1638]). We assume that the objects are connected<sup>1</sup> although their environment need not be. The objects and their environment are usually decomposed into collections of more primitive elements (termed *cells*) each of which has a location in space, a size, and a shape. These elements can either be subobjects of varying shape (e.g., a table consists of a flat top in the form of a rectangle and four legs in the form of rods whose lengths dominate their cross-sectional areas), or they can have a uniform shape. The former yields an *object-based* decomposition; the latter yields an *image-based*, or *cell-based*, decomposition. Another way of characterizing these two decompositions is that the former decomposes the objects, while the latter decomposes the environment in which the objects lie. This distinction is used commonly in computer graphics to characterize algorithms as being either object-space or image-space, respectively [622].

Each of the decompositions has its advantages and disadvantages. They depend primarily on the nature of the queries that are posed to the database. The most general queries ask *where*, *what*, *who*, *why*, and *how*. The ones that are relevant to our application are *where* and *what* [1642]. They are stated more formally as follows:

1. Feature query: Given an object, determine its constituent cells (i.e., their locations in space).
2. Location query: Given a cell (i.e., a location in space), determine the identity of the object (or objects) of which it is a member, as well as the remaining constituent cells of the object (or objects).

Not surprisingly, the queries can be classified using the same terminology that we used in the characterization of the decomposition. In particular, we can either try to find the cells (i.e., their locations in space) occupied by an object or find the objects that overlap a cell (i.e., a location in space). If objects are associated with cells so that a cell contains the identity of the relevant object (or objects), then the feature query is analogous to retrieval by contents while the location query is analogous to retrieval by location. As we will see, it is important to note that there is a distinction between a location in space and the address where information about the location is stored, which, unfortunately, is often erroneously assumed to be the same.

---

<sup>1</sup> Intuitively, this means that a  $d$ -dimensional object cannot be decomposed into disjoint subobjects so that the subobjects are not adjacent in a  $(d - 1)$ -dimensional sense.

The feature and location queries are the basis of two more general classes of queries. In particular, the feature query is a member of a broader class of queries described collectively as being *feature-based* (also *object-based*), and the location query is a member of a broader class of queries described collectively as being *location-based* (also *image-based* or *cell-based*). In computational geometry, the location query is known as the *point location query* or *problem* (e.g., [1511, 196] and Sections 2.1.3.2 and 2.1.3.3). In other domains, it is also commonly referred to as a *point query*, in which case we must be careful to distinguish it from its narrower and broader definitions. In particular, in database applications, a point query has a narrower definition—it is really an exact match query as it seeks to determine if the data point corresponding to the location is in the database (e.g., [1046] and the introduction to Chapter 1), and thus whenever possible we use the term *exact match query* in this context. On the other hand, in computer graphics applications, the point query has a broader definition and is often synonymous with the related “pick” operation (e.g., [622]), which is used to find an object that contains a given location  $l$ , and if there is none, then to find the nearest object to  $l$ . In order to avoid overloading the term *point query* in this chapter we use the term *nearest object query* when a satisfactory response includes the nearest object should no object exist that contains  $l$ .<sup>2</sup> Therefore, in this chapter, the term *point query* has the same meaning as in Chapter 3, where the response is restricted to the objects that contain  $l$ . The class of location-based queries includes the numerous variants of the *window query*, which retrieves the objects that cover an arbitrary region (often rectangular). All of these queries are used in several applications including geographic information systems (e.g., [72, 1645]) and spatial data mining (e.g., [1953]).

The most common representation of the objects and their environment is as a collection of cells of uniform size and shape (termed *pixels* and *voxels* in two and three dimensions, respectively) all of whose boundaries (with dimensionality one less than that of the cells) are of unit size. Since the cells are uniform, there exists a way of referring to their locations in space relative to a fixed reference point (e.g., the origin of the coordinate system). An example of a location of a cell in space is a set of coordinate values that enables us to find it in the  $d$ -dimensional space of the environment in which it lies. Once again, we reiterate that it should be clear that the concept of the *location* of a cell in space is quite different from that of the *address* of a cell, which is the physical location (e.g., in memory, on disk), if any, where some of the information associated with the cell is stored. This distinction between the location in space of a cell and the address of a cell is important, and we shall make use of it often.

Figure 2.1  
Example collection of three objects  
and the cells that they occupy.

In most applications (including most of the ones that we consider here), the boundaries (i.e., edges and faces in two and three dimensions, respectively) of the cells are parallel to the coordinate axes. In our discussion, we assume that the cells making up a particular object are contiguous (i.e., adjacent) and that a different, unique value is associated with each distinct object, thereby enabling us to distinguish between the objects. Depending on the underlying representation, this value may be stored with the cells. For example, Figure 2.1 contains three two-dimensional objects, A, B, and C, and their corresponding cells. Note that, although it is not the case in this example, objects are allowed to overlap, which means that a cell may be associated with more than one object. Here we assume, without loss of generality, that the volume of the overlap must be an integer multiple of the volume of a cell (i.e., pixels, voxels, etc.).

The shape of an object  $o$  can be represented either by the interiors of the cells making up  $o$ , or by the subset of the boundaries of those cells making up  $o$  that are adjacent to the boundary of  $o$ . In particular, interior-based methods represent an object  $o$  by using the locations in space of the cells that make up  $o$ , while boundary-based methods represent  $o$  by using the locations in space of the cells that are adjacent to the boundary of  $o$ .

<sup>2</sup> A more general term is *nearest neighbor query*, which is discussed in a more general context and in much greater detail in Sections 4.1–4.3 of Chapter 4.

In general, interior-based representations make it very easy to calculate properties of an object such as its mass and, depending on the nature of the aggregation process, to determine the value associated with any point (i.e., location) in the space covered by a cell in the object. On the other hand, boundary-based representations make it easy to obtain the boundary of an object.

Regardless of the representation that is used, the generation of responses to the feature and location queries is facilitated by building an index (i.e., the result of a sort) either on the objects or on their locations in space, and implementing it using an access structure that correlates the objects with the locations. Ideally, we want to be able to answer both types of queries with one representation. This is somewhat tricky, but, as we will show, it is doable.

The rest of this chapter is organized as follows. Section 2.1 discusses interior-based representations. These are the most prevalent, and thus this discussion forms the main part of the chapter. Section 2.2 discusses boundary-based representations. The discussion in these sections shows how some of the representations can be made more compact by aggregating similar elements. These elements are usually identically valued contiguous cells (possibly adjacent to identically oriented boundary elements) or even objects that, ideally, are in proximity. The representations can be made even more compact by recording only the differences between the elements. The use of difference-based compaction methods is the subject of Section 2.3. Many of the representations that we have described are based on the principle of recursive decomposition of the underlying space (as well as the aggregation of the results of the decomposition). Therefore, we conclude in Section 2.4 with a brief historical overview of this principle and some of its early uses.

As stated earlier, most of our discussion assumes that the objects can be decomposed into cells whose boundaries are parallel to the coordinate axes. Nevertheless, we discuss the representation of objects with boundaries that are hyperplanes (i.e., straight lines and planar faces for two- and three-dimensional objects, respectively), as well as objects with arbitrary boundaries (e.g., edges of arbitrary slope, nonplanar faces). In this case, the representation of the underlying environment is usually, but not always, based on a decomposition into cells whose boundaries are parallel to the coordinate axes.

## 2.1 Interior-Based Representations

In this section, we focus on interior-based representations. Section 2.1.1 examines representations based on collections of unit-size cells. An alternative class of interior-based representations of the objects and their environment removes the stipulation that the cells that make up the object collection be a unit size and permits their sizes to vary. The varying-sized cells are termed *blocks* and are the subject of Section 2.1.2. The representations described in Sections 2.1.1 and 2.1.2 assume that each unit-size cell or block is contained entirely in one or more objects. A cell or block cannot be partially contained in two objects. This means that either each cell in a block belongs to the same object or objects, or that all of the cells in the block do not belong to any of the objects. Section 2.1.3 permits both the blocks and the objects to be arbitrary polyhedra while not allowing them to intersect, although permitting them to have common boundaries. Section 2.1.4 permits a cell or block to be a part of more than one object and does not require the cell or block to be contained in its entirety in these objects. In other words, a cell or a block may overlap several objects without being completely contained in them. This also has the effect of permitting the representation of collections of objects whose boundaries do not coincide with the boundaries of the underlying blocks and also permitting them to intersect (i.e., overlap). Section 2.1.5 examines the use of hierarchies of space and objects that enable efficient responses to both the feature and location queries.

### 2.1.1 Unit-Size Cells

Interior-based representations aggregate identically valued cells by recording their locations in space. We say that a representation that makes use of an aggregation is *explicit* if the identities of the contiguous cells that form the object are hardwired into the representation. An example of an explicit aggregation is one that associates a set with each object  $o$  that contains the location in space of each cell that  $o$  comprises. In this case, no identifying information (e.g., the object identifier corresponding to  $o$ ) is stored in the cells. Thus, there is no need to allocate storage for the cells (i.e., no addresses are associated with them). One possible implementation of this set is a list.<sup>3</sup> For example, consider Figure 2.1 and assume that the origin (0,0) is at the upper-left corner. Assume further that this is also the location of the pixel that abuts this corner. Therefore, the explicit representation of object B is the set of locations  $\{(5,1) (6,0) (6,1) (7,0) (7,1)\}$ . It should be clear that using the explicit representation, given an object  $o$ , it is easy to determine the cells (i.e., locations in space) that it (the feature query) comprises.

Of course, even when using an explicit representation, we must still be able to access object  $o$  from a possibly large collection of objects, which may require an additional data structure, such as an index on the objects (e.g., a table of object-value pairs, where *value* indicates the entry in the explicit representation corresponding to *object*). This index does not make use of the spatial coverage of the objects and thus may be implemented using conventional searching techniques such as hashing [1046]. In this case, we will need  $O(N)$  additional space for the index, where  $N$  is the number of different objects. We do not discuss such indexes here.

The fact that no identifying information as to the nature of the object is stored in the cell means that the explicit representation is not suited for answering the inverse query of determining the object associated with a particular cell at location  $l$  in space (i.e., the location query). Using the explicit representation, the location query can be answered only by checking for the presence of location  $l$  in space in the various sets associated with the different objects. This will be time-consuming because it may require that we examine all cells in each set. It should be clear that the explicit representation could also be classified as being *object-based* as it clearly lends itself to retrieval only on the basis of knowledge of the objects rather than of the locations of the cells in space. We shall make use of this characterization in Section 2.1.5.

Note that since the explicit representation consists of sets, there is no particular order for the cells within each set although an ordering could be imposed based on spatial proximity of the locations of the cells in space, and so on. For example, the list representation of a set already presupposes the existence of an ordering. Such an ordering could be used to obtain a small, but not insignificant, decrease in the time (in an expected sense) needed to answer the location query. In particular, now, whenever cell  $c$  is not associated with object  $o$ , we will be able to cease searching the list associated with  $o$  after having inspected half of the cells associated with  $o$  instead of all of them, which is the case when no ordering exists.

An important shortcoming of the use of the explicit representation, which has an effect somewhat related to the absence of an ordering, is the inability to distinguish between occupied and unoccupied cells. In particular, in order to detect that a cell  $c$  is not occupied by any object, we must examine the sets associated with each object, which is quite time-consuming. Of course, we could avoid this problem by forming an additional set that contains all of the unoccupied cells and examine this set first whenever

---

<sup>3</sup> It is important to note that although, on the surface, there seems to be little difference between a list and a set, this is misleading. From a mathematical standpoint, they are worlds apart. As far as our discussion is concerned, the key distinction between them is the concept of order. In a *set*, the order of the items is irrelevant—the crucial property is the presence or absence of the item. In particular, each item can only appear once in the set. In contrast, in a *list*, the order of the items is the central property. An intuitive definition of a list is that item  $x_k$  appears before item  $x_{k+1}$ . Items may appear more than once in a list.

processing the location query. The drawback of such a solution is that it slows down all instances of the location query that involve cells that are occupied by objects.

We can avoid examining every cell in each object set, thereby speeding up the location query in certain cases, by storing a simple approximation of the object with each object set  $o$ . This approximation should be of a nature that makes it easy to check if it is impossible for a location  $l$  in space to be in  $o$ . One commonly used approximation is a minimum bounding box whose sides are parallel to the coordinate axes of the space in which the object is embedded (also known as an *axis-aligned bounding box* (AABB)). For example, for object  $B$  in Figure 2.1, such a box is anchored at the lower-left corner of cell (5,1) and the upper-right corner of cell (7,0). The existence of a box  $b$  for object  $o$  means that if  $b$  does not contain  $l$ , then  $o$  does not contain  $l$  either, and we can proceed with checking the other objects. This bounding box is usually a part of the explicit representation.

There are several ways of increasing the quality of the approximation. For example, the minimum bounding box may be rotated by an arbitrary angle so that the sides are still orthogonal while no longer having to be parallel to the coordinate axes, termed an *oriented bounding box tree* (OBB-tree) (e.g., [261, 735, 1548]). The number of sides, as well as the number of their possible orientations, may be expanded so that it is arbitrary (e.g., a convex hull [261]) or bounded, although greater than the dimensionality of the underlying space (e.g., the P-tree [939];  $g$ -degrees rotated  $x$ -range [1923]; k-DOP [1038], where the number  $k$  of possible orientations is bounded; and the minimum bounding polybox [266], which attempts to find the optimal orientations). The most general solution is the convex hull, which is often approximated by a minimum bounding polygon of a fixed number of sides having either an arbitrary orientation (e.g., the minimum bounding  $n$ -corner [504, 1687, 1688]) or a fixed orientation, usually parallel to the coordinate axes (e.g., [569]). Restricting the sides (i.e., faces in dimension higher than 2) of the polyhedron to be parallel to the coordinate axes (termed an *axis-parallel polygon*) enables simpler point-in-object tests (e.g., the vertex representation [565, 566, 567], which is discussed in greater detail in Section 2.3.3). The minimum bounding box may also be replaced by a circle, sphere (e.g., the sphere tree [895, 896, 1399, 1410, 1412, 1991]), ellipse, or intersection of the minimum bounding box with the minimum bounding sphere (e.g., the SR-tree [999]), as well as other shapes (e.g., [261]).

In the rest of this chapter, we restrict our discussion to minimum bounding boxes that are rectangles with sides parallel to the coordinate axes, although, of course, the techniques we describe are applicable to other, more general, bounding objects. Nevertheless, in the interest of brevity, we often use the term *bounding box*, even though the terms *minimum bounding box* or *minimum bounding object* would be more appropriate. For a thorough discussion of the numerous variants of the bounding boxes discussed above and algorithms for using them for collision detection in applications such as game programming, see the recent texts of van den Bergen [198] and Ericson [564].

The location query can be answered more directly if we allocate an address  $a$  in storage for each cell  $c$  where an identifier is stored that indicates the identity of the object (or objects) of which  $c$  is a member. Such a representation is said to be *implicit* as in order to determine the rest of the cells that make up (i.e., are aggregated to form) the object associated with  $c$  (and thus complete the response to the location query), we must examine the identifiers stored in the addresses associated with the contiguous cells and then aggregate the cells whose associated identifiers are the same. However, in order to be able to use the implicit representation, we must have a way of finding the address  $a$  corresponding to  $c$ , taking into account that there is possibly a very large number of cells, and then retrieving  $a$ .

Finding the right address requires an additional data structure, termed an *access structure*, such as an index on the locations in space. An example of such an index is a table of cell-address pairs, where *address* indicates the physical location where the information about the object associated with the location in space corresponding to *cell* is stored. The table is indexed by the location in space corresponding to *cell*. The index

is really an ordering and hence its range is usually the integers (i.e., one-dimensional). When the data is multidimensional (i.e., cells in  $d$ -dimensional space where  $d > 0$ ), it may not be convenient to use the location in space corresponding to the cell as an index since its range spans data in several dimensions. Instead, we employ techniques such as laying out the addresses corresponding to the locations in space of the cells in some particular order and then making use of an access structure in the form of a mapping function to enable the quick association of addresses with the locations in space corresponding to the cells. Retrieving the address is more complex in the sense that it can be a simple memory access, or it may involve an access to secondary or tertiary storage if virtual memory is being used. In most of our discussion, we assume that all data is in main memory, although, as we will see, several representations do not rely on this assumption.

Such an access structure enables us to obtain the contiguous cells (as we know their locations in space) without having to examine all of the cells. Therefore, we will know the identities of the cells that make up an object, thereby enabling us to complete the response to the location query with an implicit representation. In the rest of this section, we discuss several such access structures. However, before proceeding further, we wish to point out that the implicit representation could also be classified as *image-based* as it clearly lends itself to retrieval on the basis of knowledge only of the cells rather than of the objects. We shall make use of this characterization in Section 2.1.5.

The existence of an access structure also enables us to answer the feature query with the implicit representation, although this is quite inefficient. In particular, given an object  $o$ , we must exhaustively examine every cell (i.e., location  $l$  in space) and check if the address where the information about the object associated with  $l$  is stored contains  $o$  as its value. This will be time-consuming because it may require that we examine all the cells.

### 2.1.1.1 Cell Shapes and Tilings

There is a seemingly endless set of possible shapes for the unit-size cells. The shape that is ultimately chosen has a great effect on the operations and algorithms that can be executed on the data, especially in light of the fact that the unit-size cells will eventually be aggregated. The unit-size cells result from the application of a decomposition process to the underlying space (i.e., the environment containing the objects). In order to limit the verbosity of our explanation, we use the term *image* to refer to the environment comprising the unit-size cells that are in the objects and those that are not in any of the objects. In this section, unless otherwise stated, we restrict ourselves to the two-dimensional plane. In general, any planar decomposition that is used as a basis for an image representation should possess the following two properties:

1. The partition should be an infinitely repetitive pattern so that it can be used for images of any size.
2. The partition should be infinitely decomposable into increasingly finer patterns (i.e., higher resolution). This means that the size of the unit-size cells has no minimum.

Space decompositions can be classified into two categories, depending on the nature of the resulting shape. The shape can be either polygonal or nonpolygonal. Polygonal shapes are generally computationally simpler since their sides can be expressed in terms of linear relations (e.g., equations of lines). They are good for approximating the interior of a region. Also, they can be joined to form a tiling so that they span the entire space while being nonoverlapping.

On the other hand, the nonpolygonal shapes are more flexible since they provide good approximations, in terms of measures, of the boundaries (e.g., perimeter) of regions, as well as their interiors (e.g., area). Moreover, the normals to the boundaries of nonpolygonal shapes are not restricted to a fixed set of directions. For example, in the case of rectangular tiles, there is a 90 degree discontinuity between the normals to

boundaries of adjacent tiles. This lack of continuity is a drawback in applications in fields like computer graphics where such tasks as shading make use of the directions of the surface. However, working with nonpolygonal shapes generally requires use of floating-point arithmetic; hence, it is usually more complex. Thus, we limit our discussion to polygonal shapes.

Bell, Diaz, Holroyd, and Jackson [157] discuss a number of polygonal tilings of the plane (i.e., tessellations) that satisfy property 1. Figure 2.2 illustrates some of these tessellations. They also present a taxonomy of criteria to distinguish between the various tilings. The tilings, consisting of polygonal tiles, are described by use of a notation that is based on the degree of each vertex as the edges (i.e., sides) of the “atomic” tile (i.e., unit-size cell) are visited in order, forming a cycle. For example, the tiling described by  $[4.8^2]$  (see Figure 2.2(c)) has the shape of a triangle where the first vertex has degree four while the remaining two vertices have degree eight apiece.

A tiling is said to be *regular* if the atomic tiles are composed of regular polygons (i.e., all sides are of equal length, as are the interior angles). A *molecular tile* is an aggregation of atomic tiles to form a *hierarchy*, also more commonly referred to as a *block* in our discussion. The molecular tile (i.e., block) is not necessarily constrained to have the same shape as the atomic tile (i.e., unit-size cell). When a tile at level  $k$  (for all  $k > 0$ ) has the same shape as a tile at level 0 (i.e., it is a scaled image of a tile at level 0), then the tiling is said to be *similar*.

Bell et al. focus on the *isohedral* tilings—a tiling is said to be isohedral if all the tiles are equivalent under the symmetry group of the tiling. A more intuitive way to conceptualize this definition is to assume the position of an observer who stands in the center of a tile having a given orientation and scans the surroundings. If the view is independent of the tile, then the tiling is isohedral. For example, consider the two tilings in Figure 2.3 consisting of triangles (Figure 2.3(a)) and trapezoids (Figure 2.3(b)). The triangles are isohedral, whereas the trapezoids are not, as can be seen by the view from tiles A and B.

In the case of the trapezoidal tiling, the viewer from A is surrounded by an infinite number of concentric hexagons, whereas this is not the case for B. In other words, the trapezoidal tiling is not periodic. Also, note that all of the tiles in Figure 2.3(a) are described by  $[6^3]$ , but those in Figure 2.3(b) are either  $[3^2.4^2]$ ,  $[3^2.6^2]$ , or  $[3.4.6^2]$  (i.e., the tiles labeled 1, 2, and 3, respectively, in Figure 2.3(b)). When the isohedral tilings are classified by the action of their symmetry group, there are 81 different types [761, 762]. When they are classified by their adjacency structure, as is done here, there are 11 types.

The most relevant criterion to our discussion is the distinction between limited and unlimited hierarchies of tilings (i.e., how the unit-size cells aggregate to form blocks). A *limited* tiling is not similar. A tiling that satisfies property 2 is said to be *unlimited*. Equivalently, in a limited tiling, no change of scale lower than the limit tiling can be made without great difficulty. An alternative characterization of an unlimited tiling is that each edge of a tile lies on an infinite straight line composed entirely of edges. Interestingly, the hexagonal tiling  $[3^6]$  is limited. Bell et al. claim that only four tilings are unlimited. These are the tilings given in Figure 2.2(a–d). Of these,  $[4^4]$ , consisting of square atomic tiles (Figure 2.2(a)), and  $[6^3]$ , consisting of equilateral triangle atomic tiles (Figure 2.2(b)), are well-known regular tessellations [29]. For these two tilings, we consider only the molecular tiles given in Figure 2.4(a, b).

The tilings  $[4^4]$  and  $[6^3]$  can generate an infinite number of different molecular tiles where each molecular tile at the first level consists of  $n^2$  atomic tiles ( $n > 1$ ). The remaining nonregular unlimited triangular tilings,  $[4.8^2]$  (Figure 2.2(c)) and  $[4.6.12]$  (Figure 2.2(d)), are less understood. One way of generating  $[4.8^2]$  and  $[4.6.12]$  is to join the centroids of the tiles of  $[4^4]$  and  $[6^3]$ , respectively, to both their vertices and the midpoints of their edges. Each of the tilings  $[4.8^2]$  and  $[4.6.12]$  has two types of hierarchy.  $[4.8^2]$  has an ordinary hierarchy (Figure 2.4(c)) and a rotation hierarchy (Figure 2.4(e)),

## Section 2.1 INTERIOR-BASED REPRESENTATIONS

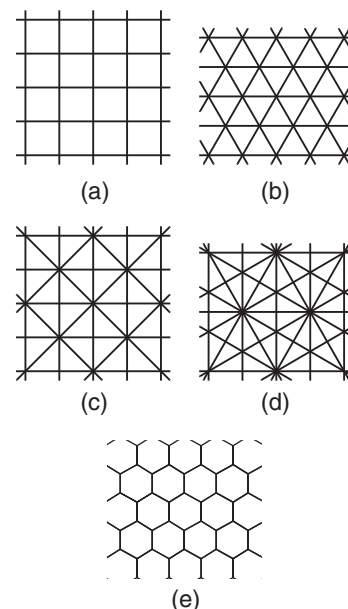

Figure 2.2  
Sample tessellations: (a)  $[4^4]$  square, (b)  $[6^3]$  equilateral triangle, (c)  $[4.8^2]$  isosceles triangle, (d)  $[4.6.12]$  30–60–90 right triangle, and (e)  $[3^6]$  hexagon.

Figure 2.3  
Examples of (a) isohedral and (b) nonisohedral tilings.

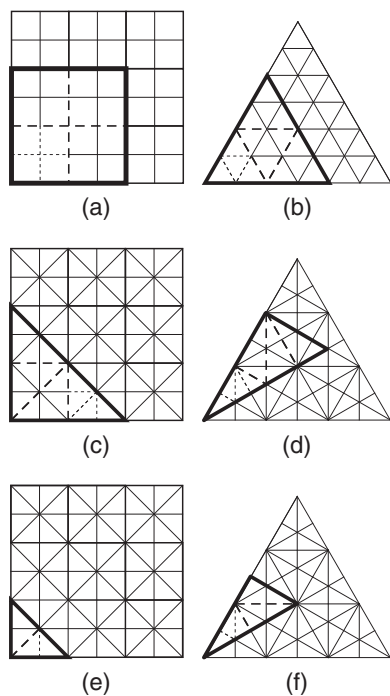

Figure 2.4  
Examples illustrating unlimited  
tilings: (a)  $[4^4]$  hierarchy, (b)  $[6^3]$   
hierarchy, (c) ordinary  $[4.8^2]$  hierar-  
chy, (d) ordinary  $[4.6.12]$  hierarchy,  
(e) rotation  $[4.8^2]$  hierarchy, and (f)  
rotation  $[4.6.12]$  hierarchy.

requiring a rotation of 135 degrees between levels.  $[4.6.12]$  has an ordinary hierarchy (Figure 2.4(d)) and a reflection hierarchy (Figure 2.4(f)), which requires a reflection of the basic tile between levels.

The distinction between the two types of hierarchies for  $[4.8^2]$  and  $[4.6.12]$  is necessary as the tiling is not similar without a rotation or a reflection when the hierarchy is not ordinary. This can be seen by observing the use of dots in Figure 2.4 to delimit the atomic tiles in the molecular tile at the deepest level of the hierarchy (i.e., level 1) using our level-labeling conventions, which consider the atomic tiles to be at level 0). Similarly, broken lines are used to delimit the components of molecular tiles at the second level. For the ordinary  $[4.8^2]$  and  $[4.6.12]$  hierarchies, each molecular tile at the first level consists of  $n^2$  ( $n > 1$ ) atomic tiles. In the reflection hierarchy of  $[4.6.12]$ , each molecular tile at the first level consists of  $3 \cdot n^2$  ( $n > 1$ ) atomic tiles. On the other hand, for the rotation hierarchy of  $[4.8^2]$ ,  $2 \cdot n^2$  ( $n > 1$ ) atomic tiles make up a molecular tile at the first level.

For example, in the case of the ordinary  $[4.8^2]$  hierarchy, the level 1 molecular tiles that make up the level 2 molecular tile have the same orientation as the atomic tiles of the molecular tile at level 1. On the other hand, in the case of the rotation  $[4.8^2]$  hierarchy, the level 1 molecular tiles that make up the level 2 molecular tile have the same orientation as the result of rotating the atomic tiles of the first molecular tile by 135 degrees in the counterclockwise direction. As another example, in the case of the ordinary  $[4.6.12]$  hierarchy, the atomic tiles of the first molecular tile have the same orientation as the level 1 molecular tiles that make up the level 2 molecular tile. On the other hand, in the case of the rotation  $[4.6.12]$  hierarchy, the level 1 molecular tiles that make up the level 2 molecular tile have the same orientation as the result of reflecting the atomic tiles of the first molecular tile about the shortest edge of the level 0 molecular tile, and repeating the reflection about the longest edge of the level 0 molecular tile.

To represent data in the Euclidean plane, any of the unlimited tilings could have been chosen. For a regular decomposition, the tilings  $[4.8^2]$  and  $[4.6.12]$  are ruled out. Comparing “square”  $[4^4]$  and “triangular”  $[6^3]$  tilings, we find that they differ in terms of adjacency and orientation. Let us say that two tiles are *neighbors* if they are adjacent either along an edge or at a vertex. A tiling is *uniformly adjacent* if the distances between the centroid of one tile and the centroids of all its neighbors are the same. The adjacency number of a tiling is the number of different intercentroid distances between any one tile and its neighbors. In the case of  $[4^4]$ , there are only two adjacency distances, whereas for  $[6^3]$ , there are three adjacency distances.

A tiling is said to have *uniform orientation* if all tiles with the same orientation can be mapped into each other by translations of the plane that do not involve rotation or reflection. Tiling  $[4^4]$  displays uniform orientation, while tiling  $[6^3]$  does not. Under the assumption that uniform orientation and a minimal adjacency distance is preferable, we say that  $[4^4]$  is more useful than  $[6^3]$ .  $[4^4]$  is also very easy to implement. Nevertheless,  $[6^3]$  has its uses. For example,  $[6^3]$  is used when the space is the surface of a sphere (e.g., [1138]).

Of the *limited* tilings, many types of hierarchies may be generated [157]; however, in general, they cannot be decomposed beyond the atomic tiling without changing the basic tile shape. This is a serious drawback of the hexagonal tiling  $[3^6]$  (Figure 2.2(e)) since the atomic hexagon can only be decomposed into triangles. Nevertheless, the hexagonal tiling is of considerable interest (e.g., [158, 234, 285, 706, 1149, 1293]). It is regular, has a uniform orientation, and, most importantly, displays a uniform adjacency (i.e., each neighbor of a tile is at the same distance from it). This property is one of the reasons for the appeal of the hexagonal tiling in strategic board games that involve control of space or reachability, and is often used as a means of modeling war games. We discuss this tiling further in Section 2.1.2.10.

## Exercises

- Given a  $[6^3]$  tiling such that each side of an atomic tile has a unit length, compute the three adjacency distances from the centroid of an atomic tile.
- Repeat Exercise 1 for  $[3^6]$  and  $[4^4]$ , again assuming that each side of an atomic tile has a unit length.
- Suppose that you are given an image in the form of a binary array of pixels. The result is a square grid. How can you view this grid as a hexagonal grid?

### 2.1.1.2 Ordering Space

There are many ways of laying out the addresses corresponding to the locations in space of the cells, each having its own mapping function. Some of the most important ones for a two-dimensional space are illustrated in Figure 2.5 for an  $8 \times 8$  portion of the space and are described briefly below. To repeat, in essence, what we are doing is providing a mapping from the  $d$ -dimensional space containing the locations of the cells to the one-dimensional space of the range of index values (i.e., integers) that are used to access a table whose entries contain the addresses where information about the contents of the cells is stored. The result is an ordering of the space, and the curves shown in Figure 2.5 are termed *space-filling curves* (e.g., [1603]).

Choosing among the space-filling curves illustrated in Figure 2.5 is not easy because each one has its advantages and disadvantages. Below, we review a few of their desirable properties, show how some of the two-dimensional orderings satisfy them, and provide some exercises to help you to explore them further:

- The curve should pass through each location in space once and only once.
- The mapping from the higher-dimensional space to the integers should be relatively simple and likewise for the inverse mapping. This is the case for all but the Peano-Hilbert order (Figure 2.5(d)). For the Morton order (Figure 2.5(c)), the mapping is obtained by interleaving the binary representations of the coordinate values of the location of the cell. The number associated with each cell is known as its *Morton number*. The Gray order (Figure 2.5(g)) is obtained by applying a Gray code (see footnote 35 in Section 1.6 of Chapter 1) to the result of bit interleaving, and the double Gray order (Figure 2.5(h)) is obtained by applying a Gray code to the result of bit interleaving the Gray code of the binary representation of the coordinate values. The U order (Figure 2.5(i)) is obtained in a similar manner to the Morton order, except for an intermediate application of  $d - 1$  “exclusive or” ( $\oplus$ ) operations on the binary representation of selected combinations of the coordinate values prior to the application of bit interleaving [1192, 1698] (see Exercise 7). Thus, the difference in cost between the Morton order and the U order in  $d$  dimensions is just the performance of additional  $d - 1$  “exclusive or” operations. This is in contrast to the Peano-Hilbert order, where the mapping and inverse mapping processes are considerably more complex (see Exercises 5 and 6).
- The ordering should be stable. This means that the relative ordering of the individual locations is preserved when the resolution is doubled (e.g., when the size of the two-dimensional space in which the cells are embedded grows from  $8 \times 8$  to  $16 \times 16$ ) or halved, assuming that the origin stays the same. The Morton, U, Gray, and double Gray orders are stable, while the row (Figure 2.5(a)), row-prime (Figure 2.5(b)), Cantor-diagonal (Figure 2.5(e)), and spiral (Figure 2.5(f)) orders are not stable (but see Exercises 1 and 2). The Peano-Hilbert order is also not stable, as can be seen by its definition (but see Exercise 3). In particular, in two dimensions, the Peano-Hilbert order of resolution  $i + 1$  (i.e., a  $2^i \times 2^i$  image) is constructed by taking the Peano-Hilbert curve of resolution  $i$  and rotating the NW, NE, SE, and SW quadrants by 90

## Section 2.1

### INTERIOR-BASED REPRESENTATIONS

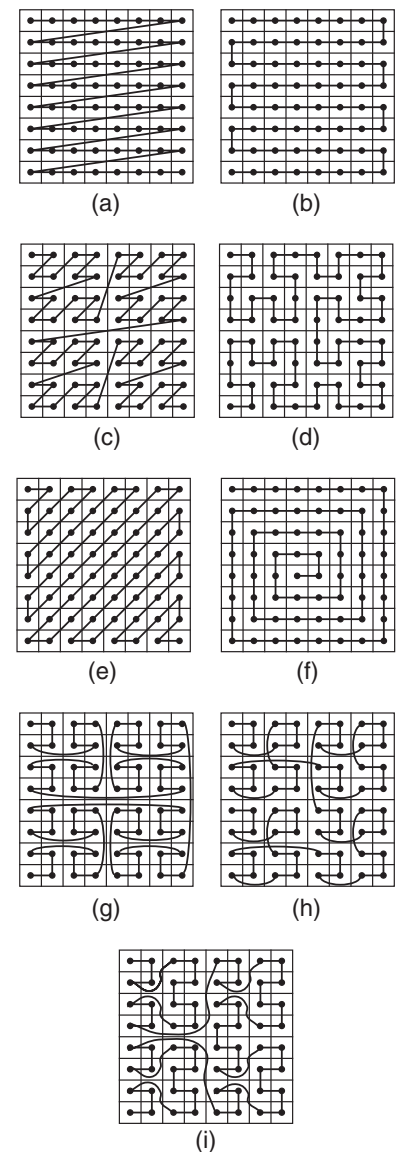

Figure 2.5

The result of applying several different space-ordering methods to an  $8 \times 8$  collection of cells whose first element is in the upper-left corner: (a) row order, (b) row-prime order, (c) Morton order, (d) Peano-Hilbert order, (e) Cantor-diagonal order, (f) spiral order, (g) Gray order, (h) double Gray order, and (i) U order.

Figure 2.6  
Peano-Hilbert curves of resolution  
(a) 1, (b) 2, and (c) 3.

degrees clockwise, 0 degrees, 0 degrees, and 90 degrees counterclockwise, respectively. For example, Figure 2.6(a–c) gives the Peano-Hilbert curves of resolutions 1, 2, and 3, respectively.

- Two locations that are adjacent (i.e., in the sense of a  $(d - 1)$ -dimensional adjacency, also known as 4-adjacent)<sup>4</sup> in space are neighbors along the curve and vice versa. In two dimensions, this means that the locations share an edge or a side. This is impossible to satisfy for all locations at all space sizes. However, for the row-prime, Peano-Hilbert, and spiral orders, every element is a 4-adjacent neighbor of the previous element in the sequence, while this is not the case for the other orders. This means that the row-prime, Peano-Hilbert, and spiral orders have a slightly higher degree of locality than the other orders.
- The process of retrieving the neighbors of a location in space should be simple.
- The order should be *admissible*—at each position in the ordering, at least one 4-adjacent neighbor in each of the lateral directions (i.e., horizontal and vertical) must have already been encountered. This is useful in several algorithms (e.g., connected component labeling [494]).<sup>5</sup> The row and Morton orders are admissible, while the Peano-Hilbert, U, Gray, and double Gray orders are not admissible. The row-prime, Cantor-diagonal, and spiral orders are admissible only if we permit the direction of the 4-adjacent neighbors to vary from position to position along the curve. For example, for the row-prime order, at positions on odd rows, the previously encountered 4-adjacent neighbors are the western and northern neighbors, while at positions on even rows, they are the eastern and northern neighbors.

The row order (Figure 2.5(a)) is of special interest to us because its mapping function is the one most frequently used by the multidimensional array (described in greater detail in Section 2.1.1.3), which is the most common access structure. Assuming that the first entry in the cell-address table indexed by the index has an index value of 0, location  $(a,b)$  in an  $8 \times 8$  collection of cells is mapped to index value  $8b + a$ . An alternative ordering that is also used in the multidimensional array is known as *column order*; the difference from row order lies in the order in which the various dimensions are scanned. In the column order, the  $y$  coordinate value varies most rapidly; in the row order, the  $x$  coordinate value varies most rapidly. The one to choose is arbitrary, although the row order is preferred as it yields a lexicographic ordering when array references are of the form  $T[i, j]$ , corresponding to an element in row  $i$  and column  $j$  of array  $T$  (i.e., at location  $(j, i)$ ).

The Morton order [1317] has a long history, having been first mentioned in 1890 by Peano [1478], and has been used by many researchers (e.g., [8, 684, 1420, 1992, 2017]). It is also known as a *Z order* [1420] and as an *N order* [1992]. The Peano-Hilbert order was first mentioned soon afterwards by Hilbert [835] and has also been used by a number of researchers (e.g., [591, 937]). The relationship of the Morton order to bit interleaving

<sup>4</sup> In two dimensions, the fact that two locations are *4-adjacent* means that the locations share an edge or a side. If the concept of adjacency also includes adjacency at a corner (i.e., diagonal adjacencies), then the locations are said to be *8-adjacent*.

<sup>5</sup> A *region*, or object, four-connected component is a maximal four-connected set of locations belonging to the same object, where a set  $S$  of locations is said to be *four-connected* (*eight-connected*) if for any locations  $p, q$  in  $S$  there exists a sequence of locations  $p = p_0, p_1, \dots, p_n = q$  in  $S$ , such that  $p_{i+1}$  is 4-adjacent (8-adjacent) to  $p_i, 0 \leq i < n$ . The process of assigning the same label to all 4-adjacent locations that belong to the same object is called *connected component labeling* (e.g., [1469, 1575]). A nonobject (often denoted as white) *region* or nonobject (white) eight-connected component is a maximal eight-connected set of locations that do not belong to any of the objects. The complement of all the regions that are contained in one of the objects consists of a union of eight-connected nonobject (white) regions. Exactly one of these nonobject (white) regions contains the infinite background of nonobject (white) locations. All the other nonobject (white) regions, if any, are called *holes* in the object regions. The set of object black regions, say  $R$ , is surrounded by the infinite nonobject (white) region, and  $R$  surrounds the other nonobject (white) regions, if any.

is discussed in greater detail in Section 1.6 of Chapter 1. Pascucci and Frank [1471, 1472] discuss the application of the Morton order to a multiresolution hierarchy where the full  $2^n \times 2^n$  space of cells can be visualized as a hierarchy of  $n$  arrays  $a_i$ , each of size  $2^i \times 2^i$  ( $0 \leq i \leq n$ ), so that  $a_{i+1}$  is at twice the resolution of  $a_i$ , and one distinguished element of every  $2 \times 2$  subset of  $a_{i+1}$  is also an element of  $a_i$ . Their motivation is to support real-time progressive traversal and visualization of large grids of data that are too large to fit in memory and thus reside in external memory.

Although conceptually very simple, the U order introduced by Schrack and Liu [1192, 1698] is relatively recent. It is a variant of the Morton order but also resembles the Peano-Hilbert order. The primitive shape is a “U,” which is the same as that of the Peano-Hilbert order. However, unlike the Peano-Hilbert order, and like the Morton order, the ordering is applied recursively with no rotation, thereby enabling it to be stable. The U order has a slight advantage over the Morton order in that more of the locations that are adjacent (i.e., in the sense of a  $(d - 1)$ -dimensional adjacency) along the curve are also neighbors in space. This is directly reflected in the lower average distance between two successive positions in the order (see Exercise 8, where we see that this cost is also lower than that of the Gray and double Gray orders). However, the price of this is that, like the Peano-Hilbert order, the U order is also not admissible. Nevertheless, like the Morton order, the process of retrieving the neighbors of a location in space is simple when the space is ordered according to the U order.

### Exercises

1. In the text, we said that the row order is not stable. This is true if the image grows by doubling or if its resolution is halved. Under what kinds of growth conditions is the row order stable?
2. In the text, we said that the spiral order is not stable. This is true if the image grows by doubling or if its resolution is halved. Under what kinds of growth conditions is the spiral order stable?
3. Examining the Peano-Hilbert order in Figure 2.5(d), it appears that, if we consider the  $2 \times 2$  square in the upper-left corner and double the resolution to yield the  $4 \times 4$  square in the upper-left corner, the relative positions of the cells in the  $2 \times 2$  square in the upper-left corner are preserved. This seems to be contradictory to our claim that the Peano-Hilbert order is not stable. Explain why this is not the case.
4. Given a Morton ordering for a  $2^n \times 2^n$  image, show how to determine the addresses associated with the locations that are adjacent to location  $c$  in the horizontal and vertical directions.
5. Give an algorithm to extract the  $x$  and  $y$  coordinates from a Peano-Hilbert order key.
6. Give an algorithm to construct the Peano-Hilbert key for a given point  $(x, y)$ . Try to make it optimal.
7. Using “exclusive or” operations, show how to construct the U order key for a point.
8. Suppose that you are given a  $2^n \times 2^n$  array of locations such that the horizontal and vertical distances between 4-adjacent locations are 1. What is the average distance between successive locations when the locations are ordered according to the orders illustrated in Figure 2.5? What about a random order?
9. Suppose that you are given a  $2^n \times 2^n$  image. Assume that the image is stored on disk in pages of size  $2^m \times 2^m$ , where  $n$  is much larger than  $m$ . What is the average cost (in terms of disk page accesses) of retrieving a pixel and its 4-adjacent neighbors when the image is ordered according to the orders illustrated in Figure 2.5?
10. Given a Morton ordering for a  $2^n \times 2^n$  image and the locations of a rectangle in the image, what is the location in the rectangle with the smallest Morton order value? Assume that the upper-left corner of the image is the first one in the Morton ordering.
11. Given a Peano-Hilbert ordering for a  $2^n \times 2^n$  image and the locations of a rectangle in the image, what is the location in the rectangle with the smallest Peano-Hilbert order value? Assume that the upper-left corner of the image is the first one in the Peano-Hilbert ordering.

12. Given a  $U$  ordering for a  $2^n \times 2^n$  image and the locations of a rectangle in the image, what is the location in the rectangle with the smallest  $U$  order value? What about the Gray and double Gray order values? Assume that the upper-left corner of the image is the first one in the  $U$  ordering.
13. The traveling salesman problem [1120] is one where a set of points is given, and it is desired to find the path of minimum distance such that each point is visited only once. This is an NP-complete problem [682]; and thus there is a considerable amount of work in formulating approximate solutions to it [170]. For example, consider the following approximate solution. Assume that the points are uniformly distributed in the unit square. Let  $d$  be the expected Euclidean distance between two independent points. Now, sort the points using the row order and the Morton order. Laurini [1111] simulated the average Euclidean distance between successive points in these orders and found it to be  $d/2$  for the row order and  $d/3$  for the Morton order. Can you derive these averages analytically? What are the average values for the other orders illustrated in Figure 2.5? What about a random order?

### 2.1.1.3 Array Access Structures

The multidimensional array (having a dimension equal to the dimensionality of the space in which the objects and the environment are embedded) is an access structure that, given a cell  $c$  at a location  $l$  in space, enables us to calculate the address  $a$  containing the identifier of the object associated with  $c$ . The array is only a conceptual multidimensional structure (it is not a multidimensional physical entity in memory) in the sense that it is a mapping of the locations in space of the cells into sequential addresses in memory. The actual addresses are obtained by the array access function (see, e.g., [1044], as well as the above discussion on space orderings), which is based on the extents of the various dimensions (i.e., coordinate axes). The array access function is usually the mapping function for the row order described above (although, at times, the column order is also used). Thus, the array enables us to implement the implicit representation with no additional storage except for what is needed for the array's descriptor. The descriptor contains the bounds and extents of each of the dimensions that are used to define the mapping function (i.e., they determine the values of its coefficients) so that the appropriate address can be calculated, given the cell's location in space.

Figure 2.7  
Array corresponding to the collection of objects and cells in Figure 2.1.

Figure 2.7 shows the contents of the array corresponding to the collection of two-dimensional objects and cells given in Figure 2.1. Each of the array elements  $T[i, j]$  is labeled with an address that specifies where an identifier is stored that indicates the identity of the object (or objects) of which the corresponding cell at location  $(j, i)$  is a member. We have labeled array elements corresponding to cells of object  $O$  as  $O_i$  and the array elements corresponding to cells that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases. When there is no need to distinguish between the various objects, we use the labels *black* (also “1” and foreground) and *white* (also “0” and background) to characterize or differentiate between the cells that lie in any of the objects and those that are not in any of the objects, respectively.

The array is called a *random access structure* because the address associated with a location in space can be retrieved in constant time independently of the number of elements in the array and does not require any search. Note that we could store the object identifier  $o$  in the array element itself instead of allocating a separate address  $a$  for  $o$ , thereby saving some space.

The array is an implicit representation because we have not explicitly aggregated all the contiguous cells that make up a particular object. They can be obtained given a particular cell  $c$  at a location  $l$  in space belonging to object  $o$  by recursively accessing the array elements corresponding to the locations in space that are adjacent to  $l$  and checking if they are associated with object  $o$ . This process is known as depth-first connected component labeling (recall the definition of connected component labeling in footnote 5 in Section 2.1.1.2).

Interestingly, depth-first connected component labeling could also be used to answer the feature query efficiently with an implicit representation if we add a data structure such as an index on the objects (e.g., a table of object-location pairs, where *location* is one of the locations in space that make up *object*). Thus, given an object *o* we use the index to find a location in space that is part of *o* and then proceed with the depth-first connected component labeling as before. This index does not make use of the spatial coverage of the objects, and thus it can be implemented using conventional searching techniques such as hashing [1046]. In this case, we will need  $O(N)$  additional space for the index, where  $N$  is the number of different objects. We do not discuss such indexes here.

Of course, we could also answer the location query with an explicit representation by adding an index that associates objects with locations in space (i.e., having the form location-objects). However, this would require  $O(S)$  additional space for the index, where  $S$  is the number of cells. The  $O(S)$  bound assumes that only one object is associated with each cell. If we take into account that a cell could be associated with more than one object, then the additional storage needed is  $O(NS)$ , if we assume  $n$  objects. Since the number of cells  $S$  is usually much greater than the number of objects  $N$ , the addition of an index to the explicit representation is not as practical as extending the implicit representation with an index of the form object-location as described above. Thus, it would appear that the implicit representation is more useful from the point of view of flexibility when taking storage requirements into account.

### 2.1.1.4 Tree Access Structures

The implicit representation can be implemented with access structures other than the array. This is an important consideration when many of the cells are not in any of the objects (i.e., they are empty). The problem is that using the array access structure is wasteful of storage, as the array requires an element for each cell, regardless of whether the cell is associated with any of the objects. In this case, we choose to keep track of only the nonempty cells.

We have two ways to proceed. The first is to use one of several multidimensional access structures, such as a point quadtree, k-d tree, or MX quadtree as described in Chapter 1. The second is to make use of one of the orderings of space shown in Figure 2.5 to obtain a mapping from the nonempty contiguous cells to the integers. The result of the mapping serves as the index in one of the familiar treelike access structures (e.g., binary search tree, range tree, B<sup>+</sup>-tree) to store the address that indicates the physical location where the information about the object associated with the location in space corresponding to the nonempty cell is stored. In this discussion, we choose the second approach because often, when the dimensionality of the space (i.e.,  $d$ ) gets large, the implementation of the first approach resorts to use of the second approach anyway.

At this point, it is worthwhile to comment on what exactly is stored in the nodes of the treelike access structure that are associated with nonempty cells. First of all, as mentioned above, each node contains an address that indicates the physical location where the information about the object associated with the location in space corresponding to the nonempty cell is stored. As in the case of the array, we could store the object identifier *o* in the node of the tree itself rather than allocating a separate address *a* for *o*, thereby saving some space. In addition, each node of the tree must also store the index value (i.e., the result of the mapping) for the nonempty cell because, unlike the array, we do not have an entry for every cell, which would have enabled us to avoid having to store the index value. Note that if we did not store this index value, we would not be able to tell if the node in the tree corresponded to a particular location through the use of a comparison. The mapping that we use must have an inverse so that, given an index value, we can determine the corresponding location in space of the cell that is associated with it.

We demonstrate the use of a tree access structure with the mapping that yields a Morton order (i.e., Figure 2.5(c)) and use it as an index in the binary search tree. Figure 2.8 shows the result of applying a Morton ordering to an  $8 \times 8$  collection of cells.

Figure 2.8  
Result of applying a Morton ordering to an  $8 \times 8$  collection of cells.

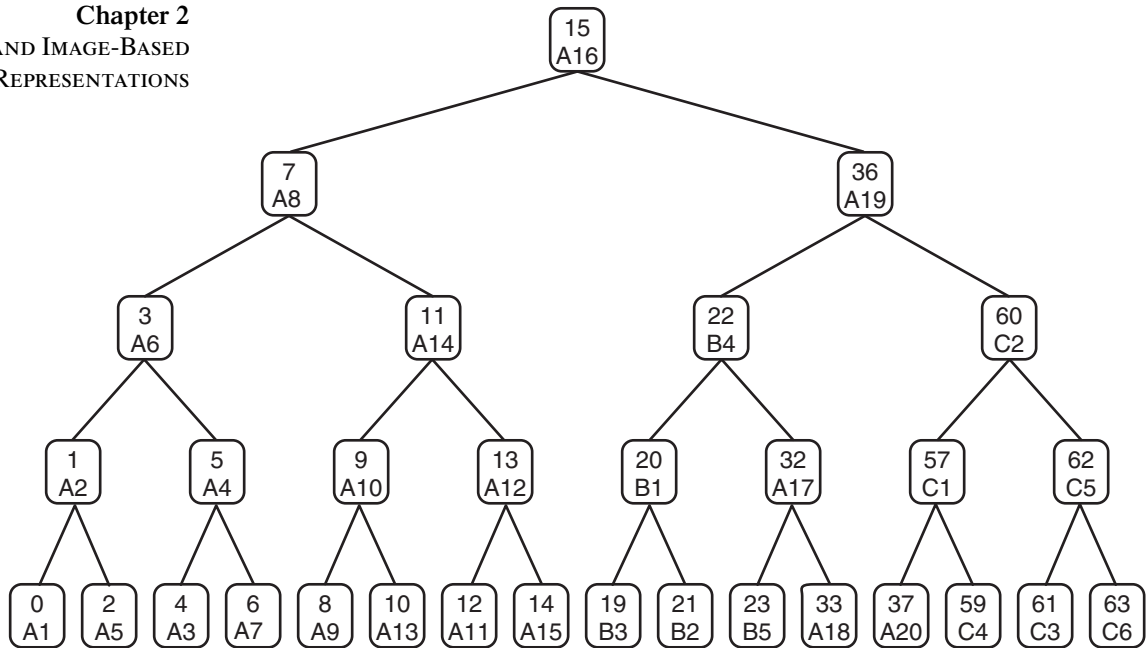

Figure 2.9  
 Result of applying a Morton order mapping to the collection of two-dimensional objects and cells in Figure 2.1 and storing the result in a binary search tree.

Figure 2.9 is the binary search tree for the collection of two-dimensional objects and cells given in Figure 2.1. Each node in the tree is labeled with the Morton order value of its corresponding cell  $c$  and an address  $a$  that specifies where an identifier is stored that indicates the identity of the object (or objects) of which  $c$  is a member. The address  $a$  in Figure 2.9 is the same as the one used in the corresponding cell in the array access structure in Figure 2.7. Notice that the empty cells (i.e., those labeled with  $W_i$  in the array access structure in Figure 2.7) are not present in Figure 2.9.

Regardless of which tree access structure is used, we can always determine the object  $o$  associated with a cell  $c$  at location  $l$ . We just apply the mapping (Morton ordering in our example) to  $l$ , yielding  $p$  (which is an address or an offset value from a base location), and then search for  $p$  in the tree (a binary search tree in our example). If  $p$  is not in the tree, then  $c$  is an empty cell; otherwise, we retrieve the object identifier  $o$  associated with it. Recall that retrieving the object identifier  $o$  associated with cell  $c$  only yields a partial response to the location query because we need to determine the remaining cells that make up  $o$ . This is achieved by accessing each of the cells adjacent to  $c$  and determining if they exist in the tree and if they do, then checking if they are associated with  $o$ . If the answer is yes to both of the above questions, then their adjacent cells are examined by a recursive application of this process. Note that for most of the orderings, we can determine the locations in space that are adjacent to  $c$  directly from the value of  $p$  without having to apply the mapping that yields the ordering or the inverse mapping (see Exercise 4 in Section 2.1.1.2). In fact, for some of the tree access structures (e.g., an MX quadtree [901, 905, 1637], which is a variant of the region quadtree, described in Section 2.1.2.4, that only merges empty cells), the adjacent cells can be determined by using just the structure of the tree (i.e., no arithmetic operations, such as those needed for address computation, are performed).

### 2.1.2 Blocks

An alternative class of representations of the objects and their environment removes the stipulation that the cells that make up the object collection be of unit size and permits

their sizes to vary. The resulting cells are termed *blocks* and are usually rectangular with sides that are parallel to the coordinate axes (this is assumed in our discussion unless explicitly stated otherwise). The volume (e.g., area in two dimensions) of the blocks need not be an integer multiple of that of the unit-size cells, although this is frequently the case (and holds for all of the representations presented in this section). Observe that when the volumes of the blocks are integer multiples of that of the unit-size cells, we have two levels of aggregation in the sense that an object consists of an aggregation of blocks that are themselves aggregations of cells. Of course, it goes without saying that all the cells in a block belong to the same object or objects. In other words, the situation that some of the cells in the block belong to object  $o_1$ , while the others belong to object  $o_2$  (and not to  $o_1$ ), is not permitted.

The aggregation process that results in the blocks is usually guided by a set of rules, although this is not always the case in the sense that the process may also be arbitrary to a certain degree. It is usually easier to describe the aggregation process in a top-down manner by specifying an equivalent decomposition process of the underlying space that is occupied by the objects, and this is the way we will proceed in our discussion whenever possible. We start out by describing two aggregation methods that are not the result of a specific decomposition process. The first simply aggregates the unit-size cells into rectangular blocks of arbitrary size and position (see Section 2.1.2.1). The second finds a set of maximal blocks based on the distance of the unit-size cells from the boundary of the objects and is known as the medial axis transformation (MAT) (see Section 2.1.2.2).

When the decomposition is recursive, we have the situation that the decomposition occurs in stages and often, although not always, the results of the stages form a containment hierarchy. This means that a block  $b$  obtained in stage  $i$  is decomposed into a set of blocks  $b_j$  that span the same space. Blocks  $b_j$  are in turn decomposed in stage  $i + 1$  using the same decomposition rule. Some decomposition rules restrict the possible sizes and shapes of the blocks, as well as their placement in space. Some examples include the following:

- All blocks at a particular stage are congruent.
- Blocks are similar at all stages (e.g., rectangles and isosceles triangles).
- All but one side of a block are unit-sized (e.g., runlength encoding).
- All sides of a block are of equal size (e.g., squares and equilateral triangles).
- All sides of each block are powers of 2.

These decomposition rules are described in Sections 2.1.2.3 to 2.1.2.9.

Other decomposition rules do not require that the blocks be axis parallel, while still others do not even require that the blocks be rectangular. For example, often, the blocks can be hexagonal (Section 2.1.2.10) or triangular (Section 2.1.2.11). As we pointed out in Section 2.1.1.1, hexagonal blocks find use in the implementation of strategic board games where the key is movement between adjacent spatial elements. Triangular blocks are often used in modeling the surface of a sphere using regular decomposition. In addition, the blocks may be disjoint or allowed to overlap. Clearly, the choice is large. These rules are described in greater detail in Sections 2.1.3 and 2.1.4.

### 2.1.2.1 Decomposition into Arbitrarily Sized Rectangular Blocks

The simplest decomposition rule is one that permits aggregation of identically valued cells in only one dimension. In essence, the decomposition assigns a priority ordering to the various dimensions; fixes the coordinate values of all but one of the dimensions, say  $i$ ; and then varies the value of the  $i$ th coordinate and aggregates all adjacent cells belonging to the same object into a one-dimensional block. This technique is commonly used in image processing applications where the image is decomposed into rows that are scanned

from top to bottom, and each row is scanned from left to right while aggregating all adjacent pixels (i.e., unit-size cells) with the same value into a block. The aggregation into one-dimensional blocks is the basis of *runlength encoding* [1595] (also see Section 2.3). The same techniques are applicable to higher-dimensional data as well.

The drawback of the decomposition into one-dimensional blocks described above is that all but one side of each block must be of unit width. The most general decomposition removes this restriction along all of the dimensions, thereby permitting aggregation along all dimensions. In other words, the decomposition is arbitrary. The blocks need not be uniform or similar—that is, the relative lengths of their sides need not satisfy any particular restriction such as being the same, which results in square blocks. The only requirement is that the blocks span the space of the environment. This general decomposition has the potential of requiring less space. However, its drawback is that the determination of optimal partition points may be a computationally expensive procedure (see Exercise 4 in Section 2.1.2.7). A closely related problem, decomposing a region into a minimum number of rectangles, is known to be NP-complete<sup>6</sup> if the region is permitted to contain holes [1179].

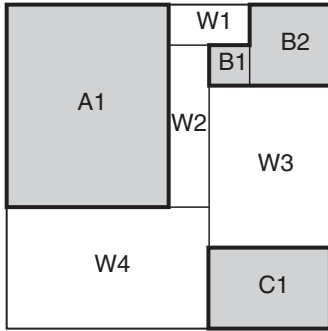

Figure 2.10  
Arbitrary block decomposition for  
the collection of objects and cells in  
Figure 2.1.

Sections 2.1.2.2 to 2.1.2.9 discuss the situation that the aggregation is subject to some rules as to which unit-size cells are to be aggregated. In this section, we assume that the blocks are disjoint, although, as we will later see, this need not be the case. We also assume that the blocks are rectangular with sides parallel to the coordinate axes, although, again, this is not absolutely necessary as there exist decompositions using other shapes as well (e.g., triangles, circles). For example, Figure 2.10 is an arbitrary block decomposition for the collection of objects and cells given in Figure 2.1. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases. When there is no need to distinguish between the various objects, we use the labels *black* (also “1” and foreground) and *white* (also “0” and background) to characterize or differentiate between the blocks whose cells all lie in any of the objects and those for which none of the constituent cells are in any of the objects, respectively. This characterization is used for all of the aggregations discussed in the rest of this section (i.e., Section 2.1.2).

It is easy to adapt the explicit representation to deal with blocks resulting from an arbitrary decomposition (which also includes the one that yields one-dimensional blocks). In particular, instead of associating a set with each object  $o$  that contains the location in space of each cell that makes up  $o$ , we need to associate with each object  $o$  the location in space and size of each block that makes up  $o$ . There are many methods for doing this, some of which are discussed in Section 3.3.1 of Chapter 3. One popular method is to specify the coordinate values of the upper-left corner of each block and the sizes of their various sides. This format is appropriate, and is the one we use, for the explicit representation of all of the block decompositions described in this section.

Using the explicit representation of blocks, both the feature and location queries are answered in essentially the same way as they were for unit-sized cells. The only

<sup>6</sup> A problem is in NP if it can be solved nondeterministically in polynomial time. A nondeterministic solution process proceeds by “guessing” a solution and then verifying that the solution is correct. Assume that  $n$  is the size of the problem (e.g., for sorting,  $n$  is the number of records to be sorted). Intuitively, then, a problem is in NP if there is a polynomial  $P(n)$  such that if one guesses a solution, it can be verified in  $O(P(n))$  time, whether the guess is indeed a correct solution. Thus, it is the verification process that is the key to determining whether a problem is in NP, not the actual solution of the problem.

A problem is NP-complete if it is “at least as hard” as any other problem in NP. Somewhat more formally, a problem  $P_1$  in NP is NP-complete if the following property holds: for all other problems  $P_i$  in NP, if  $P_i$  can be solved deterministically in  $O(f(n))$  time, then  $P_1$  can be solved in  $O(P(f(n)))$  time for some polynomial  $P$ . It has been conjectured that no NP-complete problem can be solved deterministically in polynomial time, but this is not known for sure. The theory of NP-completeness is discussed in detail in [682].

difference is that, for the location query, instead of checking if a particular location  $l$  in space is a member of one of the sets of cells associated with the various objects, we must check if  $l$  is covered by one of the blocks in the sets of blocks of the various objects. This is a fairly simple process as we know the location in space and size of each of the blocks.

An implementation of an arbitrary decomposition (which also includes the one that results in one-dimensional blocks) using an implicit representation is quite easy. We build an index based on an easily identifiable location in each block, such as its upper-left corner. We make use of the same techniques that were presented in the discussion of the implicit representation for unit-sized cells in Section 2.1.1.

In particular, we apply one of the orderings of space shown in Figure 2.5 to obtain a mapping from the coordinate values of the upper-left corner  $u$  of each block to the integers. The result of the mapping is used as the index in one of the familiar treelike access structures (e.g., binary search tree, range tree,  $B^+$ -tree) to store the address that indicates the physical location where the information about the object associated with the block with upper-left corner  $u$  is stored. Since we need to know the size of the block (i.e., the lengths of its sides), we also record this information, along with the address in the node of the tree corresponding to the block. An alternative approach is to forego the ordering and keep track of the upper-left corners of the blocks using one of several multidimensional access structures, such as a point quadtree, k-d tree, or MX quadtree. (as described in Chapter 1). Again, each node in the tree contains the corresponding block's size and the address where more information can be found about the object associated with the corresponding block.

As in the case of unit-size cells, regardless of which access structure is used, we determine the object  $o$  associated with a cell at location  $l$  by finding the block  $b$  that covers  $l$ . If  $b$  is an empty block, then we exit. Otherwise, we return the object  $o$  associated with  $b$ . Notice that the search for the block that covers  $l$  may be quite complex in the sense that the access structures may not necessarily achieve as much pruning of the search space as in the case of unit-sized cells. In particular, this is the case whenever the space ordering and the block decomposition method to whose results the ordering is being applied do not have the property that all of the cells in each block appear in consecutive order. In other words, given the cells in the block  $e$  with minimum and maximum values in the ordering, say  $u$  and  $v$ , there exists at least one cell in block  $f$  distinct from  $e$  that is mapped to a value  $w$ , where  $u < w < v$ . Thus, supposing that the index is implemented using a treelike access structure, a search for the block  $b$  that covers  $l$  may require that we visit several subtrees of a particular node in the tree (see Exercise 1).

It is also important to recall that this yields only a partial response to the location query as we also want to determine the remaining blocks that make up object  $o$ . This is done by accessing the blocks adjacent to  $b$  and checking if they are associated with  $o$ . If they are, then their adjacent blocks are examined by a recursive application of this process.

The adjacent blocks are found by using the size information about block  $b$  and the location in space of  $b$ 's upper-left corner to calculate points  $p_i$  that are adjacent to the faces (edges in two dimensions) of  $b$  and that must lie in the adjacent blocks. Next, we find the blocks  $b_i$  that contain  $p_i$ . Depending on the sizes of  $b_i$ , we may have to calculate additional neighboring points. This process can be quite tedious the less regularity exists in the decomposition process. For example, if all the blocks are of the same size, then there is just one adjacent block along each face. Otherwise, the number of adjacent blocks to  $b$  along face  $f$  can be as large as the surface area (length of an edge in two dimensions) of  $f$ . In the remaining subsections of this section, we discuss various decomposition rules that differ in the number of restrictions that they pose on the size and placement of the blocks, thereby simplifying the adjacency determination process.

- Given an arbitrary decomposition where each block is represented by the position of its upper-left corner in a Morton ordering, which is then used as an index in a binary search tree, show how to find the object  $o$  that is associated with a cell in location  $l$ .

Figure 2.11  
Medial axis transformation (MAT) for the collection of objects and cells in Figure 2.1 using a definition where the maximal block is anchored at the unit-size element at its (a) center and (b) upper-left corner (i.e., CMAT).

### 2.1.2.2 Medial Axis Transformation (MAT)

In this section, we examine one of the earliest methods of aggregating unit-size cells with the same value (e.g., belonging to the same object). It proceeds as follows. For each unit-size cell  $c$  in object  $o$ , find the largest square  $s_c$  of width  $w_c$  (i.e., radius  $w_c/2$ ) centered at  $c$  that is contained in  $o$ .  $s_c$  is called a *maximal block* if it is not contained in the largest square  $s_{c'}$  of any other cell  $c'$  in  $o$ . Each object is completely specified by the maximal blocks, their widths, and the unit-size cells at their centers—that is, the set of triples  $(c, s_c, w_c)$ —since any point in  $o$  lies completely inside at least one maximal block. The set of these triples is called the *medial axis transformation* (MAT)<sup>7</sup> of  $o$  [221, 1575]. For example, Figure 2.11(a) is the MAT corresponding to the collection of two-dimensional objects in Figure 2.1 where we have specified only the maximal blocks of the objects. Each maximal block in the figure is specified by the unit-size cell at its center and its width. We usually do not construct the MAT of the regions containing the cells that are not in any of the objects (i.e., the background of the image).

The MAT is compact as long as the objects have simple shapes. However, the MAT is somewhat wasteful of space as some maximal blocks are contained in the unions of others. Furthermore, when the MAT is defined in the above manner, the widths of the blocks are restricted to being odd integers. This means that half the possible block widths are excluded. We can overcome this by redefining the maximal blocks to be anchored at the unit-size cell at one of their corners instead of at their centers. In particular, without loss of generality, suppose we use the unit-size cell in the upper-left corner of the maximal block as the anchor. Using this definition, we now construct the MAT as follows. For each unit-size cell  $c$  in object  $o$ , find the largest square  $s_c$  of width  $w_c$  (i.e., radius  $w_c/2$ ) anchored at the upper-left corner of  $c$  that is contained in  $o$ . Again,  $s_c$  is called a *maximal block* if it is not contained in the largest square  $s_{c'}$  of any other cell  $c'$  in  $o$ . We use the term *corner medial axis transformation* (CMAT) to distinguish this formulation of the MAT from the conventional MAT when necessary. For example, Figure 2.11(b) is the CMAT corresponding to the collection of two-dimensional objects in Figure 2.1 using this revised definition. Notice that the number of maximal blocks in the CMAT for this example case is significantly smaller than when the maximal blocks are anchored at the unit-size element in the center.

The block decomposition resulting from the MAT and CMAT is handled by the explicit and implicit representations in the same way as the arbitrary decomposition. Therefore, the feature and location queries are answered in the same way as described in Section 2.1.2.1. However, the fact that the decomposition is not disjoint does make the execution of the location query more complex for the implicit representation when we want to determine all of the blocks that make up the object associated with the given location as there are more of them since the decomposition is not disjoint.

The formulation of the MAT and CMAT that we have presented has been used as an object representation by several researchers. In particular, the TID of Scott and Iyengar [1702, 1703] is similar to the MAT (see also the squarecode of Oliver and Wiseman [1396] and the rectangular coding of Kim and Aggarwal [1022, 1023]).

At this point, we digress briefly and explain the rationale behind the original definition of the MAT in terms of the unit-size cells in the centers of the maximal blocks instead of at some other positions (e.g., at the corners). Let  $S$  be the set of unit-size cells making up object  $o$ , and let  $\bar{S}$  be the set of unit-size cells outside  $o$ . We say that for a

<sup>7</sup> MAT is sometimes used to denote the *multiattribute tree* discussed in Section 1.1 of Chapter 1.

Figure 2.12 An array representation of a rectangle object, its distance values, its skeleton, and its MAT: (a) object, (b) its City Block and Chessboard distance metric values, (c) its skeleton using the City Block distance metric, (d) its skeleton using the Chessboard distance metric, (e) its MAT using the City Block distance metric, and (f) its MAT using the Chessboard distance metric.

point  $x$  and a set  $V$ , the distance  $d(x, V)$  from  $x$  to the nearest point of  $V$  is defined as  $d(x, V) = \min\{d(x, y) | y \in V\}$ , where  $d$  is a metric or distance function (also known as a distance metric). The set of elements in  $S$  having a distance from  $\bar{S}$  that is greater than or equal to that of all of its “neighbors” in  $S$  constitutes a skeletal description of  $S$  and is called a *skeleton*. The definition of a skeleton also holds when  $p$  is a unit-size cell, in which case we measure the distance between the centers of the cells.

The nature of the skeleton depends on the distance metric that we choose (usually one of the Minkowski distance metrics  $L_p$ <sup>8</sup>). For example, consider the  $7 \times 10$  rectangle object denoted by the array in Figure 2.12(a). The values of the City Block or Manhattan distance metric (i.e.,  $L_1$ ) and Chessboard or maximum value distance metric (i.e.,  $L_\infty$ ) for this object are given by Figure 2.12(b), and the corresponding skeletons are given by Figure 2.12(c, d), respectively. The Euclidean distance metric (i.e.,  $L_2$ ) is more appropriate for the continuous case, although Figure 2.13 shows the skeleton corresponding to the rectangle object in Figure 2.12(a) when using it. In this case, the skeleton consists of line segments labeled a, b, c, d, and e. Use of the Euclidean distance metric has a physical analogy to what is left when the boundary of the object is set on fire. The skeleton is used as a compact representation of the objects in many applications in image processing (such as character recognition) where the essence of the object’s shape is important.

Figure 2.13 The skeleton corresponding to the rectangle object in Figure 2.12(a), using its Euclidean distance metric values.

The MAT is simply the set of elements in  $S$  making up the skeleton and their associated distance values to  $\bar{S}$ —that is, the maximal blocks of  $S$  that they span. Figure 2.12(e, f) shows the MATs of the rectangle of Figure 2.12(a) using its City Block and Chessboard distance metric values (given in Figure 2.12(b), which are identical for this example), respectively. Note that the MATs in Figure 2.12(e, f) have distance values that are one less than the values in Figure 2.12(b). This is due to a definition of the MAT as extending to the last unit-size element within the object rather than to the first unit-size element outside the image [1574]. Note that our initial formulation of the MAT in terms of the unit-size cells in the centers of the maximal blocks makes use of the Chessboard distance metric.

<sup>8</sup> Recall that given the two-dimensional points  $(x_1, y_1)$  and  $(x_2, y_2)$ , the Minkowski distance metric is defined as  $d_{L_p}((x_1, y_1), (x_2, y_2)) = ((x_1 - x_2)^p + (y_1 - y_2)^p)^{1/p}$  for integers  $p \geq 1$ .

- Can you prove that a definition of the MAT where the maximal blocks are anchored at the unit-size elements in their upper-left corner (i.e., the CMAT) results in fewer blocks than one where the maximal blocks are anchored at the unit-size elements in their center?
- Borgefors [233] discusses four different families of metrics for binary images. The most popular is the City Block/Chessboard metric family. Other families are the Chamfer metric, Octagonal metric, and D-Euclidean metric. The rationale is to enable a reasonable approximation of the Euclidean metric that is also easy and fast to implement. It should be clear that the City Block and Chessboard metrics are analogous to inner and outer approximations, respectively, to the Euclidean metric. The Chamfer, Octagonal, and D-Euclidean metrics are so-called “closer” approximations. Given a pair of points  $p = (p_x, p_y)$  and  $q = (q_x, q_y)$ , arbitrary integers  $a$  and  $b$ , the  $(a, b)$  Chamfer metric,  $d_{C(a,b)}(p, q)$ , is defined as follows:

$$e = \|p_x - q_x\| - \|p_y - q_y\|$$

$$f = \min\{\|p_x - q_x\|, \|p_y - q_y\|\}$$

$$d_{C(a,b)}(p, q) = a \cdot e + b \cdot f.$$

The pair of values (3,4) are used as a close approximation of the Euclidean metric. Compute  $d_{C(3,4)}$  and the MAT for the rectangle of Figure 2.12(a).

- Using the definition of the Chamfer metric in Exercise 2, what is the locus of points having  $d_{C(a,b)}(p, q) \leq T$ ?
- Using the definition of the Chamfer metric in Exercise 2, find the values of  $(a, b)$  that yield the Chessboard metric. Do the same for the City Block metric.

### 2.1.2.3 Irregular Grid

A very simple decomposition rule is one that partitions a  $d$ -dimensional space having coordinate axes  $x_i$  into  $d$ -dimensional blocks by use of  $h_i$  hyperplanes that are parallel to the hyperplane formed by  $x_i = 0$  ( $1 \leq i \leq d$ ). The result is a collection of  $\prod_{i=1}^d (h_i + 1)$  blocks. These blocks form a grid of irregular-sized blocks rather than congruent blocks. There is no recursion involved in the decomposition process. For example, Figure 2.14(a) is an example block decomposition using hyperplanes parallel to the  $x$  and  $y$  axes for the collection of objects and cells given in Figure 2.1. We term the resulting decomposition an *irregular grid* as the partition lines are at arbitrary positions, in contrast to a *uniform grid* [632] where the partition lines are positioned so that all of the resulting grid cells are congruent.

The block decomposition resulting from the use of an irregular grid is handled by an explicit representation in the same way as the arbitrary decomposition. Finding a suitable implicit representation is a bit more complex as we must define an appropriate access structure. Although the blocks are not congruent, we can still impose an array access structure by adding  $d$  access structures, termed *linear scales*. The linear scales indicate the position of the partitioning hyperplanes that are parallel to the hyperplane formed by  $x_i = 0$  ( $1 \leq i \leq d$ ). Thus, given a location  $l$  in space, say  $(a, b)$  in two-dimensional space, the linear scales for the  $x$  and  $y$  coordinate values indicate the column and row, respectively, of the array access structure entry that corresponds to the block that contains  $l$ .

For example, Figure 2.14(b) is the array access structure corresponding to the block decomposition in Figure 2.14(a), and Figure 2.14(c, d) shows the linear scales for the  $x$  and  $y$  axes, respectively. In this example, the linear scales are shown as tables (i.e., array access structures). In fact, they can be implemented using treelike access structures such as a binary search tree, range tree, or segment tree. The representation described here is an adaptation for regions of the *grid file* [1376] data structure for points (see Section 1.7.2.1 of Chapter 1).

Our implementation of the access structures for the irregular grid yields a representation that is analogous to an *indirect uniform grid* in the sense that, given a cell at location  $l$ , we need to make  $d + 1$  arraylike accesses (analogous to the two memory references involved with indirect addressing in computer instruction formats) to obtain the object  $o$  associated with it instead of just one array access when the grid is uniform (i.e., all the blocks are congruent and cell-sized). The first  $d$  accesses find the identity of the array element (i.e., block  $b$ ) that contains  $l$ , and the last access determines the object  $o$  associated with  $b$ . Once we have found block  $b$ , we examine the adjacent blocks to obtain the rest of the cells making up object  $o$ , thereby completing the response to the location query by employing the same methods that we used for the array access structure for the uniform-sized cells. The only difference is that every time we find a block  $b$  in the array access structure associated with  $o$ , we must examine  $b$ 's corresponding entries in the linear scales to determine  $b$ 's size so that we can report the cells that make up  $b$  as parts of object  $o$ .

### 2.1.2.4 Region Quadtree and Region Octree

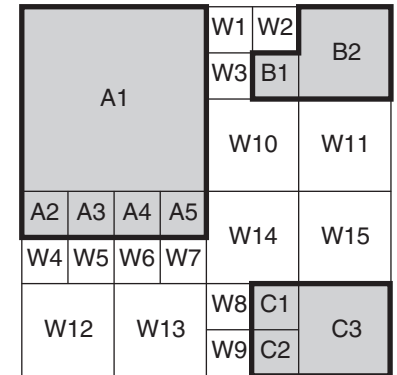

Perhaps the most widely known decompositions into blocks are those referred to by the general terms *quadtree* and *octree* [1636, 1637]. They are usually used to describe a class of representations for two- and three-dimensional data (and higher as well), respectively, that are the result of a recursive decomposition of the environment (i.e., space) containing the objects into blocks (not necessarily rectangular), until the data in each block satisfies some condition (e.g., with respect to its size, the nature of the objects it comprises, the number of objects in it). The positions and/or sizes of the blocks may be restricted or arbitrary. We shall see that quadtrees and octrees may be used with both interior-based and boundary-based representations. Moreover, both explicit and implicit aggregations of the blocks are possible.

There are many variants of quadtrees and octrees (see also Chapters 1 and 3), and they are used in numerous application areas, including high-energy physics, VLSI, finite-element analysis, and many others. Below we focus on *region quadtrees* [1035] and *region octrees* [901, 1276]. They are specific examples of interior-based representations for, respectively, two- and three-dimensional region data (variants for data of higher dimension also exist), that permit further aggregation of identically valued cells.

Region quadtrees and region octrees are instances of a restricted-decomposition rule, where the environment containing the objects is recursively decomposed into four or eight, respectively, rectangular congruent blocks until each block is either completely occupied by an object or is empty (see Exercise 2). Such a decomposition process is termed *regular*. For example, Figure 2.15(a) is the block decomposition for the region quadtree corresponding to Figure 2.1. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases. Such a quadtree is also known as a *multicolored quadtree* and is useful for applications such as a land use class map which associates colors with crops [1653]. When there is no need to distinguish between the various objects, we use the labels *black* (also “1” and foreground) and *white* (also “0” and background) to characterize or differentiate between the cells that lie in any of the objects and those that are not in any of the objects, respectively. Such a quadtree is also known as a *binary quadtree*.

Notice that in this case all the blocks are square, have sides whose size is a power of 2, and are located at specific positions. In particular, assuming an origin at the upper-left corner of the image corresponding to the environment containing the objects, the coordinate values of the upper-left corner of each block (e.g.,  $(i, j)$  in two dimensions) of size  $2^s \times 2^s$  satisfy the property that  $a \bmod 2^s = 0$  and  $b \bmod 2^s = 0$ . For an example

of a region octree, see Figure 2.16(b), which is the block decomposition for the region octree corresponding to the three-dimensional staircaselike object in Figure 2.16(a).

It is interesting to note that Kawaguchi, Endo, and Matsunaga [1005] use a sequence of  $m$  binary-valued quadtrees to encode image data of  $2^m$  gray levels, where the various gray levels are encoded by use of Gray codes (see footnote 35 in Section 1.6 of Chapter 1). This should lead to compaction (i.e., larger-sized blocks), since the Gray code guarantees that the binary representation of the codes of adjacent gray level values differ by only one binary digit. Note, though, that if the primary interest is in image compression, then there exist even better methods (see, e.g., [1508]); however, they are beyond the scope of this book (but see Chapter 8 of [1636]). In another context, Kawaguchi, Endo, and Yokota [1006] point out that a sequence of related images (e.g., in an animation application) can be stored compactly as a sequence of quadtrees such that the  $i$ th element is the result of performing an “exclusive or” operation on the first  $i$  images (see Exercise 5).

The region quadtree can be viewed as a special case of the medial axis transformation (MAT), which is discussed in Section 2.1.2.2. This can be seen by observing that in the case of the region quadtree, the widths of the maximal blocks of the MAT are restricted to be powers of 2, and the positions of their centers are constrained to being the centers of blocks obtained by a recursive decomposition of the underlying space into four congruent blocks. The notion of a MAT can be further adapted to the region quadtree by constraining only the positions of the centers of the blocks but not their sizes. The result is termed a *quadtree medial axis transform* (QMAT) [1626, 1630]. Thus, the blocks of the QMAT can span a larger area, as long as they are square-shaped. However, unlike the blocks of the region quadtree, the blocks of the QMAT are not disjoint.

The blocks of the QMAT are determined in the same way as the maximal blocks in the MAT. For each block  $b$  in the region quadtree for object  $o$ , find the largest square  $s_b$  of width  $w_b$  centered at  $b$  that is contained in  $o$ .  $s_b$  is called a *maximal block* if it is not contained in the largest square  $s_{b'}$  of any other block  $b'$  in  $o$ . Each object is completely specified by the set of maximal blocks that it comprises. The set of blocks in the quadtree that correspond to these maximal blocks is called its *quadtree skeleton*. The QMAT is the quadtree whose object blocks are the elements of the quadtree skeleton, and whose nonobject blocks correspond to empty blocks in the original quadtree as well as the object blocks whose largest square centered in the block were found to be not maximal. Associated with each object block in the QMAT is the width of its corresponding maximal block. For example, Figure 2.17(b) is the block decomposition of the QMAT corresponding to the block decomposition of the region quadtree in Figure 2.17(a). Notice that, as we pointed out above, the maximal blocks corresponding to the blocks in the QMAT are not disjoint. Observe also that in order to enable larger maximal blocks, we assume that the area outside the array of unit-size cells corresponding to the space in which object  $o$  is embedded is also part of  $o$  (e.g., the area to the north, west, and northeast of block 1 in Figure 2.17(a)). It can be shown that the quadtree skeleton is unique (see Exercise 23) [1626, 1636].

A region quadtree can be implemented using an explicit representation by associating a set with each object  $o$  that contains its constituent blocks. Each block is specified by a pair of numbers corresponding to the coordinate values of its upper-left corner and the size of one of its sides. These numbers are stored in the set in the form  $(i, j):k$ , where  $(i, j)$  and  $k$  correspond to the coordinate values of the upper-left corner and size (in terms of a power of 2), respectively, of the block. For example, the explicit representation of the collection of blocks in Figure 2.1 is given by the sets  $A=\{(0,0):2,(0,4):0,(1,4):0,(2,4):0,(3,4):0\}$ ,  $B=\{(5,1):0,(6,0):1\}$ , and  $C=\{(5,6):0,(5,7):0,(6,6):1\}$ , which correspond to blocks  $\{A1,A2,A3,A4,A5\}$ ,  $\{B1,B2\}$ , and  $\{C1,C2,C3\}$ , respectively.

An implementation of a region quadtree that makes use of an implicit representation is quite different. First of all, we allocate an address  $a$  in storage for each block  $b$  that

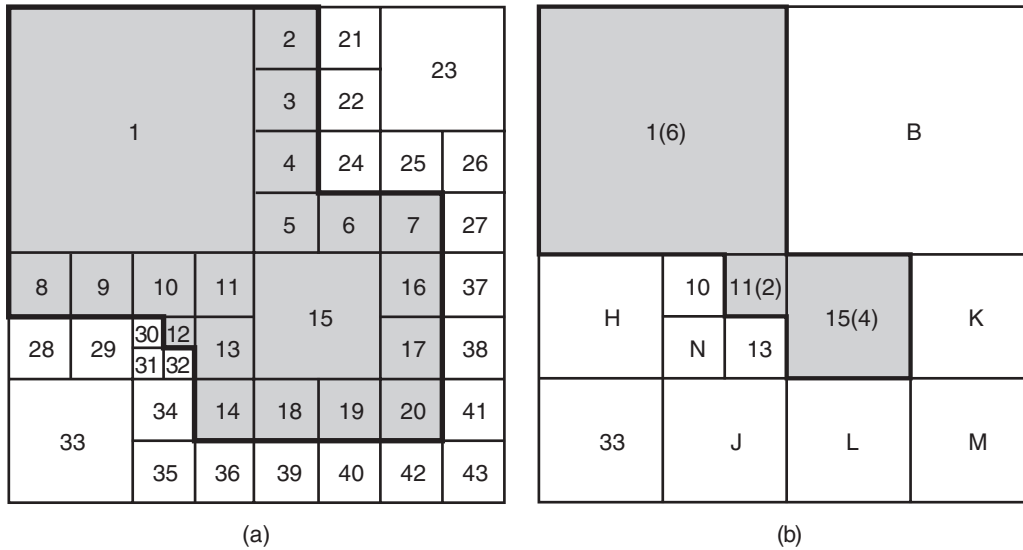

Figure 2.17 Block decomposition induced by (a) the region quadtree for an object and (b) its corresponding quadtree medial axis transform (QMAT). The radii (half the widths) of the corresponding maximal blocks are given in parentheses with each block label.

Figure 2.18 Tree representation for the region quadtree corresponding to the collection of objects and cells in Figure 2.1 whose quadtree block decomposition is given in Figure 2.15(a).

stores an identifier that indicates the identity of the object (or objects) of which  $b$  is a member. Second, it is necessary to impose an access structure on the collection of blocks in the same way as the array was imposed on the collection of unit-sized cells. Such an access structure enables us to determine easily the value associated with any point in the space covered by a cell without resorting to exhaustive search. Note that, depending on the nature of the access structure, it is not always necessary to store the location and size of each block with  $a$ .

There are many possible access structures. Interestingly, using an array as an access structure is not particularly useful as it defeats the rationale for the aggregation of cells into blocks unless, of course, all the blocks are of a uniform size, in which case we have the analog of a two-level grid.

The traditional, and most natural, access structure for a region quadtree corresponding to a  $d$ -dimensional image is a tree with a fanout of  $2^d$ . For example, Figure 2.18 is

the tree representation of the region quadtree corresponding to the collection of two-dimensional objects in Figure 2.1 whose quadtree block decomposition is given in Figure 2.15(a), while Figure 2.16(c) is the tree representation of the region octree corresponding to the three-dimensional staircaselike object in Figure 2.16(a) whose octree block decomposition is given in Figure 2.16(b). Each leaf node in the tree corresponds to a different block  $b$  and contains the address  $a$  in storage where an identifier is stored that indicates the identity of the object (or objects) of which  $b$  is a member. As in the case of the array, where we could store the object identifier  $o$  in the array element itself instead of allocating a separate address  $a$  for  $o$ , we could achieve the same savings by storing  $o$  in the leaf node of the tree. Each nonleaf node  $f$  corresponds to a block whose volume is the union of the blocks corresponding to the  $2^d$  children of  $f$ . In this case, the tree is a containment hierarchy and closely parallels the decomposition in the sense that they are both recursive processes and the blocks corresponding to nodes at different depths of the tree are similar in shape.

Again, when there is no need to distinguish between the various objects, we use the labels *black* (also “1” and foreground) and *white* (also “0” and background) to characterize or differentiate between the cells that lie in any of the objects and those that are not in any of the objects, respectively. The nonleaf nodes are characterized as *gray* nodes and likewise for their corresponding blocks. This node characterization is used for the tree access structures of all of the aggregations discussed in Sections 2.1.2.2 to 2.1.2.9.

Answering the location query using the tree access structure is different from using an array, where it is usually achieved by a table lookup having an  $O(1)$  cost (unless the array is implemented as a tree, which is a possibility [477]). In contrast, the location query is usually answered in a tree by locating the block that contains the location in space corresponding to the desired cell. This is achieved by a process that starts at the root of the tree and traverses the links to the children whose corresponding blocks contain the desired location. This process has an  $O(n + F)$  cost, where the environment has a maximum of  $n$  levels of subdivision (e.g., an environment whose sides are all of length  $2^n$ ), and  $F$  is the cardinality of the answer set.

Using a tree with fanout  $2^d$  as an access structure for a regular decomposition means that there is no need to record the size and location of the blocks since this information can be inferred from knowledge of the size of the underlying space. This is because the  $2^d$  blocks that result from each subdivision step are congruent. For example, in two dimensions, each level of the tree corresponds to a quartering process that yields four congruent blocks (rectangular here, although a triangular decomposition process could also be defined that yields four equilateral triangles; however, in such a case, we are no longer dealing with rectangular cells). Thus, as long as we start from the root, we know the location and size of every block.

There are several alternative access structures to the tree with fanout  $2^d$ . They are all based on finding a mapping from the domain of the blocks to a subset of the integers (i.e., to one dimension) and then applying one of the familiar treelike access structures, such as a binary search tree, range tree, or  $B^+$ -tree (e.g., [2]). There are many possible mappings (e.g., Chapter 2 in [1636]). The simplest is to use the same technique that we applied to the collection of blocks of arbitrary size. In particular, we can apply one of the orderings of space shown in Figure 2.5 to obtain a mapping from the coordinate values of the upper-left corner  $u$  of each block to the integers.

Since the size of each block  $b$  in the region quadtree can be specified with a single number indicating the size of the block corresponding to  $b$  (a power of two), we can simplify the representation by incorporating the size into the mapping. One mapping simply concatenates the result of interleaving the binary representations of the coordinate values of the upper-left corner (e.g.,  $(a, b)$  in two dimensions) and  $i$  of each block of size  $2^i$  so that  $i$  is at the right. The resulting number is termed a *locational code* and is a variant of the Morton number. A block that has been encoded in this way is often termed

a *Morton block*, and referring to a block using this term implies that its locational code is known. Assuming such a mapping and sorting the locational codes in increasing order yields an ordering equivalent to that which would be obtained by traversing the leaf nodes (i.e., blocks) of the tree representation (e.g., Figure 2.18) in the order NW, NE, SW, SE. This ordering is also the same as the Morton ordering of the unit-sized cells given in Figure 2.5(c).

If we also assign locational codes to the blocks corresponding to the nonleaf nodes of the tree access structure, and if we record the depth of the tree (at the right part of the locational code) at which the block is found instead of the size of the block, then the result of sorting the locational codes of all the blocks in increasing order yields the equivalent of a depth-first traversal of the tree access structure (see Exercise 20). If we vary the format of the locational codes so that we record the depth of the tree at which the block is found on the left (instead of on the right), and the number corresponding to the result of interleaving the binary representations of the coordinate values of the upper-left corner is on the right, then the result of sorting the locational codes of all the blocks in increasing order yields the equivalent of a breadth-first traversal of the tree access structure [222]. Woodwark [2017] also keeps track of the locational codes of the blocks corresponding to the nonleaf nodes but does not record the depth of the blocks. Instead, a value is recorded with each block  $b$  denoting  $b$ 's color with the color *transparent* denoting a block corresponding to a nonleaf node.

As an example of the use of locational codes for the blocks corresponding to the leaf nodes of the tree access structure, consider the collection of objects whose quadtree block decomposition is given in Figure 2.15(a). Assume an  $8 \times 8$  space, a block size value ranging between 0 and 3 (i.e., requiring two bits), an interleaving scheme that places the value of the  $y$  coordinate in a more significant position than that of the  $x$  coordinate, and assume that the block size information is on the right. Also, assume an implementation where the empty blocks are given a locational code, although they are frequently excluded in other implementations (e.g., [684]). Figure 2.15(b) shows the correspondence of blocks with locational codes.

Given a  $d$ -dimensional image spanning a space where the maximum length of the side of a block is  $2^n$ , the locational code representation requires  $n \cdot d + \lceil \log_2 n \rceil$  bits for each block. Ouksel, Sayal, and Scheuermann [1431] observe that whenever the side of a block is of size  $2^i$ , the trailing  $(n - i) \cdot d$  bits are zero. They propose to use the space occupied by the trailing zero bits to encode the size of the block using the length of the side. They represent the size of a block of side length  $2^i$  by a bit sequence consisting of a 0 followed by  $i$  1s.

Using such a scheme makes it easy to distinguish the size information from the result of interleaving the values of the bits corresponding to the upper-left corner of the block. In essence, this is achieved by a simple scan of the resulting representation from the extreme right end until encountering the first bit with value zero. Notice that the zero-valued bit serves as a flag or signal that the end of the variable-length size field has been reached. This means that  $n \cdot d + 1$  bits are needed for each block, or just one additional bit to represent the size information over that which is needed to represent the bit-interleaved address of the upper-left corner of the block. Note that sorting the resulting values in increasing order still yields the same result as traversing the leaf nodes (or the nonleaf nodes plus the leaf nodes) of the tree representation in the order NW, NE, SW, SE. The resulting representation is termed *efficient pixel interleaving compression technique* (EPICT).

As mentioned above, the ordering that we used in our mapping is an instance of the Morton ordering. The Morton ordering shown in Figure 2.5(c) (as well as the Peano-Hilbert, Gray, double Gray, and U orderings shown in Figure 2.5(d, g-i), respectively) is particularly attractive for quadtreelike block decompositions because all cells within a quadtree block appear in consecutive positions in the ordering. Alternatively, these five

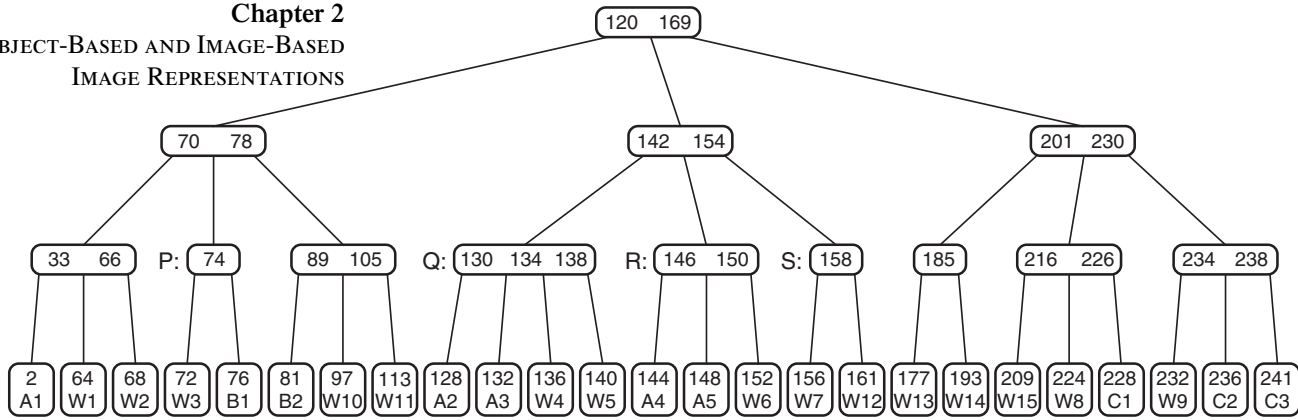

Figure 2.19  
Result of applying a  $B^+$ -tree access structure to the locational codes of the collection of objects whose quadtree block decomposition is given in Figure 2.15.

orders exhaust a quadtree block before exiting it. Note, however, that unlike the Peano-Hilbert ordering, none of the Morton, U, Gray, and double Gray orderings traverses the blocks in a spatially contiguous manner (i.e., for the Morton ordering the result has the shape of the letter “N” or “Z” and is also known as *N order* [1992] and *Z order* [1420], while for the U ordering the result has the shape of the letter “U”). The spatial contiguity property has been shown to have a good effect on the efficiency of range queries [581], thereby making a case for the use of the Peano-Hilbert order. In fact, Asano, Ranjan, Roos, Welzl, and Widmayer [101] describe an order that has the same properties as the Peano-Hilbert order except that for any square range query region, there are at most three breaks in the spatial continuity of the curve, in contrast to four for the Peano-Hilbert order (i.e., at most three out of four 4-adjacent subblocks of a square block are not neighbors along the curve, in contrast to a possibility that all four 4-adjacent subblocks are not neighbors in the Peano-Hilbert order). This property is useful for retrieval of squarelike regions in the case of a range query when the data is stored on disk in this order as each break in the continuity can result in a disk seek operation. Nevertheless, the Morton and U orderings are useful due to the ease with which the mapping and the inverse mapping can be constructed, as well as their other desirable properties described in Section 2.1.1.2.

An order 5  $B^+$ -tree access structure for these locational codes is given in Figure 2.19. It is important to note that although some of these treelike access structures also form a containment hierarchy (e.g., the range tree and the  $B^+$ -tree), unlike the tree with fanout  $2^d$ , the space spanned by the union of the blocks spanned by their nonleaf nodes does not have to consist of similar blocks (e.g., nodes P and Q in Figure 2.19); nor does it have to be a single block (e.g., node R in Figure 2.19); nor do the blocks that it comprises have to be contiguous (e.g., node S in Figure 2.19). For a representation that does constrain the blocks to be similar and the constituent blocks to be contiguous, see the discussion of the PK-tree [1952, 2043] in Section 1.8 of Chapter 1.

Using an order  $M$   $B^+$ -tree access structure for the locational codes of the blocks corresponding to the leaf nodes reduces the execution time of the location query from  $O(n)$  (i.e.,  $O(\log 2^n)$ ) to  $O(\log_M N)$ , assuming that the sides of the environment are of length  $2^s$  and that there are  $N$  leaf nodes. Amir, Efrat, Indyk, and Samet [43] have reduced this bound further to expected  $O(\log n)$  time by using a hash table to store the locational codes of both the leaf and nonleaf nodes of the tree access structure of the quadtree (octree). Their result is based on the premise that given a query point  $q$  and a depth  $k$ , we can use the hash table to determine in expected  $O(1)$  time whether there exists a block  $b$  at depth  $k$  (leaf or nonleaf) in the quadtree that contains  $q$ . It is well known that this premise holds in general for a hash table (e.g., [422]). The expected  $O(\log n)$  time is obtained by repeated application of the above query in conjunction with a binary search for  $q$  in the range of depths from 0 to  $n$  (see Exercise 18). In fact, given that  $q$  is in leaf

node  $v$  at depth  $h$ , the expected execution time is  $O(\log h)$  when using an unbounded binary search on the range of depths in the order  $1, 2, 4, 8, \dots$  (see Exercise 19).

Regardless of the access structure that is used, we determine the object  $o$  associated with a cell at location  $l$  by finding the block  $b$  that covers  $l$ . Recall that this yields only a partial response to the location query as we also want to determine the remaining blocks that object  $o$  comprises. This is done by accessing the blocks adjacent<sup>9</sup> to  $b$  and checking if they are associated with  $o$ . If they are, then their adjacent blocks are examined by a recursive application of this process. This process is known as *neighbor finding* [1625, 1635]. The actual mechanics of this process depend on the nature of the access structure (for a detailed discussion, see Chapter 3 in [1636]).

Using an access structure in the form of a tree with fanout  $2^d$  means that we can locate the adjacent blocks by just using the structure of the tree. For the sake of this discussion, assume that  $d = 2$  and that each node  $p$  in the quadtree contains an additional pointer to its immediate ancestor. Here, we restrict ourselves to lateral neighbors (i.e., in the horizontal and vertical directions) that are of size greater than or equal to that of  $p$ . Now, to locate a lateral neighbor  $q$  of  $p$ , we follow ancestor links until finding the nearest common ancestor of  $p$  and  $q$ . Once the common ancestor is found, we descend along a path that retraces the ascending path with the modification that each step is a reflection of the corresponding prior step about an axis formed by the common boundary between the two nodes  $p$  and  $q$ .

For example, when attempting to locate the eastern neighbor of node A (i.e., node G) in the box in Figure 2.20, node D is their nearest common ancestor, while the eastern edge of the block corresponding to node A is the common boundary between node A and its neighbor G. The main idea behind this neighbor finding method can be understood by examining more closely how the nearest common ancestor of node  $p$  and its eastern neighboring node  $q$  of greater than or equal size are located. In other words, as we ascend links, how do we know that we have encountered the nearest common ancestor and that it is time to descend links? The answer is obtained by observing that the nearest common ancestor has  $p$  as one of the easternmost nodes of one of its western subtrees and  $q$  as one of the westernmost nodes of one of its eastern subtrees. Thus, as long as an ancestor  $r$  of  $p$  is in a subtree that is an eastern child (i.e., NE or SE), we must ascend the tree at least one more level before locating the nearest common ancestor. C code for this process, as well as the necessary tables, is given by procedure LATERALNEIGHBOR in Figure 2.20. This technique has been shown to require an average of four links to be followed for each neighbor of equal size that is being sought [1625]. If the neighbor is larger, then the algorithm is even faster because the descent step stops sooner [1625, 1636, 1652].

Neighbor finding can also be applied when using one of the alternative access structures that are based on finding a mapping from the domain of the blocks to a subset of the integers. In this case, neighbors are obtained by calculating their locational codes and then conducting a search for them in the relevant access structure. The calculation is made using binary arithmetic [1636, 1696]. The key idea (or trick) is to calculate the coordinate values of the upper-left corner of the neighboring block without having to decompose the locational code into its individual coordinate axes components and then composing them to form the new locational code.

### Exercises

1. The region quadtree is an alternative to an image representation that is based on the use of an array or even a list. Each of these image representations may be biased in favor of the computation of a particular adjacency relation. Discuss these biases for the array, list, and quadtree representations.

---

<sup>9</sup> Adjacency between blocks from the same object is defined in an analogous manner to that for adjacent locations (i.e., pixels). In particular, two disjoint blocks,  $P$  and  $Q$ , are said to be *4-adjacent* if there exists a pixel  $p$  in  $P$  and a pixel  $q$  in  $Q$  such that  $p$  and  $q$  are 4-adjacent. The definition of 8-adjacency for blocks (as well as connected component labeling) is analogous.

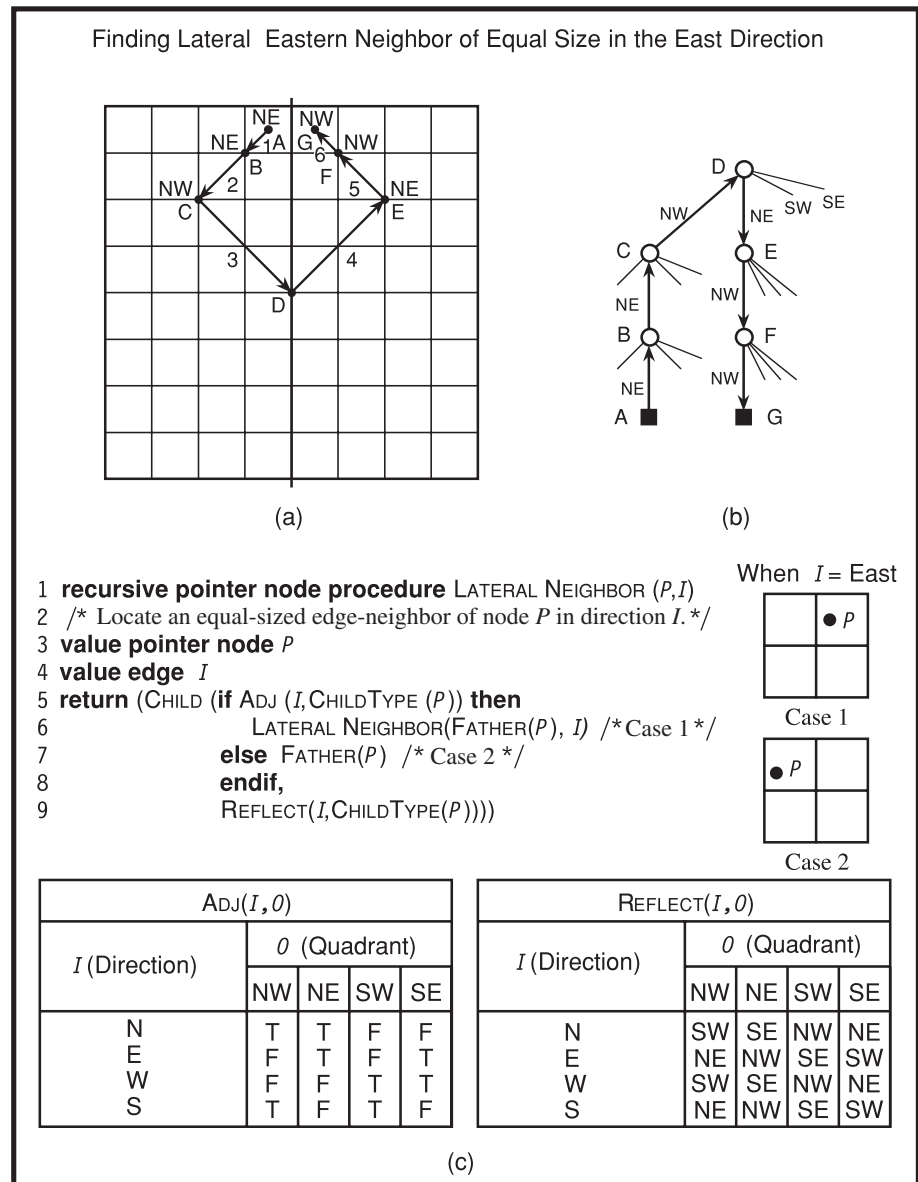

Figure 2.20 The process of locating the eastern neighbor of node A (i.e., G): (a) block decomposition, (b) the corresponding tree representation of the search process, and (c) C code of the algorithm and the necessary tables.

2. Given the array representation of a binary image, write an algorithm to construct the corresponding region quadtree.
3. Suppose that an octree is used to represent a collection of disjoint spheres. What would you use as a leaf criterion?
4. The quadtree can be generalized to represent data in arbitrary dimensions. As we saw, the octree is its three-dimensional analog. The renowned artist Escher [427] is noted for etchings of unusual interpretations of geometric objects such as staircases. How would you represent one of Escher's staircases?
5. Let  $\oplus$  denote an "exclusive or" operation. Given a sequence of related images,  $\langle P_n, P_{n-1}, \dots, P_0 \rangle$ , define another sequence  $\langle Q_n, Q_{n-1}, \dots, Q_0 \rangle$  such that  $Q_0 = P_0$  and  $Q_i = P_i \oplus Q_{i-1}$  for  $i > 0$ . Show that when the sequences  $P$  and  $Q$  are represented as quadtrees, replacing sequence  $P$  by sequence  $Q$  results in fewer nodes.

6. Prove that in Exercise 5 the sequence  $P$  can be reconstructed from the sequence  $Q$ . In particular, given  $Q_i$  and  $Q_{i-1}$ , determine  $P_i$ .
7. Suppose that you have an environment of width 32 and length 64. What are the permissible sizes of the blocks after the first region quadtree subdivision step?
8. Suppose that you have an environment of width 16 and length 24. Can the first region quadtree subdivision step result in two blocks of size  $8 \times 8$  and two blocks of size  $8 \times 16$ ? If not, explain why.
9. Given an image represented by a region quadtree with  $B$  black and  $W$  white nodes, how many additional nodes are necessary for the nonleaf nodes?
10. Given an image represented by a region octree with  $B$  black and  $W$  white nodes, how many additional nodes are necessary for the nonleaf nodes?
11. Consider the arbitrary placement of a square of size  $2^m \times 2^m$  at any position in a  $2^q \times 2^q$  image and then construct its corresponding region quadtree. Prove that in the best case  $4 \cdot (q - m) + 1$  nodes are required while the worst case requires  $4 \cdot p + 16 \cdot (q - m) - 27$  nodes. How many of these nodes are black and white, assuming that the square is black? Prove that, on the average, the number of nodes required is  $O(p + q - m)$ .
12. What are the worst-case storage requirements of storing an arbitrary rectangle in a quadtree corresponding to a  $2^q \times 2^q$  image? Give an example of the worst case and the number of nodes it requires.
13. Assume that the probability of a particular pixel's being black is  $\frac{1}{2}$  and likewise for its being white. Given a  $2^q \times 2^q$  image represented by a quadtree, what is the expected number of nodes, say  $E(q)$ , in the quadtree? Also compute the expected number of black, white, and gray nodes.
14. Suppose that instead of knowing the probability that a particular pixel is black or white, we know the percentage of the total pixels in the image that are black. Given a  $2^q \times 2^q$  image represented by a quadtree, what is the expected number of nodes in the quadtree?
15. Suppose that you are given a region quadtree, how would you obtain a uniform spatial sample of  $s$  black pixels from the black regions stored in the quadtree?
16. Prove that for a region such that  $w$  is the maximum of its horizontal and vertical extent (measured in pixel widths) and  $2^{q-1} < w \leq 2^q$ , the optimal grid resolution when building its corresponding region quadtree is either  $q$  or  $q + 1$ . In other words, show that embedding the region in a larger area than  $2^{q+1} \times 2^{q+1}$  and shifting it around will not result in fewer nodes.
17. Give an algorithm to find the optimal region quadtree, in terms of the minimum number of quadtree nodes, for an arbitrary binary image.
18. Assuming that an environment has sides of length  $2^n$ , that the nodes of the region quadtree (octree) are represented by locational codes, and that the locational codes of both the leaf and nonleaf nodes are stored in a hash table, show that the leaf node  $v$ , and its depth  $h$ , containing query point  $q$  can be determined in expected  $O(\log n)$  time. Assume further that given a depth  $k$ , we can use the hash table to determine in expected  $O(1)$  time whether there exists a block  $b$  at depth  $k$  (corresponding to a leaf or a nonleaf node) in the quadtree that contains  $q$ .
19. Continuing Exercise 18, and, again, assuming an environment with sides of length  $2^n$ , show that the block  $v$  at depth  $h$  containing  $q$  can be determined in expected  $O(\log h)$  time instead of expected  $O(\log n)$  time.
20. Suppose that you represent each block of a quadtree block decomposition by concatenating the result of applying bit interleaving to the coordinate values of one of the corners of each block (including the nonleaf blocks) and the size or depth of the block. Describe such an encoding so that when the locational codes of the leaf and nonleaf blocks of the quadtree appear in increasing order, the four sons of a node appear before their immediate ancestor when the children of the node corresponding to each nonleaf block are traversed in the order NW, NE, SW, SE. In other words, we have a bottom-up or postorder traversal of the tree.
21. Compare the use of the conventional locational code method with EPICT for representing three-dimensional data when the maximum number of bits in the locational code is 32 and 64. In other words, what is the maximum block size that can be represented using these two methods?

(a)

(b)

(c)

Figure 2.21  
(a) The region quadtree of an object and the tree representations of its corresponding QMATs using (b) property 3 and (c) property 3'. The radii (half the widths) of the maximal blocks are given in parentheses with each block label.

- Give an algorithm for finding neighbors in the direction of a vertex (i.e., diagonal) for a region quadtree that is implemented using an access structure in the form of a tree with a fanout of 4.
- A more precise definition of the quadtree skeleton of a collection of objects represented by a region quadtree is given as follows. Let  $B$  denote the set of quadtree blocks corresponding to the objects in the collection. For each block  $b$  in object  $o$ , let  $s_b$  of width  $w_b$  be the largest square centered at  $b$  that is contained in  $o$ . The quadtree skeleton consists of the set  $T$  of quadtree object blocks satisfying the following properties:
  - The set of pixels in  $B = \cup_{t \in T} s_t$ .
  - For any  $t$  in  $T$ , there does not exist  $b$  in  $B$  ( $b \neq t$ ) such that  $s_t \subseteq s_b$ .
  - For each  $b$  in  $B$ , there exists  $t$  in  $T$  such that  $s_b \subseteq s_t$ .

Property 1 ensures that the entire collection of objects is spanned by the quadtree skeleton. Property 2 is termed the *subsumption property*—block  $j$  is *subsumed* by block  $k$  when  $s_j \subseteq s_k$ . Property 2 means that the elements of the quadtree skeleton are maximal blocks. Property 3 insures that no block in  $B$  requires more than one element of  $T$  for its subsumption; for example, the case that one-half of the block is subsumed by one element of  $T$  and the other half is subsumed by another element of  $T$  is not permitted. Prove that the quadtree skeleton of a collection of objects represented by a region quadtree is unique.

- Property 2 in the definition of the quadtree skeleton in Exercise 23 means that the elements of the quadtree skeleton are the maximal blocks. Suppose that property 2 is modified as follows:
  - For any  $t$ , in  $T$ , there does not exist  $u$  in  $T$  ( $u \neq t$ ) such that  $s_t \subseteq s_u$ .

This results in ensuring that there are no extraneous elements in the quadtree skeleton. In other words, one element in the quadtree skeleton cannot be subsumed by another element in the quadtree skeleton. For example, for the region quadtree in Figure 2.17(a), this means that if the quadtree skeleton contains block 12, then it cannot contain block 11 as the maximal block of block 12 is subsumed by the maximal block of block 11. Is the resulting quadtree skeleton still unique?

- Show that the modification of property 2 (i.e., property 2') in the definition of the quadtree skeleton in Exercise 24 results in a QMAT with more blocks.
- Property 3 of the definition of the quadtree skeleton in Exercise 23 does not yield a minimal set of blocks. For example, in the region quadtree of Figure 2.21(a), Property 3 requires that the quadtree skeleton contain blocks 5, 14, and 15, while, in actuality, blocks 5 and 15 are sufficient since together they subsume block 14. Thus, if we were interested in a minimal set of block,s we could modify property 3 as follows:
  - There does not exist  $u$  in  $T$  such that  $s_u \subseteq \cup_{t \in T \text{ and } t \neq u} s_t$ .

Show that, although the number of blocks in the quadtree skeleton is reduced by this modification, the number of elements in the QMAT is not.

### 2.1.2.5 ATree

In some applications, we may require finer (i.e., more) partitions along a subset of the dimensions due to factors such as sampling frequency (e.g., when the blocks correspond to aggregates of point data), while needing coarser (i.e., fewer) partitions along the remaining subset of dimensions. This is achieved by loosening the stipulation that the region quadtree results in  $2^d$  congruent blocks at each subdivision stage and replacing it with a stipulation that all blocks at the same subdivision stage (i.e., depth)  $i$  be partitioned into  $2^{c_i}$  ( $1 \leq c_i \leq d$ ) congruent blocks. We use the term *ATree* [222] to describe the resulting structure.

For example, Figure 2.22(a) is the block decomposition for the ATree for Figure 2.1, and Figure 2.22(b) is the corresponding tree access structure. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases. The nonleaf nodes are labeled with the partition axis or axes, which must be the same for all nodes at the same level. Note that all blocks at a particular level of subdivision  $e$  are partitioned in the same way (i.e., into the same number of congruent blocks along the same axes).

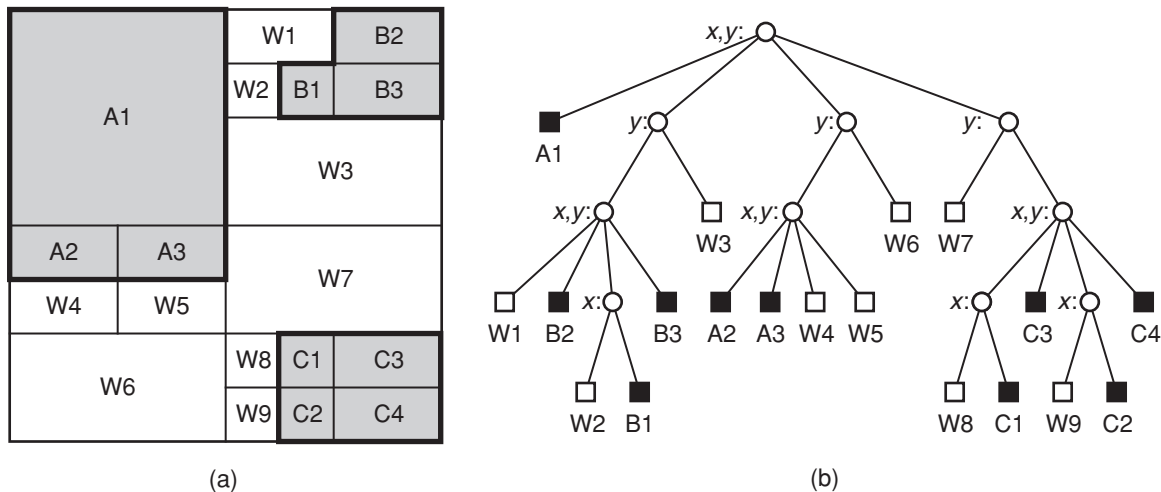

Figure 2.22  
 (a) Block decomposition for the ATree corresponding to the collection of objects and cells in Figure 2.1 and (b) the corresponding tree access structure. The nonleaf nodes are labeled with the partition axis or axes.

### 2.1.2.6 Bintree

As the dimensionality of the space (i.e.,  $d$ ) increases, each level of decomposition in the region quadtree results in many new blocks, as the fanout value  $2^d$  is high. In particular, it is too large for practical implementation of the tree access structure. In this case, an access structure termed a *bintree* [1041, 1661, 1828] with a fanout value of 2 is used. The bintree is defined in a manner analogous to the region quadtree, except that at each subdivision stage, the space is decomposed into two equal-sized parts. In two dimensions, at odd stages we partition along the  $y$  axis, and at even stages we partition along the  $x$  axis. Of course, in  $d$  dimensions, the depth of the tree may increase by a factor of  $d$ . The bintree can also be viewed as a special case of the ATree where all blocks at subdivision stage  $i$  are partitioned into a predetermined subset of the dimensions of size  $2^{c_i}$  blocks, where  $c_i = 1$ . Alternatively, the bintree is an adaptation of the PR k-d tree (see Section 1.5.2.1 of Chapter 1) to represent regions.

Figure 2.23(a) is the block decomposition for the bintree for Figure 2.1, and Figure 2.23(b) is the corresponding tree access structure. We assume that the first split is on the  $y$  coordinate value. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases. In general, in the case of  $d$  dimensions, we cycle through the different axes every  $d$  levels in the bintree.

The bintree can be generalized by relaxing the requirement that the decomposition steps cycle through the different axes while still requiring that at each subdivision stage the space be decomposed into two equal parts. We use the term *generalized bintree* to describe this structure. It is also known as the *Adaptive Hierarchical Coding* (AHC) structure [411]. For example, Figure 2.24(a) is the block decomposition for the generalized bintree for Figure 2.1, and Figure 2.24(b) is the corresponding tree access structure. Nonleaf nodes are labeled with the name of the axis of the partition. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases. The decision as to the coordinate on which to partition depends on the image. This technique may require some work to get the optimal partition from the point of view of a minimum number of nodes (see Exercise 5). Notice that the generalized bintree is not a special case of the ATree (see Exercise 1).

(b)

Figure 2.23  
 (a) Block decomposition for the bintree corresponding to the collection of objects and cells in Figure 2.1 and (b) the corresponding tree access structure. The splits alternate between the  $y$  and  $x$  coordinate values, with the first split being based on the  $y$  coordinate value.

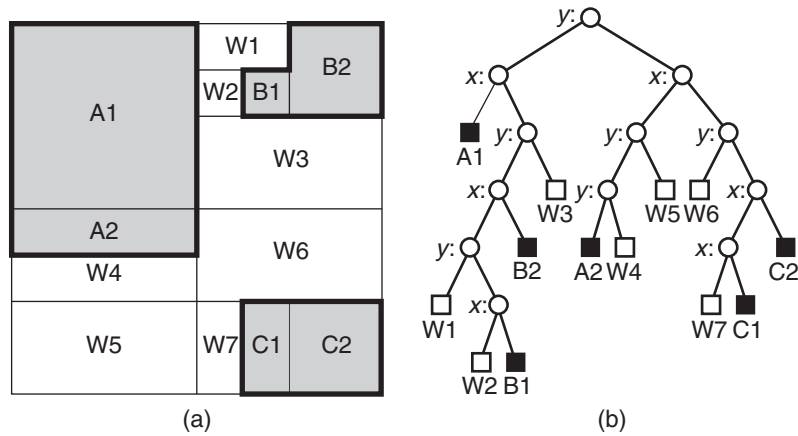

Figure 2.24  
(a) Block decomposition for the generalized bintree corresponding to the collection of objects and cells in Figure 2.1 and (b) the corresponding tree access structure. The nonleaf nodes are labeled with the partition axes.

The block decomposition resulting from the use of a bintree (as well as an ATree and a generalized bintree) can be implemented using an explicit representation in the same way as the region quadtree. Although we presented the bintree in terms of an implicit representation that uses a tree access structure with a fanout value of 2, it can be implemented with other access structures (e.g., B<sup>+</sup>-tree, etc.) that are applied once a mapping has been found from the domain of the blocks to that of the integers (e.g., locational codes). We do not discuss such techniques here, although it should be clear that they are quite easy to apply, as long as we know the order in which the decomposition process cycles through the axes in the case of the bintree or, in the case of the ATree, the identities of the partitions applied at each subdivision stage. For the generalized bintree, the situation is a bit more complex as we need to keep track of either the order in which the partitions were applied for each block or the size of each block.

### Exercises

1. Why is the generalized bintree not a special case of the ATree?
2. What is the ratio of leaf nodes to nonleaf nodes in a bintree for a  $d$ -dimensional image?
3. What is a lower bound on the ratio of leaf nodes in a bintree to that in a region quadtree for a  $d$ -dimensional image? What is an upper bound? What is the average?
4. Is it true that the total number of nodes in a bintree is always less than that in the corresponding region quadtree?
5. Suppose that you use the AHC method. How many different rectangles and positions must be examined in building such a structure for a  $2^n \times 2^n$  image?

### 2.1.2.7 Adaptation of the Point Quadtree for Regions

The region quadtree, as well as the bintree, is formed by a regular decomposition. This means that the blocks are congruent—that is, at each level of decomposition, all of the resulting blocks are of the same shape and size. We can also use decompositions where the sizes of the blocks are not restricted in the sense that the only restriction is that they be rectangular and be a result of a recursive decomposition process. In this case, the representations that we described must be modified so that the sizes of the individual blocks can be obtained. For example, the explicit representation (as described in the start of this section in conjunction with the example in Figure 2.10) needs to record both the coordinate values of the upper-left corner of each block and the lengths of its sides

along the  $d$  coordinate axes, instead of just the length of one side as is the case for the region quadtree.

When using the implicit representation, we have several options. Since the decomposition process is recursive, we can use a tree access structure where, at each level of the tree, the positions of the partition lines are recorded. An example of such a structure is an adaptation of the point quadtree [614] to regions. Although the point quadtree was designed to represent points in a higher-dimensional space, the blocks resulting from its use to decompose space do correspond to regions. The difference from the region quadtree is that, in the point quadtree, the positions of the partitions are arbitrary, whereas they are a result of a partitioning process into  $2^d$  congruent blocks (e.g., quartering in two dimensions) in the case of the region quadtree. For example, Figure 2.25(a) is the block decomposition for the point quadtree for Figure 2.1, and Figure 2.25(b) is the corresponding tree access structure. Nonleaf nodes are labeled with the location of the partition point. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases.

### Exercises

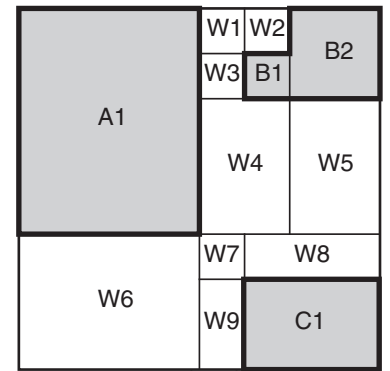

- (Ken-ichi Kanatani) The Fibonacci numbers consist of the sequence of numbers  $f_i$  that satisfy the relation  $f_i = f_{i-1} + f_{i-2}$ , with  $f_0 = 1$  and  $f_1 = 1$ . There are a number of possible quadtree decomposition rules based on this sequence. One possible quadtree splitting rule is to restrict all shapes to squares with sides whose lengths are Fibonacci numbers. Is this rule feasible?
- An alternative quadtree decomposition rule to the one proposed in Exercise 1 for a Fibonacci sequence is one that restricts the shapes to being rectangles whose sides have lengths that are either equal Fibonacci numbers or are successive Fibonacci numbers. This condition is termed the *2-d Fibonacci condition*. Give a formal specification of this condition for two dimensions in terms of a relation  $g_{m,n}$  that must be satisfied. Can you generalize it to  $d$  dimensions?
- Show that the 2-d Fibonacci condition given in Exercise 2 does not hold for all possible squares so that the smallest primitive unit is a  $1 \times 1$  square?
- Find a polynomial-time algorithm to decompose a region optimally so that its representation using the adaptation of a point quadtree requires a minimum amount of space (i.e., a minimum number of nodes). In other words, the decomposition lines need not split the space into four squares of equal size.

### 2.1.2.8 Adaptation of the K-d Tree for Regions

As in the case of the region quadtree, as the dimensionality  $d$  of the space increases, each level of decomposition in the point quadtree results in many new blocks since the fanout value  $2^d$  is high. In particular, it is too large for a practical implementation of the tree access structure. Recall that in this case we resorted to the bintree, which is an access structure with a fanout value of 2. The same reasoning motivates the replacement of the point quadtree by a k-d tree [164] in an adaptation of a point quadtree to regions. As in the point quadtree, although the k-d tree was designed to represent points in a higher-dimensional space, the blocks resulting from its use to decompose space do correspond to regions. In fact, the k-d tree is the precursor of the bintree and, in its adaptation to regions, is defined in a similar manner in the sense that, for  $d$ -dimensional data, we cycle through the  $d$  axes every  $d$  levels in the k-d tree. The difference is that in the k-d tree the positions of the partitions are arbitrary, whereas they are a result of a halving process in the case of the bintree.

For example, Figure 2.26(a) is the block decomposition for the k-d tree for Figure 2.1, and Figure 2.26(b) is the corresponding tree access structure. Nonleaf nodes are labeled with the name of the axis of the partition and the location of the partition line. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases.

## Section 2.1 INTERIOR-BASED REPRESENTATIONS

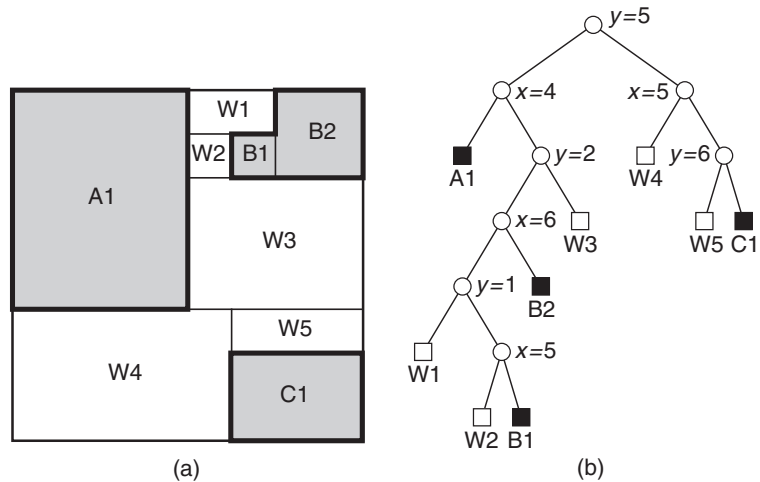

Figure 2.26  
(a) Block decomposition for the k-d tree corresponding to the collection of objects and cells in Figure 2.1 and (b) the corresponding tree access structure. The splits alternate between the  $y$  and  $x$  coordinate values, with the first split being based on the  $y$  coordinate value. The locations of the splits are indicated next to the relevant nonleaf nodes.

Figure 2.27  
(a) Block decomposition for the generalized k-d tree corresponding to the collection of objects and cells in Figure 2.1 and (b) the corresponding tree access structure. The nonleaf nodes are labeled with the partition axes and the partition values.

The k-d tree can be further generalized so that the partitions take place on the various axes in an arbitrary order. In fact, the partitions need not be made on every coordinate axis. In this case, at each nonleaf node of the k-d tree, we must also record the identity of the axis that is being split. We use the term *generalized k-d tree* to describe this structure. For example, Figure 2.27(a) is the block decomposition for the generalized k-d tree for Figure 2.1, and Figure 2.27(b) is the corresponding tree access structure. Nonleaf nodes are labeled with the name of the axis of the partition and the location of the partition line. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases.

The generalized k-d tree is really an adaptation to regions of the adaptive k-d tree [650] and the dynamic pseudo k-d tree [1444], as well as the disk-based k-d-B-tree [1567] (see Section 2.1.5.3) and the LSD tree [829]. The similarity lies in the fact that they also permit the partitions to take place on the various axes in an arbitrary order and at arbitrary positions. Although all of these representations were originally developed for points, they can be also be easily adapted to handle regions.

The generalized k-d tree can also be regarded as a special case of the *Binary Space Partitioning tree* (BSP tree) [657, 658] discussed briefly as a point representation in Section 1.5.1.4 of Chapter 1. In particular, in the generalized k-d tree, the partitioning hyperplanes are restricted to being parallel to the axes, whereas, in the BSP tree, they have arbitrary orientations. The BSP tree is used in computer graphics to facilitate viewing. The BSP tree is discussed in greater detail in Section 2.1.3.1.

Similarly, the D-tree [2035, 2036] (discussed briefly in Section 1.5.1.4 of Chapter 1) is a further generalization of the BSP tree where polylines (sequences of connected line segments of arbitrary orientation) are used instead of partitioning hyperplanes of arbitrary orientation. Unfortunately, in order to efficiently execute a point location query, the D-tree requires the imposition of an additional data structure on its associated partition of the underlying space such as the K-structure [1026] (see Section 2.1.3.2) or the separating chain method [1128] and the improved access structure for it known as the layered dag [541] (see Section 2.1.3.3).

**Exercises**

1. Exercise 2 in Section 2.1.2.7 describes a quadtree decomposition rule for a Fibonacci sequence that restricts the shapes to being rectangles whose sides have lengths that are either equal

Fibonacci numbers or are successive Fibonacci numbers. This condition was termed the *2-d Fibonacci condition*. Suppose that you use this rule in conjunction with a k-d tree instead of a quadtree. Show that this condition does not hold for all possible squares so that the smallest primitive unit is a  $1 \times 1$  square.

- From Exercises 1 and 3 in Section 2.1.2.7, we see that neither a quadtree nor a k-d tree can be used by itself as a basis for Fibonacci-based space decomposition. These solutions have assumed splitting rules that insure that vertical subdivision lines at the same level are colinear as are horizontal lines at the same level. For example, when using a quadtree splitting rule, the vertical lines that subdivide the NW and SW quadrants are colinear as are the horizontal lines that subdivide the NW and NE quadrants. One solution is to relax the colinearity restriction. However, the sides of the shapes must still satisfy the 2-d Fibonacci condition (see Exercise 2). An alternative is to combine the two rules so that either one can be used—that is, a stage can use either the k-d tree or quadtree-based rule. Explain this combined rule in greater detail.

### 2.1.2.9 X-Y Tree, Treemap, and Puzzletree

One of the shortcomings of the generalized k-d tree is that we can only decompose the underlying space into two parts along a particular dimension at each step. If we wish to partition a space into  $p$  parts along dimension  $i$ , then we must perform  $p - 1$  successive partitions on dimension  $i$ . Once these  $p - 1$  partitions are complete, we partition along another dimension. The *X-Y tree* of Nagy and Seth [1334] and the subsequently developed and equivalent *treemap* of Shneiderman [1758] (see also [153, 960, 1759]) and *puzzletree* of Dengel [478, 479, 480] are further generalizations of the k-d tree that decompose the underlying space into two or more parts along a particular dimension at each step so that no two successive partitions use the same dimension. In other words, the X-Y tree, treemap, and puzzletree compress all successive partitions on the same dimension in the generalized k-d tree. They are distinguished, in part, by their motivation. In particular, the original motivation for the treemap was a desire to visualize a containment hierarchy associated with one-dimensional data, while both the X-Y tree and the puzzletree were motivated by a desire to represent multidimensional region data. In any case, the underlying representation of the three methods is basically the same.

The treemap was developed as a means of visualizing data in the form of a one-dimensional containment hierarchy, such as a tree directory or an outline, by converting (i.e., “mapping”) it into a planar space-filling map—that is, in effect, combining aspects of a Venn diagram with a pie chart [960, 1758]. The areas of the individual regions of space into which the nodes of the containment hierarchy are mapped is made proportional to a value of some attribute (i.e., the same attribute) of the data represented by the directory. For example, in the case of a tree directory for a computer file system, each nonleaf node in the hierarchy corresponds to a subdirectory, where its area in the visualization is proportional to the sum of the sizes of the constituent files (e.g., in megabytes), and, assuming that all levels of the directory hierarchy are visualized, each leaf node corresponds to an individual file, where its area in the visualization is proportional to the file’s size. Of course, hierarchies involving other types of data are also possible.

The natural way of visualizing the treemap alternates the orientation of the boundaries of the regions corresponding to the different levels of the containment hierarchy region partitions between horizontal and vertical lines, thereby mimicking the compressed generalized k-d tree (termed *slice-and-dice* [1758]). Unfortunately, such a visualization leads to long, thin rectangles, which is not very pleasing from an aesthetic point of view. This has led to the development of techniques that make use of more “squarelike” aspect ratios for the individual regions (e.g., [153, 1759]). The drawback of these techniques is that the implicit one-dimensional ordering of the leaf nodes of the containment hierarchy (e.g., a top-to-bottom or left-to-right ordering in an outline) is lost, and there is now a need to specify an ordering of the new layout (e.g., row-major or column-major in an array) if, indeed, the relative ordering is important, which is not always the case if grouping into categories is the key motivation for the containment hierarchy (e.g., a

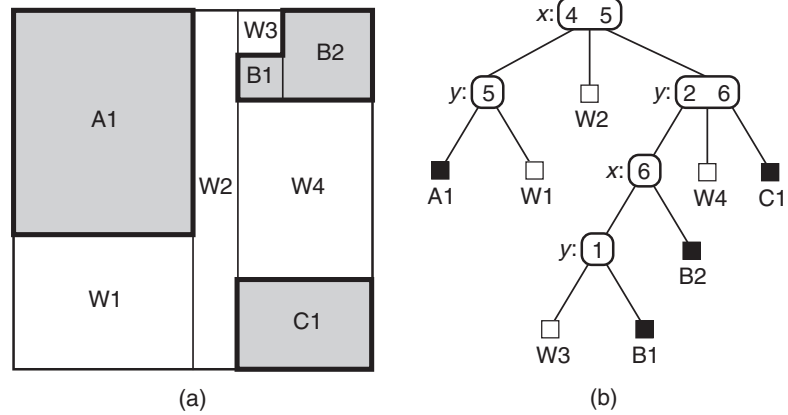

Figure 2.28  
(a) Block decomposition for the puzzletree corresponding to the collection of objects and cells in Figure 2.1 and (b) the corresponding tree access structure. The nonleaf nodes are labeled with the partition axes and the partition values.

Figure 2.29

collection of photos). In some sense, these alternative region-representation techniques resemble the imposition of gridlike partitions at the various levels of the directory.

The X-Y tree was developed as a page representation for regions in optically scanned documents, and its presentation focused on issues related to its use in this application [1334]. However, Nagy and Seth do point out in passing that the X-Y tree could be extended to three and more dimensions, which could be useful for dealing with multipage documents as well as, possibly, with other applications. In contrast, the puzzletree was developed as an object representation with a detailed discussion of the ramifications of its use in the representation of both two- and three-dimensional objects. As our interest in this section is more in object representations, the discussion in the rest of this section follows the presentation of Dengel and hence is usually in terms of the puzzletree, especially in the context of objects, although almost all that we say is equally applicable to the X-Y tree and also to the original formulation of the treemap.

Figure 2.28(a) is the block decomposition for the puzzletree for Figure 2.1, and Figure 2.28(b) is the corresponding tree access structure. Notice that the puzzletree was created by compressing the successive initial partitions on  $x = 4$  and  $x = 5$  at depths 0 and 1, respectively, and likewise for the successive partitions on  $y = 6$  and  $y = 2$  at depths 2 and 3, respectively, in Figure 2.27. Nonleaf nodes are labeled with the name of the axis of the partition and the location of the partition line. We have labeled the blocks corresponding to object  $O$  as  $O_i$  and the blocks that are not in any of the objects as  $W_i$ , using the suffix  $i$  to distinguish between them in both cases.

The fact that the puzzletree compresses all successive partitions on the same dimension means that for  $d = 2$  the partitions cycle through the different dimensions so that a different dimension is tested at each level of the decomposition. Note that for  $d \geq 3$  a requirement that the partitions cycle through the various dimensions before being permitted to repeat may prevent us from being able to use certain more perceptually appealing block combinations. For example, consider the three-dimensional four-legged chair in Figure 2.29(a) whose corresponding puzzletree has the block decomposition given in Figure 2.29(b) and the tree access structure given in Figure 2.29(c). Here, we see the impossibility of cycling through all of the dimensions in an alternating manner.

The puzzletree is motivated by a desire to overcome the rigidity in the shape, size, and position of the blocks that result from the bintree (and to an equivalent extent, the region quadtree) partitioning process (because of its regular decomposition). In particular, in many cases, the decomposition rules ignore the homogeneity present in certain regions on account of the need to place the partition lines in particular positions as well as a possible limit on the number of permissible partitions along each dimension at each

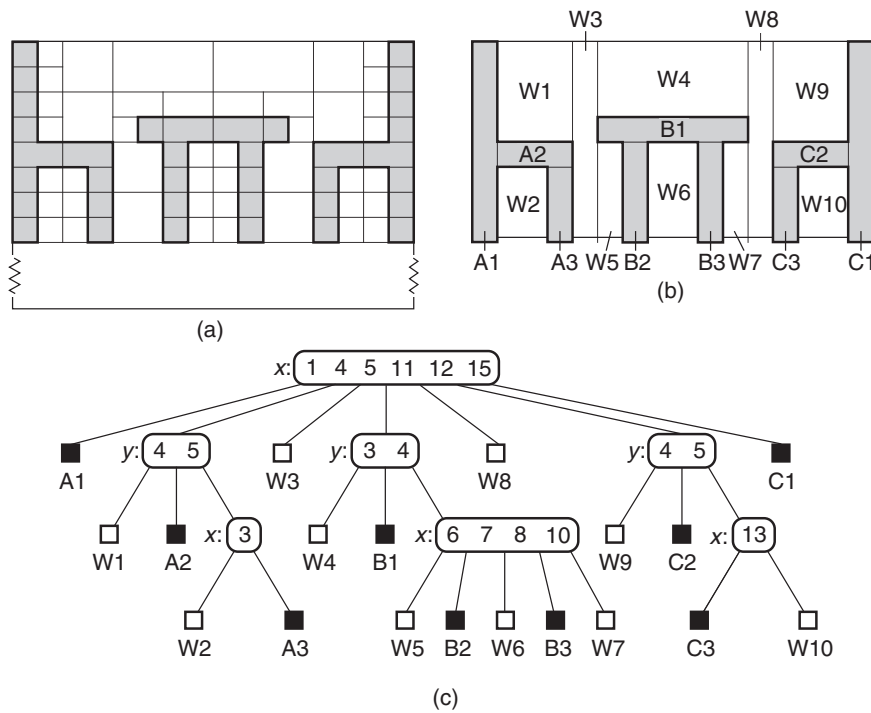

Figure 2.30  
Block decomposition for the (a) bintree and (b) puzzletree corresponding to the front view of a scene containing a table and two chairs; (c) is the tree access structure for the puzzletree in (b).

decomposition step. Often, it is desirable for the block decomposition to follow the perceptual characteristics of the objects as well as to reflect their dominant structural features.

For example, consider a front view of a scene containing a table and two chairs. Figures 2.30(a, b) shows the block decompositions resulting from the use of a bintree and a puzzletree, respectively, for this scene, and Figure 2.30(c) is the tree access structure corresponding to the puzzletree in Figure 2.30(b). Notice the natural decomposition in the puzzletree of the chair into the legs, seat, and back and of the table into the top and legs. On the other hand, the blocks in the bintree (and, to a greater extent, in the region quadtree, although not shown here) do not have this perceptual coherence. Of course, we are aided here by the separability of the objects; however, this does not detract from the utility of the representation as it only means that the objects can be decomposed into fewer parts.

Constructing the puzzletree for a particular scene is a tricky matter. The problem is that, on the one hand, we want to decompose the scene into meaningful blocks. This requires some a priori high-level knowledge about the semantic meaning of the scene's constituent parts (e.g., a chair consists of four legs, a seat, and a back). On the other hand, we usually do not have this semantic information readily available when processing the scene. In other words, ideally, we would like the puzzletree construction to be omniscient. As this is impossible, we must resort to the use of heuristics about inferring meaningful two-dimensional blocks from easily derivable measures of one-dimensional block aggregations (see Exercise 1).

The puzzletree can be shown to require no more nodes than a region quadtree and often considerably fewer nodes. Of course, the construction process of the puzzletree is more complex than that of the region quadtree. In particular, the puzzletree is not unique and relies on heuristics to identify the dominant parts so that a perceptually meaningful decomposition is obtained when we start with a collection of cells. The drawback of the puzzletree (and other representations, such as the point quadtree,

k-d tree, and generalized k-d, tree that do not use regular decomposition) is that, since the placement of the partition lines is arbitrary, a height-balanced decomposition (i.e., one that does not require too much space) will require that all the data be examined prior to building the structure. Otherwise, the structure can be skewed in a manner analogous to the worst-case behavior of a binary search tree, which is a linear list.

Of course, access structures aside from space partitions (e.g., multidimensional trees or trees that partition the space one dimension at a time) could be used as well. In this case, we again need to find a mapping from the domain of the blocks to a subset of the integers (i.e., to one dimension) and then to apply one of the familiar access structures (e.g., a binary search tree, range tree,  $B^+$ -tree). Since the sizes of the blocks are arbitrary, it does not make sense to use a mapping that concatenates the sizes to the result of interleaving the binary representations of the coordinate values of the upper-left corner of each block as was done for the regular decompositions. Instead, we employ the same techniques that we used for an arbitrary decomposition as described at the start of this section—that is, we apply one of the orderings shown in Figure 2.5 to obtain a mapping from the coordinate values of the upper-left corner  $u$  of each block to the integers.

### Exercises

1. The key to building a puzzletree is identifying the blocks. Below, we describe a variation of a technique suggested in [478, 479, 480] to choose between performing a vertical or a horizontal partition at each stage. We illustrate our discussion with the collection of cells and objects in Figure 2.31(a). Decompose each row  $j$ , having length  $L$ , into maximal, one-dimensional, identically valued blocks (i.e., each block is associated with the same object), and calculate the value  $H_j = (\sum_i x_i^2)/L^2$ , where  $x_i$  denotes the width of the  $i$ th block in row  $j$ . Perform a similar calculation for the columns—that is,  $V_j = (\sum_i y_i^2)/L^2$ , where  $y_i$  denotes the length of the  $i$ th block in column  $j$  and  $L$  is the width of column  $j$ . Clearly, a value of  $H_j = 1$  ( $V_j = 1$ ) indicates that the row (column) consists of one solid block. Once these values have been computed, there are several ways to proceed, none of which is guaranteed always to yield the minimum number of leaf nodes. We choose the partitioning axis as the one that has the maximum  $H_j$  or  $V_j$  value (e.g., into columns for the objects in Figure 2.31(a)). Ties are broken in an arbitrary manner. Once we have chosen the partitioning axis, we partition so that adjacent columns (rows) with the maximum value  $V_j$  ( $H_j$ ) and identical values in each cell form a block. This process is termed the *linear homogeneity heuristic*. Figure 2.31(a) is the block decomposition of the puzzletree resulting from its application to a collection of cells and objects whose corresponding tree access structure is given in Figure 2.31(b). Once the first level of partition has been chosen, the rest are chosen by adhering to the heuristic whenever possible. If successive application of this heuristic yields a partition on the same dimension, then the partitions are compressed. Is the puzzletree in Figure 2.28 constructed according to these rules?
2. Devise an algorithm to construct a puzzletree that makes use of the linear homogeneity heuristic described in Exercise 1.
3. Once a puzzletree has been generated, it is often possible to transform it into another puzzletree. For example, let  $a$ ,  $b$ , and  $c$  be three node positions in a puzzletree, that are occupied by nonleaf nodes such that, without loss of generality,  $b$  and  $c$  test the  $x$  and  $y$  coordinate values, respectively,  $b$  has degree of 2,  $c$  is the only child of  $b$  that is a nonleaf node, all the children of  $c$  are leaf nodes, and  $b$  is a child of  $a$ . Therefore, by the definition of a puzzletree, the nonleaf node at position  $a$  tests the  $y$  coordinate value. One possible transformation interchanges the tests at positions  $b$  and  $c$  so that  $c$  becomes a test on the  $x$  coordinate value and  $b$  becomes a test on the  $y$  coordinate value. Once the interchange has occurred, we have two successive tests on the  $y$  coordinate value at positions  $a$  and  $b$ , and we can compress these two tests into one test. For example, referring to the tree access structure in Figure 2.28(b), this transformation is applicable to the partitions on  $x = 6$  and  $y = 1$  at depths 2 and 3, respectively, in the rightmost subtree of the root. What properties must node  $c$  satisfy (i.e., nature of the objects associated with it) so that this transformation does not result in an increase in the number of leaf nodes? Can it ever lead to a decrease in the number of leaf nodes?
4. At times, we can apply a technique, that we term *common partition elimination* (analogous to common subexpression elimination in compiler code optimization [28]) to yield more optimal partitions in terms of the number of blocks. This is the case when two sibling nonleaf nodes

have at least one common partition. For example, consider the block decomposition and tree access structure in Figure 2.32. The results of the partition at the root that yields the regions  $5 \leq x < 6$  and  $6 \leq x < 8$  are both subdivided further at  $y = 2$  and  $y = 6$ . Hence, they share the common subsequent partitions  $0 \leq y < 2$ ,  $2 \leq y < 6$ , and  $6 \leq y < 8$ . The regions corresponding to these subsequent partitions can be merged if they are identically valued (i.e., their blocks are associated with the same object or are not associated with any object). For example, the pair of blocks labeled W5 and W6 and the pair labeled C2 and C3 in Figure 2.32 can be merged into larger blocks labeled W4 and C1, respectively, as shown in Figure 2.28. Notice that the effect of the common partition elimination is the removal of the partition step at  $x = 6$  from the root of the tree access structure, thereby reducing the size of the tree. The reason it is still present at depth 2 in Figure 2.28 is that the objects associated with blocks W3 and B1 are not the same as those associated with block B2. Give an algorithm COMPRESS to implement common partition elimination. In order to ease the expression of your solution, assume a recursive list representation [478, 479, 480] for the tree access structure where each node  $t$  in the tree is a list of three items having the format (A P S) where A is the split axis, P is a list containing the split locations, and S is a list containing the nodes or values corresponding to the children of  $t$ . We refer to these items by the field names A, P, and S. For example, the puzzletree corresponding to Figure 2.32 is  $(x (4 5 6) ((y (5) (A1 W1)) W2 (y (1 2 6) (W3 B1 W5 C2) (W6 C3)) (y (2 6) (B2 W6 C3))))$

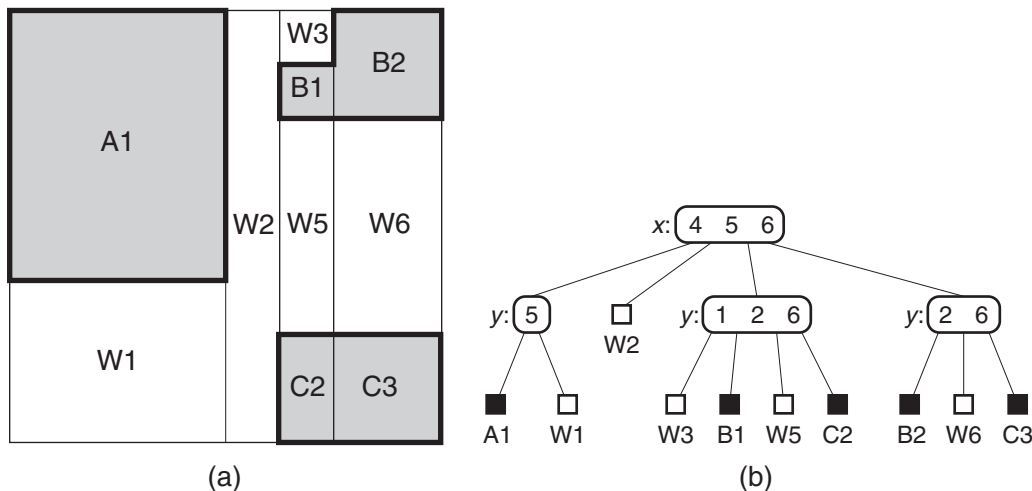

Figure 2.32  
(a) An alternative block decomposition for a puzzletree corresponding to the collection of objects and cells in Figure 2.1 and (b) the corresponding tree access structure. The nonleaf nodes are labeled with the partition axes and the partition values.

Figure 2.33  
The puzzletree resulting from the application of a common partition elimination method to the puzzle-tree in Figure 2.32 that introduces new partitions whenever none are present: (a) resulting block decomposition and (b) the corresponding tree access structure. The nonleaf nodes are labeled with the partition axes and the partition values.

W5 C2)) (y (2 6) (B2 W6 C3))). The inputs to procedure COMPRESS are the two sibling nodes being merged, the split axis separating them, and the split axis value.

5. Devise an algorithm COMPRESS TREE for the technique described in Exercise 4 to eliminate a partition for an implementation of a puzzletree that uses a tree access structure. The inputs to the algorithm are the axis  $u$  being partitioned, the partition value  $p\theta$ , and pointers to the two subtrees  $a$  and  $b$  corresponding to the two puzzletree nodes that are being merged. Assume that each nonleaf node has four fields: TEST, NUMCHILDS, CHILDS[1:NUMCHILDS], and V[1:NUMCHILDS], indicating the coordinate being tested, the number of children, pointers to the children, and the values of the coordinate being tested in increasing order, respectively. Note that in order to simplify the algorithms, V[ NUMCHILDS ] is always initialized to  $\infty$ . Each leaf node has a field called OBJECT that contains a pointer to the object associated with the block corresponding to the leaf node.
6. An alternative means of achieving common partition elimination to the one described in Exercise 4 is one that eliminates a partition step as well as introduces new partitions wherever the common partitions are not present [478, 479, 480]. For example, consider the block decomposition and tree access structure in Figure 2.32. In particular, focus on the partition at the root that yields the regions  $5 \leq x < 6$  and  $6 \leq x < 8$ . They are both subdivided further at  $y = 2$  and  $y = 6$ . Hence, they share the common partitions  $0 \leq y < 2$ ,  $2 \leq y < 6$ , and  $6 \leq y < 8$ . In this case, we modify the technique discussed in Exercise 4 to create a new partition wherever a partition is not present so that we partition the region  $0 \leq y < 2$  into  $0 \leq y < 1$  and  $1 \leq y < 2$ . The result is shown in Figure 2.33. Give an algorithm called REPARTITION to implement this approach. Assume the same recursive list representation for the nodes that was used in Exercise 4. Again, the inputs to procedure COMPRESS are the two sibling nodes being merged, the split axis separating them, and the split axis value.
7. Give an example of a puzzletree, say  $t$ , for which common partition elimination using the method of Exercise 4 results in fewer leaf nodes, while common partition elimination using the method of Exercise 6 results in more nodes. The block decomposition in  $t$  is such that all the children of the two nodes in which the common partitions are found are leaf nodes. Also,  $t$  is constructed in accordance with the linear homogeneity heuristic.
8. Assume a puzzletree block decomposition where two sibling nodes  $a$  and  $b$  have common partitions, and the children of  $a$  and  $b$  are leaf nodes. Prove that the result of common partition elimination using the method of Exercise 4 never requires more leaf nodes than the method of Exercise 6. In this exercise, the puzzletree need not necessarily be constructed in accordance with the linear homogeneity heuristic.
9. Assume a puzzletree block decomposition constructed in accordance with the linear homogeneity heuristic and two sibling nodes  $a$  and  $b$  with common partitions. Can you prove that the result of common partition elimination using the method of Exercise 4 never requires more leaf nodes than the method of Exercise 6?
10. Assume that a puzzletree block decomposition is not necessarily constructed in accordance with the linear homogeneity heuristic and that two sibling nodes  $a$  and  $b$  have common partitions. Can you prove that the result of common partition elimination using the method of Exercise 4 never requires more leaf nodes than the method of Exercise 6?

### 2.1.2.10 Hexagonal Blocks

As we pointed out in Section 2.1.1.1, the drawback of a decomposition into hexagons is that they cannot be decomposed beyond that atomic tiling without changing the basic tile shape. Also, hexagonal unit-size cells cannot be aggregated into larger hexagonal cells. Nevertheless, there are a number of different hexagonal hierarchies of blocks that are distinguished by classifying the shape of the first-level molecular tile on the basis of the number of hexagons that it contains. Three of these tiling hierarchies are given in Figure 2.34 and are called  $n$ -shapes, where  $n$  denotes the number of atomic tiles in the first-level molecular tile. Of course, these  $n$ -shapes are not unique.

The 4-shape and the 9-shape have an unusual adjacency property in the sense that no matter how large the molecular tile becomes, contact with two of the tiles (i.e., the one above and the one below) is only along one edge of a hexagonal atomic tile, while contact

with the remaining four molecular tiles is along nearly one-quarter of the perimeter of the corresponding molecular tile. The hexagonal pattern of the 4-shape and 9-shape molecular tiles has the shape of a rhombus. In contrast, a 7-shape molecular tile has a uniform contact with its six neighboring molecular tiles.

Given the various block shapes described above, the choice is usually made on the basis of the grid formed by the image sampling process. Square blocks are appropriate for square grids, and triangular blocks are appropriate for triangular grids. In the case of a hexagonal grid [285], the 7-shape hierarchy is frequently used since the shape of its molecular tile is more like a hexagon. It is usually described as *rosettelike* (i.e., a *septree*). Note that septrees have jagged edges as they are merged to form larger units (e.g., Figure 2.34(b)). The septree is used by Gibson and Lucas [706], who call it a *generalized balanced ternary* (GBT), in the development of algorithms analogous to those existing for region quadtrees.

Although the septree can be built up to yield large septrees, the smallest resolution in the septree must be decided upon in advance since its primitive components (i.e., hexagons) cannot later be decomposed into septrees. Therefore, the septree yields only a partial hierarchical decomposition in the sense that the components can always be merged into larger units, but they cannot always be broken down. For region data, a pixel is generally an indivisible unit and thus unlimited decomposition is not absolutely necessary. However, in the case of other data types such as points (see Chapter 1) and lines (see, e.g., Section 2.2.2.6), we find that the decomposition rules of some representations require that two entities be separated, which may lead to a level of decomposition not known in advance (e.g., a decomposition rule that restricts each square to contain at most one point). In this book, we restrict our discussion to hierarchies of rectangular blocks.

### 2.1.2.11 Triangular Blocks

Triangular blocks are used in triangular quadtrees that are based on a recursive decomposition of an equilateral triangle into four congruent blocks. Such a triangular decomposition results from using the  $[6^3]$  tiling. Triangular blocks are also used in triangular bintrees that are based on a recursive decomposition of an isosceles triangle into two congruent blocks. Such a triangular decomposition results from using the  $[4.8^2]$  tiling.

When the data lies on the surface of a sphere, a number of researchers have proposed the use of a representation based on an icosahedron (a 20-faced polyhedron whose faces are regular triangles) [520, 603]. The icosahedron is attractive because, in terms of the number of faces, it is the largest possible regular polyhedron. Each of the triangular faces can be further decomposed in a recursive manner into  $n^2$  ( $n > 1$ ) spherical triangles (the  $[6^3]$  tiling).

Fekete and Davis [603] let  $n = 2$ , which means that, at each level of decomposition, three new vertices are generated by halving each side of the triangle; connecting them together yields four triangles. They use the term *property sphere* to describe their representation. The property sphere has been used in object recognition; however, it is also of potential use in mapping the Earth as it can enable accurate modeling of regions around the poles. For example, see Figure 2.35, which is a property sphere representation of some spherical data. In contrast, planar quadtrees are less attractive the farther we get from the equator due to distortions in planarity caused by the Earth's curvature. Of course, for true applicability for mapping, we need a closer approximation to a sphere than is provided by the 20 triangles of the icosahedron. Moreover, we want a way to distinguish between different elevations.

Dutton [520] lets  $n = \sqrt{3}$ , which means that, at each level of decomposition, one new vertex is created by connecting the centroid of the triangle to its vertices. The result is an alternating sequence of triangles so that each level is fully contained in the level that was created two steps earlier and has nine times as many triangles as that level. Dutton uses

## Section 2.1 INTERIOR-BASED REPRESENTATIONS

Figure 2.36  
Example of a triacon hierarchy.

the term *triacon* to describe the resulting hierarchy. As an example, consider Figure 2.36, which illustrates four levels of a triacon decomposition. The initial and odd-numbered decompositions are shown with heavy lines, and the even-numbered decompositions are shown with broken and thin lines.

The icosahedron is not the only regular polyhedron that can be used to model data that lies on a sphere. Others include the tetrahedron, hexahedron (more commonly known as a cube), octahedron, and dodecahedron, which have 4, 6, 8, and 12 faces, respectively. Collectively, these five polyhedra are known as the *Platonic solids* [1490]. The faces of the tetrahedron and octahedron are equilateral triangles, while the faces of the hexahedron and dodecahedron are squares and regular pentagons, respectively.

The dodecahedron is not an appropriate primitive because the pentagonal faces cannot be further decomposed into pentagons or other similar shapes. The tetrahedron and hexahedron (the basis of the octree) have internal angles that are too small to model a sphere properly, thereby leading to shape distortions.

Dutton [520] points out that the octahedron is attractive for modeling spherical data such as the globe because it can be aligned so that the poles are at opposite vertices, and the prime meridian and the equator intersect at another vertex. In addition, one subdivision line of each face is parallel to the equator. Of course, for all of the Platonic solids, only the vertices of the solids touch the sphere; the facets of the solids are interior to the sphere.

Other decompositions for data that lies on a sphere are also possible. Tobler and Chen [1877] point out the desirability of a close relationship to the commonly used system of latitude and longitude coordinates. In particular, any decomposition that is chosen should enable the use of meridians and parallels to refer to the data. An additional important goal is for the partition to be into units of equal area, which rules out the use of equally spaced lines of latitude (of course, the lines of longitude are equally spaced). In this case, the sphere is projected into a plane using Lambert's cylindrical projection [14], which is locally area preserving. Authalic coordinates [14], which partition the projection into rectangles of equal area, are then derived. For more details, see [1877].

### Exercises

1. Show how the property sphere data structure can be used to model the Earth. In particular, discuss how to represent landmass features, such as mountain ranges, crevices, and so on.
2. Suppose that you use an icosahedron to model spherical data. Initially, there are 20 faces. How many faces are there after the first level of decomposition when  $n = 2$ ? When  $n = \sqrt{3}$ ?

### 2.1.3 Nonorthogonal Blocks

In Section 2.1.1 we assumed that each unit-sized cell is contained entirely in one or more objects. In other words, no cell  $c$  is partially contained in one object  $o_1$  and partially contained in another object  $o_2$ , or, even more generally, no cell  $c$  is partially contained in an object  $o_1$  while the rest of  $c$  is contained in any other object. Similarly, in Section 2.1.2, we stipulate that the block decomposition rules all required that each cell in each block belong to the same object or objects or that the cells not belong to any objects. In other words, the situation in which some of the cells in a block belong to object  $o_1$  while the others belong to object  $o_2$  (and not to  $o_1$ ) is not permitted. Of course, these restrictions are all subject to appropriate conventions with respect to blocks' being open and closed.

The above restrictions, coupled with the fact that both the blocks and the unit-sized cells are assumed to be axis parallel (i.e., with boundaries parallel to the coordinate axes), mean that we cannot represent objects whose boundaries do not coincide with the boundaries of the underlying blocks. A more general statement of this consequence is that we cannot represent polygonal objects whose sides are not parallel to the coordinate

axes (i.e., non-axis-parallel objects).<sup>10</sup> In essence, the problem is that for such objects we cannot, in general, obtain a decomposition so that each cell or block is completely contained in a single object or is not in any object.

In this section, we loosen some of these restrictions so as to permit both the blocks and the objects to be arbitrary polyhedra (i.e.,  $d$ -dimensional objects whose  $(d - 1)$ -dimensional faces are hyperplanes). Nevertheless, unlike Sections 2.1.1 and 2.1.2, in this section, we do not permit the objects to intersect. However, we do permit the objects to be adjacent and, thereby, to have common boundaries. This means that we do include collections of polygons where the polygons form what is termed a *polygonal map*. Although most of our discussion is with respect to two-dimensional data (i.e., the sides of polygons and polygonal maps), it is often also relevant to higher-dimensional data.

It should be clear that, for both the implicit and explicit representations, we are now freed from the need to represent the individual objects as a collection of unit-sized cells or rectangular blocks. Thus, from now on, we speak only of blocks. In fact, collections of other shapes, such as triangles, trapezoids, and convex polygons (e.g., [261, 1081]), could be used. The rationale for using these shapes is that they can capture the geometry of the object more accurately than the rectangular blocks, as well as simplify the computation of point-in-object tests in comparison to performing the test on the entire object.

The rest of this section is organized as follows. First, we briefly present the BSP tree (Section 2.1.3.1), which is a generalization of the generalized k-d tree (see Section 2.1.2.8) that yields arbitrary-shaped blocks. We also mention the BSP tree in the context of point data in Section 1.5.1.4 of Chapter 1. Next, we describe the K-structure (Section 2.1.3.2) and the separating chain (Section 2.1.3.3), which are designed to respond to the location query (i.e., determining the object associated with a particular location in space) in optimal time and optimal space. This query is known as the *point location query* in the context of these representations, and this is how we will refer to it in Sections 2.1.3.2 and 2.1.3.3. The objects are decomposed into triangles in the case of the K-structure and into arbitrary-shaped blocks satisfying the property that they are intersected no more than twice by any vertical line in the case of the separating chain. Responses to the location query are facilitated by use of an access structure that is based on a hierarchy of blocks (BSP tree), triangulations (K-structure), and “above-and-below” partitions (separating chain). The discussion of the K-structure and the separating chain is quite detailed and thus may be skipped on a first reading.

### 2.1.3.1 BSP Tree

We have already mentioned the BSP tree [657, 658] in our discussions of the k-d tree in Section 1.5.1.4 of Chapter 1 and the generalized k-d tree in Section 2.1.2.8. In the discussion of the k-d tree, the BSP was presented as one of many methods of representing a collection of multidimensional points so that retrieval operations such as point and range queries can be efficiently represented. In this section, we view the BSP tree as an object and region representation. What differentiates the BSP tree from representations based on a regular decomposition (i.e., the region quadtree, ATree, and bintree) discussed in Section 2.1.2 is that the objects are being decomposed into blocks where at least one side (more generally one  $(d - 1)$ -dimensional boundary for  $d$ -dimensional objects) of each block overlaps, even if only partially, the side (i.e., boundary) of one of the objects. Nevertheless, the BSP tree has been used by van Oosterom [1409, 1410] as an object representation in a manner analogous to the region quadtree. In particular, associated with each block  $b$  corresponding to a leaf node in the tree is a pointer to the object of which  $b$  is a member. The result is termed a *multiobject BSP tree*.

---

<sup>10</sup> To be more precise, we could not represent non-axis-parallel polygonal objects. Notice that, strictly speaking, our restrictions did not permit the representation of all hyperrectangular objects as such objects are required only to have boundaries that are orthogonal to each other, while not necessarily requiring the boundaries to be parallel to the coordinate axes.

As an example of the utility of the BSP tree, we show how it is used for retrieving the objects in an order that is consistent with their visibility from an arbitrary viewpoint (e.g., [941, 1357] and the references cited therein, as well as [196, Ch. 12]). In other words, the objects are retrieved (and displayed to the viewer) so that if object  $A$  occludes object  $B$  when viewed from viewpoint  $v$ , then  $B$  is retrieved (and displayed) before  $A$  (also known as *hidden-surface elimination*). The visibility problem is very similar to the point location query in the sense that a point is given (termed the *viewpoint*), and it is desired to determine all of the visible polygonal faces of the objects (i.e., the visible parts of the objects). We will focus on how the BSP tree is used to determine visibility in a three-dimensional scene. Of course, the BSP tree can be applied to objects of arbitrary dimensionality.

The utility of the BSP tree for visibility calculations can be understood best by examining its use for interobject visibility. Thus, for the moment, we assume that parts of an object are not occluded by other parts of the same object. This is true when the objects are convex. Suppose, further, that for the moment the objects are linearly separable. This is clearly the case if they are points and may be achievable for certain, but not all, collections of objects. Under these assumptions, partitioning the underlying space with a single hyperplane  $h$  results in giving visibility priority to all objects on the side of  $h$  that contains the viewpoint  $v$  over the objects on the other side of  $h$ . Determining the side of  $h$  in which  $v$  lies is achieved by taking the dot product of  $v$  and the normal to  $h$ .

It is important to note that a single hyperplane cannot order objects lying on the same side and thus cannot yield a total visibility ordering. One way of extending this idea to the remaining objects is to create a unique separating hyperplane for every pair of objects. However, for  $n$  objects, this would require  $O(n^2)$  separating hyperplanes, which is too large. Instead, we can reduce the number of separating hyperplanes by recursively subdividing each of the regions resulting from the first hyperplane by introducing additional separating hyperplanes, assuming that the objects are linearly separable. This can be done with as few as  $n$  hyperplanes when none of the objects overlap the separating hyperplanes. In fact, we see that the resulting structure is indeed the BSP tree that we defined earlier. Visibility is now determined by traversing the tree so that at each node the child that is drawn first is the one that does not contain the viewpoint.

Of course, in general, we cannot assume that the objects are linearly separable and that parts of an object are not occluded by other parts of the same object. Thus, in the rest of this section, we examine the more general case, which must also account for intraobject visibility. We restrict ourselves to three-dimensional (i.e., polyhedra) objects, although, of course, the BSP tree can be applied to objects of arbitrary dimensionality. We assume that the partition of the underlying space is in terms of the object's faces, which are polygons (usually triangles as graphics hardware is optimized for displaying such polygons). Such partitions are called *autopartitions*. Although such autopartitions do not necessarily result in minimum-size BSP trees, they do produce reasonably sized ones.

Therefore, in our application domain, the underlying data consists of the polygonal faces  $p_1, p_2, \dots, p_n$  of a set of three-dimensional objects. The BSP tree is constructed by choosing an arbitrary polygonal face from this set, say  $p_k$ , and splitting the three-dimensional space along the plane in which  $p_k$  lies into two subsets, say  $P_{k,L}$  and  $P_{k,R}$ .  $p_k$  is associated with the root of the tree.

$P_{k,L}$  and  $P_{k,R}$  make up the two children of the root and correspond to the two halfspaces separated by this plane. We arbitrarily choose one of the sides of the polygonal face as the "front" side and say that  $P_{k,L}$  corresponds to it, which means that  $P_{k,R}$  corresponds to the "back" side. We associate  $P_{k,L}$  and  $P_{k,R}$  with the left and right subtrees, respectively, of the root. Thus,  $P_{k,L}$  contains all polygonal faces that are in the left subtree, and  $P_{k,R}$  contains all polygonal faces that are in the right subtree.

This decomposition process is applied recursively to  $P_{k,L}$  and  $P_{k,R}$  and terminates upon encountering empty sets.

Two items are worthy of further note. First, a polygonal face, say  $p_i$ , may be contained in both the left and right subtrees of a node in the BSP tree. Such a situation arises when  $p_i$ 's plane intersects the plane of one of its ancestor nodes in the BSP tree. Second, the plane of a polygonal face is assumed to extend beyond the boundary of the polygon (i.e., it spans the entire underlying block). For example, the plane of the root's polygonal face partitions the entire scene. Moreover, for each subtree rooted at  $T$ , the polygonal face associated with  $T$ , say  $p_T$ , is extended so that  $p_T$  partitions the entire space of  $T$ .

One of the drawbacks of the BSP tree is that its shape is heavily dependent on the order in which the polygonal faces are processed and on the polygonal faces that are selected to serve as the partitioning planes. In the worst case, the BSP tree looks like a chain. Furthermore, the decomposition may be such that a polygonal face is contained in many subtrees. Such a situation arises in complex nonconvex scenes and will lead to large BSP trees. Nevertheless, it can be somewhat alleviated by choosing the root polygonal face more carefully at each stage of the BSP tree construction process.

For example, one heuristic is to choose the polygonal face, say  $M$ , in the set that splits the minimum number of the remaining polygonal faces in the set (see Exercise 5 for another approach). Fuchs, Abram, and Grant [657] have found that, in practice, there is no need to try out all possibilities to determine  $M$ . Instead, they follow a suggestion of Kedem [657] and just select a small subset of the polygonal faces at random, say  $S$ , to serve as candidates and then choose the polygonal face in  $S$  that splits the minimum number of the remaining polygonal faces in the set. In two dimensions, for  $n$  line segments, this method yields a BSP tree of expected size  $O(n \log n)$  and can be constructed in  $O(n^2)$  time [1475]. The execution time can be reduced to  $O(n \log n)$  with the same size bound by using an approach that does not yield an autopartition [1475]. In three dimensions, for  $n$  polygonal faces that are triangles, the best-known method yields an autopartition BSP tree with expected size  $O(n \log^2 n)$  and can be constructed in  $O(n \log^3 n)$  time [18], although there exist sets of data for which the size is  $\Omega(n^2)$  [1475]. Naylor observed that, in practice, three-dimensional BSP trees were usually of size  $O(n \log n)$  [1353, 1354]. An analogous approach of avoiding a check of all possibilities was used by Samet [1618] in selecting a node to replace the deleted root of a point quadtree (see Section 1.4.1.2 of Chapter 1).

To illustrate the differences in the storage requirements of the BSP tree, we use a collection of line segments instead of polygonal faces because it is easier to visualize what is happening. Each line segment has a direction. We say that its "positive" side is the one to the right of the direction of the line segment. When the line segment is treated as a separator between two halfspaces, we say that the "positive" side is the one whose equation has the form  $a \cdot x + b \cdot y + c \geq 0$ , and the "negative" side is the one whose equation has the form  $a \cdot x + b \cdot y + c < 0$ .

For example, consider the four line segments labeled A, B, C, and D in Figure 2.37. Suppose that the BSP tree is constructed by letting B be the root. The positive subset consists of D, while the negative subset consists of A, C, and D. D appears in both subsets because D crosses B when it is extended and thereby serves as a separator between two halfspaces. Now, let us build the BSP tree for the negative subset. Letting C be the root, we find that A is in the negative subset, and D is in the positive subset. The resulting BSP tree is shown in Figure 2.38(a) and partitions the plane into six regions as shown in Figure 2.38(b).

If, in the first step, we would have chosen C instead of B to be the root of the BSP tree, then the negative subset would consist of A, and the positive subset would consist of B and D. Now, let us build the BSP tree for the positive subset. Letting D be the root, we find that the positive subset is empty, and B is in the negative subset. The resulting BSP tree is

Figure 2.37  
Example set of four line segments.

(a) The BSP tree corresponding to Figure 2.37 when B is the root and (b) the partition induced by it.

Figure 2.39  
(a) The BSP tree corresponding to Figure 2.37 when C is the root and  
(b) the partition induced by it.

shown in Figure 2.39(a) and yields a partition of the plane into five regions as shown in Figure 2.39(b). Of course, there are many other BSP trees that can be constructed for this set of four line segments. For a discussion of what makes a good BSP tree, see [1353].

Using the BSP tree to determine visibility involves a traversal of the tree in an order that is determined by the position of the viewpoint, say  $V$ . Each node of the BSP tree partitions the relevant portion of the scene into two parts. They can be identified with respect to whether or not they contain  $V$ . In particular, for each node  $N$  in the BSP tree, let  $\text{INCHILD}(N, V)$  correspond to the child of  $N$  that contains  $V$ , and let  $\text{OUTCHILD}(N, V)$  correspond to the child that does not. There are two basic techniques.

The first technique assigns a visibility number to each polygon in the order in which it has been visited. This order depends on whether we are using a back-to-front or a front-to-back display algorithm. We shall assume a back-to-front algorithm. In such a case, the higher numbers correspond to a higher priority. They are assigned by traversing the BSP tree in such a way that, for a given node  $N$ , all the polygons in  $\text{INCHILD}(N, V)$  are given a lower number than  $N$ 's polygon, and all the polygons in  $\text{OUTCHILD}(N, V)$  are given a higher number than  $N$ 's polygon. It should be clear that this is nothing more than an inorder traversal with respect to the viewpoint. These priorities can be used by conventional hidden-surface elimination algorithms whenever a visibility determination must be made.

In fact, we do not even have to assign the visibility numbers. This observation forms the basis of the second technique which does not use the visibility numbers. Instead, the traversal is used to control a back-to-front (i.e., painter's) algorithm, which paints each polygon on the screen as it is encountered by the traversal. If one polygon overlaps another polygon, then the most recently painted polygon determines the color of the overlapped region. Given viewpoint  $V$ , BSP tree node  $N$ , and the previous definition of  $\text{INCHILD}$  and  $\text{OUTCHILD}$ , the polygons in  $\text{OUTCHILD}(N, V)$  are visited before the polygon in the root, which, in turn, is visited before the polygons in  $\text{INCHILD}(N, V)$ . Correctness is assured since polygons that occlude other polygons are closer to the viewpoint and are visited later in the traversal.

Visibility orderings provide an alternative to the conventional use of the  $z$ -buffer algorithm for hidden-surface elimination. This algorithm is based on scan-converting the objects in the scene in an arbitrary order once the scene has been transformed so that the viewing direction is in the positive  $z$  direction. Scan-converting an object  $o$  determines which pixels in the projection are covered by  $o$ . These are the pixels where  $o$  is potentially visible. The  $z$  buffer algorithm makes use of a frame buffer and a  $z$  buffer to keep track of the objects that it has already processed. For each pixel, the frame buffer stores the intensity of the currently visible object among all of the objects that it has already processed, while the  $z$  buffer stores the corresponding  $z$  coordinate value. When a new object  $o$  is scan-converted, for each pixel  $p_o$ , the  $z$  value  $z_{p_o}$  of the corresponding point on the visible object is compared with the current  $z$  value  $z_p$  in the  $z$  buffer. If  $z_{p_o}$  is less than  $z_p$ , then  $o$  lies in front of the currently visible object in  $p$ , and the frame and  $z$  buffer values of pixel  $p$  are updated to reflect the fact that  $o$  is now the object visible at  $p$ .

The advantage of using a visibility ordering over the  $z$  buffer algorithm is that there is no need to compute or compare the  $z$  values. This is especially advantageous as this process can be subject to numerical errors. Moreover, it eliminates the need for space to store the  $z$  buffer, which can be substantial especially if used at subpixel resolution such as  $4 \times 4$  in order to provide antialiasing.

BSP trees are used for a number of other applications besides visibility. For example, they have been used for set operations on polyhedra in solid modeling [1359, 1869], shadow generation [375], radiosity [302, 303], and beam tracing [436]. It has also been proposed to use the hierarchy of regions created by the partitioning process corresponding to the BSP tree as bounding volumes (e.g., [1357]) to speed up operations such as

point location. The use of bounding volume hierarchies is described in much greater detail in Section 2.1.5.2.

### Exercises

1. Write an algorithm to insert a line (polygonal face) into a BSP tree.
2. Write an algorithm to delete a line (polygonal face) from a BSP tree.
3. Suppose we define a predicate called  $\text{CONFLICT}(P_1, P_2)$  whose value is true if polygonal face  $P_1$  intersects the halfspace of polygon  $P_2$  and false otherwise. Is  $\text{CONFLICT}$  a symmetric relation? In other words, does  $\text{CONFLICT}(P_1, P_2) = \text{CONFLICT}(P_2, P_1)$  always hold?
4. (David M. Mount) What is the physical interpretation when  $\text{CONFLICT}(P_1, P_2)$  and  $\text{CONFLICT}(P_2, P_1)$  are both true?
5. Fuchs, Kedem, and Naylor [658] suggest that the number of polygonal faces in a BSP tree for a given database of polyhedra can be reduced by choosing as the root node of each subtree that node which eliminates the maximum number of future splits. A future split exists between polygonal faces  $P_1$  and  $P_2$  if the value of  $\text{CONFLICT}(P_1, P_2)$  is true where  $\text{CONFLICT}$  is defined in Exercise 3. Write an algorithm to build a BSP tree that makes use of this method.
6. What is the minimum number of regions in the partition of a two- (three-) dimensional space that is induced by the BSP tree for  $n$  line segments (polygonal faces)?
7. Let us use the term *tessellation* to denote the partition of space induced by the construction of the BSP tree. Under what conditions is the tessellation independent of the order in which the BSP tree is built?
8. Suppose that the tessellation is independent of the order in which the BSP tree is built. What is the maximum number of polygons (polyhedra) that can be generated by  $n$  line segments (polygonal faces) in a two- (three-) dimensional space?
9. The BSP tree can be used to determine visibility by traversing the tree in an order that is determined by the position of the viewpoint, say  $V$ . Recall that each node of the BSP tree partitions the relevant portion of the scene into two parts. They can be identified with respect to whether they contain  $V$ . In particular, for each node  $N$  in the BSP tree, let  $\text{INCHILD}(N, V)$  correspond to the child of  $N$  that contains  $V$ , and let  $\text{OUTCHILD}(N, V)$  correspond to the child that does not. Give an algorithm that makes use of this idea to determine visibility from  $V$  when the scene is represented by a BSP tree.

### 2.1.3.2 K-Structure

The K-structure of Kirkpatrick [1026] is a hierarchical representation based on triangulation rather than a regular decomposition. It is not built directly from the list of line segments in a polygonal map, but, instead, it is built from a triangulation of the map. Briefly, a triangulation of a set of  $n$  points is a maximal subset of the  $n \cdot (n - 1)/2$  possible edges so that no edge crosses any other edge. Of course, there are many possible triangulations for a given set of points, and there are many methods of obtaining the triangulations (e.g., [1511]). It is important to note the distinction between a triangulation and the method of obtaining it. All of the triangulations contain the edges of the convex hull<sup>11</sup> of the points as the triangulations are maximal, and thus these edges could not have been eliminated by virtue of crossing any of the edges in the triangulation.

The notion of hierarchy in the K-structure is radically different from that of a quadtree: instead of replacing a group of triangles by a single triangle at the next higher level, a group of triangles is replaced by a smaller group of triangles. There is no proper

---

<sup>11</sup> A set is *S convex* if the presence of points  $x$  in  $S$  and  $y$  in  $S$  implies that the closed line segment  $xy$  is contained within  $S$ . The *convex hull* of a set  $S$  is the smallest convex set that contains  $S$ . An intuitive explanation is that the convex hull is equivalent to the set that is obtained by snapping a rubber band around a set of nails driven through the points of the set.

Sample polygonal map.

Figure 2.41  
The first step in building the K-structure corresponding to Figure 2.40: (a) the result of the initial triangulation (newly introduced edges are shown by broken lines), and (b) the relationship between the triangles of (a) and the regions of Figure 2.40.

subset relationship between triangles at successive levels. In particular, a triangle at level  $i$  can be spanned by more than one triangle at level  $i + 1$ .

Triangles are grouped for replacement because they share a common vertex. The smaller group results from eliminating the common vertex and then retriangulating. This principle also forms the basis of one class of simplification methods for reducing the complexity of scenes for ease of display and other processes in computer graphics and visualization applications (see Section 2.2.3.4). At each level of the hierarchy, at least  $1/24$  of the vertices can be eliminated in this manner. Thus, the K-structure for a polygonal map of  $v$  vertices uses  $O(v)$  space, and point location can be determined in  $O(\log_2 v)$  time. Constructing a K-structure has a worst-case execution time of  $O(v)$  for a triangular subdivision and  $O(v \cdot \log_2 v)$  for a general one. The latter is dominated by the cost of triangulating the original polygonal map [834]. Below, we discuss the K-structure in greater detail, as well as illustrate how a K-structure is built for the polygonal map of Figure 2.40.

A K-structure is built by first enclosing the map with a bounding triangle anchored at points X, Y, and Z as shown in Figure 2.41(a). Next, we perform a plane-sweep triangulation by using the method of Hertel and Mehlhorn [834]. To do this, we assume that the vertices have been sorted in increasing order of their  $x$  coordinate values. Triangulation is achieved by sweeping (i.e., moving) a vertical line of infinite length from left to right along the  $x$  axis. Each time a vertex is encountered, edges are drawn from the vertex to all “visible” vertices to its left. Vertex  $V_2$  is said to be *visible* from vertex  $V_1$  if an edge can be drawn from  $V_1$  to  $V_2$  without intersecting an existing edge.

For the polygonal map of Figure 2.40, containing regions 1, 2, and 3, the vertices are processed in order X, Y, A, D, E, C, B, and Z. Processing vertex A results in creating edges AX and AY; D in DY; E in EA and ED; C in CY; B in BX; and Z in BZ and CZ. Figure 2.41(a) contains the outcome of the triangulation. The new edges are represented by broken lines. Region 1 consists of triangles a, b, C, d, i, j, and k; region 2 consists of triangles e, f, and h; and region 3 consists of triangle g. These inclusion relationships are shown in Figure 2.41(b).

Triangulating a polygonal map of  $v$  vertices has a worst-case execution time of  $O(v \cdot \log_2 v)$ . This is obtained in the following manner. Sorting the  $x$  coordinate values of the  $v$  vertices is  $O(v \cdot \log_2 v)$ . Sweeping the vertical line is  $O(v)$ . In addition, a  $\log_2 v$  factor is contributed by the visibility computation at each vertex.

Before proceeding further, let us define some terms used in the construction of the K-structure, as well as in the analysis of its space and time requirements. A *K-vertex* is a vertex that has a degree of 11 or less. We can establish that at least half of the vertices are K-vertices in the following manner. According to a corollary of Euler’s formula [801], any planar graph of  $v$  vertices (including a polygonal map) contains at most  $3 \cdot v - 6$  edges. Since each edge contributes one edge to the degree of two vertices, the average degree of a vertex is  $\leq 6$ . Therefore, at least half of the vertices have a degree of 11 or less and hence are K-vertices.

Two vertices are said to be *independent* if there is no edge connecting them. Each K-vertex is adjacent to, at most, 11 other K-vertices. Given a triangulated map with  $v_k$  K-vertices, at the minimum there is a partition into  $v_k/12 \geq v/24$  sets of vertices, each of which has a representative K-vertex. These representative K-vertices are mutually independent.

The *neighborhood of a K-vertex* is defined as the polygon formed by the union of the triangles incident at the K-vertex. Since there are, at most, 11 such triangles for a given K-vertex, the polygon from the K-vertex’s neighborhood has no more than 11 sides.

We are now ready to build the K-structure. Starting at a level corresponding to the result of the initial triangulation step, the next level of the K-structure is built in  $O(v)$  time in the following manner. First, find a set  $S$  of mutually independent K-vertices. This can be done in  $O(v)$  time from an edge-adjacency list of the map. Second, for each of

the neighborhoods of an element of the set  $S$ , perform the following reduction: remove the K-vertex from the neighborhood, and retriangulate its polygon. Thus, the triangles of the neighborhood will be linked with a smaller collection of triangles that spans the same region. The remaining levels of the K-structure are formed from an iterative performance of the building procedure until a level is reached that contains a single triangle.

At each level, the cost of building the K-structure is proportional to the number of vertices at that level. Since each level of the K-structure contains at most  $23/24$  of the number of vertices that the previous level held, the total number of vertices processed in the construction is at most  $24 \cdot v$ . Furthermore, as each of the K-vertices is guaranteed to be of degree 11 or less, the cost of retriangulating any polygon is bounded. Thus, the K-structure can be built in  $O(v)$  time. The number of levels in the K-structure is  $O(\log_2 v)$ .

Returning to our example, after the initial triangulation, we must identify the maximal subset of mutually independent K-vertices, remove them and their incident edges, and retriangulate. In Figure 2.41(a), we have several choices. We choose vertices B and D. Removing B and D and their incident edges leaves us with polygons XAYX, AECYA, XAECZX, and YCZY, which we label  $\varepsilon$ ,  $\delta$ ,  $\alpha$ , and  $\beta$ , respectively. Next, we retriangulate these polygons individually and obtain Figure 2.42(a). Polygons  $\varepsilon$  and  $\beta$  remain unchanged; polygon  $\alpha$  consists of triangles  $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$ ; and polygon  $\delta$  consists of triangles  $\delta_1$  and  $\delta_2$ . These relationships are shown in Figure 2.42(b). The edges that were introduced during the retriangulation are represented by broken lines in Figure 2.42(a).

We now have seven triangles and must choose one of vertices A, E, and C as the independent K-vertex. We choose vertex A, and after removing it and its incident edges, we are left with polygons XYECX, XCZX, ECYE, and YCZY, which we label t, u, v, and w, respectively. After retriangulating the polygons individually, we obtain Figure 2.43(a), with broken lines corresponding to the added edges. Polygons u, v, and w remain unchanged, while polygon t consists of triangles  $t_1$  and  $t_2$ . These relationships are shown in Figure 2.43(b).

Reapplying the algorithm to the five remaining triangles, we select vertex C as the independent K-vertex and remove it and its incident edges. The remaining polygons are XEYX and XEYZX, which we label q and r, respectively. Only polygon r needs to be retriangulated, resulting in triangles  $r_1$  and  $r_2$  as shown in Figure 2.44, with broken lines corresponding to the added edges. We now apply the algorithm for the final time to the three remaining triangles. Removing vertex E and its incident edges leaves us with a single triangle XYZX, which we label s as shown in Figure 2.45.

In general, the dynamic insertion of an edge into a K-structure takes  $O(v)$  time in the worst case. This poor worst-case performance follows from the fact that the triangulation must be updated. The newly inserted edge could intersect  $O(v)$  edges in the existing triangulation. For example, if the edge between vertices A and B is inserted into the triangulation of the polygon of Figure 2.46(a) (shown in Figure 2.46(b)), which has  $2 \cdot v + 2$  vertices, then the new edge will intersect  $2 \cdot v - 1$  edges in the triangulation. Updating the triangulation requires, at an absolute minimum, either the addition of a new vertex or the deletion of the old edge for each intersection of the new edge and an old edge. Hence  $O(v)$  operations may be required.

On the other hand, the K-structure can always be updated in  $O(v)$  time. To see this, observe that the triangulation can be updated by (1) removing all edges that intersect the new edge, (2) inserting the new edge, and (3) retriangulating the two polygonal regions on either side of the new edge. Step 1 takes  $O(v)$  time, and step 2 takes  $O(1)$  time. Step 3 can also be done in  $O(v)$  time. This is because the two polygons that must be triangulated are *weakly edge visible* from the new edge (i.e., each point in the region is visible from some point on the edge), and polygons with this property can be triangulated in linear time. Once the triangulation is updated, the K-structure can be completely rebuilt in  $O(v)$  time, as described earlier.

## Section 2.1 INTERIOR-BASED REPRESENTATIONS

The fourth step in building the K-structure corresponding to Figure 2.40: (a) the result of retriangulating Figure 2.43 once vertex C and its incident edges have been removed (newly introduced edges are shown by broken lines), and (b) the relationship between the polygons resulting from (a) and the triangles of Figure 2.43.

Figure 2.45  
The final step in building the K-structure corresponding to Figure 2.40: (a) the result of retriangulating Figure 2.44 once vertex E and its incident edges have been removed, and (b) the relationship between the polygons resulting from (a) and the triangles of Figure 2.44.

Point location using the K-structure is relatively straightforward. In essence, at each level, the algorithm must determine the relevant triangle that contains the point. The key is that the comparison is made with at most 11 triangles. These 11 triangles form the neighborhood that contains the triangle in which the point was found at the previous level. Thus, since the number of levels is  $O(\log_2 v)$ , point location is solved in  $O(\log_2 v)$  time.

As an example, suppose we wish to determine the region in the polygonal map of Figure 2.40 in which point P is located. Rather than give the values of the  $x$  and  $y$  coordinates of P, we have indicated its location by appropriately marking it in part (a) of Figures 2.41 to 2.45. Our explanation is facilitated by making use of part (b) of these figures.

Initially, we start with the triangle of Figure 2.45 and determine that P lies in triangle  $r_1$ . Moving down a level, we find  $r_1$  in polygon  $r$  of Figure 2.44. Searching for P in  $r$ , we find that it lies in triangle  $t_2$ . Moving down a level, we find  $t_2$  in polygon  $t$  of Figure 2.43. Searching for P in  $t$  we find that it lies in triangle  $\alpha_2$ . Moving down a level, we find  $\alpha_2$  in polygon  $\alpha$  of Figure 2.42. Searching for P in  $\alpha$ , we find that it lies in triangle  $e$ . Moving down a level, we find  $e$  in region 2 of Figure 2.41, and we are done.

### Exercises

1. Prove that a triangular subdivision on  $v \geq 3$  vertices, such that each region (including the bounding region) is bounded by three line segments, has exactly  $3 \cdot v - 6$  edges and  $2 \cdot v - 4$  regions (including the bounding region).
2. Consider the more general case of an arbitrary triangulation with  $v$  vertices so that the convex hull of the triangulation has  $c$  vertices. Prove that the triangulation has  $3 \cdot v - c - 3$  edges and  $2 \cdot v - c - 2$  regions (i.e., triangles).
3. Prove that a convex polygon containing  $v$  vertices can be triangulated in  $O(v)$  time.
4. Devise a data structure that enables the “visibility” computation of Hertel and Mehlhorn’s triangulation method [834] to be performed in  $O(\log_2 v)$  time.
5. There are many triangulation methods in use aside from the plane-sweep method of Hertel and Mehlhorn [834]. One such algorithm is known as the greedy method [1511]. Assume an arbitrary point set in the plane. The greedy method works by adding the edges in increasing order of length. It excludes an edge if a shorter edge intersects it. Prove that for  $v$  vertices and with appropriate data structures, the greedy method can be executed in  $O(v^2 \log v)$  time.
6. The plane-sweep and greedy triangulations are defined by the algorithms used to obtain them. There also exist triangulations that are defined by specific optimization criteria on the resulting edges and triangles that they form. One example of such a criterion is the “minimum-weight” triangulation (MWT) (e.g., [808]), which yields a triangulation with the smallest total edge length. For a point set in the plane, the problem of whether the minimum-weight triangulation can be computed in polynomial time is open, although it can be done in exponential time by brute-force methods. For a simple polygon (i.e., a polygon with nonintersecting edges and without holes), the minimum-weight triangulation can be obtained in polynomial time by using dynamic programming (e.g., [836]) as exemplified by the following algorithm. The key

Figure 2.46  
(a) A polygonal map and (b) its triangulation (broken lines correspond to the edges added by the triangulation).

idea is that given  $v$  vertices, for each edge  $e$  of the  $O(v^2)$  possible edges, we assume that  $e$  is in the minimum-weight triangulation, and then determine the two vertices out of the  $O(v)$  possible vertices that form the two triangles of the minimum-weight triangulation in which  $e$  participates. The algorithm is as follows:

- Let polygon  $Q$  have  $v$  vertices  $p_1p_2\dots p_v p_1$  appearing in successive order.
- Let  $e_{i,j}$  denote an edge from  $p_i$  to  $p_j$ .
- Let  $t_{i,j}$  be the MWT of the polygon with vertices  $p_i p_{i+1} \dots p_j p_i$ , and let  $w_{i,j}$  be its total edge length.
  - (a) If edge  $e_{i,j}$  is not a legal edge of the triangulation of  $Q$  (i.e., some part of it lies outside  $Q$ ), then  $t_{i,j}$  is undefined, and  $w_{i,j} = \infty$ .
  - (b) If edge  $e_{i,j}$  is a legal edge of the triangulation of  $Q$ , then there exists a vertex  $p_k$  in  $t_{i,j}$  such that  $p_i p_j p_k$  forms a triangle.
    - i.  $p_k$  is found by solving  $\min\{w_{i,k} + w_{k,j} \mid i < k < j\}$ , and
    - ii.  $w_{i,j} = w_{i,k} + w_{k,j} + \text{length}(p_i p_j)$ .
- Compute all  $t_{i,j}$  and  $w_{i,j}$  using dynamic programming. This is done with the aid of a pair of two-dimensional arrays  $t$  and  $w$ . Entry  $t_{i,j}$  has value  $k$ , indicating the third vertex  $p_k$  of a triangle whose remaining vertices are  $p_i$  and  $p_j$ . Entry  $w_{i,j}$  is the total edge length of the triangulation of the simple polygon with vertices in order  $p_i p_{i+1} \dots p_j p_i$ .
- The MWT of  $Q$  is  $t_{1,v}$ , and this is the starting point for the application of steps 1 and 2, which are applied recursively.

The actual algorithm is executed by constructing array  $w$  (and simultaneously  $t$ ) in order of increasing distances between the vertices corresponding to the indices of the array. In particular, we start with  $w_{i,i+1} = \text{length}(p_i p_{i+1})$  for all vertices  $i$  in increasing order. Next, we compute  $w_{i,i+2} w_{i,i+3} \dots w_{i,i+j} \dots w_{i,i+v-1}$ . For each value of  $j$  ( $1 \leq j \leq v-1$ ), we vary  $i$  from 1 to  $v-j$ . Show that the MWT algorithm described above takes  $O(v^3)$  time for a simple polygon.

7. Compare the approach described in Exercise 6 with one adapted from a suggestion of Posdamer [1504] that is based on sorting the vertices using a multidimensional point representation, such as a PR quadtree, and use a proximity criterion based on vertices being in the same block or in an adjacent block to determine which vertices should be connected to form an edge. This technique was originally developed for points in a three-dimensional space and, in fact, Posdamer [1504] suggests using a variant of a bucket PR octree where each block contains no more than three vertices.
8. An alternative triangulation, which is defined by specific optimization criteria on the resulting edges and triangles that they form, is the Delaunay triangulation (described in greater detail in Section 2.2.1.4). Briefly, the Delaunay triangulation has many useful properties. It is particularly attractive as the triangles are as close as possible to being equiangular, and thus it is good for interpolation of a surface (as discussed in Section 2.2.4). There are several algorithms to compute a Delaunay triangulation. They differ in part on the basis of the properties of the Delaunay triangulation that they exploit. We describe a pair of algorithms in Exercises 2 and 3 in Section 2.2.1.4 that make use of the property that none of the points in the point set being triangulated is in the circumcircles of any other triangle in the Delaunay triangulation (known as the *circle property*). Discuss how the Delaunay triangulation, as well as the greedy triangulation, method and the minimum-weight triangulation (MWT) described in Exercises 5 and 6, respectively, would be used in conjunction with the K-structure construction algorithm. Is any one of these triangulations superior to the others? How do they compare with the triangulation resulting from use of the plane-sweep method of Hertel and Mehlhorn? For a more thorough discussion of triangulations and triangulation methods, see [1597, 1965].
9. Give an  $O(v)$  time algorithm and  $O(v)$  space data structure to find a set  $S$  of mutually independent K-vertices given  $v$  vertices in the polygonal map.
10. Prove that for each independent K-vertex that has been removed in the construction of the K-structure, the number of triangles in the subsequent retriangulation has been reduced by two.
11. Write a procedure to do point location in a polygonal map that is represented by a K-structure.
12. The map overlay problem is related to the point location query, and its solution involves many of the issues discussed in this section and Section 2.1.3.3. In this case, you are given two

polygonal maps, and you are to overlay one of them on top of the other. This problem can be viewed as a generalization of the process of dynamic edge insertion: instead of inserting a single edge, you are now inserting a collection of edges (which happens already to be organized as a polygonal map). The goal is to achieve this in a manner that is more efficient than performing a sequence of dynamic line insertions. Write a set of procedures that will perform map overlay for the K-structure,

### 2.1.3.3 Separating Chain

The separating chain of Lee and Preparata [1128] is an alternative to the K-structure. Like the K-structure, the separating chain method also yields a hierarchical structure; however, this time, instead of using a hierarchy of triangulations, a hierarchy of “above-and-below” partitions consisting of groups of regions is used. In fact, the separating chain was developed before the K-structure. However, the execution time complexity of the access structure for the elements of each separating chain in the hierarchy used in the original formulation (i.e., a sorted list) was not as good as that of the K-structure. The layered dag of Edelsbrunner, Guibas, and Stolfi [541] provides an alternative access structure for the elements of each separating chain in the hierarchy so that the space requirements and time complexity of point location and structure building are the same as those for the K-structure. However, the constants of proportionality are smaller for the separating chain hierarchy when implemented with a layered dag than for the K-structure.

This section is organized as follows. We first outline the principles underlying the separating chain method, then show how it can be used to do point location when each separating chain in the hierarchy is implemented as a sorted list (Section 2.1.3.3.1). Next, we show how the separating chain solution to the point location query can be improved by using a layered dag access structure (Section 2.1.3.3.2) for the elements of each separating chain in the hierarchy. Unlike for the K-structure, our analyses of the orders of execution times and space requirements of solutions that make use of the separating chain are in terms of the number of edges, say  $m$ , in the polygonal map instead of the number of vertices, say  $v$ . However, by Euler’s formula [801], for  $v \geq 3$ , we have that  $m \leq 3 \cdot v - 6$ , and thus the two quantities are of the same order of magnitude.

Figure 2.47  
(a) Example polygonal map illustrating the use of separating chains and (b) the result of regularizing (a) with newly introduced edges represented by broken lines.

#### 2.1.3.3.1 Overview

A polygonal map is said to be a *y-monotone subdivision* if no vertical line can intersect a region’s boundary more than twice. Alternatively, the polygonal map is a *y-monotone subdivision* if every vertex of the map has at least one edge to its left and one edge to its right (see Exercise 1). For example, the polygonal map of Figure 2.47(a) is not a *y-monotone subdivision* because vertices J, L, and M have no edges to their right, and vertices A, B, and D have no edges to their left. This map has three regions labeled 1, 2, and 3. A vertical line through edges CE, DE, and DG crosses the boundary of region 1 three times. A *y-monotone subdivision* ensures that the “immediately above” relation is acyclic; that is, region 1 can either be below region 2 or above it, but it cannot be both below and above the same region.

Figure 2.48  
The result of regularizing the polygonal map of Figure 2.40. Newly introduced edges are shown by broken lines.

A polygonal map is made into a *y-monotone subdivision* by a process termed *regularization*, which inserts additional edges, as well as two vertices at the extreme left and right of the polygonal map. For example, the broken lines in Figure 2.47(b) are the result of regularizing the polygonal map of Figure 2.47(a). It has eight regions, labeled 0–7; two additional vertices,  $\alpha$  and  $\delta$ , at the extreme left and right, respectively, of the map; and the new edges  $\alpha A$ ,  $\alpha B$ ,  $CD$ ,  $JK$ ,  $L\delta$ , and  $M\delta$ .

Of course, any triangulation can be used as the basis of a *y-monotone subdivision*, but, usually, regularization requires considerably fewer edges to be inserted than a triangulation (compare Figures 2.41 and 2.48, which are the results of triangulating and regularizing, respectively, the polygonal map of Figure 2.40). However, like triangulation, regularization of a polygonal map of  $m$  edges is performed by a plane-sweep

algorithm in  $O(m \cdot \log_2 m)$  time. These definitions imply that the polygonal map has no vertical edges. However, this restriction is primarily a technical one and can be removed by the adoption of appropriate conventions (see Exercise 6).

As the polygonal map is regularized, the identity of each region immediately above and below each edge, say  $e$ , is stored with the edge using the fields ABOVE( $e$ ) and BELOW( $e$ ). In addition, a list is created of the vertices and edges of the regularized polygonal map in increasing order of  $x$  coordinate values. Once the polygonal map has been regularized, the regions are topologically sorted so that they are ordered according to an “above” relation.

Formally, given regions  $r_1$  and  $r_2$ ,  $r_1$  is above  $r_2$  (i.e.,  $r_1 \geq r_2$ ) if for every vertically aligned pair of points,  $(x, y_1)$  in  $r_1$  and  $(x, y_2)$  in  $r_2$ ,  $y_1 \geq y_2$ , and there is at least one pair where a strict inequality holds. It can be shown that the “above” relation is acyclic: it yields a partial ordering (see Exercise 8). For example, applying topological sort to the polygonal map of Figure 2.47(b) yields the regions in the order 0, 1, 2, 3, 4, 5, 6, and 7. The topological sort is performed by using the contents of the ABOVE field of each edge. Since there are  $m$  edges, this process takes  $O(m)$  time [1044].

Assuming that there are  $n$  regions, let the result of the topological sort be a list of the regions in the order  $R_0, R_1, \dots, R_{n-1}$  such that  $R_i \leq R_j$  implies that  $i < j$ . From this list we construct a complete binary tree for  $n$  regions, termed a *region tree*, such that the regions  $R_i$  appear as leaf nodes. The nonleaf nodes are labeled  $S_1, S_2, \dots, S_{n-1}$  so that an inorder traversal of the tree yields the nodes in the order  $R_0, S_1, R_1, S_2, \dots, S_{n-1}, R_{n-1}$ . For example, Figure 2.49 shows such a tree for the eight regions of Figure 2.47(b).

A nonleaf node in the region tree is termed a *separator*. The separators correspond to polygonal lines of infinite length. These lines consist of edges of the  $y$ -monotone subdivision such that each polygonal line intersects every vertical line at exactly one point. In particular, each separator  $S_k$  serves as the boundary between regions  $R_i$  and  $R_j$  such that  $i < k$  and  $j \geq k$ . In other words, a vertex or edge  $e$  belongs to  $S_k$  if and only if it is on the border of two regions,  $R_i$  and  $R_j$ , with  $i < k \leq j$ . It can be shown that the regions and separators satisfy the less than or equal ( $\leq$ ) relation in such a way that  $R_0 \leq S_1 \leq R_1 \leq S_2 \leq \dots \leq S_{n-1} \leq R_{n-1}$  (see Exercise 10). A consequence of this ordering is that if, for a given edge  $e$ ,  $R_i = \text{BELOW}(e)$  and  $R_j = \text{ABOVE}(e)$ , then edge  $e$  is contained in separators  $S_{i+1}, S_{i+2}, \dots, S_j$  and in no other separators (see Exercise 11). This result is referred to as the *edge-ordering property*.

The list of vertices making up a separator is termed a *separating chain*, and when no confusion is possible, the term *chain* is used to refer to it. For example, Figure 2.50 shows the result of labeling the nonleaf nodes of the region tree of Figure 2.49 with their chains. When the region tree is labeled in such a way, we shall call it a *chain tree*. The tree is rooted at the chain  $\alpha\text{ACDEIJKM}\delta$ , which separates regions  $R_0$ – $R_3$  (i.e., 0, 1, 2, 3)

Figure 2.49

Figure 2.51  
Example polygonal maps for which the length of each separator is  $n$ .

and regions  $R_4$ – $R_7$  (i.e., 4, 5, 6, and 7). The left child of the root is  $\alpha ACEIKM\delta$ , which separates regions  $R_0$  and  $R_1$  (i.e., 0 and 1) from regions  $R_2$ – $R_7$  (i.e., 2, 3, 4, 5, 6, and 7).

Constructing the separators is a relatively straightforward process. To do this in an efficient manner, let us assume that the  $n$  regions are stored in a table, say  $R$ , indexed from 0 to  $n-1$ . Moreover, the ABOVE and BELOW information associated with each edge is the index of the region's entry in  $R$ . As an example, for the polygonal map of Figure 2.47(b), we have table  $R$  such that index 0 corresponds to region 0, 1 to region 1, ...,  $i$  to region  $i$ , and so forth. Therefore, for edge  $E_i$  we find that  $\text{ABOVE}(E_i) = 4$  and  $\text{BELOW}(E_i) = 1$ .

The construction process makes use of the property that the output of the regularization process is a list of the vertices and edges of the regularized polygonal map in order of increasing  $x$  coordinate values. This list is processed in order, and as each edge, say  $e$ , is visited, we obtain the values of the indices of the regions below it—that is,  $i = \text{BELOW}(e)$  and  $j = \text{ABOVE}(e)$ , and then append  $e$  to each separator  $S_k$  such that  $i < k \leq j$ . The correctness of this process follows from the edge-ordering property. Therefore, we have shown that for a polygonal map with  $m$  edges, the separators can be constructed in  $O(m)$  time.

The execution time of the separator construction process described above is somewhat misleading as it is heavily influenced by the manner in which the separators are represented. If each separator is represented as an array of all of the vertices and edges contained in it, then the storage requirements are quite high as some of the edges may appear in all but a small number of the separators. In particular, assuming  $n$  regions (i.e.,  $n-1$  separators), the average length of a separator can be as large as  $O(n)$  for some classes of subdivisions (e.g., Figure 2.51). This would result in an  $O(n^2)$  storage requirement, and the time to build the structure of separators would also be  $O(n^2)$ . The same example also shows that the storage requirements can be as high as  $O(m^2)$ .

The storage requirements can be reduced in applications such as point location by noting that when an edge is common to several separators, it is sufficient just to store it with the first separator, say  $S$ , that is encountered in a search down the chain tree (i.e., in a preorder traversal).<sup>12</sup> Assume the numbering convention for regions and separators discussed above and that edge  $e$  lies between regions  $R_a$  and  $R_b$  such that  $\text{BELOW}(e) = a$  and  $\text{ABOVE}(e) = b$ . In this case,  $S$  is the least (or nearest) common ancestor of  $a$  and  $b$ , and it is denoted by  $\text{lca}(a, b)$ . Using the edge-ordering property, it can be shown that any separator that contains  $e$  will be a descendant of the least common ancestor of  $a$  and  $b$  (see Exercise 12).

<sup>12</sup> The principle of associating key information with the nearest common ancestor has also been used by Edelsbrunner [534, 537, 538] as the basis of the interval tree to yield an efficient solution of the rectangle intersection problem (see Section 3.1.2 of Chapter 3).

Figure 2.52  
The gap tree corresponding to the chain tree of Figure 2.50.

The result of such a storage scheme for separators is that each edge needs to be stored only once in the chain tree, and thus a separator node need not contain all of the edges in its corresponding separating chain. This leads to the occurrence of breaks in the separating chain. These breaks are called *gaps*. We shall use the term *gap tree* to describe the variant of the chain tree that results from these economies.

Figure 2.52 shows the gap tree corresponding to Figure 2.50. Each nonleaf node is labeled with the edges that it contains by listing their vertices. A hyphen indicates the absence of an edge between a pair of vertices (i.e., a gap). Note that gaps may also arise at the extreme ends of a chain (e.g., there is a gap at the extreme left and right of the left child of the root in Figure 2.52).

The gap tree uses  $O(m)$  space. Building a gap tree for the chain tree is done in the same way as before except that each edge needs to be inserted only once (i.e., in the separator of the least common ancestor). Insertion of an edge requires the ability to compute the index of the region corresponding to the least common ancestor of the regions adjacent to the edge. For a polygonal map of  $n$  regions, this process can take as much as  $O(\log_2 n)$  time. However, it can be computed in  $O(1)$  time by using bit manipulation techniques [541].

In such a case, a table of  $n$  values consisting of the values of the most significant bit in the binary representation of each of the indices from 0 to  $n - 1$  is precomputed, and then the least common ancestor is computed by table lookup methods. This technique uses  $O(n)$  space for the table (see Exercise 13). An alternative technique does not require additional storage but, instead, uses the reversal of the bit representation of the indices of the adjacent regions (see Exercise 14). This method takes  $O(\log_2 n)$  time since the bits are reversed. Of course, the reverse function can also be precomputed and then accessed by use of table lookup techniques. This yields an  $O(1)$  algorithm.

Now, let us consider the dynamic insertion of an edge into a polygonal map that is represented by a hierarchy of separating chains as in the gap tree. Let  $E$  denote the set of the edges introduced by the application of regularization to the original polygonal map. Addition of  $e$  may cause  $O(v)$  new vertices to be added by virtue of the intersection of  $e$  with the set  $E$ . This means that the size of the gap tree (i.e., number of regions) will be dominated by the side effects of the regularization process. To avoid this situation, we must reapply the regularization step to the  $O(v)$  vertices from which the intersected members of  $E$  emanated. In this special case, this process uses  $O(v)$  space and time since the vertices are already sorted (see Exercise 16).

For example, consider the map of Figure 2.53(a), which consists of  $4 \cdot v + 4$  vertices and resembles a collection of  $v$  toothlike objects. Figure 2.53(b) is the result of one way of regularizing this map where the added edges ( $2 \cdot v$  of them) are shown with broken lines. In particular, we add edges to the left from vertices  $a_i$  to  $b_i$  ( $1 \leq i \leq v$ ), edges to the right from  $a_i$  to  $b_{i+1}$  ( $1 \leq i < v$ ), and an edge from  $b_1$  to  $A$ . Inserting an edge between vertices  $A$  and  $B$  into the original map intersects all of the edges that were added by the

regularization. Thus, the nature of the  $2 \cdot v$  vertices  $a_i$  and  $b_i$  requires that the map be regularized again since they must have edges to their right and left.

Point location in the gap tree is achieved by an algorithm that uses two levels of binary search. At each level of the tree, the entire relevant separating chain is searched for an edge or vertex whose projection on the  $x$  axis contains the  $x$  coordinate value of the query point. The individual separating chains are sorted by the  $x$  coordinate value of the leftmost vertices of their constituent edges. The gaps are not stored in the separating chains.

Initially, we search for an edge that partitions the set of regions bounded by  $R_0$  at the bottom and  $R_{n-1}$  at the top. Let  $a$  and  $b$  designate the indices of the regions corresponding to the lower and upper boundaries, respectively, of the search space. The search starts at the separating chain stored at the root of the gap tree (i.e.,  $S_{lca(0,n-1)}$ ) with  $a = 0$  and  $b = n - 1$ . Having found the appropriate edge, say  $e$ , we determine at which node of the gap tree to continue our search by examining the value of the  $y$  coordinate of the query point.

If the query point lies below  $e$ , then the search is resumed in the regions bounded by  $R_a$  and  $R_{\text{BELOW}(e)}$ . If it lies above  $e$ , then the search is resumed in the regions bounded by  $R_{\text{ABOVE}(e)}$  and  $R_b$ . In either case, one of  $a$  and  $b$  is reset. If the query point lies on the edge, then the search ceases, and we say that the point lies in region  $R_{\text{ABOVE}(e)}$ . The actual node of the gap tree at which the search is resumed is equal to  $S_l$ , where  $l$  is the least common ancestor of  $a$  and  $b$  (i.e.,  $S_{lca(a,b)}$ ). We know that  $S_l$  is the separator that will contain the edge separating these regions by virtue of the way in which the gap tree was constructed (and by the edge-ordering property).

For example, to locate point P in the polygonal map of Figure 2.47(b), we search for it using Figure 2.52. We first examine the root that corresponds to the separator  $\alpha\text{ACDEIJKM}\delta$  and find that it lies above edge EI. The search will continue in the separating chain stored in  $S_{lca(\text{ABOVE}(EI),7)} = S_{lca(4,7)} = S_6$ , which is  $\alpha\text{BC} - -\text{DGJ} - -$  (recall that the hyphens denote gaps). Repeating the search for P, we determine that it lies below edge DG. We are now through since  $S_{lca(4,\text{BELOW}(DG))} = S_{lca(4,4)}$ , which is region 4.

Although in this example we performed a test at successive levels of the gap tree, this need not be the case always. Many times,  $S_{lca(a,b)}$  may be several levels down in the tree. To see this, let us try to locate point Q in the polygonal map of Figure 2.47(b). Again, we first examine the separator  $\alpha\text{ACDEIJKM}\delta$  in the root of its gap tree in Figure 2.52. We find that Q lies below edge EI, and now  $S_{lca(0,\text{BELOW}(EI))} = S_{lca(0,1)} = S_1$ , which means that we have skipped a level.

Figure 2.53  
(a) A polygonal map and (b) its regularization (broken lines correspond to the edges added by the regularization).

Figure 2.54  
Example polygonal map for which point location using the gap tree requires  $O(\log_2^2 m)$  time.

In the worst case, point location in the gap tree requires that we examine each separating chain on the path from the root of the tree to the desired region. Worse, we may also have to search each of these nodes in their entirety. For a regularized polygonal map with  $n$  regions and  $m$  edges, the binary search of each separating chain can be achieved in  $O(\log_2 m)$  time. This assumes that the edges are sorted by the  $x$  coordinate value of their left vertex. Since the gap tree has  $O(\log_2 n)$  levels,  $O(\log_2 n)$  separating chains must be searched. Therefore, point location takes  $O(\log_2 n \cdot \log_2 m) = O(\log_2^2 m)$  time. This bound is attainable as can be seen by constructing an example such as Figure 2.54, which has  $\sqrt{m}$  separating chains (i.e.,  $\sqrt{m} + 1$  regions) where each chain contains  $\sqrt{m}$  edges.

### Exercises

1. Prove that defining a  $y$ -monotone subdivision in terms of not permitting a vertical line to cross a region's boundary more than twice is equivalent to requiring that each vertex have at least one edge to each of its right and left sides.
2. Does adding a new edge to a regularized polygonal map always preserve  $y$ -monotonicity?
3. Is the overlay of two  $y$ -monotone subdivisions always a  $y$ -monotone subdivision?
4. Prove that regularizing a polygonal map of  $m$  edges results in a  $y$ -monotone subdivision of  $\leq 2 \cdot m$  edges.
5. Give an algorithm and data structure to regularize a polygonal map.
6. Discuss how the separating chain method can be modified to handle polygonal maps with vertical edges.
7. Can you devise an algorithm to perform regularization in time faster than  $O(m \cdot \log_2 m)$ ?
8. Prove that the "above" relation is acyclic.
9. Is the following statement correct? If not, give a counterexample. For each separator in a chain tree,  $S_k$ , there exists at least one edge  $e$  in  $S_k$  such that for a vertical line passing through  $e$  at  $(x_e, y_e)$ , all points  $(x_e, y)$  with  $y \leq y_e$  are in the regions in the left subtree while those with  $y > y_e$  are in the regions in the right subtree.
10. Assume a  $y$ -monotone subdivision such that  $R_0 \leq R_1 \leq \dots \leq R_{n-1}$ . Prove that  $R_0 \leq S_1 \leq R_1 \leq S_2 \leq \dots \leq S_{n-1} \leq R_{n-1}$ .
11. Assume a  $y$ -monotone subdivision such that  $R_0 \leq R_1 \leq \dots \leq R_{n-1}$ . Prove the edge-ordering property, which stipulates that if for a given edge  $e$ ,  $R_i = \text{BELOW}(e)$  and  $R_j = \text{ABOVE}(e)$ , then edge  $e$  is contained in separators  $S_{i+1}, S_{i+2}, \dots, S_j$  and in no other separators.
12. Suppose that edge  $e$  lies between regions  $R_a$  and  $R_b$  such that  $\text{BELOW}(e) = a$  and  $\text{ABOVE}(e) = b$ . Prove that any separator in a chain tree that contains  $e$  will be a descendant of the least common ancestor of  $a$  and  $b$ .

13. Let  $lca(i, j)$  denote the least common ancestor of  $i$  and  $j$ , where  $i$  and  $j$  are between 0 and  $n - 1$ . Let  $msb(i)$  denote the most significant bit of the binary representation of  $i$ , where  $i$  is between 0 and  $n - 1$ . In other words,  $msb(i) = lca(0, i)$ . Compute  $lca(i, j)$  in terms of  $msb$ . You should use a combination of Boolean operations such as “exclusive or” ( $\oplus$ ), “complement” ( $\neg$ ), “and” ( $\wedge$ ), and so on.
14. Let  $rev(k)$  denote a function that reverses the bits in the binary expansion of  $k$ . Using the definition of  $lca$  in Exercise 13, compute  $lca(i, j)$  in terms of  $rev$ . You should use a combination of Boolean operations such as “exclusive or” ( $\oplus$ ), “complement” ( $\neg$ ), “and” ( $\wedge$ ), and so forth.
15. In a gap tree, each separating chain is implemented as a list of the  $x$  coordinate values of the leftmost vertices of their gaps and edges. How would you cope with a query point that coincides with an endpoint of an edge?
16. Suppose that a new edge is inserted into a regularized polygonal map with  $O(v)$  vertices that is represented by the separating chain method. Show that applying the regularization process again uses  $O(v)$  space and time.
17. Let us reexamine the problem of inserting a new edge, say  $e$ , into a polygonal map that is represented by the separating chain method. Let  $E$  denote the set of the edges introduced by the application of regularization to the original polygonal map. Addition of  $e$  may cause new vertices to be added by virtue of the intersection of  $e$  with the set  $E$ . In the text and in Exercise 16, we mention that we remove all edges in  $E$  that intersect  $e$  and reapply the regularization process. Is this always a better method than simply adding new vertices whenever  $e$  intersects one of the elements of  $E$ ?
18. Write a procedure GAPTREEPOINTLOCATION to perform point location in a gap tree.

### 2.1.3.3.2 Layered Dag

The main drawback of the algorithm for point location in a gap tree is that, for each level of the gap tree, the corresponding separating chain must be searched in its entirety (notwithstanding that the elements in the chain are sorted). It is preferable to restart the search in the vicinity of the edge or gap in the appropriate child. Thus, we want a pointer from each edge or gap on the separating chain, say  $e$ , to the edges on the separating chain of each child that overlaps  $e$ .

The problem is that an edge or gap of a parent may overlap many edges or gaps of the child. For example, in the polygonal map of Figure 2.47(b), edge  $E_1$  in separating chain  $S_4$  (or equivalently gap  $E_1$  in separating chain  $S_2$ ) overlaps edges  $EF$ ,  $FH$ , and  $HI$  in separating chain  $S_1$ . Inserting these additional pointers has the potential to break up each separating chain at the  $x$  coordinate values of all of the vertices in the subdivision. Consequently, this could use quadratic space (i.e.,  $O(m^2)$ ).

To solve the problem described above, Edelsbrunner, Guibas, and Stolfi [541] propose a data structure that they call a *layered dag*. A layered dag is a separating chain that is augmented by a set of vertices. In particular, the layered dag, say  $L_u$ , corresponding to a separating chain, say  $S_u$ , is a set of  $x$ -intervals that covers the entire  $x$  axis. Each layered dag is implemented as a set of vertices and a set of edges and gaps. The  $x$ -intervals are specified in terms of these vertices, edges, and gaps. Each  $x$ -interval of  $L_u$  overlaps the  $x$ -projection of exactly one edge or gap of  $S_u$  and at most two  $x$ -intervals of the layered dags corresponding to the left and right children of  $S_u$ . As we shall see later, this condition enables us to keep the storage requirements of the resulting data structure linear.

Let  $L_u$  denote the layered dag of node  $u$  of a gap tree  $T$  whose separating chain is  $S_u$ .  $L_u$  is constructed by processing the separating chains in  $T$  in a bottom-up manner so that the layered dags corresponding to the children of  $u$  are built first.  $L_u$  consists of a set of vertices corresponding to union of the endpoints of the edges and gaps in  $S_u$  and every other vertex of those present in the layered dags of the left and right children of  $u$ . Duplicate vertices are removed. By convention, we assume that when  $u$  is a leaf node of  $T$ , then the children of  $L_u$  are empty. This process is applied recursively to every node of the gap tree. The result is that as the layered dags are constructed, at each level every

Figure 2.55  
Layered dag representation of the gap tree of Figure 2.52.

other vertex is propagated towards the layered dag that corresponds to the root of the gap tree.

As an example, let us build the layered dags corresponding to the separating chains of the gap tree of Figure 2.52. Let  $L_i$  denote the result of applying the construction to  $S_i$ . Figure 2.55 shows the result of this construction. For the sake of the current discussion, we describe only how the elements making up each layered dag are determined. Thus, for the moment, we ignore the meaning of the interconnections between elements of the layered dag, as well as how they are formed. In the figure, vertices are depicted by circles, while  $x$ -intervals are shown by boxes between circles. In particular,  $x$ -intervals corresponding to edges are depicted by solid boxes, and those corresponding to gaps are depicted by broken boxes.

Before describing the correspondence between the layered dags of Figure 2.55 and the separating chains of the gap tree of Figure 2.52, we make the following two observations. First, the  $x$ -interval is labeled with the name of the edge or gap of which it is a subset; it is not necessarily labeled with the vertices to its immediate right and left. This situation arises when the  $x$ -interval is part of an edge or gap that extends beyond the endpoints of the  $x$ -interval. For example, the  $x$ -interval corresponding to vertices A and B in  $L_4$  in Figure 2.55 is labeled AC rather than AB since  $x$ -interval AC overlaps edge AB. Second, the layered dags do not include the dummy vertices at the extreme left and right (i.e.,  $\alpha$  and  $\delta$  in Figure 2.47(b)) that are introduced by the regularization process. This means that we ignore them when building the layered dags corresponding to the separating chains. However, the  $x$ -intervals in which they participate are included in the layered dag.

In our example, the sets of  $x$ -intervals corresponding to  $L_1$ ,  $L_3$ ,  $L_5$ , and  $L_7$  are identical to the edges and gaps making up  $S_1$ ,  $S_3$ ,  $S_5$ , and  $S_7$ , respectively.  $L_1$  consists of vertices E, F, H, and I.  $L_3$  and  $L_5$  do not have any vertices.  $L_7$  consists of vertices K and L.

$L_2$  is formed by combining vertices C, E, I, and K of  $S_2$ , and alternating vertices E and H of  $L_1$ .  $L_3$  does not contribute any vertices. The result consists of vertices C, E, H, I, and K and the  $x$ -intervals between them: edges CE and IK, and gaps  $\alpha$  C, EI, EI, and K  $\delta$ .

$L_6$  is formed by combining vertices B, C, D, G, and J of  $S_6$ , and alternating vertex K of  $L_7$ .  $L_5$  does not contribute any vertices. The result consists of vertices B, C, D, G, J,

and K and the  $x$ -intervals between them: edges  $\alpha$  B, BC, DG, and GJ, and gaps CD, J  $\delta$ , and RJ  $\delta$ .

$L_4$  is formed by combining vertices A, C, D, E, I, J, K, and M of  $S_4$ ; alternating vertices C, H, and K of  $L_2$ ; and alternating vertices B, D, and J of  $L_6$ . The result consists of vertices A, B, C, D, E, H, I, J, K, and M and the  $x$ -intervals between them: edges  $\alpha$  A, AC, AC, CD, DE, EI, EI, IJ, JK, KM, and M  $\delta$ ; there are no gaps.

So far, we have described only the correspondence between the information stored in a layered dag and a chain node in the gap tree. We now show how the information in the layered dag is organized. This organization will be used subsequently in an algorithm to perform point location in  $O(\log_2 m)$  time rather than  $O(\log_2^2 m)$  time. We illustrate our presentation with Figure 2.55. We use the term *record* to refer to the box or circle in the figure that is associated with an  $x$ -interval. Our discussion makes heavy use of DOWN, UP, LEFT, and RIGHT links, which are all shown with the proper orientation in the figure.

As stated earlier, each  $x$ -interval, say  $I$ , of layered dag  $L_u$  corresponding to separating chain  $S_u$  of node  $u$  in the gap tree overlaps at most two  $x$ -intervals of the layered dags of the left and right children of  $u$ . We keep track of overlaps by using the two fields DOWN and UP in  $x$ -interval  $I$ 's record. When  $x$ -interval  $I$  of  $L_u$  overlaps only one  $x$ -interval of the layered dags of the left (right) child of  $u$ , say  $L_{\text{LEFT}(u)}$  ( $L_{\text{RIGHT}(u)}$ ), then DOWN( $I$ ) (UP( $I$ )) points to the overlapped  $x$ -interval's record. For example,  $x$ -interval HI in  $L_4$  overlaps  $x$ -interval GJ in  $L_6$ , and thus its UP link is set to point to GJ's  $x$ -interval record. Notice that, in this example,  $x$ -interval HI is associated with edge EI since it is a subset of this edge.

When  $x$ -interval  $I$  overlaps two  $x$ -intervals of one or both children, then DOWN( $I$ ) (UP( $I$ )) points to the record of the vertex that is common to the two overlapped  $x$ -intervals in  $L_{\text{LEFT}(u)}$  ( $L_{\text{RIGHT}(u)}$ ). This situation is facilitated by associating two fields LEFT and RIGHT with each vertex and letting them point to the  $x$ -intervals to the left and right of the vertex, respectively. For example,  $x$ -interval EH in  $L_4$  overlaps both  $x$ -intervals DG and GJ in  $L_6$ , and thus its UP link is set to point to G's record in  $L_6$ .

Continuing the example above, we observe that  $x$ -interval EH is associated with edge EI since it is a subset of this edge. Note also that an  $x$ -interval can be overlapped by many  $x$ -intervals (e.g., CE in  $L_2$  is overlapped by both CD and DE of  $L_4$ ). Thus, it should be clear that the layered dag representation is not a tree. In fact, it resembles the K-structure. Not surprisingly, each vertex can be common only to one  $x$ -interval (see Exercise 2).

The cost of building the layered dag representation is easy to analyze. As we saw earlier, the process consists of processing the separating chains of the gap tree in a bottom-up manner. The DOWN (UP) links of  $L_u$ , corresponding to node  $u$  in the gap tree, are set by simultaneously traversing  $L_u$  and  $L_{\text{LEFT}(u)}$  ( $L_{\text{RIGHT}(u)}$ ) from left to right. Setting the LEFT and RIGHT links of the vertices is accomplished at the same time. The entire building process is linear in the number of edges in the gap tree (i.e.,  $O(m)$ ).

However, we must still show that the amount of space necessary to store the layered dags is  $O(m)$ . This can be seen by noting that the layered dags corresponding to the gap tree consist of sequences of vertices and then counting them. It can be shown that the total number of vertices in the layered dags is bounded by four times the number of edges in the regularized polygonal map (i.e.,  $4 \cdot m$ ).

An intuitive proof of this bound is obtained by observing that if the nodes of the gap tree that correspond to chains have a total of  $m$  edges, then there are  $2 \cdot m$  vertices that serve as the endpoints of these edges. By the construction procedure, only one-half of these vertices are propagated to the parent chains, one-quarter to the grandparent chains, and so on, and the desired result follows by the properties of an infinite geometric series. For a more formal proof, see Exercise 3. Thus, the process of building the layered dag representation is  $O(m)$  in space and time.

Point location in a layered dag representation is performed in a manner very similar to that in a gap tree. The only difference is that once the initial  $x$ -interval is located in the layered dag corresponding to the root of the gap tree, there is no need to search for it in the layered dags at the lower levels. The point is located by simply traversing the appropriate links in the layered dag representation. Let  $a$  and  $b$  designate the indices of the regions corresponding to the lower and upper boundaries, respectively, of the search space. They are initialized to 0 and  $n - 1$ , respectively.

Suppose we want to locate point  $P$ . We start at the layered dag, say  $L$ , corresponding to the root of the gap tree and search for the  $x$ -interval, say  $I$ , that contains the  $x$  coordinate value of  $P$ . Once we have found  $I$ , we must decide where to continue the search. Since  $I$  must correspond to an edge, say  $e$ , after the initial search, we now check the position of the  $y$  coordinate value of  $P$  relative to  $e$ . If  $P$  lies below (above)  $e$ , then we continue the search at the  $x$ -interval pointed at by  $\text{DOWN}(I)$  ( $\text{UP}(I)$ ) in the regions bounded by  $R_a$  and  $R_{\text{BELOW}(e)}$  ( $R_{\text{ABOVE}(e)}$  and  $R_b$ ) and reset  $a$  and  $b$  as is appropriate. If  $P$  lies on  $e$ , then the search ceases, and we say that  $P$  lies in region  $R_{\text{ABOVE}(e)}$ .

$x$ -interval  $I$  in  $L$  corresponds to an edge. However, in all subsequent steps of the algorithm,  $I$  can correspond to a gap or a vertex as well as an edge. When  $I$  corresponds to a gap, then there is no test to be performed on  $P$ . Nevertheless, we must descend to the appropriate  $x$ -interval in the layered dag of the next level. In this case, we have to reconstruct the result of a test at an  $x$ -interval at a previous level. This is done by comparing the value of  $b$  with the chain number<sup>13</sup> of the layered dag containing  $I$ , say  $c$ . If  $b$  is less than  $c$ , then we follow link  $\text{DOWN}(I)$ ; otherwise, we follow link  $\text{UP}(I)$ . When  $I$  corresponds to a vertex, we check if  $P$ 's  $x$  coordinate value is less than or equal to that of  $I$ , in which case we continue the search in  $x$ -interval  $\text{LEFT}(I)$ ; otherwise, we continue in  $x$ -interval  $\text{RIGHT}(I)$ .

Note that the way we have described the organization of the vertices and  $x$ -intervals in the layered dag means that the only time that we have to perform a search is when we process  $L$  to locate the initial  $x$ -interval that contains  $P$ . This could be an  $O(m)$  process in the worst case. All other searches are achieved by traversing the appropriate links—an  $O(1)$  process per level for a total cost of  $O(m + \log_2 n)$ . The execution time can be reduced further by imposing an additional data structure in the form of a binary search tree on  $L$ .

This binary tree is built using the  $\text{LEFT}$  and  $\text{RIGHT}$  link fields of the nodes corresponding to the vertices in  $L$ . The leaf nodes of this tree consist of the  $x$ -intervals (i.e., edges), while the nonleaf nodes consist of the vertices. For example, Figure 2.56 is the modification of the layered dag representation of Figure 2.55 to include the binary search tree. This tree is rooted at vertex  $J$ , and thus all point location operations will start at node  $J$ . The result is that we have now reduced the cost of the point location operation to  $O(\log_2 m)$  since  $m$  can be larger than  $n$ . Comparing point location in a layered dag with point location in a gap tree, we find that the two levels of binary searching have been replaced by a binary search in the root and an  $O(1)$  search in the rest of the structure. This type of a transformation is an instance of a general technique known as *fractional cascading* [339, 340].

Procedure `LAYEREDDAGPOINTLOCATION`, given below, implements the point location algorithm using a layered dag. A layered dag is represented as a set of nodes of type *ldnode*, where each node has four fields. The `TYPE` field indicates whether the node corresponds to a vertex, edge, or gap. The remaining three fields depend on the type of data stored in the node.

A vertex node, say  $P$ , has three additional fields called `LEFT`, `RIGHT`, and `XVAL`. `LEFT` (`RIGHT`) points to the edge or gap nodes to the left (right) of  $P$ , and `XVAL` indicates the  $x$  coordinate value of  $P$ .

---

<sup>13</sup> Chains are assumed to be numbered from 1 to  $n - 1$  as illustrated in Figure 2.49.

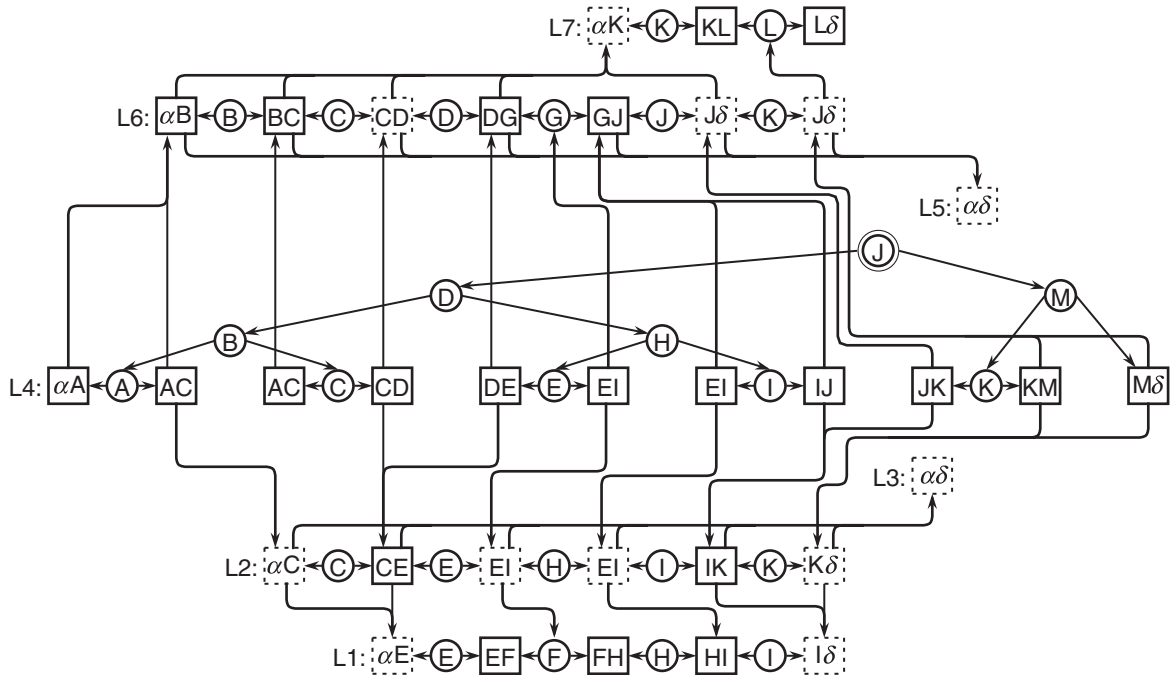

Figure 2.56 Layered dag representation of Figure 2.55 modified to include a binary search tree for the layered dag corresponding to the root of the gap tree.

An edge node, say  $E$ , has three additional fields called DOWN, UP, and EDGE. DOWN (UP) points to the edge, gap, or vertex nodes below (above)  $E$ , and EDGE points to a record of type *edge* describing edge  $E$ . A record of type *edge* has two fields called BELOW and ABOVE that indicate the regions immediately below and above it, respectively, as well as a field specifying the points it comprises, such as an equation of the line corresponding to it.

A gap node, say  $G$ , has three additional fields called DOWN, UP, and CHAINID. DOWN (UP) points to the edge, gap, or vertex nodes below (above)  $G$ , and CHAINID indicates the chain number of the node in the gap tree corresponding to the layered dag of which  $G$  is a member (i.e.,  $u$  for  $L_u$ ).

We also give a few more definitions. A point is implemented using a record of type *point* having two fields XCOORD and YCOORD corresponding to its  $x$  and  $y$  coordinate values, respectively. The relative position of the query point  $P$  with respect to an edge  $E$  (i.e., the side of  $E$  on which  $P$  lies) is determined with the aid of function FINDY, which takes the point  $P$  and the edge  $E$  as arguments and returns the value of the  $y$  coordinate of the point on  $E$  that has XCOORD( $P$ ) as the value of its  $x$  coordinate. Variables *Low* and *High* represent the lower and upper boundaries, respectively, of the search space.

```

1 integer procedure LAYEREDDAGPOINTLOCATION( $P, T, N$ )
2 /* Search the layered dag representation of a polygonal map rooted at  $T$  for
   the region that contains point  $P$  and return its value. There are  $N$  regions
   in the polygonal map. The regions are numbered from 0 to  $N - 1$ . */
3 value pointer point  $P$ 
4 value pointer lnode  $T$ 
5 value integer  $N$

33     endif
34   endif
35 enddo
36 return Low

```

The layered dag and the K-structure are solutions for the point location query in a static environment. In other words, they assume that we know the positions of the vertices and edges of the subdivision of the underlying space (i.e., the polygonal map). There has also been a substantial amount of work on the dynamic point location problem. There are several solutions [103, 142, 357, 362, 365, 652, 653, 727, 1441, 1512, 1513, 1821] that differ in the amount of time it takes for a query to be answered or for edges and vertices to be inserted and deleted, as well as for some other operations such as vertex expansion and contraction (see [142, 357, 727] for overviews and summary tables). The key to the differences is the nature of the combination of the operations, the nature of the collection of the regions that can be handled, and whether the execution-time cost bounds are worst-case cost or amortized cost.

In particular, for  $n$  regions in a connected subdivision, Cheng and Janardan [357] execute the dynamic query in  $O(\log_2^2 n)$  time with  $O(n)$  space and  $O(\log n)$  insertion and deletion (i.e., update) times. They use a combination of the interval tree [534, 537, 538] (see Section 3.1.2 of Chapter 3) and the priority search tree [1266] (see Section 1.3 of Chapter 1). Baumgarten, Jung, and Mehlhorn [142] also use  $O(n)$  space and reduce the query execution time to  $O(\log n \log \log n)$  in a general subdivision, while using amortized  $O(\log n \log \log n)$  time for insertion and amortized  $(\log^2 n)$  time for deletion. They use a combination of an interval tree, a segment tree [166] (see Section 3.1.1 of Chapter 3), fractional cascading [339, 340], and the combination of the interval tree and priority search tree used in [357]. Goodrich and Tamassia [727] obtain the same space and execution time bounds as Cheng and Janardan [357] for a monotone subdivision using a different data structure and also show how to perform vertex expansion and contraction in  $O(\log n)$  time. They use an edge-ordered dynamic tree [562], which is an extension of the link-cut tree [1776].

### Exercises

1. In the construction of the layered dag representation of the polygonal map of Figure 2.47(b), the alternating vertices were taken in the order first, third, fifth, and so on. Repeat this construction by taking them in the order second, fourth, sixth, and so forth.

2. In the layered dag representation of a polygonal map, explain why each vertex can be common only to one  $x$ -interval.
3. Prove that the total number of vertices in a layered dag representation of a regularized polygonal map of  $m$  edges is bounded by  $4 \cdot m$ . Use induction on the depth of the gap tree that serves as the basis of the construction of the layered dag representation. By letting  $a_u$  denote the number of edges in  $S_u$ ,  $b_u$  the number of vertices in  $L_u$ ,  $A_u$  the sum of  $a_v$  over all nodes  $v$  in the subtree rooted at  $u$ , and  $B_u$  the sum of  $b_v$  over all nodes  $v$  in the subtree rooted at  $u$ , the problem reduces to showing that  $B_r \leq 4 \cdot A_r = 4 \cdot m$  holds for the root node  $r$  of the gap tree.
4. Is the upper bound derived in Exercise 3 a least upper bound? Can you give an example where it is attained? If not, can you obtain a tighter bound?
5. The implementation of the layered dag described in the text is somewhat wasteful of space. Discuss how to reduce its space requirements.
6. The algorithm that we described for point location in a layered dag representation will usually visit  $\log_2 n$   $x$ -intervals, even if all but one of them correspond to gaps. In contrast, the algorithm that we described for point location in a gap tree made use of the gaps to skip some levels in the tree. Can you modify the structure of the layered dags and the point location algorithm to avoid the tests where the  $x$ -intervals correspond to gaps?
7. How would you adapt the layered dag to deal with the three-dimensional point location query? If this is not possible, explain why.
8. How would you compute map overlay (see Exercise 12 in Section 2.1.3.2) for two polygonal maps represented using a layered dag?

### 2.1.4 Arbitrary Objects

In this section, we loosen the restrictions on the cells, blocks, and objects in Sections 2.1.1 and 2.1.2 that prevented a cell or a block from being partially contained in several objects or that required a cell or a block to be contained in its entirety in a single object. In other words, a cell or a block may overlap several objects without being completely contained in these objects. Furthermore, we permit objects to be of arbitrary shapes rather than requiring their boundaries to be hyperplanes.

Loosening these restrictions enables the decoupling of the partition of the underlying space induced by the decomposition process from the partition induced by the objects. Again, as discussed in Section 2.1.3, the individual objects no longer need to be represented as collections of unit-sized cells or rectangular blocks. Instead, collections of other shapes, such as triangles, trapezoids, convex polygons, and so on, can be used. When there is no explicit relationship between the blocks and the objects that they contain (e.g., containment), then in addition to keeping track of the identities of all objects (or parts of objects) that can be covered by a block or part of a block, we must also keep track of the geometric descriptions of both the cells or blocks and the objects. This enables us to respond to the location query.

Note that without the geometric description, given a specific location  $l$  in space, finding the cell  $c$  or block  $b$  in which  $l$  is contained may not be enough to determine the identity of the object (or objects) of which  $l$  is a member, as well as the rest of the constituent cells of the object (or objects). Therefore, once we have located  $c$  or  $b$ , we must check the geometric description of the objects associated with  $c$  or  $b$  to see which ones contain  $l$ . By recording a pointer to the geometric description of the objects with each cell or block rather than the entire geometric description, we save much storage because the geometric description is recorded only once. Notice that once we have located the object (or objects) containing  $l$ , determining the remaining constituent cells of these objects is done in the same manner as described earlier (i.e., by use of appropriate variants of connected component labeling).

In Sections 2.1.2 and 2.1.3, we halted the decomposition process whenever a block was completely contained in an object or a set of objects. However, it is clear that this

rule is impossible to satisfy in general, now that the boundaries of the objects need not coincide with the boundaries of the blocks that are induced by the decomposition process. Thus, we need to find an alternative way of halting the decomposition process. There are two natural methods for achieving this result, and they are the subject of this section:

1. Restrict the number of blocks that can cover an object (i.e., parts of it); this is termed *coverage-based splitting* [242] (Section 2.1.4.1).
2. Restrict the number of objects (or parts of objects) that can be covered by a block or part of a block; this is termed *density-based splitting* [242] (Section 2.1.4.2).

### 2.1.4.1 Coverage-Based Splitting

A common way of implementing coverage-based splitting is to set the number of blocks that can cover an object to 1. In particular, this block is usually the smallest possible block that contains the object. There are many ways of implementing this strategy. One of the earliest implementations is the MX-CIF quadtree [1009]. The MX-CIF quadtree [1009] is a quadtree-like regular decomposition rule that decomposes the underlying space into four congruent blocks at each stage (i.e., level) of the decomposition process so that each object is associated with its minimum enclosing quadtree block. Figure 2.57 is an MX-CIF quadtree, where we see that more than one object is associated with some of the nodes in the tree (e.g., the root and its NE child).

Since there is no limit on the number of objects that are associated with a particular block, an additional decomposition rule may be provided to distinguish between these objects. For example, in the case of the MX-CIF quadtree, a one-dimensional analog of the two-dimensional decomposition rule is used. In particular, all objects that are associated with a given block  $b$  are partitioned into two sets: those that overlap the vertical axis passing through the center of  $b$  and those that overlap the horizontal axis. Objects that overlap the center of  $b$  are associated with the horizontal axis. Associated with each axis is a one-dimensional MX-CIF quadtree (i.e., a binary tree), where each object  $o$  is associated with the node that corresponds to  $o$ 's minimum enclosing interval. The MX-CIF quadtree is described in more detail in Section 3.4.1 in Chapter 3.

Note that the MX-CIF quadtree results in a decomposition of space into blocks that are not necessarily disjoint, although there is a containment relationship between them—that is, two blocks  $a$  and  $b$  are either disjoint,  $a \subset b$ , or  $b \subset a$ . Other researchers have also used the idea of associating each object with its minimum enclosing quadtree block. They differ in the manner in which they keep track of the minimum enclosing quadtree blocks. Abel and Smith [8] represent each block by its locational code (see Section 2.1.2.4) and store these locational codes in a  $B^+$ -tree [2]. Of course, each block must be stored as many times as there are objects for which it serves as the minimum enclosing quadtree block. The multiple instances of blocks with the same locational code can be distinguished by using a secondary key based on the actual object, such as its centroid.

The filter tree of Sevcik and Koudas [1720] keeps track of the minimum enclosing quadtree blocks by using a similar approach to that of Abel and Smith [2, 8] in that it makes use of a B-tree index. However, there are a couple of important differences. First, instead of having one B-tree for all of the blocks, the filter tree maintains one B-tree for each level in the quadtree. This means that all minimum enclosing quadtree blocks of a given size are associated with the same B-tree, and a  $2^n \times 2^n$  image space may have as many as  $n + 1$  B-trees. Second, the B-tree stores the Peano-Hilbert key corresponding to the centroid of the minimum bounding box of each object instead of the locational code of the minimum enclosing quadtree block of each object. Note that in the filter tree, as in the  $B^+$ -tree implementation of the MX-CIF quadtree, all of the objects with the same minimum enclosing quadtree block are stored contiguously.

The filter tree can be viewed as providing a variable number of grids, each one being at half the resolution of its immediate successor, where an object is associated with the grid whose cells provide the tightest fit. This concept is termed *multiresolution* and is

Figure 2.57  
(a) Block decomposition induced by the MX-CIF quadtree for a collection of rectangle objects and (b) its tree representation.

expanded upon in Section 2.1.5.1. The filter tree is based on a regular decomposition of the underlying space. The multilayer grid file [1773] is similar to the filter tree. The difference is that each grid layer corresponds to separate grid file with its own partitions that are not necessarily related, as is the case in a regular grid, which forms the basis of the filter tree. As in the filter tree, each object  $o$  is inserted into the first grid file for which it fits in a grid block without having to partition  $o$ . The R-file [909] (see also Section 3.4.2 of Chapter 3) is a cross between the multilayer grid file and the MX-CIF quadtree in the sense that, instead of being associated with its minimum enclosing quadtree block, an object is associated with its minimum containing block among the existing quadtree (actually a regular decomposition k-d tree—that is, a bintree) blocks. One of the properties of the R-file is that just because the structure contains a block  $b$ , it need not necessarily contain its siblings (i.e., the blocks that result from the decomposition of  $b$ 's parent block).

The R-file [909] is a modification of the multilayer grid file that is designed to overcome the observed low storage utilization by having just one directory instead of multiple directories. The R-file makes use of a regular decomposition in a spirit similar to the BANG file [640] (see Section 1.7.1.5 of Chapter 1) except that there is no use of holes (i.e., the bucket regions do not have the shapes of bricks with holes that correspond to regions that have been extracted as a result of the split process). In particular, one of its key features is that instead of splitting a bucket region into two halves (or four halves in the case of a quadtree-like approach), it retains the original bucket region and creates a new bucket for just one of the two halves of the original bucket region. The advantage of this method is that there is more flexibility in deciding which objects should be retained in the original bucket region and which ones should be moved to the newly created bucket region. Note that bucket regions do overlap in this case and that an object is not necessarily associated with the minimum containing block but, instead, is associated with its minimum containing block among the existing blocks. Like Abel and Smith's implementation of the MX-CIF quadtree [2] and other methods, the R-file stores a one-dimensional representative of the buckets (its locational code based on the Morton order) in a B-tree. In order to avoid searching unoccupied space, the R-file also associates with each bucket a minimum bounding box of the objects that it contains.

The drawback of restricting the number of blocks that can cover an object  $o$  to 1 (i.e.,  $o$ 's minimum enclosing quadtree block) is that the block tends to be rather large, on the average. In particular, in the worst case, a small object that straddles the top-level split partition will have the root as its minimum enclosing quadtree block (e.g., objects A and E are associated with the root in the MX-CIF quadtree in Figure 2.57).

An easy way to overcome this drawback is to decompose  $o$ 's minimum enclosing quadtree block (or the result of another space decomposition method, such as a bintree) into smaller blocks, each of which minimally encloses some portion of  $o$  (or, alternatively, some portion of  $o$ 's minimum bounding box). The expanded MX-CIF quadtree [9] is a simple example of such an approach where  $o$ 's minimum enclosing quadtree block  $b$  is decomposed once into four subblocks  $s_i$ , which are then decomposed further until obtaining the minimum enclosing quadtree block for the portion of  $o$ , if any, that is covered by  $b_i$  (see Section 3.4.3 in Chapter 3 for more details).

Orenstein [1416] proposes the *error-bound* and *size-bound* methods for deciding how much decomposition to perform to yield the blocks covering object  $o$ . In the error-bound method, the minimum enclosing block is recursively split until level  $L$  is reached, where 0 is the level of the root and  $L$  is a user-specified level threshold. In the size-bound method, the minimum enclosing block is recursively split in a breadth-first manner (see Exercise 1), and the process is terminated once a threshold number  $S$  of blocks that collectively cover the space spanned by  $o$  has been obtained. For both methods, once enough splitting has been performed, the blocks that collectively cover  $o$  are shrunk so that each one minimally encloses the portion of  $o$  inside it, and sibling blocks that both cover  $o$  are coalesced. Thus, the possible number of resulting blocks ranges from 1

through  $2^L$  for the error-bound method and from 1 through  $S$  for the size-bound method. Observe that both methods are equivalent for  $S = 1/L = 0$  and for  $S = 2^H/L = H$ , where  $H$  is the height of the space decomposition hierarchy (i.e., the maximum number of levels), but other values lead to different results for the two methods.

Orenstein [1416] suggests that the error-bound method generally leads to better query performance than the size-bound method, and this has been confirmed by experiments [242]. Of course, regardless of the method used, there is an inherent conflict in their application because the greater the number of blocks used, the higher the quality of the approximation; yet, this has the undesirable result of increasing the processing cost for a number of queries as there are more blocks associated with each object (but see [668]). Thus, minimizing the number of objects is of interest (e.g., [669, 1417]). Regardless of which method is used, the results are stored in a zkd Btree [1420] (see Section 1.6 in Chapter 1).

Frank and Barrera [628, 630] and Ulrich [1901] take a different approach by retaining the restriction that each object can be covered by just one block. One solution is to expand the size of the space that is spanned by each quadtree block  $b$  of width  $w$  by a factor  $p$  ( $p > 0$ ) so that the expanded block is of width  $(1 + p) \cdot w$ . In this case, an object would be associated with its minimum enclosing expanded quadtree block. It can be shown that the radius of the minimum bounding box for any object  $o$  that is associated with a block  $b$  of width  $w$  (on account of overlapping the horizontal or vertical axes that pass through the center of  $b$  while not lying within the expanded quadtree block of one of  $b$ 's subblocks) must be larger than  $p \cdot w/4$  (see Exercise 2). Otherwise (i.e., if the radius is smaller than  $p \cdot w/4$ ),  $o$  is associated with a smaller block. The terms *cover fieldtree* [628, 630] and *loose quadtree* [1901] are used to describe the resulting structure. We use these terms interchangeably.

Ulrich [1901] advocates setting the block expansion factor  $p$  to 1. He argues that using block expansion factors much smaller than 1 increases the likelihood that the minimum enclosing expanded quadtree block is large and that letting the block expansion factor be much larger than 1 results in the areas spanned by the expanded quadtree blocks being too large, thereby having much overlap. For example, letting  $p = 1$ , Figure 3.26 in Chapter 3 is the loose quadtree corresponding to the collection of objects in Figure 2.57(a) and their MX-CIF quadtree in Figure 2.57(b). In this example, there are only two differences between the loose and MX-CIF quadtrees:

1. Rectangle object E is associated with the SW child of the root of the loose quadtree instead of with the root of the MX-CIF quadtree.
2. Rectangle object B is associated with the NW child of the NE child of the root of the loose quadtree instead of with the NE child of the root of the MX-CIF quadtree.

The loose quadtree and the cover fieldtree are similar to the quadtree medial axis transform (QMAT) [1626] (see Section 2.1.2.4), where the factor  $p$  is bounded by 2 (i.e., it is less than 2) [1624, 1626]. In this case, for a black block  $b$  of width  $w$  in a region quadtree,  $p \cdot w/2$  represents the distance from the border of  $b$  to the nearest point that is on a boundary between a black and a white block in the structure. The QMAT is used as an alternative to the region quadtree representation of an image; it is an attempt to reduce the sensitivity of the storage requirements of the region quadtree to the position of the origin with respect to which it is built. The QMAT can also be used as a representation for a collection of objects, as is done with a loose quadtree and a cover fieldtree.

Frank and Barrera [628, 630] also propose shifting the positions of the centroids of blocks at successive levels of subdivision by half the width of the block that is being subdivided as yet another alternative approach to overcoming the problem of the minimum enclosing quadtree block of  $o$  being much larger than  $o$  (e.g.,  $o$ 's minimum bounding box). Figure 2.58 shows an example of such a subdivision. The result is termed a *partition fieldtree* by Frank and Barrera [628, 630] and is also similar to the overlapping pyramid of Burt, Hong, and Rosenfeld [286].

Figure 2.58  
Example of the subdivision induced by a partition fieldtree.

We can make several observations about the partition fieldtree:

1. The boundaries of the blocks at different levels of decomposition will never coincide.
2. The grids formed by taking the set of blocks at the different levels of decomposition use a different origin for each level (i.e., the origin has been shifted).
3. The blocks at a given level of decomposition  $l$  do not form a refinement of the blocks at the previous level of decomposition  $l - 1$ .

An important property of the partition fieldtree is that the relative size of the minimum enclosing quadtree block for object  $o$  is bounded with respect to the size of the minimum bounding box  $v$  of  $o$ . In particular, objects of the same size can be stored in nodes corresponding to larger blocks of at most three possible sizes, depending on their positions—that is, in the worst case,  $o$  will be stored in a block that is  $2^3$  (i.e., 8) times  $o$ 's size (i.e., maximum width along the axes). In order to see how this worst-case situation can arise, consider a  $32 \times 32$  universe with the origin at the lower-left corner and an object  $O$  slightly wider than unit size along the  $x$  axis and length  $\varepsilon$  ( $0 < \varepsilon < 0.5$ ) along the  $y$  axis—that is,  $O$ 's two opposite corners are at  $(14 - \delta, 16 - \varepsilon)$  and  $(15 + \delta, 16 + \varepsilon)$ . We now show that the minimum enclosing quadtree block for  $O$  is of size  $2^3 \times 2^3$ .  $O$  does not fit in a block of size  $1 \times 1$  due to its being of width  $1 + 2\delta$ . In particular,  $O$  is spanned by the  $1 \times 1$  block  $A$  with corners at  $(13.5, 15.5)$  and  $(14.5, 16.5)$  and the  $1 \times 1$  block  $B$  with corners at  $(14.5, 15.5)$  and  $(15.5, 16.5)$ . These two blocks are spanned by the  $2 \times 2$  block  $C$  with corners at  $(13, 15)$  and  $(15, 17)$  and the  $2 \times 2$  block  $D$  with corners at  $(15, 15)$  and  $(17, 17)$ . These two blocks are spanned by the  $4 \times 4$  block  $E$  with corners at  $(10, 14)$  and  $(14, 18)$  and the  $2 \times 2$  block  $F$  with corners at  $(14, 14)$  and  $(18, 18)$ . These two blocks are spanned by the  $8 \times 8$  block  $G$  with corners at  $(12, 12)$  and  $(20, 20)$ , which is the minimum enclosing quadtree block. Figure 2.59 illustrates this situation.

Note that in the case of the cover fieldtree, we do not in general have a bound on the relative size of  $o$ 's minimum enclosing quadtree block with respect to the size of  $o$ 's minimum bounding box  $v$ . However, when  $p = 1$ , the block in which  $o$  is stored is at

Figure 2.59  
Example illustrating the largest possible minimum enclosing quadtree block in a partition fieldtree. In this case, the block is almost eight times larger than the object, in terms of the block width. The object is embedded in a  $32 \times 32$  universe with the origin at the lower-left corner. The diagonally opposite corners of the object are at  $(14 - \delta, 32 - \varepsilon)$  and  $(15 + \delta, 32 + \varepsilon)$ .

most twice  $o$ 's size (i.e., maximum width). To see how this situation arises, recall that the radius of the minimum bounding box  $v$  for any object  $o$  that is associated with a block  $b$  of width  $w$  (on account of overlapping the horizontal or vertical axes that pass through the center of  $b$  while not lying within the expanded quadtree block of one of  $b$ 's subblocks) must be larger than  $p \cdot w/4$ . The desired factor of 2 is obtained by setting the radius of  $v$  to be  $w/4 + \delta$ , where  $\delta$  is close to 0. Note that as  $p$  approaches 0, the minimum size of the radius of  $v$  (i.e.,  $p \cdot w/4$ ) also decreases. In fact, for  $p = 1/2$ , the ratio of the size is at most 4; for  $p = 1/4$ , the ratio is at most 8. At  $p = 1/8$ , the ratio is at most 16, and we now find that the partition fieldtree yields a tighter fit than the cover fieldtree. Thus,  $p = 1/4$  can be said to be the point at which the partition and cover variants of the fieldtree are approximately equivalent.

At this point, it is appropriate to review the distinction between the cover and partition fieldtrees. In both cases, the goal is to expand the area spanned by the subblocks of a block in order to reduce the size of the minimum enclosing quadtree block  $b$  when an object  $o$  overlaps the axes that pass through the center of  $b$ . In the case of the cover fieldtree, the area spanned by the four subblocks is expanded. In the case of the partition fieldtree, the number of covering subblocks is enlarged by offsetting their positions while retaining their sizes—that is, a set of  $3 \times 3$  blocks of size  $u/2^{i+1} \times u/2^{i+1}$  at level  $i + 1$  spans a block of size  $u/2^i$  at level  $i$  (assuming a universe of width  $u$  and a root at level  $i$ ).

The result in both cases is that the subblocks span an area that overlaps the partition lines, which is something that would not be possible in a conventional quadtree (e.g., the region quadtree, MX-CIF quadtree, or any quadtree where the blocks are disjoint) since the edges of the blocks at successive levels of decomposition must coincide (i.e., they are collinear). Note that this distinction between the fieldtree (both the partition and the cover variants) and the conventional quadtree is always true for the partition fieldtree since it always shifts the positions of the centroids of the blocks at successive levels by one-half of the width of the field. However, this is not necessarily the case for the cover fieldtree when we use particular values of  $p$  such as 1. Nevertheless, there is also some coincidence for other values of  $p$  that are powers of 2 (both positive and negative).

Data structures employing coverage-based splitting have found use in many diverse applications. The MX-CIF quadtree [1009] was originally developed to represent design elements in applications in VLSI design (see Section 3.4.1 in Chapter 3). More recently it has been used to represent spatial objects in a peer-to-peer (P2P) setting [1846, 1847]. The fieldtree [628, 630] was developed to represent spatial objects in geographic information systems; the filter tree [1720] was developed for the same purpose in spatial databases, where it was also used for selectivity estimation [12]. Similarly, the loose quadtree and loose octree were also developed to represent spatial objects but in the context of game programming applications [1901].

### Exercises

1. Why does the size-bound method split the minimum enclosing block in a breadth-first manner instead of a depth-first manner?
2. Show why the radius of the minimum bounding box for any object  $o$  that is associated with a block  $b$  of width  $w$  (on account of overlapping the horizontal or vertical axes that pass through the center of  $b$  while not lying within the expanded quadtree block of one of  $b$ 's subblocks) in a loose quadtree must be larger than  $p \cdot w/4$ . Assume that  $p$  is the factor by which the width of the blocks has been expanded.
3. Ulrich [1901] proposes inserting an object  $o$  into a loose quadtree with  $p = 1$  by determining the depth  $d$  of the tree at which  $o$  belongs (and thus the width of the containing block).  $d$  is obtained by observing that blocks at this depth can accommodate any object whose minimum bounding box has a radius  $r$  that is less than one-quarter of the width  $w$  of the edge of the expanded block at depth  $d$ , regardless of its position. An object whose minimum bounding box has a radius less than or equal to  $w/8$  should be inserted at depth  $d + 1$ . The actual block into which  $o$  is to be inserted is identified by finding the block  $b$  at depth  $d$  that is closest to

the center of  $o$ 's minimum bounding box. Once  $b$  has been determined, we observe that it is possible for a tighter fit on account of the positioning of  $o$  so that it can be contained in one of  $b$ 's subblocks  $s$  in the sense that  $o$  is larger than  $s$  but fits into  $s$ 's expanded block. This is done by checking to see if  $o$  fits in  $b$ 's closest subblock. Can you derive an analogous procedure for arbitrary values of  $p$ ?

### 2.1.4.2 Density-Based Splitting

Density-based splitting is formally specified as stipulating that a block is decomposed whenever it is covered by more than  $T$  ( $T \geq 1$ ) objects (or parts of them).<sup>14</sup> Such a rule is known as a *bucketlike* decomposition rule. The case  $T = 1$  corresponds to halting the decomposition whenever each cell in the block  $b$  is an element of the same object  $o$  or is in no object. In other words, any cell  $c$  in  $b$  is either in  $o$  or in no object. Observe that even for the  $T = 1$  case, the result is different from the block decomposition rule described in Section 2.1.2, which required that either all the cells in  $b$  be elements of the same object or all the cells in  $b$  be in none of the objects.

There are many variants of bucketlike block decomposition rules, depending in part on the nature of the objects being represented. Without loss of generality, in this section, we assume two-dimensional data.<sup>15</sup> In particular, we focus on how to deal with collections of arbitrary polygonal objects, thereby, of course, including rectangles, which are common in applications such as VLSI and CAD. In the case of polygons, the specific variant that is used also depends on whether the polygons themselves are the objects being decomposed, which is the case in this section, or if the decomposition rule is based on the primitive objects that make up the polygon (e.g., its vertices and/or edges), which is the case in the variants described in Section 2.2.2.8.

It is straightforward to formulate bucketlike variants of the different block decomposition rules described in Section 2.1.2. Without loss of generality, in the rest of this section, we assume a quadtree-like regular decomposition rule that decomposes the underlying space into four congruent blocks at each stage (i.e., level) of decomposition. As in Section 2.1.2, the results of successive stages form a containment hierarchy. Again, as in the previous section, once the decomposition process has terminated, the result is a set of disjoint blocks. Of course, other decomposition rules could be used such as those that, among others, do not require the blocks to be congruent at a particular stage and similar at successive stages (e.g., a point quadtree), do not subdivide into just two parts as do the k-d tree and bintree (e.g., an X-Y tree and puzzletree), or do not require that the blocks be axis parallel (e.g., a BSP tree). We do not discuss such decomposition rules in this section (but see Section 2.1.3.1).

The bucketlike decomposition rule described above works well when the polygons are disjoint, and we use the term *bucket polygon quadtree* to describe the result. However, when the polygons are permitted to overlap or are adjacent, problems can arise: there exist polygon configurations for which the decomposition will never halt. In this case, our goal is to prevent as much unnecessary decomposition as possible but, at the same time, to minimize the amount of useful decomposition that is prevented from taking place. Overlapping polygons arise in several defense-analysis problems. For example, trafficability (also known as mobility) polygons are often overlapping [65]. In particular, it is frequently desired to find a path through a set of overlapping (thereby connected) polygons. Overlapping polygons also arise in VLSI and CAD applications, such as building plans. Adjacent polygons are discussed in greater detail a bit later in this section.

---

<sup>14</sup> Notice that the decomposition rule is not one that decomposes a block if it contains more than  $T$  objects. Such a rule may be difficult to satisfy in the sense that there would be very little decomposition after an initial level, as blocks usually contain portions of many objects rather than many objects in their entirety.

<sup>15</sup> Our discussion is also applicable to data of arbitrary dimensionality.

As an example of a block configuration for which the bucket polygon quadtree would require an infinite amount of decomposition, consider the situation when  $Q > T$  polygons in block  $b$  are arranged so that polygon  $p_i$  is *completely contained* in polygon  $p_{i+1}$  for  $1 \leq i < Q$ . Now, let us examine the instant when  $b$  contains  $T$  of the polygons. In this case, upon insertion of the  $(T + 1)$ st polygon, we are better off not even starting to decompose  $b$ , which now has  $T + 1$  polygons, as we can never reach the situation that all the blocks resulting from the decomposition will be part of  $T$  or fewer polygons. For example, assuming  $T = 2$ , the block containing the three polygons in Figure 2.60(a) is not split upon insertion of the third polygon. In this case, the order of inserting the polygons is immaterial.

A decomposition rule that prevents more decomposition than one that halts the decomposition only upon complete containment is one that requires the mutual intersection of all of the polygons in block  $b$ , including the polygon  $p$  being inserted, to be nonempty in order to prevent decomposition (such a quadtree decomposition rule for a collection of rectangle objects is known as an  $RR_1$  quadtree [1722]).<sup>16</sup> The mutual intersection rule is motivated by the desire to be able to deal with the situation in which many edges of the polygons have a common endpoint (e.g., in a polygonal subdivision of the plane where the polygons are adjacent but not overlapping). For example, assuming  $T = 2$ , the polygons in the block in Figure 2.60(b) are mutually intersecting, and thus the block is not split regardless of the order in which the polygons are inserted into it. In fact, the order in which the polygons are inserted is always immaterial when using the mutual intersection rule.

A decomposition rule that prevents even more decomposition than mutual intersection, and the one we suggest using, splits a block  $b$  that contains at least  $T$  polygons before inserting polygon  $p$  if  $p$  does not touch all of the polygons already contained in  $b$ . We say that two polygons  $p_1$  and  $p_2$  *touch* if  $p_1$  and  $p_2$  have at least one point in common (i.e., the polygons may overlap or just touch at their boundaries).<sup>17</sup> For example, assuming  $T = 2$ , inserting polygons 1, 2, and 3 in this order in Figure 2.60(c) avoids splitting the block. On the other hand, inserting the polygons in the order 1, 3, 2 in Figure 2.60(c) results in the block's being split. Thus, we see that the result of using the touching rule may be sensitive to the order in which the polygons are inserted. Notice that the touching rule would also not split the blocks in Figure 2.60(a, b), regardless of the order in which the polygons were inserted. This shows that the order in which the polygons are inserted is not always important for the touching rule.

It is interesting to observe that using a decomposition rule based on touching often prevents useful decompositions from taking place. For example, in Figure 2.60(c) it may be better to decompose the block. This is the case for the  $RR_2$  quadtree [1722] for rectangles, whose adaptation to polygons results in a decomposition of a block  $b$  whenever  $b$  contains more than one distinct chain of connected or touching polygons. Nevertheless, although the mutual intersection rule is really a better decomposition rule than the touching rule in the sense that it allows more useful decomposition to take place, the use of the mutual intersection rule is not suggested because its computation for the general case of polygons of arbitrary shape is expensive.

Perhaps the most common type of collection of polygons is one where all the polygons are adjacent. This is called a *polygonal map* and results in the partition of the underlying image into connected regions. It arises in many cartographic applications, such as maps. For example, a map of the United States is a polygonal map where the polygons correspond to states, and the edges of the polygons correspond to state lines. Similarly, a map of the world is a polygonal map where the polygons correspond to countries, and the edges of the polygons correspond to the borders of countries. Polygonal

Figure 2.60  
Examples of collections of three overlapping polygons and their effect on their containing block B that is not split when using (a) the completely contained decomposition rule or (b) the mutual intersection rule. (c) B is split when using the touching rule if the polygons are inserted in the order 1, 2, 3, but B is not split if the polygons are inserted in the order 1, 3, 2.

<sup>16</sup> The mutual intersection rule is *weaker* than the complete containment rule in the sense that complete containment implies mutual intersection.

<sup>17</sup> The touching rule is weaker than the mutual intersection rule in the sense that mutual intersection implies touching.

maps arise in many applications. For example, they are used for crop coverages, soil types, land usage, and so on. In addition, they are used to represent the projections of elevation models. For example, given a set of elevations such as a Digital Terrain Model (DTM) or a Digital Elevation Model (DEM), we often fit an interpolating surface consisting of triangles on the set, which is called a triangulation. The projection of the triangulation onto the plane is also a polygonal map. Thus, the representation of a polygonal map is an important issue.

In the case of adjacent polygons, use of a bucketlike decomposition rule such as the bucket polygon quadtree can still result in an infinite amount of decomposition. However, the case of an infinite amount of decomposition due to more than  $T$  polygons being contained in each other is not possible as the polygons do not overlap. Nevertheless, infinite decomposition is still possible if the polygonal map has a vertex at which more than  $T$  polygons are incident. An interesting way to overcome this problem is to use a variant of a bucket polygon quadtree, developed originally for line segment objects [1360, 1362], known as the *PMR quadtree* (see also Section 2.2.2.8 for a discussion of its use for line segment objects). It decomposes the block just once if it is a part of more than  $T$  polygons. We term the result a *PMR polygon quadtree*. Such a rule means that the shape of the resulting tree depends on the order in which the polygons are inserted into it.

An alternative solution to that provided by the PMR polygon quadtree is to introduce an additional condition that halts the decomposition whenever the block  $b$  contains a single vertex  $v$  [1541]. The motivation for this rule is the fact that when a block  $b$  contains just one vertex  $v$ , it is often the case that all of the edges in  $b$  meet at  $v$ . Note that this rule does *not* preclude a block  $b$  from containing more than one vertex, provided that  $b$  does not contain more than  $T$  polygons. In fact, this is quite a common occurrence since each polygon consists of at least three vertices! We term the result a *vertex bucket polygon quadtree*.

Once the space has been partitioned into blocks, we need to consider the representations of the polygons that make up each block. There are several possible methods. The first is to leave them alone and just associate with each block a list of the polygons that overlap it. The elements of this list are usually pointers to a polygon table that contains the full geometric description of each polygon (e.g., a list of vertices or edges). Of course, we could also apply a spatial sorting technique to the polygons in each block (e.g., by the locations of their centroids). The second is to decompose them into a collection of convex regions [1541]. This is motivated by the fact that operations on convex polygons are more efficient than operations on general or simple polygons (e.g., point location). In particular, there are two choices for the decomposition into convex regions. The first is to represent each polygon in the block by a union of convex regions, and the second as a difference of convex regions.

Subdivision into a union of convex regions can be achieved easily by methods such as a triangulation. For example, polygon B in Figure 2.61(a) is decomposed into three convex regions (i.e., triangles) in Figure 2.61(b). In fact, optimal convex decompositions can also be achieved by introducing new points (known as *Steiner points*) [337], as well as without new points [751]. The disadvantage of a subdivision into a union of convex regions is that the number of resulting polygons can increase dramatically.

When the polygons are represented as a difference of convex regions, the number of resulting polygons is considerably smaller but still larger than just leaving them alone. This is achieved by using the convex difference tree (CDT) representation for simple polygons [1878]. In this case, a simple polygon is represented as a tree. The root of the tree contains the convex hull<sup>18</sup> of the polygon. There is one child for each connected component of the difference between the original polygon and the convex hull. The children are also convex difference trees, which means that they contain the convex hull

<sup>18</sup> See the definition in footnote 11 in Section 2.1.3.2

of their polygons. Thus, we see that the representation process is recursive, with the decomposition stopping once we get a connected component difference that is convex. As a simple example, the block in Figure 2.61(a) contains two polygons, A and B. Since B is not convex, its CDT is formed by subtracting convex polygon C, as shown in Figure 2.61(c), from the convex hull of B. The two CDTs corresponding to the polygons of the entire block are given in Figure 2.61(d). The broken lines in Figure 2.61(c, d) show the convex hull of B.

The W-like shape in Figure 2.62(a) is a more complicated example of a CDT. The broken lines in Figure 2.62(b) show the various components in the CDT for Figure 2.62(a), while Figure 2.62(c) is the actual tree. In particular, the root of Figure 2.62(c) corresponds to the convex hull of the W-like shape, while its left child corresponds to the convex hull of its upper connected region A, and its right child corresponds to the lower connected region B, which is a triangle and hence is not decomposed further. The left child of the root has one child corresponding to its lower connected component C.

When the polygons in a block are represented by their CDT, it has been suggested [1541] that the block be further subdivided on the basis of whether the total number of nodes in the CDT exceeds the splitting threshold  $T$  of the underlying polygon decomposition rule (i.e., the number of polygons or parts of them that can be covered by a block or a part of the block unless it possibly contains a vertex). Each time a block is decomposed, the CDTs of all polygons in the new subblocks are calculated, and all subblocks for which the total number of CDT nodes exceeds the splitting threshold are recursively subdivided.

Regardless of the value of  $T$  that is used, when all of the polygons meet at a single vertex, the blocks that contain such vertices may be a part of many polygons, thereby possibly complicating algorithms such as point location [1541]. One way to reduce this number and, more importantly, the number of polygons that can be a part of each block is to modify the polygonal map  $m$  by preprocessing it and applying a technique termed *vertex enlargement* to each vertex  $v$  at which more than  $T$  ( $T \geq 3$ ) polygons are incident [1541]. Note that we discuss this technique not so much for its utility, which is unclear, but for the way in which it reduces the complexity of the map in a systematic manner.<sup>19</sup>

The basic operation in vertex enlargement is checking if each of the angles between the edges that meet at  $v$  in clockwise order is less than  $180^\circ$  (i.e., they form what is termed a *convex corner*). If this is the case, then  $v$  is replaced by a new small polygon at which all of these edges are incident (e.g., the polygonal map in Figure 2.63(a) is transformed to Figure 2.63(c) by the removal of vertex V). If this is not the case, then there is one angle that is greater than or equal to  $180^\circ$ , and the new polygon contains  $v$ , but now the degree of  $v$  has been reduced to two (e.g., the polygonal map of Figure 2.63(d) is transformed to that of Figure 2.63(f) by the replacement of the four polygons incident at V with just two polygons). As long as the new vertices of the newly created polygons are sufficiently close to  $v$ , the new edges of the newly created polygons will not cross existing edges, and the result will be a legal polygonal map. This process is described more precisely and formally as follows, assuming that  $v$  has degree  $d$ :

1. For each polygon  $p$  in  $m$  with  $e$  edges such that successive adjacent edges  $e_1$  and  $e_2$  in clockwise order that are incident at  $v$  for which  $e_1$  and  $e_2$  form a convex corner, choose two points  $p_1$  and  $p_2$  on edges  $e_1$  and  $e_2$ , respectively, so that the edge  $f$  between them does not cross any of the existing edges of the polygonal map. Replace  $p$  by a pair of polygons  $p'$  and  $p''$ .  $p'$  contains  $e + 1$  edges and is formed by replacing the portions of the edges between  $p_1$  and  $v$  and  $p_2$  and  $v$  in  $p$  by a new edge  $f$  (e.g., polygon JKCD in Figure 2.63(b)).  $p''$  is a triangle polygon formed by  $f$  and the edges between  $p_1$  and  $v$  and  $p_2$  and  $v$  (e.g., polygon VJK in Figure 2.63(b)).

Figure 2.63 (a–c): Example of vertex enlargement where every pair of successive edges in clockwise order that are adjacent at vertex V form a convex corner: (a) initial polygonal map, (b) intermediate result after adding edges around V, and (c) final result after V has been removed. (d–f): Example of vertex enlargement where every pair of successive edges in clockwise order that are adjacent at vertex V form a convex corner with the exception of edges VE and VB: (d) initial polygonal map, (e) intermediate result after adding edges around V, and (f) final result after all but two of the edges incident at V have been removed.

<sup>19</sup> The rest of this discussion can be skipped on an initial reading.

- For each polygon  $p$  with edges  $e_1$  and  $e_2$  incident at  $v$  such that there does not exist another polygon  $q$  with either edge  $e_1$  or  $e_2$  that does not have a convex corner at  $v$ ; remove edges  $e_1$  and  $e_2$  (e.g., edges VI and VJ in polygon VJK in Figure 2.63(b), whose result is given in Figure 2.63(c), whereas this condition is not satisfied for the same edges and polygon in Figure 2.63(e)).
- If  $v$  is isolated (i.e., it has degree 0), then mark the polygon  $q$  of  $d$  edges in which  $v$  is contained as having an enlarged vertex and remove  $v$  (e.g., vertex V in Figure 2.63(c)). Otherwise,  $v$  is a vertex of just two polygons, one of which, say  $q$ , has  $d + 1$  edges where all pairs of adjacent edges form a convex angle, and both  $v$  and  $q$  are marked as corresponding to an enlarged vertex (e.g., vertex V and polygon VIJKL in Figure 2.63(f)).

### Exercises

- Why do we need to check for angles greater than  $180^\circ$  when checking for vertex enlargement?
- Suppose that you apply vertex enlargement to a polygonal map. What is the minimum value of the maximum degree of any vertex in the resulting map, and how would you achieve this situation?
- Consider a polygonal map. Suppose that you apply vertex enlargement in conjunction with a bucketing decomposition rule that decomposes a block whenever it is a part of more than  $T$  polygons. What is a reasonable value of  $T$ ?
- Suppose that you use a vertex bucket polygon quadtree (i.e., decomposition halts whenever a block is a part of no more than  $T$  polygons or contains just one vertex). Can you guarantee that using such a rule, the decomposition process for  $T = 1$  will always halt? No vertex enlargement has been applied.
- Suppose that you preprocess every polygonal map by applying vertex enlargement to all vertices that have degree greater than  $T$  ( $T \geq 3$ ). Does this mean that we can now dispense with the stipulation that decomposition halts whenever a block contains just one vertex? In other words, does a decomposition rule that stipulates that decomposition halts whenever a block is a part of no more than  $T$  polygons yield the same decomposition as one that also halts the decomposition when the block contains just one vertex?
- Suppose that a polygonal map has been decomposed to form a vertex bucket polygon quadtree. Next, recursively subdivide the block if its CDT contains more than  $T$  nodes. Prove that decomposition of the block based on the number of CDT nodes cannot lead to a reduction in the number of polygons in a node, thereby making it impossible for a situation to arise in which merging should be applied.

## 2.1.5 Hierarchical Interior-Based Representations

Assuming the presence of an access structure, the implicit interior-based representations described in Sections 2.1.1 and 2.1.2 are good for finding the objects associated with a particular location or cell (i.e., query 2), while requiring that all cells be examined when determining the locations associated with a particular object (i.e., the feature query). In contrast, the explicit interior-based representation that we described is good for the feature query, while requiring that all objects be examined when trying to respond to the location query. In this section, we focus on interior-based representations that enable both queries to be answered without possibly having to examine every cell.

This is achieved by imposing containment hierarchies on the representations. The hierarchies differ depending on whether the hierarchy is of space (i.e., the cells in the space in which the objects are found) or of objects. In the former case, we aggregate space into successively larger-sized chunks (i.e., blocks); in the latter, we aggregate objects into successively larger groups (in terms of the number of objects that they contain). The former is applicable to implicit (i.e., image-based) interior-based representations; the latter is applicable to explicit (i.e., object-based) interior-based representations. Thus, we

see again that the distinction is the same as that used in computer graphics to distinguish between algorithms as being image space or object space [622], respectively.

The basic idea is that in image-based representations we propagate objects up the hierarchy, with the occupied space being implicit to the representation. Thus, we retain the property that associated with each cell is an identifier indicating the object of which it is a part. In fact, it is this information that is propagated up the hierarchy so that each element in the hierarchy contains the union of the objects that appear in the elements immediately below it.

On the other hand, in the object-based representations, we propagate the space occupied by the objects up the hierarchy, with the identities of the objects being implicit to the representation. Thus, we retain the property that associated with each object is a set of locations in space corresponding to the cells that make up the object. Actually, since this information may be rather voluminous, it is often the case that an approximation of the space occupied by the object is propagated up the hierarchy rather than the collection of individual cells that are spanned by the object. The approximation is usually the minimum bounding box for the object that is customarily stored with the explicit representation. Therefore, associated with each element in the hierarchy is a bounding box corresponding to the union of the bounding boxes associated with the elements immediately below it.

The use of the bounding box approximation has the drawback that the bounding boxes at a given level in the hierarchy are not necessarily disjoint. This can be overcome by decomposing the bounding boxes so that disjointness holds. The drawback of this solution is that an object may be associated with more than one bounding box, which may result in the object's being reported as satisfying a particular query more than once. For example, suppose that we want to retrieve all the objects that overlap a particular region (i.e., a window query) rather than a point, as is done in the location query.

It is very important to note that the presence of the hierarchy does not mean that the alternative query (i.e., the feature query in the case of a space hierarchy and the location query in the case of an object hierarchy) can be answered immediately. Instead, obtaining the answer usually requires that the hierarchy be descended. The effect is that the order of the execution time needed to obtain the answer is reduced from linear to logarithmic. Of course, this is not always the case. For example, the fact that we are using bounding boxes for the space spanned by the objects, rather than the exact space occupied by them, means that we do not always have a complete answer when reaching the bottom of the hierarchy. In particular, at this point, we may have to resort to a more expensive point-in-polygon test [622].

It is worth repeating that the only reason for imposing the hierarchy is to facilitate responding to the alternative query (i.e., the feature query in the case of a space hierarchy on the implicit representation and the location query in the case of an object hierarchy on the explicit representation). Thus, the base representation of the hierarchy is still usually used to answer the original query because, often, when using the hierarchy, the inherently logarithmic overhead incurred by the need to descend the hierarchy may be too expensive (e.g., when using the implicit representation with the array access structure to respond to the location query). Of course, other considerations, such as space requirements, may cause us to modify the base representation of the hierarchy, with the result that it will take longer to respond to the original query (e.g., the use of a treelike access structure with an implicit representation). Nevertheless, as a general rule, in the case of the space hierarchy, we use the implicit representation (which is the basis of this hierarchy) to answer the location query; in the case of the object hierarchy, we use the explicit representation (which is the basis of this hierarchy) to answer the feature query.

The rest of this section is organized as follows. We first show in Section 2.1.5.1 how to modify the implicit interior-based representations that are image based, and then, in Section 2.1.5.2, we address the explicit interior-based representations that are object-based. We conclude in Section 2.1.5.3 with a discussion of some disjoint object-based methods.

### 2.1.5.1 Image-Based Hierarchical Interior-Based Representations (Pyramids)

Our goal here is to be able to take an object  $o$  as input and return the cells that it occupies (the feature query) when using a representation that stores with each cell the identities of the objects of which it is a part. The most natural hierarchy that can be imposed on the cells to enable us to answer this query is one that aggregates every  $q$  cells, regardless of the values associated with them, into larger congruent blocks (unlike the aggregation of identically valued cells into multidimensional blocks, as in the region quadtree). This process is repeated recursively so that groups of  $q$  blocks are repeatedly aggregated into one block until there is just one block left. The value associated with the block  $b$  is the union of the names (i.e., object identifiers) of the objects associated with the cells or blocks that make up block  $b$ . The identities of the cells and blocks that are aggregated depends, in part, on how the collection of the cells is represented. For example, assuming a two-dimensional space, if the cells are represented as one long list consisting of the cells of the first row, followed by those of the second row, and so on, then one possible aggregation combines every successive  $q$  cells. In this case, the blocks are really one-dimensional entities.

The process that we have just outlined is described more formally below. We make the following assumptions:

- The blocks are rectangular with sides parallel to the coordinate axes.
- Each block contains  $q$  cells or  $q$  blocks so that, assuming  $d$  dimensions,  $q = \prod_{j=1}^d r_j$ , where the block has width  $r_j$  for dimension  $j$  ( $1 \leq j \leq d$ ), measured in cells or blocks, depending on the level in the hierarchy at which the block is found.
- All blocks at a particular level in the hierarchy are congruent, with the different levels forming a containment hierarchy.
- There are  $S$  cells in the underlying space, and let  $n$  be the smallest power of  $q$  such that  $q^n \geq S$ .
- The underlying space can be enlarged by adding  $L$  empty cells so that  $q^n = S + L$  and that each side of the underlying space along dimension  $j$  is of width  $r_j^n$ .

The hierarchy consists of the set of sets  $\{C_i\}$  ( $0 \leq i \leq n$ ), where  $C_n$  corresponds to the original collection of cells having  $S + L$  elements,  $C_{n-1}$  contains  $(S + L)/q$  elements corresponding to the result of the initial aggregation of  $q$  cells into  $(S + L)/q$  congruent blocks, and  $C_0$  is a set consisting of just one element corresponding to a block of size  $S + L$ . Each element  $e$  of  $C_i$  ( $0 \leq i \leq n - 1$ ) is a congruent block whose value is the union of the values (i.e., sets of object identifiers) associated with the blocks of the  $q$  elements of  $C_{i+1}$ . The value of each element of  $C_n$  is the set of object identifiers corresponding to the objects of which its cell is a part.

The resulting hierarchy is known as a *cell pyramid* [1845]<sup>20</sup> and is frequently characterized as a *multiresolution representation* since the original collection of objects is described at several levels of detail by using cells that have different sizes, although they are similar in shape. It is important to distinguish the cell pyramid from the region quadtree, which, as we recall, is an example of an aggregation into square blocks where the basis of the aggregation is that the cells have identical values (i.e., are associated with the same object, or objects if object overlap is permitted). The region quadtree is an instance of what is termed a *variable-resolution representation*, which, of course, is not limited to blocks that are square. In particular, it can be used with a limited number of nonrectangular shapes (most notably, triangles in two dimensions [157, 1637]).

---

<sup>20</sup> Actually, the qualifier *cell* is rarely used. However, we use it here to avoid confusion with other variants of the pyramid that are based on a hierarchy of objects rather than cells, as discussed in Section 2.1.5.2.

It is quite difficult to use the cell pyramid, in the form that we have described, to respond to the feature query and to the complete location query (i.e., to obtain all of the contiguous cells that make up the object associated with the query location) due to the absence of an access structure. This can be remedied by implementing a set of arrays  $A_i$  in a one-to-one correspondence to  $C_i$  ( $0 \leq i \leq n$ ), where  $A_i$  is a  $d$ -dimensional array of side length  $r_j^i$  for dimension  $j$  ( $1 \leq j \leq d$ ). Each of the elements of  $A_i$  corresponds to a  $d$ -dimensional block of side length  $r_j^{n-i}$  for dimension  $j$  ( $1 \leq j \leq d$ ), assuming a total underlying space of side length  $r_j^n$ . The result is a stack of arrays  $A_i$ , termed an *array pyramid*, which serves as an access structure to collections  $C_i$  ( $0 \leq i \leq n$ ). The array pyramid is an instance of an implicit interior-based representation consisting of array access structures. Of course, other representations are possible through the use of alternative access structures (e.g., different types of trees).

We illustrate the array pyramid for two dimensions with  $r_1 = 2$  and  $r_2 = 2$ . Assume that the space in which the original collection of cells is found is of size  $2^n \times 2^n$ . Let  $C_n$  correspond to the original collection of cells. The hierarchy of arrays consists of the sequence  $A_i$  ( $0 \leq i \leq n$ ) so that elements of  $A_i$  access the corresponding elements in  $C_i$ . We obtain  $C_{n-1}$  by forming an array of size  $2^{n-1} \times 2^{n-1}$  with  $2^{2n-2}$  elements so that each element  $e$  in  $C_{n-1}$  corresponds to a  $2 \times 2$  square consisting of four elements (i.e., cells) in  $C_n$  and has a value consisting of the union of the names (i.e., labels) of the objects that are associated with these four cells. This process is applied recursively to form  $C_i$  ( $0 \leq i \leq n-1$ ), where  $C_0$  is a collection consisting of just one element whose value is the set of names of all the objects associated with at least one cell. The arrays are assumed to be stored in memory using sequential allocation with conventional orderings (e.g., lexicographically) and are accessed by use of the  $d$ -dimensional coordinate values of the cells. For example, Figure 2.64 is the array pyramid for the collection of objects in Figure 2.1.

Using the array pyramid, it is very easy to respond to the feature query: we just examine the relevant parts of the stack of arrays. For example, suppose that we want to determine the locations that make up object  $o$ , and we use the array pyramid consisting of arrays  $A_i$  ( $0 \leq i \leq n$ ) in a two-dimensional space of size  $2^n \times 2^n$  where the blocks are squares of side length  $2^{n-i}$ . We start with  $A_0$ , which consists of just one element  $e$ , and determine if  $o$  is a member of the set of values associated with  $e$ . If it is not, then we exit, and the answer is negative. If it is, then we examine the four elements in  $A_1$  that correspond to  $e$  and repeat the test. At this point, we know that  $o$  is a member of at least one of them as otherwise  $o$  could not have been a member of the set of values associated with element  $e$  of  $A_0$ . This process is applied recursively to elements of  $A_j$  that contained  $o$  (i.e., the appropriate elements of  $A_{j+1}$  are examined for  $1 \leq j \leq n-1$ ) until we encounter  $A_n$ , at which time the process stops. The advantage of this method is that elements of  $A_{j+1}$  are not examined unless object  $o$  is guaranteed to be a member of the set of values associated with at least one of them.

The array pyramid uses a sequence of arrays as an access structure. An alternative implementation is one that imposes an access structure in the form of a tree  $T$  on the elements of the hierarchy  $\{C_i\}$ . One possible implementation is a tree of fanout  $q$  where the root  $T_0$  corresponds to  $C_0$ , nodes  $\{T_{ij}\}$  at depth  $i$  correspond to  $C_i$  ( $1 \leq i \leq n-1$ ), and the leaf nodes  $\{T_{nj}\}$  correspond to  $C_n$ . In particular, element  $t$  in the tree at depth  $j$  corresponds to element  $e$  of  $C_j$  ( $0 \leq j \leq n-1$ ), and  $t$  contains  $q$  pointers to its  $q$  children in  $T_{j+1}$  corresponding to the elements of  $C_{j+1}$  that are contained in  $e$ . The result is termed a *cell-tree pyramid*. Figure 2.65 shows the cell-tree pyramid corresponding to the collection of objects and cells in the array in Figure 2.7. This example makes use of two-dimensional data with  $r_1 = 2$  and  $r_2 = 2$ . In this case, notice the similarity between the cell-tree pyramid and the region quadtree implementation that uses an access structure that is a tree with a fanout of 4 (Figure 2.18).

Using the term *quadtree* in its most general sense (i.e.,  $d$ -dimensional blocks whose sides need not be powers of 2 or of the same length), the cell-tree pyramid can be viewed as a complete quadtree (i.e., where no aggregation takes place at the deepest level or,

Figure 2.64  
Array pyramid for the collection of objects and cells in Figure 2.1: (a) array  $A_2$ , (b) array  $A_1$ , and (c) array  $A_0$ . The block decomposition in Figure 2.1 corresponds to Array  $A_3$ .

equivalently, all leaf nodes are at the maximum depth of the tree). Nevertheless, there are some very important differences. The first difference, as we pointed out earlier, is that the quadtree is a variable-resolution representation, and the cell-tree pyramid is a multiresolution representation. The second, and most important, difference is that, in the case of the quadtree, the nonleaf nodes serve only as an access structure. They do not include any information about the objects present in the nodes and cells below them. This is why the quadtree, like the array, is not useful for answering the feature query. Of course, we could also devise a variant of the quadtree (termed a *truncated-tree pyramid* [1638]) that uses the nonleaf nodes to store information about the objects present in the cells and nodes below them (e.g., Figure 2.66). Note that both the cell-tree pyramid and the truncated-tree pyramid are instances of an implicit interior-based representation with a tree access structure.

Our definition of the pyramid was made in a bottom-up manner in the sense that we started with a block size and an underlying space size. Next, we expanded the size of the underlying space so that a containment hierarchy of congruent blocks at each level and similar blocks at different levels could be formed. We can also define a variant of the

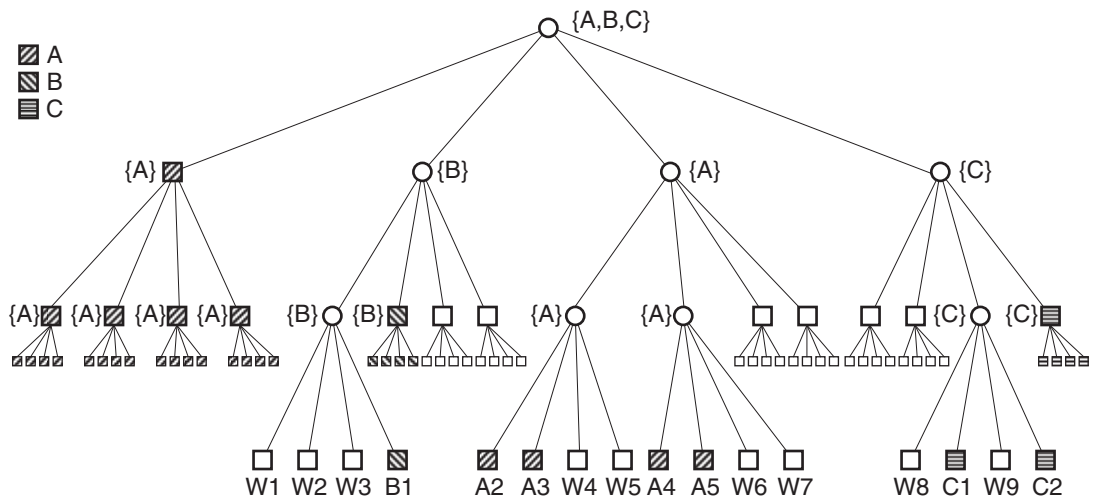

Figure 2.65  
Cell-tree pyramid for the collection of objects and cells in Figure 2.1.

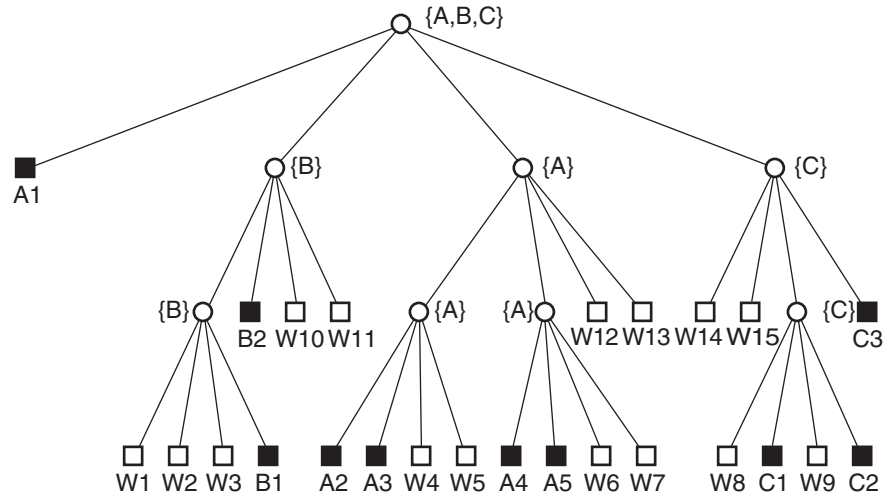

Figure 2.66  
Truncated-tree pyramid for the collection of objects and cells in Figure 2.1.

pyramid where the requirements of block congruence at each level and block similarity at different levels are relaxed. This is a bit easier if we define the pyramid in a top-down manner as we can calculate the number of cells by which the underlying space needs to be expanded as the block sizes at the different levels are defined. It should be clear that the congruence requirement is more restrictive than the similarity requirement. If we relax the requirement that the blocks at different levels be similar, but retain the requirement that the blocks at each level be congruent, then we must store at each level  $i$  the size of the block  $q_i$  (i.e., the values of the individual components  $r_{ij}$  of  $q_i = \prod_{j=1}^d r_{ij}$  for dimension  $j$  ( $1 \leq j \leq d$ )).

If we relax both the requirement that the blocks at the different levels be similar and the requirement that the blocks at each level be congruent, while still requiring that they form a containment hierarchy, then we are, in effect, permitting partitioning hyperplanes (i.e., lines in two dimensions) at arbitrary positions. In this case, we get a more general pyramid if we use a top-down definition as we can now have a different partition at each level. In this case, we have an irregular grid at each level, and thus we must store the positions of the partitioning hyperplanes (i.e., lines in two dimensions) at each level. We call the result an *irregular grid pyramid*. If the irregular grid is implemented with an array access structure, then the result is called an *irregular grid array pyramid*.

Other pyramid variants are also possible. For example, the *Dynamically Quantized Pyramid* (DQP) [1425, 1777] is a two-dimensional containment hierarchy where the blocks at the different levels are neither similar nor congruent. It differs from the irregular pyramid in that there is a possibly different  $2 \times 2$  grid partition at each block at each level rather than one grid partition at each level. Figure 1.46 in Section 1.5.1.4 of Chapter 1 is an example of a DQP for  $n = 3$ . Notice the close similarity to a complete point quadtree [614]. The DQP finds use in cluster detection, as well as multidimensional histogramming. Of course, even more general variants are possible. In particular, we could use any one of the other recursive and nonrecursive decompositions described in Section 2.1.2 at each block with the appropriate access structure.

It is interesting to observe that the interior-based representations discussed in Section 2.1.3 that permit both the blocks and the objects to be arbitrary polyhedra (i.e.,  $d$ -dimensional objects whose  $(d - 1)$ -dimensional faces are hyperplanes), while still not permitting them to intersect and not permitting an object to overlap only a part of a block, can also be used as the basis of an image hierarchy. In particular, the BSP tree, K-structure, and layered dag are hierarchies of blocks, triangles, and “above-and-below” partitions, respectively. They are designed to facilitate responses to the location query (i.e., determining the object associated with a particular location in space). If with each nonleaf node we store the identities of the objects spanned by the underlying regions, then the feature query (i.e., determining the locations associated with a particular object) is very easy to answer. In fact, these structures are variants of the cell-tree pyramid, albeit with a very irregular decomposition of the underlying space.

### Exercises

In Exercises 1–11, assume the use of an array pyramid over a  $2^n \times 2^n$  space to store an object.

1. What is the maximum number of pyramid elements that must be examined in order to answer the feature query, assuming that only one object is stored in the pyramid?
2. Define the efficiency of the pyramid,  $E_p$ , to be the ratio of the maximum number of pyramid elements examined to the total number of cells in the space (i.e., the number of elements at the deepest level of the pyramid).  $E_p$  indicates the advantage of using the array pyramid hierarchy when answering the feature query with an implicit representation over the cost that would be incurred had we not used a hierarchy and, thereby, examined every cell. Define the overhead of the pyramid,  $O_p$ , to be the ratio of the maximum number of pyramid elements examined to the total number of cells in the space that satisfy the query (i.e., are associated with the object whose constituent cells the feature query is seeking).  $O_p$  indicates the overhead incurred in using the array pyramid hierarchy when answering the feature query with an

implicit representation instead of using an explicit representation. Compute  $E_p$  and  $O_p$  for an object that occupies just one cell.

3. Compute  $E_p$  and  $O_p$  for an object that occupies the entire space (i.e.,  $2^n \times 2^n$  cells).
4. Compute  $E_p$  and  $O_p$  for a linelike object that is one cell wide, is horizontal, and spans the entire space.
5. Compute  $E_p$  and  $O_p$  for a linelike object that is one cell wide and is diagonal so that one end is in the upper-left corner of the space while the other end is in the lower-right corner of the space.
6. Compute the worst-case  $E_p$  and  $O_p$  for an object that occupies a square of size  $2 \times 2$  cells.
7. Compute average  $E_p$  and  $O_p$  values over all the possible positions of the  $2 \times 2$  square.
8. Compute the worst-case  $E_p$  and  $O_p$  for an object that occupies a square of size  $2^i \times 2^i$  cells ( $1 \leq i \leq n - 1$ ).
9. Compute an average  $E_p$  and  $O_p$  for an object that occupies a square of size  $2^i \times 2^i$  cells ( $1 \leq i \leq n - 1$ ).
10. Compute the average worst-case  $E_p$  and  $O_p$  over all values of  $i$  ( $1 \leq i \leq n - 1$ ) for an object that occupies a square of size  $2^i \times 2^i$  cells.
11. Compute the average  $E_p$  and  $O_p$  over all values of  $i$  ( $1 \leq i \leq n - 1$ ) for an object that occupies a square of size  $2^i \times 2^i$  cells.
12. Compute the average worst-case  $E_p$  and  $O_p$  over all values of  $i$  ( $1 \leq i \leq n - 1$ ) for an object that occupies a block of side length  $2^i$  in a  $d$ -dimensional space.
13. Compute the average  $E_p$  and  $O_p$  over all values of  $i$  ( $1 \leq i \leq n - 1$ ) for an object that occupies a block of side length  $2^i$  in a  $d$ -dimensional space.

### 2.1.5.2 Object-Based Hierarchical Interior-Based Representations (R-trees, Bounding Box Hierarchies)

Our goal here is to be able to take a location  $a$  as input and return the objects in which  $a$  is a member (the location query) when using a representation that stores with each object the addresses of the cells it comprises (i.e., an explicit representation). The most natural hierarchy that can be imposed on the objects that would enable us to answer this query is one that aggregates every  $M$  objects (that are hopefully in close spatial proximity, although this is not a requirement) into larger objects. This process is repeated recursively until there is just one aggregated object left. Since the objects may have different sizes and shapes, it is not easy to compute and represent the aggregate object. Moreover, it is similarly difficult to test each one of them (and their aggregates) to determine if they contain  $a$  since each one may require a different test by virtue of the different shapes. Thus, it is useful to use a common aggregate shape and point inclusion test to prune the search.

The common aggregate shape and point inclusion test that we use assumes the existence of a minimum enclosing box (termed a *bounding box*) for each object. This bounding box is part of the data associated with each object and aggregate of objects. In this case, we reformulate our object hierarchy in terms of bounding boxes. In particular, we aggregate the bounding boxes of every  $M$  objects into a box (i.e., block) of minimum size that contains them. This process is repeated recursively until there is just one block left. The value associated with the bounding box  $b$  is its location (e.g., the coordinate values of its diagonally opposite corners for two-dimensional data). It should be clear that the bounding boxes serve as a filter to prune the search for an object that contains  $a$ .

In this section, we expand on hierarchies of objects that actually aggregate the bounding boxes of the objects. Section 2.1.5.2.1 gives an overview of object hierarchies and introduces the general concepts of an object pyramid and an object-tree pyramid, which provides a tree access structure for the object pyramid. Sections 2.1.5.2.2 to 2.1.5.2.4

present several aggregation methods. In particular, Section 2.1.5.2.2 discusses ordering-based aggregation methods. Section 2.1.5.2.3 discusses extent-based aggregation techniques, which result in the R-tree representation, and Section 2.1.5.2.4 describes the R\*-tree, which is the best of the extent-based aggregation methods. Next, we discuss methods of updating or loading an object-tree pyramid with a large number of objects at once, termed *bulk insertion* (Section 2.1.5.2.5) and *bulk loading* (Section 2.1.5.2.6), respectively. Section 2.1.5.2.7 concludes the presentation by reviewing some of the shortcomings of the object-tree pyramid and discussing some of the solutions that have been proposed to overcome them. For a comparative look at these different aggregation methods, see the VASCO (Visualization and Animation of Spatial Constructs and Operations) [243, 244, 245, 246] set of JAVA applets found at <http://www.cs.umd.edu/~hjs/quadtrees/index.html>. The VASCO system also includes many other indexing techniques for points, lines, rectangles, and regions that are based on space decomposition (see also the SP-GiST system [70] described in Section 1.9 of Chapter 1), Other libraries that are based on object hierarchies include GiST [817] and XXL (Extensible and Flexible Library) [193].

Most of the research on the use of object hierarchies has been in the context of a sequential environment, and this is the focus of this section. Nevertheless, there has been some work in a parallel environment. In particular, Hoel and Samet [860, 865, 862, 861, 867, 869] discuss data-parallel algorithms for a number of spatial operations for R-trees. Note that this work involves the use of a large number of processors and should be contrasted with the work on “parallel R-trees” of Kamel and Faloutsos [982], where the parallelism involves issues in the distribution of R-tree data to multiple disks rather than multiple execution paths. There has also been some interest of late in issues arising from the implementation of R-trees in a peer-to-peer (P2P) setting (e.g., [1307]). These constructs are beyond the scope of this book and will not be discussed further.

### 2.1.5.2.1 Overview

The nature of the aggregation (i.e., using bounding boxes), the number of objects that are being aggregated at each step (as well as whether this number can be varied), and, most importantly, the decision as to which objects to aggregate are quite arbitrary although an appropriate choice can make the search process much more efficient. The decision as to which objects to aggregate assumes that we have a choice in the matter. It could be that the objects have to be aggregated in the order in which they are encountered. This could lead to poor search performance when the objects are not encountered in an order that correlates with spatial proximity. Of course, this is not an issue as long as we just have less than or equal to  $M$  objects.

It should be clear that the issue of choice only arises if we know the identities of all the objects before starting the aggregation process (unless we are permitted to rebuild the hierarchy each time we encounter a new object or delete an object) and if we are permitted to reorder them so that objects in aggregate  $i$  need not necessarily have been encountered prior to the objects in aggregate  $i + 1$ , and vice versa. This is not always the case (i.e., a dynamic versus a static database), although, for the moment, we do assume that we know the identities of all of the objects before starting the aggregation and that we may aggregate any object with any other object. Observe also that the bounding boxes in the hierarchy are not necessarily disjoint. In fact, the objects may be configured in space in such a way that no disjoint hierarchy is possible. By the same reasoning, the objects themselves need not be disjoint.

The process that we have just outlined can be described more formally as follows. Assume that there are  $N$  objects in the space, and let  $n$  be the smallest power of  $M$  such that  $M^n \geq N$ . Assume that all aggregates contain  $M$  elements with the exception of the last one at each level, which may contain less than  $M$  as  $M^n$  is not necessarily equal to  $N$ . The hierarchy of objects consists of the set  $D$  of sets  $\{D_i\}$  ( $0 \leq i \leq n$ ), where  $D_n$  corresponds to the set of bounding boxes of the individual objects;  $D_{n-1}$  corresponds to

the result of the initial aggregation of the bounding boxes into  $N/M$  bounding boxes, each of which contains  $M$  bounding boxes of objects; and  $D_0$  is a set containing just one element corresponding to the aggregations of all of the objects and is a bounding box that encloses all of the objects. We term the resulting hierarchy an *object pyramid*. Once again, we have a *multiresolution representation* as the original collection of objects is described at several levels of detail by virtue of the number of objects whose bounding boxes are grouped at each level. This is in contrast with the cell pyramid, where the different levels of detail are distinguished by the sizes of the cells that make up the elements at each level.

Searching an object pyramid consisting of sets  $D_i$  ( $0 \leq i \leq n$ ) for the object containing a particular location  $a$  (i.e., the location query) proceeds as follows. We start with  $D_0$ , which consists of just one bounding box  $b$  and determine if  $a$  is inside  $b$ . If it is not, then we exit, and the answer is negative. If it is, then we examine the  $M$  elements in  $D_1$  that are covered by  $b$  and repeat the test using their bounding boxes. Note that unlike the cell pyramid, at this point,  $a$  is not necessarily included in the  $M$  bounding boxes in  $D_1$  as these  $M$  bounding boxes are not required to cover the entire space spanned by  $b$ . In particular, we exit if  $a$  is not covered by at least one of the bounding boxes at this level. This process is applied recursively to all elements of  $D_j$  for  $0 \leq j \leq n$  until all elements of  $D_n$  have been processed, at which time the process stops. The advantage of this method is that elements of  $D_j$  ( $1 \leq j \leq n$ ) are not examined unless  $a$  is guaranteed to be covered by at least one of the elements of  $D_{j-1}$ .

The bounding boxes serve to distinguish between occupied and unoccupied space, thereby indicating whether the search for the objects that contain a particular location (i.e., the location query) should proceed further. At a first glance, it would appear that the object pyramid is rather inefficient for responding to the location query because, in the worst case, all of the bounding boxes at all levels must be examined. However, the maximum number of bounding boxes in the object pyramid, and hence the maximum number that will have to be inspected, is  $\sum_{j=0}^n M^j \leq 2N$ .

Of course, we may also have to examine the actual sets of locations associated with each object when the bounding box does not result in any of the objects being pruned from further consideration since the objects are not necessarily rectangular in shape (i.e., boxes). Thus, using the hierarchy provided by the object pyramid results in at most an additional factor of 2 in terms of the number of bounding box tests while possibly saving many more tests. Therefore, the maximum amount of work to answer the location query with the hierarchy is of the same order of magnitude as that which would have been needed had the hierarchy not been introduced.

As we can see, the way in which we introduced the hierarchy to form the object pyramid did not necessarily enable us to make more efficient use of the explicit interior-based representation to respond to the location query. The problem was that once we determined that location  $a$  was covered by one of the bounding boxes, say  $b$ , in  $D_j$  ( $0 \leq j \leq n-1$ ), we had no way to access the bounding boxes making up  $b$  without examining all of the bounding boxes in  $D_{j+1}$ . This is easy to rectify by imposing an access structure in the form of a tree  $T$  on the elements of the hierarchy  $D$ . One possible implementation is a tree of fanout  $M$ , where the root  $T_0$  corresponds to the bounding box in  $D_0$ .  $T_0$  has  $M$  links to its  $M$  children  $\{T_{1k}\}$ , which correspond to the  $M$  bounding boxes in  $D_1$  that  $D_0$  comprises. The set of nodes  $\{T_{ik}\}$  at depth  $i$  correspond to the bounding boxes in  $D_i$  ( $0 \leq i \leq n$ ), while the set of leaf nodes  $\{T_{nk}\}$  correspond to  $D_n$ . In particular, node  $t$  in the tree at depth  $j$  corresponds to bounding box  $b$  in  $D_j$  ( $0 \leq j \leq n-1$ ), and  $t$  contains  $M$  pointers to its  $M$  children in  $T_{j+1}$  corresponding to the bounding boxes in  $D_{j+1}$  that are contained in  $b$ . We use the term *object-tree pyramid* to describe this structure.

Figure 2.67 gives the specifications for the example object-tree pyramid shown in Figure 2.68(a) for a collection of nine rectangle objects with  $M=3$  (and thus  $n=2$ ). The rectangles are assumed to be embedded in a  $2^6 \times 2^6$  grid with an origin in

Figure 2.67 Specifications for a collection of rectangles embedded in a  $2^6 \times 2^6$  grid with an origin in the lower-left corner. The centroid values are truncated in order to be integers. The Peano-Hilbert order entry is based on coordinate values  $x_{\text{centroid}}$  and  $y_{\text{centroid}}$ .

Figure 2.68 (a) Object-tree pyramid for a collection of rectangle objects whose specifications are given in Figure 2.67 with  $M=3$ , and (b) the spatial extents of the objects and the bounding boxes of the nodes in (a). Notice that the leaf nodes in the index also store bounding boxes, although this is shown only for the nonleaf nodes.

the lower-left corner. Figure 2.68(b) shows the spatial extents of the objects and the bounding boxes of the nodes in Figure 2.68(a), with broken lines denoting the bounding boxes corresponding to the leaf nodes. Note that the object-tree pyramid is not unique. Its structure depends heavily on the order in which the individual objects and their corresponding bounding boxes are aggregated.

The object-tree pyramid that we have just described still has a worst case where we may have to examine all of the bounding boxes in  $D_j$  ( $1 \leq j \leq n$ ) when executing the location query or its variants (e.g., a window query). This is the case if query location  $a$  is contained in every bounding box in  $D_{j-1}$ . Such a situation, although rare, can arise in practice because  $a$  may be included in the bounding boxes of many objects (termed a *false hit*) as the bounding boxes are not disjoint, while  $a$  is contained in a much smaller number of objects. Equivalently, false hits are caused by the fact that a spatial object may be spatially contained in full or in part in several bounding boxes or nodes while being associated with just one node or bounding box.

However, unlike the object pyramid, the object-tree pyramid does guarantee that only the bounding boxes that contain  $a$ , and no others, will be examined. Thus, we have not improved on the worst case of the object pyramid although we have reduced its likelihood, because we may still have to examine  $2N$  bounding boxes. It is interesting to observe that the object pyramid and the object-tree pyramid are instances of an explicit interior-based representation since it is still the case that associated with each object  $o$  is a set containing the addresses of the cells that it comprises. Note also that the access structure facilitates only the determination of the object associated with a particular cell and not which cells are contiguous. Thus, the object-tree pyramid is not an instance of an implicit interior-based representation.

The decision as to which objects to aggregate is an important factor in the efficiency of the object-tree pyramid in responding to the location query. The efficiency of the object-tree pyramid for search operations depends on its abilities to distinguish between occupied space and unoccupied space and to prevent a node from being examined needlessly due to a false overlap with other nodes.

The extent to which these efficiencies are realized is a direct result of how well our aggregation policy is able to satisfy the following two goals. The first goal is to minimize the number of aggregated nodes that must be visited by the search. This goal is accomplished by minimizing the area common to sibling aggregated nodes (termed *overlap*). The second goal is to reduce the likelihood that sibling aggregated nodes are visited by the search. This is accomplished by minimizing the total area spanned by the bounding boxes of the sibling aggregated nodes (termed *coverage*). A related goal to that of minimizing the coverage is minimizing the area in sibling aggregated nodes that is not spanned by the bounding boxes of any of the children of the sibling aggregated nodes (termed *dead area*). Note that this definition of dead area is slightly different from one that minimizes the part of the area that is spanned by the bounding box of any aggregated node that is not spanned by the bounding boxes of any of its children as it ignores the area that is spanned by the bounding boxes of children of siblings of the aggregated nodes. Dead area is usually decreased by minimizing coverage, and thus minimizing dead area is often not taken into account explicitly. Another way of interpreting these goals is that they are designed to ensure that objects that are spatially close to each other are stored in the same node. Of course, at times, these goals may be contradictory.

Figure 2.69  
(a) Four bounding boxes and the aggregations that would be induced (b) by minimizing the total area (i.e., coverage) of the covering bounding boxes of the two nodes and (c) by minimizing the area common (i.e., overlap) to the covering bounding boxes of the two nodes. The dead area for the two possible aggregations is shaded. Note that the dead area for one covering node may be part of the objects in another aggregated node, as in (b).

For example, consider the four bounding boxes in Figure 2.69(a). The first goal is satisfied by the aggregation in Figure 2.69(c); the second goal is satisfied by the aggregation in Figure 2.69(b). The dead area is shown shaded in Figure 2.69(b, c). Note that the dead area in Figure 2.69(b) is considerably smaller than the dead area in Figure 2.69(c) on account of the smaller amount of coverage in the children in Figure 2.69(b). Also observe that the dead area for the bounding box of one aggregated node may be part of the objects in another aggregated node, as seen in Figure 2.69(b).

These goals could be satisfied by using trial-and-error methods that examine all possible aggregations and choosing the one that yields the minimum amount of overlap or coverage among the constituent bounding boxes of the nodes, as well as among the nodes at a given level (e.g., Exercise 2 in Section 2.1.5.2.2). The cost is clearly prohibitive. These trial-and-error methods can be made more intelligent by use of iterative optimization [698] (see Exercise 3 in Section 2.1.5.2.2). However, the cost is still too high.

The aggregation techniques described above take the space (i.e., volume) occupied by (termed the *extent of*) the bounding boxes of the individual spatial objects into account. They are described in Sections 2.1.5.2.3 and 2.1.5.2.4. An alternative is to order the objects prior to performing the aggregation. However, in this case, the only choice that we may possibly have with respect to the identities of the objects that are aggregated is when the number of objects (or bounding boxes) being aggregated at each step is permitted to vary. The most obvious order, although it is not particularly interesting or

useful, is one that preserves the order in which the objects were initially encountered (i.e., objects in aggregate  $i$  have been encountered before those in aggregate  $i + 1$ ). The more common orders are based on proximity or on the values of a small set of parameters describing a common property that is hopefully related to the proximity (and, to a lesser degree, to the shape and extent) of the objects or their bounding boxes in one or all of the dimensions of the space in which they lie [983, 1303, 1588]. Ordering-based aggregation techniques are discussed in Section 2.1.5.2.2.

*Exercise*

1. Given a set of  $M$  rectangles, devise an algorithm to compute their minimum bounding box (i.e., rectangle). What is the execution time of the algorithm?

**2.1.5.2.2 Ordering-Based Aggregation Techniques**

The most frequently used ordering technique is based on mapping the bounding boxes of the objects to a representative point in a lower-, the same, or a higher-dimensional space and then applying one of the space-ordering methods described in Section 2.1.1.2 and shown in Figure 2.5 (see Exercise 23 in Section 2.1.5.2.4). We use the term *object number* to refer to the result of the application of space ordering.<sup>21</sup> For example, two-dimensional rectangle objects can be transformed into one of the following representative points (e.g., [1637]):

1. The centroid
2. The centroid and the horizontal and vertical extents (i.e., the horizontal and vertical distances from the centroid to the relevant sides)
3. The  $x$  and  $y$  coordinate values of the two diagonally opposite corners of the rectangle (e.g., the upper-left and lower-right corners)
4. The  $x$  and  $y$  coordinate values of the lower-right corner of the rectangle and its height and width.

For example, consider the collection of 22 rectangle objects given in Figure 2.70, where the numbers associated with the rectangles denote the relative times at which they were created. Figure 2.71 shows the result of applying a Morton order (Figure 2.71(a)) and Peano-Hilbert order (Figure 2.71(b)) to the collection of rectangle objects in Figure 2.70 using their centroids as the representative points.

Once the  $N$  objects have been ordered, the hierarchy  $D$  is built in the order  $D_n, D_{n-1}, \dots, D_1, D_0$ , where  $n$  is the smallest power of  $M$  such that  $M^n \geq N$ .  $D_n$  consists of the set of original objects and their bounding boxes. There are two ways of grouping the items to form the hierarchy  $D$ : one-dimensional and multidimensional grouping.

In the one-dimensional grouping method,  $D_{n-1}$  is formed as follows. The first  $M$  objects and their corresponding bounding boxes form the first aggregate, the second  $M$  objects and their corresponding bounding boxes form the second aggregate, and so on.  $D_{n-2}$  is formed by applying this aggregation process again to the set  $D_{n-1}$  of  $N/M$  objects and their bounding boxes. This process is continued recursively until we obtain the set  $D_0$  containing just one element corresponding to a bounding box that encloses all of the objects. Note, however, that when the process is continued recursively, the

---

<sup>21</sup> Interestingly, we will see that no matter which of the implementations of the object-tree pyramid is being deployed, the ordering is used primarily to build the object-tree pyramid, although it is used for splitting in some cases such as the Hilbert R-tree [984]. The actual positions of the objects in the ordering (i.e., the object numbers) are not usually recorded in the object-tree pyramid, which is somewhat surprising as this could be used to speed up operations such as point location.

Figure 2.70  
A collection of 22 rectangle objects, where the numbers associated with the rectangles denote the relative times at which they were created.

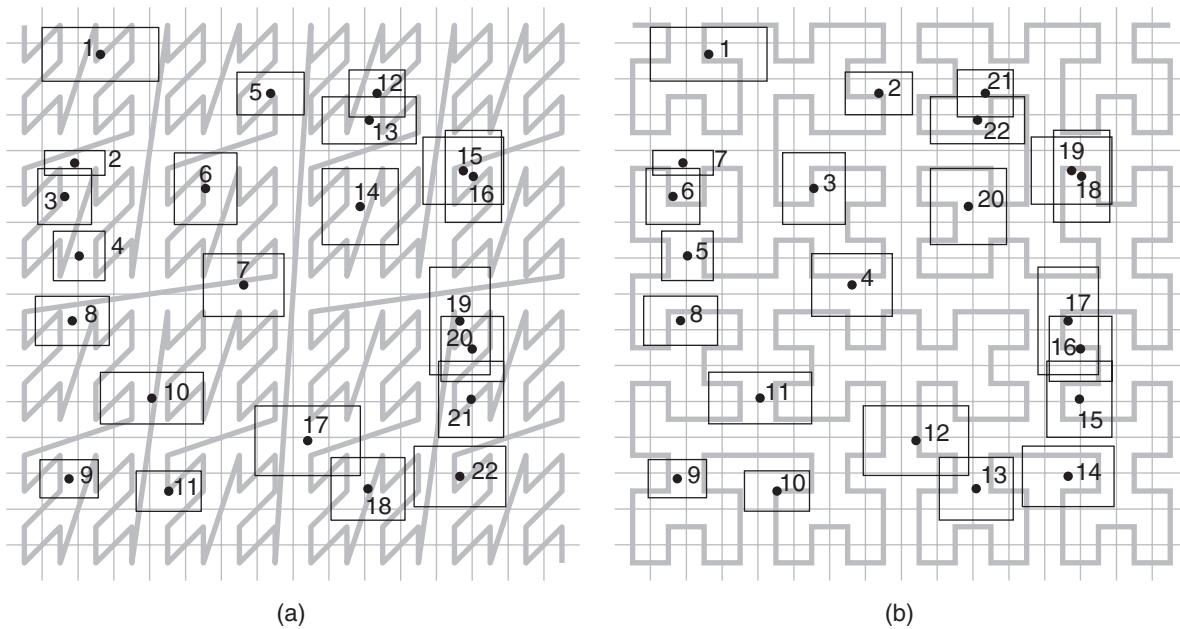

Figure 2.71  
The result of applying (a) a Morton order and (b) a Peano-Hilbert order to the collection of 22 rectangle objects in Figure 2.70 using their centroids as the representative points.

elements of the sets  $D_i$  ( $0 \leq i \leq n - 1$ ) are not necessarily ordered in the same manner as the elements of  $D_n$ .

There are several implementations of the object-tree pyramid using the one-dimensional grouping methods. For example, the *Hilbert packed R-tree* [983] is an object-tree pyramid that makes use of a Peano-Hilbert order. It is important to note that only the leaf nodes of the Hilbert packed R-tree are ordered using the Peano-Hilbert order. The nodes at the remaining levels are ordered according to the time at which they were created. For example, Figure 2.72(a) shows the bounding boxes corresponding to the first level of aggregation for the Hilbert packed R-tree for the collection of 22 rectangle objects

in Figure 2.70 with  $M = 6$ . Similarly, Figure 2.72(b) shows the same result were we to build the same structure using a Morton order (i.e., a Morton packed R-tree), again with  $M = 6$ . Notice that there is quite a bit of overlap among the bounding boxes as the aggregation does not take the extent of the bounding boxes into account when forming the structure.

A slightly different approach is employed in the *packed R-tree* [1588], which is another instance of an object-tree pyramid. The packed R-tree is based on ordering the objects on the basis of some criterion, such as increasing value of the  $x$  coordinate or any of the space-ordering methods shown in Figure 2.5. Once this order has been obtained, the leaf nodes in the packed R-tree are filled by examining the objects in increasing order, where each leaf node is filled with the first unprocessed object and its  $M - 1$  nearest neighbors that have not yet been inserted into other leaf nodes. Once an entire level of the packed R-tree has been obtained, the algorithm is reapplied to add nodes at the next level using the same nearest neighbor criterion, terminating when a level contains just one node. The only difference between the ordering that is applied at the levels containing the nonleaf nodes from that used at the level of the leaf nodes is that, in the former case we are ordering the bounding boxes while, in the latter case, we are ordering the actual objects.

Besides the difference in the way nonleaf nodes are formed, we point out that the packed R-tree construction process makes use of a proximity criterion in the domain of the actual data rather than the domain of the representative points, which is the case of the Hilbert packed R-tree. This distinction is quite important because it means that the Hilbert packed R-tree construction process makes no attempt to reduce or minimize coverage and overlap, which, as we shall soon see, are the real cornerstones of the R-tree data structure [791]. Therefore, as we point out below, this makes the Hilbert packed R-tree (and, to a lesser extent, the packed R-tree) much more like a B-tree that is constructed by filling each node to capacity. For example, Figure 2.72(c) shows the bounding boxes corresponding to the first level of aggregation for the packed R-tree for the collection of 22 rectangle objects in Figure 2.70. In this case, the objects were initially ordered using a Peano-Hilbert order.

The *sort-tiler-recurse method* (STR method) of Leutenegger, López, and Edgington [1153] is an example of the multidimensional grouping method. Our explanation

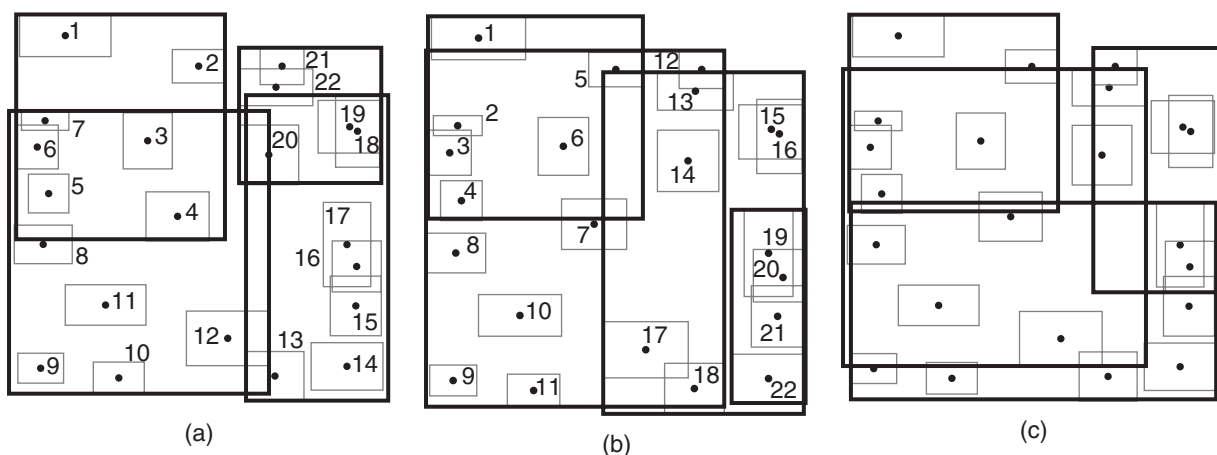

Figure 2.72  
The bounding boxes corresponding to the first level of aggregation for the (a) Hilbert packed R-tree, (b) Morton packed R-tree, and (c) packed R-tree (using a Peano-Hilbert order for the initial ordering) for the collection of 22 rectangle objects in Figure 2.70 with  $M = 6$ . The numbers associated with the rectangle objects in (a) and (b) denote the positions of their corresponding centroids in the order.

assumes, without loss of generality, that the underlying space is two-dimensional, although the extension of the method to higher dimensions is straightforward. Assuming a total of  $N$  rectangles and a node capacity of  $M$  rectangles per leaf node,  $D_{n-1}$  is formed by constructing a tiling of the underlying space consisting of  $s$  vertical slabs, where each slab contains  $s$  tiles. Each tile corresponds to an object-tree pyramid leaf node that is filled to capacity. Note that the result of this process is that the underlying space is being tiled with rectangular tiles, thereby resembling a grid, but, most importantly, unlike a grid, the horizontal edges of horizontally adjacent tiles (i.e., with a common vertical edge) do not form a straight line (i.e., are not connected). Using this process means that the underlying space is tiled with approximately  $\sqrt{N/M} \times \sqrt{N/M}$  tiles and results in approximately  $N/M$  object-tree pyramid leaf nodes. The tiling process is applied recursively to these  $N/M$  tiles to form  $D_{n-2}, D_{n-3}, \dots$  until just one node is obtained.

The STR method builds the object-tree pyramid in a bottom-up manner. The actual mechanics of the STR method are as follows. Sort the rectangles on the basis of one coordinate value of some easily identified point that is associated with them, say the  $x$  coordinate value of their centroid. Aggregate the sorted rectangles into  $\sqrt{N/M}$  groups of  $\sqrt{NM}$  rectangles, each of which forms a vertical slab containing all rectangles whose centroid's  $x$  coordinate value lies in the slab. Next, for each vertical slab  $v$ , sort all rectangles in  $v$  on the basis of their centroid's  $y$  coordinate value. Aggregate the  $\sqrt{NM}$  sorted rectangles in each slab  $v$  into  $\sqrt{N/M}$  groups of  $M$  rectangles each. Recall that the elements of these groups form the leaf nodes of the object-tree pyramid. Notice that the minimum bounding boxes of the rectangles in each tile are usually larger than the tiles. The process of forming a gridlike tiling is now applied recursively to the  $N/M$  minimum bounding boxes of the tiles, with  $N$  taking on the value of  $N/M$  until the number of tiles is no larger than  $M$ , in which case all of the tiles fit in the root node, and we are done.

A couple of items are worthy of further note. First, the minimum bounding boxes of the rectangles in each tile are usually larger than the tiles. This means that the tiles at each level will overlap. Thus, we do not have a true grid in the sense that the elements at each level of the object-tree pyramid are usually not disjoint. Second, the ordering that is applied is quite similar to a row order (actually column order to be precise) as illustrated in Figure 2.5(a) where the  $x$  coordinate value serves as a primary key to form the vertical slabs while the  $y$  coordinate value serves as the secondary key to form the tiles from the vertical slabs. Nevertheless, the ordering serves only to determine the partitioning lines to form the tiles but is not used to organize the collection of tiles.

Leutenegger, et al. [1153] compare the results of the STR packing method with those of the Hilbert packed R-tree [983] and an incorrect version of the packed R-tree of Roussopoulos and Leifker [1588]. In particular, they erroneously assume that the packing occurs solely in the order of the  $x$  coordinate value of the centroid of each rectangle and do not use the nearest neighbor heuristic actually employed by Roussopoulos and Leifker [1588]. The comparison is in terms of the number of disk accesses made when performing point and region queries on point and region data. They find the STR method to be superior to the packed R-tree in all cases, whereas the result of the comparison of the STR method with the Hilbert packed R-tree is not so conclusive. For mildly skewed data, the STR method is usually better than the Hilbert packed R-tree, while for highly skewed data, neither method is always better than the other.

Notice that the STR method is a bottom-up technique. However, the same idea could also be applied in a top-down manner so that we originally start with  $M$  tiles that are then further partitioned. In other words, we start with  $\sqrt{M}$  vertical slabs containing  $\sqrt{M}$  tiles apiece. This is instead of the initial  $\sqrt{N/M}$  vertical slabs containing  $\sqrt{N/M}$  tiles in the bottom-up method. The disadvantage of the top-down method is that it requires that we make roughly  $2 \log_M N$  passes over all of the data, whereas the bottom-up method has the advantage of making just two passes over the data (one for the  $x$  coordinate value and one for the  $y$  coordinate value) since all recursive invocations of the algorithm deal with centroids of the tiles.

The top-down method can be viewed as an ordering technique in the sense that the objects are partitioned, thereby creating a partial ordering, according to their relative position with respect to some criterion such as a value of a statistical measure for the set of objects as a whole. For example, in the VAMSplit R-tree of White and Jain [1989], which is applied to point data, the split axis (i.e.,  $x$  or  $y$  or  $z$ , etc.) is chosen on the basis of having the maximum variance from the mean in the distribution of the point data (for more detail, see Section 1.7.1.7 of Chapter 1). Once the axis is chosen, the objects are split into two equally sized sets constrained so that the resulting nodes are as full as possible. This process is applied recursively to the resulting sets.

Regardless of how the objects are aggregated, the object-tree pyramid is analogous to a height-balanced  $M$ -ary tree where only the leaf nodes contain data (objects in this case), and all of the leaf nodes are at the same level. Thus, the object-tree pyramid is good for static datasets. However, in a dynamic environment where objects are added and deleted at will, the object-tree pyramid needs to be rebuilt either entirely or partially to maintain the balance, order, and node-size constraints. In the case of binary trees, this issue is addressed by making use of a B-tree, or a  $B^+$ -tree if we wish to restrict the data (i.e., the objects) to the leaf nodes as is the case in our application. Below, we show how to use the  $B^+$ -tree to make the object-tree pyramid dynamic.

When the aggregation in the object-tree pyramid is based on ordering the objects, the objects and their bounding boxes can be stored directly in the leaf nodes of the  $B^+$ -tree. We term the result an *object  $B^+$ -tree*. The key difference between the object  $B^+$ -tree and the object-tree pyramid is that the  $B^+$ -tree (and likewise the object  $B^+$ -tree) permits the number of objects and nodes that are aggregated at each step to vary (i.e., the number of children per node). This is captured by the order of the  $B^+$ -tree: for an order  $(m, M)$   $B^+$ -tree, the number of children per node usually ranges between  $m \geq \lceil M/2 \rceil$  and  $M$ , with the root having at least two children unless it is a leaf node (see Appendix A). The only modification to the  $B^+$ -tree definition is in the format of the nodes of the object  $B^+$ -tree. In particular, the format of each nonleaf node  $p$  is changed so that if  $p$  has  $j$  children, then  $p$  contains the following three items of information for each child  $s$ :

1. A pointer to  $s$
2. The maximum object number associated with any of the children of  $s$  (analogous to a key in the conventional  $B^+$ -tree)
3. The bounding box  $b$  for  $s$  (e.g., the coordinate values of a pair of diagonally opposite corners of  $b$ )

Notice that  $j$  bounding boxes are stored in each node corresponding to the  $j$  children instead of just one bounding box as called for in the definition of the object-tree pyramid. This is done to speed up the point inclusion tests necessary to decide which child to descend when executing the location query. In particular, it avoids a disk access when the nodes are stored on disk.

A leaf node  $p$  in the object  $B^+$ -tree has a similar format, with the difference that instead of having pointers to  $j$  children that are nodes in the tree,  $p$  has  $j$  pointers to records corresponding to the  $j$  objects that it represents. Therefore,  $p$  contains the following three items of information for each object  $s$ :

1. A pointer to the actual object corresponding to  $s$
2. The object number associated with  $s$
3. The bounding box  $b$  for  $s$  (e.g., the coordinate values of a pair of diagonally opposite corners of  $b$ )

Observe that unlike the object-tree pyramid, the object  $B^+$ -tree does store object numbers in both the leaf and nonleaf nodes in order to facilitate updates. The update algorithms (i.e., data structure creation, insertion, and deletion) for an object  $B^+$ -tree are identical to those for a  $B^+$ -tree with the added requirement of maintaining the bounding

box information, while the search algorithms (e.g., the location query, window queries) are identical to those for an object-tree pyramid. The performance of the object  $B^+$ -tree for answering range queries is enhanced if the initial tree is built by inserting the objects in sorted order filling each node to capacity, subject to the minimum occupancy constraints, thereby resulting in a tree with minimum depth. Of course, such an initialization will cause subsequent insertions to be more costly because it will inevitably result in node split operations, although this would not necessarily be the case if the nodes were not filled to capacity initially. The *Hilbert R-tree* [984] is an instance of an object  $B^+$ -tree that applies a Peano-Hilbert space ordering (Figure 2.5(d)) to the centroid of the bounding boxes of the objects.<sup>22</sup>

Figure 2.73(a) shows the bounding boxes corresponding to the first level of aggregation for the Hilbert R-tree for the collection of 22 rectangle objects in Figure 2.70 with  $m = 3$  and  $M = 6$  when the objects are inserted in the order in which they were created (i.e., their corresponding number in Figure 2.70). Similarly, Figure 2.73(b) shows the corresponding result when using a Morton order instead of a Peano-Hilbert order. Notice that, for pedagogical reasons, the trees were not created by inserting the objects in sorted order as suggested above because, in this case, the resulting trees would be the same as the Hilbert packed R-tree and Morton packed R-tree in Figure 2.72(a, b), respectively.

As another example, consider Figure 2.74(a) which is the Hilbert R-tree for the collection of rectangle objects whose specifications are given in Figure 2.67 with  $m = 2$  and  $M = 3$ . Figure 2.74(b) shows the spatial extent of the bounding boxes of the nodes in

<sup>22</sup> As we will see, the name *Hilbert B-tree* is more appropriate because the update algorithms (e.g., insertion) do not make use of the bounding box information to reduce the coverage and overlap, whereas this is the key to their operation in the R-tree [791]. Although experiments for the Hilbert R-tree and the very closely related Hilbert packed R-tree [983] (which is the result of the initial Hilbert R-tree construction process given  $N$  objects) exhibit good behavior, this is primarily on account of the use of pointlike data such as very small line segments. Experiments using objects with greater extent (e.g., longer line segments) may be different. The Hilbert R-tree is closely related to the *Hilbert tree* [1121], which applies the same ordering to a set of points and then stores the result in a height-balanced binary search tree (see also [1891], which makes use of a Morton order and a 1-2 brother tree [1430]).

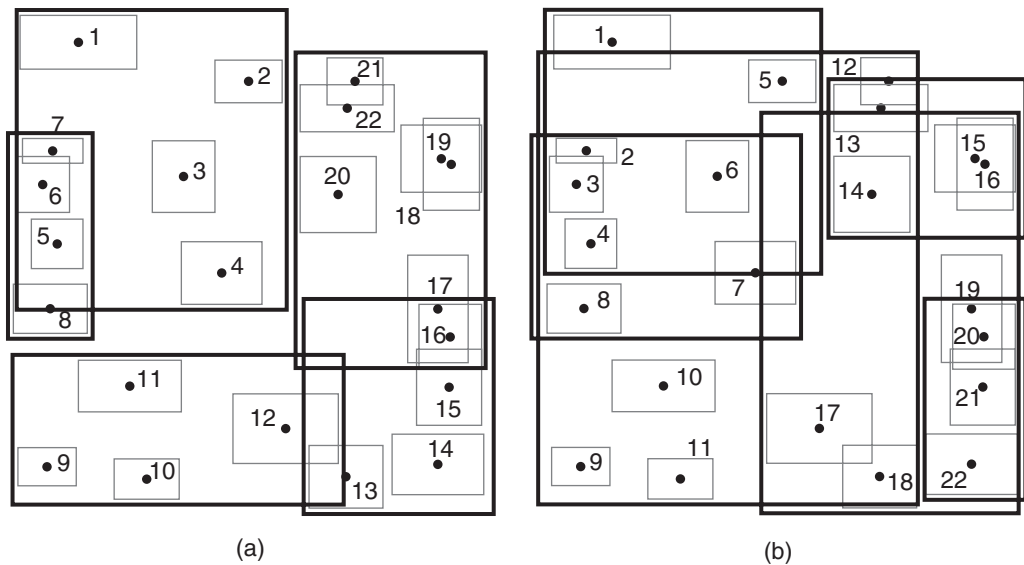

Figure 2.73  
The bounding boxes corresponding to the first level of aggregation for the (a) Hilbert R-tree and (b) Morton R-tree for the collection of 22 rectangle objects in Figure 2.70 with  $m = 3$  and  $M = 6$ .

Figure 2.74(a), with broken lines denoting the bounding boxes corresponding to the leaf nodes and gray lines denoting the bounding boxes corresponding to the subtrees rooted at the nonleaf nodes. Each node also indicates the Peano-Hilbert code of the centroid of the corresponding bounding box. We have filled each node to capacity, subject to the constraint that each node must have a minimal number of children. We have also tried to aggregate objects in each node based on the proximity of their positions in the Peano-Hilbert order.

Notice that there is much overlap between the bounding boxes of the nodes. Rearranging the objects that are aggregated in each node can alleviate this problem, but only to a very limited extent as the order of the leaf nodes must be maintained—that is, all elements of leaf node  $i$  must have a Peano-Hilbert order number less than all elements of leaf node  $i + 1$ . Thus, all we can do is change the number of elements that are aggregated in the node subject to the node capacity constraints. Of course, this means that the resulting trees are not unique. For example, in Figure 2.74, we could aggregate objects E and 3 into R3 and objects G, 2, and D into R4. However, the real problem is that objects 2 and F should be aggregated, but this is impossible as their corresponding positions in the Peano-Hilbert order are so far apart (i.e., 598 and 3496, respectively). The problem is caused, in part, by the presence of objects with nonzero extent and the fact that neither the extent of the objects nor their proximity is taken into account in the ordering-based aggregation techniques (i.e., they do not try to minimize coverage or overlap, which are the cornerstones of the R-tree). This deficiency was also noted earlier for the Hilbert packed R-tree. This is in contrast to experimental results [983] that encourage ordering the objects on the basis of the Peano-Hilbert order of their centroids. The problem is that these experiments were conducted with objects with little or no extent (i.e., pointlike objects or line segments with unit length).

**Exercises**

1. Give two possible representative points for circle objects.
2. What is the cost of an algorithm to build a packed R-tree that starts out by examining the  $N$  objects and finding the  $M$  objects with the smallest total bounding box, followed by the next  $M$  remaining objects with the smallest bounding box, until  $N/M$  bounding boxes have been obtained? This process is repeated recursively until there is just one box left [1588].
3. Write an algorithm to build a packed R-tree for a collection of two-dimensional objects that minimizes the total area covered by the bounding boxes at all of the levels.

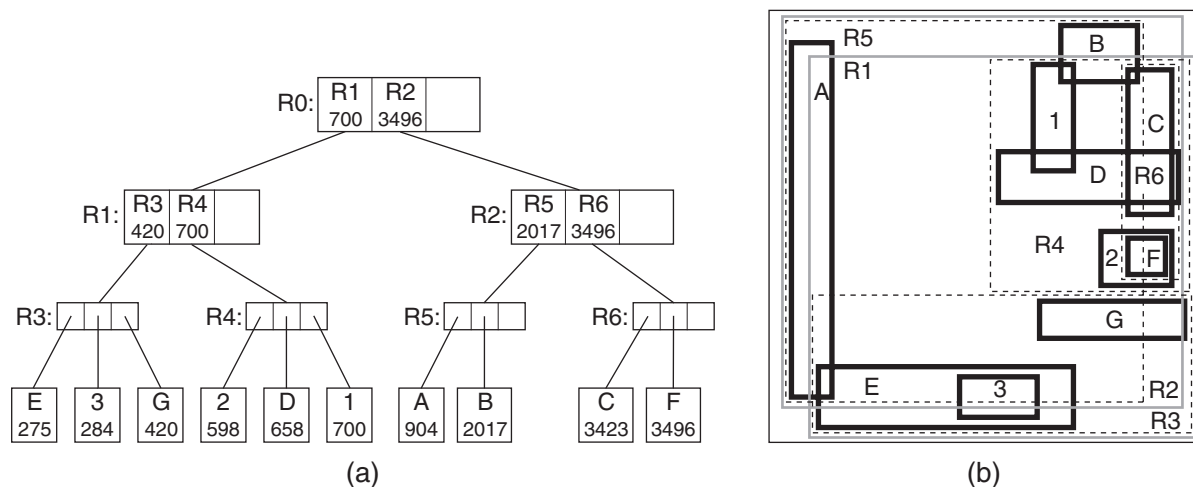

Figure 2.74  
(a) Hilbert R-tree for a collection of rectangle objects whose specifications are given in Figure 2.67 with  $m = 2$  and  $M = 3$  and (b) the spatial extents of the bounding boxes.

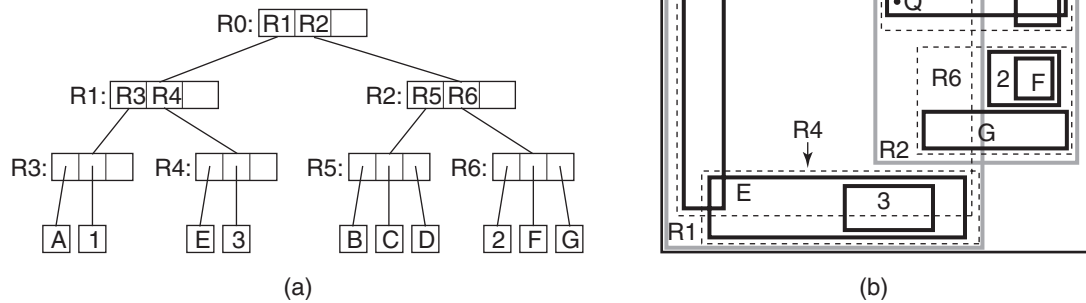

Figure 2.75  
(a) R-tree for a collection of rectangle objects whose specifications are given in Figure 2.67 with  $m = 2$  and  $M = 3$  and (b) the spatial extents of the objects and the bounding boxes of the nodes in (a). Notice that the leaf nodes in the index also store bounding boxes, although this is shown only for the nonleaf nodes.

### 2.1.5.2.3 Extent-Based Aggregation Techniques

When the objects are to be aggregated on the basis of their extent (i.e., the space occupied by their bounding boxes), then good dynamic behavior is achieved by making use of an *R-tree* [791]. An R-tree is a generalization of the object-tree pyramid where, for an order  $(m, M)$  R-tree, the number of objects or bounding boxes that are aggregated in each node is permitted to range between  $m \leq \lceil M/2 \rceil$  and  $M$ . On the other hand, it is always  $M$  for the object-tree pyramid. The root node in an R-tree has at least two entries unless it is a leaf node, in which case it has just one entry corresponding to the bounding box of an object. The R-tree is usually built as the objects are encountered rather than after all objects have been input. Of the different variations on the object-tree pyramid that we have discussed, the R-tree is the one used most frequently, especially in database applications.

Figure 2.75(a) is an example R-tree for a collection of rectangle objects whose specifications are given in Figure 2.67 with  $m = 2$  and  $M = 3$ . Figure 2.75(b) shows the spatial extents of the objects and the bounding boxes of the nodes in Figure 2.75(a), with broken lines denoting the bounding boxes corresponding to the leaf nodes and gray lines denoting the bounding boxes corresponding to the subtrees rooted at the nonleaf nodes. Note that the R-tree is not unique. Its structure depends heavily on the order in which the individual objects were inserted into (and possibly deleted from) the tree.

Given that each R-tree node can contain a varying number of objects or bounding boxes, it is not surprising that the R-tree was inspired by the B-tree. This means that nodes are viewed as analogous to disk pages. Thus, the parameters defining the tree (i.e.,  $m$  and  $M$ ) are chosen so that a small number of nodes is visited during a spatial query (i.e., variants of the location query), which means that  $m$  and  $M$  are usually quite large.

The need to minimize the number of disk accesses also affects the format of each R-tree node. Recall that in the definition of the object-tree pyramid, each node  $p$  contains  $M$  pointers to  $p$ 's children and one bounding box corresponding to the union of the bounding boxes of  $p$ 's children. This means that in order to decide which of node  $p$ 's children should be descended, we must access the nodes corresponding to these children to perform the point-inclusion test. Each such access requires a disk I/O operation. In order to avoid these disk I/O operations, the format of R-tree node  $p$  is modified so that  $p$  contains  $k$  ( $m \leq k \leq M$ ) pointers to  $p$ 's children and the  $k$  bounding boxes of  $p$ 's

children, instead of containing just one bounding box corresponding to the union of the bounding boxes of  $p$ 's children as is the case for the object-tree pyramid.<sup>23</sup> Recall that this format is also used in the definition of a node in the object  $B^+$ -tree. Once again, we observe that the  $k$  point inclusion tests do not require any disk I/O operations at the cost of being able to aggregate a smaller number of objects in each node since  $m$  and  $M$  are now smaller, assuming that the page size is fixed.

As long as the number of objects in each R-tree leaf node is between  $m$  and  $M$ , no action needs to be taken on the R-tree structure other than adjusting the bounding boxes when inserting or deleting an object. If the number of objects in a leaf node decreases below  $m$ , then the node is said to *underflow*. In this case, the objects in the underflowing nodes must be reinserted, and bounding boxes in nonleaf nodes must be adjusted. If these nonleaf nodes also underflow, then the objects in their leaf nodes must also be reinserted. If the number of objects in a leaf node increases above  $M$ , then the node is said to *overflow*. In this case, it must be split, and the  $M + 1$  objects that it contains must be distributed in the two resulting nodes. Splits are propagated up the tree.

Underflows in an R-tree are handled in an analogous manner to the way they are dealt with in a B-tree (see Exercise 7). In contrast, the overflow situation points out a significant difference between an R-tree and a B-tree. Recall that overflow is a result of attempting to insert an item  $t$  in node  $p$  and determining that node  $p$  is too full. In a B-tree, we usually do not have a choice (but see Exercise 2) as to the node  $p$  that is to contain  $t$  since the tree is ordered. Thus, once we determine that  $p$  is full, we must either split  $p$  or apply a rotation (also known as *deferred splitting*) process. On the other hand, in an R-tree, we can insert  $t$  into any node  $p$ , as long as  $p$  is not full. However, once  $t$  is inserted into  $p$ , we must expand the bounding box associated with  $p$  to include the space spanned by the bounding box  $b$  of  $t$ . Of course, we can also insert  $t$  in a full node  $p$ , in which case we must also split  $p$ .

The need to expand the bounding box of  $p$  has an effect on the future performance of the R-tree, and thus we must make a wise choice with respect to  $p$ . As in the case of the object-tree pyramid, the efficiency of the R-tree for search operations depends on its abilities to distinguish between occupied space and unoccupied space and to prevent a node from being examined needlessly due to a false overlap with other nodes. Again, as in the object-tree pyramid, the extent to which these efficiencies are realized is a direct result of how well we are able to satisfy our goals of minimizing coverage and overlap. These goals guide the initial R-tree creation process and are subject to the previously mentioned constraint that the R-tree is usually built as the objects are encountered rather than after all objects have been input.

In the original definition of the R-tree [791], the goal of minimizing coverage is the one that is followed. In particular, an object  $t$  is inserted by a recursive process that starts at the root of the tree and chooses the child whose corresponding bounding box needs to be expanded by the smallest amount to include  $t$ . As we will see, other researchers make use of other criteria such as minimizing overlap with adjacent nodes and even perimeter (e.g., in the  $R^*$ -tree [152] as described in Section 2.1.5.2.4). Theodoridis and Sellis [1865] try to minimize the value of an objective function consisting of a linear combination of coverage, overlap, and dead area with equal weights. García, López, and Leutenegger [679] also make use of a similar objective function to build the entire R-tree in a top-down manner. The fact that nodes in the tree are constrained to be as full as possible means that there is no need to check all possible configurations of split positions and groupings of objects, which is otherwise exponential in  $N$  (i.e.,  $O(2^N)$ ).

---

<sup>23</sup> The A-tree [1607], different from the ATree discussed in Section 2.1.2.5, is somewhat of a compromise. The A-tree stores quantized approximations of the  $k$  bounding boxes of  $p$ 's children, where the locations of the bounding boxes of  $p$ 's children are specified relative to the location of the bounding box of  $p$ , thereby enabling them to be encoded with just a small number of bits. For more detail on other uses of such methods, see Section 4.4.3 of Chapter 4.

Not surprisingly, these same goals also guide the node-splitting process. In this situation, one goal is to distribute the objects among the nodes so that the likelihood that the two nodes will be visited in subsequent searches will be reduced. This is accomplished by minimizing the total area spanned by the bounding boxes of the resulting nodes (equivalent to what we have termed *coverage*). The second goal is to reduce the likelihood that both nodes are examined in subsequent searches. This goal is accomplished by minimizing the area common to both nodes (equivalent to what we have termed *overlap*). Again, we observe that, at times, these goals may be contradictory.

Several node-splitting policies have been proposed that take these goals into account. They are differentiated on the basis of their execution-time complexity and the number of these goals that they attempt to meet. An easy way to see the different complexities is to look at the following three algorithms [791], all of which are based on minimizing the coverage. The simplest is an exhaustive algorithm [791] that tries all possibilities. In such a case, the number of possible partitions is  $2^M - 1$  (see Exercise 8). This is unreasonable for most values of  $M$  (e.g.,  $M = 50$  for a page size of 1,024 bytes).

The exhaustive approach can be applied to obtain an optimal node split according to an arbitrary cost function that can take into account coverage, overlap, and other factors. Interestingly, although we pointed out earlier that there are  $O(2^M)$  possible cases to be taken into account, the exhaustive algorithm can be implemented in such a way that it need not require  $O(2^M)$  time. In particular, Becker, Franciosa, Gschwind, Ohler, Thiemt, and Widmayer [146] present an implementation that takes only  $O(M^3)$  time for two-dimensional data and  $O(dM \log M + d^2 M^{2d-1})$  time for  $d$ -dimensional data.

García, López, and Leutenegger [680] present an implementation of the exhaustive approach that uses the same insight as the implementation of Becker et al. [146], which is that some of the boundaries of the two resulting minimum bounding boxes are shared with the minimum bounding box of the overflowing node. This insight constrains the number of possible groupings of the  $M$  objects in the node that is being split. The algorithm is flexible in that it can use different cost functions for evaluating the appropriateness of a particular node split. However, the cost function is restricted to being “extent monotone,” which means that the cost function increases monotonically as the extent of one of the sides of the two bounding rectangles is increased (this property is also used by Becker et al. [146], although the property is stated somewhat differently).

Although the implementations of Becker et al. [146] and García, et al. [680] both find optimal node splits, the difference between them is that the former has the added benefit of guaranteeing that the node split satisfies some balancing criteria, which is a requirement in most R-tree implementations. The rationale, as we recall, is that in this way the nodes are not too full, which would cause them to overflow again. For example, in many R-tree implementations there is a requirement that the split be such that each node receive exactly half the rectangles or that each receive at least 40% of the rectangles. Satisfying the balancing criteria is more expensive, as could be expected, and, in two dimensions, the cost of the algorithm of Becker et al. [146] is  $O(M^3)$ , as opposed to  $O(M^2)$  for the algorithm of García, et al. [680].

García, et al. [680] found that identifying optimal node splits yielded only modest improvements in query performance, which led them to introduce another improvement to the insertion process. This improvement is based on trying to fit one of the two groups resulting from a split of node  $a$  into one of  $a$ 's siblings instead of creating a new node for every split. In particular, one of the groups is inserted into the sibling  $s$  for which the cost increase, using some predefined cost function, resulting from movement into  $s$  is minimized. Once a sibling  $s$  has been chosen, we move the appropriate group and reapply the node-splitting algorithm if the movement caused  $s$  to overflow. This process is applied repeatedly as long as there is overflow, while requiring that we choose among the siblings that have not been modified by this process. If we find that there is overflow in node  $i$  and there is no unmodified sibling left, then a new node is created containing one of the new groups resulting from the split of  $i$ . Even if each node overflows, this process

is guaranteed to terminate because, at each step, there is one fewer sibling candidates for motion.

The process described above is somewhat similar to what is termed *forced reinsertion* in the R\*-tree (see Section 2.1.5.2.4), with the difference that forced reinsertion results in reinsertion of the individual entries (i.e., objects in the case of leaf nodes and minimum bounding boxes in the case of nonleaf nodes) at the root, instead of as a group into one of the siblings. This reinsertion into siblings is also reminiscent of rotation (i.e., “deferred splitting”) in the conventional B-tree with the difference being that there is no order in the R-tree, which is why motion into all unmodified siblings had to be considered. This strategy was found to increase the node utilization and, thereby, to improve query performance (by as much as 120% in experiments [680], compared with the Hilbert R-tree [984]).

The remaining two node-splitting algorithms have a common control structure that consists of two stages. The first stage “picks” a pair of bounding boxes  $j$  and  $k$  to serve as “seeds” for the two resulting nodes, while the second stage redistributes the remaining bounding boxes into the nodes corresponding to  $j$  and  $k$ . The redistribution process tries to minimize the “growth” of the area spanned by  $j$  and  $k$ . Thus, the first and second stages can be described as *seed picking* and *seed growing*, respectively.

The first of these seed-picking algorithms is a quadratic cost algorithm [791] (see Exercise 15) that initially finds the two bounding boxes that would waste the most area were they to be in the same node. This is determined by subtracting the sum of the areas of the two bounding boxes from the area of the covering bounding box. These two bounding boxes are placed in the separate nodes, say  $j$  and  $k$ . Next, the remaining bounding boxes are examined, and for each bounding box, say  $i$ ,  $d_{ij}$  and  $d_{ik}$  are computed, which correspond to the increases in the area of the covering bounding boxes of nodes  $j$  and  $k$ , respectively, when  $i$  is added to them. Now, the bounding box  $r$  such that  $|d_{rj} - d_{rk}|$  is a maximum is found, and  $r$  is added to the node with the smallest increase in area. This process is repeated for the remaining bounding boxes. The motivation for selecting the maximum difference  $|d_{rj} - d_{rk}|$  is to find the bounding box having the greatest preference for a particular node  $j$  or  $k$ .

The second of these seed-picking algorithms is a linear cost algorithm [791] (see Exercise 11) that examines each dimension and finds the two bounding boxes with the greatest separation. Recalling that each bounding box has a low and a high edge along each axis, these two bounding boxes are the one whose high edge is the lowest along the given axis and the one whose low edge is the highest along the same axis. The separations are normalized by dividing the actual separation by the width of the bounding box of the overflowing node along the corresponding axis. The final “seeds” are the two bounding boxes having the greatest normalized separation among the  $d$  pairs that we found. The remaining bounding boxes are processed in arbitrary order and placed in the node whose bounding box (i.e., of the entries added so far) is increased the least in area as a result of their addition (see Exercise 19). Empirical tests [791] showed that there was not much difference between the three node-splitting algorithms in the performance of a window search query (i.e., in CPU time and in the number of disk pages accessed). Thus, the faster linear cost node-splitting algorithm was found to be preferable for this query, even though the quality of the splits was somewhat inferior.

An alternative node-splitting policy is based on minimizing the overlap. One technique that has a linear cost [60] applies  $d$  partitions (one for each of the  $d$  dimensions) to the bounding boxes in the node  $t$  being split, thereby resulting in  $2d$  sets of bounding boxes. In particular, we have one set for each face of the bounding box  $b$  of  $t$ . The partition is based on associating each bounding box  $o$  in  $t$  with the set corresponding to the closest face along dimension  $i$  of  $b$ .<sup>24</sup> Once the  $2d$  partitions have been constructed (i.e.,

---

<sup>24</sup> Formally, each bounding box  $o$  has two faces  $f_{oil}$  and  $f_{oih}$  that are parallel to the respective faces  $f_{bil}$  and  $f_{bih}$  of  $b$ , where  $l$  and  $h$  correspond to the low and high values of coordinate or dimension  $i$ .

Figure 2.76  
Example collection of rectangles demonstrating a linear node-splitting algorithm that minimizes overlap rather than coverage.

each bounding box  $o$  has been associated with  $d$  sets), select the partition that ensures the most even distribution of bounding boxes. In case of a tie, choose the partition with the least overlap. In case of another tie, choose the partition with the least coverage. For example, consider the four bounding boxes in Figure 2.76. The partition along the  $x$  axis yields the sets  $\{1,2\}$  and  $\{3,4\}$ , and the partition along the  $y$  axis yields the sets  $\{1,3\}$  and  $\{2,4\}$ . Since both partitions yield sets that are evenly distributed, we choose the one that minimizes overlap (i.e., along the  $y$  axis).

The algorithm is linear as it examines each bounding box once along each dimension (actually, it is  $O(dM)$  for  $M$  objects, but  $d$  is usually much smaller than  $M$ ). Experiments with randomly generated rectangles [60] resulted in lower coverage and overlap than the linear and quadratic algorithms described above [791], which are based on minimizing the coverage. The window search query was also found to be about 16% faster with the linear algorithm based on minimizing overlap than with the quadratic algorithm based on minimizing coverage. The drawback of this linear algorithm (i.e., [60]) is that it does not guarantee that the two nodes resulting from the partition will contain an equal number of bounding boxes. This is because the partitions are based on proximity to the borders of the bounding box of the node being split. In particular, when the data is not uniformly distributed, although the resulting nodes are likely to have little overlap (as they are likely to partition the underlying space into two equal areas), they will most likely contain an uneven number of bounding boxes (see Exercise 21).

Extent-based aggregation techniques have also been applied to the representation of collections of moving rectangle objects, each of which is represented by a moving box. The result is an R-tree where the bounding boxes for a set of static rectangles are replaced by moving bounding boxes for a set of moving boxes (e.g., [296, 1610]). As in the case of R-trees, there are many ways of defining the moving bounding boxes. The *parametric R-tree* [296] and the *TPR-tree* [1610] (as well as the more recent improvement, the *TPR\*-tree* [1855], which makes use of more sophisticated node-splitting and other basic algorithms for insertion and deletion) are two examples of such R-trees that are based on minimizing coverage, with the parametric R-tree providing tighter coverage vis-à-vis the TPR-tree. In particular, the parametric R-tree makes use of a minimum moving bounding box, termed a *time-parametric rectangle* [295], that takes the time intervals during which each of the individual rectangle objects are moving, which need not necessarily be the same, in calculating the moving bounding boxes of collections of moving bounding boxes. Thus, for example, in the time period  $tp = [0, 10]$ , some of the objects may only be moving during a subset of  $tp$  (e.g., object  $A$  is moving during  $[0, 8]$  while object  $B$  is moving during  $[4, 10]$ ). The minimum moving bounding boxes in the parametric R-tree are calculated on the basis of a principle similar to a convex hull. On the other hand, in the TPR-tree and the TPR\*-tree the minimum moving bounding boxes assume that the objects are in motion during the entire time interval that is spanned by the minimum moving bounding box. The general discussion of moving objects is beyond the scope of this discussion.

### Exercises

1. What is the difference between the definition of a node in an R-tree and a node in a B-tree?
2. In an R-tree, we always have a choice with respect to the node in which an object is to be inserted. This is not always the case in a B-tree. When do you have a choice as to the B-tree node in which an item with key  $k$  can be inserted?

---

For each dimension  $i$ , there are two sets  $S_{il}$  and  $S_{ih}$  corresponding to faces  $f_{bil}$  and  $f_{bih}$  of  $b$ , and the algorithm inserts  $o$  into  $S_{il}$  if  $x_i(f_{oil}) - x_i(f_{bil}) < x_i(f_{bih}) - x_i(f_{oih})$  and into  $S_{ih}$  otherwise, where  $x_i(f)$  is the  $i$ th coordinate value of face  $f$ . A similar idea of grouping bounding boxes by their proximity to the closest face along a particular dimension is also used in the priority R-tree [86], which is an R-tree designed for efficient bulk loading (see Section 2.1.5.2.6).

3. What is the maximum height of an R-tree of order  $(m, M)$  with  $N$  objects or bounding boxes (not nodes)?
4. What is the maximum number of nodes in an R-tree of order  $(m, M)$  with  $N$  objects or bounding boxes?
5. What is the total cost of inserting an object in an R-tree of order  $(m, M)$  when no node splitting is needed?
6. Write an algorithm to insert an object into an R-tree of order  $(m, M)$ . You will have to choose one of the described techniques for splitting a full node with  $M + 1$  records.
7. Write an algorithm to delete an object from an R-tree.
8. Prove that there are  $2^M - 1$  possible partitions of a node in an R-tree of order  $(m, M)$  with  $M + 1$  records into two nonempty subsets.
9. Theodoridis and Sellis [1865] suggest a seed-picking algorithm that sorts the bounding boxes of the objects in the node to be split according to some value such as the Peano-Hilbert code of their centroid and then uses the ones with the minimum and maximum value as the seeds. Compare the result of using this technique with the linear and quadratic node-splitting algorithms proposed by Guttman [791] based on reducing coverage, as well as the linear node-splitting algorithm based on reducing overlap proposed by Ang and Tan [60]. For the method of Theodoridis and Sellis [1865] use the same seed-growing algorithm as in the linear node-splitting algorithm based on reducing coverage.
10. Repeat the comparison in Exercise 9 by using the seed-picking algorithm of Theodoridis and Sellis [1865] in conjunction with a seed-growing algorithm that selects the node into which the objects are to be inserted by minimizing the value of an objective function consisting of a linear combination of coverage, overlap, and dead area with equal weights. Once the seeds have been chosen, the objects are processed using the ordering resulting from sorting the bounding boxes. In particular, if the last object was assigned to the group associated with the seed corresponding to the lowest (highest) value in the ordering, then the next object to be processed is the highest (lowest) valued one remaining in the ordering.
11. The seed-picking stage of the linear cost R-tree node-splitting algorithm proposed by Guttman [791] finds the two bounding boxes with the maximum normalized separation along all of the dimensions. This is based on a definition of separation in terms of the maximum distance between the farthest of the parallel sides of two bounding boxes. Suppose that the definition of farthest was changed to be the maximum separation between the closest of the parallel sides of the two bounding boxes [750]. Is the cost of the resulting algorithm still linear (i.e.,  $O(M)$ ) for an R-tree of order  $(m, M)$ ?
12. Explain why the seeds picked by the quadratic cost R-tree node-splitting algorithm proposed by Guttman [791] tend to be small and far apart.
13. Suppose that the seeds picked by the quadratic cost R-tree node-splitting algorithm proposed by Guttman [791] are small. Suppose further that there exists a bounding box  $r$  far away from one of the seeds  $s$  where  $d - 1$  of the coordinate values of  $r$  are almost in agreement with those of  $s$ . Show that  $r$  is highly likely to be the first to be distributed and will be distributed to the bounding box of  $s$ .
14. Let  $b_1$  be the first bounding box to be redistributed by the quadratic cost R-tree node-splitting algorithm proposed by Guttman [791] and suppose that it is redistributed to seed  $s$ . Explain why the algorithm has a tendency to prefer seed  $s$  for the next bounding box  $b_2$  to be redistributed. What happens to the remaining bounding boxes in this case (i.e., after  $b_1$  and  $b_2$  have been redistributed)?
15. Prove that the quadratic cost R-tree node-splitting algorithm proposed by Guttman [791] requires  $O(M^2)$  time for an order  $(m, M)$  R-tree.
16. Both the linear and quadratic cost R-tree node-splitting algorithms proposed by Guttman [791] consist of a stage that picks seeds  $j$  and  $k$ , and a stage that redistributes the remaining bounding boxes into the nodes corresponding to  $j$  and  $k$ . The linear cost algorithm redistributes the remaining bounding boxes by inserting them into the node  $j$  or  $k$  whose bounding box is increased (i.e., that *grows*) the least by their addition. This is based on the principle of minimizing coverage. An alternative approach picks an axis in the first stage for which the normalized separation between the seeds is a maximum. In addition, instead of seed-growing,

an alternative redistribution algorithm is used that sorts the bounding boxes by their low value along the chosen split axis and then assigns the first  $M/2$  bounding boxes to one node and the remaining bounding boxes to the other node [750]. In this case, there is no minimization of growth in the sense that, once the sort has taken place, the redistribution just depends on the value of  $M$ . Compare the performance of this alternative redistribution algorithm in conjunction with the following two approaches to picking the split axis:

- (a) The axis with the greatest normalized separation for the two seeds  $j$  and  $k$  selected by the quadratic cost algorithm. The separations are normalized by dividing the actual separation by the length of the side of the bounding box of  $j$  and  $k$  along the appropriate axes.
  - (b) The variation on the technique used in the linear cost algorithm described in Exercise 11 that finds the two bounding boxes  $j$  and  $k$  with the maximum separation between the closest of the parallel sides of  $j$  and  $k$ .<sup>25</sup>
17. What is the cost of the variation of the node-splitting algorithm that makes use of the second technique in Exercise 16 for an R-tree of order  $(m, M)$ ?
  18. What is the drawback of using the alternative redistribution algorithm described in Exercise 16, which sorts the bounding boxes in an order  $(m, M)$  R-tree by their low value along the chosen split axis and then assigns the first  $M/2$  bounding boxes to one node and the remaining bounding boxes to the other node [750]?
  19. The seed-growing step of the linear cost node-splitting algorithm proposed by Guttman [791] redistributes the remaining bounding boxes in arbitrary order to the seed whose associated group's minimum bounding box is increased the least by the addition. Thus, if the bounding boxes happen to be redistributed in sorted order along one of the dimensions, then the algorithm is plagued by the same problem described in Exercise 14. In particular, once the first bounding box has been distributed to one of the seeds  $s$ , the redistribution step will tend to favor  $s$  for the next bounding box, and so on, and most of the bounding boxes will be distributed to  $s$  subject to the minimum storage utilization constraints. One way to avoid this problem completely is to redistribute the remaining bounding boxes one by one in arbitrary order to the seed whose original bounding box is increased the least by the addition. In this case, the order in which the bounding boxes are redistributed makes no difference in the final result. Perform a quantitative comparison of the two methods in terms of their coverage, overlap, and whether the resulting two nodes have approximately the same number of elements.
  20. An alternative implementation of the seed-growing step of the linear cost node-splitting algorithm proposed by Guttman [791] is to remember the dimension  $i$  with the highest normalized separation and to redistribute the remaining bounding boxes to the seed whose associated group's minimum bounding box is increased the least along  $i$  by the addition. Perform a quantitative comparison of this method with the original method in terms of their coverage, overlap, and whether the resulting two nodes have approximately the same number of elements.
  21. Ang and Tan [60] describe experiments that show that a linear R-tree node-splitting algorithm based on reducing overlap results in lower coverage and overlap than the linear and quadratic algorithms proposed by Guttman [791]. The experiments used randomly generated rectangles. In this case, the data is well-distributed throughout the underlying space, and thus the algorithm will naturally result in creating partitions that have approximately the same number of bounding boxes. In contrast, this may not be the case for nonrandom data. Perform a similar comparison using real data. The comparison should be qualitative and quantitative. The qualitative comparison should examine the resulting space decomposition, as in Figure 2.79 (discussed in Section 2.1.5.2.4). This can be achieved by choosing a sample dataset and drawing the output. The quantitative comparison should tabulate coverage and overlap, storage utilization, and the time for construction, as well as the times for intersection (i.e., determining all pairs of intersecting objects), window, and point queries.
  22. Write an algorithm to perform a point query in an R-tree.
  23. Consider an R-tree built for objects whose centroids and extents are uniformly distributed in the unit space and point queries that are also uniformly distributed over the same unit space.

---

<sup>25</sup> The first technique is erroneously attributed to [750] in [152], whereas the second technique is really the one described in [750].

- Prove that the expected number of R-tree nodes visited by a point query is equal to the sum of the  $d$ -dimensional volumes of the bounding boxes of all of the nodes.
24. Write an algorithm to perform a window query in an R-tree.
  25. Using the same environment as in Exercise 23, consider a rectangular window query to retrieve all objects whose bounding boxes have a nonempty intersection with window  $w$  having width  $w_i$  in dimension  $i$ . Prove that the expected number of R-tree nodes visited is  $\sum_j \prod_{i=1}^d (b_{ji} + w_i)$ , where  $b_j$  is the bounding box of R-tree node  $q_j$ , and  $b_{ji}$  is the width of  $b_j$  along dimension  $i$ .
  26. Write an algorithm to find the nearest object to a point in an R-tree.
  27. Write an algorithm to solve the rectangle intersection problem for an R-tree.
  28. Prove that the worst-case execution time of the rectangle intersection problem for  $N$  rectangles using an R-tree is  $O(N^2)$ .
  29. What is the expected cost of the rectangle intersection problem for  $N$  rectangles using an R-tree?

#### 2.1.5.2.4 R\*-Tree

Better decompositions in terms of less node overlap and lower storage requirements than those achieved by the linear and quadratic node-splitting algorithms have also been reported in [152], where three significant changes have been made to the R-tree construction algorithm, including a different node-splitting strategy. An R-tree that is built using these changes is termed an *R\*-tree* [152].<sup>26</sup> These changes are described below. Interestingly, these changes also involve using a node-splitting policy that, at times, tries to minimize both coverage and overlap.

The first change is the use of an intelligent object insertion procedure that is based on minimizing overlap in the case of leaf nodes, while minimizing the increase in area (i.e., coverage) in the case of nonleaf nodes. The distinction between leaf and nonleaf nodes is necessary as the insertion algorithm starts at the root and must process nonleaf nodes before encountering the leaf node where the object will ultimately be inserted. Thus, we see that the bounding box  $b$  for an object  $o$  is inserted into the leaf node  $p$  for whom the resulting bounding box has the minimum increase in the amount of overlap with the bounding boxes of  $p$ 's siblings (children of nonleaf node  $s$ ). This is in contrast to the R-tree, where  $b$  is inserted into the leaf node  $p$  for whom the increase in area is a minimum (i.e., based on minimizing coverage). This part of the R\*-tree object insertion algorithm is quadratic in the number of entries in each node (i.e.,  $O(M^2)$  for an order  $(m, M)$  R\*-tree where the number of objects or bounding boxes that are aggregated in each node is permitted to range between  $m \leq \lceil M/2 \rceil$ ) as the overlap must be checked for each leaf node child  $p$  of the selected nonleaf node  $s$  with all of  $p$ 's  $O(M)$  siblings (but see Exercise 4).

The second change is that when a node  $p$  is found to overflow in an R\*-tree, instead of immediately splitting  $p$  as is done in the R-tree, first an attempt is made to see if some of the objects in  $p$  could possibly be more suited to being in another node. This is achieved by reinserting a fraction (30% has been found to yield good performance [152]) of these objects into the tree (termed *forced reinsertion*). Forced reinsertion is similar in spirit to rotation (also known as *deferred splitting*) in a conventional B-tree, which is also a technique developed to avoid splitting a node (see Exercise 1).

There are several ways of determining the objects to be reinserted. One suggestion is to sort the bounding boxes in  $p$  according to the distance of the centers of their bounding boxes from the center of the bounding box of  $p$ , and to reinsert the designated fraction

---

<sup>26</sup> The “\*” is used to signify its “star”-like performance [1707] in comparison with R-trees built using the other node-splitting algorithms, as can be seen in examples such as Figures 2.77 and 2.79(b), discussed later in this section.

that is the farthest away. Once we have determined the objects to be reinserted, we need to choose an order in which to reinsert them. There are two obvious choices: from farthest to closest (termed *far-reinsert*) or from closest to farthest (termed *close-reinsert*). Beckmann, Kriegel, Schneider, and Seeger [152] make a case for using close-reinsert on the basis of the results of experiments. One possible explanation is that if the reinsertion procedure places the first object to be reinserted in  $p$ , then the size of the bounding box of  $p$  is likely to be increased more if far-reinsert is used rather than close-reinsert, thereby increasing the likelihood of the remaining objects' being reinserted into  $p$  as well. This has the effect of defeating the motivation for the introduction of the reinsertion process, which is to try to reorganize the nodes. However, it could also be argued that using far-reinsert is more likely to result in the farthest object being reinserted in a node other than  $p$ , on account of the smaller amount of overlap, which is one of the goals of the reinsertion process. Thus, the question of which method to use is not completely settled.

The sorting step in forced reinsertion takes  $O(M \log M)$  time. However, this cost is greatly overshadowed by the fact that each invocation of forced reinsertion can result in the reinsertion of  $O(M)$  objects, thereby increasing the cost of insertion by a factor of  $O(M)$ . One problem with forced reinsertion is that it can lead to overflow in the same node  $p$  again when all of the bounding boxes are reinserted in  $p$  or even to overflow in another node  $q$  at the same depth. This can lead to an infinite loop. In order to prevent the occurrence of such a situation, forced reinsertion is applied only once at each depth for a given object. Note also that forced reinsertion is applied in a bottom-up manner in the sense that resolving overflow in the leaf nodes may also lead to overflow of the nonleaf nodes, in which case we apply forced reinsertion to the nonleaf nodes as well. When applying forced reinsertion to a nonleaf node  $p$  at depth  $l$ , we reinsert only the elements in  $p$  and at depth  $l$ .

Forced reinsertion is quite important as, usually, an R-tree is built by inserting the objects one by one as they are encountered in the input. Thus, we do not usually have the luxury of processing the objects in sorted order. This can lead to some bad decompositions in the sense that the redistribution stage may prefer one of the seed nodes over the other in a consistent manner (see Exercise 14 in Section 2.1.5.2.3). Of course, this can be overcome by taking into account the bounding boxes of all of the objects before building the R-tree; but now the representation is no longer dynamic. Forced reinsertion is a compromise in the sense that it permits us to rebuild periodically part of the R-tree as a means of compensating for some bad node-placement decisions.

The third change involves the manner in which an overflowing node  $p$  is split. Again, as in the original R-tree node-splitting algorithm, a two-stage process is used. The difference is in the nature of the stages. The process follows closely an approach presented in an earlier study of the R-tree [750] (see Exercise 16 in Section 2.1.5.2.3), which did not result in the coining of a new name for the data structure! In particular, in contrast to the original R-tree node-splitting strategy [791], where the first stage picks two seeds for the two resulting nodes, which are subsequently grown by the second stage, in the R\*-tree (as well as in the approach described in [750]), the first stage determines the axis (i.e., hyperplane) along which the split is to take place, and the second stage determines the position of the split. In two dimensions, for example, the split position calculated in the second stage serves as the boundary separating the left (or an equivalent alternative is the right) sides of the bounding boxes of the objects that will be in the left and right nodes resulting from the split.

Note that the result of the calculation of the split position in the second stage has the same effect as the redistribution step in the linear and quadratic cost R-tree node-splitting algorithms as it indicates which bounding boxes are associated with which node. In particular, as we will see below, the first stage makes use of the result of sorting the faces of the bounding boxes along the various dimensions. Moreover, it would appear that the first and last bounding boxes in the sort sequence play a somewhat similar role to that of the seeds in the original R-tree node-splitting algorithms. However, this comparison is false as there is no growing process in the second stage. In particular, these seeds do

not grow in an independent manner in the sense that the bounding boxes  $b_i$  that will be assigned to their groups are determined by the relative positions of the corresponding faces of  $b_i$  (e.g., in two dimensions, the sorted order of their left, right, top, or bottom sides).

This two-stage process is implemented by performing  $2d$  sorts (two per axis) of the bounding boxes of the objects in the overflowing node  $p$ . For each axis  $a$ , the bounding boxes are sorted according to their two opposite faces that are perpendicular to  $a$ . The positions of the faces of the bounding boxes in the sorted lists serve as the candidate split positions for the individual axes. There are several ways of using this information to determine the split axis and split position along the axis.

Beckmann et al. [152] choose the split axis as the axis  $a$  for which the average perimeter of the bounding boxes of the two resulting nodes for all of the possible splits along  $a$  is the smallest while still satisfying the constraint posed by  $m$  and  $M$ . An alternative approach (although not necessarily yielding the desired result as shown below and discussed further in Exercise 9) is one that chooses the split axis as the axis  $a$  for which the perimeter of the two resulting nodes is a minimum. Basing the choice on the value of the perimeter is related to the goal of minimizing coverage by favoring splits that result in nodes whose bounding boxes have a squarelike shape (see Exercise 7). Basing the choice of the split axis on the minimum average perimeter results in giving greater weight to the axis where the majority of the possible splits result in nodes whose bounding boxes have squarelike shapes (see also Exercise 9). This stage takes  $O(dM \log M)$  time as the sort takes  $O(M \log M)$  time for each axis while the average perimeter computation can be done in  $O(M)$  time for each axis when scanning the faces of the bounding boxes in sorted order (see Exercise 8).

The position of the split along the axis  $a$  selected by the first stage is calculated by examining the two sorted lists of possible split positions (i.e., faces of the bounding boxes) for  $a$  and choosing the split position for which the amount of overlap between the bounding boxes of the two resulting nodes is the smallest (but see Exercises 10 and 21) while still satisfying the constraint posed by  $m$  and  $M$ . Ties are resolved by choosing the position that minimizes the total area of the resulting bounding boxes, thereby reducing the coverage. Minimizing the overlap reduces the likelihood that both nodes will be visited in subsequent searches. Thus, we see that the R\*-tree's node-splitting policy tries to address the issues of minimizing both coverage and overlap. Determining the split position requires  $O(M)$  overlap computations when scanning the bounding boxes in sorted order. Algorithms that employ this sort-and-scan paradigm are known as *plane-sweep techniques* [119, 1511, 1740].

Figure 2.77 shows the bounding boxes corresponding to the first level of aggregation for an R\*-tree in comparison to that resulting from the use of an R-tree that deploys the exhaustive (Figure 2.78(a)), linear cost (Figure 2.78(b)), quadratic cost (Figure 2.78(c)), and linear cost reducing overlap (Figure 2.78(d)) [60] node-splitting algorithms for the collection of 22 rectangles in Figure 2.71. It is quite clear from the figure, at least for this example dataset, that the combined criterion used by the R\*-tree node-splitting algorithm that chooses the split that minimizes the sum of the perimeters of the bounding boxes of the two resulting nodes, as well as their overlap, seems to be working. Whether this is indeed the change in the definition that leads to this behavior is unknown (see Exercises 5 and 6).

Figure 2.79 contains a more complex example consisting of a sample collection of 1,700 line-shaped objects (Figure 2.79(a)) for which R-trees have been constructed using different node-splitting rules using  $m = 20$  and  $M = 50$ . In particular, it shows the space decomposition for this example dataset resulting from the use of the R\*-tree (Figure 2.79(b)) in comparison to that resulting from the use of an R-tree that makes use of the linear cost (Figure 2.79(c)) and quadratic cost (Figure 2.79(d)) node-splitting algorithms. Notice the squarelike boxes corresponding to nodes at the bottom level of

Figure 2.77  
The bounding boxes corresponding to the first level of aggregation for an R\*-tree for the collection of 22 rectangles in Figure 2.71.

Figure 2.78  
The bounding boxes corresponding to the first level of aggregation for an R-tree built using different node-splitting policies: (a) exhaustive, (b) linear, (c) quadratic, and (d) the linear algorithm of [60] for the collection of 22 rectangles in Figure 2.71.

the R\*-tree and the small amount of overlap between them. Again, as in the example in Figures 2.77 and 2.78, it is quite clear that the R\*-tree behaves best.

Empirical studies have shown that use of the R\*-tree node-splitting algorithm instead of the conventional linear and quadratic cost R-tree node-splitting algorithms leads to a reduction in the space requirements (i.e., improved storage utilization) ranging from 10% to 20% [152, 866], while requiring significantly more time to build the R\*-tree [866]. The effect of the R\*-tree node-splitting algorithms vis-à-vis the conventional linear and quadratic cost node-splitting algorithms on query execution time is not so clear due to the need to take factors such as paging activity, and node occupancy, into account [152, 866, 1303].

Although the definition of the R\*-tree makes three changes to the original R-tree definition [791], it can be argued that the main distinction, from a conceptual point of view rather than based on its effect on performance, is in the way an overflowing node is split and in the way the bounding boxes are redistributed in the two resulting nodes.<sup>27</sup>

<sup>27</sup> On the other hand, it could also be argued that forced reinsertion is the most important distinction as it has the ability to undo the effect of some insertions that may have caused undesired increases in overlap and coverage.

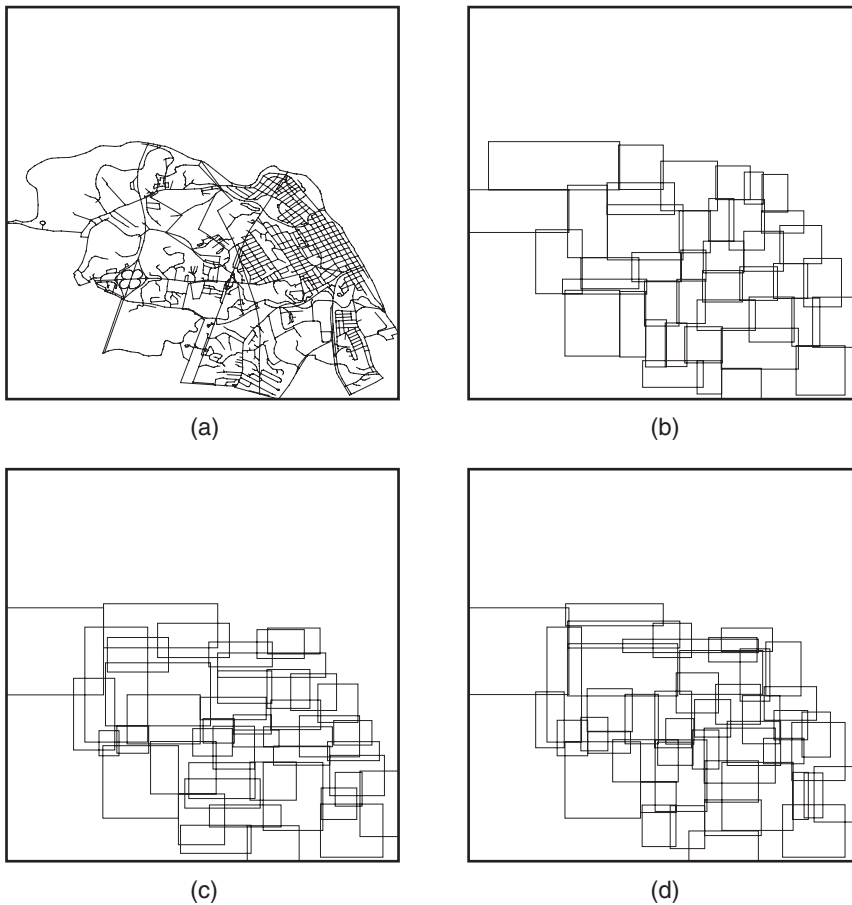

Figure 2.79  
(a) A sample collection of 1,700 line-shaped objects and the space decomposition resulting from the use of (b) an R\*-tree, as well as R-trees that make use of (c) linear cost and (d) quadratic cost node-splitting algorithms. All trees are order ( $m = 20$ ,  $M = 50$ ).

In particular, the original R-tree node-splitting algorithms [791] determine seeds, while the R\*-tree algorithm determines a split axis and an axis split value. The bounding boxes of the objects are redistributed about these seeds and axis, respectively. At this point, it is important to reemphasize that the motivation for these redistribution strategies is to avoid the exhaustive search solution that looks at all possible partitions.

The R\*-tree redistribution method first sorts the boundaries of the bounding boxes along each of the axes and then uses this information to find the split axis  $a$  (with respect to the minimum average perimeter of the bounding boxes of the resulting nodes) and split position (with respect to the minimal overlap once the split axis was chosen). This is a heuristic that attempts to approximate the solution to the  $d$ -dimensional problem (i.e., optimal partitioning with minimal coverage or overlap) with an approximation of the optimal one-dimensional solution along one of the axes (see Exercise 20). Intuitively, the validity of this approximation would appear to decrease as  $d$  (i.e., the dimensionality of the underlying space) increases since more and more splits are eliminated from consideration. However, the opposite conclusion might be true as it could be argued that although the number of eliminated splits grows exponentially with  $d$ , the majority of the eliminated splits are bad anyway. This is a problem for further study.

The remaining changes involving forced reinsertion and intelligent object insertion could have also been used in the R-tree construction algorithms. In particular, although the original R-tree definition [791] opts for minimizing coverage in determining the subtree into which an object is to be inserted, it does leave open whether minimizing

coverage or overlap is best. Similarly, using forced reinsertion does not change the R-tree definition. It can be applied regardless of how a node is split and which policy is used to determine the node into which the object is to be inserted. The evaluation of the R\*-tree conducted in [152] involves all three of these changes. An evaluation of R-trees constructed using these remaining changes is also of interest (see Exercises 5 and 6).

The node-splitting rules that form the basis of the R\*-tree have also been used in conjunction with some of the methods for constructing instances of the object-tree pyramid such as the Hilbert packed R-tree. In particular, DeWitt, Kabra, Luo, Patel, and Yu [489] suggest that it is not a good idea to fill each leaf node of the Hilbert packed R-tree to capacity. Instead, they pack each leaf node  $i$ , say up to 75% of capacity, and then, for each additional object  $x$  to be placed in  $i$ , they check if the bounding rectangle of  $i$  needs to be enlarged by too much (e.g., more than 20% in area [489]) in order to contain  $x$ , in which case they start packing another node. In addition, whenever a node has been packed, the contents of a small number (e.g., 3 [489]) of the most recently created nodes are combined into a large node, which is then resplit using the R\*-tree splitting methods. Although experiments show that these modifications lead to a slower construction time than that for the conventional Hilbert packed R-tree, the query performance is often improved (e.g., up to 20% in the experiments [489]).

### Exercises

1. Explain why forced reinsertion is unlikely to be useful in a B-tree (i.e., why it would not necessarily enable us to avoid having to split a B-tree node)?
2. In the study of the linear R-tree node-splitting algorithm that is based on reducing overlap [60], all comparisons were made with a quadratic algorithm that was based on minimizing coverage (i.e., [791]). Conduct a similar study as in Exercise 21 for both random and real data using an R\*-tree. This means that now the comparison uses a quadratic node-splitting algorithm that attempts to reduce both overlap and coverage as this is the motivation for the R\*-tree.
3. What is the total cost of inserting an object into an R\*-tree when no node splitting is needed?
4. When inserting an object into an R\*-tree, we insert its bounding box  $b$  into the leaf node  $p$  for whom the resulting bounding box has the minimum increase in the amount of overlap with  $p$ 's siblings that are children of nonleaf node  $s$ . This algorithm is quadratic in the number of entries in each node. We can improve on this bound by observing that insertion of  $b$  into the bounding boxes of sibling leaf nodes that are far from  $b$  is unlikely to result in minimizing the overlap. How would you take advantage of this to modify the insertion algorithm to avoid the quadratic cost and get an approximated minimum overlap solution?
5. Compare the performance of the R\*-tree with R-trees that make use of the linear and quadratic cost node-splitting algorithms proposed by Guttman [791], both of which are implemented with forced reinsertion. The comparison should be qualitative and quantitative. The qualitative comparison should examine the resulting space decomposition as in Figure 2.79. This can be achieved by choosing a sample dataset and drawing the output. The quantitative comparison should tabulate coverage and overlap, storage utilization, and the time for construction, as well as the times for intersection (i.e., determining all pairs of intersecting objects), window, and point queries. You should use real data, if possible.
6. Compare the performance of the R\*-tree with R-trees that make use of the linear and quadratic cost node-splitting algorithms proposed by Guttman [791], both of which are implemented with an intelligent object insertion procedure that is based on minimizing overlap in the case of leaf nodes, while minimizing the increase in area in the case of nonleaf nodes. Perform a similar comparison as in Exercise 5.
7. The R\*-tree node-splitting rule tries to address both the issue of minimizing coverage and of minimizing overlap. Thus, it does not make use of a rule that minimizes just one of these factors. Instead, it makes use of a two-stage node-splitting process, where the first stage finds the axis along which the split takes place, and the second stage calculates the position of the split. Given that we want a rule that minimizes coverage while still leading to a reduction in overlap, explain why it may be better for the first stage that chooses the split axis to try to

- minimize the average of the perimeters of the bounding boxes of the resulting nodes rather than to try to minimize the total area spanned (i.e., the coverage) by their bounding boxes?
8. Prove that once the faces of the bounding boxes have been sorted, when splitting an overflowing node in an  $R^*$ -tree of order  $(m, M)$  in  $d$  dimensions, the split axis can be computed in  $O(d \cdot M)$  time.
  9. The first stage of the  $R^*$ -tree node-splitting algorithm determines the axis  $a$  for which the average of the perimeters of the bounding boxes of the two nodes is the smallest, and the second stage calculates a split position  $s$  along axis  $a$  for which the amount of overlap between their bounding boxes is the smallest. Suppose that we modify the first stage of the  $R^*$ -tree node-splitting algorithm to find the split axis  $a$  having the split position  $s'$  for which the perimeter of the bounding boxes resulting from the split is the smallest. What is the drawback of this approach with respect to the second stage of the node-splitting algorithm?
  10. Suppose that you use the method described in Exercise 9 to determine the split axis when an  $R^*$ -tree node overflows. In particular, it finds the split axis  $a$  having the split position  $s'$  for which the perimeter of the bounding boxes resulting from the split is the smallest. The second stage calculates a new (possibly different) split position  $s$  along axis  $a$  for which the amount of overlap between their bounding boxes is the smallest. Use the split position  $s'$  in the second stage, and dispense with the search for the split position that minimizes overlap. Explain why  $s'$  may not necessarily minimize overlap? Give an example of this phenomenon.
  11. Despite the result of Exercise 10, compare the performance of using it with the variant described in Exercise 9 that computes the split position in the second stage and also with the conventional  $R^*$ -tree definition that uses the split axis for which the average perimeter of the bounding boxes over all of the possible split positions for each axis is a minimum.
  12. Repeat Exercise 5 with the variation of the  $R^*$ -tree definition given in Exercise 9.
  13. Repeat Exercise 6 with the variation of the  $R^*$ -tree definition given in Exercise 9.
  14. Repeat Exercise 5 with the variation of the  $R^*$ -tree definition given in Exercise 10.
  15. Repeat Exercise 6 with the variation of the  $R^*$ -tree definition given in Exercise 10.
  16. Suppose that the node-splitting algorithm in the  $R^*$ -tree is modified to find the split axis  $a$  having the split position  $s$  for which the amount of overlap between the bounding boxes of the two resulting nodes is the smallest, and also use  $s$  as the position of the split. Compare the performance of using it with the variant described in Exercise 9 that finds the split axis  $a$  having the split position  $s'$  for which the perimeter of the bounding boxes resulting from the split is the smallest. Also compare it with the conventional  $R^*$ -tree definition that uses the split axis for which the average perimeter of the bounding boxes over all of the possible split positions for each axis is a minimum.
  17. Repeat Exercise 5 with the variation of the  $R^*$ -tree definition given in Exercise 16.
  18. Repeat Exercise 6 with the variation of the  $R^*$ -tree definition given in Exercise 16.
  19. Suppose that we modify the second stage of the  $R^*$ -tree node-splitting algorithm so that, instead of choosing the split position for which the amount of overlap between the bounding boxes of the resulting nodes is the smallest, we choose the position for which the overlap along the split axis is minimized. This technique is useful if we choose to organize the elements of each  $R^*$ -tree node using a k-d tree so that searching within the node is fast. In fact, this technique is used in the hybrid tree [317] (see Sections 1.7.1.2 of Chapter 1 and 4.4.3 of Chapter 4), which is a combination of an R-tree and k-d-B-tree for high-dimensional point data. First, project the bounding boxes on the split axis (i.e., the one-dimensional edges of the bounding boxes that are collinear with the split axis), thereby forming line segments. Second, sort the line segments into two sets on the basis of their left and right edges from left to right and right to left, respectively. Third, choose segments from the two sorted lists in alternating fashion, forming a left and a right partition until the minimum storage utilization constraints are satisfied. At this point, insert the remaining line segments in the partition that needs to be enlarged the least without worrying about the utilization. Once the minimum storage utilization constraints are satisfied, is the order in which the remaining line segments are inserted into the two partitions important?
  20. Given a set of  $M$  bounding boxes of two-dimensional objects, suppose that you want to subdivide the set into two nonempty sets so that the sum of the perimeters of their bounding

boxes is minimized subject to the node-utilization constraints. This is a variant of the method used by Beckmann et al. [152] in the  $R^*$ -tree that attempts to minimize the average perimeter of the bounding boxes of the two resulting nodes for all possible splits along the different axes. For two-dimensional data, this variant would be incorporated in the  $R^*$ -tree node-splitting algorithm by decomposing this problem into four plane-sweep subproblems, one in each of the two dimensions and two sweep directions, as follows. Sort the left sides of all of the bounding boxes and then sweep a vertical line across this set stopping at every left boundary  $l$ , treating it as the separator between two sets  $L$  and  $R$  containing all of the bounding boxes whose left sides are less than or equal to  $l$  and those whose left sides are greater than  $l$ , respectively. Compute the sum of the perimeters of the bounding boxes of  $L$  and  $R$  retaining the position if it is smaller than the previous minimum. Repeat this sort-and-sweep process for the right sides of the bounding boxes and, likewise, for the top and bottom sides of the bounding boxes. Is this approach guaranteed to find the partitioning for which the sum of the perimeters of their bounding boxes is a minimum? In other words, is it possible that a better partition can be obtained where, without loss of generality, it is not the case that one of the nodes contains all of the bounding boxes whose left (right) sides are less than or equal to  $l$  and the other node contains all of the bounding boxes whose left (right) sides are greater than  $l$ ? Note that the  $R^*$ -tree algorithm only examines  $dM$  of the number of possible partitions, which is much smaller than the maximum number of possible partitions (see Exercise 8). Prove that this guarantee holds, or give a counterexample. If the guarantee does not hold, can you obtain an optimal solution by the use of an auxiliary data structure, such as a segment tree [166] or an interval tree [534, 537, 538], to keep track of the bounding boxes that are still active during the sweep process?

21. Repeat Exercise 20 for the problem of subdividing a set of  $M$  bounding boxes into two nonempty sets so that instead of minimizing the sum of their perimeters, we now try to minimize the area common to their bounding boxes.
22. As we saw, the  $R^*$ -tree algorithms try to minimize the coverage, perimeter, and overlap in the node insertion process. Each of these factors is taken into account separately in different stages of the algorithm. An alternative approach is to define an objective function that takes these three factors, with appropriate weights, into account simultaneously and to try to minimize it. This objective function is applied when determining which node is to contain the new object, as well as during the node-splitting process. Investigate the use of this approach by defining some factors, and compare your results with the  $R^*$ -tree node insertion algorithm that we described.
23. Measure the performance of point queries and window queries (in terms of the number of  $R$ -tree nodes visited) on packed  $R$ -trees for two-dimensional rectangle objects of your choice that have been transformed into the four representative point transformations described in the text and sorted using the row, Morton, and Peano-Hilbert orders. Generate the queries for uniformly distributed points and, likewise, for windows whose centroids and horizontal and vertical extents are drawn from a uniform distribution. Compare your results with those for an  $R$ -tree constructed using the  $R^*$ -tree, linear cost, and quadratic cost node-splitting algorithms where the objects are inserted in the same order as in the packed  $R$ -tree for the corresponding space-ordering technique.

#### 2.1.5.2.5 Bulk Insertion

Up to now, our discussion of building the object-tree pyramid has been differentiated on the basis of whether it is done in a static or a dynamic environment. The static methods, exemplified by the various packing methods, such as the packed  $R$ -tree, Hilbert packed  $R$ -tree, and the STR method, were primarily motivated by a desire to build the structure as quickly as possible. This is in addition to the secondary considerations of maximizing storage utilization and, possibly, faster query performance as a result of a shallower structure since each node is filled to capacity, thereby compensating for the fact that these methods may result in more coverage and overlap. The dynamic methods, exemplified by the  $R$ -tree and the  $R^*$ -tree, were motivated equally by a desire to avoid rebuilding the structure as updates occur (primarily as objects are added and, to a lesser extent, deleted) and by a desire for faster query performance due to a reduction of coverage and overlap.

At times, it is desired to update an existing object-tree pyramid with a large number of objects at once. Performing these updates one object at a time using the implementations of the dynamic methods described above can be expensive. The CPU and I/O costs can be lowered by grouping the input objects prior to the insertion. This technique is known as *bulk insertion*. It can also be used to build the object-tree pyramid from scratch, in which case it is also known as *bulk loading*. In fact, we have seen several such techniques already in our presentation of the static methods that employ packing. The difference is that, although the bulk loading methods that we discuss in Section 2.1.5.2.6 are based on grouping the input objects prior to using one of the dynamic methods of constructing the object-tree pyramid, the grouping does not involve sorting the input objects, which is a cornerstone of the bulk loading methods that employ packing. We discuss the bulk insertion methods first.

A simple bulk insertion idea is to sort all of the  $m$  new objects to be inserted according to some order (e.g., Peano-Hilbert) and then insert them into an existing object-tree pyramid in this order [985]. The rationale for sorting the new objects is to have each new object be relatively close to the previously inserted object so that, most of the time, the nodes on the insertion path are likely to be the same, which is even more likely to be the case if some caching mechanism is employed. Thus, the total number of I/O operations is reduced. This technique works fine when the number of objects being inserted is small relative to the total number of objects. Also, it may be the best choice when the collection of new objects is spread over a relatively large portion of the underlying space, as, in such cases, the use of other methods (see below) may lead to excessive overlap (but see discussion of generalized bulk insertion (GBI) [381] below). It can be used with any of the methods of building an object-tree pyramid. A related approach, which also uses sorting, can be applied when the existing object-tree pyramid was built using one of the static methods, such as a packed R-tree. In this case, the new packed R-tree can be constructed by merging the sorted list of new objects with the sorted list of the existing objects, which is obtained from the leaf nodes of the existing packed R-tree. This approach is used in the cubetree [1587], a packed R-tree-like structure for data warehousing and online analytic processing (OLAP) [329] applications, which is not discussed further here.

Another related bulk insertion method, due to Kamel, Khalil, and Kouramajian [985], first orders the new objects being inserted according to the Peano-Hilbert order and then aggregates them into leaf nodes, where each node is filled to a predetermined percentage of the capacity (e.g., 70%) as if we are building just the leaf nodes of a Hilbert packed R-tree for the new objects. These leaf nodes are inserted into an object-tree pyramid in the order in which they were built. Intuitively, the algorithm should yield a speedup of the order of the number of objects that can fit in a leaf node compared to inserting the objects one by one. Unfortunately, the algorithm is also likely to increase the degree of overlap in the existing object-tree pyramid and thus produce a worse index in terms of query performance. The reason for the increase in overlap is that the new leaf nodes may overlap existing leaf nodes in the object-tree pyramid. This is compounded by the fact that two new objects that are adjacent in Peano-Hilbert order (and thus inserted into the same node) may actually be far apart, leading to leaf nodes with large bounding rectangles. Empirical results reported support this observation [985]. In fact, the authors propose an alternative method of inserting the actual objects one at a time after sorting when the set of new objects is small or when it is spread over a large area as described above.

The *Small-Tree-Large-Tree* (STLT) method of Chen, Choubey, and Rundensteiner [347] can be viewed as a generalized variant of the method of Kamel, Khalil, and Kouramajian [985]: instead of inserting the leaf nodes of the object-tree pyramid  $T$  of the new data, it just inserts the root of  $T$ . First, an object-tree pyramid is built for the new data using any of the static or dynamic methods. Next, the root of the new object-tree pyramid  $T$ , of height  $h_T$ , is inserted into the existing object-tree pyramid  $E$ , of height  $h_E$ , using one of several dynamic R-tree insertion algorithms so that  $T$  ends up as an

element in a node  $Q$  in  $E$  at depth  $h_E - h_T - 1$ . In other words, the leaf nodes of  $T$  are now at the same depth as the leaf nodes of  $E$ . Once the node  $Q$  has been determined, check if the insertion of  $T$  in  $Q$  will cause  $Q$  to overflow. If this is the case, then heuristics employing a combination of traditional dynamic R-tree and B-tree insertion techniques are used to make space for  $T$ . These heuristics attempt some local reorganization of the subtree rooted at  $Q$  in order to ensure that  $T$  can be inserted in one operation.

Although using the STLT method leads to significantly faster insertion compared with the dynamic insertion (i.e., when the objects are inserted one by one) when the new data covers the same area as the existing data, there is a considerable degradation in query performance due to the significant overlap between the nodes in  $T$  and  $E$ . In order to overcome this problem, Choubey, Chen, and Rundensteiner [381] introduce a new method (termed *Generalized Bulk Insertion* (GBI)) that uses cluster analysis to divide the new data into clusters. Small clusters (e.g., containing just one point) are inserted using a regular dynamic insertion method. On the other hand, for larger clusters, a tree is built and inserted using the STLT method. In other words, the STLT method is really a subcomponent of the GBI method. This reduces the amount of overlap, which can be very high for the STLT method. On the other hand, if there is little overlap between the nodes in  $T$  and  $E$ , then the query performance of the STLT method should be satisfactory.

It is interesting to observe the close relationship between the above three methods. In particular, all three methods reorganize the existing object-tree pyramid. They differ in the extent to which the new objects are interleaved with the objects in the existing object-tree pyramid. The cubetree method of Roussopoulos, Kotidis, and Roussopoulos [1587], as well as the one-object-at-a-time alternative method of Kamel, Khalil, and Kouramajian [985] that we described, merges the list of the individual new objects with the existing objects. On the other hand, the one-node-at-a-time method of Kamel, Khalil, and Kouramajian [985] and the GBI method of Chen, Choubey, and Rundensteiner [347] first build a partial or full object-tree pyramid for the new objects. The latter two methods differ in what parts of the new object-tree pyramid for the new objects are inserted into the existing tree. In particular, the method of Kamel, Khalil, and Kouramajian [985] inserts only the leaf nodes of the new object-tree pyramid. On the other hand, the GBI method of Chen, Choubey, and Rundensteiner [347] inserts only the root node of the new object-tree pyramid.

The result is that, in terms of construction time, the methods range in speed with the cubetree of Roussopoulos, Kotidis, and Roussopoulos [1587] and the one-object-at-a-time alternative method of Kamel, Khalil, and Kouramajian [985] as the slowest, followed by the one-node-at-a-time method of Kamel, Khalil, and Kouramajian [985] and the method of Chen, Choubey, and Rundensteiner [347] as the fastest. In contrast, query performance is best for the cubetree method of Roussopoulos, Kotidis, and Roussopoulos [1587] and the one-object-at-a-time alternative method of Kamel, Khalil, and Kouramajian [985] since the resulting tree is identical to that obtained had we constructed an object-tree pyramid for the new and old objects together using the same insertion order. The one-node-at-a-time method of Kamel, Khalil, and Kouramajian [985] is better than the GBI method of Chen, Choubey, and Rundensteiner [347] because more restructuring of the existing tree takes place. In fact, the method of Chen, Choubey, and Rundensteiner [347] will most likely result in very poor query performance after several successive applications because the amount of overlap will be quite high. Thus, we see that the costs of these methods reflect the trade-offs that must be made in choosing between fast construction and fast query performance.

### Exercise

1. Perform an empirical comparison of the performance of the one-object-at-a-time and one-node-at-a-time methods of Kamel, Khalil, and Kouramajian [985] with the GBI method of Chen, Choubey, and Rundensteiner [347] for a window query of different window sizes.

### 2.1.5.2.6 Bulk Loading

The bulk loading methods that we describe [87, 194] are quite different from the bulk insertion methods described in Section 2.1.5.2.5 as the individual objects are inserted using the dynamic insertion rules. In particular, the objects are not preprocessed (e.g., via an explicit sorting step or aggregation into a distinct object-tree pyramid) prior to insertion as is the case for the bulk insertion methods. In particular, the sorting can be viewed as a variant of a lazy evaluation method, where the sorting is deferred as much as possible. Nevertheless, at the end of the bulk loading process, the data is ordered on the basis of the underlying tree structure and hence can be considered sorted. These methods are general in that they are applicable to most balanced tree data structures that resemble a B-tree, including a large class of multidimensional index structures, such as the R-tree. They are based on the general concept of the buffer tree of Arge [85], in which case each internal node of the buffer tree structure contains a buffer of records stored on disk. A main memory buffer is employed when transferring records from the buffer of a node to the buffers of its child nodes.

The basic idea behind the methods based on the buffer tree is that insertions into each nonleaf node of the buffer tree are batched. In particular, insertions into the buffer occur in association with the root node and slowly trickle down the tree as buffers are emptied when they are full. The buffers enable the effective use of available main memory, thereby resulting in large savings in I/O cost over the regular dynamic insertion method (although the CPU cost may be higher, in part, due to the large fanout when using one of the methods [194], as we shall see below). Nevertheless, the actual execution of a single insertion could be slower in comparison to a non-bulk loading method in the case that many overflowing buffers need to be trickled down.

When a buffer  $b_r$  associated with a nonleaf node  $r$  is full, the contents of  $b_r$  are distributed to the children of  $r$  (but see Exercise 1). During this process, only one block (i.e., the amount of data that can be transferred in one I/O operation from the disk to main memory) of records from the buffer of  $r$  needs to be in main memory, with one block of records from the buffers of each of its children. The distribution process depends on whether the children are nonleaf nodes or leaf nodes.

- If the children are nonleaf nodes, then the contents of  $b_r$  are inserted into the buffer  $b_{s_i}$  associated with one of the  $m$  children of  $r$ , say  $s_i$  ( $1 \leq i \leq m$ ). Once the contents of all of the blocks in  $b_r$  have been emptied, a check is made to see if any of the buffers, say  $b_{s_i}$ , associated with the children of  $r$  are full. If they are, then the process is reapplied to the blocks in  $b_{s_i}$  and possibly to their children if they are full, and so on, until leaf nodes are encountered, at which time a node split is needed if the nodes contain more entries than the block size.
- If the children are leaf nodes, then the content of  $b_r$  is inserted into the leaf nodes (recall that only the nonleaf nodes have buffers). During the distribution process, some children of  $r$  (which are leaf nodes) may be split. If such a split causes  $r$  to have more than  $c$  children, then  $r$  is also split, and the remaining contents of  $b_r$  are distributed into the buffers of the two nodes resulting from the split.

It may be somewhat difficult to understand fully the actual process from the above recursive definition. In simpler terms, the process works as follows. We keep inserting into the buffer of the root node until its buffer is full. At this time, we distribute its content, as described above, and possibly reapply the process to the children if they are full, and so on, until encountering leaf nodes, at which time a node split is needed if the nodes contain more entries than the block size. Once all full buffers have been emptied, the root's buffer is filled with more data, and the insertion process is repeated.

Once all of the objects in the dataset have been processed, a pass is made over the buffer associated with the root node, and the remaining entries are inserted into the appropriate children of the tree rooted at the node. The same process is applied to

the buffers associated with the children of the root and their descendants so that all nonempty buffers in the tree have been emptied. At this point, the leaf nodes of the object-tree pyramid have been constructed. Next, apply the same building process to the minimum bounding boxes of the leaf nodes, thereby constructing the level of the object-tree pyramid corresponding to the parents of the leaf nodes. This process is continued until the number of leaf nodes is less than the maximum capacity of an object-tree pyramid leaf node.

Buffer tree methods try to make maximum use of available memory by increasing the fanout  $c$  of each internal node of the tree structure. When distributing the contents of the buffer of an internal node  $s$  to the buffers of its children, we need one block of size  $B$  (i.e., the amount of space occupied by one disk block) for the internal node  $s$  and one block for each of its  $c$  children for reading  $s$ 's buffer and writing the new buffer contents for the children. Thus, the internal memory requirements are  $B \cdot (c + 1)$ , in addition to the size of each internal node. Given an internal memory buffer of size  $M$ , we would choose  $c$  to be large enough so that the memory requirements are as close to  $M$  as possible. Note that  $c$  is much larger than  $B$ , which means that the intermediate object-tree pyramid is of a shallower maximum depth than the final object-tree pyramid. Thus, when buffer tree methods are applied to an object-tree pyramid, the intermediate tree has a larger fanout than the final object-tree pyramid.

Recall that the above method, proposed by van den Bercken, Seeger, and Widmayer [194], builds the object-tree pyramid recursively in stages in a bottom-up manner. There is one stage per level of the final object-tree pyramid, that has maximum depth  $d$ . At each stage  $i$ , an intermediate tree structure is built where the nodes at the deepest level correspond to the nodes at depth  $d - i$  of the final object-tree pyramid. The drawbacks of this method are the need to build an intermediate structure and the multiple passes. These drawbacks are overcome by Arge, Hinrichs, Vahrenhold, and Vitter [87] by attaching buffers to nodes only at certain levels of a regular object-tree pyramid structure (i.e., the nodes have a normal amount of fanout to fill a disk page, whereas, in the method of van den Bercken et al. [194], the fanout depends on the amount of available main memory). In essence, assuming an intermediate tree fanout  $c$  and object-tree pyramid node fanout  $f$ , buffers are attached to object-tree pyramid nodes at depths where the total number of child nodes is approximately  $c^i$ . Such nodes are found at depths that are integer multiples of  $\log_f c$ . Therefore, all of the nodes of the object-tree pyramid exist as we distribute the objects, thereby avoiding the need to build the intermediate structure and thus enabling the object-tree pyramid to be built in one pass. In addition, as we will see below, this also makes the method of Arge et al. [87] suitable for bulk insertion.

The method of Arge et al. [87] has some other differences from the method of van den Bercken et al. [194], including the maximum size of the buffers and the specific details of how buffers are emptied. In particular, Arge et al. [87] propose to read the entire buffer contents to memory at the beginning of the distribution process rather than one block at a time. This reduces the overall seek time since it is paid only once rather than for each block. Furthermore, Arge et al. [87] also propose a method for increasing the storage utilization of the leaf nodes, which generally results in object-tree pyramids that have better query performance.

The construction of Arge et al. [87] yields the same object-tree pyramid as would have been obtained using conventional dynamic insertion methods without buffering (with the exception of the R\*-tree, where the use of forced reinsertion is difficult to incorporate in the buffering approach). In contrast, this is not the case for the method of van den Bercken et al. [194], where as soon as the first stage has been completed, the next stage makes use of the minimum bounding boxes of the nodes at the immediately lower level of the tree. In addition, the method of [87] supports bulk insertions (as opposed to just initial bulk-loading) and bulk queries, and, in fact, intermixed insertions and queries. In contrast, bulk insertions are not so easy to support with the method of van den Bercken et al. [194] because only the intermediate structures have buffers associated with the internal nodes, whereas the final object-tree pyramid has no buffers.

Bulk loading is generally not nonblocking, although it may appear to be nonblocking to the user in the sense that, since the insertion must trickle down to the leaf nodes of the structure, the trickling down could be implemented in such a way that it is transparent to the user. In particular, it could be implemented using a thread (e.g., [1030]), in which case the next insertion should wait until the current operation is completed, although other operations could be executed simultaneously, thereby leading to the impression that the algorithm is nonblocking.

### Exercise

1. When using the buffer tree method for the object-tree pyramid, if we always completely empty the buffer of node  $r$  when distributing its contents to its children, we may find that the buffers of some of the children of  $r$  will overflow before we have finished distributing the contents of  $r$ . How would you avoid this problem?

### 2.1.5.2.7 Shortcomings and Solutions

In this section, we point out some of the shortcomings of the object-tree pyramid, as well as some of the solutions. As we are dealing with the representations of objects, which are inherently of low dimension, we do not discuss the shortcomings and solutions for high-dimensional data, which are discussed in Section 4.4 of Chapter 4 (e.g., the X-tree [190]). One of the drawbacks of the object-tree pyramid (i.e., the R-tree, as well as its variants, such as the R\*-tree) is that as the node size (i.e., page size—that is,  $M$ ) gets large, the performance starts to degrade. This is somewhat surprising because, according to conventional wisdom, performance should increase with node size as the depth of the tree decreases, thereby requiring fewer disk accesses. The problem is that as the node size increases, operations on each node take more CPU time. This is especially true if the operation involves search (e.g., finding the nearest object to a point) as the bounding boxes in each node are not ordered [864].

This problem can be overcome by ordering the bounding boxes in each node using the same ordering-based aggregation techniques that were used to make the object-tree pyramid more efficient in responding to the location query. For example, we could order the bounding boxes by applying Morton or Peano-Hilbert space ordering to their centroids. We term the result an *ordered R-tree* (see Exercise 1). Interestingly, the ordered R-tree can be viewed as a hybrid between an object B<sup>+</sup>-tree and an R-tree in the sense that nodes are ordered internally (i.e., by their constituent bounding box elements) using the ordering of the object B<sup>+</sup>-tree, while they are ordered externally (i.e., vis-à-vis each other) using an R-tree.

Although the R-tree is height balanced, the branching factor of each node is not the same. Recall that each node contains between  $m$  and  $M$  objects or bounding boxes. This has several drawbacks. First, it means that the nodes are not fully occupied, thereby causing the tree structure to be deeper than it would be had the nodes been completely full. Therefore, the number of data objects in the leaf nodes of the descendants of sibling nonleaf nodes is not the same and, in fact, can vary quite greatly, thereby leading to imbalance in terms of the number of objects stored in different subtrees. This can have a detrimental effect on the efficiency of retrieval. Second, satisfying the branching factor condition often requires compromising the goal of minimizing total coverage, overlap, and perimeter. The packed R-tree and the Hilbert packed R-tree are two methods to overcome this problem as they initially have a branching factor of  $M$  at all but the last node at each level. However, they are not necessarily designed to meet our goals of minimizing total coverage, overlap, and perimeter.

The S-tree [22] is an approach to overcome the above drawbacks of the R-tree and its packed variants by trading off the height-balanced property in return for reduced coverage, overlap, and perimeter in the resulting minimum bounding boxes. The S-tree has the property that each node that is not a leaf node or a penultimate node (i.e., a node

whose children are all leaf nodes) has  $M$  children. In addition, for any pair of sibling nodes (i.e., with the same parent)  $s_1$  and  $s_2$  with  $N_{s_1}$  and  $N_{s_2}$  objects in their descendants, respectively, we have that  $p \leq N_{s_1}/N_{s_2} \leq 1/p$  ( $0 < p \leq 0.5$ ), where  $p$ , termed the *skew factor*, is a parameter that is related to the skewness of the data and governs the amount of trade-off, thereby providing a worst-case guarantee on the skewness of the descendants of the node. In particular, the number of objects in the descendants of each of a pair of sibling nodes is at least a fraction  $p$  of the total number of objects in the descendants of both nodes. This guarantee is fairly tight when  $p$  is close to 0.5, while it is quite loose when  $p$  is small. In other words, when  $p = 0.5$ , the difference in the number of objects that will be found in the subtrees of a pair of sibling nodes is within a factor of 2, whereas this ratio can get arbitrarily large in a conventional R-tree (see Exercise 6). In addition, the S-tree construction process makes use of an overlap factor parameter  $o$  (ranging between 0 and 1) defined to be the area covered by the intersection of the bounding boxes divided by the sum of the corresponding areas of the bounding boxes.

The *cost-based unbalanced R-tree* (CUR-tree) of Ross, Sitzmann, and Stuckey [1578] is another variant of an R-tree where the height-balanced requirement is relaxed in order to improve the performance of point and window queries in an environment where all the data is in main memory. In particular, the CUR-tree is constructed by considering the following two factors:

1. A cost model for the data structure (i.e., the R-tree) that accounts for the operations, such as reading the node and making the comparisons needed to continue the search
2. A query distribution model that includes uniformly distributed points and rectangular windows, as well as a skewed-point distribution

Unlike a conventional R-tree, operations on a CUR-tree are invoked not only upon overflow (and to a lesser extent underflow). Instead, upon every insertion and deletion, every node on the insertion path is examined to determine if its entries should be rearranged to lower the cost function. The result is that nodes can be split, and their entries can be promoted or demoted. Ross et al. [1578] compared the CUR-tree with the conventional R-tree and the R\*-tree and found the performance of the CUR-tree for search queries to be better. Of course, the insertion time for the CUR-tree was found to be slower than both the conventional R-tree and the R\*-tree. Note again that these comparisons and the cost model all assume that the data is in main memory, thereby somewhat limiting their applicability.

García, López, and Leutenegger [681] propose to improve the query performance of R-trees by restructuring the tree. Such restructuring can be performed after an R-tree has been built (termed *postoptimization*), say, for example, using one of the methods outlined in Section 2.1.5.2.6 (i.e., a static R-tree). Alternatively, a dynamically constructed R-tree can be restructured gradually as it is being updated (termed *incremental refinement*). Their approach consists of selecting a node  $e$  to be restructured and then applying the restructuring process to  $e$  and its ancestors. Several alternatives are proposed for choosing  $e$ ; the simplest is to choose a point  $p$  at random and find a leaf node  $e$  that contains  $p$ . Once  $e$  has been determined,  $e$  is restructured by considering the siblings that overlap  $e$  (after recursively restructuring  $e$ 's ancestors in the same manner). For each such sibling  $s$ , the entries in  $s$  are inserted into  $e$ , and  $s$  is deleted (i.e.,  $s$  is merged with  $e$ ). If  $e$  overflows, then split  $e$  (e.g., using an optimal node-splitting algorithm; see Section 2.1.5.2.3) and arbitrarily set  $e$  to one of the resulting nodes (while the other node is marked as having been processed already). Note that merging and resplitting overlapping sibling nodes  $e$  and  $s$  tends to reduce the amount of overlap among  $e$  and  $s$  (as resulting from the resplitting).

In the static case (i.e., postoptimization), García et al. [681] suggest performing  $n$  restructuring operations for a tree of  $n$  nodes. In the dynamic case (i.e., incremental refinement), García et al. [681] suggest performing a restructuring operation with some fixed probability for each insertion operation (e.g., so that 1 out of every 20 insertions leads to restructuring, on the average). Also, García et al. [681] point out that restructuring of an R-tree can be invoked during idle periods (e.g., at night). In an empirical study,

for both the static and dynamic cases, such restructuring was found to reduce the query cost (in terms of the number of disk accesses) by 25–50%, while the cost of restructuring was relatively modest (i.e., 10% in the case of incremental refinement).

At a first glance, restructuring is similar to forced reinsertion in the case of an R\*-tree (see Section 2.1.5.2.4). However, upon closer scrutiny, they are quite different. Forced reinsertion takes individual node entries and reinserts them at the root. In contrast, restructuring operates on groups of node entries by repeatedly merging and resplitting them, as necessary, in order to obtain better query performance through greater storage utilization and less overlap.

A shortcoming of all of the representations that are based on object hierarchies (i.e., including all of the R-tree variants) is that when the objects are not hyperrectangles, use of the bounding box approximation of the object eliminates only some objects from consideration when responding to queries. In other words, the actual execution of many queries requires knowledge of the exact representation of the object (e.g., the location query). In fact, the execution of the query may be quite complex using this exact representation. At times, these queries may be executed more efficiently by decomposing the object further into smaller pieces and then executing the query on the individual pieces, thereby overcoming the shortcoming associated with the approximation.

Some suggested implementations include a decomposition into shapes, such as triangles, trapezoids, convex polygons, and so on (e.g., [261, 1081]), as mentioned in Section 2.1.3 when discussing a representation of nonorthogonal objects (i.e., objects whose sides are not orthogonal) using a decomposition into nonorthogonal blocks. The TR\*-tree [261, 1692] is an example of such a representation that decomposes each object in an R\*-tree into a collection of trapezoids. The DR-tree [1142] is a related approach where the minimum bounding box is recursively decomposed into minimum bounding boxes until the volume of each box is less than a predefined fraction of the volume of the initial bounding box. The result of the decomposition process is represented as a binary tree, which is stored separately from the hierarchy that contains the minimum bounding boxes of the objects and can be processed in memory once it has been loaded. Of course, these techniques are also applicable to other R-tree variants.

### Exercises

1. Implement an ordered R-tree using the different node-splitting algorithms (i.e., R\*-tree, linear cost, and quadratic cost), and compare its performance with the corresponding nonordered versions. Implement the ordered R-tree by applying the Morton and Peano-Hilbert space orderings to their representative points. Use the following two types of representative points for the bounding boxes:
  - (a) The centroid
  - (b) The centroid and the horizontal and vertical extents (i.e., the horizontal and vertical distances from the centroid to the relevant sides)

The comparison should include the time for construction, as well as the times for intersection (i.e., determining all pairs of intersecting objects), window, point, and nearest object queries. You should use real data, if possible (e.g., a collection of rectangle objects or lines).
2. Write an algorithm to perform a point query in an ordered R-tree.
3. Write an algorithm to perform a window query in an ordered R-tree.
4. Write an algorithm to find the nearest object to a point in an ordered R-tree.
5. Write an algorithm to solve the rectangle intersection problem for an ordered R-tree.
6. Consider an R-tree where each node contains between  $m$  and  $M$  objects or bounding boxes. The S-tree is designed to provide a guarantee of the relative difference in the number of objects found in the subtrees of two sibling nodes. In particular, for skewness factor  $p$ , given a pair of sibling nodes  $s_1$  and  $s_2$  with  $N_{s_1}$  and  $N_{s_2}$  objects in their descendants, respectively, we have that  $p \leq N_{s_1}/N_{s_2} \leq 1/p$  ( $0 < p \leq 0.5$ ). Show that the ratio  $N_{s_1}/N_{s_2}$  can get arbitrary large in an R-tree.

### 2.1.5.3 Disjoint Object-Based Hierarchical Interior-Based Representations (k-D-B-Tree, R<sup>+</sup>-Tree, and Cell Tree)

In our descriptions of the object pyramid and the object-tree pyramid in Section 2.1.5.2, we observed that we may have to examine all of the bounding boxes at all levels when attempting to determine the identity of the object  $o$  that contains location  $a$  (i.e., the location query). This was caused by the fact that the bounding boxes corresponding to different nodes may overlap. Because each object is associated with only one node while being contained in possibly many bounding boxes (e.g., in Figure 2.75, rectangle 1 is contained in its entirety in R1, R2, R3, and R5), the location query may often require several nonleaf nodes to be visited before determining the object that contains  $a$ . This problem also arises in the R-tree, as seen in the following example.

Suppose that we wish to determine the identity of the rectangle object(s) in the collection of rectangles given in Figure 2.75 that contains point Q at coordinate values (22,24). We first determine that Q is in R0. Next, we find that Q can be in both or either R1 or R2, and thus we must search both of their subtrees. Searching R1 first, we find that Q can be contained only in R3. Searching R3 does not lead to the rectangle that contains Q, even though Q is in a portion of rectangle D that is in R3. Thus, we must search R2, and we find that Q can be contained only in R5. Searching R5 results in locating D, the desired rectangle. The drawback of the R-tree, as well as of other representations that make use of an object pyramid, is that, unlike those based on the cell pyramid, they do not result in a disjoint decomposition of space. Recall that the problem is that an object is associated with only one bounding box (e.g., rectangle D in Figure 2.75 is associated with bounding box R5; yet, it overlaps bounding boxes R1, R2, R3, and R5). In the worst case, this means that when we wish to respond to the location query (e.g., given a point, determining the containing rectangle in a rectangle database or an intersecting line in a line segment database, etc., in the two-dimensional space from which the objects are drawn), we may have to search the entire database. Thus, we need a hierarchy of disjoint bounding boxes.

An obvious way to overcome this drawback is to use one of the hierarchical image-based representations described in Section 2.1.5.1. Recall that these representations make use of a hierarchy of disjoint cells that completely spans the underlying space. The hierarchy consists of a set of sets  $\{C_j\}$  ( $0 \leq j \leq n$ ), where  $C_n$  corresponds to the original collection of cells, and  $C_0$  corresponds to one cell. The sets differ in the number and size of the constituent cells at the different depths, although each set is usually a containment hierarchy in the sense that a cell at depth  $i$  usually contains all of the cells below it at depth  $i + 1$ . The irregular grid pyramid is an example of such a hierarchy.

A simple way to adapt the irregular grid pyramid to our problem is to overlay the decomposition induced by  $C_{n-1}$  (i.e., the next to the deepest level) on the bounding boxes  $\{b_i\}$  of the objects  $\{o_i\}$ , thereby decomposing the bounding boxes and associating each part of the bounding box with the corresponding covering cell of the irregular grid pyramid. Note that we use the set at the next deepest level (i.e.,  $C_{n-1}$ ) rather than the set at the deepest level (i.e.,  $C_n$ ) as the deepest level contains the original collection of unit-sized cells  $c_{nk}$  and thus does not correspond to any aggregation. The cells  $c_{jk}$  at the remaining levels  $j$  ( $0 \leq j \leq n - 2$ ) are formed in the same way as in the irregular grid pyramid—that is, they contain the union of the objects corresponding to the portions of the bounding boxes associated with the cells making up cell  $c_{jk}$ . Using our terminology, we term the result an *irregular grid bounding-box pyramid*. It should be clear that the depth of the irregular grid bounding-box pyramid is one less than that of the corresponding irregular grid pyramid.

The definition of the irregular grid pyramid, as well as of the other hierarchical image-based representations, stipulates that each unit-sized cell is contained in its entirety in one or more objects. Equivalently, a cell cannot be partially in object  $o_1$  and partially in object  $o_2$ . The same restriction also holds for block decompositions, which are not hierarchical (see Section 2.1.2). In contrast, in the case of the irregular grid bounding-

box pyramid, the fact that the bounding boxes are just approximations of the objects enables us to relax this restriction in the sense that we allow a cell (or a block in the case of the block decompositions of Section 2.1.2) to contain parts of the bounding boxes of several objects. In other words, cell (or block)  $b$  can be partially occupied by part of the bounding box  $b_1$  of object  $o_1$ , by part of the bounding box  $b_2$  of object  $o_2$ , and it may even be partially empty.

The irregular grid bounding-box pyramid is a hierarchy of grids, although the grid sizes are permitted to vary in an arbitrary manner between levels. This definition is still overly restrictive in the sense that we want to be able to aggregate a varying, but bounded, number of cells at each level (in contrast to a predefined number) that depends on the number of bounding boxes or objects that are associated with them so that we can have a height-balanced dynamic structure in the spirit of the B-tree. We also wish to use a hierarchy that makes use of a different block decomposition rule (e.g., a k-d tree, generalized k-d tree, point quadtree, bintree, region quadtree, thereby forming a bounding-box variant of the cell-tree pyramid that we describe as a *bounding-box cell-tree pyramid*) instead of a grid, as in the case of an irregular grid bounding-box pyramid.

Our solution is equivalent to a marriage of the bounding-box cell-tree pyramid hierarchy with one of the block decompositions described in Section 2.1.2. This is done by choosing a value  $M$  for the maximum number of cells (actually blocks) that can be aggregated and a block decomposition rule (e.g., a generalized k-d tree). As we are propagating the identities of the objects associated with the bounding boxes up the hierarchy rather than the space occupied by them, we use an object-based variant of the block decomposition rule. This means that a block is decomposed whenever it contains the bounding boxes of more than  $M$  objects rather than on the basis of the absence of homogeneity. Note that the occupied space is implicit to the block decomposition rule and thus need not be explicitly propagated up the hierarchy.

It should be clear that each object's bounding box can appear only once in each block as the objects are continuous. If more than  $M$  of the bounding boxes overlap each other in block  $b$  (i.e., they all have at least one point in common), then there is no point in attempting to decompose  $b$  further as we will never be able to find subblocks  $b_i$  of  $b$  so that each of  $b_i$  does not have at least one point in common with the overlapping bounding boxes. Observe also that although the block decompositions yield a partition of space into disjoint blocks, the bounding boxes at the lowest level of the hierarchy may not necessarily be disjoint. For example, consider a database of line segment objects and the situation of a vertex where five of the line segments meet. It is impossible for the bounding boxes of the line segments to be disjoint. The object-based variants of the block decomposition rules are quite different from their image-based counterparts discussed in Section 2.1.2, which base the decomposition on whether the space spanned by the block is completely covered by an object. It is important to reiterate that the blocks corresponding to the leaf nodes do not represent hyperrectangular aggregates of identically valued unit-sized cells, as in the conventional pyramid. Instead, they represent hyperrectangular aggregates of bounding boxes of objects or pieces thereof.

Without loss of generality, assuming a generalized k-d tree block decomposition rule, the hierarchy of sets  $\{H_j\}$  ( $1 \leq j \leq n$ ) is defined as follows:  $H_0$  consists of one block.  $H_1$  consists of a subset of the nodes of a generalized k-d tree decomposition  $Z$  of the underlying space so that  $Z$  has a maximum of  $M$  elements whose corresponding blocks span the entire underlying space.  $H_2$  is formed by removing from  $Z$  all nodes corresponding to members of  $H_1$  and their ancestors and then applying the same rule that was used to form  $H_1$  to each of the blocks in  $H_1$  with respect to  $Z$ . In other words,  $H_2$  consists of generalized k-d tree decompositions of the blocks  $h_{1k}$  ( $1 \leq k \leq M$ ) that make up  $H_1$ . Each element of  $H_2$  contains no more than  $M$  blocks for a maximum of  $M^2$  blocks. This process is repeated at each successive level down to the leaf level at depth  $n - 1$ . The nodes at the leaf level contain the bounding boxes of the objects or parts of the bounding boxes of the objects. The pyramid means that the hierarchy must be height

balanced with all leaf nodes at the same level, and that the cells at depth  $j$  are disjoint and span the space covered by the cells at the immediately lower level at depth  $j + 1$ .

We term the resulting data structure a *generalized k-d tree bounding-box cell-tree pyramid* on account of the use of the generalized k-d tree as the building block of the pyramid and the use of a tree access structure, although it is more commonly known as a *k-d-B-tree* [1567] on account of the similarity of the node structure to that of a B-tree. If we had used the point quadtree or the bintree as the building block of the hierarchy, then we would have termed the result a *point quadtree bounding-box cell-tree pyramid* or a *bintree bounding-box cell-tree pyramid*, respectively. It is interesting to note that the k-d-B-tree was originally developed for storing pointlike objects (see the discussion in Section 1.7.1 of Chapter 1) although the extension to objects with extent is relatively straightforward, as shown here (but see Exercise 1).

Figure 2.80 is an example of one possible k-d-B-tree for the collection of rectangles whose specifications are given in Figure 2.67. Broken lines denote the leaf nodes, and thin lines denote the space spanned by the subtrees rooted at the nonleaf nodes. Of course, other variations are possible since the k-d-tree is not unique. This particular tree is of order (2,3) (i.e., having a minimum and maximum of two and three entries, respectively), although, in general, it is not possible always to guarantee that all nodes will have a minimum of two entries; nor is the minimum occupancy requirement a part of the definition of the k-d-B-tree. Notice that rectangle object D appears in three different nodes, while rectangle objects A, B, E, and G appear in two different nodes. Observe also that the example uses a partition scheme that cycles through the axes in the order  $x, y, x, y$ , and so on, although, as we shall see below, this cycling is not guaranteed to hold once objects are inserted and deleted.

Our definition of the structure was given in a top-down manner. In fact, the structure is often built in a bottom-up manner by inserting the objects one at a time. Initially, the hierarchy contains just one node corresponding to the bounding box of the single object. As each additional object  $o$  is processed, we insert  $o$ 's bounding box  $b$  into all of the leaf nodes that overlap it. If any of these nodes become too full, then we split these nodes using an appropriate block decomposition rule and determine if the parent is not too full so that it can support the addition of a child. If it is not, then we recursively apply the same decomposition rule to the parent. The process stops at the root, in which case overflow will usually cause the hierarchy to grow by one level.

Figure 2.80  
(a) k-d-B-tree for a collection of rectangle objects whose specifications are given in Figure 2.67 with  $m = 2$  and  $M = 3$  and (b) the spatial extents of the nodes. Notice that only in the leaf nodes are the bounding boxes minimal.

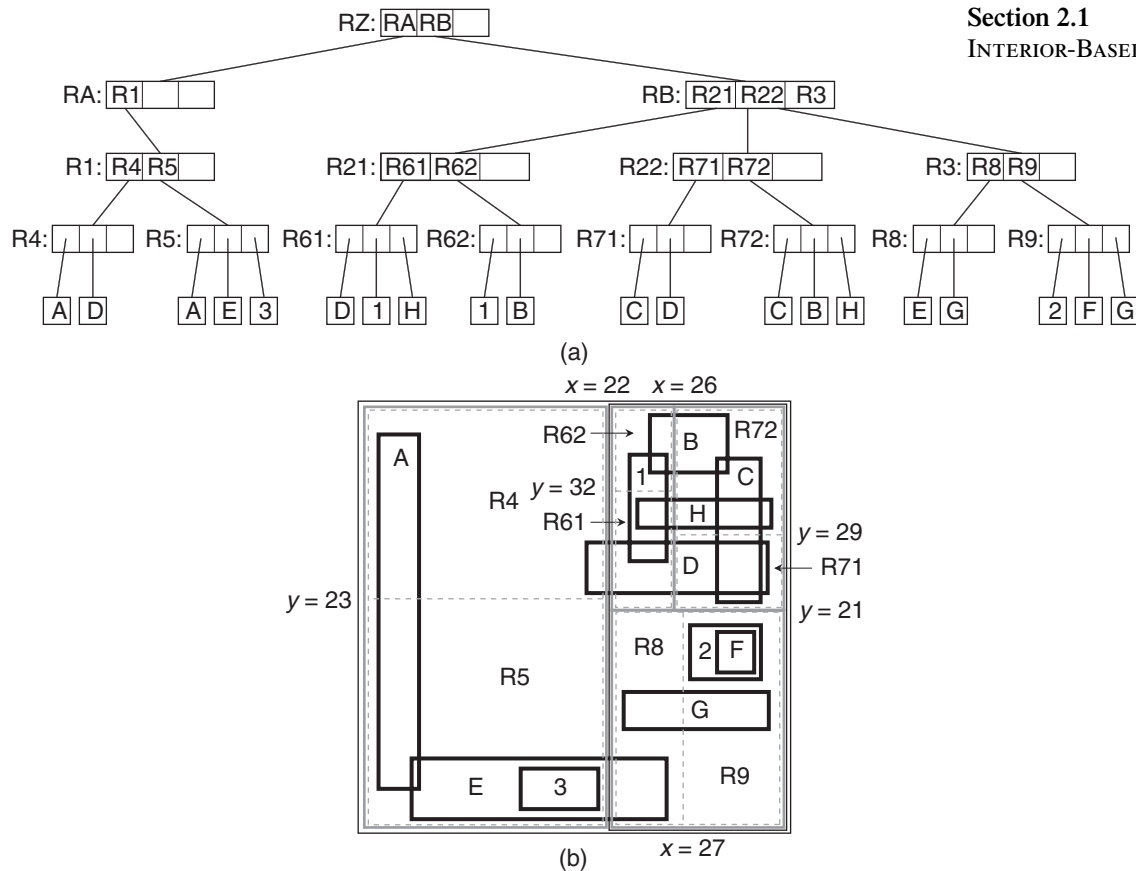

Figure 2.81  
(a) k-d-B-tree resulting from the insertion of rectangle object H into the k-d-B-tree of Figure 2.80 when the root node is split at  $x = 22$  and (b) the spatial extents of the nodes. Once the root node has been split, no further partitioning and reinsertion at deeper levels is needed. Notice that only in the leaf nodes are the bounding boxes minimal.

For example, consider the insertion of rectangle object H with a lower-left corner at  $(22, 29)$  and an upper-right corner at  $(38, 32)$  in the k-d-B-tree in Figure 2.80. H overlaps leaf nodes R6 and R7, and its insertion causes them to overflow. R6 is split into nodes R61 and R62 at  $y = 32$ , while R7 is split into nodes R71 and R72 at  $y = 29$ . These four nodes (i.e., R61, R62, R71, and R72) now become the children of node R2, which causes R2 to overflow. R2 is split at  $x = 26$  into nodes R21 (containing nodes R61 and R62) and R22 (containing nodes R71 and R72).

These two nodes (i.e., R21 and R22) replace R2 as the children of the root node R0, along with R1 and R3, which now causes R0 to overflow. At this point, we split R0 along  $x = 22$  into two nodes, RA and RB, where RA consists of node R1, and RB consists of nodes R21, R22, and R3. This causes the height of the tree to grow by one level, thereby resulting in the creation of a new root node RZ, as shown in the k-d-B-tree given in Figure 2.81. Notice that the resulting tree is no longer order  $(2, 3)$ .

The process that we have described is analogous to that used in a B-tree upon overflow. The difference is that there are several ways to deal with overflow, in the sense of where the node and the underlying space are to be partitioned. The most straightforward one is to split the node along the partition line that corresponds to the partition at the root of the k-d tree of the underlying space that is spanned by the node that has overflowed. In fact, this is the strategy pursued in the example illustrated in Figure 2.81. In particular, we split node R0 at  $x = 22$  so that the newly created root node RZ has one child RA containing R1 and a second child RB containing R21, R22, and R3.

The advantage of splitting the node in this way is that once the node has been split, we do not need to worry about repartitioning nodes at lower levels in the tree. Interestingly, the same split strategy is also used in the LSD tree [829] (see Section 1.7.1.3 of Chapter 1, where its use for point data is discussed).

Unfortunately, an undesirable side effect of the split strategy described above is that the resulting tree may be unbalanced heightwise, which may cause it to be deeper than necessary. The LSD tree tries to address the issue of balance by having two types of nodes with varying capacities that do not contain objects (see Section 1.7.1.3 of Chapter 1 for more detail). In the k-d-B-tree, the issue of balance can be overcome by choosing another partition line, as well as an axis for partitioning the overflowing node. The drawback of such a solution is that this may force the repartitioning of nodes at deeper levels in the hierarchy and the reinsertion of the regions corresponding to the new partitions in the appropriate nodes.

In order to see the need for repartitioning, let us return to the example showing the result of inserting rectangle object H in the k-d-B-tree in Figure 2.80. Assume that all splits at levels deeper than the root have been made as in the earlier discussion and that we are now processing the root R0, which has overflowed (see Figure 2.81(b)). Now, instead of partitioning R0 at  $x = 22$ , we introduce a new partition at  $x = 26$ , yielding nodes RA and RB. Again, this causes the height of the tree to grow by one level, thereby resulting in the creation of a new root node RZ.

The difference from the partition that was performed at  $x = 22$  is that we must now also repartition some of the nodes at deeper levels in the tree. In particular, we have to split node R3 into two parts: R31, which belongs in RA, and R32, which belongs in RB. Therefore, RA consists of R1, R21, and R31, while RB consists of R22 and R32. At the next level of the tree, we see that a further ramification of the split of R3 is that R8 has been split into two parts, R81 and R82. The effect of this split is that R81 is now a part of R31, and R82 is now a part of R32, which also contains R9. Figure 2.82 shows the result of pursuing this alternative.

When choosing the partition line and axis as in Figure 2.82(b), we must take care so that the newly created nodes do not overflow. For example, suppose that we choose to partition the overflowing node R0 in Figure 2.82(b) at line  $l$  at  $y = 15$  (instead of at  $x = 22$  or at  $x = 26$  as in Figure 2.82(b)). Figure 2.83 shows the result of this partition at the level of node R0. Again, let RA and RB represent the newly created nodes corresponding to the area below and above  $y = 15$ , respectively. Therefore, all elements of R0 that are below  $l$  (e.g., none in Figure 2.81(b)) are inserted into RA, while all elements of R0 that are above  $l$  (e.g., regions R21 and R22 in Figure 2.81(b)) are inserted into RB. In addition, the elements of R0 whose regions are intersected by  $l$  (e.g., R1 and R3) must be split and new regions created, which are inserted into RA and RB.

The result is that RA contains two regions, while RB contains four regions. However, each node can contain a maximum of three entries. Therefore, RB has overflowed, which means that RB must also be split, thereby causing the k-d-B-tree to grow by yet an additional level. With the appropriate choice of partition lines, this process can be applied repeatedly to create much larger k-d-B-trees. Clearly, this is undesirable, and we should choose another partition line and axis. In fact, it is not difficult to construct another example where both of the newly created nodes have overflowed (see Exercise 1 in Section 1.7.1.1 of Chapter 1).

All of the example partitionings of the overflowing k-d-B-tree node that we have described result in the growth of the k-d-B-tree by one level. We propose to avoid this growth by making use of a technique analogous to rotation (also known as *deferred splitting*) in B-trees and R-trees (as discussed in Section 2.1.5.2). The idea is that instead of partitioning the overflowing node  $R$  into just two nodes, resulting in the growth of the height of the tree, we repartition the space  $S$  spanned by  $R$  several times (as long as  $R$  does not overflow), and then rebuild the k-d-B-tree in a top-down manner. Notice that in this case no new node is added when the process starts. Of course, we may have to

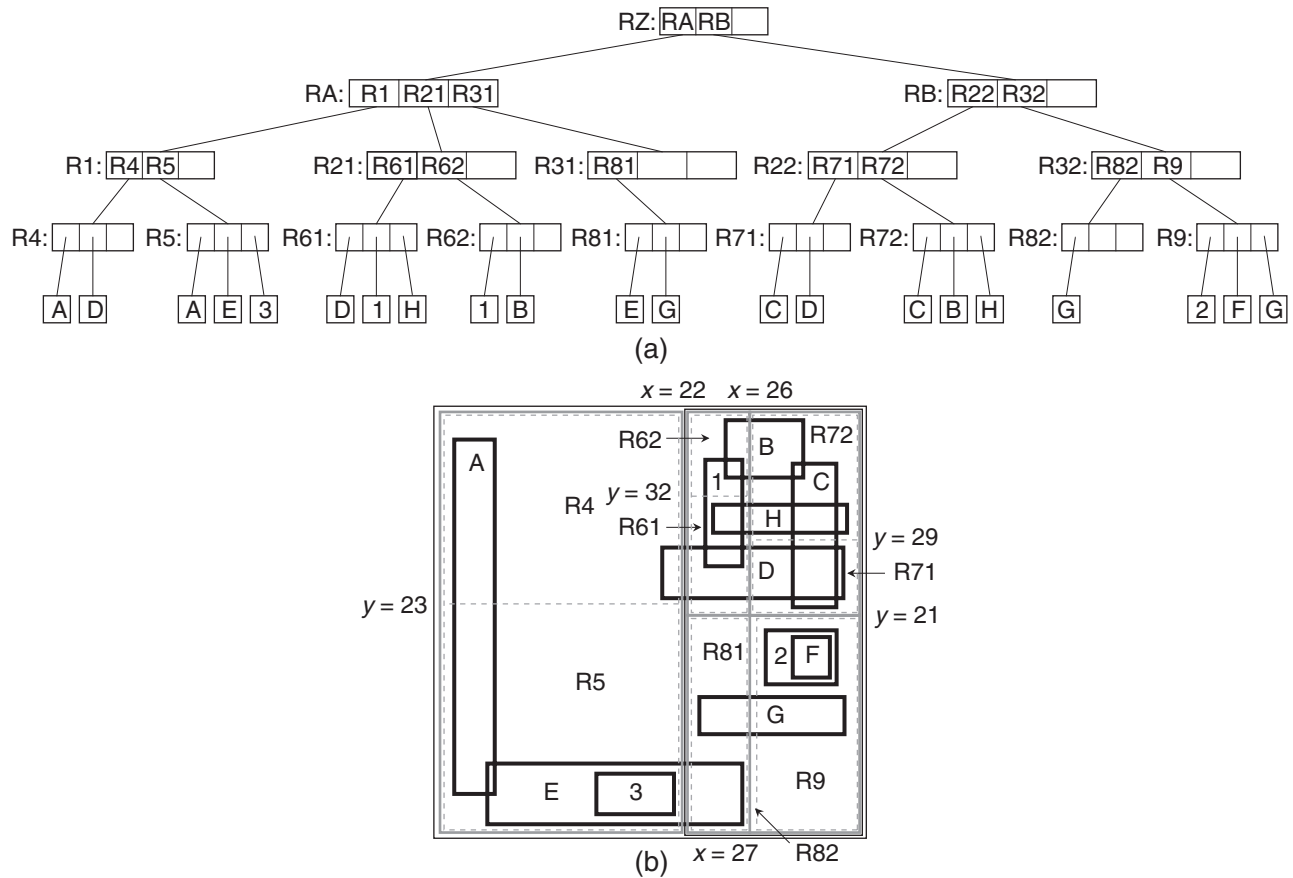

Figure 2.82  
 (a) k-d-B-tree resulting from the insertion of rectangle object H into the k-d-B-tree of Figure 2.80 when the root node is split at  $x = 26$  and (b) the spatial extents of the nodes. Once the root node has been split, further partitioning is needed at deeper levels. Notice that only in the leaf nodes are the bounding boxes minimal.

perform many reinsertions, which may in turn result in the addition of nodes. We use the term *k-d-B-tree resplitting* to describe this overflow strategy.

As an illustration of the use of k-d-B-tree resplitting, let us return to the example showing the result of inserting rectangle object H in the k-d-B-tree in Figure 2.80. Assume that all splits at levels deeper than the root have been made as in the earlier discussion and that we are currently processing the root  $R_0$ , which has overflowed (see Figure 2.81). We now repartition  $R_0$  at  $x = 26$  into a left half, which is partitioned further at  $y = 21$  into two halves, T1 and T2, and a right half, T3. In this case, the height of the tree stays the same. T1 is split into a left half, T4, at  $x = 22$ , which is similar to R4, and a right half, which is partitioned further at  $y = 32$  into the two halves, R61 and R62. T2 is split at  $x = 22$  into a left half, T5, which is similar to R5, and a right half, T8, which is similar to R8. T3 is split at  $y = 21$  into a bottom half, T9, which is similar to R9, and a top half, which is partitioned further at  $y = 29$  into the two halves, R71 and R72.

Figure 2.84 shows the result of using the k-d-B-tree resplitting overflow strategy. Notice that k-d-B-tree resplitting requires that we repartition a number of the original nodes. In particular, R5 is split into two parts: R51, which is inserted into T4, and R52, which is inserted into T5. Similarly, R8 is split into two parts: R81, which is inserted into T8, and R82, which is inserted into T9. In this case, the reinsertion is simple as these nodes are absorbed into the existing nodes as the subobjects that they comprise are identical. In other words, the merging does not cause the merged node to contain more objects, and hence it cannot overflow, thereby guaranteeing that there will be no more

Figure 2.83  
 The result of partitioning the overflowing node  $R_0$  in Figure 2.81 at line  $y = 15$ .

reinsertion. For example, R82 consists of just a part of G and thus can be grafted onto the part of G that makes up T9 (the old R9). In general, using k-d-B-tree resplitting can become quite complex (as is also the case with rotation in a conventional B-tree), and thus its use is not recommended.

Variants of the bounding-box cell-tree pyramid, such as the k-d-B-tree, are good for answering both the feature and location queries. However, in the case of the location query, they act only as a partition of space. They do not distinguish between occupied and unoccupied space. Thus, in order to determine if a particular location  $a$  is occupied by one of the objects associated with cell  $c$ , we need to check each of the objects associated with  $c$ , which can be time-consuming, especially if  $M$  is large. We can speed this process by modifying the general definition of the bounding-box cell-tree pyramid so that a bounding box is stored in each node  $r$  in the hierarchy, regardless of  $r$ 's depth, that covers the bounding boxes of the cells that make up  $r$ . Thus, associated with each node  $r$  is the union of the objects associated with the cells making up  $r$ , as well as a bounding box of the union of their bounding boxes. We term the result a *disjoint object pyramid*. Recall that the depth of any variant of the bounding-box pyramid is one less than that of the corresponding conventional pyramid, and the same is true for the disjoint object pyramid.

A key difference between the disjoint object pyramid and variants of the conventional pyramid, and to a lesser extent the bounding-box pyramid (including the bounding-box cell-tree pyramid), is that the elements of the hierarchy of the disjoint object pyramid are also parts of the bounding boxes of the objects rather than just the cells that make up the objects, which is the case for both variants of the bounding-box and conventional pyramids. The representation of the disjoint object pyramid, and of variants of the

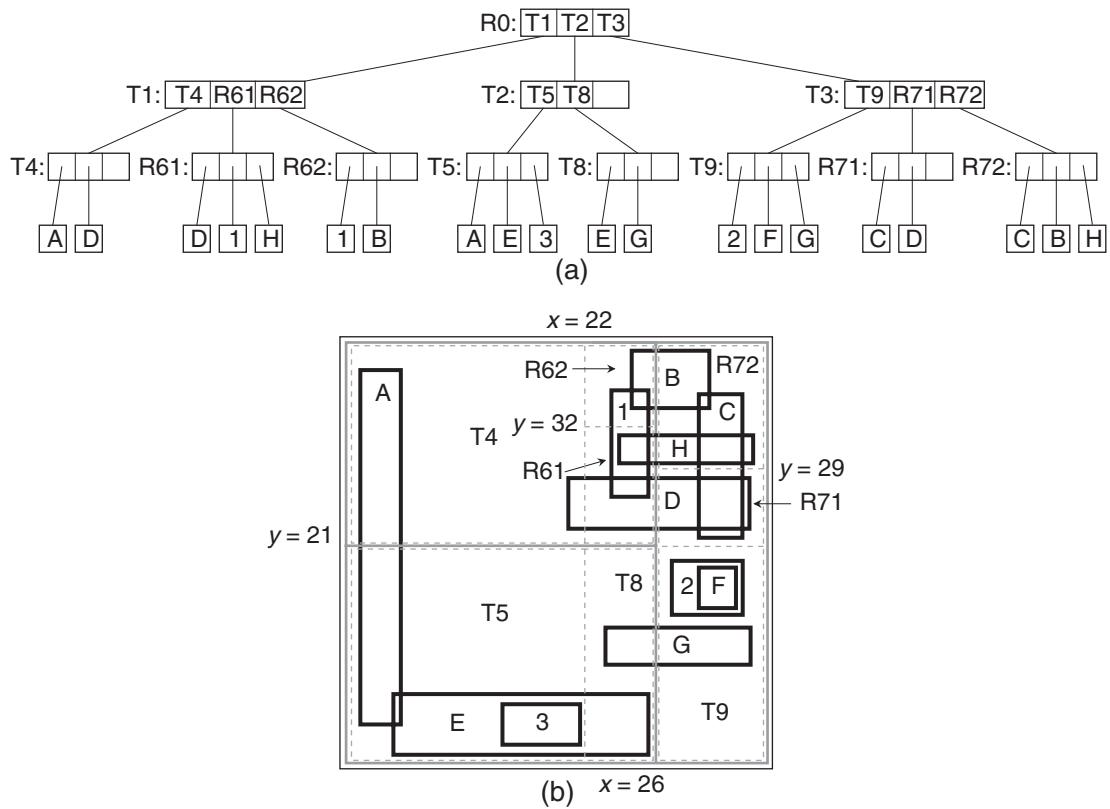

Figure 2.84  
(a) k-d-B-tree resulting from the insertion of rectangle object H into the k-d-B-tree of Figure 2.80 when using the k-d-B-tree resplitting overflow strategy and (b) the spatial extents of the nodes. Notice that only in the leaf nodes are the bounding boxes minimal.

bounding-box pyramid such as the k-d-B-tree, is also much simpler as they both just decompose the objects until a criterion involving the number of objects present in the block, rather than one based on the homogeneity of the block, is satisfied. This results in avoiding some of the deeper levels of the hierarchy that are needed in variants of the conventional pyramid.

There are many variants of the disjoint object pyramid. They differ according to which of the block decomposition rules described in Section 2.1.2 is used. They are usually referred to by the general term  $R^+$ -tree [593, 1718, 1803] on account of their similarity to the R-tree since they both store a hierarchy of bounding boxes. However, the block decomposition rule is usually left unspecified, although a generalized k-d tree block decomposition rule is often suggested. An alternative is not to use any decomposition rule, in which case each node is just a collection of blocks, as in Figure 2.10.

$R^+$ -trees are built in the same incremental manner as any of the bounding-box cell-tree pyramids that we have described (e.g., the k-d-B-tree). Again, as each additional object  $o$  is processed, we insert  $o$ 's bounding box  $b$  into all of the leaf nodes that overlap it. If any of these nodes become too full, then we split them using the appropriate block decomposition rule and determine if the parent is not too full to support the addition of a child. If it is not, then we recursively apply the same decomposition rule to the parent. The process stops at the root, in which case the  $R^+$ -tree may grow by one level. The difference from the method used in the bounding-box cell-tree pyramids is that we also propagate the minimum bounding box information up the hierarchy. The entire process is analogous to that used in a B-tree upon overflow. The difference is that, at times, as is also the case for the k-d-B-tree, the decomposition at a nonleaf node may result in the introduction of a new partition that may force the repartitioning of nodes at deeper levels in the  $R^+$ -tree.

Figure 2.85 is an example of one possible  $R^+$ -tree for the collection of rectangles whose specifications are given in Figure 2.67. Broken lines denote the bounding boxes corresponding to the leaf nodes, and thin lines denote the bounding boxes corresponding to the subtrees rooted at the nonleaf nodes. In this case, we have simply taken the k-d-B-tree of Figure 2.80 and added bounding boxes to the nonleaf nodes. This particular tree is of order (2,3), although, in general, it is not possible always to guarantee that all nodes will have a minimum of two entries. Notice that rectangle D appears in three different

Figure 2.85  
(a)  $R^+$ -tree for a collection of rectangle objects whose specifications are given in Figure 2.67 with  $m = 2$  and  $M = 3$  and (b) the spatial extents of the bounding boxes. Notice that the leaf nodes in the index also store bounding boxes, although this is shown only for the nonleaf nodes.

nodes, while rectangles A, B, E, and G appear in three different nodes. Of course, other variants are possible since the  $R^+$ -tree is not unique.

The *cell tree* of Günther [769, 774] is similar to the  $R^+$ -tree. The difference is that the nonleaf nodes of the cell tree are convex polyhedra instead of bounding rectangles. The children of each node, say  $P$ , form a binary space partition (BSP) [658] of  $P$  (see Section 2.1.3.1 and Section 1.5.1.4 of Chapter 1). The cell tree is designed to deal with polyhedral data of arbitrary dimension. As in the  $R^+$ -tree, the polyhedral data being represented may be stored in more than one node.

### Exercises

1. We have discussed several methods of dealing with an overflowing node in a k-d-B-tree. One way to ensure greater balance in the tree is to partition the overflowing node at a position other than the one that corresponds to the partition at the root of the k-d tree of the underlying space spanned by the node (i.e., as in the LSD tree). The drawback of this solution is that we may have to repartition some of the nodes at deeper levels of the tree. We pointed out that these repartitions may lead to overflow, possibly resulting in an infinite loop. Why is this not a problem for point objects?
2. Compare the amount of information that must be stored in k-d-B-tree and  $R^+$ -tree nodes. Do they require the same amount of storage?
3. What are the minimum and maximum heights of an  $R^+$ -tree of order  $(m, M)$  with  $N$  objects (not nodes)?
4. Write an algorithm to insert an object into an  $R^+$ -tree, assuming a generalized k-d tree block decomposition rule.
5. Analyze the expected cost of inserting an object into an  $R^+$ -tree.
6. Write an algorithm to delete an object from an  $R^+$ -tree, assuming a generalized k-d tree block decomposition rule.
7. Write an algorithm to perform a point query in an  $R^+$ -tree.
8. Write an algorithm to perform a window query in an  $R^+$ -tree.
9. Prove that the worst-case execution time of the rectangle intersection problem for  $N$  rectangles using a  $R^+$ -tree is  $O(N^2)$ .
10. What is the expected cost of the rectangle intersection problem for  $N$  rectangles using a  $R^+$ -tree?

## 2.2 Boundary-Based Representations

Boundary-based representations are more amenable to the calculation of properties pertaining to shape (e.g., perimeter, extent). Not surprisingly, the nature of the boundaries plays an important role in the representation that is chosen. Often, the boundary elements of the objects are constrained to being hyperplanes (e.g., polygons in two dimensions and polyhedra in three dimensions), which may, in addition, be constrained to being axis-parallel. Much of the following presentation is in the context of such constraints unless explicitly stated otherwise, although we will also discuss the more general case.

Assuming that these two constraints hold, a simple representation is one that records the locations of the different boundary elements associated with each cell of each object and their natures (i.e., their orientations and the locations of the cells to which they are adjacent). For example, in two dimensions, the boundary elements are just the sides of the cells (i.e., unit vectors), while in three dimensions, the boundary elements are the faces of the cells (i.e., squares of unit area, with directions normal to the object). Boundary-based representations aggregate identically valued cells whose boundary elements have

the same direction, rather than just identically valued cells as is done by interior-based representations. In two dimensions, the aggregation yields boundary elements that are vectors whose lengths can be greater than 1.

Whichever boundary-based representation is used and regardless of whether any aggregation takes place, the representation must also enable the determination of the connectivity between individual boundary elements. The connectivity may be implicit or explicit (e.g., by specifying which boundary elements are connected). Thus, we notice that this distinction (i.e., implicit versus explicit) between boundary-based representations is different from the one used with interior-based representations, which is based on the nature of the specification of the aggregation.

As an example of a boundary-based representation, let us consider two-dimensional objects for which the boundary elements are vectors. The location of a vector is given by its start and end vertices. An object  $o$  has one more boundary (i.e., a collection of connected boundary elements) than it has holes. Connectivity may be determined implicitly by ordering the boundary elements  $e_{i,j}$  of boundary  $b_i$  of  $o$  so that the end vertex of vector  $v_j$  corresponding to  $e_{i,j}$  is the start vertex of vector  $v_{j+1}$  corresponding to  $e_{i,j+1}$ . The result of applying such an ordering when identically valued cells whose boundary elements have the same direction are aggregated yields a representation known as the *polygon representation*. This term is also used to describe the representation of arbitrary objects whose boundaries need not be axis parallel.

In two dimensions, the most general example of a nonpolygonal object boundary is the curvilinear line segment. Straight line segments with arbitrary slopes are less general. A curvilinear line segment is often approximated by a set of line segments termed a *polyline*. In order to comply with our assumption that the objects are made up of unit-sized cells (i.e., pixels), we digitize the line and then mark the pixels through which it passes. An alternative is to classify the pixels on the basis of the slope of the part of the line that passes through them. One such representation is the *chain code* [638], in which case the slopes are restricted to the four or eight principal directions. The chain code is of particular interest when the slopes are restricted to the four principal directions as this is what is obtained when the boundaries of the objects are parallel to the coordinate axes. The chain code is discussed in more detail in Section 2.3.

In dimensions higher than 2, the relationship between the boundary elements associated with a particular object is more complex, as is its expression. Whereas in two dimensions we have only one type of boundary element (i.e., an edge or a vector consisting of two vertices), in  $d > 2$  dimensions, given our axis-parallel constraint, we have  $d - 1$  different boundary elements (e.g., faces and edges in three dimensions). As we saw, in two dimensions, the sequence of vectors given by a polygon representation is equivalent to an implicit specification of the boundary because each boundary element of an object can be adjacent to only two other boundary elements. Thus, consecutive boundary elements in the representation are implicitly connected. This is not possible in  $d > 2$  dimensions; assuming axis-parallel objects comprising of unit-size,  $d$ -dimensional cells, there are  $2^{d-1}$  different adjacencies per boundary element. Therefore, it is difficult to adapt the polygon representation to data of dimensionality greater than 2. Of course, it can be used to specify a spatial entity comprising of a sequence of edges in  $d$ -dimensional space that forms a cycle (i.e., the starting vertex is the same as the final vertex). However, the spatial entity need not be planar.

Nevertheless, in higher dimensions, we do have a choice between an explicit and an implicit boundary-based representation. The boundary model (also known as the *BRep* [141, 1637]) is an example of an explicit boundary-based representation. Observe that in three dimensions, the boundary of an object with planar faces is decomposed into a set of faces, edges, and vertices. The result is an explicit model based on a combined geometric and topological description of the object. The topology is captured by a set of relations that indicate explicitly how the faces, edges, and vertices are connected to

Figure 2.86  
(a) A three-dimensional object, (b) its CSG tree, and (c) its boundary model.

each other. For example, the object in Figure 2.86(a) can be decomposed into the set of faces having the topology shown in Figure 2.86(c). The geometry of the faces can be specified by use of appropriate geometric entities (e.g., planes in the case of polyhedra). In  $d$  dimensions, the boundary of object  $o$  will be decomposed into  $d$  sets  $s_i$  ( $0 \leq i < d$ ), where  $s_i$  contains all constituent  $i$ -dimensional elements of  $o$ . This forms the basis of the boundary model and is discussed in greater detail in Section 2.2.1. Although this representation is quite general, it is easy to constrain it to handle axis-parallel objects. We do not discuss this further here.

Constructive solid geometry (CSG) [1557] is another example of an implicit representation that is applicable to objects of arbitrary dimensionality. Although it is usually thought of as an interior-based representation, it also has a boundary-based interpretation. In the interior-based formulation, primitive instances of objects are combined to form more complex objects by use of geometric transformations and regularized Boolean set operations (e.g., union, intersection). The representation is usually in the form of a tree where the leaf nodes correspond to primitive instances and the nonleaf nodes correspond to the regularized Boolean set operations.<sup>28</sup> For example, the object in Figure 2.86(a) can be decomposed into three primitive solids with the CSG tree shown in Figure 2.86(b), where the operation  $A \cap -B$  denotes set difference. The key is that this representation is procedural. Thus, it indicates how an item can be constructed—that is, what operations are necessary. Often these operations have physical analogs (e.g., drilling). A disadvantage of the CSG representation is that it is not unique. In particular, there are frequently several ways of constructing an object (e.g., from different primitive elements).

When the primitive instances in CSG are halfspaces, and the objects have planar faces, the result is an implicit boundary-based representation. In this case, the boundary of a  $d$ -dimensional object  $o$  consists of a collection of hyperplanes in  $d$ -dimensional space (i.e., the infinite boundaries of regions defined by the inequality  $\sum_{i=0}^d a_i x_i \geq 0$ , where  $x_0 = 1$ ). We have one halfspace for each  $(d - 1)$ -dimensional boundary element of  $o$ . Both of these representations (i.e., primitive instances of objects and halfspaces) are implicit because the object is determined by associating a set of regular Boolean set operations with the collection of primitive instances (which may be halfspaces), the result of which is the object. Again, although these representations are quite general, it is easy to constrain them to handle axis-parallel objects.

It is usually quite easy to determine the cells that make up an object (i.e., the feature query) when using boundary-based representations since the boundaries are usually associated with the individual objects. In contrast, one of the principal drawbacks of boundary-based representations is the difficulty of determining the value associated with an arbitrary point of the space given by a cell (i.e., the location query) without testing each boundary element using operations, such as point-in-polygon tests (e.g., [622]) or finding the nearest boundary element. The problem is that these representations are very local in the sense that, generally, they just indicate which boundary element is connected to which other boundary element rather than the relationships of the boundary elements to the space that they occupy. Thus, if we are at one position on the boundary (i.e., at a particular boundary element), we do not know anything about the rest of the boundary without traversing it element by element.

This situation can be remedied in two ways. The first is by aggregating the cells that make up the boundary elements of the objects and their environment into blocks, such as those obtained by using a region quadtree, a region octree, or a k-d tree variant, and then imposing an appropriate access structure on the blocks. Such methods are reviewed in Section 2.2.2. The second is by aggregating the boundary elements of the

<sup>28</sup> Regularized versions of the Boolean set operations [1555] are used in order to guarantee that the resulting objects correspond to our intuitive notion of solids. In such a case, the result of any Boolean set operation involving objects in  $d$ -space is always either null or has a nonzero  $d$ -dimensional measure. Regularized Boolean set operations form a Boolean algebra [1555] so that, for instance, De Morgan's laws hold for them.

objects themselves by using variants of bounding boxes to yield successively coarser approximations and then imposing appropriate access structures on the bounding boxes. These methods are presented in Section 2.2.3. Not surprisingly, the distinction between these representations is the same as that made earlier between image-based and object-based methods, respectively.

The boundary representations discussed above and in Sections 2.2.2 and 2.2.3 generally assume that the boundaries of the objects lie on hyperplanes or can be approximated by hyperplanes or some interpolation method. In these cases, the shape of the objects is the main focus of the applications that make use of these representations. In other applications, the main focus of the application is the boundary of the object, which is like a 2.5-dimensional image, such as a terrain, and is highly irregular. In this case, the object is treated as a surface boundary. This is the subject of Section 2.2.4.

## 2.2.1 The Boundary Model (BRep)

In this section, we assume that the objects are three-dimensional. We first give a general overview of the boundary model, or BRep (Section 2.2.1.1). The boundary model treats the objects as graphs whose basic elements are vertices, edge, and faces. There are a number of possible implementations of the boundary model. They are differentiated on the basis of being edge-based, such as the winged-edge data structure (Section 2.2.1.2), or vertex-based, such as the lath family of representations (Section 2.2.1.3). Face-based implementations are also possible and are shown to be duals of the vertex-based ones, although their utility is quite limited and thus they are only briefly mentioned (Section 2.2.1.3). The quad-edge data structure, results from a particular interpretation of the winged-edge data structure, whose use enables the simultaneous representation of the Voronoi diagram and the Delaunay triangulation of a given set of points (Section 2.2.1.4) and the constrained and conforming Delaunay triangulations (Section 2.2.1.5). Higher-dimension variants of the Delaunay triangulation, such as the Delaunay tetrahedralization, are also discussed briefly (Section 2.2.1.6). We conclude with a discussion of some applications of edge-based representation, such as the winged-edge data structure (Section 2.2.1.7).

### 2.2.1.1 Overview

The topology in the boundary model can be represented by a graph. Before proceeding further, let us review the definitions of a few terms. A graph is *planar* if it can be drawn on the plane in such a way that all the edges intersect only at vertices. Given a planar graph  $G$ , a *face* of  $G$  is an area of the plane bounded by edges of  $G$  that does not contain any edges or vertices of  $G$  in its interior. The *frontier* of a face is the set of all edges that “touch” it. The frontier of face  $f$  can also be specified in terms of the faces that share an edge or a vertex with  $f$ . Notice that a face is defined in terms of an area and not in terms of its boundary (i.e., the edges making it up). In particular, the frontier of a face need not be connected (e.g., the region with holes in Figure 2.87). Two faces are *adjacent* if they have at least one edge in common; however, their vertices need not necessarily be connected. We say that two faces  $f_i$  and  $f_j$  are *connected* if there is a sequence of distinct faces  $(f_i, f_{i+1}, \dots, f_{j-1}, f_j)$  such that  $f_k$  is adjacent to  $f_{k+1}$  ( $i \leq k < j$ ).

Our domain of three-dimensional objects is restricted to ones bounded by compact,<sup>29</sup> orientable, two-manifold surfaces [1326] (see Exercise 1 in Section 2.2.1.7).<sup>30</sup> In such a

Figure 2.87  
Example face with holes.

---

<sup>29</sup> The term *compact* means (1) topologically closed and (2) bounded. The closedness implies that for every edge  $e$ ,  $e$ 's endpoints are part of the surface and, for every face  $f$ ,  $f$ 's edges are part of the surface. The boundedness means that edges and faces that lead to infinity are not permitted.

<sup>30</sup> In the rest of this section, unless otherwise stated, when we use the term *two-manifold surface*, we mean *compact, orientable two-manifold surface*. Similarly, unless otherwise stated, when we use

Figure 2.88  
Example nut illustrating the concept  
of a loop.

domain, only two faces may meet at an edge. Also, the faces are two-sided, thereby ruling out a Möbius strip and a Klein bottle. More general objects that do not satisfy the two-manifold surface condition fall into the class of nonmanifold objects and are beyond the scope of this book. Readers interested in representations for such objects should consult, for example, the radial-edge data structure of Weiler [1979], the extension of the half-edge data structure of Campagna, Kobbelt, and Seidel [301], and the partial-entropy structure of Lee and Lee [1140], as well as additional representations described in the recent survey of De Florian and Hui [457]. In three dimensions, it is convenient to view the nodes of the graph as the set of vertices, edges, and faces of the object. On the other hand, the arcs are the relations between pairs of these three entities. We elaborate on these relations later. We call the graph an *object graph*.

Vertices, edges, and faces form the three primitive topological entities of the object graph. The description of objects with multiply connected faces (e.g., holes) and internal cavities is facilitated by the addition of two higher-level, nonprimitive topological entities, termed the *shell* and the *loop*. A shell in an object  $O$  is defined as any maximally connected set of faces of  $O$ . For example, the object with an internal cavity formed by a cube within another cube has two shells, an internal shell and an external shell. A loop on a face  $f$  of  $O$  is defined as a closed chain of edges (i.e., a cycle) bounding  $f$ . For example, consider an object, such as a nut (e.g., Figure 2.88), in which case the top and bottom faces each have two loops, an internal loop and an external loop. Note that the set of nodes of the object graph has now been expanded to include the shell and the loop.

The boundary model is *unambiguous*—that is, each boundary model corresponds to a single object. It is also unique when the boundary is partitioned into maximally connected faces. This is especially relevant when the object has planar faces. In this case, we achieve such a partition when we merge all faces that are coplanar (provided that their union is connected).

The representation of the boundary model is conceptually hierarchical. Objects are decomposed into shells. Each shell is a collection of faces. Each face is represented by its surface equation and by a collection of its bounding loops. Each loop is a chain of edges. Often, a single curved edge is approximated by several linear segments. Each segment is represented by a pair of vertices that correspond to its endpoints.

The boundary model has both a geometric and topological component; neither is sufficient by itself to describe a three-dimensional object. The geometric component consists of the shape and location in space of each of the primitive topological entities. The topological component consists of a subset of the adjacency relationships between pairs of individual topological entities (e.g., edges and vertices). There are 25 different adjacency relationships—each one consists of a unique ordered pair from the five topological entities described above [1978]. Since the relationships are ordered, there is, for example, a difference between an edge-face relation and a face-edge relation. In particular, the edge-face relation associates with each edge the pair of faces that share it, while the face-edge relation associates with each face the edges that bound it.

It should be clear that the 25 different adjacency relationships are nothing more than a generalization of the vertex-based and edge-based representations of a graph to three dimensions. Note that the vertex-based representation associates with each vertex, say  $p$ , a list of all of the vertices, say  $V$ , that are connected to  $p$  by virtue of the existence of an edge between  $p$  and  $q$ , where  $q \in V$ . This is the same as a vertex-edge relationship.

---

the term *nonorientable two-manifold surface*, we mean *compact, nonorientable two-manifold surface*. Intuitively, a two-manifold surface is a surface in which the neighborhood of each point is topologically equivalent to an open disc or to an open half-disc if the surface has a boundary (e.g., the surface of a sphere does not have a boundary, while boundaries primarily arise when dealing with nonobjects such as terrains on a subset of the Earth).

The edge-based representation associates with each edge its constituent vertices. This is the same as an edge-vertex relationship.

Many of the data structures that have been proposed to represent the boundary model store the edge-vertex and edge-face relations. In this case, the representation of the object is accessed by knowing the identities of its edges. When the objects have multiple shells and multiply connected faces, then, for example, the edge-face and face-edge relations can be expressed as a combination of the edge-loop and loop-face and the face-loop and loop-edge relations, respectively [1978]. The advantage of introducing the combination involving the loop is that, from a hierarchical standpoint, the loop lies somewhere between a face and an edge.

At times, it is desirable to be able to access the information represented by the boundary model by using the identity of a particular face or vertex instead of just an edge. This is the motivation behind the symmetric structure [2016], which stores the face-edge and vertex-edge relations, as well as the edge-face and edge-vertex relations. A disadvantage of using relations such as the face-edge or vertex-edge is that the amount of information associated with the first element of the relation is not fixed.<sup>31</sup> For example, each instance of the face-edge relation contains the edges that bound the face, and each instance of the vertex-edge relation contains the edges that are incident at the vertex. On the other hand, for all relations in which the edge appears as the first element, the amount of information associated with an instance of the relation is fixed. This observation forms the basis of the *winged-edge data structure* of Baumgart [141]. It is an edge-based specification (i.e., it stores the edge-vertex and edge-face relations explicitly), and Section 2.2.1.2 describes an implementation of a special case of it that also stores the face-edge and vertex-edge relations implicitly.

### Exercises

1. Give the boundary model representation for the parallelepiped of Figure 2.90 (discussed in Section 2.2.1.2) using a (a) face-vertex relation and (b) face-edge and edge-vertex relations.
2. What is the maximum number of loops with which an edge can be associated?
3. Can a face have more than two loops associated with it? If it can, then give an example.
4. Give two methods of implementing the loop-face relation. Which method is preferable?
5. Recalling that a loop  $l$  belongs to a face  $f$  if  $f$  contains all the edges forming  $l$ , what is the maximum number of faces with which a loop can be associated? Can you give an example?

### 2.2.1.2 Edge-Based Methods Using Winged Edges

In this section, we examine edge-based object representations. This means that we represent both the faces and the vertices of an object by the set of edges that they comprise and that are incident at them, respectively. Of course, many other representations are possible. In particular, each face could also be represented in terms of its constituent vertices, and, likewise, each edge could be represented in terms of the vertices that it comprises. The latter is the basis of what are termed *vertex-based object representations*. There are a number of ways of implementing these sets, ranging from a list to an adjacency matrix and differing by the amount of time needed to verify a particular adjacency, which is inversely related to the storage cost. In this and the next section, we discuss both edge-based and vertex-based object representations where the storage cost is proportional to the number of constituent edges and vertices, respectively, while the execution time cost of the queries that use them is proportional to the size of the query result set. In the rest of this section, we focus on the representation of the faces and vertices of the objects using the edges.

---

<sup>31</sup>In database terminology, this means that the relation violates the first normal form (i.e., 1nf) [554].

Assume that the faces of the objects do not have internal loops and are composed of a single shell.<sup>32</sup> Each face is represented as a sequence of the edges it comprises (i.e., a face-edge relation), while the edges are specified as ordered pairs of their constituent vertices (i.e., an edge-vertex relation). The sequence of edges must be oriented consistently. We adopt the convention that the edges are listed in a clockwise order as the face is viewed from the outside of the object. Since we are dealing with objects whose faces are compact, orientable two-manifolds, only two faces are adjacent at each edge. Therefore, each edge appears in only two faces, once in each of its orientations.

In other words, these consistency considerations (i.e., that the face is represented by a clockwise ordering of the edges that it comprises) mean that, given edge  $e = (v_1, v_2)$ ,  $e$  appears in one face  $f$  as  $(v_1, v_2)$  and in the other face  $f'$  as  $(v_2, v_1)$ . This information is captured by recording an orientation with each reference to  $e$  (i.e., positive or negative, corresponding to whether  $e$  is part of the face  $f$  for which  $e$ 's direction makes  $e$  a part of a traversal of  $f$  in the clockwise or counterclockwise directions, respectively), although, as we shall see, the orientation is not always used. With this information, we can implement one part of the face data structure (i.e., the face-edge relation) as a table of fixed-length records by storing with each face only the identity of one of its constituent edges and a flag indicating the orientation of the edge. We use the term *face-edge table* to refer to this structure. Moreover, with each edge, say  $e$ , we keep track of the two edges that precede  $e$  and the two edges that follow  $e$  (one for each of the two faces in which  $e$  is a member). The result is that this part of the face data structure (i.e., the rest of the face-edge relation) is implemented as a linked list in which the pointers are stored as part of the edge records.

We represent the vertices of the objects as a sequence of the edges that are incident at them (i.e., a vertex-edge relation), while the edges are specified as ordered pairs of their constituent vertices (i.e., an edge-vertex relation). This sequence of edges must be oriented consistently. We adopt the convention that the edges are listed in a clockwise order as the vertex is viewed from the outside of the object. Since we are dealing with objects whose faces are compact, orientable two-manifolds, there is just one edge between any two vertices. Thus, each edge is incident at just two vertices, once at each of its two endpoints.

In other words, these consistency considerations (i.e., that the vertex is represented by a clockwise ordering of the edges incident at it) mean that, given edge  $e = (v_1, v_2)$ ,  $e$  is incident at one vertex  $v_1$  as  $(v_1, v_2)$  and at the other vertex  $v_2$  as  $(v_2, v_1)$ . This information is captured by recording an orientation with each reference to the edge (i.e., positive or negative, corresponding to whether the edge is directed into the vertex or away from the vertex, respectively), although, again, as we shall see, the orientation is not always used. With this information, we can implement one part of the vertex data structure (i.e., the vertex-edge relation) as a table of fixed-length records by storing with each vertex only the identity of one of its incident edges and a flag indicating the orientation of the edge. We use the term *vertex-edge table* to refer to this structure. Moreover, with each edge, say  $e$ , we keep track of the two edges that precede  $e$  and the two edges that follow  $e$  (one for each vertex that the edge comprises). The result is that this part of the vertex data structure (i.e., the rest of the vertex-edge relation) is implemented as a linked list in which the pointers are stored as part of the edge records.

The above combinations of vertex and face tables and edge records using records of uniform size form the basis of the *winged-edge representation* or *data structure* [141]. The rationale for the name is that the representation is based on visualizing each edge  $e$  as a line in space with a maximum of four wings, two at each of  $e$ 's vertices, where the wings correspond to adjacent edges along  $e$ 's two adjacent faces or, equivalently, to adjacent edges incident at  $e$ 's two constituent vertices. Each edge is assigned an arbitrary

---

<sup>32</sup> Objects with multiple shells and faces with internal loops require further elaboration in the model (see [1977]).

direction (i.e., orientation) by designating one of its vertices as  $VSTART$  and the other as  $VEND$  so that the different wings and adjacent faces may be identified in a consistent manner. There are numerous variants of the winged-edge data structure. They differ in the interpretation of the wings (i.e., as adjacent edges along adjacent faces, adjacent edges incident at constituent vertices, or combinations thereof), in the amount of information that they store for each edge, and in whether they keep track of the orientations of the edges explicitly, or their orientation is checked each time the representation is navigated in the process of responding to a query.

Initially, we assume an interpretation of edge  $e$ 's wings as adjacent edges along adjacent faces of  $e$ . Using this interpretation and the above orientation of  $e$ , let  $FCW(e)$  ( $FCCW(e)$ ) denote the face  $f$  ( $f'$ ) adjacent to  $e$  such that  $e$ 's direction makes  $e$  a part of a traversal of  $f$  ( $f'$ ) in the clockwise  $CW$  (counterclockwise  $CCW$ ) direction. We use  $CF$  and  $CCF$  to refer to the next edges in a clockwise ( $C$ ) and counterclockwise ( $CC$ ), respectively, traversal of the edges that make up a face ( $F$ ).<sup>33</sup> Alternatively, we can interpret edge  $e$ 's wings as adjacent edges incident at the vertices that  $e$  comprises. In this case, we use  $CV$  and  $CCV$  to refer to the next edges in a clockwise ( $C$ ) and counterclockwise ( $CC$ ), respectively, traversal of the edges that are incident at a vertex ( $V$ ).<sup>34</sup> These alternative naming conventions make it easier to see that the presence of the four wings enables us to obtain the edges that make up each face in both clockwise and counterclockwise orders and, likewise, to obtain the edges that are incident at each vertex in both of these orders. Figure 2.89(a) is an example of such an edge  $e$ , while Figure 2.89(b) illustrates an example of a physical interpretation of these concepts for an edge  $e$  of a parallelepiped where each face is viewed from the outside of the object, regardless of the direction of the edge that is actually stored.

We use the term *winged-edge-face* to describe the variant of the winged-edge data structure that results from the interpretation of edge  $e$ 's wings as adjacent edges along adjacent faces of  $e$ . It can be summarized as capturing the following information for the relations involving vertices, edges, and faces, given edge  $e$ :

1. Edge-vertex relation: the two constituent vertices ( $VSTART(e)$  and  $VEND(e)$ )
2. Edge-face relation: the two adjacent faces ( $FCW(e)$  and  $FCCW(e)$ )
3. Edge-edge relation: the preceding edges ( $CCF(FCW(e))$  and  $CCF(FCCW(e))$ ) and the next edges ( $CF(FCW(e))$  and  $CF(FCCW(e))$ ) in the two faces, thereby incorporating the face-edge relation, as well as the vertex-edge relation when using an alternative interpretation of the wings of the edge.

Similarly, we use the term *winged-edge-vertex* to describe the variant of the winged-edge data structure that results from the interpretation of edge  $e$ 's wings as adjacent edges incident at the vertices that make up  $e$ . It can be summarized as capturing the following information for the relations involving vertices, edges, and faces, given edge  $e$ :

1. Edge-vertex relation: the two constituent vertices ( $VSTART(e)$  and  $VEND(e)$ )
2. Edge-face relation: the two adjacent faces ( $FCW(e)$  and  $FCCW(e)$ )

---

<sup>33</sup> An equivalent naming convention for the wings that finds common use (e.g., [1232, 1637]) lets  $EPCW(e)$  ( $ENCW(e)$ ) and  $EPCCW(e)$  ( $ENCCW(e)$ ) denote the preceding  $P$  (next  $N$ ) edges in a clockwise traversal of faces  $FCW(e)$  and  $FCCW(e)$ , respectively. Note that the clockwise and counterclockwise directions are synonymous with next and preceding, respectively, given our assumption that the edge-edge relation stores a traversal of the edges in a clockwise order around a face in the winged-edge-face representation.

<sup>34</sup> Use of the equivalent naming convention for the wings described in footnote 33 (e.g., [1232, 1637]) results in  $ENCCW(e)$  ( $EPCW(e)$ ) and  $ENCW(e)$  ( $EPCCW(e)$ ) denoting the preceding  $P$  (next  $N$ ) edges in a clockwise traversal of the edges incident at vertices  $VSTART(e)$  and  $VEND(e)$ , respectively. Again, we note that the clockwise and counterclockwise directions are synonymous with next and preceding, respectively, given our assumption that the edge-edge relation stores a traversal of the edges incident at a vertex in a clockwise order in the winged-edge-vertex representation.

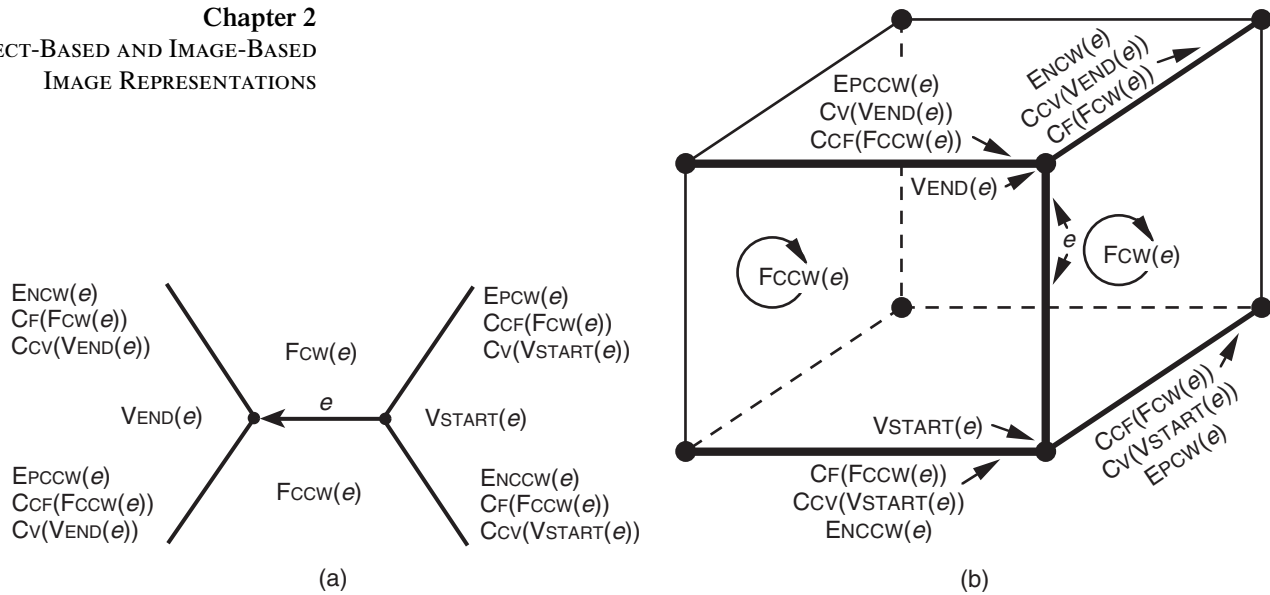

Figure 2.89  
(a) Example of an edge  $e$  and its four wings and (b) the physical interpretation of  $e$  and its wings when  $e$  is an edge of a parallelepiped represented by the winged-edge data structure.

Figure 2.90  
Sample parallelepiped with vertices (V1–V8), edges (E1–E12), and faces (F1–F6).

- Edge-face relation: the preceding faces (CCF(VSTART( $e$ )) and CCF(VEND( $e$ ))) and the next faces (CV(VSTART( $e$ )) and CV(VEND( $e$ ))) incident at the two vertices, thereby incorporating the vertex-edge relation, as well as the face-edge relation when using an alternative interpretation of the wings of the edge.

As an example of the winged-edge data structure, consider the parallelepiped in Figure 2.89(b), whose individual vertices, edges, and faces are labeled and oriented according to Figure 2.90. One possible implementation of a winged-edge representation for it is given by tables VERTEXEDGETABLE and FACEEDGETABLE in Figures 2.91 and 2.92, which correspond to the partial vertex-edge and face-edge relations, respectively, and the collection of edge records that make up the edge-edge relation given by Figure 2.93. Observe that VERTEXEDGETABLE and FACEEDGETABLE are really indexes (i.e., access structures) that enable an efficient response to queries on the basis of the value of a given vertex  $v$  or face  $f$ , such as finding all of the edges incident at  $v$  or the edges that  $f$  comprises, respectively, in both the clockwise and counterclockwise orders. This information is accessed by the field EDGE as the tables may contain additional information, such as the actual  $x$ ,  $y$ , and  $z$  coordinate values of the vertex in the case of VERTEXEDGETABLE.

FACE $f$	EDGE
F1	E1
F2	E5
F3	E11
F4	E9
F5	E4
F6	E8

Figure 2.92  
FACEEDGETABLE[ $f$ ].

In particular,  $\text{EDGE}(\text{VERTEXEDGETABLE}[v]) = e$  contains a pointer to an edge record  $e$  that is incident at vertex  $v$ , while  $\text{EDGE}(\text{FACEEDGETABLE}[f]) = e$  contains a pointer to an edge record  $e$  that is part of face  $f$ .

It is also important to note that, given a pointer to an edge record  $e$ , the edge-edge relation makes use of fields  $\text{CCFFCW}(e)$ ,  $\text{CVVSTART}(e)$ ,  $\text{CFFCW}(e)$ ,  $\text{CCVVEND}(e)$ ,  $\text{CCFFCCW}(e)$ ,  $\text{CVVEND}(e)$ ,  $\text{CFFCCW}(e)$ , and  $\text{CCVSTART}(e)$ , instead of  $\text{CCF}(\text{FCW}(e))$ ,  $\text{CV}(\text{VSTART}(e))$ ,  $\text{CF}(\text{FCW}(e))$ ,  $\text{CCV}(\text{VEND}(e))$ ,  $\text{CCF}(\text{FCCW}(e))$ ,  $\text{CV}(\text{VEND}(e))$ ,  $\text{CF}(\text{FCCW}(e))$ , and  $\text{CCV}(\text{VSTART}(e))$ , respectively. This is done in order to indicate that the pointer to the appropriate edge record in the corresponding field in the relation is obtained by storing it there explicitly instead of obtaining it by dynamically computing the relevant functions each time the field is accessed (e.g., the field  $\text{CCFFCW}(e)$  stores the value  $\text{CCF}(\text{FCW}(e))$  directly rather than obtaining it by applying the function  $\text{CCF}$  to the result of applying  $\text{FCW}$  to  $e$  each time this field is accessed).

A crucial observation is that the orientations of the edges are not given either in  $\text{VERTEXEDGETABLE}$  or  $\text{FACEEDGETABLE}$  or in the edge-edge relation. The absence of the orientation is compensated for by the presence of the  $\text{VSTART}$ ,  $\text{VEND}$ ,  $\text{FCW}$ , and  $\text{FCCW}$  fields in the edge-edge relation. This means that, given a face  $f$  (vertex  $v$ ), the edge  $e$  stored in the corresponding  $\text{FACEEDGETABLE}$  ( $\text{VERTEXEDGETABLE}$ ) entry is not sufficient by itself to indicate the next or previous edges in  $f$  (incident at  $v$ ) without checking whether  $f$  is the value of the clockwise  $\text{FCW}(e)$  or the counterclockwise  $\text{FCCW}(e)$  face field ( $v$  is the value of the start  $\text{VSTART}(e)$  or end  $\text{VEND}(e)$  vertex field) of record  $e$  in the edge-edge relation. Thus, the algorithms that use this orientationless representation must always check the contents of  $\text{FCW}(e)$  and  $\text{FCCW}(e)$  ( $\text{VSTART}(e)$  and  $\text{VEND}(e)$ ) for the use of face  $f$  (vertex  $v$ ). The same is also true upon making a transition from one edge to another edge when the edge has not been obtained from  $\text{VERTEXEDGETABLE}$  or  $\text{FACEEDGETABLE}$ .

As an example of the use of these tables, consider procedure  $\text{EXTRACTEDGESOF-FACE}$  given below, which extracts the edges of face  $f$  in either clockwise or counterclockwise order. Let  $e$  denote an edge in  $f$ , obtained from  $\text{FACEEDGETABLE}$ , and use the interpretation of  $e$ 's wings as adjacent edges along adjacent faces of  $e$  (i.e., the winged-edge-face variant). For a clockwise ordering, if  $f = \text{FCW}(e)$ , then the next edge is  $\text{CFFCW}(e)$ ; otherwise,  $f = \text{FCCW}(e)$ , and the next edge is  $\text{CFFCCW}(e)$ . For a counterclockwise ordering, if  $f = \text{FCW}(e)$ , then the next edge is  $\text{CCFFCW}(e)$ ; otherwise,

Figure 2.93  
Edge-edge relation.

$f = FCCW(e)$ , and the next edge is  $CCFCCW(e)$ . This process terminates when we encounter the initial value of  $e$  again. For example, extracting the edges of face  $F_1$  in Figure 2.90 in clockwise order yields  $E_1, E_2, E_3$ , and  $E_4$ . The execution time of `EXTRACTEDGESOFFACE` is proportional to the number of edges in  $f$  as each edge is obtained in  $O(1)$  time. This is a direct consequence of the use of `FACEEDGETABLE`, without which we would have had to find the first edge by a brute-force (i.e., a sequential) search of the edge-edge relation. Similarly, by making use of `VERTEXEDGETABLE` to obtain an edge incident at vertex  $v$ , we can extract the edges incident at  $v$  in time proportional to the total number of edges that are incident at  $v$  as each edge can be obtained in  $O(1)$  time (see Exercise 2).

```

1  procedure EXTRACTEDGESOFFACE( $f, CWFlag$ )
2  /* Extract the edges making up face  $f$  in clockwise (counterclockwise) order
   if flag  $CWFlag$  is true (false). */
3  value face  $f$ 
4  value Boolean  $CWFlag$ 
5  pointer edge  $e, FirstEdge$ 
6   $e \leftarrow FirstEdge \leftarrow EDGE(FACEEDGETABLE[f])$ 
7  do
8  output  $e$ 
9  if  $CWFlag$  then
10      $e \leftarrow$  if  $FCW(e) = f$  then  $CFFCW(e)$ 
11         else  $CFCCW(e)$ 
12     endif
13 else  $e \leftarrow$  if  $FCW(e) = f$  then  $CCFFCW(e)$ 
14         else  $CCFFCCW(e)$ 
15     endif
16 endif
17 until  $e = FirstEdge$ 
18 enddo

```

The above interpretations are not the only ones that are possible. Another interpretation, among many others, which finds much use, interprets the four wings in terms of the next edges at each of the faces that are adjacent to  $e$  and the next edges incident at each of the two vertices that make up  $e$ . In this case, we have combined the interpretations of the wings  $CF(FCW(e))$  and  $CF(FCCW(e))$  as used in the winged-edge-face data structure with the interpretations of the wings  $CV(VSTART(e))$  and  $CV(VEND(e))$  as used in the winged-edge-vertex data structure. The result is known as the *quad-edge data structure* [767]. It keeps track of both the edges that make up the faces in the clockwise direction and the edges that are incident at the vertices in the clockwise direction.

The quad-edge data structure is of particular interest because it automatically encodes the dual graph, which is formed by assigning a vertex to each face in the original graph and an arc to each edge between two faces of the original graph. In other words, we just need to interpret the cycles through the edges around the vertices in the original graph as faces in the dual graph and the cycles through the edges that the faces comprise in the original graph as vertices in the dual graph. In addition, the exterior face, if one exists, in the original graph is also assigned a vertex in the dual graph, which is connected to every face in the original graph that has a boundary edge. This makes the quad-edge data structure particularly attractive in applications where finding and working with the dual mesh is necessary or useful. For example, this is the case when the mesh corresponds to a Voronoi diagram whose dual is the Delaunay triangulation (DT). We discuss this further in Section 2.2.1.4. Another advantage of the quad-edge data structure over the winged-edge-face and winged-edge-vertex data structures is that, in its most general formulation, the quad-edge data structure permits making a distinction between the two sides of a surface, thereby allowing the same vertex to serve as the two endpoints of an edge, as well as allowing dangling edges, and so on.

From the above, we see that the winged-edge-face, winged-edge-vertex, and quad-edge data structures are identical in terms of the information that they store for each

Figure 2.94  
The physical interpretation of the (a) winged-edge-face, (b) winged-edge-vertex, and (c) quad-edge data structures for a pair of adjacent faces of a simple object. Assume an implementation that links the next and preceding edges in clockwise order for faces in (a), for vertices in (b), and next edges in clockwise order for both faces and vertices in (c).

edge (i.e., the edge-edge relation entries are the same). However, they do have different physical interpretations, as can be seen in Figure 2.94. In particular, this figure shows that both the winged-edge-face (Figure 2.94(a)) and winged-edge-vertex (Figure 2.94(b)) data structures associate two doubly linked circular lists with each edge  $e$  (one list for each of the two faces adjacent to  $e$  in the case of the winged-edge-face data structure and one list for each of the two vertices at which  $e$  is incident in the case of the winged-edge-vertex data structure), while the quad-edge data structure (Figure 2.94(c)) associates four singly linked circular lists with each edge  $e$  (one list for each of the two faces adjacent to  $e$  and one list for each of the two vertices that are incident at  $e$ ). Thus, all three data structures make use of four circular lists, and, in fact, they are isomorphic in the sense that they all provide access to the same topological information with identical running times up to a constant factor.

It is interesting to point out that other combinations of four circular lists can be formed to yield additional physical interpretations of the winged-edge data structure. In particular, we could have also defined the quad-edge data structure in terms of the preceding edges in clockwise order for each of the two adjacent faces and incident vertices, which is the same as a counterclockwise order because “preceding” in clockwise order is equivalent to “next” in counterclockwise order. In fact, this implementation is used by the U.S. Bureau of the Census in the TIGER representation of road networks [280],<sup>35</sup> which are planar graphs and to whose representation our methods are applicable. As can be seen, many combinations are possible. However, not all combinations of next/preceding, clockwise/counterclockwise for the vertex/face pairs are allowed. In essence, the key to determining if a combination is permitted is to ascertain whether the combination permits obtaining all of the edges that make up a face and all of the edges that are incident at a vertex in constant time for both clockwise and counterclockwise traversal orders. For example, an invalid combination is one that keeps track of the next edges for the vertices that make up the edge in clockwise (counterclockwise) order while keeping track of the next edges that make up the adjacent faces in counterclockwise (clockwise) order. This combination will not let us obtain the edges that are incident at a vertex (that make up a face) in counterclockwise (clockwise) order in time proportional to the number of edges that are found (see Exercise 4 for the invalid combinations).

We can also try to make use of fewer circular lists (i.e., two), which essentially means that we are keeping track of a subset of the edge-edge relation. In particular, this is done in a data structure known as the *D-CEL* [1322], which, for a given edge  $e$ , stores either the preceding edges in the two faces ( $CCF(FCW(e))$  and  $CCF(FCCW(e))$ ) or the next edges in the two faces ( $CF(FCW(e))$  and  $CF(FCCW(e))$ ), but not both (see Figure 2.95(a), which corresponds to a clockwise traversal of the edges that make up the faces of the simple object in Figure 2.94, where there is one circle around each face that is adjacent to an edge). The D-CEL incorporates both the face-edge and vertex-edge relations with the limitation that, as a result, we can traverse either the faces (vertices) in clockwise (counterclockwise) order or the faces (vertices) in counterclockwise (clockwise) order, respectively, in time proportional to the number of edges, but not in both orders. The advantage of the D-CEL is that less information must be recorded for each edge, at the loss of some query-processing power. Of course, we still need the face-edge table and vertex-edge table to determine the edges associated with a face and a vertex, as well as the FCW, FCCW, VSTART, and VEND fields if we want to avoid keeping track of the orientation.

Note that we could also interpret the D-CEL data structure as storing either the preceding edges incident at each of the two vertices that make up the edges ( $CCV(VSTART(e))$  and  $CCV(VEND(e))$ ) or the next edges incident at each of the two vertices ( $CV(VSTART(e))$  and  $CV(VEND(e))$ ), but not both (see Figure 2.95(b), which corresponds to a counterclockwise traversal of the edges that are incident at the vertices of the simple object in Figure 2.94, where there is one circle around each vertex at which an edge is incident).

Figure 2.95  
The physical interpretation of the (a) D-CEL-face and (b) D-CEL-vertex data structures for a pair of adjacent faces of the simple object in Figure 2.94. Assume an implementation that links the next edges in clockwise order for faces in (a) and in counterclockwise order for vertices in (b).

<sup>35</sup> Actually, the oriented variant (discussed later in this section) is the one used.

We distinguish between these two interpretations by using *D-CEL-face* to refer to the former and *D-CEL-vertex* to refer to the latter. From Figure 2.95, it is interesting to observe that, as in the case of the winged-edge-face, winged-edge-vertex, and quad-edge data structures, although the physical interpretations of the D-CEL-face and D-CEL-vertex data structures differ, for the traversal orders that we have used (i.e., clockwise around the faces and counterclockwise around the vertices), the two data structures are isomorphic (as are the winged-edge-face, winged-edge-vertex, and quad-edge data structures for all orders) in the sense that they all provide access to the same topological information with identical running times up to a constant factor. This isomorphism can be seen also when, given a traversal order  $o$ , say clockwise, without loss of generality, we interpret the D-CEL data structure so that, for each edge  $e$ , it stores the following information:

1. The preceding or next edge  $e'$  (i.e., in order  $o$ ) in one of the faces  $f$  adjacent to  $e$  such that vertex  $v'$  is common to both  $e$  and  $e'$
2. The next or preceding edge  $e''$  around the vertex  $v''$ , in order opposite to  $o$  (i.e., counterclockwise, without loss of generality, in our example), where  $v''$  is the other vertex of  $e$

We can use *D-CEL-face-vertex* to refer to this variant of the D-CEL data structure. Note that the D-CEL-face-vertex data structure is not the same as a data structure that contains two singly linked lists so that there is one singly linked list around one of the two constituent vertices of each edge and one singly linked list around one of the two faces adjacent to each edge (see Exercise 7).

As we pointed out, our implementation of the winged-edge data structures ignores the orientation of the edges. This is possible because the identity of the faces that are adjacent to the edge, as well as the identity of the vertices at which the edge is incident, is stored explicitly in all of the variants of the data structure. Thus, knowing the identity of the face  $f$  (vertex  $v$ ) that is being traversed enables the algorithms to determine the appropriate transition because, once an edge  $e$  is identified as either one of the edges in the face (incident at the vertex) via the face-edge (vertex-edge) table or as an intermediate edge in the face (incident at the vertex), then the orientation is determined by the face (vertex) field entry in the edge-edge relation whose value is  $f$  ( $v$ ). Therefore, the algorithms must perform an extra lookup operation in the edge-edge relation before determining the next edge after  $e$  in the face  $f$  (incident at the vertex  $v$ ), which is achieved by the tests  $\text{FCW}(e) = f$  or  $\text{FCCW}(e) = f$  ( $\text{VSTART}(e) = v$  or  $\text{VEND}(e) = v$ ).

By keeping track of the orientation, we can eliminate the extra lookup operation, thereby avoiding having to store the adjacent faces and incident vertices in the edge-edge relation—that is, removing the need for the FCW, FCCW, VSTART, and VEND fields. This allows us to have an implicit variant of the winged-edge data structure where the topology of the objects is decoupled from the information about the identities of the vertices, edges, and faces that the object comprises. Nevertheless, as we saw earlier, just knowing the identity of an edge is not sufficient to identify an object, as the edge can be a part of two faces; likewise, the edge can be incident at two vertices. Thus, in order to have an implicit winged-edge representation, our representation needs to be able to distinguish between the two faces (vertices) that are adjacent to (make up) the edge. In particular, the various next-edge fields of the edge-edge relation in the implicit variants of the winged-edge data structure must indicate more than just the next edge  $e$ —that is, they also need to indicate whether this next edge  $e$  is a part of a traversal of a clockwise or counterclockwise adjacent face (starting or ending vertex). Similarly, the face-edge (vertex-edge) table must indicate more than just an edge in the edge-edge relation corresponding to an edge  $e$  in the face (incident at the vertex)—that is, it also needs to indicate whether this edge  $e$  is a part of a traversal of a clockwise or counterclockwise adjacent face (starting or ending vertex). Therefore, in essence, the table entries (i.e., face-edge and vertex-edge) and next-edge fields of the edge-edge relation in an implicit winged-edge representation can be characterized as *oriented edges* in contrast to the unoriented edges in the explicit winged-edge representation (i.e., the nonoriented winged-edge data structure)

VERTEX $v$	X	Y	Z	ORIENTEDEDGE

V8	X8	Y8	Z8	-E8

Figure 2.96  
ORIENTEDVERTEXEDGETABLE[ $v$ ].

Figures 2.96 to 2.98 illustrate an example of one possible implementation of the implicit winged-edge representation corresponding to the winged-edge representation given by the partial vertex-edge and face-edge relations in tables VERTEXEDGETABLE and FACEEDGETABLE of Figures 2.91 and 2.92, respectively, and the collection of edge records that make up the edge-edge relation given by Figure 2.93. In particular, tables ORIENTEDFACEEDGETABLE and ORIENTEDVERTEXEDGETABLE correspond to tables VERTEXEDGETABLE and FACEEDGETABLE, respectively. This implementation uses the orientation of the edges given by the VSTART and VEND fields in Figure 2.93. Notice that we have also included the VSTART, VEND, FCW, and FCCW fields in Figure 2.98, although they are not needed in the execution of most of the queries. We use the term *oriented winged-edge* representation to describe this structure.

FACE $f$	ORIENTEDEDGE

F2	E5
F3	E11
F4	E9
F5	-E4
F6	-E8

Figure 2.97  
ORIENTEDFACEEDGETABLE[ $f$ ].

The implementation in Figures 2.96 to 2.98 is such that a positive orientation value for a transition to edge  $e$  from one of the edges  $e'$  in the oriented edge-edge relation or in an ORIENTEDFACEEDGETABLE entry for face  $f$  indicates that  $e$ 's direction makes  $e$  a part of a clockwise traversal of a clockwise adjacent face  $f$  (i.e.,  $FCW(e) = f$ ), while a negative orientation value indicates that  $e$ 's direction makes  $e$  a part of a clockwise traversal of a counterclockwise adjacent face  $f$  (i.e.,  $FCCW(e) = f$ ). Similarly, in the context of the vertices, this assignment of orientations means that a positive orientation value for a transition to edge  $e$  from one of the edges  $e'$  in the oriented edge-edge relation or in an ORIENTEDVERTEXEDGETABLE entry for vertex  $v$  indicates that  $e$ 's direction

Figure 2.98  
Oriented edge-edge relation.

makes  $e$  a part of a clockwise traversal of an ending vertex  $v$  of  $e$  (i.e.,  $VEND(e) = v$ ), and thus  $e$  is directed towards  $v$ . A negative orientation value indicates that  $e$ 's direction makes  $e$  a part of a clockwise traversal of a starting vertex  $v$  of  $e$  (i.e.,  $VSTART(e) = v$ ), and thus  $e$  is directed away from  $v$  (see Exercise 5).

The entries in `ORIENTEDFACEEDGETABLE`, `ORIENTEDVERTEXEDGETABLE`, and the oriented edge-edge relation that correspond to pointers to oriented edges are implemented as pointers to records of type `edge_orientation_pair`, with two fields `EDGE` and `ORIENT` containing a pointer to the edge record in the oriented edge-edge relation corresponding to one of the edges  $e$  that are adjacent to the appropriate face  $f$  (incident at the appropriate vertex  $v$ ) and  $e$ 's orientation, as defined above, respectively. Observe the difference from the unoriented variant, where the corresponding entries were pointers to records of type `edge`. Again, as in the case of the edge-edge relation, we note that for a given edge  $e$ , the oriented edge-edge relation (Figure 2.98) makes use of fields `CCFFCW(e)`, `CVVSTART(e)`, `CFFCW(e)`, `CCVVEND(e)`, `CCFFCCW(e)`, `CVVEND(e)`, `CFFCCW(e)`, and `CCVVSTART(e)`, instead of `CCF(FCW(e))`, `CV(VSTART(e))`, `CF(FCW(e))`, `CCV(VEND(e))`, `CCF(FCCW(e))`, `CV(VEND(e))`, `CF(FCCW(e))`, and `CCV(VSTART(e))`, respectively. As we pointed out before, this is done in order to indicate that the appropriate edge value in the corresponding field in the table is obtained by storing it there explicitly instead of obtaining it by dynamically computing the relevant functions each time the field is accessed (e.g., the field `CCFFCW(e)` stores the value `CCF(FCW(e))` directly rather than obtaining it by applying the function `CCF` to the result of applying `FCW` to  $e$  each time this field is accessed).

It should be clear that, as is the case with the explicit variants of the winged-edge data structures (i.e., the winged-edge-face, winged-edge-vertex, and quad-edge), the values for the various fields of the elements of the oriented edge-edge relation for all of the oriented variants are also still the same.

As an example of the use of these tables, consider procedure `EXTRACTORIENTED-EDGESOFFACE`, given below, which extracts the edges of face  $f$  in either clockwise or counterclockwise order. Let  $e$  denote an edge in  $f$ , obtained from the face-edge table `ORIENTEDFACEEDGETABLE`. For a clockwise ordering, if  $e$ 's orientation is positive (i.e.,  $f = FCW(e)$ ), then the next edge is `CFFCW(e)`; otherwise,  $e$ 's orientation is negative (i.e.,  $f = FCCW(e)$ ), and the next edge is `CFFCCW(e)`. For a counterclockwise ordering, if  $e$ 's orientation is positive (i.e.,  $f = FCW(e)$ ), then the next edge is `CCFFCW(e)`; otherwise,  $e$ 's orientation is negative (i.e.,  $f = FCCW(e)$ ), and the next edge is `CCFFCCW(e)`. This process terminates when we encounter the initial value of  $e$  again. For example, extracting the edges of face `F1` in Figure 2.90 in clockwise order yields `E1`, `E2`, `E3`, and `E4`. Again, as in the nonoriented case, the execution time of `EXTRACTORIENTEDEDGESOFFACE` is proportional to the number of edges in  $f$  as each edge is obtained in  $O(1)$  time. Note that, in contrast to the unoriented variant of the algorithm (i.e., procedure `EXTRACTEDGESOFFACE`), only one lookup operation in the oriented edge-edge relation is performed at each traversal step in the algorithm (although the oriented edge is accessed twice, once to determine the orientation and once to determine the next edge to which the transition is to be made). Similarly, by making use of the vertex-edge table `ORIENTEDVERTEXEDGETABLE` to obtain an edge incident at vertex  $v$ , we can extract the edges incident at  $v$  in time proportional to the total number of edges that are incident at  $v$  as each edge can be obtained in  $O(1)$  time (see Exercise 6).

- 1 **procedure** `EXTRACTORIENTEDEDGESOFFACE(f, CWFlag)`
- 2 /\* Extract the edges making up face  $f$  in clockwise (counterclockwise) order if flag `CWFlag` is true (false) in an oriented winged-edge-face data structure. For each edge  $e$ , a positive orientation value indicates that  $e$ 's direction makes  $e$  a part of a traversal of a clockwise adjacent face  $f$  (i.e.,  $FCW(e) = f$ ), while a negative value indicates that  $e$ 's direction makes  $e$  a part of a traversal of a counterclockwise adjacent face  $f$  (i.e.,  $FCCW(e) = f$ ). \*/

```

17     endif
18   endif
19   until EDGE(p) = FirstEdge
20 enddo

```

Notice that, theoretically speaking, the implicit representation does not contain any identifying information for the vertices and faces, which means that all query responses are in terms of edges. For example, a face would be identified by a list of its constituent edges, and a vertex would be identified by a list of the edges that are incident at it. As the latter method of identifying the vertices making up an edge is somewhat cumbersome, an edge is usually identified by its constituent vertices, which are obtained from an auxiliary table or are stored as part of the edge in the implicit representation, although they are not accessed during the process of determining the transitions to the next edges when traversing the edges incident at a vertex.

One of the drawbacks of the implicit representation is that responding to queries, such as finding the next or preceding edge to a particular edge  $e$  in face  $f$  (incident at vertex  $v$ ) in order  $o$ , requires us to know if  $f(v)$  is a clockwise or counterclockwise adjacent face (starting or ending vertex). This is relatively easy in the case of queries that involve vertices (i.e., finding the preceding or next edge incident at vertex  $v$  relative to edge  $e$ ), because, as we pointed out, the edge is usually identified by its constituent vertices, which are stored in an auxiliary table. Alternatively, we can augment the oriented winged-edge data structure by also storing this information along with the edge, although it is not accessed in determining transitions to the next edges when traversing the edges incident at a vertex. Without this information, we cannot tell if  $v$  is a starting or ending vertex of edge  $e$  unless we perform a search starting in the ORIENTEDVERTEXEDGETABLE entry corresponding to  $v$  and traverse all of the edges incident at  $v$  in order  $o$  in search of  $e$ . Similarly, in order to be able to respond to queries involving faces (i.e., finding the preceding or next edge in face  $f$  relative to edge  $e$ ) as well, we should also augment the oriented winged-edge data structure with an auxiliary table that stores the adjacent faces for each edge. Otherwise, again, without this information, we cannot tell if  $f$  is a clockwise or counterclockwise adjacent face of edge  $e$  unless we perform a search starting in the ORIENTEDFACEEDGETABLE entry corresponding to  $f$  and traverse all of the edges making up  $f$  in order  $o$  in search of  $e$ . Therefore, incorporating these auxiliary tables into the oriented winged-edge data structure means that the augmented oriented winged-edge data structure is almost identical to the original winged-edge data structure with the difference that the execution of queries, such as finding all edges a face comprises (incident at a vertex), does not require more than one lookup operation in the oriented edge-edge relation per edge.

Note that knowing the orientation of the edge  $e$  whose next or preceding edge in  $f$  (or incident at  $v$ ) is sought in the implicit representation only ensures that the next edge is along the same face or incident at the same vertex—that is, the same clockwise adjacent face (ending vertex) when the orientation is positive and the same counterclockwise

Figure 2.99  
The physical interpretation of the fields of a half-edge-face data structure (i.e., the face variant of the half-edge data structure that is based on a traversal of the edges making up a face).

adjacent face (starting vertex) when the orientation is negative. However, knowing the orientation of the edge and  $f(v)$  may lead to some confusion when  $e$  has a positive orientation and  $f(v)$  is really the counterclockwise adjacent face (starting vertex) of  $e$ , and vice versa, when  $e$  has a negative orientation. In other words, a positive orientation means that  $f = FCW(e)$  ( $v = VEND(e)$ ), while a negative orientation means that  $f = FCCW(e)$  ( $v = VSTART(e)$ ).

The orientation issues described above are eliminated in the half-edge data structure [196], which decouples the clockwise and counterclockwise face (starting and ending vertex) information in the winged-edge data structure by storing each edge twice, once for each direction, where each instance is called a *half-edge* and each of the two half-edges corresponding to a single edge is referred to as the *companion half-edge* of the other half-edge. In particular, instead of  $n$  edges, we now have  $2n$  directed half-edges. With each half-edge  $h$ , we record the following information (see Figure 2.99):

1. Starting vertex ( $VSTART(h)$ )
2. Companion half-edge ( $h'$ )
3. Face ( $FCW(h)$ ) along whose boundary  $h$  lies when moving in clockwise order
4. Preceding half-edge ( $CCF(FCW(h))$ ) in clockwise order along the face on whose boundary  $h$  lies
5. Next half-edge ( $CF(FCW(h))$ ) in clockwise order along the face on whose boundary  $h$  lies

Thus, the half-edge data structure is equivalent to a partition of the winged-edge data structure so that there is one element (i.e., half-edge) for each face in which the edge is a member. As in the winged-edge data structure, the half-edge data structure makes use of a face-edge table and vertex-edge table to determine the half-edges associated with a face and a vertex, respectively, although it identifies the relevant half-edges instead of the relevant edges, as in the corresponding winged-edge data structure. Similarly, as in the oriented winged-edge data structure, traversing the edges that make up a face is achieved with one lookup operation per edge in the half-edge data structure, in the sense that the information is encoded explicitly in the structure (again using  $CCF(FCW(h))$  and  $CF(FCW(h))$  instead of  $CCF(FCW(h))$  and  $CF(FCW(h))$ , respectively). This is in contrast to the winged-edge data structure, where we saw that two lookup operations are needed for each traversal step. Note that traversing the edges that are incident at a vertex using the half-edge data structure is a bit more complex as we first need to find the incoming edge and then to use its companion half-edge, thereby obtaining the next edge incident at  $v$  in clockwise order. Observe that the variant of the half-edge data structure that we have presented above is defined in terms of a traversal of edges making up the faces. We can also construct a variant of the half-edge data structure that is defined in terms of a traversal of the edges that are incident at the vertices (see Exercise 11). When necessary, we differentiate between these two variants of the data structure by using the terms *half-edge-face* and *half-edge-vertex* to refer to the former and the latter, respectively.

The only drawback of the half-edge data structure is the need to store the pointer to the companion half-edge, thereby requiring more storage than the winged-edge data structure (i.e., 10 items of information per edge instead of 8). However, we can save the space needed for the pointer to the companion half-edge by storing the two half-edges in consecutive locations. In this way, we need only determine which of the two half-edges we are currently processing and then access the companion half-edge. At this point, we can continue the traversal along the appropriate half-edge. This means that the storage requirements of the winged-edge and half-edge data structures are now the same.

### Exercises

1. The face-edge, vertex-edge, and edge-edge relations that make up the winged-edge data structure can be viewed as a set of relations involving vertices, edges, and faces in a relational database management system. The format of the relations is often described as satisfying

several rules called *normal forms* (e.g., [554]). Do these relations satisfy the second normal form (2NF)? Do they satisfy the third normal form (3NF)? Do they satisfy the Boyce-Codd normal form (BCNF)?

2. Give an algorithm to extract the entire set of edges that is incident at each vertex when using the winged-edge-face data structure.
3. The winged-edge-face data structure is defined in such a way that the edge-edge relation encodes a traversal of the faces adjacent to an edge in clockwise order. In other words, we can obtain all of the edges adjacent to clockwise face  $f$  in clockwise (counterclockwise) order by following the CFFCW (CCFFCW) fields, while we can obtain all of the edges adjacent to counterclockwise face  $f'$  in clockwise (counterclockwise) order by following the CFFCCW (CCFFCCW) fields—that is, all edges  $e$  satisfy  $FCW(e) = f$  in the former and  $FCCW(e) = f'$  in the latter. Give a similar interpretation to the winged-edge-vertex data structure in terms of the traversal of edges incident at a vertex  $v$  in clockwise (counterclockwise) order around  $v$  where either all edges  $e$  satisfy  $VEND(e) = v$  or  $VSTART(e) = v$ .
4. What are the invalid combinations of next/preceding, clockwise/counterclockwise for the vertex/face pairs that can be used to form a quad-edge data structure?
5. Can you give an explanation or rationalization for why the assignment of edge orientations used in the implementation of the implicit (i.e., oriented) winged-edge data structure when the transitions are interpreted in terms of being in the same face (i.e., a winged-edge-face data structure) so that positive (negative) orientations are associated with clockwise traversals of the clockwise (counterclockwise) adjacent faces correspond to clockwise traversals of the ending (starting) vertices when the transitions are interpreted in terms of being incident at the same vertex (i.e., a winged-edge vertex data structure)? In other words, why do we associate FCW and VEND (FCCW and VSTART) with the positive (negative) orientations instead of FCW and VSTART (FCCW and VEND)?
6. Write an algorithm EXTRACTORIENTEDEDGESINCIDENTATVERTEX to extract the edges that are incident at vertex  $v$  in clockwise (counterclockwise) order in an oriented winged-edge-face data structure.
7. Can you define a variant of the D-CEL data structure that contains two singly linked lists so that there is one singly linked list around one of the two constituent vertices of each edge and one singly linked list around one of the two faces adjacent to each edge? Note that this variant is not the same as the D-CEL-face-vertex data structure.
8. How would you find the two vertices that make up an edge when using the half-edge-face data structure (i.e., the face variant of the half-edge data structure given in the text)?
9. Give an algorithm to extract the entire set of edges making up a face when using the half-edge-face data structure (i.e., the face variant of the half-edge data structure given in the text).
10. Give an algorithm to extract the entire set of edges that are incident at each vertex when using the half-edge-face data structure (i.e., the face variant of the half-edge data structure given in the text).
11. Define the half-edge-vertex data structure (i.e., the vertex variant of the half-edge data structure).
12. Repeat Exercise 8 for the half-edge-vertex data structure (i.e., the vertex variant of the half-edge data structure).
13. Repeat Exercise 9 for the half-edge-vertex data structure (i.e., the vertex variant of the half-edge data structure).
14. Repeat Exercise 10 for the half-edge-vertex data structure (i.e., the vertex variant of the half-edge data structure).

### 2.2.1.3 Vertex-Based and Face-Based Methods Using Laths

The winged-edge representation is an implementation of a BRep in terms of the edge-edge relation. It is an edge-based representation in that the boundary of the object is represented in terms of its edges, where there is one record for each edge. The advantage of this representation is that each record is of uniform size. Moreover, as

we saw in Section 2.2.1.2, the winged-edge representation enables us to calculate the full set of adjacency relationships (termed *queries* below) involving the vertex, edge, and face primitive entities (i.e., all nine of them) in all orders (e.g., clockwise and counterclockwise around a vertex and a face, and opposite in the case of an edge) in time proportional to the size of the result set.

For example, using the winged-edge representation, we can extract the edges and vertices forming a face  $f$  or the edges and faces incident at a vertex  $v$  in both clockwise and counterclockwise orders in time proportional to the number of edges or vertices in  $f$  and the number of edges or faces incident at  $v$ , respectively. Of course, this assumes the presence of an index (i.e., access structure) that is really a pair of additional tables, known as FACEEDGETABLE and VERTEXEDGETABLE, that partially capture the vertex-edge and face-edge relations, thereby facilitating the search to locate an edge in face  $f$  or an edge incident at vertex  $v$ . The exact identity of the edge that is stored in the access structure is not important for most of the queries—that is, all that is required is the ability to locate one of the edges efficiently. In fact, other queries that can be performed using the same execution time include finding all edges incident at the two vertices of an edge, all faces sharing an edge or a vertex with a given face (i.e., a variant of the frontier of the face), and all vertices that share an edge with a given vertex. The remaining queries to determine all vertices incident at an edge and faces adjacent to an edge are performed by a simple lookup operation as this information is stored directly in the winged-edge and quad-edge data structures.

Uniform-sized representations that are vertex based are also possible. Their advantage is that the vertex is the simplest topological entity, whereas the edge and face are more complex and can be expressed in terms of the vertex objects they comprise. However, the drawback of the vertex-based methods is that we cannot have one record per vertex because the topological information associated with each vertex is more complex than that which is associated with each edge. In particular, whereas the full topological description of an object (i.e., in terms of the other primitive elements) can be obtained (i.e., derived) by knowing a subset of the edges that are associated with each edge as a direct result of the fact that each edge is associated with just two vertices and two faces (assuming a two-manifold), in contrast, there can be a variable number of edges and faces associated with each vertex. In other words, in order to obtain the full topological description of an object given each of its vertices, we need to know the full connectivity of each vertex, which precludes the use of a uniform-sized representation where there is one record per vertex. Similarly, if we want to use a face-based representation, we cannot have a uniform-sized representation where there is one record per face because there is a variable number of edges and vertices associated with each face.

Nevertheless, by examining the set of adjacency relations, we can have a uniform-sized representation where there is a variable number of records for each vertex. In particular, we observe that an object can be fully described by the set of all possible edge-face pairs (edge-face relation), the set of all possible edge-vertex pairs (edge-vertex relation), or the set of all possible face-vertex pairs (face-vertex relation) that it comprises whose cardinality is easily seen to be the same (i.e., twice the number of edges) in the absence of special treatment for boundaries (see Exercise 1). This idea is the principle behind the lath family of data structures of Joy, Legakis, and MacCracken [973], who use the term *lath* to denote a specific instance or element of these data structures. In particular, each object is described by the set of laths it comprises using the appropriate lath data structure. It should be clear that, being vertex based, in each of the different lath representations, a single vertex is associated with each lath, although in all cases, with the exception of a BRep that consists of an isolated vertex, more than one lath is associated with each vertex. Similarly, a single edge is associated with each lath; likewise, a single face is associated with each lath. Since an edge consists of two vertices, it is clear that two laths are associated with each edge. On the other hand, in the case of a face  $f$ , there are as many laths associated with  $f$  as there are vertices (equivalently, as many laths as there are edges) making up  $f$ . Moreover, for laths that do not involve a vertex explicitly

such as the edge-face laths, the associated vertex is chosen in such a way that a unique vertex is associated with each of the laths that make up  $f$ .

In the rest of this section, we expand on the lath family of vertex-based data structures. It is organized as follows. Section 2.2.1.3.1 presents the different lath data structures for two-manifold objects. Section 2.2.1.3.2 shows how to use the lath data structures to handle unstructured meshes where the data has boundaries. Section 2.2.1.3.3 compares the different lath data structures while pointing out some of their desirable properties, as well as gives a brief description of face-based lath data structures. It also shows how most of the edge-based representations described in Section 2.2.1.2 can be formulated as combinations of vertex-based representations defined in terms of laths.

### Exercise

1. Prove that, given a two-manifold object with no boundary edges, the number of possible edge-vertex pairs, the number of possible edge-face pairs, and the number of possible face-vertex pairs are all the same.

#### 2.2.1.3.1 Lath Data Structures for Manifold Objects

Unlike the winged-edge data structure, the lath data structures do not encode the edge-edge relation. They also do not encode the edge-face, edge-vertex, or face-vertex relations (or, alternatively, the face-edge, vertex-edge, and vertex-face relations), although they are very similar. Instead, the basic entity of the lath data structure is one of the three combinations: edge-face, edge-vertex, or face-vertex.<sup>36</sup> In particular, let  $(a, b)$  denote the instance of the lath data structure that is being used, where  $a$  and  $b$  are bound to distinct elements of  $\{vertex, edge, face\}$ . Thus, the data structure encodes the  $(a, b) - (a, b)$  relation (or, more generally, the lath-lath relation). In order to be able to execute the various queries, at the minimum, we must be able to navigate between instances (i.e., elements or laths) of the lath data structure that is being used. Therefore, given a specific lath  $(x, y)$  instance of lath data structure  $(a, b)$ , we must be able to transition to the lath corresponding to the next object of type  $b$  for object  $x$  and to transition to the lath corresponding to the next object of type  $a$  for object  $y$ . We wish to execute the queries by storing the minimum amount of information with each instance of the data structure, which is three, corresponding to the associated vertex  $v$  and the two transitions, which are termed the *primitive transitions*. Thus, letting  $c$  denote *next*, each instance of the lath data structure  $(a, b)$  stores  $v$  and transitions  $ca$  and  $cb$ . Depending on the binding of  $a$  or  $b$ , we may have a choice between a transition to the next object or to a prior object. In particular, this is the case for vertices ( $v$ ) and faces ( $f$ ), in which case we speak of clockwise ( $c$ ) and counterclockwise ( $cc$ ) transitions instead of next and prior transitions, respectively. In the case of an edge ( $e$ ), we only have a next ( $c$ ) transition, which we characterize as transitioning to a *companion*.

Before presenting more precise definitions of the different lath data structures, we point out that all queries that involve laths are mappings from one lath to another lath or from one lath to a set of laths. Determining the corresponding edge, vertex, and face, or sets of laths often requires the execution of additional steps that usually involve a few lookup operations or at least a constant number of operations per element making up the result of the operation that is to be returned (e.g., if we want to return all vertices or edges that make up a face). We have seen similar considerations in terms of lookup costs in our discussion of the distinction between the half-edge data structure and the implicit (i.e., oriented) variants of the winged-edge data structure, on the one hand, versus the explicit variants of the winged-edge data structure, on the other hand, in determining the edges associated with a face or incident at a vertex (Section 2.2.1.2).

---

<sup>36</sup> We could have also used the terms *face-edge*, *vertex-edge*, and *vertex-face*, respectively.

It is also important to note that the lath data structures used in the vertex-based representations can be distinguished from the explicit winged-edge data structures that are based on the edge-edge relation by observing that the explicit winged-edge data structures include explicit information on both the topology of the faces containing the edges and the identity of the faces and vertices that are incident at them. In contrast, the lath data structures decouple these two pieces of information and only represent the topological information explicitly. In particular, only the vertices are represented explicitly in the lath data structures.

The identities of the faces that are adjacent to an edge, as well as the identity of one of the vertices that makes up an edge, are represented implicitly in the lath data structures instead of being stored explicitly, as is the case in the explicit winged-edge data structures. In addition, only a subset of the transitions from an edge to an adjacent edge along a face or incident at the same vertex is stored explicitly in the lath data structures, whereas a greater number of these transitions are stored explicitly in the winged-edge data structures. Therefore, for example, in order to identify the face or edge associated with a specific edge-face pair in an edge-face lath data structure, we need to retrieve all of the laths it comprises and look up the associated vertices, thereby enabling us to identify the face and edges in terms of their constituent vertices. This is not surprising given that the vertex is the primitive entity of the lath representations, and hence their characterization as being vertex based.

Of course, regardless of which lath data structure is used, we also need the analog of the face-edge and vertex-edge tables used in the winged-edge data structures to enable the execution of the queries. Recall that these tables serve as an index (i.e., access structure) that enables the search to locate an edge in face  $f$  or an edge incident at vertex  $v$ . In the case of the lath data structures, these tables record a lath (not necessarily unique) that is associated with the distinct instance of the relevant object type, which is an element of  $\{vertex, edge, face\}$ . Unlike the winged-edge data structures, where the principal element was an edge, the lath data structures are in terms of pairs of object types (i.e., edge-face, edge-vertex, and face-vertex), and thus we also need an edge-lath table instead of just a vertex-lath and a face-lath table. These three tables enable the efficient response to queries that seek, for example, all faces adjacent to and vertices making up a specific edge, all vertices and edges making up a specific face, and all edges and faces incident at a specific vertex—that is, the edge-face and edge-vertex relations, face-vertex and face-edge relations, and vertex-edge and vertex-face relations, respectively. We use the terms *face-lath table*, *vertex-lath table*, and *edge-lath table* to refer to these tables.

It should be clear that the execution of some of the queries may be faster (from a computational complexity standpoint) if additional information is stored or capable of being derived easily, for each instance of the lath data structure. In other words, although we only store information about two primitive transitions for each lath, some queries may be simpler to perform given information about the other nonprimitive transitions. For example, extracting the edges incident at a vertex  $v$  or the edges making up a face  $f$  in counterclockwise order is easier if the laths store explicit, or make it easy to derive, information about how to make counterclockwise transitions instead of just clockwise transitions.

In the following, we describe in greater detail three members of the lath family of data structures, one for each of the three combinations: edge-face, edge-vertex, and face-vertex. Letting  $(a, b)$  denote the instance of the lath data structure that is being described, where  $a$  and  $b$  are bound to two distinct elements of  $\{vertex, edge, face\}$ , and  $o$  is bound to the remaining element of the set, and assuming that the primitive transitions  $ca$  and  $cb$  are stored with each lath instance of  $(a, b)$ , we also show how the other transitions  $cca$ ,  $ccb$ , and  $co$  (as well as possibly  $ca$  and  $cb$ , if one of  $b$  or  $a$ , respectively, is bound to an element for which only transitions to the next laths are possible rather than transitions to both next and prior laths) can be made.

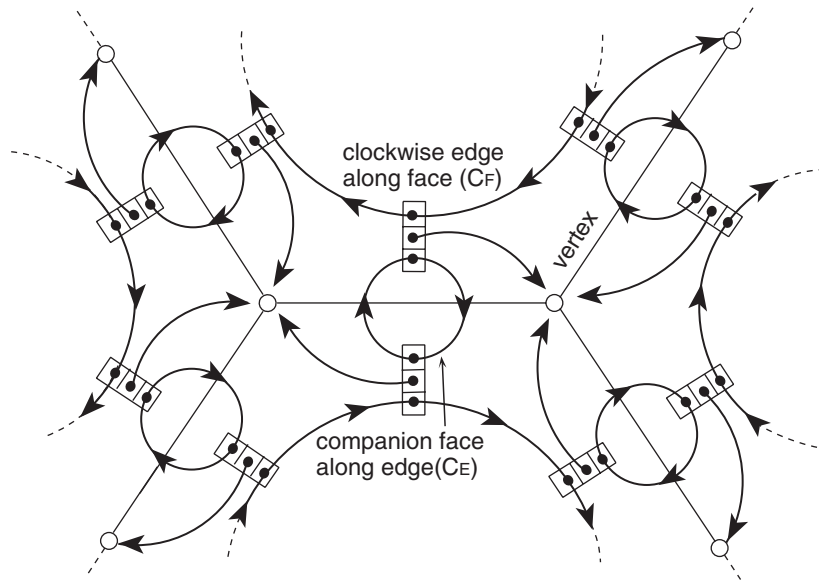

Figure 2.100  
Example set of split-face lath elements and some transitions.

We use the terms *split-face*, *split-vertex*, and *corner* to refer to the three lath data structures corresponding to the edge-face, edge-vertex, and face-vertex pairs, respectively. Our naming convention differs slightly from that of Joy, Legakis, and MacCracken [973], who used the terms *split-edge*, *half-edge*, and *corner*, respectively. We have chosen this approach in order to avoid confusion with the well-known half-edge data structure [196] (see Section 2.2.1.2). Note that our naming conventions also capture the actions that lead to the creation of the pairs. In particular, a *split-face* denotes an edge-face pair, which results from splitting an edge record into two parts (one per adjacent face), while a *split-vertex* denotes an edge-vertex pair, which results from splitting an edge record into two parts (one per constituent vertex). A *corner* denotes a face-vertex pair, which corresponds to a corner of a face.

The lath-based split-face data structure represents the object by a lath record  $L = (e, f)$  that contains the following information for the edge-face pair corresponding to edge  $e$  and face  $f$ , assuming the orientation in Figure 2.100:

1. A pointer to the vertex  $v$  associated with  $L$
2. A pointer to the lath record corresponding to the other face  $f$  adjacent to  $e$ , as well as the vertex of edge  $e$  opposite to the one associated with  $L$  (i.e., the next edge-face pair along  $e$ )—that is,  $CE(L)$
3. A pointer to the lath record corresponding to the next edge that follows  $L$  in a clockwise traversal of face  $f$  (i.e., the next edge-face pair along  $f$ )—that is,  $CF(L)$

The nonprimitive transitions are defined as follows.  $CCV(L)$  is obtained by  $CF(CE(L))$ , which is easy to compute as it makes use of the primitive transitions  $CE$  and  $CF$ .  $CV(L)$  can be obtained by either successively traversing the laths representing face  $f$  using  $CF$  until obtaining a lath  $L'$  such that  $CF(L') = L$  and then applying  $CE(L')$  to obtain  $L''$  so that  $CV(L) = L''$ , or by successively traversing the laths surrounding the vertex associated with  $L$  using  $CCV$  until obtaining a lath  $L'$  such that  $CCV(L') = L$ , which means that  $CV(L) = L'$ .  $CCF(L)$  is obtained by  $CE(CV(L))$ . As we see, given lath  $L = (e, f)$ , whose associated vertex is  $v$ , the split-face lath representation is not conducive to finding the lath corresponding to the next edge incident at vertex  $v$  in the clockwise direction ( $CV$ ) or the next edge in face  $f$  in the counterclockwise direction ( $CCF$ ) efficiently. Figure 2.101 is an example of the split-face lath data structure for a pair of adjacent faces of the simple object in Figure 2.94.

Figure 2.101  
An example split-face lath data structure for a pair of adjacent faces of the simple object in Figure 2.94. Assume an implementation that links the laths corresponding to the next edges that make up a face in clockwise order. A pointer is shown from each lath to its associated vertex and to the lath corresponding to the face on the other side of the corresponding edge.

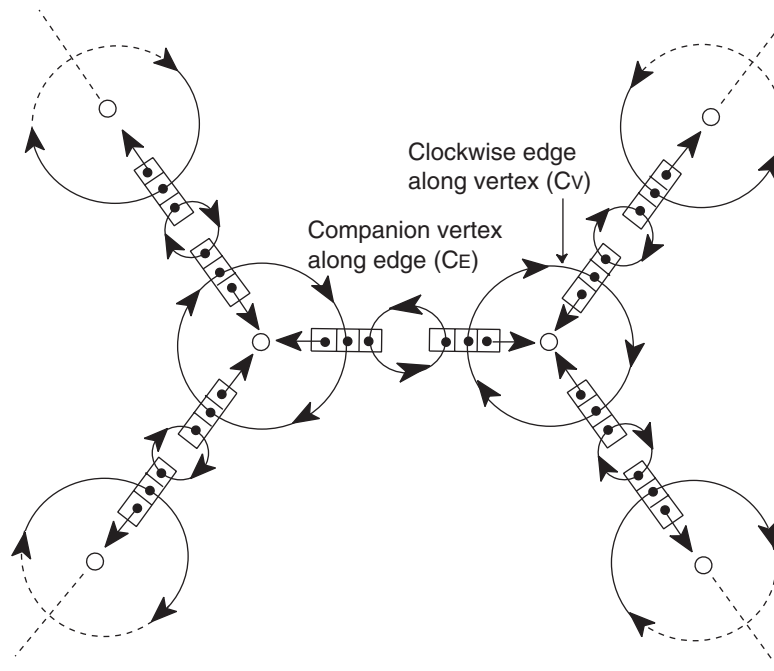

Figure 2.102  
Example set of split-vertex lath elements and some transitions.

The lath-based split-vertex data structure represents the object by a lath record  $L = (e, v)$  that contains the following information for the edge-vertex pair corresponding to edge  $e$  and vertex  $v$ , assuming the orientation in Figure 2.102:

1. A pointer to the vertex  $v$  associated with  $L$
2. A pointer to the lath record that represents the same edge  $e$  as  $L$  but the opposite vertex of  $e$  (i.e., the next edge-vertex pair along  $e$ )—that is,  $CE(L)$
3. A pointer to the lath record corresponding to the next edge that follows  $L$  in a clockwise traversal of vertex  $v$  (i.e., the next edge-vertex pair along  $v$ )—that is,  $CV(L)$

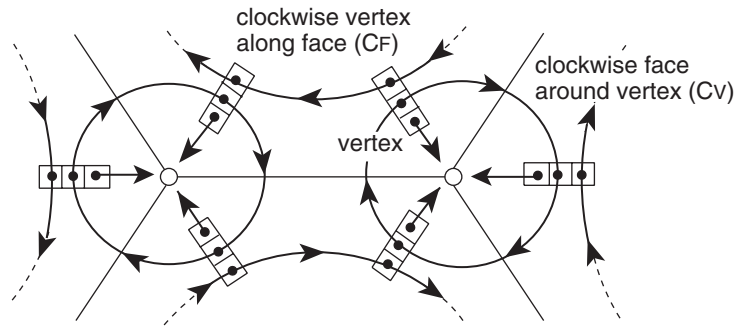

Figure 2.104  
Example set of corner lath elements and some transitions.

The nonprimitive transitions are defined as follows:  $CCF(L)$  is obtained by  $CE(CV(L))$ , which is easy to compute as it makes use of the primitive transitions  $CE$  and  $CV$ .  $CF(L)$  can be obtained in two ways. The first is by applying  $CE(L)$  to obtain the lath  $L'$  of the same edge  $e$  but opposite vertex  $v'$  and then successively traversing the laths surrounding  $v'$  using  $CV$  until obtaining a lath  $L''$  such that  $CV(L'') = L'$ , which means that  $CF(L) = L''$ . The second is by successively traversing the laths representing the face  $f$  in which  $L$  is a member using  $CCF$  until obtaining a lath  $L'$  such that  $CCF(L') = L$ , which means that  $CF(L) = L'$ .  $CCV(L)$  is obtained by  $CF(CE(L))$ . As we see, given lath  $L = (e, v)$ , whose associated face is  $f$ , the split-vertex lath representation is not conducive to finding the lath corresponding to the next edge in face  $f$  in the clockwise direction ( $CF$ ) or the next edge incident at vertex  $v$  in the counterclockwise direction ( $CCV$ ) efficiently. Figure 2.103 is an example of the split-vertex lath data structure for a pair of adjacent faces of the simple object in Figure 2.94.

The lath-based corner data structure represents the object by a lath record  $L = (f, v)$  that contains the following information for the face-vertex pair corresponding to face  $f$  and vertex  $v$ , assuming the orientation in Figure 2.104:

1. A pointer to the vertex  $v$  associated with  $L$
2. A pointer to the lath record corresponding to the next vertex that follows  $L$  in a clockwise traversal of face  $f$  (i.e., the next face-vertex pair along  $f$ )—that is,  $CF(L)$
3. A pointer to the lath record corresponding to the next face that follows  $L$  in a clockwise traversal of vertex  $v$  (i.e., the next face-vertex pair along  $v$ )—that is,  $CV(L)$

The nonprimitive transitions are obtained as follows.  $CE(L)$  is obtained by  $CV(CF(L))$ .  $CCF(L)$  is obtained by  $CE(CV(L))$ .  $CCV(L)$  is obtained by  $CF(CE(L))$ . All three nonprimitive transitions are easy to compute because they all make use of the primitive transitions  $CF$  and  $CV$ . It is interesting to note that, unlike the split-face and split-vertex lath representations, all of the transitions can be implemented in the corner lath representation in constant time, except along the boundary, as we point out in Section 2.2.1.3.2. Figure 2.105 is an example of the corner lath data structure for a pair of adjacent faces of the simple object in Figure 2.94.

### Exercises

1. Why can we not define a lath data structure variant in which the primitive transitions are the pairs  $CF$  and  $CCF$ ?
2. Repeat Exercise 1 for a lath data structure variant in which the primitive transitions are the pairs  $CV$  and  $CCV$ .

## Section 2.2 BOUNDARY-BASED REPRESENTATIONS

Figure 2.103  
An example split-vertex lath data structure for a pair of adjacent faces of the simple object in Figure 2.94. Assume an implementation that links the laths corresponding to the next edges that are incident at a vertex in clockwise order. A pointer is shown from each lath to its associated vertex and to the lath corresponding to the vertex on the other side of the corresponding edge.

Figure 2.105  
An example corner lath data structure for a pair of adjacent faces of the simple object in Figure 2.94. Assume an implementation that links the laths corresponding to the next edges that make up a face in clockwise order and likewise links the laths corresponding to the next edges that are incident at a vertex in clockwise order. A pointer is shown from each lath to its associated vertex.

3. Given a lath  $L$  in a lath representation of a two-manifold object with no boundary edges, show that, regardless of which of the split-face, split-vertex, and corner lath representations is used,  $CE(L)$  is uniquely determined.
4. Our definition of the split-face lath data structure assumes an orientation for each edge-face pair lath that is reflected by the vertex that is associated with each lath. Given that we are dealing with two-manifold objects, since an edge is made up of two vertices and is adjacent to two faces, there are two possible orientations for each lath. Referring to Figure 2.100, suppose that you reverse the orientation by associating the left, instead of the right, vertex with the lath. What effect does this change of orientation have on the definitions of the transitions for the split-face lath data structure in the case of objects?
5. Repeat Exercise 4 for the split-vertex lath data structure, referring to Figure 2.102.
6. Repeat Exercise 4 for the corner lath data structure, referring to Figure 2.104.

### 2.2.1.3.2 Lath Data Structures for Meshes with Boundaries

The data structures that we have described assume that the mesh corresponds to a manifold object (a two-manifold for three-dimensional objects with two-dimensional surfaces). They can also be used to describe unstructured two-dimensional meshes where the data has boundaries. This means that, unlike the three-dimensional object where all of the faces are part of the object, we also have a face that is not part of the object, termed the *boundary face*. Thus, some of the edges and vertices are members of the boundary of the mesh (i.e., of both the mesh and the boundary face). A key issue in the incorporation of a boundary is how to indicate its presence. There are a number of possible solutions.

The first is to add a flag to each lath record to indicate whether the associated vertex and edge combination is part of the boundary of a face in the mesh, in contrast to not being part of the boundary of any of the faces in the mesh, assuming that laths corresponding to vertex and edge combinations in the boundary face are not present. This is a simple solution whose cost is the storage that is required for the flag in the form of an additional bit in each lath record. An alternative solution, and the one that we adopt, is to overload one of the primitive operations (transitions to lath  $L'$ ) on the lath  $L$  to use the value `NIL` (i.e.,  $L'$  is set to `NIL`) to indicate that  $L$  is part of the boundary (i.e., the vertex and edge combination associated with  $L$  corresponds to a boundary edge whose associated face  $f$  is not the boundary face and hence  $f$  is in the mesh) while the face  $f'$  associated with the next lath  $L'$  is the boundary face and hence  $f'$  is not in the mesh.

At this point, we discuss how to choose which of the primitive transitions in an instance  $L = (x, y)$  of lath data structure  $(a, b)$  should use the value `NIL` when  $(x, y)$  is part of the boundary to indicate that the next instance  $L' = (x', y')$  is part of the boundary face. We have at most two choices. We can either let the next  $(a, b)$  pair (i.e., lath) corresponding to an instance of object type  $b$  for instance  $x$  of object type  $a$  be `NIL` (i.e.,  $ca(L)$ ), or let the next  $(a, b)$  pair (i.e., lath) corresponding to an instance of object type  $a$  for instance  $y$  of object type  $b$  be `NIL` (i.e.,  $cb(L)$ ). The important criterion that dictates our choice is that the object instance and lath for which the transition is being performed must both be a boundary element and also be in the mesh for which it serves as a boundary element (otherwise, it might not be encountered during normal processing of the mesh), while the object instance and lath that is the result of the transition (i.e., that is pointed at and set to `NIL`) must be a part of the boundary (i.e., in the boundary face) and not be in the mesh for which it serves as a member of the boundary. In other words, in the latter case, we are not replacing an object instance that is on the boundary, while its corresponding lath is not, with `NIL` (this would be the case, for example, if, in the split-vertex lath data structure, we were to choose to set  $CV(L)$  to `NIL` instead of choosing to set  $CE(L)$  to `NIL` when  $L$  corresponds to a lath that is in the mesh).

Given the above considerations, the following transitions are the ones that are set to `NIL` to indicate that lath instance  $L = (x, y)$  of the corresponding lath data structure is part of the boundary. For the split-face lath data structure,  $CE(L)$  is set to `NIL` because it denotes the situation that  $L$  corresponds to a boundary edge object  $x$ , and its value is the

next face object, which is the boundary face object. For the corner lath data structure,  $CV(L)$  is set to  $NIL$  because it denotes the situation that  $L$  corresponds to a boundary vertex object  $y$ , and its value is the next face object, which is the boundary face object. For the split-vertex lath data structure, the situation is a bit more complex as neither of the objects  $x$  or  $y$  is the boundary face, while both  $x$  and  $y$  lie on the boundary. Thus, the decision must be made on the basis of which value is in the boundary face. In this case, we see that  $CE(L)$  is set to  $NIL$  because it denotes the situation that  $L$  corresponds to a boundary edge object  $x$  and its value is the next vertex object  $y'$  whose associated lath  $L' = (x, y')$  is part of the boundary face. In contrast, we do not set  $CV(L)$  to  $NIL$  because it denotes the situation that  $L$  corresponds to a boundary vertex object  $y$  whose value is the next edge object  $x'$  whose associated lath  $L'' = (x', y)$  is not on the boundary face.

Regardless of the lath data structure that is used, the manner in which we incorporate the boundary results in boundary edges that are distinguished from nonboundary edges by having only one lath associated with them instead of two—that is, the companion lath  $CE(L)$  is not present when lath  $L$  is associated with boundary edge  $e$ , whether explicitly (as in the split-face and split-vertex lath data structures) or implicitly (as in the corner lath data structure), and thus  $CE(L) = NIL$ . It is easy to see that this is also true for the corner lath data structure that is not explicitly defined in terms of edge objects as  $CE(L) = CV(CF(L))$ , which is  $NIL$  for a face-vertex pair on the boundary. Therefore, disregarding the order (clockwise or counterclockwise) and starting edge have been specified. Moreover, the same algorithm can be used to determine the set of boundary laths for all of the lath data structures (see Exercise 2). Nevertheless, some of the transitions for the different lath data structures must be modified to deal with the presence of  $NIL$  values and the absence of some of the companion laths of the boundary edges. This is discussed in greater detail below.

First of all, irrespective of which lath data structure is used, when lath  $L$  corresponds to a boundary edge  $e$ , no laths can follow  $L$  in the counterclockwise direction around vertex  $v$  associated with  $L$ , and thus  $CCV(L)$  is always  $NIL$ . Since  $CCV(L)$  is defined in terms of  $CE(L)$  (i.e.,  $CCV(L) = CF(CE(L))$ ), the definition of  $CF$  is modified not to apply  $CF$  if  $CE(L)$  is  $NIL$  and simply to return  $NIL$  as the result in this case. The absence of a companion lath means that nonprimitive transitions that involve transitions through the missing lath, as is the case when the transitions are in the form of a successive traversal of the laths surrounding  $v$ , cannot be used. Therefore, in the case of the split-face lath data structure, given lath  $L$  corresponding to edge-face pair  $(e, f)$ , only use the definition of  $CV$  that successively traverses the laths representing face  $f$  using repeated invocations of  $CF$  until obtaining a lath  $L'$  such that  $CF(L') = L$ , followed by an application of  $CE(L')$  to obtain  $L''$  so that  $CV(L) = L''$ . Similarly, in the case of the corner lath data structure, given lath  $L$  corresponding to face-vertex pair  $(f, v)$ , do not use the definition  $CCF(L) = CE(CV(L))$ . Instead, use a definition of  $CCF$  that successively traverses the laths representing the face  $f$  in which  $L$  is a member, using  $CF$  until obtaining a lath  $L'$  such that  $CF(L') = L$  and thus  $CCF(L) = L'$ . For example, Figure 2.106(a) is the split-face lath data structure for the unstructured mesh corresponding to Figure 2.101 with laths on the boundary having  $NIL$   $CE$  values, while Figure 2.106(c) is the corresponding corner lath data structure for Figure 2.105 with laths on the boundary having  $NIL$   $CV$  values.

On the other hand, in the case of the split-vertex lath data structure, the absence of the companion lath  $L' = (e, v')$  of the lath  $L$  corresponding to edge-vertex pair  $(e, v)$  when  $e$  is a boundary edge requires modifications to both primitive and nonprimitive transitions. First of all,  $L$  replaces  $L'$  as the next lath in clockwise order after lath  $L'' = (e', v')$  around vertex  $v'$ —that is,  $CV(L'') = L$  instead of  $CV(L'') = L'$ . In addition, since  $CCF$  is defined in terms of  $CV$ ,  $CCF(L'') = CE(CV(L''))$  must be redefined to yield  $L$  when  $CV(L'') = L$  and  $CE(CV(L'')) = NIL$ . Second, as we pointed out above, the absence of a companion lath means that nonprimitive transitions that involve transitions through the missing lath, as is the case when the transitions are in the form of a successive traversal of the laths

## Section 2.2 BOUNDARY-BASED REPRESENTATIONS

Figure 2.106 Examples of (a) split-face, (b) split-vertex, and (c) corner lath data structures for an unstructured mesh consisting of a pair of adjacent triangles analogous to the pair of adjacent faces in Figures 2.101, 2.103, and 2.105, respectively. Assume implementations that link the laths corresponding to the next edges that make up a face in (a) and (c) in clockwise order and that links the laths corresponding to the next edges that are incident at a vertex in (b) and (c) in clockwise order. A pointer is shown from each lath to its associated vertex. Laths on the boundary in (a) and (b) are shown with  $NIL$   $CE$  values, while in (c) they are shown with  $NIL$   $CV$  values.

surrounding  $v$ , cannot be used. Therefore, only use the definition of CF that successively traverses the laths representing the face  $f$  associated with  $L$  using repeated invocations of CCF until obtaining a lath  $L'$  so that  $CCF(L') = L$ , which means that  $CF(L) = L'$ . For example, Figure 2.106(b) is the split-vertex lath data structure for the unstructured mesh corresponding to Figure 2.103 with laths on the boundary having NIL CV values.

The main problem caused by the absence of a companion lath in our implementation for all three lath data structures is that a lath that corresponds to an edge of the boundary face (i.e., a companion lath of a boundary edge) cannot be returned as a valid value of a transition. In particular, this is the case when the companion lath is to be returned as the value of CV( $L$ ), which is NIL, for a lath  $L$  associated with vertex  $v$  regardless of whether  $L$  corresponds to a boundary edge (e.g., laths A and B in the example split-face lath data structure in Figure 2.106(a), corresponding to boundary and nonboundary edges, respectively). This problem is encountered when we execute the query that seeks the laths corresponding to all of the edges incident at vertex  $v$ . The presence of the boundary means that, in general, obtaining a response to this query starting at the lath of an arbitrary edge requires making use of two successive traversals starting at  $v$ , one for each of the clockwise and counterclockwise directions around  $v$ .

Nevertheless, the response will not contain a lath corresponding to an edge of the boundary face. Assuming the orientations of the laths in Figures 2.100, 2.102, and 2.104, we can overcome this absence by using the lath  $L'$  corresponding to  $CCF(L) = CE(CV(L))$  (e.g., C in Figure 2.106(a) for  $CCF(B)$ ), which is obtained by successively traversing the laths representing the face  $f$  in which  $L$  is a member using CF until obtaining a lath  $L'$  such that  $CF(L') = L$  and thus  $CCF(L) = L'$ . However,  $L'$  must be used with caution as the vertex  $v'$  associated with  $L'$  is not the same as the vertex  $v$  associated with  $L$  (e.g., vertex E is associated with lath B in Figure 2.106(a) while vertex G is associated with lath C =  $CCF(B)$ ). Alternatively, we can choose to return NIL in this case. Note that, although we illustrated this problem with the aid of the split-face lath data structure, the problem also arises for the remaining lath data structures (i.e., split-vertex and corner, as can be seen in Figure 2.106(b, c) using the same laths and vertices).

A similar problem arises when the companion lath  $L'$  is to be returned as the value of CE( $L$ ) for a lath  $L$  associated with boundary edge  $e$  such that  $L$  is in the mesh and not in the boundary face, while  $L'$  is in the boundary face and not in the mesh, and for which CE( $L$ ) = NIL. This problem is encountered in all of the lath data structures when we execute the query that seeks the laths corresponding to all of the vertices that are incident at boundary edge  $e$  (see also Exercise 1). The presence of the boundary means that the response to this query starting at the lath  $L$  associated with edge  $e$  and vertex  $v$  involves the vertex  $v'$  associated with the companion lath  $L'$  whose associated edge is  $e$  where  $L'$  is in the boundary face. Thus, we cannot report  $L'$  because it is not present. However, assuming the orientations of the laths in Figures 2.100, 2.102, and 2.104, we can overcome this problem by using the lath  $L''$  corresponding to CF( $L$ ) (e.g., B in Figure 2.106 for CF(C)). This is a primitive transition for the split-face and corner lath data structures, but in the case of the split-vertex lath data structure, we make use of the definition of CF that successively traverses the laths representing the face  $f$  in which  $L$  is a member using CCF until obtaining a lath  $L''$  such that  $CCF(L'') = L$ , which means that  $CF(L) = L''$ . However, regardless of which lath data structure is used,  $L''$  must be used with caution as the edge  $e'$  associated with  $L''$  is not the same as the edge  $e$  associated with  $L$  (e.g., edge EF is associated with lath B = CF(C) in Figure 2.106, while edge EG is associated with lath C).

Joy et al. [973] incorporate the boundary in the split-vertex lath data structure in a different way, thereby avoiding some of the problems described above. Their implementation is based on an observation that given boundary edge-vertex lath instance  $L = (x, y)$  and its companion lath instance  $L' = (x, y')$ , it is impossible for the instances of the next objects to be of object type *face*, which precludes the boundary face from serving as the object of the transition that is set to NIL as in the other lath data structures. Thus, they choose one of the instances of the object types in the two laths that is on the

boundary and set the transition to the next instance of the other object type to NIL. In particular, they choose the lath and object type for which the transition is to an instance of the other object that is in the boundary face rather than on the boundary but not in the mesh. Therefore,  $CV(L')$  is set to NIL because it denotes the situation that  $L'$  corresponds to a boundary vertex object  $y'$ , and its value is the next edge object  $x'$  that is in the boundary, face and is not part of the boundary, as the role of  $x$  in  $L'$  is as an edge object which is on the boundary but not in the mesh. Note that this means that Joy et al. retain the definition of CE, where  $CE(L') = L$  and  $CE(L) = L'$ .

The implementation of Joy et al. [973] described above has the property that, unlike the split-face and corner lath data structures, each boundary edge is represented by two laths instead of one. This means that incorporating the boundary in the split-vertex lath data structure using this implementation requires fewer modifications to the definitions of the transitions in the original variant described earlier that does not make provisions for the boundary. In particular, besides setting  $CV(L')$  to NIL for all laths  $L'$  that are companions of laths  $L$  whose associated face is in the mesh while also having an associated edge that is on the boundary, we also need to guarantee that the remaining transitions are implemented in such a way that they avoid successive traversals of laths for which CV is NIL, unless this is the desired effect. This is achieved by ensuring that transitions that could be defined in terms of successive traversals of laths surrounding a vertex (using CV) are instead defined in terms of successive traversals of laths representing a face (using CCF). In particular,  $CF(L)$  is implemented by successively traversing the laths representing the face  $f$  associated with  $L$  using CCF until obtaining the lath  $L''$  such that  $CCF(L'') = L$  and thus  $CF(L) = L''$  (but see Exercise 5). For example, Figure 2.107 is the split-vertex lath data structure for the unstructured mesh corresponding to Figure 2.103 with laths on the boundary having NIL CV values.

In addition, the implementation of Joy et al. [973] means that tracing the boundary of the mesh represented by the modified split-vertex lath data structure uses a different algorithm (see Exercise 3) than the one used for the split-face and corner lath data structures (see Exercise 2). Actually, we can use the same algorithm (i.e., the one in Exercise 2) for all three lath data structures if we further modify the split-vertex lath data structure also to set  $CE(L)$  to NIL for all laths  $L$  where  $CV(L') = \text{NIL}$  for the companion lath  $L'$  of  $L$ —that is, the face associated with  $L$  is in the mesh while also having an associated edge that is on the boundary (see Exercise 16). In this case,  $CE(L')$  is still pointing at  $L$  because, otherwise, there may be a loss in querying power for certain mesh configurations as some of the transitions may not be possible (see Exercise 15). Moreover, regardless of whether we make this modification (see Exercise 6) or not (see Exercise 4), we can also trace the boundary and provide the response in terms of the companion laths  $L'$  for which  $CV(L') = \text{NIL}$ .

Figure 2.107  
The implementation of Joy et al. [973] of the split-vertex lath data structure for an unstructured mesh consisting of a pair of adjacent triangles analogous to the pair of adjacent faces in Figure 2.103. Assume an implementation that links the laths corresponding to the next edges that are incident at a vertex in clockwise order. A pointer is shown from each lath to its associated vertex and to the lath corresponding to the vertex on the other side of the corresponding edge. Laths corresponding to boundary edges are shown with NIL CV values in the companion lath.

### Exercises

1. In the text, we pointed out that our incorporation of the boundary resulted in boundary edges being distinguished from nonboundary edges by having only one lath associated with them instead of two—that is, the companion lath  $CE(L)$  is not present when lath  $L$  is associated with boundary edge  $e$ , whether explicitly (as in the split-face and split-vertex lath data structures) or implicitly (as in the corner lath data structure), and thus  $CE(L) = \text{NIL}$ . This meant that the companion laths cannot be returned as valid values of a transition. We observed that this is a drawback because it means that some queries cannot be performed, such as determining the laths corresponding to all of the edges incident at a given vertex or the laths corresponding to all of the vertices that are incident at a given edge. The problem is that some of these laths are part of the boundary face. Are there any other queries that share this drawback?
2. Give a pair of algorithms to trace the laths corresponding to the edges that make up the boundary face of a lath data structure in both counterclockwise and clockwise orders where the response is in terms of the laths  $L$  for which  $CE(L) = \text{NIL}$ .

3. Repeat Exercise 2 for an implementation of the split-vertex lath data structure using the variant proposed by Joy et al. [973] where a boundary edge  $e = (v_1, v_2)$  with vertices  $v_1$  and  $v_2$  is represented by the two edge-vertex pair laths  $L = (e, v_1)$  and  $L' = (e, v_2)$  such that  $L'$  is part of the boundary face where  $CE(L) = L'$ ,  $CE(L') = L$ , and  $CV(L') = \text{NIL}$ .
4. Using the implementation of the split-vertex lath data structure of Joy et al. [973] that retains the companion laths  $L'$  of laths  $L$  for edges on the boundary of the mesh and for which  $CV(L') = \text{NIL}$ , give an algorithm to trace the boundary of the split-vertex lath data structure in both counterclockwise and clockwise orders by reporting the laths  $L'$  for which  $CV(L') = \text{NIL}$ , instead of the laths  $L$  for which  $CE(L) = \text{NIL}$ , as in Exercise 3. In other words, the response is in terms of the companion laths that correspond to edge-vertex pairs whose associated face is the boundary face. Note that this is only possible for this variant of the split-vertex lath data structure as it is the only one for which the companion laths of boundary edges are present (i.e., they are not present for the split-face and corner lath data structures).
5. Assume that the boundary has been incorporated in the split-vertex lath data structure using the method of Joy et al. [973] (i.e., by setting  $CV(L')$  to  $\text{NIL}$  for the companion lath  $L'$  of the lath  $L$  that corresponds to a boundary edge). In the text we argued that, in this case, since  $CV(L')$  is  $\text{NIL}$ , it is best not to define a nonprimitive transition in terms of successive traversals of laths surrounding a vertex (using  $CV$ ). We followed this line of reasoning in the definition of the  $CF$  transition by basing it on the  $CCF$  transition rather than a successive traversal around the vertex associated with the companion of  $L$  using  $CV$ . However, closer scrutiny reveals that  $CCF$  is also defined in terms of  $CV$ —that is,  $CCF(L) = CE(CV(L))$ . How can you rationalize this apparent contradiction?
6. Repeat Exercise 4 for the modification of the split-vertex lath data structure discussed in the text where  $CE(L)$  is also set to  $\text{NIL}$  for all laths  $L$  for edges on the boundary, when  $CV(L') = \text{NIL}$  for the companion lath  $L'$  of  $L$ . Recall that  $CE(L')$  is still set to  $L$ .
7. What is the cost of determining the laths that make up the boundary in counterclockwise order for the split-face lath data structure when the boundary is incorporated so that only one lath is associated with each edge?
8. What is the cost of determining the laths that make up the boundary in clockwise order for the split-face lath data structure when the boundary is incorporated so that only one lath is associated with each edge?
9. Repeat Exercise 7 for the corner lath data structure.
10. Repeat Exercise 8 for the corner lath data structure.
11. Repeat Exercise 7 for the split-vertex lath data structure.
12. Repeat Exercise 8 for the split-vertex lath data structure.
13. Repeat Exercise 7 for the implementation of Joy et al. [973] of the split-vertex lath data structure.
14. Repeat Exercise 8 for the implementation of Joy et al. [973] of the corner lath data structure.
15. Suppose that you incorporate a boundary edge in the split-vertex lath data structure so that the  $CE$  transitions of both laths that are associated with the boundary edge are  $\text{NIL}$  while retaining the same meaning for the remaining transitions—that is, boundary edge  $e = (v_1, v_2)$  with vertices  $v_1$  and  $v_2$  is represented by the two edge-vertex pair laths  $L = (e, v_1)$  and  $L' = (e, v_2)$  such that  $L'$  is part of the boundary face, and  $CE(L) = CE(L') = CV(L') = \text{NIL}$ . Is there a loss in querying power in the sense that some of the queries that involve the boundary edges are no longer possible? If so, which queries and for what type of a mesh? Also, why do such problems not arise when only  $CV(L')$  is set to  $\text{NIL}$ ?
16. Is there a loss in querying power by making the modification of the split-vertex lath data structure discussed in the text where  $CE(L)$  is also set to  $\text{NIL}$  (instead of  $L'$ ), while still retaining the setting of  $CE(L') = L$ , for all laths  $L$  for edges on the boundary where  $CV(L') = \text{NIL}$  for the companion lath  $L'$  of  $L$ ?
17. Repeat Exercise 4 in Section 2.2.1.3.1 for unstructured meshes with boundaries.
18. Repeat Exercise 6 in Section 2.2.1.3.1 for unstructured meshes with boundaries.

### 2.2.1.3.3 Summary

In Section 2.2.1.2 we pointed out that by swapping the roles of the faces and vertices in the mesh and assigning an arc to each edge between two faces of the mesh, we obtain the dual of the mesh. This means that we interpret the cycles through the edges around the vertices of the original mesh as faces in the dual mesh and the cycles through the edges that make up the faces in the original mesh as vertices in the dual mesh. Doing this, we find that, if the mesh is represented by a split-face lath data structure, then each clockwise loop around a face is transformed into a clockwise loop around a vertex in the dual. Similarly, we find that if the mesh is represented by a split-vertex lath data structure, then each clockwise loop around a vertex is transformed into a clockwise loop around a face in the dual. Thus, the split-face lath data structure on the mesh induces a split-vertex lath data structure on the dual mesh, and vice versa—that is, the split-vertex lath data structure on the mesh induces a split-face lath data structure on the dual mesh (compare Figures 2.101 and 2.103).

Turning now to the corner lath data structure, we see that the dual mesh induced by the original mesh is also a corner lath data structure. In particular, a clockwise loop around a vertex in the original mesh is transformed into a clockwise loop around a face in the dual mesh, and a clockwise loop around a face in the original mesh is transformed into a clockwise loop around a vertex in the dual mesh. This duality is analogous to that exhibited by the interpretation of the four wings of each edge that led to the quad-edge data structure (recall Section 2.2.1.2), where we pointed out that one of the advantages of the quad-edge interpretation over the winged-edge-face and interpretations is that the dual graph is automatically encoded in the quad-edge data structure, as is also the case in the corner lath data structure.

The self-duality of the corner lath data structure and the fact that all transitions (i.e., CE, CF, CCF, CV, and CCV) can be implemented in constant time when we are not positioned at the boundary of the mesh make a strong case for preferring it. On the other hand, all three lath data structures have the same behavior when the mesh has a boundary in that not all of the transitions can be implemented in constant time. Moreover, incorporation of the boundary so that only one lath is associated with each boundary edge (i.e., the absence of the companion lath) means that some queries whose responses include objects whose corresponding laths are in the boundary face (e.g., finding all edges incident at a vertex or finding all vertices incident at an edge) fail to return these laths as part of the response, and thus the complete response to the query cannot be obtained. In the case of the split-vertex lath data structure, the implementation of Joy et al. [973] overcomes this problem by including the companion lath for boundary edges. Thus, assuming that a boundary edge  $e$  is represented by the laths  $L$  and  $L'$  such that  $CE(L) = L'$  and  $CV(L') = \text{NIL}$ , we have that the laths that make up the boundary can be reported in two ways: using the laths  $L$  on the boundary of the mesh (see Exercise 3 in Section 2.2.1.3.2) and using the companion laths  $L'$  in the boundary face (see Exercise 4 in Section 2.2.1.3.2). It also requires less special handling for the transitions that involve boundary laths in the sense that only a CV primitive transition must be redefined, but this is at the expense of a different algorithm for tasks such as extracting the laths making up the boundary in both of the directions (compare Exercises 2 and 3 in Section 2.2.1.3.2). Note, though, that the method of incorporating the boundary that we have described does make it easy to obtain the laths making up the boundary in counterclockwise order for the corner and split-face lath data structures and in clockwise order for the split-vertex lath data structure, regardless of the implementation and whether the laths are in the mesh or in the boundary face. However, the process is complex for the reverse orders (see Exercises 7–14 in Section 2.2.1.3.2).

Contrary to claims by Joy et al. [973], the split-vertex lath data structure is the least suited to the incorporation of the boundary if we use just one lath (i.e., remove the companion lath) to represent elements on the boundary. The reason for their claim that the split-vertex lath data structure was the best suited for the incorporation of a boundary was

that they retained the companion lath in their implementation. The implementation that we described was more consistent in the sense that all of the different lath data structures incorporated the boundary in the same way, and, in this case, we saw that the corner and split-face lath data structures are simpler in that the definitions of the transitions required the least amount of redefinition. In particular, in our implementation of the split-vertex lath data structure, almost all of the transitions needed to be redefined. However, in the case of the split-face and corner lath data structures we only needed to remove the companion lath that corresponded to the boundary face. Upon further reflection, this is not surprising as the face object is an explicit part of the split-face and corner lath data structures, and thus setting a transition to it to NIL is simple. In contrast, the face object is only implicitly represented in the split-vertex lath data structure, and hence the need for more complex methods for incorporating its presence.

It is worth mentioning that the three instances of the lath data structures (i.e., the split-face, split-vertex, and corner) that we described are not the only ones possible. In fact, given the presumed orientations of the laths in Figures 2.100, 2.102, and 2.104, we have a choice of eight possible structures as there are three possible combinations of two out of the three primitive entities, vertex, edge, and face. In particular, the remaining data structures are counterclockwise variants of the split-face (edge-face pair making use of CCF instead of CF), split-vertex (edge-vertex pair making use of CCV instead of CV), and corner (face-vertex making use of CCF with CCV instead of CF with CV) lath data structures, as well as two additional variants of the corner lath data structure that make use of a combination of a clockwise neighboring face (CF) with a counterclockwise neighboring vertex (CCV) and a combination of a counterclockwise neighboring face (CCF) with a clockwise neighboring vertex (CV).

The counterclockwise variants of the split-face (CE and CCF) and split-vertex (CE and CCV) lath data structures have the same duality properties (i.e., they are duals of each other) and execution time behavior as the clockwise variants except that their worst cases are obtained by interchanging clockwise and counterclockwise. The counterclockwise variant of the corner lath data structure (CCF and CCV) has the same desirable behavior as the clockwise variant of the corner lath data structure that we used. In particular, all transitions can be implemented in constant time when not positioned at the boundary of the mesh, and all queries can be executed in time proportional to the size of the result set. It is also a self-dual. The two additional variants of the corner lath data structure (CF with CCV and CCF with CV) are similar to the corner lath data structure in terms of behavior at the boundary of the mesh but do not have the constant time behavior for all transitions; nor are they strict duals of each other in the sense that the directions of the transitions are swapped in the dual. These two variants are termed the *corner\* lath data structure* [973].

Note that, in the above, we assumed that the laths are oriented as in Figures 2.100, 2.102, and 2.104. If we also take into account the alternative orientations that are possible (i.e., two for each of the two possible lath data structures), then we have twice as many possible structures for a total of 16. Note that the difference between the additional eight data structures for the alternative orientation and the original ones lies in the implementation and semantics of the constituent transitions (see Exercises 4–6 in Section 2.2.1.3.1). Otherwise, they are identical to the original ones in terms of the transitions and directions that define them (e.g., the corner lath data structure is defined in terms of the CF and CV transitions for both orientations), as well as their execution time behavior and duality properties.

Besides self-duality and ignoring boundary considerations, the corner lath data structure consisting of face-vertex pairs and the quad-edge interpretation of the winged-edge data structure consisting of edges have other similarities. In particular, they have the same execution time behavior, enabling all of the transitions to be implemented in constant time and all queries to be executed in time proportional to the size of the query result set. Moreover, while the quad-edge data structure associates four singly linked circular lists (one for each of the faces adjacent to an edge and one for each of

vertices incident at the same edge) in the same direction with each edge, the corner lath representation associates two singly linked circular lists (one for the vertex that makes up a face-vertex lath and one for the face that makes up the same face-vertex lath) in the same direction with each lath. However, since there are two face-vertex laths for each edge, the total number of elements in the two sets of circular lists associated with each element of the corner lath data structure is the same as the total number of elements in the four sets of circular lists associated with each element of the quad-edge data structure. In fact, given these observations, we could have also used the term *split-quad* to refer to the corner lath data structure to highlight the connection between it and the quad-edge data structure. In particular, in this way we see that the manner in which the corner lath representation is formed is equivalent to splitting an edge in the quad-edge interpretation of the winged-edge data structure into two in a manner analogous to the way in which an edge in the more general formulation of the winged-edge data structure was split into two parts, thereby creating the half-edge data structure [196]. In fact, perhaps a more appropriate name is *half-quad*.

Interestingly, the variants of the corner lath data structure, where the direction of the traversals of the transitions are not the same, do not lead to constant-time behavior for all transitions, which is analogous to the behavior of the variant of the quad-edge data structure where the direction of the two singly linked circular lists associated with the two vertices incident at the same edge and the direction of the two singly linked circular lists associated with the two faces adjacent to the same edge are not the same.

The execution time behavior of the split-face and split-vertex representations is similar to that of the D-CEL [1322] (see Section 2.2.1.2) where only two singly linked circular lists, one for each of the faces associated with the edge (D-CEL-face) or equivalently, under an alternative interpretation of the wings of the winged-edge data structure, one for each of the vertices at which the edge is incident (D-CEL-vertex) and in the same direction instead of four, are associated with each element of the winged-edge data structure. In fact, the D-CEL-face (D-CEL-vertex) data structure can be viewed as representing each edge  $e$  as a pair of edge-face (edge-vertex) laths that are companions of each other and that are elements of the split-face (split-vertex) lath data structure. The difference between the D-CEL and its lath counterparts is that the transitions in the D-CEL are in terms of edges rather than laths, which means that there is no need in the D-CEL for the transitions to the mutually companion laths. Given lath  $L$ , and letting  $V(L)$ ,  $F(L)$ ,  $E(L)$ , and  $CE(L)$  denote its associated vertex, face, edge, and companion lath, respectively, Figure 2.108(a, b) shows the relationship between the two possible variants of the D-CEL and the corresponding split-face and split-vertex lath data structures, respectively, using the various interpretations of the wings of the winged-edge data structure in Figure 2.89.

Ignoring boundary considerations, the storage required for the lath data structures can be shown to be essentially the same as that for the winged-edge data structures. In particular, the winged-edge data structures have one record per edge, while the lath data structures have one record per lath (regardless of whether the lath corresponds to an edge-face, edge-vertex, or face-vertex pair), which is equal to twice the number of edges. However, each lath contains just three items of information, while each record of the winged-edge data structure contains between five and nine items of information, depending on whether we are dealing with an oriented variant of the winged-edge data structure. Recall that the oriented variants do not record any information about the vertices incident at the edge or about the faces adjacent to the edge. The three items of information in the lath account for half the pointers and half the vertices in the winged-edge data structure. Thus, it would seem that the oriented variants of the winged-edge data structure are slightly more efficient spacewise since the number of laths is twice the number of edges, which means that the amount of storage required by the lath data structure exceeds that required by the winged-edge data structure by a quantity equal to the number of edges.

## Section 2.2 BOUNDARY-BASED REPRESENTATIONS

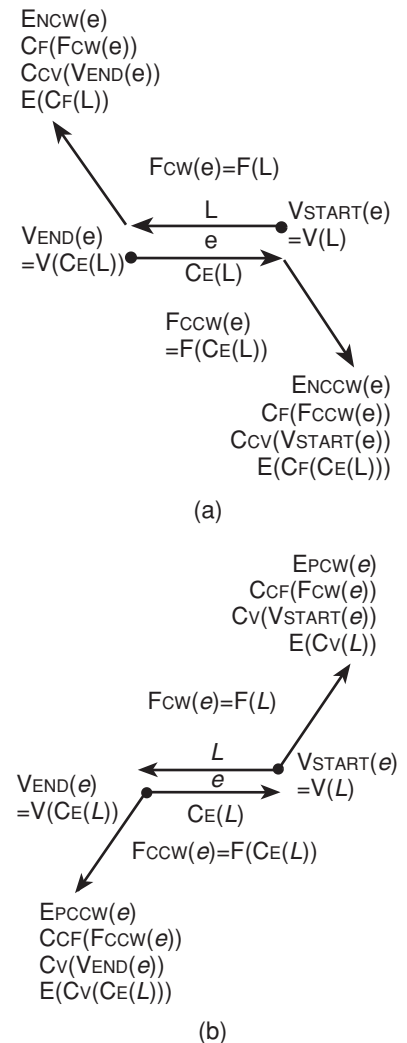

Figure 2.108 Examples of (a) D-CEL-face and (b) D-CEL-vertex data structures and the physical interpretations of their fields using the various interpretations of the wing of the winged-edge data structure in Figure 2.89, thereby yielding analogs of the (a) split-face and (b) split-vertex lath data structures.

Of course, since the oriented variant of the winged-edge data structure that we assumed does not store the identities of the vertices or faces explicitly, some queries are rather cumbersome. For example, in order to obtain a vertex that is represented implicitly in the oriented winged-edge data structure, we must retrieve all of the edges that are incident at it. On the other hand, the lath-based data structures do not store the identities of the edges or faces explicitly, and thus other queries are cumbersome. For example, in order to obtain a face that is represented implicitly in the lath-based data structure, we must retrieve the laths for all of its constituent vertices, while the identity of the associated faces is recorded explicitly in the nonoriented variant of the winged-edge data structures (two of them). Thus, the two data structures effectively use the same amount of storage, once we also store the associated face explicitly with the lath-based data structures, and we observe that the two vertices associated with each edge in the winged-edge data structure are distributed into the two companion laths in each of the lath-based data structures.

We have classified the lath representation as vertex-based. However, from duality considerations, we see that we can also define an equivalent face-based lath data structure where each lath contains a pointer to the face associated with the lath instead of the vertex. Once again, we will have three different representations identical to the split-face, split-vertex, and corner lath data structures. The only drawback of such face-based representations is that the identities of the edges and vertices that make up the faces will only be represented implicitly. Therefore, in order to identify the vertex or edge associated with a specific edge-vertex pair, we will need to retrieve all the laths that it comprises and look up the associated faces, which will enable us to identify the edge and vertex in terms of their adjacent and incident faces. This is not surprising given that the primitive entity of the redefined lath representations is the face, and hence their characterization as being face-based. Since we do not usually represent an object by its constituent faces, the face-based lath representations are not very useful.

At this point, we observe that the manner in which each edge is represented by two unique elements (i.e., a unique edge-face pair, a unique edge-vertex pair, and a unique face-vertex pair) in each of the variants of the lath data structures is reminiscent of the half-edge data structure described in Section 2.2.1.2. In particular, recall that the half-edge data structure was one of the methods proposed to resolve one of the drawbacks of the winged-edge representation—that is, the need to attribute a direction to an edge in order to be able to distinguish between the two faces that are adjacent to the edge, whereas in reality the edge has no direction. Another way of describing this drawback is to point out that, in the winged-edge representation, the single edge record serves a dual role of providing both directional information and information about the faces adjacent to the edge.

In fact, it is not too hard to see that the half-edge data structure that is based on a traversal of the edges that make up the faces is very closely related to the corner lath data structure. In particular, for each face-vertex lath  $L$ , the corner lath data structure records the transitions to both the next lath  $CF(L)$  along the face  $F$  associated with  $L$  and to the next lath  $CV(L)$  incident at the vertex  $V$  associated with  $L$ , and both in the same direction (i.e., clockwise in this example).

The key to the close relationship is the observation that the transition to the next lath  $CV(L)$  incident at  $V$  is equivalent to the transition to the companion half-edge of the previous half-edge  $CE(CF(L))$  along  $F$  (see Figure 2.109). Recalling that, given half-edge  $L$ , the half-edge data structure is defined in terms of  $CE(L)$ ,  $CF(L)$ , and  $CCF(L)$  leads to the desired result as we have formulated  $CV(L)$  in terms of two of the existing half-edge primitives (i.e.,  $CE(L)$  and  $CCF(L)$ ). Alternatively, we can show that the transition to the companion half-edge  $CE(L)$  of half-edge  $L$  is equivalent to the transition to the next lath  $CV(CF(L))$  along the face associated with the next lath  $CF(L)$  incident at  $V$ . Similarly, we know that we can obtain the transition to the half-edge  $CCF(L)$  by simply following  $CE(CV(L)) = CV(CF(CV(L)))$ . Recalling that, given

Figure 2.109  
Example showing the relationship of the half-edge and corner lath data structures in terms of the physical interpretations of their fields using the various interpretations of the wing of the winged-edge data structure in Figure 2.89.

lath  $L$ , the clockwise variant of the corner lath data structure is defined in terms of  $CF(L)$  and  $CV(L)$  leads to the desired result as we have formulated both  $CE(L)$  and  $CCF(L)$  in terms of the two existing primitives of the clockwise variant of the corner lath data structure (i.e.,  $CF(L)$  and  $CV(L)$ ).

A similar relationship can be obtained for the half-edge data structure that is based on a traversal of the edges that are incident at the vertices described in Exercise 11 of Section 2.2.1.2 (see Exercise 1 of this section). At this point, let us reemphasize that the key difference between the clockwise variant of the corner lath data structure and the half-edge data structure is that we can obtain  $L$ 's companion lath by applying the pair of operations  $CV(CF(L))$  in the corner lath data structure. This enables us to avoid the need to store the transition  $CE$  to the companion explicitly, as is usually done in the half-edge data structure, although we have already pointed out that this can be avoided by storing the two half-edges in consecutive locations. Note also that, as in the corner lath data structure, there is no need to store the identity of the associated face explicitly in the half-edge data structure.

From the above discussion, it should be clear that the edge-based methods are simply combinations of the vertex-based methods where, usually, a pair of laths is associated with each edge. Moreover, as we pointed out before, just as there are a number of other possible lath data structures that can be obtained by varying the orientations of the laths and the pair of transitions that are recorded, there are also many other possible ways of combining pairs of laths to obtain variants of the winged-edge family of data structures. The variants that we have presented are the ones that find principal use. This is primarily due to their ability to respond to the basic queries, regardless of the order (i.e., clockwise and counterclockwise, or equivalently, next and preceding) in time proportional to the size of the query result set. Not all possible variants have this property. For example, as we point out in Section 2.2.1.2, a variant of the quad-edge data structure that keeps track of the transitions to the next edges along each of the two adjacent vertices for each edge, while keeping track of the transitions to the preceding edges along each of the two adjacent faces for each edge, does not have this execution time property for both directions. In particular, the execution time is proportional to the size of the result query set for just one of the orders.

Exercise

1. Show how the half-edge-vertex data structure (i.e., the vertex variant of the half-edge data structure) is closely related to the counterclockwise variant of the corner lath data structure. In this case, recall from Exercise 11 of Section 2.2.1.2 that, given half-edge  $L$ , the vertex variant of the half-edge data structure is defined in terms of  $CV(L)$  and  $CCV(L)$ .

### 2.2.1.4 Voronoi Diagrams, Delaunay Graphs, and Delaunay Triangulations

In Sections 2.2.1.2 and 2.2.1.3, we pointed out that an advantage of the quad-edge interpretation of the winged-edge data structure over the other interpretations (e.g., the winged-edge-face and winged-edge-vertex) is that the quad-edge data structure is a self-dual. As an example of where this duality is useful, consider the Voronoi diagram [1941] (also known as a Thiessen polygon [1870] and a Dirichlet domain [497]) and its dual, the Delaunay graph (e.g., [1424]), as shown in Figure 2.110. Briefly, given a set of points (termed *sites*), a Voronoi diagram is a partition of the plane into regions so that each point in a region is closer to its region's site than to any other site. These regions are termed *Voronoi regions* or *Voronoi cells*. For example, Figure 2.110(a) is the Voronoi diagram for the given set of points shown with solid circles, while the vertices of the diagram are shown with hollow circles.

Figure 2.110  
 (a) Example Voronoi diagram, (b) its dual Delaunay triangulation and the corresponding circumcircles (shown with broken lines), (c) the result of superposing the Delaunay triangulation (shown with broken lines) on the Voronoi diagram, (d) the result of superposing the Delaunay triangulation (shown with broken lines) and the corresponding circumcircles (shown with broken lines) on the Voronoi diagram. The hollow circles denote the centers of the circumcircles and the vertices of the Voronoi diagram. The arrowheads on some of the edges of the Voronoi diagram correspond to “infinite” edges that meet at some infinite vertex.

A Voronoi diagram has many applications. For example, if we consider the sites as the locations of fire stations, then, using the Voronoi diagram, we can determine which fire station is the closest (using the Euclidean distance—that is, as the crow flies) to any point. Another example places distribution centers at the sites of the Voronoi diagram, and, as a result, we can tell what is the closest distribution center (as the crow flies) to a store located at any point. The process of determining the closest site to a query point is usually implemented by making use of an index on the regions or the boundaries that make up the Voronoi diagram (e.g., the K-structure and layered dag discussed in Section 2.1.3 or the representations discussed in Section 2.2.2) and executing a variant of a point location algorithm on the query point. These methods generally have a logarithmic behavior because they are based on sorting. Alternatively, we could also use a graph approach. In this case, we represent the Voronoi diagram as a graph where each site is a node, and there is an edge between any two sites whose Voronoi regions share an edge. Using this approach, finding the nearest site to a query point  $q$  is achieved by starting at an arbitrary site and making a transition along the edge that leads us to a site that is the closest to  $q$ . The algorithm terminates once we are at a site  $p$  such that no further transition can be made, and thus  $p$  is the nearest site. The drawback to this approach is that its worst-case execution time is  $O(n)$ , where  $n$  is the number of sites. Note that this approach to point location can be characterized as one that uses the A\*-algorithm [1594], where the heuristic function that serves as the estimate of the cost from a given site  $s$  to the ultimate closest site corresponding to the Voronoi region  $v_q$  that contains  $q$  is the Euclidean distance from  $s$  to  $q$ .

The graph representation of the neighbor structure of the Voronoi diagram is called a *Delaunay graph*. As mentioned above, the Delaunay graph of a point set  $P$  is an embedding of the dual graph of the Voronoi diagram of  $P$ . It can be shown that the Delaunay graph of a planar point set is a plane graph (e.g., [196, Theorem 9.5]). Given a planar point set  $P$ , all the faces of the Delaunay graph of  $P$  are triangles if no four elements of  $P$  (i.e., sites of the Voronoi diagram of  $P$ ) are cocircular. To see this, we observe that the vertices of the Voronoi diagram of  $P$  are equidistant from the sites of all of the Voronoi regions whose edges are incident at them. In particular, if a vertex  $v$  of the Voronoi diagram of  $P$  is a vertex for the Voronoi regions for the sites  $p_1, p_2, \dots, p_k$ , then the corresponding face  $f$  in the Delaunay graph of  $P$  has  $p_1, p_2, \dots, p_k$  as its vertices, and they lie in a circle around  $v$  as they are all equidistant from  $v$ . In fact,  $f$  is convex and is a triangle if it consists of just three sites. When all the faces of the Delaunay graph are triangles, then we have a special case of the Delaunay graph known as the *Delaunay triangulation* (DT) [474]. Of course, a triangulation can be obtained for a Delaunay graph when there are four elements of  $P$  that are cocircular by adding edges as needed, although it is clear that the resulting triangulation will not be unique.

An equivalent way of defining the Delaunay triangulation of a set of points  $S$  is as a triangulation through the points in  $S$  so that none of the points in  $S$  are in the circumcircles of any other triangle (known as the *circle property*). The Delaunay triangulation is unique as long as no local configuration of four or more points in  $S$  is cocircular. Such a Delaunay triangulation is said to be *nondegenerate*, and likewise for a Voronoi diagram with sites  $S$ . For example, Figure 2.110(b) is the Delaunay triangulation for the set of points given in Figure 2.110(a), where the circumcircles of the triangles are shown using broken lines, while the centers of the circumcircles are shown with hollow circles. The Delaunay triangulation has several interesting properties that make it a desirable triangulation:

1. An edge between two points  $q$  and  $r$  in  $S$  is an edge of the Delaunay triangulation of  $S$  if and only if there exists at least one circle  $c$  through  $q$  and  $r$  such that no other point in  $S$  lies inside  $c$  (termed the *disc property*). This property is related to the circle property in the sense that satisfaction of the circle property implies satisfaction of the disc property.
2. It maximizes the minimum interior vertex angle, thereby avoiding small angles that cause distortion (termed the *minimum angle property*). This property can be stated more formally as follows: The Delaunay triangulation produces the lexicographically

largest possible nondecreasing sequence of angles in any triangulation of a given set of points. Thus if  $a_1 \leq a_2 \leq \dots \leq a_i \leq \dots$  is the sequence of angles in a Delaunay triangulation and if  $b_1 \leq b_2 \leq \dots \leq b_i \leq \dots$  is the sequence of angles in another triangulation of the same set of points, then there exists an  $i$  such that  $a_i > b_i$ .

3. Every interior edge of a Delaunay triangulation satisfies the *angle property*, which can be stated as follows: Let  $prq$  and  $qsp$  be two opposite interior angles of an arbitrary triangulation. The vertices  $prqs$  (in that order) constitute the edge quadrilateral  $Q$  of the edge  $pq$ . Edge  $pq$  satisfies the angle property if it connects the opposite interior angles of  $Q$  having the largest sum—that is, if the angle rooted at  $r$  facing edge  $pq$  plus the angle rooted at  $s$  facing edge  $pq$  is smaller than or equal to the angle rooted at  $p$  plus the angle rooted at  $q$  (see also Exercise 4).
4. It is biased against large circumcircles.
5. It is biased against “thin” triangles.
6. The triangles are as close as possible to being equiangular.
7. It effectively chooses edges that connect natural neighbors. This means that the data points corresponding to the vertices of the Delaunay triangulation are closer to their mutual circumcenter than is any other data point. Thus, the Delaunay triangulation is a form of local optimization.

As pointed out above, the Delaunay triangulation is a special case of the Delaunay graph, which is the geometric dual of the Voronoi diagram. The actual physical interpretation of the duality is that the centers of the circumcircles of the triangles in the Delaunay triangulation (of which there is one for each face) serve as the vertices of the Voronoi diagram, while the sites of the Voronoi diagram (of which there is one per face) serve as the vertices of the Delaunay triangulation. Figure 2.110(c) shows the dual graph by superimposing the Delaunay triangulation (shown with broken lines) on top of the Voronoi diagram, while Figure 2.110(d) adds the circumcenters (shown with hollow circles) and circumcircles (shown with broken lines). In both cases, the centers of the circumcircles (which are also the vertices of the Voronoi diagram) are shown with hollow circles. Notice that the dual of the “infinite edges” of the Voronoi diagram (i.e., the edges that extend to infinity) are the edges of the convex hull<sup>37</sup> of the Delaunay triangulation (equivalently of its vertices), which are also elements of the Delaunay triangulation. We can imagine that these infinite edges of the Voronoi diagram all meet at some common point at infinity. This “infinite vertex” of the Voronoi diagram is the dual of the exterior face of the Delaunay triangulation. Although we cannot draw this infinite vertex, we show its implicit existence by attaching outgoing arrowheads to the infinite edges in Figure 2.110(a, c, d). It is interesting to observe that this additional “infinite vertex” of the Voronoi diagram is what makes the Voronoi diagram a compact two-manifold (and likewise for the exterior face of the Delaunay triangulation).

### Exercises

1. Given a Delaunay triangulation, write an algorithm to construct its Voronoi diagram.
2. There are several ways of computing a Delaunay triangulation. They differ in part on the basis of the properties of the Delaunay triangulation that they exploit. For example, the following method [1268] makes use of the circle property of the Delaunay triangulation (i.e., that none of the points in the point set that is being triangulated is in the circumcircles of any other triangle in the triangulation). The method starts by computing the convex hull of the point set and then pushes into a queue each edge  $e$  whose orientation is such that the rest of the point set is to the left of  $e$ . While the queue is not empty, perform the following steps:
  - (a) Pop an edge  $ab$  from the queue.
  - (b) Find the point  $c$  to the left of  $ab$  so that the circle through  $a$ ,  $b$ , and  $c$  is empty. Such an edge is guaranteed to exist by virtue of the circle property.

---

<sup>37</sup> See the definition in footnote 11 in Section 2.1.3.2.

- (c) If  $ac$  is not in the Delaunay triangulation, then insert  $ac$  into the Delaunay triangulation, and push  $ac$  in the queue.
- (d) If  $cb$  is not in the Delaunay triangulation, then insert  $cb$  into the Delaunay triangulation, and push  $cb$  in the queue.

Prove that, given a point set with  $v$  vertices, the algorithm takes  $O(v^2)$  time. How can you reduce the execution time of the algorithm?

3. In Exercise 2, we showed how to compute the Delaunay triangulation in an inward manner by starting with the convex hull and adding edges while proceeding inwards. An alternative approach works in an outward manner [1964] as follows. Initially, start with one large triangle  $t$  that contains the entire point set. Select one point  $p$  at random and join  $p$  to the vertices of  $t$ . Now, apply the following algorithm to the remaining points in arbitrary order, starting with point  $q$ .
  - (a) Find all existing triangles whose circumcircles contain  $q$ . This can be done by finding the existing triangle  $abc$  (with vertices  $a$ ,  $b$ , and  $c$ ) that contains  $q$  and walking along its edges.
    - i. If the circumcircle of triangle  $abd$  (i.e., adjacent to  $abc$  along edge  $ab$ ) contains  $q$ , then recursively apply these steps to the triangles adjacent to  $abd$  along edges  $ad$  and  $bd$ .
    - ii. Otherwise, apply this step to the edges adjacent to edge  $ab$  in triangle  $abc$ .
  - (b) Form a polygon from the union of the triangles found in step (a) and remove its interior edges.
  - (c) Form new triangles in the interior of the polygon obtained in step (b) by joining  $q$  to all of the polygon's vertices.

Some of the steps in the algorithm are justified as follows. The triangles found in step (a) are the only triangles that are affected by the insertion of  $q$  since the circumcircles of the remaining triangles are empty and thus belong to the new Delaunay triangulation as well. The new polygon formed in step (b) is star shaped since, for each edge  $ab$  and triangle  $abc$  that have been removed,  $q$  lies in the region bounded by  $ab$  and the circumcircle of  $abc$ , which means that  $q$  can “see” edges  $ac$  and  $bc$ . Watson [1964] claims that the circumcircles of the triangles formed in step (c) will not contain any of the remaining points as these points all lie on circumcircles that do not contain  $q$  and thus the resulting triangulation is a Delaunay triangulation. An alternative way of showing that step (c) yields a Delaunay triangulation is as follows. From step (a), we know that all of the edges that lie on the boundary of the star-shaped polygon are elements of the Delaunay triangulation. However, we must prove that the newly added edges from  $q$  to the vertices of the star-shaped polygon formed in step (c) are elements of the Delaunay triangulation. We want to show that the triangulation process in step (c) yields a Delaunay triangulation of the entire set of points. In particular, we want to show that the edges chosen in step (c) are Delaunay edges. We use contradiction. Consider convex quadrilateral  $qdef$ , where  $d$ ,  $e$ , and  $f$  are adjacent vertices of the star-shaped polygon such that edge  $qe$  is not an edge of the Delaunay triangulation. We are not interested in nonconvex polygons as they have a unique triangulation. Let us swap  $qe$  with the opposite diagonal  $df$  of  $qdef$ . The circumcircle  $C$  of triangle  $def$  cannot be empty as, otherwise, it would have been a triangle of the Delaunay triangulation before the addition of  $q$ .  $C$  cannot contain  $q$  as, in this case, it would have been eliminated by step (a). Therefore,  $C$  must contain other points, which means that we cannot obtain a Delaunay triangulation of the star-shaped region by the swap operation. This contradicts the assumption that the original triangulation obtained in step (c) is not a Delaunay triangulation. Prove that given a point set with  $v$  vertices, the algorithm takes  $O(v^2)$  time.

4. As we pointed out in the text, the angle property can be used to define the Delaunay triangulation in two dimensions in terms of the values of the sums of the interior angles that share each of the edge of a triangulation. The following definition of the Delaunay triangulation in two dimensions is based on similar reasoning. In particular, for points  $u$  and  $v$ , let us define  $\alpha$  to be the largest angle seen by other points in the dataset  $S$ . That is,  $\alpha = \max_{y \in S - \{u, v\}} \angle uyv$ , and let  $p \in S - \{u, v\}$  be the point such that  $\alpha = \angle upv$ . Note that the line passing through  $uv$  divides  $S - \{u, v\}$  into two parts. Let  $S_p$  denote the points in  $S - \{u, v\}$  that are on the same side of  $p$  with respect to line  $uv$ , and let  $O_p$  denote the set of points in  $S - \{u, v\}$  that are on the other side of line  $uv$ . We have  $O_p \cup S_p = S - \{u, v\}$ . Prove that  $\forall w \in O_p, \angle uwp \leq \pi - \alpha$  if and only if edge  $uv$  belongs to the Delaunay triangulation.

5. Suppose that you are given a two-dimensional polygonal map  $T$  (i.e., a set of edges and vertices) that is also a Voronoi diagram. How would you obtain the locations of its sites? What is the complexity of your algorithm? Assume that the vertices are in general position, which means that all Voronoi vertices have degree 3—that is, there are no sets of four or more sites that are cocircular, and some face of the Voronoi diagram has at least two vertices.
6. Repeat Exercise 5 for the more general case of the Voronoi diagram where the vertices are not required to be in general position (i.e., the vertices may have a degree higher than 3). What is the complexity of your algorithm?

### 2.2.1.5 Constrained and Conforming Delaunay Triangulations

Although the Delaunay triangulation is formally defined over a point set, in many applications (e.g., finite-element analysis, solutions to partial differential equations) the point set is usually defined by some shape. The fact that the Delaunay triangulation is defined over a point set means that the boundary triangles of the Delaunay triangulation are those with an edge on the convex hull of the point set. This has the effect of restricting the boundaries for the shapes for which we can compute a Delaunay triangulation to be convex. Therefore, if we simply compute the Delaunay triangulation of the vertices of a nonconvex polygon, we may find that not every edge of the polygon will be on the convex hull of the vertices and thus will not necessarily be a member of the Delaunay triangulation of the vertices. For example, Figure 2.111(b) is the Delaunay triangulation of the vertices of a nonconvex polygon.

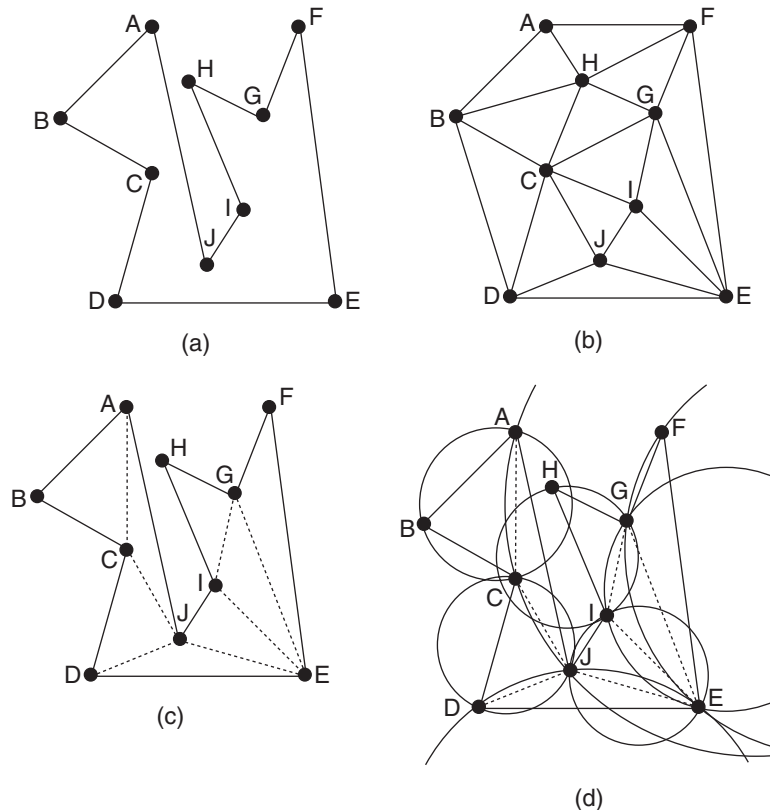

Figure 2.111  
 (a) Example nonconvex polygon, (b) the Delaunay triangulation of its vertices, (c) its constrained Delaunay triangulation (additional edges shown with broken lines), and (d) the result of superposing the circumcircles of the triangles of the constrained Delaunay triangulation.

of the vertices of the nonconvex polygon in Figure 2.111(a). Notice that edges AJ and HI of the original nonconvex polygon are not in the Delaunay triangulation of its vertices.

Often we wish to find the Delaunay triangulation of a nonconvex shape so that every edge of the polygon is a member of the Delaunay triangulation of the polygon. In fact, we want to handle the more general case where the point set defines a graph with edges that are straight lines in the plane and that need not necessarily be connected. Actually, the graph may even have isolated vertices as well as vertices with degree 1. The result is termed a *Planar Straight Line Graph* (PSLG) and is the subject of the rest of this discussion. Of course, the PSLG includes polygons (both convex and nonconvex) as well as polygonal maps (i.e., polygonal subdivisions). The requirement that every edge of the PSLG  $P$  be a member of the Delaunay triangulation of the point set of  $P$  is satisfied by the use of the constrained Delaunay triangulation [1131] or the conforming Delaunay triangulation [1600].

The constrained Delaunay triangulation [1131] of a PSLG  $P$  with vertex set  $Q$  is an adaptation of the Delaunay triangulation that modifies the circle property so that the interior of the circumcircle  $c$  of every triangle  $t$  contains no point of  $Q$  that is visible to all the three vertices of  $t$ . In other words, any vertices  $V$  that are in  $c$  cannot be seen by any of the vertices of  $t$  due to the existence of some additional edge that passes through  $t$ . This property is known as the *modified empty circle property*. For example, Figure 2.111(c) is the constrained Delaunay triangulation of the nonconvex polygon in Figure 2.111(a), while Figure 2.111(d) shows the circumcircles of the various triangles in the constrained Delaunay triangulation. Notice that the circumcircle of triangle ABC contains vertex H, which is not visible from A, B, and C because it is blocked by edge AJ, which passes through it. Similarly, the circumcircle of triangle GHI contains vertex C, which is not visible from G, H, and I because it is blocked by edge AJ, which passes through it.

The constrained Delaunay triangulation is unique [1127]. For an arbitrary PSLG with  $v$  vertices, Chew [361] gives an  $O(v \log v)$  time algorithm to obtain its constrained Delaunay triangulation. This is optimal because, even when we ignore the constraints, if the vertices form a convex polygon, then a sorted order can be derived from any triangulation of the points and the constrained Delaunay triangulation is one instance of a triangulation. The lower bound follows from the well-known  $O(v \log v)$  bound on sorting  $v$  points.

The conforming Delaunay triangulation [1600] inserts additional points, termed *Steiner points*, to ensure that all the edges of the PSLG  $P$  are members of the Delaunay triangulation of the point set of  $P$ . The Steiner points need only be placed on the existing edges of the PSLG  $P$ . This process is known as *edge refinement*. For example, Figure 2.112 is the conforming Delaunay triangulation of the nonconvex polygon in Figure 2.111(a). Three Steiner points K, L, and M have been added.

There are a number of algorithms for constructing a conforming Delaunay triangulation with different complexities in terms of execution time and the number of Steiner points that are inserted, which affects the quality of the resulting triangulation (e.g., [545, 1328, 1333, 1592, 1600]). Note that all of these methods make use of the disc property (i.e., an edge  $e$  of a PSLG  $P$  with vertex set  $V$  is an edge of the Delaunay triangulation of  $V$  if and only if there exists a circle around  $e$  that contains none of the points of  $V$  in its interior) to determine how to split an existing edge of the PSLG. For example, no particular algorithm was used to select the Steiner points in the conforming Delaunay triangulation in Figure 2.112, and, in fact, it may be possible to obtain a conforming Delaunay triangulation with just two Steiner points.

### Exercises

1. Give an algorithm to obtain the constrained Delaunay triangulation of a nonconvex polygon.
2. Give an algorithm to obtain the conforming Delaunay triangulation of a nonconvex polygon.

Figure 2.112  
The conforming Delaunay triangulation of the nonconvex polygon in Figure 2.111(a) obtained by adding Steiner points K, L, and M. Only edges of the conforming Delaunay triangulation that lie within the polygon are shown. Edges of the conforming Delaunay triangulation that lie outside of the polygon have been removed.

### 2.2.1.6 Delaunay Tetrahedralizations

Neither the Voronoi diagram nor its geometric dual, the Delaunay graph and the special case of a Delaunay triangulation, is restricted to planar point sets. Both can be defined in arbitrary dimensions. For example, in three dimensions, the topological analog of the Delaunay triangulation is the Delaunay tetrahedralization, where the Delaunay graph is a tetrahedralization whenever no five sites are cospherical (i.e., lie on a sphere). Nevertheless, there are a number of properties of triangulations that do not generalize to three dimensions or higher. In the rest of this section, we examine some of the properties of triangulations that were discussed above that do not hold for tetrahedralizations and, therefore, also do not hold for the  $d$ -dimensional analog of the triangulation.

Figure 2.113  
Example tetrahedralizations of a set of five points: (a) two tetrahedra resulting from the sharing of triangle abc and (b) three tetrahedra resulting from the sharing of edge de.

One of the biggest differences is that, unlike the planar case where the number of triangles in the triangulation of a particular point set is constant, the size of the tetrahedralization of a particular point set is not constant. For example, in two dimensions, a set of four points can be triangulated in two ways, depending on the choice of the diagonal of the quadrilateral formed by their convex hull. However, regardless of the diagonal that is chosen, there are only two triangles in the triangulation. In contrast, in three dimensions, for a given point set, the number of tetrahedra can vary dramatically. For example, consider a set of five points. It can have a number of different tetrahedralizations, some consisting of two tetrahedra and others consisting of three tetrahedra. In particular, Figure 2.113(a) shows a tetrahedralization of the point set  $\{a, b, c, d, e\}$  that yields the two tetrahedra  $(a, b, c, d)$  and  $(a, b, c, e)$  resulting from the sharing of triangle  $(a, b, c)$ . On the other hand, Figure 2.113(b) shows a tetrahedralization of the same point set that yields the three tetrahedra  $(a, b, d, e)$ ,  $(a, c, d, e)$ , and  $(b, c, d, e)$  resulting from the sharing of edge  $(d, e)$ . Although in many real-world applications the number of tetrahedra for a given point set of size  $v$  is reasonable (e.g.,  $O(v)$  [1328, 1820]), examples can be constructed that have  $O(v^2)$  tetrahedra [1328] and even a superlinear number of tetrahedra [563].

Figure 2.114  
Example Piecewise Linear Complex consisting of three nonintersecting lines in three-dimensional space that cannot be tetrahedralized without some of the edges of the tetrahedra intersecting some of the edges of the PLC.

Another important difference is that there is no obvious generalization of the constrained Delaunay triangulation to three dimensions. It is clear that, given an arbitrary point set, we can always find a tetrahedralization. However, when the point set forms the three-dimensional analog of the PSLG (Planar Straight Line Graph), termed a *Piecewise Linear Complex* (PLC),<sup>38</sup> we cannot always find a tetrahedralization without having to add points (i.e., Steiner points) on the boundary or in the interior so that all edges of the tetrahedra are edges of the PLC (i.e., construct a conforming tetrahedralization regardless of whether it satisfies the Delaunay constraints). For example, Shewchuk [1752] points out that the PLC formed by the three nonintersecting line segments in Figure 2.114 cannot be tetrahedralized without some of the edges of the tetrahedra intersecting some of the edges of the PLC. In particular, any tetrahedron formed by choosing any four of the six vertices will be intersected by one of the three edges of the PLC. Therefore, the manner in which the remaining tetrahedra are formed is irrelevant, and thus this complex is not tetrahedralizable without the addition of Steiner points so that all edges of the tetrahedra are edges of the PLC. Deciding whether a set of line segments is tetrahedralizable without any Steiner points is an open problem [1328]. Murphy, Mount, and Gable [1328, 1329] present a point placement strategy for obtaining a conforming Delaunay tetrahedralization for a PLC  $P$  that, unlike other approaches (e.g., [1296, 1753]), makes no restrictions on the angles of  $P$ .

Even when the point set forms a polyhedron, an example can be given of a polyhedron that cannot be tetrahedralized without the addition of Steiner points so that all edges of

<sup>38</sup> The PLC is the most general adaptation of the PSLG to three dimensions. Unlike other definitions of three-dimensional “flat” objects that make various assumptions such as that every face of the object has simply connected boundaries or that the object’s surface is a two-manifold, it makes no such assumptions. Thus, it is possible for three or more faces to be incident at an edge, for faces to have polygonal holes, to have isolated vertices and edges, and so forth. The only essential requirement is that the object be a topological complex, which means that, if faces intersect, then they must intersect along an edge; if edges intersect, then they must intersect at a vertex, and so forth.

the tetrahedra are edges of the polyhedron. Such a polyhedron is the Schönhardt Twisted Prism [1694], whose top view is shown in Figure 2.115. This polyhedron is formed by taking a prism whose top and bottom are triangles, followed by slightly twisting one of the triangle faces in its plane, and concluding by triangulating the three remaining faces that were quadrilaterals. These faces are triangulated by adding the reflex diagonals (i.e., the diagonals whose interior dihedral angle is greater than 180 degrees) so that the result is a nonconvex polyhedron. The twisted prism is constructed in such a way that the tetrahedra formed by taking any four of its vertices will have an edge that lies outside the polyhedron. In fact, since each vertex has degree 4 and there are only six vertices, only three tetrahedra can be formed as there is only one unconnected vertex for each vertex. However, these three tetrahedra do not cover the space spanned by the polyhedron, and thus the polyhedron is not tetrahedralizable unless Steiner points are inserted either on its boundary or in its interior. Deciding whether a polyhedron is tetrahedralizable with less than  $k$  Steiner points ( $k > 1$ ) is NP-complete [1593] (recall footnote 6 in Section 2.1.2.1). For some algorithms for tetrahedralizing a nonconvex polyhedron by adding Steiner points, see [120, 335, 341, 959].

### BOUNDARY-BASED REPRESENTATIONS

Figure 2.115  
Example polyhedron consisting of a prism whose top and bottom are triangles, where the top triangle has been slightly twisted, and the three remaining faces that were quadrilaterals are diagonalized so that the resulting polyhedron is nonconvex.

### Exercises

1. As we pointed out earlier, the Voronoi diagram is not restricted to planar point sets. It can be defined in arbitrary dimensions and likewise for its geometric dual, the Delaunay graph and the special case of a Delaunay triangulation. The  $d$ -dimensional elements that are topologically equivalent to the triangle and a triangulation are known as *simplexes* and *simplicial complexes*, respectively (e.g., [870]). Describe the extension to  $d$  dimensions of the special cases of the Delaunay graph that yield constructs that are topological analogs of the Delaunay triangulation.
2. Suppose that you are given a point set  $S$  with  $d + 2$  points in a  $d$ -dimensional space. The  $d$ -dimensional analog of the triangle is known as a  $d$ -dimensional simplex and is the convex hull of  $d + 1$  points, while the  $d$ -dimensional topological equivalent of the triangulation is known as a  $d$ -dimensional simplicial complex (or *simplex* and *simplicial complex*, respectively, for short if there is no confusion about the dimensionality of the domain of the point set). How many different  $d$ -dimensional triangulations (simplicial complexes) of  $S$  are possible in terms of the number of  $d$ -dimensional simplexes in them?

### 2.2.1.7 Applications of the Winged-Edge Data Structure (Triangle Table, Corner Table)

The winged-edge data structure, as well as its variants (e.g., the quad-edge data structure), are not restricted to the representation of the surfaces of three-dimensional objects that are two-manifolds (e.g., [501], where they are applied to three-dimensional subdivisions). In particular, these representations can be applied to two-manifolds in any dimension. The key to their applicability is the cyclic nature of the neighborhood of any vertex or any face in a two-manifold (see Exercise 1), which can be represented with a simple linked list using the primitives “next” and “previous.” In our examples with surfaces of three-dimensional objects, we have captured this cyclic nature by requiring that the two-manifolds be orientable and thus used the orientation concepts of clockwise and counterclockwise.<sup>39</sup> It is important to note that the winged-edge data structure and its variants can also be used to represent a nonorientable two-manifold surface (i.e., a surface with no means of distinguishing between an inner and an outer face [870]), such as a Klein bottle or a Möbius strip. In this case, the orientation concepts of clockwise and counterclockwise are replaced by the simpler cyclic concepts of next and previous.

<sup>39</sup> Although these orientation concepts can be generalized to  $d$  dimensions, where the orientation of  $d + 1$  points is defined to be the sign of the  $(d + 1) \times (d + 1)$  determinant of homogeneous point coordinates [540], they no longer capture the cyclic nature (i.e., when  $d \geq 3$ ). Thus, more complex representations would be required.

Figure 2.116  
The physical representation of a sample triangle table entry.

As an application of the utility of the winged-edge data structure and its variants, recall that, in Section 2.2.1.4, we point out that the quad-edge data structure can be used to represent Voronoi diagrams and Delaunay triangulations in the plane, which are planar subdivisions. In the case of planar subdivisions where all the faces are triangles, we can use a simpler variation known as the *triangle table method* [714, 806] (see also Exercise 3). In this case, the basic unit is the triangle instead of the edge. In particular, we represent each triangle  $t$  by a six-tuple containing pointers to the three vertices that make up  $t$  and pointers to the entries in the triangle table to the three triangles that are adjacent to  $t$  along the edges of  $t$ . In addition, we have a vertex table that contains a pointer to the entry in the triangle table of one of the triangles that are incident at the vertex. Note that the triangle table stores the edges that make up each triangle implicitly as they can be derived from the vertices. The physical representation of a sample triangle table entry corresponding to triangle  $T$ , its three vertices  $V1$ ,  $V2$ , and  $V3$ , and its three adjacent triangles  $T1$ ,  $T2$ , and  $T3$  is shown in Figure 2.116. The *corner table* method of Rossignac, Safanova, and Szymczak [1580] is equivalent to the triangle table method. The difference is that, instead of storing pointers to the adjacent triangles of  $t$ , the corner table stores pointers to the vertices of these triangles that are not in  $t$  (e.g.,  $V1'$ ,  $V2'$ , and  $V3'$ , instead of  $T1$ ,  $T2$ , and  $T3$ , respectively, in Figure 2.116).

The analogy between the triangle table and the winged-edge data structure is that, with each triangle (the analog of a face in the winged-edge data structure), we have a fixed amount of information, in contrast with a face in the winged-edge data structure, which can have a varying number of edges. Thus, in the case of a triangular subdivision, we have two entities with which a fixed amount of information is associated (i.e., faces and edges, in contrast to just edges in the more general case). Storing the adjacent triangles to each triangle (the primitive entity) in the triangle table method is analogous to storing the two faces that are adjacent to each edge (the primitive entity) in the winged-edge data structure.

Higher-dimensional analogs of the triangle table method can be used to represent simplicial complexes (e.g., [870]) in higher dimensions.<sup>40</sup> For example, we can use a tetrahedron table for tetrahedralizations in three dimensions where we represent each tetrahedron  $t$  by an eight-tuple containing pointers to the four vertices that make up  $t$  and pointers to the entries in the tetrahedron table to the four tetrahedra that are adjacent to  $t$  along the faces of  $t$ . In addition, we have a vertex table that contains a pointer to the entry in the tetrahedron table of one of the tetrahedra that are incident at the vertex. Note that the tetrahedron table stores the edges and faces that make up each tetrahedron implicitly as they can be derived from the vertices since we are dealing with a simplicial complex of three dimensions.

### Exercises

1. From the text, we see that for the polyhedral objects in which we are interested, each edge belongs to exactly two faces. This is one of three restrictions that lead to a two-manifold regardless of compactness or orientability. The other two restrictions are (1) that every vertex is surrounded by a single cycle of edges and faces, and (2) that faces may not intersect each other, except at common edges or vertices. An alternative definition is that a two-manifold is a connected surface where each point on the surface is topologically equivalent to an open disc [1978]. What are some examples of physically realizable objects that are not two-manifolds?
2. Using the definition of a two-manifold given in Exercise 1, are two-manifold objects closed under Boolean set operations?

<sup>40</sup> Recall from Exercise 2 in Section 2.2.1.6 that a *simplicial complex* is the topological equivalent of a triangulation in any dimension. It consists of simplexes, where a  $d$ -dimensional *simplex* is the convex hull of  $d + 1$  points.

3. Peucker and Chrisman [1487] suggest an alternative method of representing a planar subdivision where all the faces are triangles that keeps track only of the vertices. It makes use of a vertex table that contains the coordinate values of each vertex. In addition, associated with each vertex  $v$  is a pointer to an entry in another table, termed a *connectivity table*, that contains a list of the vertices (actually pointers to the corresponding vertex table entries) that are connected to  $v$  in cyclic order. Given  $V$  vertices and  $T$  triangles, and ignoring the size of the vertex table, show that the connectivity table requires  $3T + V$  storage units while the triangle table requires  $6T$  storage units. In other words, the connectivity table requires about one-half the storage needed by the triangle table.
4. Given  $T$  triangles, prove that the storage requirements of the connectivity table method described in Exercise 3 are bounded by  $5T + 4$ . *Hint:* In your answer, you may want to make use of the following properties of a planar graph:
  - (a) Given  $V$  vertices,  $E$  edges, and  $F$  faces (including the external face), according to Euler's formula,  $V - E + F = 2$ .
  - (b) The sum of the face degrees is equal to twice the number of edges, and the same is true for the sum of the degrees of the vertices.
5. One of the shortcomings of a vertex-based method, such as the connectivity table method as described in Exercise 3, is that the triangles are only represented implicitly. This means that, given a vertex  $v$ , once we have identified a triangle  $T = vv'v''$  by accessing vertices  $v$  and  $v''$  through the connectivity table entry of  $v$ , we cannot identify in  $O(1)$  time the triangle  $t' = v'v''w$  such that  $t$  and  $t'$  have edge  $v'v''$  in common. The *star-vertex data structure* of Kallmann and Thalmann [979] is designed to overcome this shortcoming of the connectivity table by storing an additional pointer with each vertex  $v'$  in the connectivity table of vertex  $v$  to the connectivity table entry of another vertex  $v''$  that forms a triangle  $t = vv'v''$ . More precisely, for every triangle  $t = vv'v''$ , the entry corresponding to  $v'$  in the connectivity table of  $v$  contains a pointer to the entry corresponding to  $v''$  in the connectivity table of  $v'$ . Similarly, the entry corresponding to  $v''$  in the connectivity table of  $v$  contains a pointer to the entry corresponding to  $v'$  in the connectivity table of  $v''$ . This facilitates making a transition in  $O(1)$  time from triangle  $t$  to the triangle  $t'$  that shares edge  $v'v''$ . Given  $V$  vertices and  $T$  triangles and ignoring the size of the vertex table, show that the connectivity table requires  $6T + V$  storage units, thereby making it equivalent in functionality and storage requirements to the triangle table and corner table.

## 2.2.2 Image-Based Boundary Representations

In this section, we focus on image-based boundary representations of objects. This means that the environment in which the objects lie is recursively decomposed using some regular decomposition process. Below, we discuss several quadtree-like decompositions of the underlying space into four congruent blocks (or, in the case of three-dimensional data, octree-like decompositions into eight congruent blocks). Of course, other decompositions are possible (e.g., into noncongruent blocks, as well as a varying number of blocks), but, in the interest of space, we do not discuss them further here. In addition, we do not dwell on the nature of the access structures because the options are the same as those described in Section 2.1.2.

We start with the line quadtree (Section 2.2.2.1), where both the objects and their environment are composed of cells of uniform size and shape (i.e., pixels and voxels). This is overly restrictive, and hence we waive this requirement in the rest of the subsections. This means that, unlike Section 2.1, we no longer require that the boundaries of the objects (i.e., edges and faces in two and three dimensions, respectively) be axis parallel. This can be seen in the discussion of the MX quadtree and MX octree (Section 2.2.2.2), edge quadtree (Section 2.2.2.3), and face octree (Section 2.2.2.4), as well as of the adaptively sampled distance field, which is similar to a dual of the edge quadtree and face octree (Section 2.2.2.5). All of these representations can handle arbitrary boundaries. In fact, in Sections 2.2.2.9 and 2.2.2.10, we even waive the requirement that the objects and their environment be decomposed into polygonal cells by decomposing the underlying

(a)

(b)

(c)

Figure 2.117  
(a) Example partition of the plane into six objects (i.e., regions), (b) the block decomposition corresponding to its line quadtree, and (c) the tree access structure with blocks for the nonleaf nodes instead of the actual tree. All heavy lines indicate that an edge of the block is on the border of an object or the underlying space.

space into sectors of a circle and cones of a sphere for two- and three-dimensional data, respectively.

The remaining subsections deal with representations of objects whose boundaries are usually hyperplanes. In the case of two-dimensional data, besides two-dimensional objects whose boundaries are line segments, we also discuss the representation of data that is a collection of connected straight-line segments that partition the underlying space into a collection of polygons termed a *polygonal map* (or *map* for short). The PM quadtree family (Section 2.2.2.6) is an example of a representation that can deal with such data. In three dimensions, the data is a collection of objects with planar faces (i.e., polyhedra) and can be handled by the PM octree (Section 2.2.2.7), although we also show that the PM octree can be adapted to deal with more general data. As we will see, the vertices of the line segments and polyhedra play a crucial role in the decomposition that is induced by the PM quadtree and PM octree. The bucket PM quadtree and PMR quadtree (Section 2.2.2.8) relax this dependence on the vertices by basing the decomposition on the number of edges or faces that are present.

### 2.2.2.1 Line Quadtree

The simplest decomposition into blocks is obtained by using a region quadtree decomposition of the underlying space. Associated with each block  $b$  is the relevant information about the portion of the boundary  $e$  of the objects of which  $b$  is a part or the portion of the boundary  $e$  of the environment (i.e., the underlying space) in which the objects are embedded that is shared by  $b$ . This adaptation of the region quadtree serves as the basis of the line quadtree [1663, 1664].

The *line quadtree* partitions the underlying space via a recursive decomposition technique that successively subdivides the space until obtaining blocks (possibly single pixels) that have no boundary elements passing through their interior. With each block, a code is associated that indicates which of its four sides forms a boundary (not a partial boundary) of any single object (including the underlying space). Thus, instead of distinguishing blocks on the basis of whether they are part of the background and of the identity of the object in which they lie, we use the nature of the boundary information.

For example, Figure 2.117(b) is the block decomposition corresponding to the space partition given in Figure 2.117(a). Notice the use of heavy lines to denote the existence of a complete border on an edge  $e$  of a particular block  $b$ . The absence of a heavy line means that the edge  $e$  of  $b$  is not completely on the border of a block. In particular,  $e$  can be partially on the border. The extent of its presence on a border is determined by examining its neighbor  $c$  along the edge. In particular, if  $c$  along  $e$  is of equal size to that of a side of  $b$ , then  $e$  is not an edge of an object or of the underlying space.

Several access structures are possible. Using a tree access structure with fanout 4 is particularly attractive as we can store the boundary information in a hierarchical manner (i.e., in the nonleaf nodes). In essence, wherever a nonleaf node does not form a T-junction with any of the boundaries of its descendants along a particular edge  $e$ , then  $e$  is marked as being adjacent to a boundary by use of a heavy line. Figure 2.117(c) shows the blocks corresponding to all of the nodes (i.e., both leaf and nonleaf) in the tree access structure with fanout 4 for the line quadtree in Figure 2.117(a). Notice the use of heavy lines to denote the edges that are along the boundary, including that of the underlying space.

### Exercises

1. Prove that the line quadtree of a polygonal map has the same number of nodes as does the region quadtree for the same map when each polygon is treated as a region of another color.
2. The definition of the line quadtree given here stores redundant information with many of the nonleaf nodes. This redundancy can be alleviated by recording the boundary information for

just two sides of each node instead of for all four sides. Let us refer to this structure as a *revised line quadtree*. This will affect the merging criteria since now we can merge four nodes only if their corresponding boundaries are identical. For example, suppose that for each node we record only the boundary information for its northern and eastern sides. Use the polygonal map of Figure 2.117(a) to show that the number of leaf nodes in the revised line quadtree is greater than the number of leaf nodes in the conventional line quadtree.

3. What is the maximum increase in the number of nodes in a revised line quadtree over the line quadtree?

### 2.2.2.2 MX Quadtree and MX Octree

Note that the line quadtree is also applicable to polygonal maps. In this case, the line segments are parallel to the coordinate axes. In fact, the line quadtree is really an approximation of an arbitrary polygonal map where the edges of the polygonal map are approximated by lines in the four principal directions. An alternative approximation is provided by the *MX quadtree* [901, 905]. In this case, the edges of the polygonal map are approximated by the pixels through which they pass.

For two-dimensional data such as a polygonal map, the MX quadtree is built by digitizing the line segments and labeling each unit-sized cell (i.e., pixel) through which it passes as of type `BOUNDARY`. The remaining pixels are labeled `WHITE` and are merged, if possible, into larger and larger quadtree blocks, as is done in the region quadtree. Figure 2.118(b) is the MX quadtree for the collection of line segment objects in Figure 2.118(a). A drawback of the MX quadtree is that it associates a thickness with a line. In addition, given an MX quadtree representation of a polygonal map, it is difficult to detect the presence of a vertex whenever five or more line segments meet. The problem is that, once the polygonal map has been digitized, thereby forming the basis of the MX quadtree, there is no one-to-one correspondence between them. At best, we can represent the intersection of four line segments (e.g., the vertex at which they meet) by four adjacent pixels. However, five or more lines will also likely be represented by four adjacent pixels.

A similar approximation for three-dimensional data, such as polyhedra or objects bounded by arbitrary surfaces, is provided by the *MX octree*, where the faces (as well as edges) of the object are approximated by the voxels through which they pass. The MX octree can be formed in a similar manner as the MX quadtree. In particular, we can make use of a scanning device, with the result that all voxels through which the surface passes are labeled as type *boundary*. The remaining voxels are labeled `WHITE` and are merged, if possible, into larger and larger octree blocks, as is done in the region octree. The MX octree has the same drawbacks as the MX quadtree. In particular, it is not invertible, and it is difficult to capture the incidence of many faces (and edges) at a vertex. We do not discuss the MX octree in great detail because its properties are similar to those of the MX quadtree.

The MX quadtree has the property that an upper bound can be derived on the number of nodes needed when using it to represent a simple polygon (i.e., with nonintersecting edges and without holes) [901]. It is obtained in the following manner. First of all, we observe that a curve of length  $d + \epsilon$  ( $\epsilon > 0$ ) can intersect at most six squares of side width  $d$ . Now consider a polygon, say  $G$ , having perimeter  $p$ , that is embedded in a grid of squares each of side width  $d$ . Mark the points at which  $G$  enters and exits each square. Choose one of these points, say  $P$ , as a starting point for a decomposition of  $G$  into a sequence of curves. Define the first curve in  $G$  to be the one extending from  $P$  until six squares have been intersected and a crossing is made into a different, seventh square. This is the starting point for another curve in  $G$  that intersects six new squares, not counting those intersected by any previous curve.

We now decompose  $G$  into a series of such curves. Since each curve adds at most six new squares and has length of at least  $d$ , we see that a polygon with perimeter  $p$  cannot intersect more than  $6 \cdot \lceil p/d \rceil$  squares. Given a quadtree with a root at level  $q$  (i.e., the

## Section 2.2 BOUNDARY-BASED REPRESENTATIONS

(a)

(b)

(c)

Figure 2.118  
(a) Collection of line segments, (b) its MX quadtree, and (c) its edge quadtree.

grid of squares is of width  $2^q$ ), at level  $i$  each square is of width  $2^i$ . Therefore, polygon  $G$  cannot intersect more than  $B(i) = 6 \cdot \lceil p/2^i \rceil$  quadrants at level  $i$ . Recall that our goal is to derive an upper bound on the total number of nodes. This bound is attained when each boundary node at level  $i$  has three sibling nodes that are not intersected. Of course, only boundary nodes can have children, and thus no more than  $B(i)$  nodes at level  $i$  have children. Since each node at level  $i$  is a child of a node at level  $i + 1$ , there are at most  $4 \cdot B(i + 1)$  nodes at level  $i$ . Summing up over  $q$  levels (accounting for a root node at level  $n$  and four children), we find that the total number of nodes in the tree is bounded by

$$\begin{aligned}
 & 1 + 4 + \sum_{i=0}^{q-2} 4 \cdot B(i + 1) \\
 & \leq 5 + 24 \cdot \sum_{i=0}^{q-2} \left\lceil \frac{p}{2^{i+1}} \right\rceil \\
 & \leq 5 + 24 \cdot \sum_{i=0}^{q-2} \left( 1 + \frac{p}{2^{i+1}} \right) \\
 & \leq 5 + 24 \cdot (q - 1) + 24 \cdot p \cdot \sum_{i=0}^{q-2} \frac{1}{2^{i+1}} \\
 & \leq 24 \cdot q - 19 + 24 \cdot p.
 \end{aligned}$$

Therefore, we have proved the following:

**Theorem 2.1** *The quadtree corresponding to a polygon with perimeter  $p$  embedded in a  $2^q \times 2^q$  image has a maximum of  $24 \cdot q - 19 + 24 \cdot p$  (i.e.,  $O(p + q)$ ) nodes.*

Theorem 2.1 is also known as the *Quadtree Complexity Theorem*. In all but the most pathological cases (e.g., a small square of unit width centered in a large image), the  $q$  factor is negligible and thus the number of blocks is  $O(p)$ . The Quadtree Complexity Theorem also holds for three-dimensional data [1273] (i.e., represented by a MX octree), where perimeter is replaced by surface area, as well as for objects of higher dimensions  $d$ , for which it is proportional to the size of the  $(d - 1)$ -dimensional interfaces between the objects [1948]. These results also hold for the region quadtree and region octree.

The most important consequence of the Quadtree Complexity Theorem is that it means that most algorithms that execute on a quadtree representation of an image (with an appropriate access structure), instead of simply imposing an array access structure on the original collection of cells, usually have an execution time proportional to the number of blocks in the image rather than the number of unit-sized cells.

In its most general case, the Quadtree Complexity Theorem indicates that the use of the quadtree representation, with an appropriate access structure, to solve a problem in  $d$ -dimensional space will lead to a solution whose execution time is proportional to the  $(d - 1)$ -dimensional space of the surface of the original  $d$ -dimensional image. On the other hand, use of the array access structure on the original collection of cells results in a solution whose execution time is proportional to the number of cells that make up the image. Therefore, quadtrees and octrees act like dimension-reducing devices.

### Exercises

1. The proof of Theorem 2.1 is based on a decomposition of the polygon into a sequence of curves, each of which intersects at most six squares. However, this bound can be tightened by examining patterns of squares to obtain minimum lengths and corresponding ratios of possible squares per unit length. For example, observe that once a curve intersects six squares, the next curve of length  $d$  in the sequence can intersect at most two new squares. In contrast, it is easy to construct a sequence of curves of length  $d + \varepsilon$  ( $\varepsilon > 0$ ) such that almost each curve intersects two squares of side length  $d$ . Prove that such a construction leads to an upper bound of the form  $a \cdot q + b + 8 \cdot p$ , where  $a$  and  $b$  are constants.

2. Decompose the polygon used in the proof of Theorem 2.1 into a sequence of curves in the following manner: Mark the points where  $G$  enters and exits each square of side width  $d$ . Choose one of these points, say  $P$ , and define the first curve in  $G$  as extending from  $P$  until four squares have been intersected and a crossing is made into a different fifth square. This is the starting point for another curve in  $G$  that intersects four new squares, not counting those intersected by any previous curve. Prove that all of the curves, except for the last one, must be of at least length  $d$ . Using this result, prove that the upper bound on the number of nodes in the MX quadtree is  $16 \cdot n - 11 + 16 \cdot p$ .
3. In this exercise and in Exercise 4, we show that the bounds given in Theorem 2.1 are attainable. We first look at the base 2 logarithm  $q$  of the image width. Consider a square of side width 2 that consists of the central four  $1 \times 1$  squares in a  $2^q \times 2^q$  image (see Figure 2.119). Prove that its MX quadtree has  $16 \cdot q - 11$  nodes. This shows that the bound given in Theorem 2.1 is attainable
4. Continuing Exercise 3, we now show that the bound in terms of the perimeter given in Theorem 2.1 is attainable. Take a curve that follows a vertical line through the center of a  $2^q \times 2^q$  image and lengthen it slightly by making it intersect all of the pixels on either side of the vertical line (see Figure 2.120). In particular, prove that as  $q$  increases, the total number of nodes in the corresponding MX quadtree approaches  $8 \cdot p$ , where  $p = 2^q$ .
5. Using a technique analogous to that used in Exercise 4, construct a polygon of perimeter  $p$  by approximating a square in the center of the image whose side is one-fourth the side of the image. Prove that its MX quadtree has approximately  $8 \cdot p$  nodes.
6. Prove that  $O(p + q)$  is a least upper bound on the number of nodes in a MX quadtree corresponding to a polygon. Assume that  $p \leq 2^2 q$  (i.e., the number of pixels in the image). Equivalently, the polygon boundary can touch all of the pixels in the most trivial way but can be no longer. Decompose your proof into two parts, depending on whether  $p$  is greater than  $4 \cdot q$ .
7. Theorem 2.1 can be recast by measuring the perimeter  $p$  in terms of the length of a side of the image in which the polygon is embedded—that is, for a  $2^q \times 2^q$  image,  $p = p' \cdot 2^q$ . Thus, the value of the perimeter no longer depends on the resolution of the image. Restating Theorem 2.1 in terms of  $p'$  results in an MX quadtree having  $O(p' \cdot 2^q + q)$  nodes. This means that the number of nodes in the MX quadtree doubles as the resolution is doubled, while the number of pixels in the array representation quadruples as the resolution is doubled. Can you prove a similar result for an arbitrary MX quadtree (rather than just one for a simple polygon)?
8. Prove the analog of Theorem 2.1 for a three-dimensional polyhedron represented as an octree (i.e., an MX octree). In this case, the perimeter corresponds to the surface area.
9. Prove the  $d$ -dimensional analog of Theorem 2.1 for the  $d$ -dimensional MX quadtree that corresponds to a  $d$ -dimensional polyhedron.
10. Assuming an image of resolution  $q$  that is not necessarily a polyhedron and measuring the perimeter, say  $p$ , in terms of the number of border pixels, prove that the total number of nodes in a  $d$ -dimensional quadtree is less than or equal to  $4 \cdot q \cdot p$ .
11. Assuming an image of resolution  $q$  that is not necessarily a polyhedron and measuring the perimeter, say  $p$ , in terms of the number of border pixels, prove that the total number of black nodes in a  $d$ -dimensional quadtree is less than or equal to  $(2^d - 1) \cdot q \cdot p/d$ .
12. How tight are the bounds obtained in Exercises 10 and 11 for the number of nodes in a  $d$ -dimensional quadtree for an arbitrary region? Are they realizable?

mately  $8 \cdot p$  nodes.

### 2.2.2.3 Edge Quadtree

The MX quadtree results in a decomposition of the underlying space so that there is a unit-sized cell for each pixel through which an edge or curve passes, while all other cells are merged as much as possible using the quadtree aggregation rule (i.e., four sibling blocks of the same type are merged into a larger block of the same type). A slight reduction in the storage requirements can be achieved by halting the decomposition upon encountering a  $2 \times 2$  cell through which an edge passes and then storing a templatelike representation of the edge [1401] (see also [1231]). This is quite similar to the MX quadtree, except that the data is now edges rather than points.

The edge quadtree [1762, 1961] is a more general refinement of the MX quadtree based on the observation that the number of blocks in the decomposition can be reduced by terminating the subdivision whenever the block contains a single curve that can be approximated by a single straight line given an error tolerance value. Thus, the edge quadtree is defined for collections of line segments that are curves as well as straight lines. For example, Figure 2.118(c) is the edge quadtree for the collection of line segment objects in Figure 2.118(a) with a zero error tolerance.

It is interesting to observe that, in terms of the necessary storage requirements, Figure 2.118(b) represents the worst case of the edge quadtree in the sense that, since the underlying data is a polygonal map, and the error tolerance is zero, no approximation is taking place—that is, we are actually approximating straight lines with straight lines of zero error tolerance. This is why we have to decompose the underlying space to the maximum level of decomposition in the vicinity of corners or intersecting edges. Therefore, in the case of polygonal maps, using an edge quadtree with zero error tolerance results in quadtrees where long edges are represented by large blocks or a sequence of large blocks, while small blocks are needed in the vicinity of corners or intersecting edges. Of course, many blocks will contain no edge information at all. Nevertheless, it is important to note that when the curves are not straight lines, it is pointless to use the edge quadtree with a zero error tolerance because, in such a case, it yields the same result as the MX quadtree.

Another byproduct of using a zero error tolerance is that the maximum level of decomposition is determined by the resolution of the space in which the polygonal map is embedded since the cells at this depth are needed for the vertices and the locations where the edges or curves intersect. On the other hand, once a nonzero error tolerance is used, it determines the maximum level of decomposition, which need not be at the resolution of the underlying space (i.e. at the pixel level). Thus, the error tolerance value acts like a smoothing function. The error tolerance value can also be used to define a band around the original curve that serves to depict the extent of the approximation. Moreover, most importantly, use of a nonzero error tolerance means that the resulting approximation has induced a new polygonal map whose vertices are anchored on the quadtree subdivision lines. This is because we are approximating subcurves of the curve with a straight line whose vertices lie on the boundaries (i.e., edges) of the quadrant containing the approximating line—that is, we have created a piecewise linear approximation of the curve, which is the rationale for using the term *edge quadtree* to describe it. Thus, using a nonzero error tolerance enables the edge quadtree, to avoid having to decompose to the maximum resolution (i.e., the pixel level).

Actually, once we approximate a subcurve of the curve by a line and create the corresponding quadtree block, the approximating line of the next subcurve in the sequence is naturally anchored at the quadtree subdivision lines that now serve as the new vertices of the piecewise linear approximation of the curve. For example, the object in Figure 2.121(a) illustrates a more realistic application of the edge quadtree, where the object's boundary consists of curved lines. Figure 2.121(b) is the corresponding edge quadtree using a zero error tolerance, which is the same as the MX quadtree for the object boundaries that are neither straight lines nor points of intersection of straight lines. On the other hand, Figure 2.121(c) is an edge quadtree using an error tolerance of 0.4. As mentioned above, at times, the extent of the approximation is depicted by using a band, which is illustrated by Figure 2.121(d) for the edge quadtree in Figure 2.121(c). Notice that the bands of neighboring nodes overlap at the common quadrant boundary, but not completely. The union of all the bands of the curve defines a “thick curve” with a width that is twice the error tolerance that contains the true curvilinear boundary of the object. The result is analogous to what is obtained by using a strip tree [121] (see Section 2.2.3.1), with the distinction that the strip tree is an object-based representation while the edge quadtree is an image-based representation that uses regular decomposition.

Closely related to the edge quadtree is the *least square quadtree* [1248]. In that representation, leaf nodes correspond to regions that contain a single curve that can be

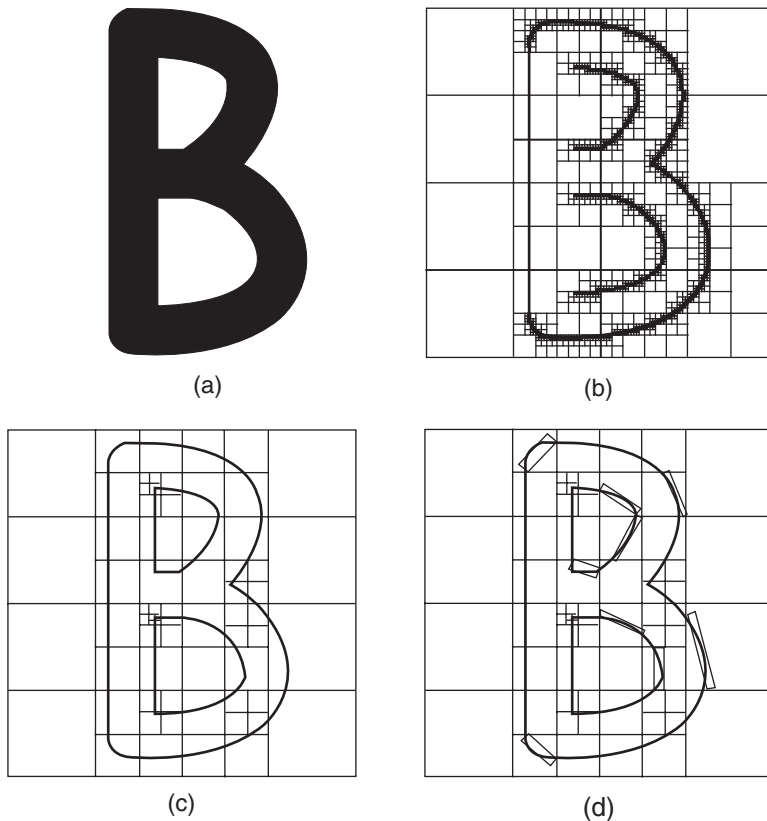

Figure 2.121  
(a) Example object, (b) its edge quadtree with a zero error tolerance, (c) its edge quadtree with a 0.4 error tolerance, and (d) bands illustrating the extent of the approximation induced by (c).

approximated by  $K$  (fixed a priori) straight lines within a least square tolerance. This enables handling curved lines with greater precision and uses fewer nodes than the edge quadtree.

*Exercise*

1. Give an algorithm to construct an edge quadtree for a given polygonal map.

### 2.2.2.4 Face Octree

The region octree and the MX octree are difficult to work with when trying to represent objects whose faces are not restricted to being rectilinear. They both yield an approximation that is inadequate for many applications, such as solid modeling. Of course, if the faces are mutually orthogonal, then a suitable rotation operation can be applied to yield rectilinear faces. However, we are dealing with a more general case. One solution is to store surface normals in the visible surface nodes as discussed by Meagher [1279] (see Section 7.1.4 of [1636]). Chien and Aggarwal [369] show how to do this directly from boundaries of multiple silhouettes. We do not discuss this approach here.

An alternative solution, and the one we discuss in the remainder of this section, is to adapt the edge quadtree to three dimensions. Initially, we restrict our discussion to polyhedral objects. A simple adaptation is a variant of the MX octree that halts the decomposition whenever a block contains just one face. The result is termed a *face octree* [270, 1349]. An alternative adaptation, which is not used much, halts the decomposition whenever the block contains just one face or one edge, provided that all

the faces in the block meet at this edge. The result is termed a *face-edge octree* [1349]. Observe that, in the former, decomposition occurs around an edge and a vertex, while, in the latter, decomposition occurs only around a vertex. In either case, the result is the three-dimensional analog of the edge quadtree where the objects are polyhedra instead of polygonal maps.

The storage requirements of the face octree—and, to a lesser extent, of the face-edge octree—can be reduced by modifying the halting condition for the decomposition process to be based on an error tolerance for a planar approximation of the surface. This halting condition forms the basis of a variant of the face octree proposed by Brunet [270] that, as in the case of polyhedral objects, only allows empty, full, and face nodes, where the face nodes contain the planar approximation, as well as a pointer to the complete geometrical description of the face (i.e., surface) that is being approximated. This variation of the face octree is very useful when the objects are not constrained to be polyhedra. In particular, it avoids the need to decompose around edges where the interior angle formed by the adjacent faces is small, as is the case for most objects. Thus, with this modification, the face-edge octree becomes less important, and we do not discuss it further here.

Although we have described the face octree in terms of objects with arbitrary surfaces, the face octree can also be used to represent polyhedra, in which case the representation is exact in the sense that it enables the reconstruction of the original polyhedron, provided that each face of the polyhedron is pointed at by at least one face node. The advantage of using a nonzero error tolerance in the case of polyhedra is that its use enables avoiding some of the decomposition that would otherwise be necessary around some of the edges and vertices. Numerous algorithms have been given for solid modeling operations involving face octrees (for polyhedra as well as objects with more general surfaces) as well as analyses of their storage requirements (e.g., [272, 274, 975, 1497, 1498, 1784]).

Every face node in a face octree can be interpreted as a three-dimensional hyperrectangle-shaped band of width equal to the error tolerance and oriented so that it is parallel to the planar approximation of the surface of the object. Thus, the surface can be viewed as a sequence of hyperrectangle-shaped bands. These bands change orientation at octant boundaries, and these positions play a role somewhat analogous to vertices when the object is a polyhedron. Using such an interpretation yields a result similar to the prism tree of Ponce and Faugeras [1501] and its predecessor, the polyhedral approximation [597] (see Section 2.2.3.2), which are three-dimensional generalizations of the strip tree [121] (see Section 2.2.3.1). The distinction is that the prism tree is an object-based representation while the face octree is an image-based representation that uses regular decomposition.

### *Exercise*

1. Give an algorithm to construct a face octree for a given polyhedron.

## 2.2.2.5 Adaptively Sampled Distance Fields

The adaptively sampled distance field (ADF) of Frisken, Perry, Rockwood, and Jones [654, 655, 1482], applied to two- and three-dimensional data, yields a decomposition of the underlying space that is analogous to that obtained by the edge quadtree (Section 2.2.2.3) and face octree (Section 2.2.2.4), respectively. In fact, the adaptively sampled distance field can be viewed as the dual of the edge quadtree and face octree (see Exercise 3) in two and three dimensions, respectively. In this section, the discussion is primarily in terms of three-dimensional data because this is where the adaptively sampled distance field finds most use. Nevertheless, almost all of our comments are equally applicable to two-dimensional data, and, in fact, the example that we give makes use of a two-dimensional object as it is easier to visualize.

The basic idea is to represent an object by a *distance field*—a scalar field that specifies the distance to the nearest point on the surface of the object from every point in the space in which the object is embedded, where the distance is usually signed to distinguish between the inside and outside of the object [707]. The rationale for using the distance field is to overcome some of the drawbacks of methods based on volume graphics [1002].

Conventional representations (e.g., those that use collections of voxels or hierarchical aggregations of similarly valued voxels such as the region and MX octrees) are good for Boolean set operations and visualization of the interiors of the objects. The data usually originates as binary data. The discrete sampling process, by which the data is acquired and the associated representations are built, makes it difficult to use these representations to represent arbitrarily oriented surfaces very well. Estimation of surface normals for binary data is complicated by the fact that the discrete sampling process by which they have been acquired has led to the loss of prior information about the surface of the object. Moreover, the binary nature of the data inherently leads to abrupt changes in value at the surface of the object.

Being able to represent the surface accurately is important for a number of reasons [707]. For example, it is useful for dealing with interactions between different models, as in the case of the calculation of impact forces, which requires knowledge of the positions and surface normals of the contact points. Precise knowledge of the location and orientation of the surface is also needed for proper use of a lighting and shading model to obtain high-quality rendering. When the sample data is intensity based, the surfaces are not represented well enough because the intensity varies smoothly in the interiors of the objects while, as pointed out above, it varies rapidly (abruptly) at their surfaces. This makes shading in volume graphics difficult. During the rendering process, these abrupt changes are detected and used to determine the intensity and direction of the surface. In particular, these abrupt changes correspond to high spatial frequencies in the data, which means that high sampling rates are needed to reconstruct the image and its gradient near the surface.

Using a distance field has a number of important properties that overcome some of the above problems. First, the gradient of the distance field yields the direction of the surface normal. Second, unlike object representations that are based on intensity, the distance field varies smoothly across object surfaces, thereby avoiding high spatial frequencies at object boundaries. In other words, surfaces in sampled data, as is common in volume graphics, can be reconstructed accurately using low sampling rates. Thus, the distance fields are used to implicitly encode surfaces into the sampled volumetric data so that high-quality shading can be performed in volume rendering of such data. Although we mention an implicit encoding, the idea is similar to the manner in which we use a PM quadtree (Section 2.2.2.6) or a PM octree (see Section 2.2.2.7) to encode the line segment or face that passes through a block. In particular, instead of storing the full description of the intersecting curve or face with the block through which it passes, we only associate a pointer to the real data with the block.

The distance field permits a very precise description of the shape. However, its storage requirements are prohibitive as fine detail in the shape still requires dense sampling. The high storage costs associated with keeping the entire distance field are reduced by making use of an adaptively sampled distance field [655], which permits varying the sampling rates so that the density of the sampling is directly proportional to the variation of the field. Adaptively sampled distance fields are formed in an analogous manner to a region octree or an MX octree, with the difference being that, instead of decomposing the space until each block is either completely occupied by an object or empty (i.e., a region octree) or obtaining unit voxel-sized blocks through which the boundary of the shape passes (i.e., an MX octree), the space is decomposed whenever the distance field within the block is not well approximated by a trilinear interpolation of the block's corner values.

There are a number of ways of measuring the approximation error (e.g., relative, absolute, average), although no specific one is prescribed [655]. If the approximation error function is a relative one, then the sampling is more frequent around the object boundary, where the distance field is close to zero and hence the sampled distance field should follow the distance field more closely. On the other hand, if the approximation error function is an absolute one, then the approximation error threshold determines how far the sampled distance field can deviate from the actual distance field based on an absolute value. In this case, the sampling will be more uniform across the entire space.

If the application is only concerned with the distance field around the boundary of the object, then we can increase the approximation error threshold as the distance of the sampled points from the boundary of the object increases. The effect of such an approach is similar to a relative approximation error function. However, the problem is that such a solution tends to oversample at the boundary of the object. Hence, we can combine the two and use an absolute approximation error  $e_a$  if the sampled point  $p$  is sufficiently close to the boundary of the object, say within  $d$  of the boundary of the object, and use a relative approximation error  $e_r$  otherwise. Such an approximation error function  $e_p$  is given by

$$e_p = \min(e_a, e_r \times |d_p|)$$

which we characterize as an *adaptive approximation error*.

Being able to vary the approximation error at different locations is one of the main reasons for the attractiveness of the adaptively sampled distance field. This can be seen by observing that the distance field undergoes a change of sign at the boundary of the object as this is its zero-crossing. These changes are important and may require a relatively low approximation error threshold for their proper handling. On the other hand, the distance field undergoes rapid changes (i.e., points of discontinuity of the first derivative) at points on the skeleton (recall the definition in Section 2.1.2.2) of the object as the identity of the nearest object changes at these locations. In other words, the normal of the distance field surface is discontinuous at the object's skeleton, thereby requiring much decomposition in the skeleton's neighborhood when a low approximation error threshold is used, regardless of whether it is relative or absolute. On the other hand, there is little need for decomposition at the skeleton, and thus adaptively varying the approximation error threshold so that it is low around the boundary of the object and high at the neighborhood of the skeleton is very useful. In essence, an adaptive sampling of the distance field based on the values of the distance is being done, and hence the rationale for the name adaptively sampled distance field.

Regardless of how the approximation error threshold is measured, even highly curved edges and faces can be efficiently represented using adaptively sampled distance fields. In particular, since trilinear (bilinear) interpolation can represent curved surfaces (edges) well, cells with smoothly curved faces (edges) do not require many levels in the adaptively sampled distance field hierarchy, and thus much decomposition is only concentrated at corners, cusps, and sharp edges.

For example, Figure 2.122(a) is the adaptively sampled distance field for the two-dimensional object in Figure 2.121(a) using a relative approximation error threshold of 0.9. Notice the similarity in the decomposition to the edge quadtree in Figure 2.121(b, c). This is not surprising as it is a direct result of our observation of the duality of these representations.

It is interesting to observe that the distance field is somewhat of an indirect representation of the shape of an object as it describes the object by associating information with the parts of the space that are not occupied by it rather than the parts of the space that are occupied by it. In addition, note that, although the concept of distance is also used in the definition of a medial axis transformation (MAT) and a quadtree medial axis

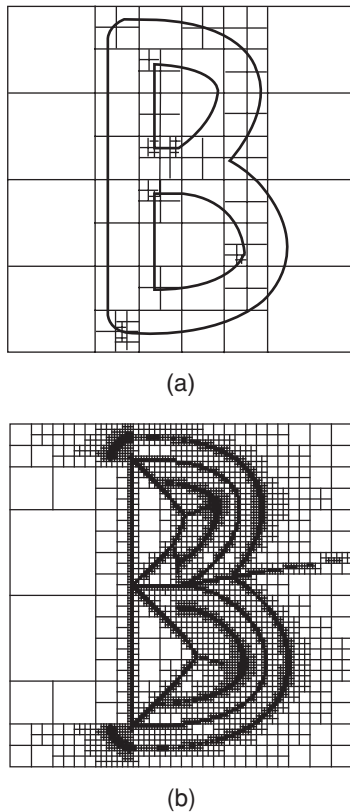

Figure 2.122  
The adaptively sampled distance field for the two-dimensional object in Figure 2.121(a) using a relative approximation error threshold of (a) 0.9 and (b) 0.01.

transform (QMAT) (see Section 2.1.2.2),<sup>41</sup> thereby seeming similar to a distance field, they are different. In particular, the MAT and QMAT are methods of describing the interior of a shape by a collection of blocks of different radii (distance values), while the distance field describes the relationship of the boundary of the shape to the rest of the space (both inside and outside the object).

The decomposition induced by the adaptively sampled distance field is also closely related to the concept of a skeleton in the sense that some of the locations at which there is much decomposition in the adaptively sampled distance field coincide with the skeleton. This becomes more apparent when we examine Figure 2.122(b), which is the adaptively sampled distance field for the two-dimensional object in Figure 2.121(a) using a relative approximation error threshold of 0.01. In this case, the adaptively sampled distance field results in decomposing the underlying space around both the boundary of the shape and its skeleton. Here we see that the skeleton is computed for the region corresponding to the object (i.e., the solid part representing the letter “B”) and its holes. Note that when the relative approximation error threshold is sufficiently high, as in the adaptively sampled distance field in Figure 2.122(a), there is no decomposition around the skeleton of the object.

### Exercises

1. Give an algorithm to construct an adaptively sampled distance field for a given two-dimensional object.
2. Give an algorithm to construct an adaptively sampled distance field for a given three-dimensional object.
3. In the text, we pointed out that the adaptively sampled distance field can be viewed as the dual of the edge quadtree (face octree) in two (three) dimensions. Is there any correlation between the error tolerance used to define the edge quadtree (face octree) and the error used to create the bilinear (trilinear) interpolation approximation of the distance field within a block so that the resulting decompositions of the underlying space are the same? If there is not, then give a counterexample.

### 2.2.2.6 PM Quadtrees

The PM quadtree family [1360, 1665] (see also edge-EXCELL [1822]) represents an attempt to overcome some of the problems associated with the edge quadtree in the representation of a polygonal map. In particular, the edge quadtree is an approximation because vertices are represented by pixels. Also, when the lines are curves, the decomposition stops when they can be approximated by a single straight line for a predefined tolerance. There are several variants of the PM quadtree. These variants are either vertex based or edge based. They are all built by applying the principle of repeatedly breaking up the collection of vertices and edges (forming the polygonal map) until a subset is obtained that is sufficiently simple that it can be organized by some other data structure.

$PM_1$ ,  $PM_2$ , and  $PM_3$  quadtrees [1665] are vertex based. The  $PM_1$  quadtree is the simplest variant. Its decomposition rule stipulates that partitioning occurs as long as a block contains more than one line segment, unless the line segments are all incident at the same vertex, which is also in the same block. The fact that the structure is defined in a top-down manner means that each block is maximal. It should be clear that each block contains at most one vertex. For example, Figure 2.123(a) is the  $PM_1$  quadtree corresponding to the collection of line segment objects in Figure 2.118(a).

The number of blocks in a  $PM_1$  quadtree depends on the following three factors:

<sup>41</sup> Although the quadtree medial axis transform is defined for two-dimensional data, it is equally applicable for three-dimensional data.

## Section 2.2 BOUNDARY-BASED REPRESENTATIONS

(a)

(b)

(c)

Figure 2.123  
(a)  $PM_1$  quadtree, (b)  $PM_2$  quadtree, and (c)  $PM_3$  quadtree for the collection of line segments of Figure 2.118(a).

1. The minimum separation between two vertices
2. The minimum separation between a vertex and a line segment
3. The minimum separation between two nonintersecting line segments in a block that contains no vertices

Given a polygonal map whose vertices are drawn from a grid (say  $2^m \times 2^m$ ), and where line segments are not permitted to intersect at points other than the grid points (i.e., vertices), it can be shown that these factors imply that the maximum depth of any leaf node in a tree access structure for the  $PM_1$  quadtree is bounded from above by  $4m + 1$  [1656]. This is useful if we want to represent the collection of blocks using one of the alternative access structures to a tree discussed in Section 2.1.2. Recall that they are all based on finding a mapping from the domain of the blocks to a subset of the integers (i.e., to one dimension) and then applying one of the familiar treelike access structures (e.g., a binary search tree, range tree,  $B^+$ -tree). The depth bound enables a determination of the maximum amount of storage that will be necessary for the locational code of each block.

The amount of storage necessary to represent the  $PM_1$  quadtree can be reduced by removing some of the factors on which its depth depends. For example, we can remove the dependence on the minimum separation between two nonintersecting line segments in a block that contains no vertices by modifying the definition of the  $PM_1$  quadtree so that a block is not split if all of the line segments that it contains intersect at a vertex outside of the block. In other words, we modify the decomposition rule so that partitioning occurs as long as a block contains more than one line segment, unless the line segments are all incident at the same vertex, regardless of its location. The result is termed a  $PM_2$  quadtree and is illustrated in Figure 2.123(b).

The amount of storage necessary to represent the  $PM_1$  quadtree can be further reduced by removing the dependence on the minimum separation between a vertex and a line segment so that partitioning occurs only when a block contains more than one vertex. The result is termed a  $PM_3$  quadtree and is illustrated in Figure 2.123(c). The  $PM_3$  quadtree is the same as a PR quadtree (see Section 1.4.2.2 of Chapter 1), which is a representation for point data. As we see, the line segments play no role in the decomposition process. The sole dependence of the decomposition rule leading to the  $PM_3$  quadtree on the existence of just one vertex per block shows why we say that the  $PM_3$  quadtree is vertex based and, to a lesser extent, why we also say that the  $PM_1$  and  $PM_2$  quadtrees are vertex based. The  $PM_3$  quadtree has been used by Ibbs [917] to store vector data in a commercial mapping program.

All variants of the PM quadtree (including the PMR quadtree discussed in Section 2.2.2.8 and the three-dimensional variants discussed in Section 2.2.2.7) are characterized as employing *spatial indexing* because, with each block, the only information that is stored is whether the block is occupied by the object or part of the object that is stored there. This information is usually in the form of a pointer to a descriptor of the object. For example, in the case of a collection of line segment objects in the PMR quadtree of Figure 2.128 (to be discussed in Section 2.2.2.8), the shaded blocks record only the fact that the line segments (i.e., a, b, and e) cross it or pass through it. The part of the line segment that passes through the block (or terminates within it) is termed a *q-edge* (*q-face* in three dimensions). It is determined by clipping [1568] an edge of the polygonal map against the border of the block through which it passes. Each q-edge in the block is represented by a pointer to a record containing the endpoints of the line segment of which the q-edge is a part [1360]. The pointer is really nothing more than a spatial index and hence the use of this term to characterize this approach. Thus, no information is associated with the shaded block as to what part of the line (i.e., q-edge) crosses it. Instead, this information is represented implicitly, and, as we point out above, it is obtained by clipping [622] the original line segment to the block. This is important because often the precision necessary to compute these intersection points is not available. This feature makes such representations particularly attractive for dealing with vector data (in con-

trast to raster data) and has led them to be called *vector quadtrees* (and *vector octrees* in three dimensions) [1666, 1667].

The  $PM_2$  quadtree is particularly useful for storing polygonal maps that correspond to triangulations or, more generally, to polygonal maps where all vertices have degree 3 (e.g., nondegenerate Voronoi diagrams where no four sites are cocircular) as the space requirements are often considerably smaller than those of the  $PM_1$  quadtree, while not being much larger than the  $PM_3$  quadtree. This is especially true for the Delaunay triangulation, which satisfies the minimum angle property and thus maximizes the minimum interior angle, thereby implying that the constituent triangles are as close as possible to being equiangular (recall properties 2 and 6 of the Delaunay triangulation in Section 2.2.1.4). This can be seen in Figure 2.124(a–c), which shows the block decompositions induced by the  $PM_1$ ,  $PM_2$ , and  $PM_3$  quadtrees, respectively, for the Delaunay triangulation given in Figure 2.110(b) in Section 2.2.1.4, where the corresponding Voronoi diagram is shown using broken lines. Notice the difference in the maximum depth of the decomposition between the  $PM_1$  and  $PM_2$  quadtrees, while there is no difference in this example between the  $PM_2$  and  $PM_3$  quadtrees.

In fact, in such a case, instead of storing with each leaf block  $b$  the set of edges that pass through  $b$ , we use an alternative implementation where each leaf block  $b$  stores the vertex, if any, that is common to the edges that pass through  $b$  [453]. If only one edge passes through  $b$ , then one of its vertices is arbitrarily chosen to be stored. In any case, regardless of how many edges pass through  $b$ , the vertices are usually part of an auxiliary data structure (e.g., a triangle table or some other variant of the winged-edge data structure) that keeps track of the topological properties of the polygonal map. The auxiliary structure serves to facilitate a number of operations that involve visiting adjacent triangles that are necessary for updating the polygonal map in a consistent manner so that it remains a triangulation of a particular type or even operations such as point location. For another related application of the  $PM_2$  quadtree, see the discussion of the approximate Voronoi diagram (AVD) [799] in Section 4.4.5 of Chapter 4. In particular, see the (3,0)-AVD [97, 98], which, for two-dimensional polygonal maps that correspond to Voronoi diagrams, yields an identical partition of the underlying space into blocks as does the  $PM_2$  quadtree.

### Exercises

Exercises 1–6 assume the following implementation for the PM quadtree. The basic entities are vertices and edges. Each vertex is represented as a record of type *point*, which has two fields called XCOORD and YCOORD that correspond to the  $x$  and  $y$  coordinate values, respectively, of the point. They can be real or integer numbers, depending on implementation considerations such as floating-point precision.

An edge is implemented as a record of type *line* with four fields, P1, P2, LEFT, and RIGHT. P1 and P2 contain pointers to the records containing the edge's vertices. LEFT and RIGHT are pointers to structures that identify the regions that are on the two sides of the edge. We shall use the convention that LEFT and RIGHT are with respect to a view of the edge that treats the vertex closest to the origin as the start of the edge.

Each node in a PM quadtree is a collection of  $q$ -edges, which is represented as a record of type *node* containing seven fields. The first four fields contain pointers to the node's four children corresponding to the directions (i.e., quadrants) NW, NE, SW, and SE. If  $P$  is a pointer to a node, and  $I$  is a quadrant, then these fields are referenced as  $CHILD(P, I)$ . The fifth field, NODETYPE, indicates whether the node is a leaf node (LEAF) or a nonleaf node (GRAY). The sixth field, SQUARE, is a pointer to a record of type *square*, which indicates the size of the block corresponding to the node. It is defined for both leaf and nonleaf nodes. It has two fields CENTER and LEN. CENTER points to a record of type *point* that contains the  $x$  and  $y$  coordinate values of the center of the square. LEN contains the length of a side of the square that is the block corresponding to the node in the  $PM_1$  quadtree.

DICTIONARY is the last field. It is a pointer to a data structure that represents the set of  $q$ -edges that are associated with the node. Initially, the universe is empty and consists of no

 Example polygonal map where vertex A lies on the border of a quadtree node. The decomposition lines are those induced by a  $PM_1$  quadtree definition in which a vertex is inserted in each of the nodes on whose border it lies.

edges or vertices. It is represented by a tree of one node of type LEAF whose DICTIONARY field points to the empty set.

In the implementation given here, the set of q-edges for each LEAF node is a linked list whose elements are records of type *edgelist* containing two fields, DATA and NEXT. DATA points to a record of type *line* corresponding to the edge of which the q-edge is a member. NEXT points to the record corresponding to the next q-edge in the list of q-edges. Although the set of q-edges is stored as a list here, it really should be implemented by a data structure that supports efficient updating and searching, as well as variants of set union and set difference operations.

1. Give an algorithm PMINSERT to insert a list of edges pointed at by  $p$  in the  $PM_1$  quadtree rooted at  $r$ . Also write a procedure CLIPLINES to clip the edges to the blocks corresponding to the nodes. Assume the existence of predicates INTERSECTLINESQUARE and PTINSQUARE. INTERSECTLINESQUARE indicates if an edge has at least one point in common with a square (i.e., it intersects some of its boundaries or lies completely inside it) while PTINSQUARE indicates if a vertex lies in a square. They are responsible for enforcing the conventions with respect to vertices and edges that lie on the boundaries of blocks.

Assume that each vertex is a part of all nodes through which its incident q-edges pass, as shown in Figure 2.125. Note that this means that a vertex is a part of all nodes (and possibly more) through which its incident q-edges pass. This is why the NW, NE, and SE quadrants in the figure are split—that is, they contain vertices A and D, A and E, and A and F, respectively, which cannot be in the same node. Otherwise, if we follow the customary open and closed conventions described in Section 1.1 of Chapter 1 that the lower and left boundaries of each block are closed while the right and upper boundaries of each block are open (given an origin at the lower-left corner of the space spanned by the region that contains the line segments), then we will have a problem when at least three edges meet at a vertex on the border of a quadtree node such that two of the edges are in the open quadrant (i.e., the one not containing the vertex). These two edges may have to be decomposed to a very deep level in order to separate them (e.g., edges AB and AC in the SW quadrant of the figure).

Q-edges that lie on the border of a quadtree node or that pass through one of its corners are inserted into the quadrants for which the border is closed. Assuming the open and closed conventions described in Section 1.1 of Chapter 1, for a block  $b$  with center at  $p$  with four children, we have the following:

- (a) Vertical edges coincident with the  $y$  axis through  $p$  are inserted into the NE and SE quadrants of  $b$ .
- (b) Horizontal edges coincident with the  $x$  axis through  $p$  are inserted into the NW and NE quadrants of  $b$ .
- (c) Diagonal edges from the NW quadrant of  $b$  to the SE quadrant of  $b$  are inserted into the NW, NE, and SE quadrants of  $b$ .
- (d) Diagonal edges from the NE quadrant of  $b$  to the SW quadrant of  $b$  are inserted into the NE and SW quadrants of  $b$ .

Assume further that, whenever an edge  $e$  is inserted into the  $PM_1$  quadtree,  $e$  does not intersect an existing edge. Otherwise, the block containing the intersection point will have to be decomposed forever as the intersection point is not treated as a vertex. In addition, it is assumed that  $e$  does not have an endpoint that is an existing isolated vertex (i.e., an edge with zero length). In the case of a  $PM_1$  quadtree,  $e$  cannot already exist in the tree, unless each of  $e$ 's q-edges are incident at the vertices of  $e$ . Otherwise,  $e$ 's q-edges that are not incident at the vertices of  $e$  would occur more than once in a block  $b$ , which would cause the decomposition of  $b$  to go on forever. You need not check for the occurrence of duplicate instances of edges.

2. Give an algorithm PMDELETE to delete a list of edges pointed at by  $p$  from the  $PM_1$  quadtree rooted at  $r$ . The process is analogous to that used in insertion. The difference is that, once the edge has been deleted, we process its ancestor nodes, and an attempt is made to merge their child nodes. The check for merging is analogous to the check for collapsing when deleting a point from a PR quadtree. The difference is that, for the  $PM_1$  quadtree, a check for the possibility of merging is made at each level of the tree in which processing one of the children of a nonleaf node has resulted in the deletion of a q-edge. In particular, merging can occur if at least one of the children of a nonleaf node is a leaf node. There are two situations where merging must occur. The first situation arises when the deletion of an edge has resulted in four sibling leaf nodes having zero or one edge pass through them. The second situation is somewhat tricky. It arises when deletion causes all of the remaining edges in the descendants

- of the nonleaf node, say  $N$ , to have a common vertex that lies in one of the children of  $N$  (not a descendant of  $N$ , who is not a child!). In this case, merging can occur, thereby making  $N$  a leaf node.
3. Modify procedure PMINSERT given in Exercise 1 to insert a list of edges pointed at by  $p$  in the  $PM_2$  quadtree rooted at  $r$ . Again, assume that whenever an edge  $e$  is inserted into the  $PM_2$  quadtree,  $e$  does not intersect an existing edge, and  $e$  does not have an endpoint that is an existing isolated vertex. Duplicate instances of an edge are allowed.
  4. Modify procedure PMDELETE given in Exercise 2 to delete a list of edges pointed at by  $p$  in the  $PM_2$  quadtree rooted at  $r$ .
  5. Modify procedure PMINSERT given in Exercises 1 and 3 to insert a list of edges pointed at by  $p$  in the  $PM_3$  quadtree rooted at  $r$ . Again, assume that whenever an edge  $e$  is inserted into the  $PM_3$  quadtree,  $e$  does not intersect an existing edge, and  $e$  does not have an endpoint that is an existing isolated vertex. Duplicate instances of an edge are allowed.
  6. Modify procedure PMDELETE given in Exercises 2 and 4 to delete a list of edges pointed at by  $p$  in the  $PM_3$  quadtree rooted at  $r$ .
  7. Prove that for a given polygonal map the average depth of a vertex node in a  $PM_3$  quadtree is smaller than in a  $PM_2$  (and  $PM_1$ ) quadtree.
  8. Using a random lines model and geometric probability as in the analysis of [1175], derive asymptotic bounds on the number of blocks that are necessary to store a triangulation using the different variants of the PM quadtree, the PMR quadtree (see Section 2.2.2.8), and the MX quadtree. Can you take advantage of the fact that you are using a  $PM_2$  quadtree to represent the triangulation so that only the identity of the vertex, instead of the set of intersecting lines, is stored in each block, thereby making the amount of data stored in each block independent of the number of edges that intersect it?
  9. How would you perform point location in a  $PM_1$  quadtree? In this case, you wish to find the nearest  $q$ -edge to the query point  $q$ .
  10. How would you compute map overlay (see Exercise 12 in Section 2.1.3.2) for two polygonal maps represented with the different variants of the PM quadtree?
  11. Prove that two PM quadtrees can be overlaid in  $O(v)$  time, where  $v$  is the number of vertices in the trees.
  12. What are some issues in the use of PM quadtrees to represent collections of line segments in three-dimensional space? In other words, can you use, for example, a  $PM_1$  quadtree to represent a collection of line segments in three-dimensional space where we recursively decompose the underlying space until each block contains at most one line segment or all of the line segments meet at a vertex within the block?

### 2.2.2.7 PM Octree

A more general adaptation of the MX octree to deal with three-dimensional objects that are polyhedra whose faces are not constrained to be rectilinear is obtained by modifying the decomposition rule of the face-edge octree so that it is also halted when all the faces and edges in the block meet at the same vertex, which is also in the block. This decomposition rule can be restated as stipulating that no block contains more than one face, edge, or vertex unless the faces all meet at the same vertex or are adjacent at the same edge inside the block. The result is analogous to what takes place in the neighborhood of a vertex node in the PM quadtree—that is, the decomposition around a node containing a vertex is halted as long as all of the edges that pass through the block are also incident at the vertex. Thus, we have defined the three-dimensional analog of the PM quadtree. Observe that, as in the PM quadtree family, the fact that the decomposition process is defined in a top-down manner means that each block is maximal. The result is usually called a *PM octree*, although the name *PM<sub>1</sub>octree* is a more precise characterization for the adaptation that we have described. In our discussion, we use the term *PM octree* unless a more precise distinction is necessary.

Figure 2.126  
(a) Example three-dimensional object and (b) its corresponding PM<sub>1</sub> octree.

Figure 2.127  
The two possible configurations for the cross section of an edge node in a PM octree: (a) a convex edge is the result of the intersection of the planes of the two faces that meet at the edge and (b) a concave edge is the result of the union of the plane of the two faces that meet at the edge. The arrows indicate the direction of the object relative to the faces. The broken lines correspond to the parts of the planes that do not form the boundary of the object. The shaded region corresponds to the object.

The space requirements of the PM octree are considerably harder to analyze than those of the region octree and the MX octree [1349] (see Exercise 6). Nevertheless, it should be clear that the PM octree for a given object is much more compact than the corresponding region octree. For example, Figure 2.126(b) is a PM octree decomposition of the object in Figure 2.126(a) (i.e., eight blocks with appropriate information about the primitives that lie in them).

At this point, let us briefly trace the history of the PM octree (see also [2020]). Quinlan and Woodwark [1526] describe a decomposition rule requiring that a leaf node contain at most one vertex. Otherwise, the node can either contain a number of faces or a number of edges and faces. The notion of a “number” is analogous to the manner in which Tamminen’s edge-EXCELL method [1822, 1824] makes use of a bucket (see also Section 2.2.2.8) in the representation of a collection of line segments. The result is somewhat like a three-dimensional adaptation of a combination of EXCELL and a PM<sub>3</sub> quadtree. In fact, Tamminen [1822] does describe an adaptation of EXCELL for three-dimensional data in which faces take the place of line segments.

The PM octree formulation that we have described was reported almost simultaneously by three research groups who, of course, each gave it a different name [116, 308, 662]. Ayala, Brunet, Juan, and Navazo [116, 272] called it an *extended octree*. Carlbom, Chakravarty, and Vanderschel [308] called it a *polytree*. They say that it was initially investigated by Hunter [902], who termed it a *geomertree*. They also state that the geomertree is a simplification of a data structure described by Vanderschel [1915], who named it a *divided-leaf octal tree*. Fujimura and Kunii [662] termed it a *hierarchical space indexing method*. Regardless of its name(s), it is a useful method. The most extensive treatment of this data structure is to be found in the Ph.D. dissertation of Navazo [1349], who also points out the progressive transition from the MX octree to the face, face-edge, and PM<sub>1</sub> octrees. This work contains a detailed analysis of the storage requirements of the representation. It also includes algorithms for Boolean set operations involving it and for conversion between it and a boundary model.

An implementation of the PM octree consists of leaf nodes of type vertex, edge, and face, as well as empty and full, corresponding to the cell being completely outside or inside the object, respectively. Nevertheless, for the proper execution of many operations, the mere classification of the type of the node is not sufficient to characterize the object properly. At times, Carlbom, Chakravarty, and Vanderschel [308] store with each node the polygons determined by the boundary of the object that intersects the node. This is somewhat cumbersome and requires a considerable amount of extra information. Moreover, the vertices of the polygons cannot be specified exactly as most often they are not the vertices of the object. In particular, they are artifacts of the decomposition process. In fact, the edges of the polygons are analogous to the q-edges discussed in Section 2.2.2.6 in the context of the PM quadtree family. Thus, using that terminology, the polygons are more appropriately termed *q-faces*.

Navazo [1349] uses a more efficient representation. In the case of a face node, the equation of the plane of the face that is associated with the node is recorded with the node. In addition, the direction of the object relative to the face is noted. For nodes of type edge and vertex, the configuration of the faces (i.e., the planes) that make up the edge and vertex must also be recorded. This information is used to classify a point inside the node with respect to the object so that the PM octree can be built.

For example, in the case of an edge node, we must know if it is convex or concave. The two possibilities are shown in Figure 2.127. The intersection of the planes of the two faces that meet at the edge results in a convex edge (Figure 2.127(a)), and the union results in a concave edge (Figure 2.127(b)). Note the use of arrows to indicate the direction of the object relative to the planes of the faces. In the case of a vertex node, the situation is more complex because the number of possible configurations depends on the number of faces that are adjacent at the vertex.

In [1350], Navazo presents an elegant generalized treatment of vertices with  $n$  faces that permits the configurations to be classified on the basis of their constituent edge configurations and stores them by their type along with pointers to the plane equations of their faces. This generalized approach is then used as the basis of algorithms to compute Boolean set operations involving PM octrees (for another approach, see [307]).

One of the drawbacks of the PM octree as defined above (i.e., the  $PM_1$  octree) is that it is possible to produce subtrees of arbitrary depth near the edges and vertices of the objects when two faces or edges are very close to each other because the decomposition only halts when all the faces meet at an edge in the block or all the faces meet at a vertex in the block. This results in what are termed *black holes* by Dürst and Kunii [519]. One way to overcome this problem is to resort to the face octree with a nonzero tolerance as described by Brunet [270] (see Section 2.2.2.4).

Wyvill and Kunii [2028] suggest overcoming this problem by halting the decomposition at some predetermined depth and classifying the corresponding nodes as *nasty* (e.g., [2028]). Such nodes are termed *terminal gray nodes* by Navazo [1349]. In this case, the nodes contain the same information as in the corresponding vertex node, thereby capturing the full geometry of the parts of the objects in the corresponding block.

Dürst and Kunii [519] suggest an alternative method of overcoming this problem by making use of what they call an *integrated polytree*. The integrated polytree is constructed using the same techniques employed by Samet and Webber [1665] that led to the formation of the  $PM_2$  and  $PM_3$  quadtrees, thereby yielding  $PM_2$  and  $PM_3$  octrees, respectively. The  $PM_3$  octree is defined in the same manner as the  $PM_3$  quadtree: we simply decompose the underlying space until each block contains at most one vertex.

The  $PM_2$  octree is more complex. In particular, Dürst and Kunii suggest the use of three additional node types called *edge'*, *vertex'*, and *vertex''* so that there are now eight node types. The node types labeled with a prime and double prime symbol account for the possibility that the faces and edges that share a common vertex or edge may do so both inside and outside the block. The exact definition of the node types is now as follows (see Exercise 2):

1. *Empty*: completely inside the object
2. *Full*: completely outside the object
3. *Face*: contains one face
4. *Edge*: contains several faces and the edge at which they meet
5. *Vertex*: contains several faces, the edges at which they meet, and the vertex at which they meet; alternatively, contains one vertex and the edges and faces that meet at it
6. *Edge'*: contains several faces, all of which meet at the same edge, which is outside the node
7. *Vertex'*: contains several edges and the corresponding adjacent faces, all of which meet at the same vertex, which is outside the node
8. *Vertex''*: contains several faces, all of which meet at the same vertex, which is outside the node

It should be clear that not all of the above node types are needed in the sense that the definitions of the *edge* and *vertex* node types can be generalized so that the common edge or vertex can be both inside and outside the node. Thus, the revised definition of node type *edge* subsumes node type *edge'*, and the revised definition of the *vertex* node type subsumes both node types *vertex'* and *vertex''*. Therefore, the result would have the following form:

1. *Empty*: completely inside the object
2. *Full*: completely outside the object

3. *Face*: contains one face
4. *Edge*: contains several faces that meet at the same edge whether or not the edge is in the node
5. *Vertex*: contains several edges and faces that meet at the same vertex whether or not the vertex or the common edges are in the node

The advantage of the  $PM_2$  octree is that the maximum depth of the tree is now bounded by the smallest distance between two elements (i.e., vertices, edges, or faces) that are topologically connected. Therefore, unlike the  $PM_1$  octree, there are no black holes in the  $PM_2$  octree. The same holds for the  $PM_3$  octree. Nevertheless, Dürst and Kunii state that, whereas in the two-dimensional case the reduction in storage requirements when using a  $PM_2$  quadtree over a  $PM_1$  quadtree is not large, thereby leading to the formulation of the  $PM_3$  quadtree, this is not the case in three dimensions, which is why, among other reasons, they omit the  $PM_3$  octree from further consideration.

The definition of the PM octree that we have given makes an implicit assumption that objects are well-formed in the sense that at most two faces meet at a common edge. However, for our purposes, it is permissible to have more than two faces meet at a common edge. Of course, such a situation cannot arise when modeling solids that are bounded by compact, orientable two-manifold surfaces (i.e., only two faces may meet at an edge—see Exercise 1 in Section 2.2.1.7).<sup>42</sup> Nevertheless, the more general case is plausible when three-dimensional objects are represented by their surfaces.

Unfortunately, two-manifolds are not closed under Boolean operations. In other words, the result of applying such an operation between two two-manifold polyhedra can be a nonmanifold, which is not representable using an extended octree. This problem also arises with constructive solid geometry (CSG), in which case it is resolved by restricting the Boolean set operations to be regularized Boolean set operations (see the discussion in the prologue of Section 2.2). Instead, Brunet and Navazo [272] permit the representation of any nonmanifold object by adding a node type called a *Boolean node* to the *empty*, *full*, *face*, *edge*, *vertex*, and *terminal gray* node types. The Boolean node is a Boolean expression involving the individual face, edge, and vertex nodes that make up the solid in the cell. In order to reduce the storage requirements further, Brunet and Navazo [272] make use of another node type, called a *nearby node*, that halts the decomposition when a node contains two or more faces that meet at a vertex outside the node (i.e., a node of type *vertex'* using the terminology of Dürst and Kunii [519]).

Navazo, Fontdecaba, and Brunet [1352] discuss the conversion from a CSG representation to a PM octree. If the objects have planar faces, then the conversion process yields an exact representation. The algorithm proceeds in a top-down manner and employs pruning rules similar to those used by Samet and Tamminen [1658, 1662] in the conversion of a CSG tree to a bintree. The principal difference is that Navazo et al. also need to compute the vertex configuration that must be associated with each vertex node in the PM octree. The computational complexity of the algorithm is the same as that of Samet and Tamminen [1658, 1662] when the initial CSG tree is *well behaved*—that is, no faces are tangential to each other, which means that the boundaries of the objects do not coincide but are permitted to intersect along one-dimensional edges. The construction of a CSG tree from the PM octree is more complex (see Exercise 11).

With the above conversion algorithms at hand, the PM octree can serve as the basis of a hybrid solid modeling system. In such a case, a dual representation can be used, and operations will be performed in the model that most easily supports them. For example, Boolean set operations are more easily performed in the PM octree, as well as in other octrees such as the region quadtree, than in the boundary model. Similarly, recursive subdivision, as is present in the PM octree as well as in other octree variants, can facilitate the evaluation of CSG trees; e.g., the analysis [1143, 1144, 1947] and display [1525,

---

<sup>42</sup> By *oriented* we mean two-sided. Thus, it is not like a Möbius strip or a Klein bottle.

2019, 2021, 2022], as well as the computation of geometric properties, such as mass, of solid objects modeled by them. In other words, they can be performed more easily in the PM octree representation than in the CSG representation.

PM octree techniques have also been extended to handle curvilinear surfaces. Primitives, including cylinders and spheres, have been used in conjunction with a decomposition rule limiting the number of distinct primitives that can be associated with a leaf node [661, 2028]. In particular, the PM octree serves as the basis of the *PM-CSG tree* [2028]. In this case, the decomposition criteria are such that no block contains more than one CSG primitive. This representation does not handle a pure CSG representation as it does not permit a full complement of CSG operations. Instead, it uses a subset consisting of union and subtraction of sets (i.e., set difference). The set intersection operation is not allowed because, in this case, its constituent primitives cannot be separated so that each one is in only one block. Moreover, the set union operation is not general in that it requires that the two operand sets be disjoint. Thus, it is more like a set addition operation. This means that no two objects can occupy the same space. An alternative physical analogy is that the operations of set addition and subtraction correspond to gluing and cutting, respectively. For more details, see [1636, Section 5.5.2].

Another approach [1351] extends the concepts of face node, edge node, and vertex node to handle faces represented by biquadratic patches. The use of biquadratic patches enables a better fit with fewer primitives than can be obtained with planar faces, thereby reducing the size of the octree. The resulting decomposition and the contents of the blocks are quite similar to those obtained by use of the adaptively sampled distance field of Frisken et al. [654, 655, 1482] (see Section 2.2.2.5). The difficulty in organizing curved surface patches by using octrees lies in devising efficient methods of calculating the intersection between a patch and an octree node. Observe that, in this approach (i.e., [1351]), we are organizing a collection of patches in the image space. This is in contrast to decomposing a single patch in the parametric space by use of quadtree techniques, as discussed in [1636, Section 7.1.6].

Fujimura and Samet [663] treat time as an additional dimension (see also [708, 711, 933, 1658, 2050]) and use a PM octree to represent moving objects in the plane. Their goal is to perform path planning for a robot in an environment that contains moving obstacles. The environment is two-dimensional, and the obstacles are represented using  $PM_1$  quadtrees. The addition of the time dimension yields a PM octree. A safe path is one in which the obstacles do not collide with each other or with the robot. The path is obtained by use of heuristic search.

### Exercises

1. Give a precise definition of a  $PM_1$  octree in terms of the number of vertices, edges, and faces that a block can contain.
2. At a first glance, it seems that the *vertex'* and *vertex''* node types in the definition of a  $PM_2$  octree are identical. What is the difference between them?
3. Under what circumstances are the space requirements of the face octree less than those of the  $PM_1$  octree?
4. Suppose that a vertex node is determined by three faces with plane equations  $h_1$ ,  $h_2$ , and  $h_3$ . How many different configurations are possible when circular permutations are considered equivalent?
5. Suppose that a vertex node is determined by four faces with plane equations  $h_1$ ,  $h_2$ ,  $h_3$ , and  $h_4$ . How many different configurations are possible when circular permutations are considered equivalent?
6. In Section 2.2.2.2, we pointed out that the space requirements of the region octree of a polyhedral object are proportional to the object's surface area. Can you prove that the space requirements of the PM octree for a polyhedral object are proportional to the sum of the lengths of its edges?

7. Write an algorithm to compute the intersection of two objects represented by PM octrees.
8. Write an algorithm to compute the union of two objects represented by PM octrees.
9. Given a position of an observer, write an algorithm to display an object that is represented by a PM octree.
10. Write an algorithm to convert from a boundary model to a PM octree.
11. Write an algorithm to convert from a CSG representation to a PM octree.
12. Write an algorithm to convert from a PM octree to a boundary model.
13. Write an algorithm to convert from a PM octree to a CSG representation.
14. How would you solve the point location problem when a polyhedral subdivision is represented by a  $PM_1$  octree?

### 2.2.2.8 Bucket PM Quadtree and PMR Quadtree

As mentioned above, the different variants of the PM quadtree that we have discussed are all vertex based. They differ in the degree to which the edges play in the decomposition process—that is, from some ( $PM_1$ ), to little ( $PM_2$ ), to none ( $PM_3$ ). A drastic alternative is to remove completely the dependence of the decomposition on the vertices and just take into account the edges that make up the polygonal map. As we saw in the PM quadtrees, it is impossible for all of the blocks to contain just one line segment. Thus, one approach to defining an edge-based decomposition is to stipulate that each block is split until it contains no more than  $T$  line segments. In this case,  $T$  acts like a bucket capacity, and we term the result a *bucket PM quadtree*. The drawback of such a representation is that the decomposition does not stop in the neighborhood of a vertex  $v$  with degree greater than  $T$  (i.e., more than  $T$  edges are incident at  $v$ ).

There are several options. The first option is analogous to ignoring the problem by setting an upper limit on the level of decomposition. The second option is to formulate bucketlike analogs of the vertex-based PM quadtrees where the bucketing condition involves the number of line segments that pass through the block. However, this is not as simple as it appears. The problem is that, if we add the proviso that a block is not split if it has  $T$  or fewer line segments, then we may violate the vertex condition. For example, a natural bucket analog of the  $PM_1$  quadtree is one that decomposes the underlying space until each block  $b$  contains no more than  $T$  line segments or if all of the line segments in  $b$  meet at the same vertex  $v$ , which is in  $b$ . The bucket analog of the  $PM_2$  quadtree will be defined similarly, with the added proviso that block  $b$  can contain more than  $T$  line segments if they all meet at the same vertex  $v$ , and  $v$  need not be in  $b$ . There is no logical bucket analog of the  $PM_3$  quadtree as the number of line segments in the block plays no role in the decomposition process.

The shortcoming of these bucket decomposition rules is that, even though a block  $b$  may contain several vertices, no decomposition takes place when  $b$  has  $T$  or fewer line segments. Thus, the bucket analogs must be defined more directly in terms of the number of vertices that they permit. In other words, the primary condition is one that limits the number of vertices in each block, with the bucket capacity, in terms of the number of line segments, being a secondary condition.

Using such a condition priority, we define the bucketlike analogs of the  $PM_1$  and  $PM_2$  quadtrees as follows. A *bucket  $PM_1$  quadtree* contains at most one vertex  $v$  per block and no line segments that do not meet at  $v$ . Each block that contains no vertices can contain at most  $T$  line segments. A *bucket  $PM_2$  quadtree* is defined using a similar rule, with the added proviso that a block  $b$  that contains no vertices can contain more than  $T$  line segments if they all meet at the same vertex  $v$  where  $v$  is not in  $b$ . It is meaningless to define a bucketlike analog of the  $PM_3$  quadtree because the number of line segments does not enter into the  $PM_3$  quadtree decomposition rule, and thus we do not do so.

The third option is similar to the first option in the sense that it is motivated by the rationale that, since an infinite level of decomposition is possible, why not decompose the bucket PM quadtree just once each time an edge is inserted into a block that contains more than  $T$  line segments? Of course, the tree will still have a maximum level of decomposition; however, it will be attained only if there really is a lot of insertion activity in the blocks that are being repeatedly decomposed rather than just because we happened to insert a line segment having a vertex whose degree exceeded  $T$ . We say that the decomposition is based on a probabilistic splitting rule. We term the result a *PMR quadtree* [1360], an edge-based variant of the PM quadtree.

It should be clear that a PMR quadtree block is permitted to contain a variable number of line segments. The PMR quadtree is constructed by inserting the line segments one by one into an initially empty structure consisting of one block. Each line segment is inserted into all the blocks that it intersects or occupies in its entirety. During this process, the occupancy of each block that is intersected by the line segment is checked to see if the insertion causes it to exceed a predetermined *splitting threshold*. If the splitting threshold is exceeded, the block is split once, and only once, into four blocks of equal size.

Figure 2.128(e) is the PMR quadtree for the collection of line segment objects in Figure 2.118(a) with a splitting threshold value of 2. The nine line segments, labeled a–i, are inserted in alphabetical order. It should be clear that the shape of the PMR quadtree for a given polygonal map is not unique; instead, it depends on the order in which the line segments are inserted into it. In contrast, the shapes of the  $PM_1$ ,  $PM_2$ , and  $PM_3$  quadtrees, as well as their bucket analogs, are unique. Figure 2.128 shows some of the steps in the process of building the PMR quadtree of Figure 2.128(e). In each part of Figure 2.128, the line segment that caused the subdivision is denoted by a thick line, while the gray regions indicate the blocks where the most recent subdivisions have taken place.

The insertion of line segments c, e, g, h, and i cause the subdivisions in parts (a), (b), (c), (d), and (e), respectively, of Figure 2.128. The insertion of line segment i causes three blocks to be subdivided (i.e., the SE block in the SW quadrant, the SE quadrant, and the SW block in the NE quadrant). The final result is shown in Figure 2.128(e). Note the difference from the  $PM_1$  quadtree in Figure 2.123—that is, the NE block of the SW quadrant is decomposed in the  $PM_1$  quadtree, but the SE block of the SW quadrant is not decomposed in the  $PM_1$  quadtree.

A line segment is deleted from a PMR quadtree by removing it from all the blocks that it intersects. During this process, the occupancy of the block and its siblings is checked to see if the deletion causes the total number of line segments in them to be fewer than the predetermined splitting threshold. If the splitting threshold exceeds the occupancy of the block and its siblings, then they are merged, and the merging process is reapplied to the resulting block and its siblings. Notice the asymmetry between the splitting and merging rules.

Notice that the splitting threshold is a different concept from the bucket capacity used in the definition of the bucket  $PM_1$  and  $PM_2$  quadtrees, although it plays the same role. Thus, it should be clear that the number of line segments in a PMR quadtree block can exceed the value of the splitting threshold. In fact, it can be shown [1637, Exercise 4.75, p. 268] that the maximum number of line segments in a PMR quadtree block is bounded by the sum of the splitting threshold and the depth of the block (i.e., the number of times the original space has been decomposed to yield this block). Interestingly, the number of line segments in a quadtree block can also exceed the bucket capacity  $T$  for the  $PM_3$  quadtree and for both the  $PM_1$  and  $PM_2$  quadtrees, as well as their bucket analogs, since the presence of a vertex in a block  $b$  results in the possibility that  $b$  (as well as other blocks for the  $PM_2$  quadtree) contains more than  $T$  line segments.

Once the decomposition into blocks has been obtained, we also need to decide how to organize the line segments that pass through the block. This is a relatively difficult issue to which not much attention has been paid in the past. However, the right choice has a dramatic effect on the performance of geometric operations as the blocks are often treated

Figure 2.128  
PMR quadtree for the collection of line segments of Figure 2.118(a): (a–e) snapshots of the construction process, with the final PMR quadtree given in (e). Gray regions indicate the blocks where the most recent subdivisions have taken place.

as buckets of nontrivial sizes (e.g., 32, 64, and even higher values). This is especially the case when the buckets take on the role of disk pages. Thus, the buckets provide an initial sort of the underlying space. However, once we access the appropriate bucket, we do not want to have to execute a sequential search to find the relevant data when the bucket can contain many elements. For example, some possibilities for line segments include the following:

1. Sort the lines on the basis of their nearness to one of the axes.
2. Sort the lines that meet at a vertex in clockwise or counterclockwise order.
3. Represent the portion of the line that passes through the block by its midpoint, and store it in a point representation such as a PR quadtree.

The PMR quadtree is very good for answering queries like finding the nearest line to a given point [863] (see [864] for an empirical comparison with hierarchical object representations, such as the R-tree and R<sup>+</sup>-tree). It is preferred over the PM<sub>1</sub> quadtree (as well as the PM<sub>2</sub>, PM<sub>3</sub>, MX, and edge quadtrees) as it results in far fewer subdivisions. In particular, in the PMR quadtree, there is no need to subdivide in order to separate line segments that are very “close” or whose vertices are very “close,” which is the case for the PM<sub>1</sub> quadtree. This is important since four blocks are created at each subdivision step. Thus, when many subdivision steps that occur in a PM<sub>1</sub> quadtree result in creating many empty blocks, the storage requirements of the PM<sub>1</sub> quadtree are considerably higher than those of the PMR quadtree. Generally, as the splitting threshold is increased, the storage requirements of the PMR quadtree decrease, while the time necessary to perform operations on it increases.

Using a random lines model and geometric probability (e.g., [1673]), it has been shown [1175] theoretically and empirically, using both random and real map data, that for sufficiently high values of the splitting threshold (i.e.,  $\geq 4$ ), the number of blocks in a PMR quadtree is asymptotically proportional to the number of line segments and is independent of the maximum level of decomposition. In contrast, using the same model, the number of nodes in the PM<sub>1</sub> quadtree is a product of the number of lines and the maximal level of decomposition (i.e.,  $n$  for a  $2^n \times 2^n$  image). The same experiments and analysis for the MX quadtree confirmed the results predicted by the Quadtree Complexity Theorem, which is that the number of blocks is proportional to the total length of the line segments.

### Exercises

Exercises 1–4 assume the use of the vertex bucket polygon quadtree defined in Section 2.1.4. In this case, decomposition halts whenever a block is a part of no more than  $T$  polygons or contains just one vertex.

1. Prove or disprove that the vertex bucket polygon quadtree decomposition rule yields the same decomposition as a bucket PM<sub>1</sub> quadtree decomposition rule for line segments.
2. Prove or disprove that the vertex bucket polygon quadtree decomposition rule yields the same decomposition as a bucket PM<sub>2</sub> quadtree decomposition rule for line segments.
3. Prove or disprove that the vertex bucket polygon quadtree decomposition rule yields the same decomposition as a PM<sub>3</sub> quadtree decomposition rule for line segments.
4. Consider a special case of the vertex bucket polygon quadtree where  $T = 2$ . Prove or disprove that the vertex bucket polygon quadtree decomposition is the same as one of the vertex-based PM quadtree decomposition rules for line segments.
5. Prove that the maximum number of line segments that can occur in a node in a PMR quadtree, say  $P$ , is the sum of the splitting threshold and the depth of the tree at which  $P$  is found.
6. Suppose that the set of line segments intersect but that their intersections are not considered as vertices (i.e., they are nonplanar). We saw that this does not pose a problem for the PMR quadtree. What about the PM<sub>1</sub>, PM<sub>2</sub>, and PM<sub>3</sub> quadtrees?

7. Prove that, on the average, if lines are drawn from a sample distributed uniformly in space and orientation, then the average number of quadrants intersected by a line passing through a quartered block is two. This can be done by showing that, for lines drawn from a set of parallel lines, say  $L$ , passing through the block at angle  $\theta$ , the average number of blocks intersected by a line is two, independent of  $\theta$ .
8. Assuming that the line segments that are stored in a node in the PMR quadtree are uncorrelated, use the result of Exercise 7 to compute the distribution of occupancies when a node is split into quadrants given a splitting threshold  $c$ . Normalize your result so that the expected total number of quadrants is four.
9. Prove that the average occupancy of the nodes produced when a PMR quadtree node is split is bounded and smaller than the size of the parent.
10. Continuing Exercise 9, prove that the average size of parent nodes in a PMR quadtree is also bounded by considering the case when the node occupancy  $i$  is greater than the splitting threshold  $c$ .
11. Give an algorithm to insert a line segment into a PMR quadtree.
12. Give an algorithm to delete a line segment from a PMR quadtree.
13. Do polygonal maps that correspond to Delaunay triangulations (see Section 2.2.1.4) behave better in the sense that their quadtree decompositions require fewer blocks than the quadtree decompositions of other triangulations of the same set of points? In other words, do they have some properties that avoid some of the bad, degenerate cases of many decompositions? For example, the Delaunay triangulation of a given set of points satisfies the minimum angle property, which means that it maximizes the minimum interior angle in the entire triangulation, thereby avoiding the presence of thin triangles that would cause much decomposition in the case of a  $PM_1$  quadtree (and in a  $PM_2$  quadtree to a lesser extent). Consider the various PM quadtree decompositions based on line segments, as well as the polygon decomposition rule that stipulates that decomposition halts whenever a block is a part of no more than  $T$  polygons or contains just one vertex (i.e., the vertex bucket polygon quadtree discussed in Section 2.1.4).

### 2.2.2.9 Sector Tree

In all of the previous sections, regardless of whether we have chosen to represent an object by its interior or by its boundary, the underlying space has been decomposed into polygonal blocks. This is the prevalent method in use today. However, for certain applications, the use of polygonal blocks can lead to problems. For example, suppose that we have a decomposition based on square blocks. In this case, as the resolution is increased, the area of the approximated region approaches the true value of the area. However, this is not true for a boundary measure such as the perimeter. To see this, consider a quadtree approximation of an isosceles right triangle where the ratio of the approximated perimeter to the true perimeter is  $4/(2 + \sqrt{2})$  (see Exercise 1). Other problems include the discontinuity of the normals to the boundaries of adjacent tiles. Recall from Section 2.2.2.5 that overcoming this problem is one of the motivations behind adaptively sampled distance fields (ADFs).

There are a number of other ways of attempting to overcome these problems. The *hierarchical probe model* of Chen [352] is an approach based on treating space as a polar plane and recursively decomposing it into sectors. We say that each sector consists of an origin, two sides (labeled 1 and 2 corresponding to the order in which they are encountered when proceeding in a counterclockwise direction), and an arc. The points at which the sides of the sector intersect (or touch) the object are called *contact points*.  $(\rho, \theta)$  denotes a point in the polar plane. Let  $(\rho_i, \theta_i)$  be the contact point with the maximum value of  $\rho$  in direction  $\theta_i$ . Each sector represents a region bounded by the points  $(0,0)$ ,  $(\rho_1, \theta_1)$ , and  $(\rho_2, \theta_2)$ , where  $\theta_1 = 2k\pi/2^n$  and  $\theta_2 = \theta_1 + 2\pi/2^n$  such that  $k$  and  $n$  are nonnegative integers ( $k < 2^n$ ). The arc between the two nonorigin contact points  $(\rho_1, \theta_1)$  and  $(\rho_2, \theta_2)$  of a sector is approximated by the linear parametric equations ( $0 \leq t \leq 1$ ):

$$\rho(t) = \rho_1 + (\rho_2 - \rho_1) \cdot t \theta(t) = \theta_1 + (\theta_2 - \theta_1) \cdot t.$$

Successive sector tree approximations for the object of Figure 2.129: (a)  $\pi$  intervals, (b)  $\pi/2$  intervals, (c)  $\pi/4$  intervals, and (d)  $\pi/8$  intervals.

Figure 2.131  
Binary tree representation of the sector tree of Figure 2.129.

Note that the interpolation curves are arcs of spirals due to the linear relation between  $\rho$  and  $\theta$ . The use of the arcs of spirals to represent the boundary is what leads us to characterize the sector tree as a boundary representation.

The *sector tree* is a binary tree that represents the result of recursively subdividing sectors in the polar plane into two sectors of equal angular intervals. Thus, the recursive decomposition is only with respect to  $\theta$ , not  $\rho$ . Initially, the universe is the interval  $[0, 2\pi)$ . The decomposition stops whenever the approximation of a part of an object by a sector is deemed adequate. The computation of the stopping condition is implementation dependent. For example, it can be the maximum deviation in the value of  $\rho$  between a point on the boundary and the corresponding point (i.e., at the same value of  $\theta$ ) on the approximating arc of a spiral. In fact, the use of the arcs of spirals to represent the boundary leads us to characterize the sector tree as a boundary representation.

In the presentation, we assume that the origin of the polar plane is contained within the object. See Exercise 7 for a discussion of how to represent an object that does not contain the origin of the polar plane. The simplest case arises when the object is convex. The result is a binary tree where each leaf node represents a sector and contains the contact points of its corresponding arc. For example, consider the object in Figure 2.129. The construction of its sector tree approximation is shown in Figure 2.130. The final binary tree is given in Figure 2.131, with interval endpoints labeled according to Figure 2.130(d).

The situation is more complex when the object is not convex. This means that each side of a sector may intersect the boundary of the object at an arbitrary, and possibly different, number of contact points. In the following, each sector will be seen to consist of a set of alternating regions that are within the object and outside the object. These regions are either three- or four-sided and have at least one side that is colinear with a side of the sector. We illustrate our discussion with the object of Figure 2.132(a), whose sector tree decomposition is given in Figure 2.132(b). The final binary tree is given in Figure 2.133. A better indication of the quality of the approximation can be seen by examining Figure 2.132(c), which contains an overlay of Figures 2.132(a) and 2.132(b).

When the boundary of the object intersects a sector at two successive contact points, say  $P$  and  $Q$ , that lie on the same side, say  $S$ , of the sector, then the region bounded by  $S$  and  $PQ$  must be approximated. Without loss of generality, assume that the region is inside the object. There are two choices. An inner approximation ignores the region by treating the segment of  $S$  between  $P$  and  $Q$  as part of the approximated boundary (e.g., the region between points 9 and 10 in sector  $[9\pi/8, 5\pi/4)$  in Figure 2.132(b)).

An outer approximation inserts two identical contact points, say  $R$  and  $T$ , on the other side of the sector and then approximates the region by the three-sided region formed by the segment of  $S$  between  $P$  and  $Q$  and the spiral arc approximations of  $PR$  and  $QT$ . The value of  $R$  (and hence  $T$ ) is equal to the average of the value of  $\rho$  at  $P$  and  $Q$ . For example, the region between points 4 and 5 in sector  $[5\pi/4, 3\pi/2)$  in Figure 2.132(b) is approximated by the region formed with points C and D.

Of course, the same approximation process is applied to the part of the region that is outside the object. In Figure 2.132(b), we have an inner approximation for the region between points 7 and 8 in sector  $[3\pi/2, 2\pi)$  and an outer approximation for the region between points 5 and 6 in sector  $[9\pi/8, 5\pi/4)$ , by virtue of the introduction of points A and B.

One of the drawbacks of the sector tree is that its use can lead to the creation of holes that do not exist in the original object. This situation arises when the decomposition is not carried out to a level of sufficient depth. For example, consider Figure 2.132(b), which has a hole bounded by the arcs formed by points A, B, 6, 7, C, D, and 5. This is a result of the inner approximation for the region between points 7 and 8 in sector  $[3\pi/2, 2\pi)$  and an outer approximation for the region between points 4 and 5 in sector  $[5\pi/4, 3\pi/2)$ .

Of course, this situation can be resolved by further decomposition in either or both of sectors  $[3\pi/2, 2\pi)$  and  $[5\pi/4, 3\pi/2)$ .

The result of the above approximation process is that each sector consists of a collection of three- and four-sided regions that approximate the part of the object contained in the sector. This collection is stored in the leaf node of the sector tree as a list of pairs of points in the polar plane. It is interesting to observe that the boundaries of the interpolated regions are not stored explicitly in the tree. Instead, each pair of points corresponds to the boundary of a region. Since the origin of the polar plane is within the object, an odd number of pairs of points is associated with each leaf node. For example, consider the leaf node in Figure 2.133 corresponding to the sector  $[5\pi/4, 3\pi/2)$ . The first pair, together with the origin, define the first region (e.g., (6,7)). The next two pairs of points define the second region (e.g., (5,C) and (4,D)), with each successive two pairs of points defining the remaining regions.

The sector tree is a partial polar decomposition as the subdivision process is only based on the value of  $\theta$ . A total polar decomposition would partition the polar plane on the basis of both  $\rho$  and  $\theta$ . The result is analogous to a quadtree, and we shall term it a *polar quadtree*. There are a number of possible rules for the decomposition process (see Exercise 13). For example, consider a decomposition that recursively halves both  $\rho$  and  $\theta$  at each level. In general, the polar quadtree is a variant of a maximal block representation. As in the sector tree, the blocks are disjoint. Unlike the sector tree, blocks in the polar quadtree do have standard sizes. In particular, all blocks in the polar quadtree are either three-sided (i.e., sectors) or four-sided (i.e., quadrilaterals, two of whose sides are arcs). Thus, the sides of polar quadtree blocks are not based on interpolation.

The sector tree can be used for performing many operations, some of which are easy to implement while others are more difficult. Boolean set operations, such as union and intersection, are straightforward. Scaling is trivial as the sector tree need not be modified. In particular, all values of  $\rho$  are interpreted as scaled by the appropriate scale factor. The

number of nodes in a sector tree is dependent on its orientation—that is, on the points chosen as the origin and the contact point chosen to serve as  $(\rho, 0)$ . Rotation is not so simple: it cannot be implemented by simply rearranging pointers (but see Exercise 11). Translation is computationally expensive since the change in the relative position of the object with respect to the origin means that the entire sector tree must be reconstructed.

### Exercises

1. Prove that, for an isosceles right triangle represented by a region quadtree, the ratio of the approximated perimeter to the true perimeter is  $4/(2 + \sqrt{2})$ .
2. Repeat Exercise 1 for a circle (i.e., find the ratio).
3. When the objects have linear sides, a decomposition of the underlying space into polygonal blocks is superior. How would you use the sector tree decomposition method with polygonal blocks?
4. In our discussion of the situation arising when the boundary of the object intersects a sector at two successive contact points, say  $P$  and  $Q$ , that lie on the same side, say  $S$ , of the sector, we assume that the region bounded by  $S$  and  $PQ$  is inside the object. Suppose that this region is outside the object. How does this affect the inner and outer approximations?
5. Can you traverse the boundary of an object represented by a sector tree by visiting each leaf node just once?
6. When using a sector tree, how would you handle the situation that the boundary of the object just touches the side of a sector without crossing it (i.e., a tangent if the boundary is differentiable)?
7. How would you use a sector tree to represent an object that does not contain the origin of the polar plane?
8. When you build a sector tree, the outer approximation always yields a three-sided region. Two of the sides are arcs of spirals with respect to a common origin. This implies a sharp discontinuity of the derivative at the point at which they meet. Can you devise a way to smoothen this discontinuity?
9. When you build a sector tree, does the inner approximation always underestimate the area? Similarly, does the outer approximation always overestimate the area?
10. Compare the inner and outer approximations used in building a sector tree. Is there ever a reason to prefer the outer approximation over the inner approximations (or vice versa)?
11. Define a complete sector tree in an analogous manner to a complete binary tree—that is, all leaf nodes are at the same level, say  $n$ . Prove that a complete sector tree is invariant under rotation in multiples of  $2\pi/2^n$ .
12. Write an algorithm to trace the boundary of an object that is represented by a sector tree.
13. Investigate different splitting rules for polar quadtrees. In particular, you do not need to alternate the splits—that is, you could split on  $\rho$  several times in a row, and so forth. This technique is used in the adaptive k-d tree [650] (see Section 1.5.1.4 of Chapter 1) by decomposing the quartering process into two splitting operations—one for the  $x$  coordinate and one for the  $y$  coordinate. What are the possible shapes for the quadrants of such trees (e.g., a torus, a doughnut, wheels with spokes)?

#### 2.2.2.10 Cone Tree<sup>43</sup>

The *cone tree* is an extension of the sector tree of Chen [352] (see Section 2.2.2.9) to deal with three-dimensional data. In particular, it is a boundary representation of an object's surface where the space is treated as a polar sphere and is recursively decomposed into cones. The motivation for its development is the same as that for the sector tree. In particular, we want a representation that provides a good approximation, in terms of a measure, of both the boundary (e.g., surface area) of an object as well as its interior

---

<sup>43</sup> This section contains material of a specialized nature and can be skipped on an initial reading.

(e.g., volume). In addition, the normals to the surface should have a minimum amount of discontinuity between adjacent surface elements.

Let  $(\rho, \theta, \phi)$  denote a point in the polar sphere.  $\theta$  and  $\phi$  are called the *polar* and *azimuth* angles, respectively.  $\theta$  ranges between 0 and  $\pi$ , and  $\phi$  ranges between 0 and  $2\pi$ . Each cone consists of an origin, four edges (alternatively, pairs of edges form sectors), and a spherical patch. The points at which the edges of the cones intersect (or touch) the object are called *contact points*.

Let  $(\rho_{ij}, \theta_i, \phi_j)$  be the contact point with the maximum value of  $\rho$  in direction  $(\theta_i, \phi_j)$ . Each cone (e.g., Figure 2.134) represents a region bounded by the points  $(0,0,0)$ ,  $(\rho_{11}, \theta_1, \phi_1)$ ,  $(\rho_{12}, \theta_1, \phi_2)$ ,  $(\rho_{21}, \theta_2, \phi_1)$ , and  $(\rho_{22}, \theta_2, \phi_2)$ .  $\theta_1 = k\pi/2^n$  and  $\theta_2 = \theta_1 + \pi/2^n$ , such that  $k$  and  $n$  are nonnegative integers ( $k < 2^n$ ).  $\phi_1 = 2m\pi/2^n$  and  $\phi_2 = \phi_1 + 2\pi/2^n$ , such that  $m$  and  $n$  are nonnegative integers ( $m < 2^n$ ).

The spherical patch having the four nonorigin contact points as its corners is approximated by three parametric equations in  $s$  and  $t$  such that  $0 \leq s \leq 1$  and  $0 \leq t \leq 1$  (see Exercise 1). Note that the interpolation curves will be nonlinear functions of the parameters  $s$  and  $t$ . However, at the edges of the patch (e.g.,  $s = 0$ ,  $s = 1$ ,  $t = 0$ ,  $t = 1$  in Figure 2.134), the approximation is a linear function.

The cone tree is analogous to a region quadtree that represents the result of recursively subdividing cones in the polar sphere into four cones of square spherical intervals (i.e.,  $\Delta\theta = \Delta\phi$ ). The spherical intervals form a two-dimensional space. Since the range of  $\phi$  is twice as large as that of  $\theta$ , the  $\phi - \theta$  space is initially subdivided into two cones at  $\phi = \pi$ . All subsequent decompositions are into four cones of equal square spherical intervals. The decomposition stops whenever the approximation of a part of an object by the spherical patches represented by the cone is deemed adequate. The computation of the stopping condition is implementation dependent. In our presentation, we assume that the origin of the polar sphere is contained within the object.

Assume that the object is convex. Nonconvex objects are beyond the scope of our discussion. The result is a quadtree where each leaf node represents a spherical patch. It contains the contact points of its corresponding patch, which are the corners of the node's block. Unfortunately, there exist discontinuities in the approximated surfaces represented by the cone tree. The problem arises when adjacent blocks in the  $\phi - \theta$  space are of different sizes. For example, consider the block decomposition in Figure 2.135. The approximated surface for block A is computed by using the contact points 1, 2, 3, and 5. The approximated surface for block B is computed by using the contact points 3, 4, 6, and 7. The approximated surface for block C is computed by using the contact points 4, 5, 7, and 8. We now see that the approximated surface of A does not match the approximated surface of B and C along the common side of their cone tree blocks (see Figure 2.136).

Chen suggests that this situation can be alleviated, in part, by replacing the contact points of the smaller block by points on the approximated surface of the larger adjacent block and subsequently subdividing the larger block if the error is too large. However, a better solution is to use an approach similar to the restricted quadtree [1453, 1771, 1772, 1940] (described in Section 2.2.4). In this case, nodes that have a neighbor whose level in the tree is more than one level deeper are subdivided further until the condition holds.

The cone tree can be used to facilitate the same kind of operations as the sector tree. For example, Boolean set operations, such as union and intersection, are straightforward. Scaling is trivial as the cone tree need not be modified. All values of  $\rho$  are interpreted as scaled by the appropriate scale factor. Rotating a cone tree is more complex than rotating a sector tree since two angles must be involved. Translation is expensive because the position of the object relative to the origin changes. Thus, the entire cone tree must be reconstructed.

## Section 2.2 BOUNDARY-BASED REPRESENTATIONS

Figure 2.134  
Example cone.

Example quadtree decomposition of a surface in  $\phi - \theta$  space.

Figure 2.136  
The cone tree representation of the left half of the surface in Figure 2.135. The shaded area represents a discontinuity in adjacent spherical patches.

1. Give the three parametric equations in  $s$  and  $t$  for a spherical patch at points  $(\rho_{11}, \theta_1, \phi_1)$ ,  $(\rho_{12}, \theta_1, \phi_2)$ ,  $(\rho_{21}, \theta_2, \phi_1)$ , and  $(\rho_{22}, \theta_2, \phi_2)$ .
2. How would you use a cone tree to represent an object that is not convex?
3. How would you use a cone tree to represent an object that does not contain the origin of the polar sphere?
4. Write an algorithm to determine if a specific point is inside or outside an object represented by a cone tree.
5. How would you adapt the restricted quadtree [1453, 1771, 1772, 1940] (see Section 2.2.4) to avoid the discontinuities that are present in the approximated surfaces represented by a cone tree.

### 2.2.3 Object-Based Boundary Representations

In Sections 2.1.5.2 and 2.1.5.3, we examine two hierarchical representations (i.e., the R-tree and the  $R^+$ -tree) that propagate object approximations in the form of bounding boxes. In both of these cases, the location query is facilitated by imposing a tree access structure on the elements of the hierarchy. In this section, we review several related hierarchical representations of the boundaries of objects. Section 2.2.3.1 presents the strip tree and some variants for the representation of boundaries of two-dimensional objects. Section 2.2.3.2 discusses the prism tree, which is a generalization of the strip tree to the boundaries of three-dimensional objects. The bounding boxes used by these methods are variants of polyhedra as well as ellipses. Section 2.2.3.3 describes the HAL tree, which makes use of variants of spherical bounding boxes. Section 2.2.3.4 gives a brief overview of simplification methods that are commonly used in computer graphics to provide varying levels of detail for approximate display, as well as to speed up computations. They have been motivated by the need to process rapidly very large collections of polygons (usually triangles) on the surface of objects. They are closely related to the methods discussed in Sections 2.2.3.1 to 2.2.3.3 but differ in the motivation for their development and the extent of their use. All of these representations are also accompanied by a tree access structure so that the location query can be executed efficiently. Of course, other access structures could also be used, but they are not discussed here.

#### 2.2.3.1 Strip Tree, Arc Tree, and BSPR

When using the R-tree or  $R^+$ -tree as an object approximation, the sides of the bounding boxes must be parallel to the coordinate axes of the space from which the objects are drawn. In contrast, the *strip tree* [121] is a hierarchical representation of a single curve that successively approximates segments of it with bounding boxes that do not require that the sides be parallel to the coordinate axes. The only requirement is that the curve be continuous; it need not be differentiable.

The strip tree data structure is supplemented by an access structure in the form of a binary tree whose root represents the bounding rectangle of the entire curve. For example, consider Figure 2.137, where the curve between points P and Q, at locations  $(x_P, y_P)$  and  $(x_Q, y_Q)$ , respectively, is modeled by a strip tree. The rectangle associated with the root, A in this example, corresponds to a rectangular strip that encloses the curve, whose sides are parallel to the line joining the endpoints of the curve (i.e., P and Q). The curve is then partitioned in two at one of the locations where it touches the bounding rectangle (these are not tangent points as the curve only needs to be continuous; it need not be differentiable). Each subcurve is then surrounded by a bounding rectangle, and the partitioning process is applied recursively. This process stops when the width of each strip is less than a predetermined value. Figure 2.138 shows the binary tree corresponding to the decomposition into strips in Figure 2.137(a).

Figure 2.137  
A curve and its decomposition into strips.

Figure 2.137 is a relatively simple example. In order to be able to cope with more complex curves such as those that arise in the case of objects rather than curves, the relationship between the bounding box and the underlying curve needs some further elaboration. In particular, closed curves and curves that extend past their endpoints require some special treatment. This issue can be resolved in several ways. One way is to change the nature of the bounding box. For example, we could make use of spherical bounding boxes as is done in the sphere tree (e.g., [895, 896, 1527]). However, there is really no need to do so as the strip tree can be modified so that such curves are enclosed by boxes that are split into two rectangular strips, and from now on the strip tree is used as before. For example, see Figure 2.139

For a related approach, see the *arc tree* [780]. The arc tree starts out by decomposing the curve into segments of equal length, thereby forming the deepest level in the hierarchy. Successive levels of the hierarchy are built by aggregating pairs, pairs of pairs, and so on. An access structure in the form of a complete binary tree (i.e., a one-dimensional pyramid) is imposed on the hierarchy. Thus, the result is analogous to imposing a one-dimensional uniform grid on the curve, where the width of each one-dimensional grid cell (i.e., interval) is based on the total length of the curve.

The arc tree makes use of ellipses as the bounding boxes for the subarcs. This, coupled with the fact that the aggregation is based on curve length, means that closed curves need no special treatment when represented by an arc tree. In particular, the foci of the ellipses are placed at the endpoints of each subarc, and the principal (i.e., major) axis is as long as the subarc. The result is that all subarcs lie completely within each ellipse, thereby obviating the need for special treatment for subarcs that extend past their endpoints (see Exercise 17). The drawback of the arc tree is that we need to be able to compute the length of an arc (see Exercise 16), which may be quite complex (e.g., if we have a closed form for the curve, then we need an elliptical integral).

The manner in which we have described the strip tree leads to it being characterized as top-down approach to curve approximation. The strip tree can also be built by a bottom-up process where the curve is assumed to be represented by a sequence of points. The construction process simply pairs up successive points and forms their strips, which are bounding boxes. It then pairs up the strips forming their strips, which are also bounding boxes. This process is applied repeatedly until one strip is obtained. It is interesting to note that the resulting approximations are not as good as those obtained by the top-down method.

The strip tree is rooted in the Douglas-Peucker line generalization algorithm [508] (also known as the *iterative endpoint fit* method in pattern recognition [514]). Generalization is a cartographic transformation from a large scale to a small scale (e.g., [1269]), where large scale corresponds to less detail while small scale corresponds to more detail. The Douglas-Peucker algorithm is a top-down process whose input is a polyline  $L$ , which is a set of connected points  $S = p_1 \dots p_n$ . The algorithm attempts to approximate  $L$  with another polyline  $L'$  whose vertices are a subset of  $S$  where each line segment in  $L'$  is an approximation of a subset of the line segments in  $L$  subject to a given error tolerance

Figure 2.138  
Strip tree corresponding to Figure 2.137.

Strip tree representation of (a) a closed curve and (b) a curve that extends past its endpoints.

$\epsilon$ . Of course, other approximation-quality measures can be used, such as a minimum number of points or the preservation of the fractal dimension of the line (e.g., [1225]).

The Douglas-Peucker algorithm for arbitrary values of  $\epsilon$  can be represented by a binary tree where the root corresponds to the line segment  $(p_1, p_n)$ . The error for this approximation is determined by the point  $p_k$  in  $S$ , which has the greatest distance  $d$  from it. Now make  $p_k$  the root of the tree and store the error  $d$ , add two children to the tree corresponding to the line segments  $(p_1, p_k)$  and  $(p_k, p_n)$ , and apply the process recursively to the two subtrees until all the points have been accounted for. The result is termed a *Binary Line Generalization Tree* (BLG-tree) [1410, 1411] (see also the PR-file 147).

Given an error tolerance  $\epsilon$ , the Douglas-Peucker line generalization algorithm traverses the BLG-tree in a top-down manner and halts each time it encounters a node with an error tolerance less than  $\epsilon$ . Interestingly, the distance values that are stored in the nodes of the BLG-tree do not necessarily become smaller as the tree is descended (see Exercise 24).

Note that the BLG-tree can be viewed as a generalization of the *Multi-scale Line Tree* [965, 966], which stores the result of the application of the Douglas-Peucker algorithm for several values of the error tolerance  $\epsilon$ . In particular, the top level of the Multi-scale Line Tree corresponds to the points of the original line that are retained as a result of the application of the Douglas-Peucker algorithm at the coarsest error tolerance. Successive levels of the tree correspond to the result of the application of the Douglas-Peucker algorithm at finer error tolerances and contain the points that lie in between two points at the immediately preceding level. It should be clear that the BLG-tree is more general than the Multi-scale Line Tree as the BLG-tree does not require a commitment to a particular set of error tolerance values. Note also the similarity of the Multi-scale Line Tree to a multiresolution representation such as a pyramid.

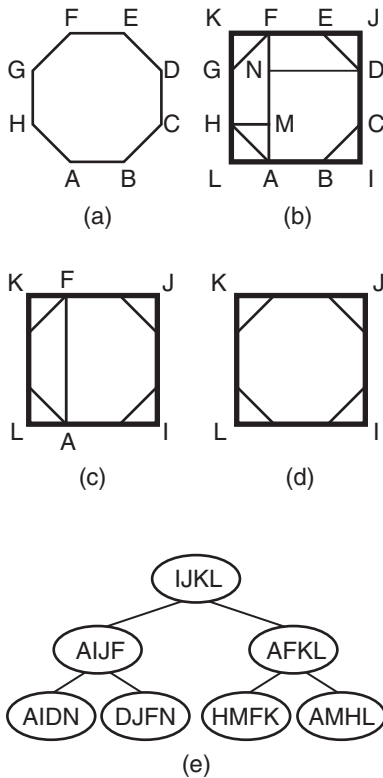

Figure 2.140  
(a) A regular octagon, (b–d) the three successive approximations resulting from the use of BSPR, and (e) the resulting BSPR.

Burton [293] defines a structure termed *Binary Searchable Polygonal Representation* (BSPR), which is closely related to the strip tree obtained by the bottom-up construction process in the sense that the BSPR is also a bottom-up approach to curve approximation. Once again, the primitive unit of approximation is a box; however, unlike the strip tree, in the case of the BSPR, all boxes are upright (i.e., they have a single orientation).

The curve to be approximated by the BSPR is decomposed into a set of *simple* sections, where each simple section corresponds to a segment of the curve that is monotonic in both the  $x$  and  $y$  coordinate values of the points it comprises. The tree is built by combining pairs of adjacent simple sections to yield *compound* sections. This process is repeatedly applied until the entire curve is approximated by one compound section. Thus, we see that leaf nodes correspond to simple sections, and nonleaf nodes correspond to compound sections. For a curve with  $2^n$  simple sections, the corresponding BSPR has  $n$  levels. Thus, we see that, unlike the strip tree, which is constructed in a top-down manner, the BSPR does not allow for a variation in the approximation at the lowest level since the initial bounding boxes are determined by the simple sections (i.e., the monotonic curves).

As an example of a BSPR, consider the regular octagon in Figure 2.140(a) with vertices A–H. It can be decomposed into four simple sections: ABCD, DEF, FGH, and HA. Figure 2.140(b) shows a level 1 approximation to the four simple sections consisting of rectangles AIDN, DJFN, HMFk, and AMHL, respectively. Pairing up adjacent simple sections yields compound sections AIJF corresponding to AIDN and DJFN, and AFKL corresponding to HMFk and AMHL (see Figure 2.140(c)). More pairing yields the rectangle for compound section IJKL (see Figure 2.140(d)). The resulting BSPR tree is shown in Figure 2.140(e). Using the BSPR, Burton shows how to perform point-in-polygon determination and polygon intersection. These operations are implemented by tree searches and splitting operations.

**Section 2.2**  
BOUNDARY-BASED  
REPRESENTATIONS

Strip trees and their variants are useful in applications that involve search (e.g., point inclusion) and set operations (e.g., intersection for interference detection). For example, suppose that we wish to determine if a road crosses a river. Using a strip tree representation for these features, answering this query requires that we perform an intersection of the corresponding strip trees. Three cases are possible, as is shown in Figure 2.141. Figure 2.141(a, b) corresponds to the answers NO and YES, respectively, while Figure 2.141(c) requires us to descend further down the strip tree. Notice the distinction between the task of detecting the possibility of an intersection and the task of computing the actual intersection, if one exists. The strip tree is well-suited to the former task. In particular, we often save much work when an intersection is impossible (e.g., [507, 1596]). The technique is similar to that used by Little and Peucker [1185] for bands (see Exercise 10). Other operations that can be performed efficiently by using the strip tree data structure include the computation of the length of a curve, areas of closed curves, intersection of curves with areas, point membership, and so on.

Figure 2.141  
Three possible results of intersecting two strip trees: (a) null, (b) clear and (c) possible.

**Exercises**

1. The strip tree is designed primarily for the situation where a closed form representation of the curves is not known; otherwise, the strip tree is not so useful since many problems (e.g., curve intersection) can be solved directly. Thus, it is designed for the case that the curve is specified as an ordered sequence of points  $t_0, t_1, \dots, t_n$ . Successive pairs of points define line segments, some of which may be collinear. The points are considered to be connected, although this restriction can be relaxed. The algorithm that we described for building a strip tree proceeds in a top-down manner. Given a sequence of  $n$  points, prove that this method takes  $O(n \cdot \log_2 n)$  time.
2. Write a procedure `TOPDOWNSTRIP` to build a strip tree using the top-down method.
3. In the text, we also describe an alternative method of constructing a strip tree that proceeds in a bottom-up manner as follows. Take successive pairs of points,  $(t_0, t_1)$   $(t_1, t_2)$  ...  $(t_{n-1}, t_n)$ , and find their strips, say  $S_0, S_1, \dots, S_{n-1}$ . Now, pair up these strips—that is,  $(S_0, S_1)$   $(S_2, S_3)$  ... , and cover them with larger strips. Continue to apply this process until there is a single strip. Prove that this method takes  $O(n)$  time.
4. Write a procedure `BOTTOMUPSTRIP` to build a strip tree using the bottom-up method.
5. Prove that the top-down method of constructing a strip tree always yields a tighter approximation of the curve than the bottom-up method.
6. Give an example curve where the rectangular strip has a larger area than the rectangle of minimum bounding area.
7. Why is it advantageous to use the rectangular strip in the top-down method instead of the rectangle of minimum bounding area?
8. Give an algorithm to construct the rectangle with minimum bounding area for an arbitrary curve.
9. Suppose that you are given two curves,  $C_1$  and  $C_2$ , whose strip trees have depths  $d_1$  and  $d_2$ , respectively. What is the worst-case order of the curve intersection algorithm?
10. Little and Peucker [1185] represent curves by bands that are strips of infinite length. They are analogous to the strip that is found at the root of the strip tree. Determining if two curves intersect reduces to determining if their bands intersect. The key idea is that, if they do, then the region formed by the intersection of their bands is used to clip the curves, bands are built for the clipped curves, and the algorithm is applied recursively. Implement this algorithm.
11. How would you use a strip tree to represent a closed curve whose corresponding region has a hole?
12. Write a procedure `AREASTRIP` to compute the area within a closed curve that is represented by a strip tree.
13. Write a procedure `CURVEAREA` to compute the intersection of a curve represented by a strip tree and an area represented by a strip tree. The result is the portion of the curve that overlaps the area.

14. Write a procedure AREAAREA to compute the intersection of two areas represented by strip trees. The result is an area.
15. Is the arc tree unique?
16. Suppose you are given a curve that is specified by  $y = f(x)$ . What is its length between points  $a$  and  $b$ ?
17. Prove that every subarc in an arc tree is completely internal to its approximating ellipse.
18. How do you determine if a point is inside or outside an ellipse?
19. Write a procedure MEMBERAREAARC to determine whether a point is inside or outside an area represented by an arc tree.
20. What conditions must be satisfied by the ellipses of two subarcs of an arc tree if the subarcs intersect? Prove that your answer is true.
21. Write a procedure to compute the intersection points of two curves represented by arc trees.
22. Can you use the result of Exercise 21 to determine if two areas represented by arc trees overlap?
23. Write a procedure to compute the arc tree corresponding to the intersection of two areas represented by arc trees. How would you handle the situation arising when the two areas have some common edges?
24. Explain with an example why the distance values that are stored in the nodes of the BLG-tree do not necessarily become smaller as the tree is descended.

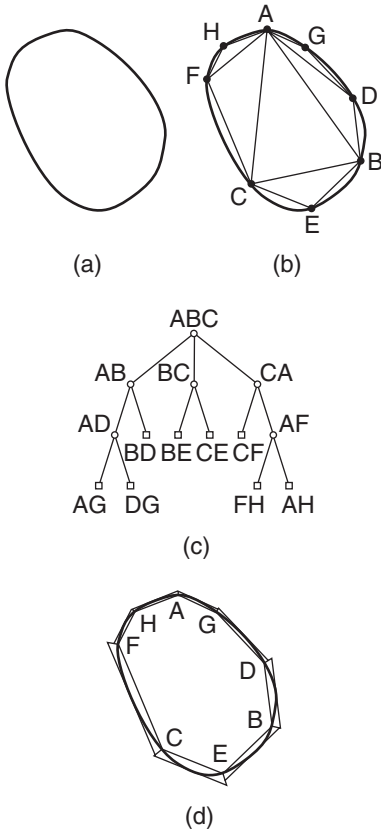

Figure 2.142  
A two-dimensional prism tree: (a) object, (b) polyhedral approximation, (c) tree representation, and (d) prism tree.

### 2.2.3.2 Prism Tree

The strip tree can also be generalized to represent boundaries of three-dimensional objects (i.e., their surface). These objects are usually polyhedra or the result of applying some process (such as range finding) to the original data that yields a polyhedron. The OBBTree of Gottschalk, Lin, and Manocha [735] is an example of such a generalization, where instead of a straight line joining the endpoints of the curve, principal component analysis (PCA) (e.g., [665]) is used to find the least-squares best-fit plane to the vertices of the objects (assuming polyhedral objects). Another example of such a generalization is the *prism tree* of Ponce and Faugeras [1501]. It is a hierarchical representation of an approximation that is used to model the surfaces of three-dimensional objects that are polyhedra of genus 0 (i.e., they have no holes). The prism tree is best understood by examining its predecessor, termed a *polyhedral approximation* [597].

To simplify the presentation, consider the construction of a polyhedral approximation of a two-dimensional object as in Figure 2.142(a). The object is initially modeled by a triangle with vertices that lie on the object's boundary. Assume for this example that the object is convex. Thus, no part of the triangle lies outside the object. For each side of the triangle, say  $E$ , find a point on the object's boundary, say  $M$ , whose distance from  $E$  is a local maximum. If the distance from  $M$  to  $E$  is greater than a predefined threshold, say  $\epsilon$ , then repeat this step for the two new sides of the triangle formed by  $M$  and the endpoints of  $E$ . This process is repeated for all the new triangles until all of the approximations represented by their sides are within  $\epsilon$  or the number of decomposition steps exceeds a predefined value. For example, Figure 2.142(b) is a possible polyhedral approximation for the object in Figure 2.142(a).

The polyhedral approximation provides a hierarchical representation of the boundary. The results of the process of successive subdivision of the boundary can be used by imposing a tree access structure on it where, with the exception of the root node, each node represents a straight line and the associated segment of the boundary. For example, Figure 2.142(c) is the tree structure corresponding to the polyhedral approximation of Figure 2.142(b). Notice that the root has three children, while all remaining nodes have two children. Often, the exact description of the segment of the boundary corresponding to the node is difficult to manipulate (e.g., detecting intersections between boundaries of adjacent objects). This is facilitated by storing a bounding box with each node. In this

case, the bounding box is a quadrilateral approximation, in the form of a trapezoid, of the corresponding boundary segment. The resulting approximation is the two-dimensional version of the *prism tree*. For example, Figure 2.142(d) is the two-dimensional prism tree corresponding to the polyhedral approximation given in Figure 2.142(b). Notice that the shape of a trapezoid for a given boundary segment, say  $S$ , depends on the lines that approximate the segments that are adjacent to  $S$ .

To model three-dimensional objects (without holes), the polyhedral approximation uses tetrahedra and prisms (actually truncated pyramids) instead of triangles and quadrilaterals, respectively. The polyhedral approximation is built as follows. Start by forming a triangle, say  $T$ , that splits the surface of the object into two segments,  $S_1$  and  $S_2$ . For each segment  $S_i$ , pick a point  $M_i$  on  $S_i$  such that the distance from  $S_i$  to  $T$  is a maximum. The result is a pair of tetrahedra with  $T$  as their common base and that form a triangular bipyramid (i.e., hexahedron), that serves as the initial polyhedral approximation. The rest of the approximation procedure consists of recursively attempting to replace each of the triangular faces of the tetrahedra with a new tetrahedron by finding the point  $M_i$  on triangular face  $F_i$  with the distance  $d_i$  to  $F_i$  that is a local maximum. If  $d_i$  exceeds a predefined error tolerance  $\varepsilon$ , then  $F_i$  is replaced by the tetrahedron formed by the three vertices of  $F_i$  and  $M_i$ ; otherwise,  $F_i$  is retained as part of the approximation. The above decomposition process (termed a *split step*) is augmented with a couple of additional modifications to correct for

1. thin and elongated triangles,
2. edges between adjacent triangles for which the deviation from the actual surface is too large (termed an *adjustment step*).

Thin and elongated triangles are avoided by splitting each triangle  $T$  into three to six triangles instead of just three triangles. In particular, any edges that are common to two subdivided triangles are split at their points with the highest errors. It is important to observe that the triangles  $T_1$  and  $T_2$  that are split along edges appear at the same subdivision level and do not have the same immediate ancestor (i.e., they are not siblings when the decomposition process is represented as a tree). For example, Figure 2.143(b–e) shows the four ways the triangle in Figure 2.143(a) can be split.

When the deviation from the actual surface is too large for edges formed by vertices  $v_1$  and  $v_2$  between two adjacent triangles  $T_1$  and  $T_2$ , the following adjustment step is applied. Add a new sample point  $M$  so that the space on the surface spanned by two adjacent noncoplanar triangles (e.g., Figure 2.144(a, b) is now spanned by four adjacent noncoplanar triangles (e.g., Figure 2.144(c, d), respectively).  $M$  satisfies the following three properties:

1.  $M$  is on the surface.
2.  $M$  is on the plane that bisects the two triangles that are being replaced.
3. Of all the points satisfying properties 1 and 2,  $M$  is the farthest from the edge that is being removed.

In particular, letting  $u_1$  and  $u_2$  be the two remaining vertices of  $T_1$  and  $T_2$ , respectively, this adjustment tends to replace a pair of adjacent thin and elongated triangles  $T_1$  and  $T_2$  by four triangles  $u_1v_1M$ ,  $u_2v_1M$ ,  $u_1v_2M$ , and  $u_2v_2M$ , which are closer to being equiangular. There are two choices for the adjustment, depending on whether the elevation of  $M$  is lower than  $M$ 's projection on the surface formed by the four vertices of the adjacent noncoplanar triangles (e.g., Figure 2.144(c)) or higher (e.g., Figure 2.144(d)).

The polyhedral approximation results in the modeling of a three-dimensional object by a collection of tetrahedra. The surface of the objects is represented by the visible triangular faces of the tetrahedra. As in the two-dimensional case, the result is a hierarchical representation of the boundary that can be used by imposing a tree structure where, with the exception of the root node, each node represents a triangular face and the associated portion of the surface. The root has two children, one for each of the tetrahedra that have

Figure 2.143  
A triangle (a) and the four possible ways of splitting it: (b) split at an interior point and possible splits at (c) one edge, (d) two edges, and (e) three edges, depending on how many of the edges are common to two subdivided triangles at the same subdivision level.

Figure 2.144  
Illustration of the result of the adjustment step in the construction of a prism tree that replaces two adjacent triangles (a) and (b) whose common edge elevation deviates too much from the actual surface with four triangles, depending on whether the elevation of the new vertex is (c) lower or (d) higher than its projection on the surface formed by the four vertices of the adjacent noncoplanar triangles. This results in the deletion of the common edge.

a common triangular base. The remaining nodes have between three and six children if the decomposition step does not require an adjustment step; otherwise, there are just two children since a triangle has been replaced by two triangles instead of between three and six triangles.

### Exercises

1. The prism tree is not a true generalization of the strip tree since the approximating shapes are rectangular parallelepipeds for the former while, for the latter, they are truncated pyramids. Is there an advantage to using trapezoids (truncated pyramids) over rectangles (rectangular parallelepipeds)?
2. Define a three-dimensional strip tree so that the approximating shapes are rectangular parallelepipeds.
3. What is the motivation for the adjustment step in the construction of the polyhedral approximation?
4. In the description of the prism tree approximation, it is stated that the surface of the object is represented by a collection of tetrahedra where, for each tetrahedron, at most three faces are visible. Why are there not three visible faces for each tetrahedron?
5. It would seem that using a collection of tetrahedra to approximate the surface of a polyhedron is not good for polyhedral-like objects because it may result in an approximating object with many points, where the solid angle formed by the three incident faces is less than  $90^\circ$ . How is this situation avoided in the algorithm for obtaining a polyhedral approximation?
6. In the adjustment step of the polyhedral approximation construction process, it is necessary to find adjacent triangles. How would you achieve this?
7. Write an algorithm to build a three-dimensional prism tree.
8. What is the space and time complexity of the process of building a three-dimensional prism tree for a polyhedron with  $n$  faces?
9. Consider a three-dimensional prism tree such that all faces of adjacent, approximating, truncated pyramids are coplanar. Must these coplanar faces also be identical?

10. Define a prism to be *regular* if the three nonparallel faces of the prism lie in the bisecting planes. Prove that, if the approximated surface is convex, then all prisms at all levels of the prism tree representation of the surface are regular.
11. Use the definition of a regular prism given in Exercise 10. Suppose that you are approximating an object with a concave surface. Is it possible for all the approximating prisms to be regular?
12. Adapt the definition of regularity given in Exercise 10 to a strip tree.
13. Give an algorithm to find the intersection of two three-dimensional objects represented by prism trees.
14. How would you extend the concepts of a polyhedral approximation and a prism tree to more general surfaces than genus 0?

### 2.2.3.3 HAL Tree

The development of hierarchical boundary-based object representations, such as the strip tree and the variants that we have discussed, has been motivated by the desire to speed up the processing of such objects by avoiding unnecessary operations. As we have seen, the speed up is accomplished by use of two mechanisms: approximation and localization [1927]. Approximating an object by using fewer elements enables faster display. The quality of the approximation depends on the extent to which it minimizes the loss of the sense of reality. Localization provides information about the volume and position of the boundary of the object in order to enable fast point location and testing for intersection (e.g., for applications such as interference detection and collision detection). Localization is achieved by making use of the hierarchies of bounding boxes.

Up to now, we have made use primarily of bounding boxes consisting of hyperrectangles (both aligned and not aligned with the coordinate axes), prisms, as well as spheres and ellipses. Spheres and ellipses have an advantage over some methods that make use of hyperrectangles (such as the strip tree) in that there is no need to make special provisions for closed curves or curves that extend past their endpoints. The principal advantage of spherical bounding boxes is that they are rotation invariant. Furthermore, testing for point inclusion (i.e., point-in-polygon) and intersection of bounding boxes is very simple for spherical bounding boxes. In particular, testing for point inclusion is just a matter of computing the distance from the point to the center of the sphere and comparing it with the radius of the sphere. Similarly, determining if two spheres intersect is just a matter of computing the distance between their corresponding centers and comparing it with the sum of their radii.

The drawback of spherical bounding boxes is that they are not very tight fitting, thereby resulting in the traversal of more levels in the hierarchy when performing some operations such as intersection testing. In fact, this is cited by Gottschalk et al. [735] as one of the reasons for the observed superior performance of hierarchies of non-axis-aligned bounding hyperrectangles, such as the OBBTree [735], over hierarchies of bounding spheres, such as the sphere tree (e.g., [895, 896, 1527]), in the context of interference detection (and also applicable to collision detection). Veltkamp's *hierarchical approximation and localization tree* (HAL tree) [1927] is designed to overcome this drawback. In particular, in some cases, the HAL tree can provide an even tighter fit than a hierarchy of spherical bounding boxes by constraining the bounding boxes to being either the intersection of two discs or a disc and a halfspace when the objects are restricted, as before, to have planar faces and no holes. Below, we briefly describe how the HAL tree represents the boundary of a two-dimensional object.

The root of the HAL tree corresponds to the minimum bounding disc of the boundary of the object where at least two of the vertices of the object's boundary lie on the disc's boundary. The object's boundary is split into two parts by finding the two vertices, say  $v_1$  and  $v_2$ , that are the farthest apart, thereby obtaining two polylines. These two polylines serve as the left and right children of the root. Notice that, in the case of the children of the root, the approximation of both polylines is the same line—that is, the straight line

Figure 2.145  
Example of a bounding box that is formed by the intersection of (a) two discs and (b) a disc and a halfspace. The boundary is shown with a thick line.

between  $v_1$  and  $v_2$ . We now show how to form the minimum bounding box of a polyline  $P = (v_s \dots v_e)$  in the HAL tree. Let  $a$  denote the directed line from  $v_s$  to  $v_e$ . Let  $v_l$  ( $v_r$ ) denote the vertex to the left (right) of  $a$  so that the disc formed by  $(v_s, v_e, v_l)$  ( $(v_s, v_e, v_r)$ ) contains all vertices to the left (right) of  $a$ . If there are no vertices to the left (right) of  $a$ , then the disc is replaced by the halfspace formed by the infinite extension of  $a$ . The minimum bounding box of the polyline is the intersection of the two discs (or a disc and a halfspace) corresponding to the sets of vertices on the two sides of  $a$ . Figure 2.145(a) is an example of a bounding box that is formed by the intersection of two discs, while Figure 2.145(b) is an example of a bounding box that is formed by the intersection of a disc and a halfspace.

Each polyline  $P = (v_s \dots v_e)$  is decomposed into two polylines,  $P_1 = (v_s \dots v)$  and  $P_2 = (v \dots v_e)$ , by letting  $v = v_l$  ( $v = v_r$ ) if the curvature (radius) of the disc corresponding to  $v_l$  ( $v_r$ ) is greater (smaller) than that of the curvature (radius) of the disc corresponding to  $v_r$  ( $v_l$ ) (note that the radius of a halfspace is  $\infty$ ). The rationale for the choice is the same as the one used in the Douglas-Peucker line generalization algorithm in the sense that  $v$  is the vertex that is furthest from the approximating line of the polyline. However, the difference is that, in the HAL tree, instead of  $v$  being the farthest vertex from the approximating line, we have that  $v$  lies on the disc segment that has largest maximal distance to that line. For example,  $v = v_l$  in Figure 2.145(a, b). The process is applied recursively until the error of each edge is less than a given tolerance or an edge of the original polygon is encountered. It should be clear that testing for point inclusion and intersection of bounding boxes in the HAL tree is quite simple. In essence, we just apply the same tests as for spherical bounding boxes with the difference that the number of spheres involved in the test is doubled.

The HAL tree represents three-dimensional objects in a similar manner except that bounding spheres are used instead of bounding discs. Initially, a bounding sphere is constructed for the polyhedron object that touches at least three vertices of the polyhedron. These three vertices partition the surface of the polyhedron into two parts, termed *polysurfaces*, that are defined by determining the shortest paths of the edges of the polyhedron between these vertices. The initial approximation of these two polysurfaces is the triangle connecting the three vertices. These two polysurfaces form the left and right children of the root. Again, as in the two-dimensional case for the children of the root, the approximation of both polysurfaces is the same triangle. The minimum bounding box of each of the polysurfaces is obtained by determining the vertices, say  $v_l$  and  $v_r$ , of each polysurface on the two sides of the approximating triangle so that the bounding sphere formed by them and the vertices of the approximating triangle includes all vertices on the particular side. Having determined the bounding spheres of the two sides, the minimum bounding box of the polysurface is the intersection of the two spheres.

Each polysurface is decomposed into three polysurfaces using either  $v_l$  or  $v_r$  and the vertices of the corresponding approximating triangle  $(v_i, v_j, v_k)$ . The choice of  $v_l$  or  $v_r$  depends on the curvature of the corresponding spheres. In any event, the resulting polysurfaces are approximated by triangles. Note that, in effect, the initial polyhedron is usually approximated by a pair of tetrahedra having a triangle as a shared common base.<sup>44</sup> Thus, each of the remaining nodes in the tree will have three children corresponding to the three exterior triangular faces of the tetrahedron that is being partitioned as a result of the approximation process.

Unfortunately, the process for decomposing the triangles that we have described will almost immediately result in the new triangles being very elongated because the angles at the vertices are subdivided at each decomposition stage. This leads to a very bad approximation. Thus, Veltkamp [1927] proposes heuristics that decompose the triangles

<sup>44</sup> If the object is a 2.5-dimensional image, such as the surface of a terrain, then, initially, we have just one tetrahedron where one side does not form part of the surface and hence is not decomposed further.

into more than three triangles. The drawback of these heuristics is that there is no longer a guarantee that the minimum bounding box is the intersection of two spheres, but, instead, may need to be their union. This arises because the two bounding spheres are constrained to pass through the vertices of the triangle. Of course, one can always find a single sphere that contains all of the vertices of the polyhedral surface, but this is contrary to our desire to find a tighter-fitting bounding box than a sphere or a hyperrectangle.

Observe that the approximation hierarchy that we have described is analogous to the prism tree [1501], which also makes use of one or two tetrahedra for the initial approximation of the polyhedron and then proceeds to approximate the triangular faces of the tetrahedra. However, the primary difference from the prism tree is the nature of the bounding boxes that, in the HAL tree, are intersections or unions of bounding spheres instead of prisms (i.e., truncated pyramids), which complicates its use. The fact that the minimum bounding box can be the union of the two bounding spheres makes the HAL tree unattractive in theory for such data unless further heuristics are devised to avoid this situation, although it rarely occurs in practice [1927]. Nevertheless, even if we are successful at one stage in obtaining a minimum bounding box that is the intersection of two bounding spheres, there is no guarantee that the bounding boxes at subsequent intermediate stages will indeed be the intersection of bounding spheres because they could, in fact, be unions of bounding spheres [1927].

### Exercises

1. What is the complexity of constructing the HAL tree for a two-dimensional polygon with  $n$  vertices?
2. Show how a two-dimensional polygon with  $n$  vertices can be stored in a HAL tree with  $O(n)$  space.

### 2.2.3.4 Simplification Methods and Data Structures

Hierarchical representations of the boundaries of objects play an important role in computer graphics and visualization applications. In particular, modern systems are required to process and display scenes of enormous complexity, which can be very time-consuming. One way to speed the process is to make use of special-purpose hardware. In this case, the scenes usually consist of very large collections of triangles (actually polygons that have been triangulated) as the triangle primitive is well-suited to the special-purpose graphics hardware for fast rendering. This has led to work in automatically simplifying the scenes by reducing the number of triangles that are necessary in order to take advantage of situations where full accuracy is not required or used. These methods are known as *simplification methods* (e.g., [392, 692, 812]) and are often supported by specialized data structures to enable viewing the scenes at varying levels of resolution (also known as *level of detail* [1212]). A data structure that exhibits such a behavior is frequently referred to as a *multiresolution model* (e.g., [692]). In this section, we give a brief overview of some simplification methods and the relevant data structures.

It should be clear that use of a simplification method results in an approximation of the surface of the objects (or objects in a scene). We assume three-dimensional data. The quality of the surface approximation is evaluated by several measures. A common measure is similarity of appearance where, for example, we can use the average sum of the squared differences in the intensities of corresponding pixels that are produced by the renderer (e.g., [1178]). The advantage of such a measure is that occluded regions play no role in the evaluation. The drawback is that we must be careful to sample adequately a wide range of viewpoints. An additional drawback is the fact that each sample usually requires an expensive rendering step.

This has led to the adoption of geometric measures of approximation error. In this case, the geometric similarity serves as a substitute for visual similarity while also yielding approximations that may be useful for applications other than rendering (e.g.,

collision detection). This duality has been termed *approximation and localization* in Section 2.2.3.3. The most commonly used geometric measures employ the Euclidean (i.e.,  $L_2$ ) and Chessboard (i.e.,  $L_\infty$ ) distances. The advantage of the Euclidean distance is that it is better at indicating an overall fit, thereby discounting large but highly localized deviations. On the other hand, the Chessboard distance provides a global absolute bound on the distance between the original and the approximation, thereby providing quality guarantees.

One of the problems with measuring the distance between general surfaces (e.g., free-form surfaces) rather than terrainlike surfaces is that there is no single distinguished direction along which to measure the distance (in contrast to along the vertical direction corresponding to elevation in the case of terrain data). Thus, instead, the distance between closest pairs of points is used. This must be done for every point on both the original and approximating surface. In other words, for each point on the original surface, we find the closest point on the approximating surface, and for each point on the approximating surface, we find the closest point on the original surface—that is, we make use of a concept related to the Hausdorff distance (e.g., [911]).<sup>45</sup> Needless to say, in practice, such error measures are quite costly to compute exactly. Thus, they are usually computed by sampling the distances at a discrete set of points on the two surfaces (e.g., the Metro system [394]). Further computational savings are achieved by restricting the search for the closest point to a particular neighborhood for each sample point, thereby obtaining a localized distance (e.g., [692]).

The two most common surface simplification paradigms are refinement and decimation [692, 812]. A refinement algorithm starts with a coarse approximation and adds elements at each step, thereby resulting in more detail. In contrast, a decimation algorithm starts with the original surface and removes elements iteratively at each step. Another way of distinguishing between these two paradigms is to observe that refinement is a top-down process, while decimation is a bottom-up process.

An important distinction between different implementations of these paradigms is whether or not they perform topological simplification on the surface. Geometric simplifications reduce the number of primitives that describe the objects (e.g., the number of vertices, edges, and triangles when the primitive elements are triangles). Topological simplifications reduce the number of holes, tunnels, cavities, and so on. Some methods specifically prohibit topological simplification [408, 737]. This makes sense in applications such as medical imaging where, for example, preserving a hole in the image of an organ is much more important than preserving the exact shape of the surface. However, in most algorithms, the topology is simplified implicitly as a side effect of the geometric conditions that form the basis of the simplification. Nevertheless, there are algorithms that explicitly take the surface topology into account in conjunction with geometric simplification (e.g., [550, 804]).

<sup>45</sup> The Hausdorff distance between two sets  $A$  and  $B$  is the distance to the farthest nearest neighbor. It is computed by a two-step process. First, find the nearest neighbor in  $B$  of each element of  $a$  in  $A$ . Now, find the distance to the farthest nearest neighbor—that is,  $h(A, B)$ , where  $h(A, B) = \max_{a \in A} \min_{b \in B} d(a, b)$ .  $h(A, B)$  is called the *directed Hausdorff distance*. It is not symmetric and thus is not a metric. Next, repeat the computation for the nearest neighbor in  $A$  of each element  $b$  in  $B$ . Now, again, find the distance to the farthest nearest neighbor—that is,  $h(B, A)$ , where  $h(B, A) = \max_{b \in B} \min_{a \in A} d(b, a)$ . The *Hausdorff distance*  $H(A, B)$  is the maximum of  $h(A, B)$  and  $h(B, A)$ —that is,  $H(A, B) = \max(h(A, B), h(B, A))$ .

The Hausdorff distance is used to measure the degree of mismatch between two sets. In essence, if the Hausdorff distance between  $A$  and  $B$  is  $\delta$ , then every point of  $A$  must be within distance  $\delta$  of at least one point of  $B$  and vice versa. The Hausdorff distance is a metric over all closed, bounded sets—that is, it is nonnegative and symmetric and obeys the triangle inequality.

The directed Hausdorff distance is useful in that, given  $h(A, B) \leq \delta$ , we know that, if we compute the expansion of  $B$  by  $\delta$  (termed the Minkowski sum of  $B$  and  $\delta$ ) yielding  $B'$ , then we are guaranteed that every point in  $A$  is in the expanded region  $B'$ —that is,  $A \subset B'$ .

For example, at times, we may want to perform both types of simplifications. In particular, it may be the case that further geometric simplification cannot be applied in the sense that certain geometric error tolerance criteria can no longer be satisfied without the application of some form of topological simplification. One simple way to obtain topological simplification that has been proposed is to roll a sphere over the boundary of the objects and fill up the regions that are not accessible to the sphere, thereby simplifying the topology in a gentle manner, after which further geometric simplification can be applied [550]. Observe that it is preferable to define the sphere using  $L_\infty$  instead of  $L_2$  in order to ensure that the newly created regions can be described with planes rather than objects with spherical faces [550].

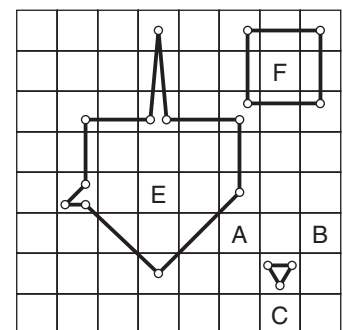

Note, however, that preserving topology may not necessarily be the most important consideration in the simplification. We may also need to be concerned about preserving the domain. In particular, if the objects in the image are two-manifolds, then the result of the simplification should also be a two-manifold. This is not the case, for example, when the result consists of two objects that are adjacent at a point or an edge. If the two objects are treated as one object, then that object is not a two-manifold. Notice the similarity to regularized Boolean set operations in constructive solid geometry (CSG), where, for example, we do not allow the intersection of two objects that have a common face (see the discussion in the opening of Section 2.2). In other words, while the intersection is allowed, the result is the empty set.

The refinement paradigm has a long history of usage in the simplification of curves and functions. The best-known example is the Douglas-Peucker line generalization algorithm for applications in cartography (see Section 2.2.3.1). It has also been widely used for terrain approximation where the typical implementation starts with the minimal approximation and iteratively inserts points where the approximating and original surfaces are the farthest apart. This is sometimes referred to as the *greedy insertion technique* [692].

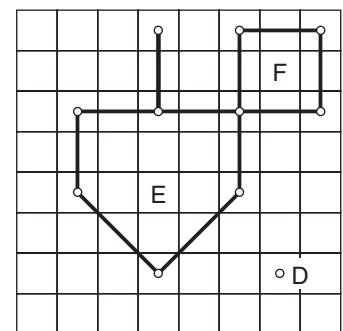

The refinement paradigm has also been applied to the simplification of polygonal surfaces. Some examples include three-dimensional variants of the strip tree, such as the prism tree and the OBBTree (see Section 2.2.3.2). Nevertheless, the decimation method is the one that has been more commonly used for simplification. This stems, in part, from the difficulty of dealing with the topology of the original object. In particular, if we want to preserve the topology of the original object, then we must actually know it, and often this is not easy to discover. Thus, refinement is used more for surfaces that correspond to terrains, where the topology is relatively simple. Note that, as in the case of the refinement method, we will see that the simplification resulting from use of the decimation method is useful for other applications than display (e.g., collision detection).

There are three principal surface decimation methods: vertex clustering, vertex decimation, and face decimation. Vertex clustering works by spatially partitioning the vertices into a set of clusters and then merging all vertices in a cluster into one vertex. This is typically implemented by imposing a uniform grid on the data where each grid cell corresponds to a cluster and hence merging all vertices that lie in each grid cell (e.g., [1579]). For example, Figure 2.146(b) is the result of applying vertex clustering to the collection of polygons in Figure 2.146(a). It should be clear that vertex clustering can result in substantial modifications to the topology of the original object. In particular, some objects can be reduced to points (e.g., if all of the vertices lie in the same grid cell, as is the case for the object consisting of vertices A, B, and C in Figure 2.146(a), which becomes isolated vertex D in Figure 2.146(b)), while separate components can be joined together and thus the result is not required to be a two-manifold (e.g., objects E and F in Figure 2.146).

Observe that the results of vertex clustering are quite sensitive to the manner in which the grid is imposed on the data. Some of these problems can be overcome by use of an adaptive grid, such as an octree (e.g., [1211]). Another alternative to the uniform grid is the use of a set of cluster cells, such as cubes or spheres, about certain vertices [1205].

(b) the result of applying vertex clustering to it.

Figure 2.147  
(a) An example triangulation, and (b, c) a couple of possible retriangulations of the result of removing vertex  $v$ .

Cells are centered around their vertex of highest weight, and when a vertex lies in the intersection of several cells, it is associated with the cell whose center is the closest.

There are many formulations of vertex decimation. The simplest formulation, termed *vertex removal* (e.g., [391, 1031, 1049, 1699, 1791]), initially ranks the vertices of the object according to their importance (e.g., the error that would result from their removal). At each step, a vertex is selected for removal, and all edges (faces) incident at it are removed from the object, thereby creating a hole. The hole is retriangulated (e.g., Figure 2.147). This process is repeated until the desired number of vertices is obtained or as long as the approximation error is within the desired tolerance. The retriangulation is often a constrained Delaunay triangulation (e.g., [1031, 1791]). Recall that vertex decimation also served as a central component of the K-structure construction process (see Section 2.1.3.2).

A more complex variant of vertex decimation is triangle decimation (e.g., [795]), where a triangle  $t$  is replaced by a new vertex  $v$ , thereby causing the removal of its constituent vertices  $\{v_1, v_2, v_3\}$  and the replacement of the edges incident at them by new edges incident at  $v$ . This approach can be characterized as a *triangle collapse*. The triangle collapse differs from the vertex removal method. In particular, once the collapsed triangle has been chosen, the resulting surface is fully determined (i.e., there is no choice as to how it is to be retriangulated). In contrast, if we only perform triangle removal without the introduction of a new vertex, then the region forming the hole will be retriangulated, which might be time-consuming if the region has many vertices and is not convex.

The most common formulation of vertex decimation proceeds by the iterative contraction of vertex pairs. The vertex pair is replaced by a new vertex (termed *vertex simplification*) by virtue of a vertex or edge collapse operation. The result of the simplification process is often represented as a hierarchy of vertices, thereby serving as a basis for a multiresolution model.

The two main issues in vertex simplification are determining

1. the vertex pair  $(v_1, v_2)$  to be collapsed,
2. the position of the replacement vertex  $v$ .

Most of the algorithms use a simple greedy procedure to determine the sequence of vertex pairs to be contracted, where the cost metric is intended to reflect the extent of the geometric error that they introduce, which is to be minimized. Once the lowest-cost pair has been contracted, it is not reconsidered again. A simple approach for choosing the replacement vertex is to pick one of the two vertices  $v_1$  or  $v_2$  either at random or via some algorithm (e.g., [2031]). In this case, the solution is similar to the first formulation of vertex decimation that we described. However, a better approach is to position  $v$  so that some approximation error measure is minimized (termed *optimal placement* [692]). Nevertheless, the advantage of the first approach is that when it serves as the basis of a multiresolution model, less information needs to be stored as we have not introduced any new vertices.

The simplest cost metrics use local properties, such as minimizing the edge length (e.g., [2032]), making the dihedral angle as close as possible to 180 degrees (e.g., [837]), or even minimizing the area affected by the collapse, and so on. Other more sophisticated cost metrics take the original surface into account (e.g., [408, 694, 763, 875, 1569]). For example, some methods (e.g., [875]) are based on the minimization of an energy function, one of whose primary components is a geometric term based on  $L_2$ . This method maintains a set of sample points on the original shape and uses the distance between these points and the corresponding closest points on the approximated shape to determine the geometric error. It is a simplified version of earlier work [878] that permitted edge swap and edge split operations, as well as made use of a more complex error metric that also included a term that penalized meshes with many vertices and a spring term that penalized long edges in the triangulation. Topological modifications are permitted as long as they reduce the global error. Note that the output vertices are not constrained to be a subset of the input vertices. This is a direct result of the positioning of  $v$  so that the error is minimized.

Other methods (e.g., [763]) compute a tolerance volume around the approximation so that the original surface is guaranteed to lie within that volume. This method is quite similar to the simplification envelope method [408, 1919], developed independently, which consists of approximations to offset surfaces (termed *envelopes*), where the only vertices that are removed are those that would create triangles that lay within the envelopes. On the other hand, some methods, such as [1177], only take the current approximation into account, thereby leading to a characterization as *memoryless*. In particular, this method is based on the preservation of local volume.

It is important to recall that a side effect of dealing with these issues using purely geometric considerations is that the original topology of the object may be implicitly simplified by the contraction. In fact, it has been proposed to loosen the requirement that an edge exist between the pair of vertices that are being contracted in order to enable the merging of topologically separate components during simplification (e.g., [694, 1502, 551]).

Vertex hierarchies are usually represented by binary trees where the leaf nodes are the vertices of the original object and the nonleaf nodes correspond to the vertex that is formed by the contraction. The resulting tree captures the sequence of collapse operations as well as the dependencies. It has been used for view-dependent reconstruction of surface approximations at runtime (e.g., [876, 1211, 2032]). It is interesting to note that vertex hierarchies can also be viewed as hierarchies of vertex neighborhoods, where the neighborhood of a vertex consists of its adjacent or incident faces (e.g., [692, 693, 1050, 1123]). In particular, when two vertices are contracted, their corresponding neighborhoods are merged to form a new neighborhood. Thus, each node in the hierarchy corresponds to a disjoint set of vertices on the original surface and, in fact, corresponds to the surface region formed by the union of the neighborhoods of all of the vertices in its set.

There are many ways of achieving face decimation. For example, the process of iterative contraction of vertex pairs can also be applied in such a way so as to merge the two faces adjacent to the collapsed edge. We use the term *face simplification* to describe this process. Its result is often represented as a hierarchy of faces, thereby serving as a basis for a multiresolution model. Face simplification is very reminiscent of the processes used to build a strip tree in a bottom-up manner. The difference is that, instead of starting with pixels or polylines, we start with a surface that has been triangulated and then, in a bottom-up manner, build a hierarchy of faces that are not necessarily triangles (and are rarely so). The *hierarchical face clustering* method of Garland, Willmott, and Heckbert [693, Ch. 8; 2004, Ch. 5; 695] is an example of such an approach. In this case, the initial triangular faces can be viewed as objects, and the hierarchical face clustering method chooses which faces to aggregate in the process of forming an object hierarchy.

Figure 2.148  
(a) Example of face collapsing in face simplification: the edge between the nodes corresponding to faces  $f_1$  and  $f_2$ , denoted by hollow circles, on the left is collapsed leading to the merging of  $f_1$  and  $f_2$ , yielding  $f$ , as shown on the right. (b) Example of vertex or edge collapsing in vertex simplification: the edge between vertices  $V_1$  and  $V_2$  on the left is collapsed, thereby merging  $V_1$  and  $V_2$  to yield the vertex  $V$ , as shown on the right.

Hierarchical face clustering is analogous to vertex simplification methods, where, now, the hierarchy is one of faces rather than one of vertices. They both have the same goal of yielding automatic simplification of highly detailed polygonal models into faithful approximations using fewer polygons. The key idea in hierarchical face clustering is the performance of face collapsing (e.g., Figure 2.148(a)) instead of vertex or edge collapsing (e.g., Figure 2.148(b)), as is done in vertex simplification, whose result can also be viewed as a hierarchy of sets of triangular faces. Face collapsing is achieved by operating on the dual of the original triangulated surface, where vertices in the dual correspond to faces in the original triangulated surface, and edges in the dual correspond to adjacent faces in the original triangulated surface.

An edge collapse in the dual is equivalent to merging faces in the original triangulated surface. The edge collapse in the dual is termed a *dual contraction* [695]. The result of applying many dual contractions is to obtain a face hierarchy. The surface is assumed to be a *manifold with boundary* (i.e., a surface all of whose points have a neighborhood that is topologically equivalent to a disc or half-disc) so that every surface edge has at most two adjacent faces.<sup>46</sup> This guarantees that the number of dual edges is no greater than the number of edges in the original surface mesh.

Face hierarchies cluster neighboring groups of faces instead of iteratively merging vertex neighborhoods, as in vertex hierarchies. In particular, each node in the vertex hierarchy corresponds to a disjoint set of vertices on the original surface. The node also corresponds to a surface region that is the union of the neighborhoods of all the vertices in its set. Because the face clusters are disjoint sets of faces, they also partition the surface in a well-defined way. In addition, face clusters are more likely to have a single normal that is a good match for the surface normals of the faces in the cluster, and thus are more likely to be nearly planar. In other words, the advantage of the face hierarchy over a vertex hierarchy is that local neighborhoods high in the vertex hierarchy are usually nonplanar (they are usually cone-shaped with the vertex at the apex). This is because any

<sup>46</sup> This assumption is motivated by the same rationale that led to polyhedral objects being assumed to be two-manifolds, in which each point has a neighborhood that is topologically equivalent to a disc; see Section 2.2.1.1. Note that a two-manifold is a manifold with boundary whose boundary is empty.

planar vertex neighborhood will be removed very early during the vertex simplification process. In addition, in the vertex hierarchy, the set of triangles on the original surface corresponding to a particular vertex may have a very irregular shape. In particular, most standard vertex simplification algorithms provide no mechanism to control this shape. Another drawback of hierarchies based on vertex simplification is that the bounding box of a node cannot be guaranteed to contain the surface of its children fully.

Briefly, in hierarchical face clustering, the face hierarchy is constructed iteratively by a greedy procedure that assigns a cost of contraction to each dual edge, and then the dual edge of minimal cost is contracted. Each iteration results in a partition of the original surface into disjoint sets of connected faces. This is in contrast to vertex simplification methods, where, after every iteration, the result is an approximate surface.

We now provide more detail on the process of constructing the face hierarchy. Start with an initial surface partition where each face of the original triangulated surface belongs to its own singleton cluster. The process of iterative dual contraction produces a sequence of partitions with successively fewer clusters. The process is greedy in the sense that it assigns a cost of contraction to each dual edge and inserts it into a priority queue that is sorted by the cost of its elements. It then extracts the dual edge  $e = (v_1, v_2)$  of minimum cost from the priority queue and contracts it, forming a new dual vertex  $v_n$ . Next, it removes any dual edge  $e = (v_i, v_j)$  from the priority queue, where  $v_j$  is equal to  $v_1$  or  $v_2$ , and inserts a new dual edge  $e_n = (v_i, v_n)$  with its associated cost into the priority queue. This process is continued until there is one face cluster for each connected component of the surface. It should be clear that while clusters are always connected sets of faces, they may have holes. The face hierarchy is represented as a binary tree where each nonleaf node corresponds to a dual contraction, and the leaf nodes are the faces of the original triangulated surface (e.g., Figure 2.149).

One of the key issues with this construction method is deciding which faces to contract at each step. In other words, we would like to know what factors make for a good face cluster. This is the basis of the cost function. Garland, Willmott, and Heckbert [695] argue for the metric to be based primarily on planarity. In this case, using principal component analysis (PCA) (e.g., [665]), they find the least-squares best-fit plane to the vertices that make up the faces that make up the cluster. This will naturally tend to merge clusters that are collectively nearly planar. However, a surface may fold back on itself (termed a *foldover* [2032]). Thus, it will seem nearly planar, but the normal of the optimal plane will not be a good fit for all the surface normals of the constituent faces. In order to take this into account, an additional error term is used in the cost function that measures the average deviation of the plane normal from that of the individual surface normals.

It should be clear that, in some applications, planarity is not the only factor of importance. In particular, the shape of the face clusters should also be compact. This is achieved by using a measure termed *irregularity* (more commonly known as *circularity* [748]), which is defined as

$$\frac{P^2}{4\pi A'}$$

where  $P$  and  $A$  are the perimeter and area, respectively, of the face cluster. Irregularity indicates the extent to which the shape deviates from that of a circle (whose irregularity is 1). Irregularity is taken into account in the cost function by stipulating that the cost of merging two face clusters having irregularity  $\gamma_i$  to form a cluster with irregularity  $\gamma$  is

$$\text{cost} = \frac{\gamma - \max(\gamma_1, \gamma_2)}{\gamma}$$

If the irregularity of the resulting face cluster is greater than that of the face clusters that are merged, then the contraction of the edge incurs a penalty; otherwise, the cost is negative and is treated as a positive factor.

A drawback of the construction algorithm is the time needed to compute a fitting plane. Garland, Willmott, and Heckbert [695] suggest that the execution time can be

Figure 2.149  
Example of a partial face hierarchy corresponding to the triangulated surface in Figure 2.148.

reduced significantly by using PCA to compute the fitting planes only at the upper levels of the hierarchy and using a cheaper method to compute approximating planes at the lower levels of the hierarchy. In addition, the trees corresponding to the resulting hierarchies are not necessarily balanced. This can be resolved by either making use of parallel merging of a maximal independent set of dual edges (e.g., [2032]) or adding a balance bias to the error metric that is used to select the next edge to be collapsed.

The idea of iterative clustering is not new. It has been in use for many years, usually being applied to point sets (e.g., [48]), often in high dimensions, rather than to surface elements. Point sets are usually clustered on the basis of distance, whereas clustering surface elements requires taking into account factors such as adjacency and orientation. The simplification work of Kalvin and Taylor [980], resulting in “superfaces,” is related to hierarchical face clustering. However, it differs in that it is based on growing the clusters around randomly chosen “seed” faces by adding faces one at a time until a planarity threshold is exceeded. This is in contrast to hierarchical face clustering, which works in a pairwise manner, producing a hierarchical structure of clusters rather than a single static partition that is heavily dependent on the choice of the seed faces. Some other related work includes an algorithm by DeRose, Kass, and Truong [481], which is only based on adjacency, and thus the elements of the clusters may possibly not be coplanar. The prism tree [1501], as mentioned earlier, is another example of a face clustering method.

The fact that the hierarchical face clustering method works in a bottom-up fashion and is useful for collision detection makes it conceptually similar to the BOXTREE of Barequet, Chazelle, Guibas, Mitchell, and Tal [125], which builds a bottom-up hierarchy of boxes by merging adjacent boxes. However, the BOXTREE is built in quite a different manner as Barequet et al. focus more on the properties of the bounding boxes rather than the surface regions that are being bounded. In particular, their definition of box adjacency is based on spatial overlap rather than on the connectivity of corresponding regions on the surface (e.g., planarity, normals, and compactness, as in the hierarchical face clustering method). They rank pairs of boxes for merging on the basis of properties of the resulting boxes, such as volume, rather than on the basis of any property of the local surface. Thus, the considerations are similar to those taken into account in other object-based hierarchies, such as the R-tree (see Section 2.1.5.2), where overlap and perimeter of the resulting bounding box are factors in deciding on how to group the boxes in an overflowing node. However, unlike the R-tree, the hierarchy is a binary tree and thus each node has an outdegree of 2. The BOXTREE is used in ray tracing applications.

The resulting face hierarchies can be used for many applications, including, but not limited to, surface simplification for ease of display. In the case of surface simplification for ease of display, the surface is partitioned into clusters whose boundaries are simplified, after which the clusters are retriangulated. Note that the result is similar to, but not the same as, that obtained by using the *superface* algorithm of Kalvin and Taylor [980]. The principal difference is that the superface algorithm seeks to minimize the maximum deviation of any point from its approximating plane, while the hierarchical face clustering method seeks to minimize the average deviation without guaranteeing any bound on the maximum.

One of the natural applications of the resulting face hierarchies is to serve as a basis for the construction of a hierarchy of bounding volumes (i.e., box). Each face cluster can be enclosed by a bounding volume on the basis of the best-fit plane for each cluster. The resulting hierarchy is similar to the OBBTree structure of Gottschalk, Lin, and Manocha [735] in that they also make use of Principal Component Analysis (PCA) to compute best-fit planes. However, their algorithm works in a top-down manner to partition the vertices of the original model. In contrast, the hierarchical face clustering method proceeds in a bottom-up manner to produce the bounding boxes. These bounding boxes are well approximated by a plane, which means that most nodes will correspond to surface regions with a reasonably well-defined orientation. This facilitates collision detection. Other applications of hierarchical face clustering include multiresolution radiosity [2004, 2005], computation of distance to the surface, and intersection queries

useful in applications such as ray tracing. The key advantage over methods that are based on decompositions of the underlying space (such as variants of region octrees) is that the hierarchies are attached to the surface rather than to the entire space occupied by the surface.

The hierarchies that we have described are used to define a simplification method, and their results are often used to build a multiresolution model. Ideally, the multiresolution model should have approximately the same size as the most detailed approximation alone, although a small constant factor increase in size is usually acceptable. There are two types of multiresolution models: discrete and continuous. Discrete multiresolution models are usually based on having a set of increasingly simpler approximations (i.e., simplifications). These simplifications are usually performed offline in a preprocessing step at a fixed number of levels of resolution. The renderer selects a particular approximation to use and renders the approximation in the current frame. Discrete multiresolution models are adequate when a constant level of detail is needed.

Continuous multiresolution models enable the desired approximation to be extracted at runtime. They are useful for applications, such as terrain flyovers, dynamic walk-throughs, and so on, where the desired level of resolution is only known at runtime. In particular, they support view-dependent simplification (e.g., [459, 876, 1211, 2032]), where a particular scene may require several levels of resolution, depending on the position of the viewpoint, in the sense that parts of the scene at a greater distance can be displayed using a coarser resolution than nearby parts. A typical example is a terrain viewed at close range at an oblique angle, as might arise in a flight-simulator application. Thus, they permit a gradual transition to take place between different levels of resolution for different parts of an object or a scene, thereby providing a way of eliminating the visual “popping” effect. In addition, they support progressive transmission (e.g., [875, 1862]). Nevertheless, there are situations where a discrete model may be preferable to a continuous model. For example, the discrete model is simpler to program, has lower runtime requirements, and may be more amenable to the use of compression methods, such as triangle strips (e.g., [467, 549]), for faster display.

In the case of terrain data, a number of continuous representations have been developed. They are based on a regular adaptive subdivision of the terrain surface such as that provided by a region quadtree (e.g., [513, 576, 1176]). For more details, see Section 2.2.4. In the case of general triangulated surfaces, multitriangulations [460, 461] provide a general framework that encompasses most of the commonly used multiresolution models. This includes those methods that make use of vertex hierarchies (e.g., [764, 876, 877, 2032]), where the continuous multiresolution model is obtained as a byproduct of the decimation-based simplification algorithms used to construct them. The generality of the multitriangulation method lies in its independence of the simplification method used to construct the hierarchy and in its ability to capture the partial ordering, which enables the different triangulations to be extracted. In particular, one of the key features differentiating multitriangulation from other multiresolution models is its ability to represent the result of a simplification that makes use of an edge swap operation, in contrast to most multiresolution models that capture a sequence of vertex pair collapses (e.g., [875]).

### *Exercise*

1. Give an algorithm to simplify a surface using the hierarchical face clustering method.

## **2.2.4 Surface-Based Boundary Representations**

Section 2.2.3 has focused on object-based representations of the boundaries of two- and three-dimensional objects, such as polygons and polyhedra. However, in many applications, we are just interested in representing an arbitrary surface rather than the boundary of an entire object (i.e., a partial boundary). An especially important special

case of this problem arises when we are really dealing with a 2.5-dimensional image—that is, for each pair  $(x, y)$  corresponding to the projection of the surface on the  $x$ - $y$  plane, there corresponds a unique value of  $z$  (also known as an *elevation* value). In the rest of this section, we give a brief overview of hierarchical representations of 2.5-dimensional images in the context of processing topographic data (i.e., terrains). The data consists of elevation values sampled at various locations on the plane.

The goal is to reconstruct the surface. This reconstruction is facilitated by choosing a sampling process and representation that adapt to changes in the terrain. The most common method of sampling the data is to use a uniformly spaced rectangular or triangular grid known as a gridded Digital Terrain Model (DTM) or a Digital Elevation Model (DEM). In this case, we do not have to know where the special features are because the sampling process is given a resolution that ensures that any point on the surface is within a bounded distance of a sample point. An alternative method, which is more compact, is capable of capturing point and line features (e.g., peaks, pits, passes, ridges, and valleys) exactly by explicitly recording the elevations of the points corresponding to their location on the surface.

For both methods, the actual surface can be approximated by a network (termed a *mesh*) of planar nonoverlapping triangles. Interpolation is used to obtain the elevation at nonsample locations. In the former uniformly-spaced sampling method, all triangles are of equal size, and hence the interpolation uses the nearest samples. The drawback of this method is that some maxima and minima will be missed if they do not occur at sample points. In the latter more compact method, known as a *Triangular Irregular Network* (TIN) [1487], there is a high likelihood that the triangles are thin and elongated. This has the drawback that interpolation of the elevation of the nonsample point  $s$ , using the vertices of the triangle containing  $s$ , will not necessarily use the closest vertices to  $s$ . In other words, it is preferable that the triangles be as equiangular as possible. The Delaunay triangulation (DT) (see Section 2.2.1.4) is one approach to achieve such a goal. For a more thorough discussion of some of the earlier developed techniques, see the survey of De Floriani [452].

Figure 2.150  
Example triangular decompositions:  
(a) ternary and (b) quaternary.

When the amount of data is large, the TIN approach becomes unwieldy in terms of storage requirements. In this case, there are two possible solutions. The first is a pyramidlike approach that represents the surface at different predefined levels of precision (i.e., multiple resolution). The second approach, and the one we focus on in this section, represents different parts of the surface at different levels of resolution. Representations based on such an approach are usually characterized as hierarchical. The hierarchical methods that are commonly used are based on either triangulations or rectangular decompositions.

Hierarchical triangular decomposition methods are differentiated on the basis of whether the decomposition is into three (termed *ternary*) or four (termed *quaternary*) [129, 722, 1790] subtriangles. Ternary hierarchical triangular decompositions are formed by taking an internal point  $p$  of one of the triangles, say  $T$ , and joining  $p$  to the vertices of  $T$  (e.g., Figure 2.150(a)). Quaternary hierarchical triangular decompositions are formed by joining three points, each on a different side of a given triangle (e.g., Figure 2.150(b)). The added points at which the subsequent decomposition takes place are usually the data points with the largest distance from the approximating triangle (edges) in the ternary (rectangular) triangular decomposition.<sup>47</sup> Hierarchical triangulations (i.e., triangular decompositions) are represented by trees, where the root corresponds to the initial enclosing rectangle; the out degree is 3 or 4, depending on the type of decomposition (i.e., whether it is ternary or quaternary, respectively). In the case of a ternary triangular decomposition, each triangle is adjacent to at most one triangle on each side.

<sup>47</sup> As we shall see, a more precise definition of the error involves projections of the points and the approximating triangle (edges).

In contrast, in the case of a quaternary triangular decomposition, each triangle may be adjacent to several triangles along a side.

Hierarchical triangulations result in the approximation of a surface, say  $S$ , by planar triangular patches whose vertices are a subset of the data points that define  $S$ . For each such patch, an approximation error is computed that is usually the maximum error of the data points with projections on the  $x$ - $y$  plane overlapping the projection of the patch on the  $x$ - $y$  plane. If the approximation error exceeds a predefined tolerance, then the patch is subdivided further. The resulting surface depends on the nature of the decomposition.

In the case of a ternary hierarchical triangular decomposition, the approximated surface described by the triangulation is usually continuous at every level. Formally, we say that the network, or mesh, is *conforming* as all polygons in the mesh have the same number of vertices and edges (i.e., three in the case of a ternary triangular decomposition). However, the triangles are often thin and elongated since the point at which the triangle is decomposed is internal to the triangle. Thus, equiangularity is generally not satisfied.

There are a number of ways of alleviating the elongation. We have already seen one way in our discussion of the prism tree in Section 2.2.3, where the triangular faces of the approximation of the object are decomposed using a ternary decomposition rule that splits each triangle into between three and six triangles instead of three. It should be clear that the prism tree can also be adapted to 2.5-dimensional data, in which case we simply have just one tetrahedron as the initial approximation instead of two.

Another way is to make use of the triacon hierarchy of Dutton [520], which creates an alternating containment hierarchy so that each level of decomposition is fully contained in the level that was created two steps previously. The partition fieldtree [628, 630] (see Section 2.1.4.1) treats a quadtree decomposition into squares on the plane in a similar manner.

Scarlatos and Pavlidis [1679] avoid the thin and elongated triangles by basing the approximation error that is the key to further decomposition of a triangular patch  $t$  on the maximum error along the edges of  $t$ , as well as the projection of the patch on the  $x$ - $y$  plane. This results in five possible partitions of  $t$  as illustrated in Figure 2.151, termed an *adaptive hierarchical triangulation* (AHT). Let  $e$  be the maximum error allowed—that is, errors larger than  $e$  cause decomposition to take place. Let  $e_t$  denote the maximum error in  $t$ , and let  $e_i$  ( $1 \leq i \leq 3$ ) denote the maximum error along edge  $i$  of  $t$ . Similarly, let the maximum errors occur at points  $p_t$  on  $t$  and  $p_i$  along  $e_i$  ( $1 \leq i \leq 3$ ). Triangle  $t$  is decomposed depending on which of the following conditions hold:

1. Split at the interior (Figure 2.151(a)): If  $e_t > e$  and  $e_i < e$  for  $1 \leq i \leq 3$ , then split at  $p_t$ , and join  $p_t$  to the vertices of  $t$ .
2. Split at one edge (Figure 2.151(b)): If  $e_i > e$ ,  $e_t < e$ , and  $e_j < e$  for  $j \neq i$ , then split at  $p_i$ , and join  $p_i$  to the vertex opposite  $e_i$ .
3. Split at one edge and at the interior (Figure 2.151(c)): If  $e_i > e$ ,  $e_t > e$ , and  $e_j < e$  for  $j \neq i$ , then split at  $p_t$  and  $p_i$ , and join  $p_t$  to the vertices of  $t$  and to  $p_i$ .
4. Split at two edges (Figure 2.151(d)): If  $e_i > e$ ,  $e_j > e$  ( $i \neq j$ ), and  $e_k < e$  ( $k \neq i$  and  $k \neq j$ ), then split by joining  $p_i$  and  $p_j$  and also  $p_i$  (or  $p_j$ ) to the vertex opposite to  $e_i$  (or  $e_j$ ). The choice is arbitrary and can be made on the basis of the point with the largest error.
5. Split at three edges (Figure 2.151(e)): If  $e_i > e$  for  $1 \leq i \leq 3$ , then split  $t$  by joining the three points on the edges—that is,  $p_1$  to  $p_2$ ,  $p_2$  to  $p_3$ , and  $p_3$  to  $p_1$ .

Notice that we do not distinguish between the case that the error on  $t$  is less than  $e$  and the case that it is greater than  $e$  when the error along just two (see Exercise 3) or three of the edges is greater than  $e$  (see Exercise 2).

Figure 2.151  
Possible partitions of a triangular patch when using the adaptive hierarchical triangulation method: (a) split at the interior, (b) split at one edge, (c) split at one edge and at the interior, (d) split at two edges, and (e) split at three edges.

This partitioning process is applied repeatedly until the maximum error on all triangle patches and their edges is less than the predefined maximum. Observe that a partition along the edge of one triangular patch  $t$  will also cause the adjacent triangular patch  $a$  to be partitioned. However, the condition for partitioning of a common edge of  $t$  and  $a$  depends only on the error value along the edge and not on the error in the adjacent triangles. It should be clear that partitions along an adjacent triangle  $a$  cascade to  $a$ 's neighbors whenever more than one edge of  $a$  is split. Notice also the similarity of this approach to that used in the prism tree in Section 2.2.3, although one difference is the presence of condition 5 (Figure 2.151(e)), which is not accounted for in the prism tree.

Although the triangles resulting from the adaptive hierarchical triangulation are less likely to be thin and elongated in comparison to those obtained by the conventional ternary triangular decomposition, this problem does not disappear in its entirety. In order to increase the likelihood that the resulting triangles are as equiangular as possible, De Floriani and Puppo [463, 465] propose to use the Delaunay triangulation of each triangle whose maximum error exceeds the predefined tolerance. The result is termed a *hierarchical Delaunay triangulation* (HDT).

Notice that, in a realistic setting where the source data is a uniformly spaced rectangular or triangular grid, it is very unusual to find data points that lie on the edges of the triangles that are being decomposed. Thus, the solution is to consider any data point that lies within some small distance, say  $\varepsilon$ , of an edge of the triangular patch  $t$  that is being decomposed as lying on the edge. The area within  $\varepsilon$  of the edges of  $t$  is known as a *corridor* or a *buffer*. It is important to observe that the buffer also spans data in the triangular patches that are adjacent to  $t$ . The buffer is used with both the adaptive hierarchical triangulation and the hierarchical Delaunay triangulation.

The ternary hierarchical triangular decomposition is usually used when the surface is defined at points that are randomly located. De Floriani, Falcidieno, Nagy, and Pienovi [454, 455] discuss its use for surface interpolation, as well as its use as a data compression mechanism. We have also seen its use in the prism tree in Section 2.2.3.

In the case of a quaternary hierarchical triangular decomposition, each triangle can be adjacent to several triangles on each of its sides. The decomposition may be regular (e.g., [129, 603]) or based on the actual data (e.g., [722]). Thus, the approximated surface defined on it is generally not continuous (i.e., does not form a conforming mesh), thereby resulting in what are termed *cracks* (for more details, see, e.g., [1373], as well as the discussion below of hierarchical rectangular decompositions), unless all of the triangles are uniformly split—that is, the resulting tree is a complete quadtree. If the initial approximating triangle is equilateral, and the triangles are always subdivided by connecting their midpoints, then equiangularity holds, and the interpolation is ideal. The quaternary hierarchical triangular decomposition is especially attractive when the data points are drawn from a uniformly spaced grid.

Hierarchical rectangular decompositions are similar to hierarchical triangulations that are based on a quaternary decomposition. Of course, the difference is that a ternary hierarchical rectangular decomposition is meaningless. Thus, we often drop the qualifier “quaternary” when discussing them. Hierarchical rectangular decompositions are used when the data points are the vertices of a rectangular grid. In this case, a rectangle is split by choosing an internal point and joining it to its projections on the four sides of the rectangle. When the data is uniformly spaced, and the internal points are midpoints (e.g., [469, 1864]), the result is analogous to a region quadtree.

For example, Carlson [309] subdivides a surface into rectangular patches for use in algorithms that perform intersection of sculptured surfaces. Schmitt, Barsky, and Du [1690] use adaptive subdivision for surface fitting in conjunction with a parametric piecewise bicubic Bernstein-Bézier surface. They start with a rough approximating surface and recursively refine it where the data is poorly approximated. Chen and Tobler [355] evaluate the use of different approximations in each rectangular patch in terms of numerical accuracy, execution time, and storage.

Figure 2.152  
Example illustrating the alignment problem for a quaternary hierarchical decomposition that makes use of (a) a triangular decomposition and (b) a rectangular decomposition.

A hierarchical rectangular decomposition has the same continuity problem as the quaternary hierarchical triangular decomposition (i.e., neither forms a conforming mesh). We discuss them together below using the term *quaternary hierarchical decomposition*. In particular, in a quaternary hierarchical decomposition, each triangle or rectangle can be adjacent to several triangles or rectangles on each of its sides since the triangles and rectangles are always subdivided by connecting the midpoints of their sides. The disadvantage of quaternary hierarchical decompositions is that, when we apply a planar triangulation to the three-dimensional points (i.e., the vertices with their elevation values) in the triangular decomposition or fit a patch (e.g., by using a ruled surface [622]) to them in the rectangular decomposition, the resulting surface is not continuous (termed the *alignment problem*) unless all of the triangles or rectangles in the underlying decomposition have been split uniformly—that is, the resulting quadtree (whether triangular or rectangular) is always complete. Figure 2.152(a, b) illustrates the alignment problem for a quaternary hierarchical decomposition on the plane that makes use of triangles and rectangles, respectively. Notice the cracks (shown shaded), which are the result of the discontinuity in the interpolated surfaces corresponding to the triangles and rectangles.

The alignment problem can be resolved for both of the quaternary hierarchical decompositions. In the case of a triangular decomposition, one solution is simply to use the interpolated point instead of the true point [128]. For example, in Figure 2.152(a), the elevation of point H used in triangles 2, 3, and HON would be replaced with the interpolated elevation at the midpoint of the edge between B and C. This is undesirable as we are giving up some of the original sample points. The same problem would arise in the case of a rectangular decomposition, where we would replace the elevation of point R in patches 3 and 5 in Figure 2.152(b) with the interpolated elevation at the midpoint of the edge between N and L.

Instead, it is better to decompose triangle ABC, as shown in Figure 2.153(a), into a hierarchy of triangles so that there are triangles in ABC adjacent to edge BC that are of the same size as triangles 1, 2, 3, and 4 in triangle BCF [602]. This is achieved by adding the points p, q, r, s, t, and u, as well as the edges between them (shown with light lines) and the vertices along edge BC (i.e., B, G, H, I, and C).

There are two types of newly added points. The first type are midpoints of known edges. The second type are midpoints of newly created edges lying between known vertices or midpoints of known edges. In the strictest sense, the first type do not represent new samples (since they lie on existing edges), while the second type do. In both cases, their elevation values are obtained by applying linear interpolation to the elevation values at the endpoints of these known or newly created edges. For example, q is obtained

Figure 2.153  
Example illustrating how to resolve the alignment problem for a hierarchical quaternary decomposition corresponding to Figure 2.152 that makes use of (a) a triangular decomposition and (b) a rectangular decomposition. Newly added edges are shown with light lines.

by applying linear interpolation to the elevations at A and B. In contrast, both s and t are obtained by applying linear interpolation to the elevation at H and the interpolated elevation just computed at p and q, respectively.

Observe that a similar process must be applied to triangle HON in Figure 2.153(a) so that there are triangles in HON adjacent to edges HO and HN that are of the same size as triangles 2 and 5 in triangle BOH and triangles 3 and 6 in triangle HNC, respectively. This is achieved by adding the point v, as well as the edges between it and vertices L and K of triangles BOH and HNC, respectively.

Unfortunately, we are not yet through in the sense that we may also have to apply the same process to the other edge neighbors of triangle BCF (i.e., the ones adjacent along edges BF and CF). This is the case if their atomic triangles that share edges BM and CJ are larger than triangles 1 and 4, respectively.

A similar technique can be applied to a quaternary hierarchical rectangular decomposition, thereby obtaining a hierarchy of rectangles so that there are adjacent rectangles of equal size along the edges (see Figure 2.153(b)). For example, in Figure 2.153(b), there are rectangles in rectangle IFDG adjacent to edge IF that are the same size as rectangles 2, 5, and 6 in IFDG. As in the quaternary hierarchical triangular decomposition, several new points have been added. We decompose these points into two sets: those that lie on existing edges (e.g., n, r, t, u, and w) and those that do not (e.g., v, x, y, and z). The former, as in the case of the triangular decomposition, do not represent new samples since they are midpoints of known edges. However, their elevation values depend on the type of patch that is being fit through them.

The patch is defined by the four curves that make up its boundary. The simplest patch arises when the curves are linear, in which case the resulting patch is a ruled surface. Of course, more complex curves, such as quadratics, could be used, thereby leading to more complex surface patches. When the curves are linear, the elevation values of all newly added points that lie on existing edges are obtained by applying linear interpolation to the elevation values at the endpoints of the edges for which they serve as midpoints. For example, r is obtained by interpolating the elevations at D and F, while w is obtained by applying linear interpolation to the elevation at F and the interpolated elevation just computed at r.

The newly added points that do not lie on existing edges represent new samples. Thus, we must also obtain an elevation value for them. There are two choices for some of them since they fall at the midpoints of edges between the midpoints of both a horizontal and a vertical edge. We choose to take the average of the two interpolated values. For example,  $v$  is obtained by taking the average of the values obtained by applying linear interpolation to the elevation values at  $L$  and  $t$  and the elevation values at  $u$  and  $r$ . The same technique is applied to obtain the elevation value at  $z$  once we have obtained the elevation values at  $x$ ,  $y$ , and  $w$ .

At this point, let us briefly compare the two different quaternary hierarchical decompositions. As we saw, both methods suffer from the alignment problem when we try to fit a surface through their vertices. However, as we have demonstrated, this problem can be overcome through the addition of the appropriate triangles and rectangles. For the triangular decomposition, we obtained a planar surface because we were able to use a planar triangulation. For the rectangular decomposition, we obtained a nonplanar surface because it is impossible to fit a plane through the four vertices of each rectangle.

It could be argued that a nonplanar surface is a better approximation of a nonplanar surface than a planar one, thereby making the rectangular decomposition more attractive than the triangular decomposition. Of course, we could also fit a nonplanar surface through the vertices of the triangles. However, it is well-known that the more sample points that are used in a surface patch, the better is the approximation of the underlying surface. Thus, such reasoning implies that the rectangular decomposition is preferable to the triangular decomposition.

An argument could also be made that the planar approximation of the surface provided by the triangle is preferable to the nonplanar approximation provided by the rectangle. This is especially true if ease of interpolation is an issue. In fact, we could also obtain a planar approximation using rectangles by splitting each rectangle into two triangles by adding a diagonal edge between two opposing vertices. There are two choices as shown in Figure 2.154. As long as the four vertices are not coplanar, one will result in a ridgelike planar surface (Figure 2.154(a)), while the other will result in a valleylike planar surface (Figure 2.154(b)). We usually choose the diagonal edge whose angle is the most obtuse.

Neither of the above solutions to the alignment problem that employ a quaternary hierarchical decomposition (whether they use a triangular or rectangular decomposition) yields a conforming mesh because not all of the polygons that make up the mesh have the same number of vertices and edges. Nevertheless, the quaternary hierarchical decomposition that makes use of a rectangular quadtree can form the basis of a conforming mesh and overcome the alignment problem. The idea is to apply a planar triangulation to the result of transforming the underlying rectangular quadtree to a restricted quadtree [1453, 1771, 1772, 1940]. The *restricted quadtree* has the property that all rectangles that are edge neighbors are either of equal size or of ratio 2:1. Such a quadtree is also termed a *1-irregular quadtree* [124], a *balanced quadtree* [204], and a *1-balanced quadtree* [1312]. A somewhat tighter restriction requires that all vertex neighbors either be of equal size or of ratio 2:1 (termed a *0-balanced quadtree* [1312]). It should be clear that a 0-balanced quadtree is also a 1-balanced quadtree but not vice versa (see Exercise 4).

Given an arbitrary quadtree decomposition, the restricted quadtree is formed by repeatedly subdividing the larger nodes until the 2:1 ratio holds. For example, Figure 2.155(a) is the restricted quadtree corresponding to the rectangular decomposition in Figure 2.152(b). Note that the SE quadrant of Figure 2.152(b) has to be decomposed once, in contrast to twice when building the hierarchy of rectangles in Figure 2.153(b). This method of subdivision is also used in finite-element analysis (e.g., [1147]) as part of a technique called *h-refinement* [1013] to refine adaptively a mesh that has already been analyzed, as well as to achieve element compatibility.

## Section 2.2 BOUNDARY-BASED REPRESENTATIONS

Figure 2.154  
Example illustrating the ambiguity that results when each rectangle is split into two triangles by adding a diagonal edge between (a) vertices B and C and (b) vertices A and D.

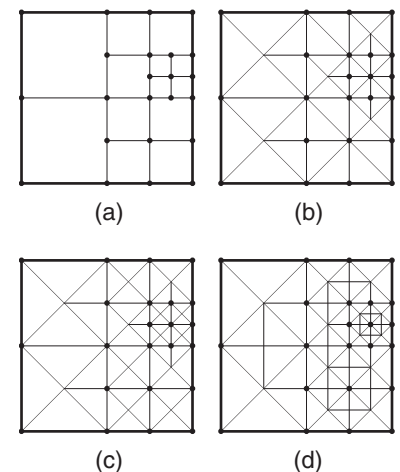

Figure 2.155  
(a) Restricted quadtree corresponding to the rectangular decomposition in Figure 2.152(b) and the result of triangulating it using a (b) two-triangle rule, (c) four-triangle rule, and (d) eight-triangle rule.

A conforming triangular mesh is obtained by triangulating the rectangles in the restricted quadtree uniformly using one of the following three rules:

1. Decompose each atomic rectangle into two triangles in such a way that the partition line passes through the center of the rectangle's immediately containing node. If there is just one atomic rectangle, then the orientation of the partition line is arbitrary. For each triangle  $t$  whose adjacent triangle  $u$  is larger, if the bordering triangle  $u$  of any triangle  $t$  is larger, then recursively partition  $u$  in half until the resulting triangle shares an edge with  $t$ . Apply the decomposition to the newly created triangles as necessary (e.g., Figure 2.155(b)).
2. Decompose each atomic rectangle into four triangles, or one triangle per edge, unless the edge borders a smaller rectangle. In that case, two triangles are formed along the edge (e.g., Figure 2.155(c)).
3. Decompose each atomic rectangle into eight triangles, or two triangles per edge, unless the edge borders a larger rectangle. In that case, only one triangle is formed along the edge (e.g., Figure 2.155(d)).

Even though the decomposition into eight triangles requires more space than the decomposition into two and four triangles because it results in more triangles, it is nevertheless preferred [1940] as it avoids problems when displaying (i.e., shading [1568]) the resulting object (see also [1636, Section 7.1.6]).

If we are interested in reducing the number of triangles beyond the amount required by using the restricted quadtree with a decomposition into four triangles, then we can use a rule that decomposes each atomic rectangle into two triangles without first building a restricted quadtree where all rectangles that are edge neighbors are either of equal size or of ratio 2:1. We term the result a *restricted bintree*. It has been used by several researchers (e.g., [513, 576, 651, 702, 810, 1176, 1259, 1522, 1564, 1565]). Although we use the qualifier “restricted” to describe the structure, as we explain below, it is formed in a rather different way from the restricted quadtree.

Figure 2.156  
(a) Result of the initial step of forming the restricted bintree corresponding to the rectangular decomposition in Figure 2.152(b) using the bottom-up method and (b) the final restricted bintree so that the alignment problem is resolved.

The key idea behind the restricted bintree is that the square corresponding to the entire space spanned by the adaptively sampled rectangular grid is initially decomposed into two isosceles right triangles by using one of the two diagonals. These two isosceles right triangles are subsequently recursively decomposed into two isosceles right triangles by bisecting the right angle of each one as necessary. This process is continued until a conforming mesh is obtained (i.e., the resulting triangular mesh does not suffer from the alignment problem and thus there are no T-junctions, and all of the sample points are vertices of triangles). For example, Figure 2.156(b) is the restricted bintree corresponding to the rectangular decomposition in Figure 2.152(b). Notice that, as in the restricted quadtree, all adjacent triangles are either of equal size, or the length of the leg of one triangle  $t$  is half the length of the hypotenuse of its larger adjacent triangle  $u$ , or the length of  $t$ 's hypotenuse is twice the length of the leg of its smaller adjacent triangle  $s$ .

The above definition of the restricted bintree is top down. We can also define the restricted bintree in a bottom-up manner. Such a definition resembles more closely the definition of the restricted quadtree with the four- or eight-triangle rule. In particular, the initial transformation of the rectangular decomposition in Figure 2.152(b) is such that each square block  $b$  corresponding to node  $a$  in the quadtree is split into two isosceles right triangles by the addition of a diagonal edge  $e$  that is oriented in such a way that  $e$  passes through the center of the parent of  $a$  (i.e., the immediately containing block). The only time we have a choice as to the orientation of the diagonal (i.e., from the NW corner to the SE corner or from the NE corner to the SW corner) is in the case of the block corresponding to the root, in which case either orientation is acceptable as there are only two triangles left anyway. Figure 2.156(a) shows the result of applying this triangulation process to the rectangular decomposition in Figure 2.152(b). Once we have obtained the initial triangulation, we decompose the remaining triangles until a conforming mesh is obtained (i.e., the resulting triangular mesh does not suffer from the alignment problem).

At a first glance, the restricted bintree (Figure 2.156(b)) appears quite similar to the restricted quadtree with a decomposition into two triangles (Figure 2.155(b)). However, regardless of the how the restricted bintree is defined, we see that it does yield a different decomposition. In particular, the fact that, in order to obtain the restricted bintree, we did not initially have to build the restricted quadtree (i.e., decompose the underlying rectangles so that all adjacent rectangles are either of equal size or of ratio 2:1) meant that decomposition lines in rectangles that were created to ensure the 2:1 ratio could be eliminated if they were subdividing larger triangles. This may preclude the subsequent subdivision of larger adjacent triangles (e.g., the two triangles in the SW quadrant in Figure 2.156(b), which had to be subdivided in Figure 2.155(b)).

The principle of decomposing each element of the decomposition into two triangles can also be applied to a quaternary hierarchical decomposition that makes use of a triangular decomposition (e.g., Figure 2.152(a)) to obtain a conforming mesh. In this case, when two sides of a triangle have no sample points between their vertices, then we can repeatedly split the triangle into two triangles using the sample points on the other side as the vertices. For example, triangle ABC in Figure 2.152(a) would initially be split into triangles ACH and ABH. Since edges CH and BH contain sample points between their vertices, we split triangles ACH and ABH, resulting in triangles ACI, AIH, AHG, and ABG. In the case of triangle HON, the situation is more complicated as two of its sides contain sample points. For such a situation, it is best to decompose the triangle into four equilateral triangles after adding point  $v$ , which is the midpoint of edge NO (i.e., triangles HKL, KL $v$ , KN $v$ , and LO $v$ ). Once this is done, we split triangle FON into two triangles FN $v$  and FO $v$ . The result of the application of such a policy to the triangular decomposition in Figure 2.152(a) is shown in Figure 2.157(a).

The drawback of such a solution is that successive partitioning of a triangle and the resulting triangles into two triangles will lead to thin and elongated triangles. As mentioned earlier, equiangularity is preferred. In order to overcome this problem, it has been proposed to disallow a partition of triangle  $t$  into two triangles when the parent  $f$  of  $t$  has already been split into two triangles. Instead, the split of  $f$  into two triangles is undone, and  $f$  is now split into four equilateral triangles. These four triangles are split into two triangles as necessary to ensure that the alignment problem does not arise [124, 211]. For example, Figure 2.157(b) shows the result of the application of such a rule to triangle ABC in Figure 2.152(a). In particular, instead of splitting ABC into triangles ACH and ABH, followed by triangles ACI, AIH, AHG, and ABG, as in Figure 2.157(a), we now add points  $p$  and  $q$  at the midpoints of edges AC and AB, respectively, and split triangle ABC into the four equilateral triangles Apq, BHq, CHp, and Hpq. Of course, we must also split triangles AEC into triangles AEp and CEp, ABD into ADq and BDq, CHP into Clp and Hlp, and BHq into BGq and GHq.

Figure 2.157  
(a) Result of applying a two-triangle rule to resolve the alignment problem for the example quaternary decomposition that makes use of a triangular decomposition in Figure 2.152(a) and (b) result of replacing two successive partitions of a triangle and its two resulting triangles into two triangles by a partition into four triangles followed by appropriate partitions into two triangles.

### Exercises

1. Consider a hierarchical triangulation that is based on a ternary decomposition. Let  $t$  be the number of triangles and  $v$  the number of vertices. Prove that  $t < 2 \cdot v$ .
2. In the adaptive hierarchical triangulation method [1679], why is it not necessary to distinguish between the case that the error on  $t$  is less than  $e$  and the case that it is greater than  $e$  when the error along three of the edges is greater than  $e$ ?
3. In the adaptive hierarchical triangulation method [1679], why is it not necessary to distinguish between the case that the error on  $t$  is less than  $e$  and the case that it is greater than  $e$  when the error along only two of the edges is greater than  $e$ ?
4. Prove that a restricted quadtree where all vertex neighbors are either of equal size or of ratio 2:1 (i.e., a *0-balanced quadtree* [1312]) is also one where all edge neighbors are either of equal size or of ratio 2:1 (i.e., a *1-balanced quadtree* [1312]), but not vice versa.
5. Prove that the use of the restricted quadtree increases the number of nodes in the quadtree by at most a factor of 8.

6. Suppose that you define a restricted quadtree where each block is subdivided into a  $3 \times 3$  set of congruent blocks instead of a  $2 \times 2$  set of congruent blocks. Prove that the use of the restricted quadtree in this case increases the number of nodes in the quadtree by at most a factor of 6.
7. Suppose that you define a restricted triangular quadtree in the same manner as the restricted rectangle quadtree so that all edge neighbors are either of equal size or of ratio 2:1. Prove that the use of the restricted triangular quadtree in this case increases the number of nodes in the quadtree by at most a factor of 10.
8. Can you show that the use of a restricted  $d$ -dimensional quadtree where every  $(d - 1)$ -dimensional neighbor is either of equal size or of ratio 2:1 increases the number of nodes in the quadtree by at most a factor of  $3^d - 1$ ?
9. Consider a quaternary hierarchical decomposition that makes use of a rectangular decomposition implemented using a restricted bintree with a triangular mesh  $T$ . Suppose that a sample point is added at the midpoint of the hypotenuse  $h$  of triangle  $t$  in  $T$ . At this point,  $T$  must be adjusted to resolve the alignment problem. Prove that for each size  $z$  greater than or equal to that of  $t$ , no more than two triangles of size  $z$  will be split, and no triangles smaller than  $t$  will be split.
10. Evans, Kirkpatrick, and Townshend [576] point out that instead of using a restricted bintree that results in a hierarchy of isosceles right triangles, a similar subdivision of a 30-60 right triangle can be used. In this case, we start with one 30-60 right triangle, which is recursively decomposed as necessary into four 30-60 right congruent triangles of one-fourth the size. The 30, 60, and 90 degree vertices have degrees of 12, 6, and 4, respectively. Suppose that a sample point is added so that a triangle  $t$  needs to be split. Evans, Kirkpatrick, and Townshend [576] claim that, for each size  $z$  greater than or equal to that of  $t$ , at most 12 triangles of size  $z$  will be split, and no triangles smaller than  $t$  will be split. Prove that this is true.

## 2.3 Difference-Based Compaction Methods

Some interior-based and boundary-based representations (regardless of whether they are implicit or explicit) can be made more compact by making use of an ordering on the data whether it is the locations (i.e., the cells, blocks, boundary elements, etc.) or values that they record (if one exists). In particular, instead of just recording the actual values of the cells or the actual locations of the cells, such methods record the *change* (i.e., the difference) in the values of the cells or the locations of the cells where the value changes. The ordering is used to reconstruct the original association of locations with values (i.e., the feature query) or values with their locations (i.e., the location query) whenever we want to answer one of our basic queries for determining what locations are associated with a particular feature (i.e., the feature query) or what value is associated with a particular location (i.e., the location query). In other words, these compaction methods are not designed to facilitate responding to either the feature or location queries.

Naturally, this reconstruction process is costly because it requires traversing the entire representation (i.e., all the objects). However, this is not necessarily a problem when execution of the operations inherently requires that the entire representation be traversed (e.g., Boolean set operations, data structure conversion, erosion, dilation). On the other hand, operations that require the ability to access a cell at random in the representation (e.g., neighbor finding) are inefficient in this case unless an additional access structure is imposed on the compact representation. However, note that, if the representation records relative changes in the values rather than the actual values, then an access structure may not be of much use since we still need the reconstruction process to determine the value associated with a particular cell.

In this section, we discuss several difference-based compaction methods. We start with runlength encoding (Section 2.3.1), which is designed primarily for use with interior-based representations. Next, we review the chain code (Section 2.3.2), which is the classical method used to make boundary-based representations of two-dimensional data more compact. The chain code is inapplicable to data of dimensionality greater than

2. We conclude by presenting the vertex representation (Section 2.3.3). It uses the basic elements of the chain code (i.e., the vertices) to yield a variant of runlength encoding that is similar in spirit to constructive solid geometry (CSG) and that is applicable to the interiors of objects of arbitrary dimensionality. All of the sides (i.e., faces in dimensions higher than 2) of the objects in this section are restricted to being parallel to the coordinate axes (termed an *axis-parallel polygon*).<sup>48</sup>

### 2.3.1 Runlength Encoding

*Runlength encoding* [1595] is an example of a method that can be applied to make an interior-based representation, such as the array, more compact. The actual locations of the cells are not recorded. Instead, contiguous, identically valued cells are aggregated into one-dimensional rectangles for which only the value associated with the cells making up the rectangle and the length of the rectangle are recorded. The one-dimensional rectangles are ordered in raster-scan order, which means that row 1 is followed by row 2, and so on. The same technique is applicable to higher-dimensional data, in which case the one-dimensional rectangles are ordered in terms of the rows, planes, and so forth.

For example, consider the object in Figure 2.158(a), which is embedded in an  $8 \times 8$  image array. The cells that make up the object are shown shaded. Assuming an origin at the upper-left corner and that the image is binary with B and W denoting foreground and background, respectively, we have a runlength encoding of (W,8), (W,8), (W,4), (B,4), (W,4), (B,4), (W,3), (B,5), (W,2), (B,6), (W,2), (B,4), (W,2), (W,2), (B,3), (W,3). Given the location of any cell  $c$  in one-dimensional rectangle  $r$ , the value associated with  $c$  can be computed by referring to the location of the starting position of the entire representation and accumulating the lengths of the one-dimensional rectangles encountered before the position of  $r$  in the ordering.

Runlength encoding can be made even more compact by just recording the change in the value associated with the cell rather than the value itself. We use the term *change-based runlength encoding* to describe this method, thereby distinguishing it from the previous variant, which we will refer to as *value-based runlength encoding* when the need arises.<sup>49</sup> Change-based runlength encoding is especially attractive in the case of a binary image, where we have just two possible values (i.e., 0 and 1 or B and W, respectively, in our examples). In this case, once we know the value associated with the first cell in each row, we do not need to keep track of the remaining values in the row. Thus, we just record the value of the first cell in each row, followed by a sequence of numbers corresponding to the lengths of the one-dimensional rectangles of alternating values. For example, given the image in Figure 2.158(a), we have the following change-based runlength encoding: (W,8), (W,8), (W,4,4), (W,4,4), (W,3,5), (W,2,6), (W,2,4,2), (W,2,3,3).

Runlength encoding can also be adapted to deal with rectangular aggregates (i.e., blocks) in higher dimensions. Once again, we assume that the locations of the blocks are not recorded. If the blocks are of a uniform size and orientation, then the adaptation is easy as it is analogous to a grid of cells of uniform size, and we apply the same methods as before. If the blocks are not of a uniform size, then the problem is more complex. Recall that since we do not record the locations of the blocks, we must make use of the ordering of the blocks. Such an ordering exists if there is a regularity to the manner in which the blocks of differing sizes are created. Of course, in such a case, we must specify the block sizes. A block decomposition that results from a regular decomposition of space, such as a region quadtree, region octree, bintree, has such an ordering.

## Section 2.3 DIFFERENCE-BASED COMPACTION METHODS

Figure 2.158  
(a) Example object in an  $8 \times 8$  image array and (b) its corresponding region quadtree block decomposition.

<sup>48</sup> Such an object was termed an *orthogonal polygon* in [566, 567, 569], although the term *axis-parallel polygon* is more appropriate, and we shall use it here.

<sup>49</sup> We use the general term *runlength encoding* whenever either of the two methods is applicable and no confusion is possible.

As an example, consider two-dimensional data represented by a region quadtree (i.e., a regular decomposition into four congruent rectangular blocks) where we ignore the imposed access structure (i.e., the tree). Its ordering is obtained in the same manner as the block decomposition—that is, we recursively decompose the embedding space into four congruent blocks (labeled NW, NE, SW, SE, in this order) until each block is either completely occupied by an object or is empty, at which time their size and value are placed in the list. For example, assuming a list of pairs  $(a, b)$ , where  $a$  and  $b$  correspond to the value and size (i.e., power of 2), respectively, of each block, the region quadtree in Figure 2.158(b) corresponding to the object in Figure 2.158(a) is represented as  $(W, 2)$ ,  $(W, 1)$ ,  $(W, 1)$ ,  $(B, 1)$ ,  $(B, 1)$ ,  $(W, 1)$ ,  $(W, 0)$ ,  $(B, 0)$ ,  $(B, 0)$ ,  $(B, 0)$ ,  $(W, 1)$ ,  $(B, 1)$ ,  $(B, 1)$ ,  $(B, 1)$ ,  $(B, 0)$ ,  $(B, 0)$ ,  $(B, 0)$ ,  $(W, 1)$ .

This ordering can also be obtained by associating with each block  $b_i$  a unique base 4 number  $m_i$  formed by interleaving the bits in the binary representation of the  $x$  and  $y$  coordinate values of  $b_i$ 's upper-left corner (termed a *Morton number* [1317, 1636]), assuming an origin at the upper-left corner of the image, and then sorting the  $m_i$  values in increasing order. The resulting order is the same as the *Morton order* (see Sections 2.1.1.2 and 2.1.2.4, as well as Figure 2.5(c)). We term this representation a Morton size ordering. It contains the same data.

Assuming a Morton size ordering representation, given the location of the upper-left corner of any cell  $c$ , and the size (must be a power of 2) of the space  $S$  in which the objects are embedded, then the value associated with  $c$  can be computed by an accumulation process that starts at the location of the upper-left corner of  $S$ . This is done by reconstructing the embedding space using the principle that, each time a block of width  $2^m$  is encountered, it must be followed by three more blocks  $\{b_1, b_2, b_3\}$ , each of width  $2^m$  or satisfying the constraint that the area spanned by the constituent blocks of  $b_i$  ( $1 \leq i \leq 3$ ) have a total width of  $2^m$ . As each block  $b$  of the Morton size ordering is added, we check if  $b$  contains  $c$  and report  $b$ 's value as that of  $c$  when the containment test is satisfied.

From a theoretical standpoint, other orderings than the Morton order could be applied to the blocks (e.g., see Figure 2.5), thereby resulting in different block orders than that in the Morton size ordering. For example, we could try to use the Peano-Hilbert order given in Figure 2.5(d) to obtain a Peano-Hilbert size ordering. However, in this case, determining the value associated with a particular block or cell may be rather complex (see Exercise 8).

It is interesting to observe that an analogous representation to that of the Morton size ordering can be obtained by not completely ignoring the treelike nature of the block decomposition process, which is a tree having the property that each node has either four children or is one of the blocks. The ordering is obtained by traversing the resulting tree in the order NW, NE, SW, SE and forming a list of the values of the nodes or blocks encountered. Nonleaf nodes have a value that is different from those associated with the blocks (say  $l$  denoting a nonleaf node). In this case, there is no longer a need to record the size of the individual blocks, as in the Morton size ordering, since we can determine it by an accumulation process that keeps track of how many nonleaf nodes have been encountered in the traversal that starts at the root of the tree. This representation is also known as a *DF-expression* [1004] (denoting a depth-first traversal ordering). For example, the DF-expression of the region quadtree in Figure 2.158(b) is given by  $lWlWWBBlWlWBBBWBIBBIBBBWW$ . Some implementations of the DF-expression associate a value with each nonleaf node such as an average of the values of the descendants (e.g., [1395]) in which case an additional flag is needed to distinguish between the value types. Other implementations such as the *compressed quadtree* [2018] try to reduce the number of times that the same value of a leaf node appears by just keeping track of the nonleaf nodes by using a set of 52 patterns to describe the four possible value configurations of the children of each nonleaf node. For each pattern that

has child leaf nodes, their values immediately follow the pattern in the list of values in the ordering.

The DF-expression stores the structure of the tree along with the values of the leaf nodes. Thus, in the case of a binary image, it may be a bit wasteful in its storage requirements because it requires two bits to encode each of the possible values, although there are really just three different values. An alternative is to separate the structure of the tree from that of the values of the leaf nodes by using two separate bitstrings [1830], termed a *linear tree* and a *color table*. The resulting structure is known as an *S-tree* [970]. The linear tree corresponds to the structure of the tree and uses 0 and 1 to represent nonleaf and leaf nodes, respectively. In the case of a binary image, the color table makes use of 0 and 1 to represent the values of the leaf nodes, while more than one bit is needed for each value when the image has a greater range of possible values. In order to simplify our examples, in the rest of this discussion, we assume, without loss of generality, that the image is binary. Both the linear trees and the color tables are formed by a preorder traversal of the underlying quadtree. For example, the S-tree corresponding to the region quadtree in Figure 2.158(b) has 0101111010111111011011111 as its linear tree and 0001100111011111100 as its color table.

The space saving provided by the S-tree should be quite clear. For example, in the case of a binary image, the S-tree contains one bit (in the linear tree) for each nonleaf node in the original tree, while containing two bits (one in the linear tree and one in the color table) for each leaf node in the original tree. The trade-off is in the amount of time necessary to determine the value associated with a particular cell in the image as, now, the process takes twice as much time as in the DF-expression representation since two lists must be traversed in tandem (i.e., the linear tree and the color table). Again, we note that the S-tree could also be used for nonbinary images with even greater space-saving relative to the DF-expression.

The principal drawback of the S-tree, as well as the DF-expression, is the fact that determining the value associated with a particular cell may require that the entire representation be examined. This is quite time-consuming, especially for large images whose S-tree or DF-expression representation may span many pages. In this case, the S-tree is decomposed into several string segments that are stored on the different pages (e.g., we can distribute the bits of the string corresponding to the linear tree so that each group of consecutive  $m$  bits is on a separate page). This drawback can be overcome by identifying each string segment by the node  $N$  (leaf or nonleaf) in the original tree corresponding to the first element in the segment and then imposing an access structure on these node identifiers. This is the basis of the  $S^+$ -tree [970], which uses a  $B^+$ -tree as the access structure with the values of these node identifiers serving as the keys.<sup>50</sup> Below we describe the  $S^+$ -tree for binary images.

The simplest way of representing the first node  $N$  in each segment is to use the sequence of directional codes in the original tree corresponding to the path from the root of the tree to  $N$ . In this case, we can use the codes 0, 1, 2, and 3, corresponding to NW, NE, SW, and SE, respectively. Transitions are made in the  $B^+$ -tree on the basis of comparisons from left to right using these key values. Given two keys  $i$  and  $j$ , we say that  $j > i$  whenever  $j$  is greater in value than  $i$ , once the two strings corresponding to  $i$  and  $j$  have been made the same length by padding the shorter one on the right with digits having the value D such that D is less than 0 in the sort sequence. Note that, if  $i$  is a substring of  $j$ , then  $j > i$ . Also, observe that the identifier consisting of the empty string corresponds to the root of the tree, which is not necessarily empty.

---

<sup>50</sup> The original formulation of the S-tree and  $S^+$ -tree makes use of a bintree [1041, 1661, 1828] (described in Section 2.1.2.6); however, this makes no difference here.

Figure 2.159  
An  $S^+$ -tree corresponding to the region quadtree in Figure 2.158(b). “id,” “lt,” and “ct” denote the identifier, linear tree, and color table, respectively, for each leaf node in the tree. Note the presence of horizontal links in the leaf nodes of the tree in order to facilitate sequential access.

For example, the linear tree of the  $S$ -tree corresponding to the region quadtree in Figure 2.158(b) could be decomposed into three segments (of nearly equal size) on three consecutive pages as follows:

1. 010111101 with color table 000110 and no identifier (i.e., the root is the first node on the page).
2. 0111111 with color table 011101 and identifier 21. This is the portion of the tree starting with the NE child of the SW child of the root.
3. 011011111 with color table 1111100 and identifier 3. This is the portion of the tree starting with the SE child of the root.

The resulting  $S^+$ -tree is given in Figure 2.159. The identifier values are used as the index values in the nonleaf nodes of the  $B^+$ -tree. Note that the actual keys (i.e., the values of the identifiers) are also stored in the leaf nodes of the  $S^+$ -tree, which are linked, in order to facilitate operations on the actual data stored in the nodes, such as traversing the image in its entirety. In addition, observe that we have varied slightly the definition of the  $B^+$ -tree given in Appendix A in that, in our implementation, if a key value  $k$  is stored in a nonleaf node between pointers to subtrees  $p$  and  $q$ , then all key values in  $p$  are less than  $k$ , and all key values in  $q$  are greater than or equal to  $k$ .<sup>51</sup> For an extension of the  $S^+$ -tree to handle nonbinary images, see the  $S^*$ -tree of Nardelli and Proietti [1345].

The Morton size ordering did not record the locations of the blocks. Instead, it just recorded their values and sizes in a particular order. As we saw, this information was sufficient to determine the value associated with any block or cell in the image, given its location. We can achieve a similar effect by just recording the locations of the blocks instead of their sizes, while still recording their values. In this case, we record the location of the block’s upper-left corner and use the same ordering as in the Morton size ordering. In other words, its ordering is obtained in the same manner as the block decomposition—that is, by recursively decomposing the embedding space into four congruent blocks (labeled NW, NE, SW, and SE, in this order) until each block is either completely occupied by an object or is empty, at which time the location of the upper-left corner of the block and the block’s value are placed in the list. We term the resulting representation a *Morton location ordering*. The presence of the ordering enables us to determine the size of the block.

For example, assuming a list of pairs  $(a, b)$ , where  $a$  and  $b$  correspond to the value and location, respectively, of each block, the Morton location ordering representation of the region quadtree in Figure 2.158(b) corresponding to the object in Figure 2.158(a) is  $(W, (0,0)), (W, (4,0)), (W, (6,0)), (B, (4,2)), (B, (6,2)), (W, (0,4)), (W, (2,4)),$

<sup>51</sup> This is in contrast to the other definition, which stipulates that, if a key value  $k$  is stored in a nonleaf node between pointers to subtrees  $p$  and  $q$ , then all key values in  $p$  are less than or equal to  $k$ , and all key values in  $q$  are greater than  $k$ .

(B,(3,4)), (B,(2,5)), (B,(3,5)), (W,(0,6)), (B,(2,6)), (B,(4,4)), (B,(6,4)), (B,(4,6)), (B,(5,6)), (B,(4,7)), (W,(5,7)), (W,(6,6)).

The size of each block in the Morton location ordering is determined by making use of its Morton number and that of the block that immediately follows it in the ordering. In particular, given the location of the upper-left corner of any block  $b$  in the set and the size  $M$  (must be a power of 2) of the space  $S$  in which the objects are embedded, the size of  $b$  is determined by taking the logarithm to the base 4 of the difference between the Morton numbers of the immediately following block in the ordering and  $b$ . The Morton number of the block following the last block in the ordering is  $M^2$ .

The key to understanding why the Morton location ordering works is to observe that the Morton order is a space-filling curve that accounts for all of the pixels in each block before moving to the next block in the block sequence. Thus, the Morton numbers of two successive blocks  $A$  and  $B$  in the sequence (where  $B$  follows  $A$ ) differ by the size of  $A$  since the Morton number of a block corresponds to the first pixel in the block (i.e., the pixel in the upper-left corner of the block). For example, rewriting the Morton location ordering representation given above of the region quadtree in Figure 2.158(b) corresponding to the object in Figure 2.158(a) yields (W,0), (W,16), (W,20), (B,24), (B,28), (W,32), (W,36), (B,37), (B,38), (B,39), (W,40), (B,44), (B,48), (B,52), (B,56), (B,57), (B,58), (W,59), (W,60).

Given the location of the upper-left corner of any cell  $c$ , determining the value associated with  $c$  using a Morton location ordering is very easy. We simply construct the Morton number  $m_c$  corresponding to  $c$  and find the block  $b$  in the ordering with the largest Morton number that is less than or equal to  $m_c$ . This query can be executed even more efficiently if we impose an access structure on the Morton numbers such as a  $B^+$ -tree as now our search for the Morton number takes logarithmic time instead of being a sequential search. The ability to impose the access structure on the location field is an advantage of the Morton location ordering over the Morton size ordering, although, of course, the Morton location ordering does require more space than the Morton size ordering.

Both the Morton size and location orderings record the values and sizes or locations of each block in the image. This may be wasteful if the same value is associated with consecutive blocks in the image. One way to reduce the storage requirements is just to keep track of the blocks where the values change. This is not possible in the case of the Morton size ordering since only the sizes of the blocks are recorded and thus there is no easy way to identify the locations of the blocks where the values change. However, in the case of the Morton location ordering, such an approach does work since we can determine the size of the individual blocks in the ordering by making use of their Morton numbers and their relative position in the ordering. Thus, all we need to do is to keep track of the locations where the values change (i.e., the location of the first block in the ordering associated with each value), as well as the values. Such an adaptation of runlength encoding is termed *two-dimensional runlength encoding* [1115]. As in the case of the Morton location ordering, a sufficient location is the address of the upper-left corner of the block.

For example, assuming an origin at the upper-left corner of the space in which the objects are embedded, the two-dimensional runlength encoding of the region quadtree in Figure 2.158(b) is given by (W,(0,0)), (B,(4,2)), (W,(0,4)), (B,(3,4)), (W,(0,6)), (B,(2,6)), (W,(5,7)). Notice the similarity of this approach to the polygon representation of the boundary of an object that just records the locations of the vertices (i.e., the starting point of each vector).

Given the location of the upper-left corner of any cell  $c$  in the image, determining the value associated with  $c$  using a two-dimensional runlength encoding is done in the same manner as with the Morton location ordering. Once again, we simply construct the Morton number  $m_c$  corresponding to  $c$  and find the block  $b$  in the ordering with the largest Morton number that is less than or equal to  $m_c$ . As in the case of the Morton

location ordering, this query can be executed even more efficiently if we impose an access structure on the Morton numbers of the blocks, such as a  $B^+$ -tree, as now our search for the Morton number takes logarithmic time instead of being a sequential search. We can also determine the locations and sizes of all of the blocks in the image using techniques similar to those used to compute the size of the blocks in the Morton location ordering (see Exercise 17).

As in the array representation, two-dimensional runlength encoding can be made more compact by just recording the change in the value associated with the block rather than the value itself. In fact, if the image is binary, then we need to record only the value of the first block in the ordering because all the rest of the blocks in the ordering will alternate in value (although we did not do so in our example). Another alternative to two-dimensional runlength encoding when the image is binary is just to record the locations and sizes of all blocks of a given color. The locations and sizes of the remaining blocks can be determined by a process similar to that used in determining the locations and sizes of the blocks of the same color in the two-dimensional runlength encoding (see Exercise 24).

### Exercises

1. Give an algorithm to construct the value-based runlength encoding for an  $M \times M$  image represented by an array.
2. Give an algorithm to determine the value associated with a cell  $c$  in an  $M \times M$  image represented by a value-based runlength encoding.
3. Give an algorithm to construct the change-based runlength encoding for an  $M \times M$  binary image represented by an array.
4. Give an algorithm to determine the value associated with a cell  $c$  in an  $M \times M$  binary image represented by a change-based runlength encoding.
5. The runlength encoding that we have described traverses the cells in a row-by-row manner. An alternative is to traverse the cells in Morton order or Peano-Hilbert order. Repeat Exercises 1–4 for a runlength encoding based on a traversal of the cells in Morton and Peano-Hilbert order.
6. Give the Morton size ordering of the blocks of the region quadtree in Figure 2.15 in the form of a list of ordered pairs  $(a, b)$ , where  $a$  and  $b$  correspond to the value and size (i.e., power of 2) of each block. Assume that the tree is traversed in the order NW, NE, SW, and SE.
7. Give an algorithm to determine the value associated with a cell  $c$  having an upper-left corner at location  $(x, y)$  in an  $M \times M$  image ( $M$  is a power of 2) represented by a Morton size ordering.
8. Give an algorithm to determine the value associated with a cell  $c$  having an upper-left corner at location  $(x, y)$  in an  $M \times M$  image ( $M$  is a power of 2) represented by a Peano-Hilbert size ordering.
9. Give the DF-expression for the region quadtree in Figure 2.15 assuming a traversal of the tree in the order NW, NE, SW, and SE.
10. Give an algorithm to determine the value associated with a cell  $c$  having an upper-left corner at location  $(x, y)$  in an  $M \times M$  image ( $M$  is a power of 2) represented by a DF-expression.
11. Give an algorithm to determine the value associated with a cell  $c$  having an upper-left corner at location  $(x, y)$  in an  $M \times M$  image ( $M$  is a power of 2) represented by an S-tree.
12. The original formulation of the  $S^+$ -tree [970] uses a slightly different representation for the identifier corresponding to the first node  $N$  in each segment  $S$ . If the node is the root of the tree (which is not necessarily empty), then the identifier is empty. If the tree consists of just one leaf node and no nonleaf nodes, then the identifier is 1. Otherwise, the identifier consists of a sequence of directional codes corresponding to the path from the root of the tree to  $N$ , where each code is represented by a variable-length sequence of the two binary digits 0 and 1 as follows:

- (a) NW: 0,
- (b) NE: 01,
- (c) SW: 011,
- (d) SE: 0111.

This string is equivalent to the linear tree encoding of a tree  $T$  containing  $N$  having the property that all leaf nodes at positions preceding  $N$  are of the same color  $R$ , where  $R$  is different from the color of  $N$ . This encoding of the identifier is termed the *linear prefix* of  $S$ . Of course, the first page has no linear prefix. Give an algorithm to build an  $S^+$ -tree using this representation of the identifier corresponding to the first node  $N$  in each segment  $S$ .

Assume the following implementation for the  $S^+$ -tree [970]. In order for each segment to be self-contained, corresponding parts of the linear tree and the color table are stored on the same page, as is the linear prefix. Each page is assumed to be of the same size. Since the goal is to utilize as much of the available storage on each page as possible, the linear prefix and the linear tree are represented as one consecutive bitstring, while the color table is represented as another bitstring. These two bitstrings are stored in the page as stacks that grow towards each other. Use of the stacks means that two top-of-stack pointers must be stored with each page to indicate the positions of their last elements as some of the positions in the page may be unoccupied. In order to distinguish between the linear prefix and the linear tree, the length of the linear prefix is also recorded with each page

13. In the original presentation of the  $S^+$ -tree [970], each page was required to terminate with a leaf node. Is this absolutely necessary?
14. In the original presentation of the  $S^+$ -tree, it is described as a variant of a prefix  $B^+$ -tree [144] (see Appendix A), whereas, as we have seen, it is really just a  $B^+$ -tree. Using the definition of an  $S^+$ -tree in terms of a linear prefix given in Exercise 12, explain how such a characterization could have been made. *Hint:* Think about the possible interpretations of the values that serve as the keys in the two data structures.
15. Why can we not compute the size of each block in the Morton location ordering directly from the locations of successive blocks in the list instead of having to use the difference between their Morton numbers? For example, why can we not use the maximum or minimum differences between the corresponding  $x$  and  $y$  coordinate values of their location entries?
16. Suppose that you use a Peano-Hilbert location ordering. How can you determine the size of each block? Assume that, for each block  $b$ , we record the location of the pixel in  $b$ 's upper-left corner.
17. Give an algorithm to determine the locations and sizes of all blocks of the same value in a two-dimensional runlength encoding, given the locations of the upper-left corners of two successive blocks  $b_1$  and  $b_2$  with Morton numbers  $C_1$  and  $C_2$ , respectively. The result includes all blocks starting with  $b_1$  up to, but not including,  $b_2$ .
18. Suppose that in the Morton location ordering, instead of recording the location of each block's upper-left corner, the location of its lower-right corner (i.e., the location of the last pixel in the block is instead recorded). How would you compute the size of each block?
19. Suppose that the two-dimensional runlength encoding sequence is defined to consist of the last element of each subsequence of blocks of the same value rather than the first element. Give the resulting encoding of the region quadtree in Figure 2.158(b). Assume that the tree is traversed in the order NW, NE, SW, and SE.
20. Suppose that the two-dimensional runlength encoding sequence is defined to consist of the last element of each subsequence of blocks of the same value rather than the first element. Give a procedure similar to that given in Exercise 17 to reconstruct the Morton numbers of the blocks of the region quadtree given the Morton numbers of two successive blocks. If this is not possible, then how can you redefine the Morton number associated with each block so that it will work? Again, the inputs are the locations of the upper-left corners of two successive blocks  $b_1$  and  $b_2$  with Morton numbers  $C_1$  and  $C_2$ , respectively.
21. Give the two-dimensional runlength encoding for the region quadtree in Figure 2.15. Assume that the tree is traversed in the order NW, NE, SW, and SE.

22. Give an algorithm to determine the value associated with a cell  $c$  having an upper-left corner at location  $(x, y)$  in an  $M \times M$  image ( $M$  is a power of 2) represented by a two-dimensional runlength encoding.
23. Suppose that you base the two-dimensional runlength encoding on the Peano-Hilbert location ordering instead of the Morton location ordering. Give an algorithm to determine the value associated with a block  $b$  having an upper-left corner at location  $(x, y)$  in an  $M \times M$  image ( $M$  is a power of 2) represented by this variant of the two-dimensional runlength encoding.
24. Consider a binary image for which only the locations and sizes of the black blocks are recorded. Give an algorithm to determine the locations and sizes of the white blocks.
25. Give an algorithm to determine the value associated with a cell  $c$  having an upper-left corner at location  $(x, y)$  in an  $M \times M$  image ( $M$  is a power of 2) for which only the locations and sizes of the black blocks are recorded.

### 2.3.2 Chain Code

The same principles used in adapting runlength encoding to interior-based representations can also be used to a limited extent with some boundary-based representations. For example, in two dimensions, a common boundary-based representation is the chain code [638], which indicates the relative locations of the cells that make up the boundary of object  $o$ . In particular, it specifies the direction of each boundary element and the number of adjacent unit-sized cells that make up the boundary element. Given the location of the first cell in the sequence corresponding to the boundary of  $o$ , we can determine the boundary of  $o$  by just following the direction of the associated boundary element. Thus, there is no need to record the actual cells or their locations as now  $o$  is uniquely identified. Therefore, in the chain code, the locations of the boundary elements (i.e., the cells that are adjacent to them) are given implicitly while the nature of the boundary elements is given explicitly (i.e., the direction of the boundary element). Each object has a separate chain code. Of course, an object with holes (e.g., a doughnut) has several chain codes (i.e., 2 for a doughnut). In particular, it has one more chain code than holes. In the rest of this discussion, we assume, without loss of generality, that the objects do not have holes.

In order to see how the chain code is constructed, consider the object in Figure 2.158(a), which, as we recall, is embedded in an  $8 \times 8$  image array. Assume boundary elements in the form of unit vectors in the four principal directions (corresponding to the boundaries of the cells) so that the interior of the object is always to the right of the unit vectors. Without loss of generality, represent the directions by integer numbers  $i$  ranging from 0 to 3 corresponding to a unit vector having direction  $90 \cdot i$  degrees. In this case, starting from the lower-left corner of the object in Figure 2.158(a) and moving clockwise so that the interior of the object will be to the right of the unit vectors, the chain code for the boundary of the object is  $1^3 0^1 1^1 0^1 1^2 0^4 3^4 2^2 3^1 2^1 3^1 2^3$ , where the exponent is used as a shorthand notation to indicate the length (i.e., multiplicity) of the individual boundary elements in terms of the number of unit vectors they comprise. Notice the similarity of this approach to that used in obtaining the change-based runlength encoding from the value-based runlength encoding discussed earlier for the interior-based representations.

The chain code as described by us does not just record all of the possible changes that could be taking place in that it also records absolute values. In particular we recorded only the relative change of the locations of the cells adjacent to the boundary elements, while we recorded the absolute values of the directions of the boundary elements. Of course, we could also record the relative change in the directions of the boundary elements. We have just two possible changes in direction corresponding to a transition to the right (denoted as positive) or to the left (denoted as negative). A change in direction of 180 degrees would be meaningless as it would mean that the adjacent cell had zero area. Thus, we have achieved compression as, now, our directional component only requires one bit (corresponding to two possible choices) instead of two (corresponding to four possible choices), as is the case for the conventional chain code. Using such an implementation

and assuming that the first element of the chain code must contain the direction, the chain code for the object in Figure 2.158(a) becomes  $\uparrow^3 +^1 -^1 +^1 -^2 +^4 +^4 +^2 -^1 +^1 -^1 +^3$ . Once again, the exponent is used as a shorthand notation to indicate the length (i.e., multiplicity) of the individual boundary elements in terms of the number of unit vectors they comprise.

Using any of the variants of the chain code that we have described, determining the value associated with a particular cell  $c$  is not easy. The problem is that the chain code does not provide a mechanism to find the closest part of the boundary to the location of  $c$  without reconstructing the boundary. In other words, there is no correlation between the boundary segments and their locations. We know only their absolute directions or directions relative to the immediately preceding boundary element. We do not know their starting and ending positions without reconstructing the entire boundary, which is possible as we do know the starting position of the boundary. This process is analogous in spirit to the accumulation process used to determine the value associated with a cell in the case of the runlength encoding, with the difference that now we are accumulating lengths of the boundary with the same direction rather than lengths of sequences of consecutive pixels with the same value. Once the boundary has been reconstructed, we can find the value by use of a point-in-polygon test (e.g., [622]), although it is a rather tedious task without the aid of an index (recall Section 2.2).

### Exercises

1. Suppose that you use a chain code that records the relative change in the directions of the boundary elements. Prove that the number of positive transitions is always three more than the number of negative transitions. Assume that the object has no holes.
2. Suppose that you use a chain code that makes use of unit vectors in the four principal directions so that the interior of the object is always to the right of the unit vectors. Assume that the directions are represented by integer numbers  $i$  ranging from 0 to 3 corresponding to a unit vector having direction  $90 \cdot i$  degrees. Prove that the sum of the lengths of the boundary elements encoded by 0 is equal to those encoded by 2. Similarly, prove that the sum of the lengths of the boundary elements encoded by 1 is equal to those encoded by 3.

### 2.3.3 Vertex Representation

Unfortunately, as we mentioned earlier, the chain code cannot be used for data in a higher dimension than 2 for the same reasons that the polygon representation cannot be used. The problem is that, regardless of the dimension of the underlying space, the boundary elements lie on hyperplanes whose dimension is one less than the space in which they are embedded, and, in these cases, no obvious natural order for traversing them exists.

Nevertheless, even though boundary elements cannot be easily ordered on the basis of connectivity, the fact that vertices serve as locations where change takes place can be used as the basis of a data structure, known as the *vertex representation* [1744], for the interiors of regions. The vertex representation is similar in spirit to runlength encoding. The regions are not restricted to polygons. In particular, they can also be collections of rasters.

The vertex representation was originally developed for storing and processing VLSI masks [1744]. It was recently extended to handle axis-parallel polygons of arbitrary dimension [566, 567]. It applies techniques similar to that of runlength encoding across several dimensions to axis-parallel polygons that are represented using blocks of arbitrary size located at arbitrary positions. Its use results in decomposing space into multidimensional blocks (not necessarily disjoint), which are aggregated using techniques, such as CSG (see Section 2.2), by attaching weights to the blocks. These weights enable the blocks to be manipulated in a manner analogous to the use of regularized set-union and set-difference operations in CSG. However, instead of using combining elements that

Figure 2.160  
Example of a vertex representation  
for an axis-parallel polygon.

are blocks of finite area or halfspaces as in CSG, the vertex representation makes use of *vertices* that serve as tips of infinite cones.

Each cone is equivalent to an unbounded object formed by the intersection of  $d$  halfspaces that are parallel to the  $d$  coordinate axes passing through a particular point, termed the *vertex*, which is the tip of the cone. As stated above, in some sense, the vertex representation resembles CSG where the primitive elements are halfspaces. In particular, the vertex plays the role of a CSG primitive, and the region that it represents is equivalent to the intersection of the halfspaces that pass through it. However, unlike CSG, the vertex representation of an object is unique (but see Exercise 3). The vertices have signs (termed *weights* and defined below) associated with them, indicating whether the space spanned by their cones is included in, or excluded from, the object being modeled. The space spanned by the union of the cones defines the object being modeled. It is interesting to observe that the cones corresponding to the vertices are like infinite blocks, thereby slightly resembling a region octree in the sense that the object being modeled is also defined by the union of the blocks. However, unlike the region octree, since the blocks need not be disjoint, the vertex representation of a particular object (i.e., the constituent blocks) is invariant under translation.

Ignoring for the moment the way in which the weights and vertices are determined (but see below), Figure 2.160 is an example of a vertex representation for an axis-parallel polygon. Notice that the vertices labeled with a weight of +1 correspond to infinite cones that are “included” while those labeled with a weight of -1 correspond to infinite cones that are “excluded.”

Now, let us turn to a more formal definition of the vertex representation. The vertex representation is primarily designed to represent axis-parallel scalar fields (i.e., objects whose boundaries are parallel to the coordinate axes in our application). A scalar field is simply a function that maps points of the domain, which is a  $d$ -dimensional space, to scalar values. An axis-parallel scalar field is a scalar field where regions of the domain that are mapped to the same value are delimited by faces parallel to the coordinate axes. Thus, each cone is a scalar field. The overall idea behind the use of the vertex representation for modeling axis-parallel polygons is to view the polygons as scalar fields where points inside the polygons are mapped to 1, and points outside the polygons are mapped to 0.

Figure 2.161  
(a) A vertex (black dot) and some of  
the points influenced by it (black  
squares). (b) The point (black  
square) is influenced only by the  
vertices shown as black dots.

A vertex<sup>52</sup>  $v$  is defined as a pair  $(p, \alpha)$ , where  $p$  is the location of  $v$  (i.e., it is a point), and  $\alpha$  is a nonzero integer value known as the *weight* of  $v$ . The weight  $\alpha$  is used to determine the value of the scalar field anchored at location  $p$ . In particular, a vertex at a location  $p = (p_1, p_2, \dots, p_d)$  with weight  $\alpha$  has the effect of adding  $\alpha$  to the mapping of all points  $q = (q_1, q_2, \dots, q_d)$  such that  $q_i \geq p_i$  for all  $i = 1 \dots d$  (see Figure 2.161(a)). As a consequence, we can tell if a point  $q$  is inside or outside the polygon by adding the weights of all vertices that contribute to its mapping—that is, a vertex at point  $p$  contributes to the mapping of  $q$  if and only if  $p_i \leq q_i$  for all  $i = 1 \dots d$  (see Figure 2.161(b)). Therefore, given a particular cell  $c$  with a lower-left corner at location  $l$ , determining the value associated with  $c$  is a simple process, consisting of finding all vertices whose corresponding cones contain  $l$  and adding up their weights. An alternative way of characterizing this process is to say that we add the weights of all vertices whose location is dominated (e.g., [1511]) by  $l$ . The process of determining the relevant cones can be made efficient by using an index on the vertices, such as a variant of a point quadtree, point k-d tree, and so on (see Chapter 1).

The weights enable us to represent axis-parallel polygons as a collection of vertices by using negative weight values at some of the vertices. In particular, a set of vertices  $V = \{v_1, v_2, \dots, v_n\}$  induces a scalar field  $Q_V = \sum_{i=1}^n Q_{v_i}$ . In other words, the scalar field induced by a set of vertices is the sum of the scalar field induced by each vertex separately.

<sup>52</sup> Note that we use the term *vertex* to refer to a mathematical entity that does not necessarily correspond to the common definition of “vertex” in geometry.

This means that the operation of addition is well defined for vertices. For example, recall Figure 2.160, which is the vertex representation for a simple polygon.

At this point, it is important to ask how we determine the locations that make up the vertices and their weights. Intuitively, the vertices are the locations where different boundary elements meet, and hence the boundary changes (i.e., it bends by 90 degrees). There are three methods of identifying the vertices. The first method is visual and is the natural and intuitive way. Once the location  $l$  of a vertex  $v$  has been identified, its weight may be determined by analyzing how the scalar field changes in the immediate neighborhood of  $l$ . For instance, in two dimensions, the scalar field must be evaluated immediately to the northeast, northwest, southeast, and southwest of  $l$ . Once this is done, it is possible to determine the weight of  $v$  by inspection (we discuss how to perform the actual computation below). Of course, more neighbors must be examined in three dimensions and higher. As we can see, this method is simple in two dimensions. However, it becomes increasingly more complex in three dimensions and higher because it requires that we be able to visualize the object, which is not an easy task, especially in four dimensions and higher.

The second method is very similar to the first method except that it is more formal. In particular, it consists of interpreting the vertex representation as a differential code for rasters and just retaining the locations with a nonzero weight. To explain why this works, we make two important observations. These observations are in the context of two-dimensional data, but the extensions to higher-dimensional data are not difficult. Our first observation is that, if a vertex  $p$  is placed at a certain point of the domain space, then its weight represents the difference between the sum of the fields induced by all other vertices that have  $p$  inside their cones and the actual value of the field inside the cone having its tip at  $p$ . For example, in Figure 2.162,  $p$  is inside the cones of vertices  $a$ ,  $b$ ,  $c$ , and  $d$ . Therefore, if we want to map the shaded region to the value  $S$ , then we must add to the representation a vertex placed at  $p$  with weight  $S - \text{wgt}(a) - \text{wgt}(b) - \text{wgt}(c) - \text{wgt}(d)$ , where  $\text{wgt}(v)$  refers to the weight of vertex  $v$ .

Our second observation is based on a definition of the *weight of a cell  $c$  corresponding to a pixel* as being the weight of a vertex placed at the lower-left corner of  $c$ . Using this definition, we observe that the weight of a vertex that lies in the center of a  $2 \times 2$  block of pixels is dependent only on the values of the pixels of the block. This observation is aided by considering the four adjacent cells (i.e., pixels) with values  $A$ ,  $B$ ,  $C$ , and  $D$  of a two-dimensional raster, as depicted in Figure 2.163. The cell with value  $A$  is influenced by vertices lying in regions  $R_1$  and  $R_2$ , the cell with value  $B$  by vertices lying in region  $R_2$ , and the cell with value  $C$  by vertices lying in regions  $R_2$  and  $R_3$ . Thus, if we want the upper-right cell to have a value of  $D$ , then a vertex should be placed at point  $p$  with weight equal to the difference between  $D$  and the weights of all vertices in regions  $R_1$ ,  $R_2$ , and  $R_3$ . These weight sums can be rewritten in terms of  $A$ ,  $B$ ,  $C$ , and  $D$  by observing that

- $A = \text{sum}(R_1) + \text{sum}(R_2)$ ,
- $B = \text{sum}(R_2)$ ,
- $C = \text{sum}(R_2) + \text{sum}(R_3)$ .

From this we have that

- $\text{sum}(R_1) = A - B$ ,
- $\text{sum}(R_2) = B$ ,
- $\text{sum}(R_3) = C - B$ .

Subtracting these values from  $D$  leads to the weight for the vertex at  $p$  being given by

$$\text{wgt}(D) = D - (A - B) - B - (C - B) = D + B - A - C.$$

### Section 2.3 DIFFERENCE-BASED COMPACTION METHODS

Figure 2.162  
Vertices that influence the scalar field at a point  $p$ .

Figure 2.163  
Example of how the interpretation of the vertex representation as a differential code for rasters is used to determine the weight of the vertex at  $p$  to be  $D + B - A - C$ .

Figure 2.164  
Pixel patterns that generate nonzero  
vertex weights.

The importance of this second observation lies in the fact that it permits us to encode the images by computing the weight at a particular pixel (e.g., the one at the upper-right cell in a  $2 \times 2$  block) without having to keep track of the weight sums over all possible regions. In particular, the weight at the upper-right corner depends only on the values of the pixels at the lower-left, lower-right, upper-right, and upper-left corners. Moreover, using this result, we see that, when we apply the differential coding scheme to a general raster, vertices (i.e., points with nonzero weights) will be generated only at certain positions. In order to see this, consider a two-dimensional raster representing a monochromatic image, where black pixels are mapped to 1 and white pixels to 0. We examine the 16 possible configurations of  $2 \times 2$  pixels focusing on a pixel at position D using the labeling given in Figure 2.163. In particular, vertices will be generated in just 10 out of the 16 configurations, as depicted in Figure 2.164. By inspection, we notice that regions that are uniformly black or white, as well as regions containing strictly horizontal or vertical boundaries, do not generate vertices. In summary, not surprisingly, we find that only groups of pixels near corners of features generate nonzero codes (i.e., vertices).

The third method is procedural. It is best understood by examining the construction of the vertex representation of hyperrectangles in  $d$  dimensions. The idea is to sweep a hyperrectangle in  $d - 1$  dimensions along the  $d$ th axis. The process starts out with the equivalent of a hyperrectangle in one dimension ( $x$ ), which is an interval. In particular, it is the scalar field that maps the interval  $[a_1, b_1]$  to 1 and all other points to 0. This field is represented with two vertices: one at  $x = a_1$  with weight  $+1$  and another at  $x = b_1$  with weight  $-1$ .

Next, we transform this one-dimensional interval into a two-dimensional interval by adding to each vertex a second coordinate ( $y$ ) equal to  $a_2$ . This results in a two-dimensional scalar field where the region of space being mapped to 1 is bounded by line  $y = a_2$  but extends towards  $+\infty$  along the  $y$  axis. Thus, we need to add two other vertices with coordinates  $(a_1, b_2)$  and  $(b_1, b_2)$  and weights  $-1$  and  $+1$ , respectively, which will provide another boundary adjacent to line  $y = b_2$ .

This idea can be extended easily to higher dimensions. If we start with a set  $L$  of vertices representing a hyperrectangle in  $(d - 1)$ -dimensional space, then we may represent a hyperrectangle defined in  $d$ -dimensional space by a set  $L'$  obtained through the following process:

1. Copy  $L$  to  $L'$ , adding a new coordinate to each vertex, say,  $a_d$ .
2. Append  $L$  to  $L'$ , adding a new coordinate to each vertex, say,  $b_d$ , where  $b_d > a_d$ , and with weights changed from  $+1$  to  $-1$  and vice versa.

Figure 2.165 shows how this process can be repeated in order to build a vertex representation for a hyperrectangle in three dimensions—that is, a parallelepiped.

This method can also be applied to objects that need not be hyperrectangles. In particular, it can be applied to arbitrary rasters by using the sweep method to construct one-dimensional vertex representations for successive rows in the image, followed by sweeping the rows along the columns and subtracting the weights of vertices in corresponding positions. The same technique is applied to higher-dimensional data by applying the sweep-subtraction paradigm to the planes.

This procedure is best understood by examining the result of its application to the two-dimensional raster given in Figure 2.166(a). Figure 2.166(b) is the result of the application of the algorithm to the individual rows, and Figure 2.166(c) is the final vertex representation. Figure 2.166(a) is similar to the result obtained using traditional runlength encoding, which applies compression only in one dimension; the vertex representation, however, applies compression in the remaining dimensions as well, as seen in Figure 2.166(c). Since we are constructing a differential code, we must assume a reference value of 0 for the pixels that are outside the region spanned by the two-dimensional raster and on its boundary. Thus, when we process the first pixel of a row (as well as an entire row in the sweep of rows phase), we assume a (nonexistent) previous pixel (or entire row) with a value of 0.

Figure 2.165 Construction of a hyperrectangle in three dimensions. The line segment from  $a_1$  to  $b_1$  shown in (a) is swept in the  $y$ -direction from  $a_2$  to  $b_2$  to form the two-dimensional rectangle given in (b), which in turn is swept along the  $z$  axis from  $a_3$  to  $b_3$ , resulting in the 3-D parallelepiped given in (c).

It should be clear that the algorithm that we described for the hyperrectangles is a subset of the general algorithm given above in that the starting point of the one-dimensional interval corresponds to the cone that is included in the object, and the ending point of the one-dimensional interval corresponds to the cone that is excluded from the object. The general algorithm determines the weights of the locations that make up the vertices in a systematic manner by traversing the locations in each row, followed by the rows that make up each plane, and so on. This order is known as *inverse lexicographic order* and is illustrated in Figure 2.167 for the vertices  $a$ ,  $b$ ,  $c$ , and  $d$ , which would be visited in the order  $c$ ,  $d$ ,  $a$ , and  $b$ .

This traversal process is facilitated by storing the vertices in a list in the order in which they are visited (i.e., inverse lexicographic order). For example, in two dimensions, they are sorted first on the basis of their  $y$  coordinate value and then by their  $x$  coordinate value. This representation is termed a *vertex list*, and it has been used as the basis of several algorithms for operations on the vertex representation, including set operations [567, 565] and coarsening [569]. The utility of the vertex list representation is that it permits these algorithms to employ the plane-sweep paradigm (or line-sweep in two dimensions) [1511]. For example, in two dimensions, this is compatible with the sweeping of a line perpendicular to the  $y$  axis in the direction of increasing  $y$  coordinate values.

As an example of the utility of implementing the vertex representation using a vertex list, we examine the conversion of rasters to a vertex representation implemented as a vertex list. This is given below by the following recursive algorithm, called RASTERTOVLIST, with parameters  $d$  and  $R$  corresponding to the  $d$ -dimensional raster  $R$  being processed.

1. If  $d = 1$ , then for each pair of adjacent pixels  $R(i)$ ,  $R(i + 1)$  at locations  $i$  and  $i + 1$ , respectively, along the least significant coordinate value, compute  $weight = R(i + 1) - R(i)$ . Output a vertex at location  $i$  if  $weight$  is nonzero.
2. Otherwise (i.e.,  $d > 1$ ), for each pair of consecutive  $(d - 1)$ -dimensional rasters  $R(i)$  and  $R(i + 1)$  at  $i$  and  $i + 1$ , respectively, along the  $d$ th coordinate value,
  - (a) Compute vertex lists  $L_i$  and  $L_{i+1}$  for  $(d - 1)$ -dimensional rasters  $R(i)$  and  $R(i + 1)$ , respectively, by recursive invocation of procedure RASTERTOVLIST (i.e., steps 1 and 2).

Figure 2.166 (a) A sample 2-D raster; in (b), each row was processed to yield 1-D vertex lists, and in (c), consecutive 1-D vertex lists are subtracted to yield a 2-D vertex list for the raster.

Figure 2.167 Vertices  $a$ ,  $b$ ,  $c$ , and  $d$  would be visited by the sweeping line in the order  $c$ ,  $d$ ,  $a$ ,  $b$ .

(a)

(b)

(c)

(d)

Figure 2.168  
Example object whose vertex representations differ depending on how its boundary is interpreted. Interpreting the boundary as in (a) yields the vertex representation in (b), whereas interpreting it as in (c) results in the vertex representation given in (d).

- (b) Compute  $S = add(L_{i+1}, L_i, -1)$ , which subtracts the two vertex lists.
- (c) Make all vertices of  $S$   $d$ -dimensional by appending  $i$  as the value of the  $d$ th coordinate value to their positions, and output them.

Given a particular cell  $c$  having a lower-left corner at location  $l$ , determining the value associated with  $c$  is achieved by finding all vertices whose corresponding cones contain  $l$  and adding up their weights. This process requires that we take into account the fact that we are dealing with a vertex list implementation of the vertex representation, which means that we need to process the list in a particular order. A simple approach would partially reconstruct the raster in an analogous manner to that used by chain-based runlength encoding (i.e., a process of accumulating changes in values) by scanning the vertex list element-by-element, adding up the weights of vertices that are “dominated” by  $l$ . A more elegant (and general, in terms of arbitrary dimensions) way of describing this process is to use a procedure that works in the inverse manner as the RASTERTOVLIST procedure given above (see Exercises 5 and 6).

The vertex list implementation of the vertex representation demonstrates why we say that the vertex representation is a variant of runlength encoding. In particular, observe that the only pixels for which values are recorded in the vertex list are those at which the pixel values change. The facts that the vertex list implementation of the vertex representation orders the pixels in raster-scan order (i.e., the pixel values in the image are ordered by rows) and that only changes in the values are recorded demonstrate why we say that the vertex representation is a variant of runlength encoding. The main difference from the process of runlength encoding for the multidimensional array described earlier that was applied only to the rows is that, in the case of the vertex representation, we are not restricted to blocks of a fixed size (e.g., squares or congruent blocks). Of course, this is not quite true because we restrict ourselves to congruent blocks of infinite size (anchored at the vertices). In essence, the vertex representation is a combination of an implicit interior-based representation and an implicit boundary-based representation in the sense that both the interiors and boundaries of regions are represented implicitly through the aid of a single vertex, which is the tip of a cone. Moreover, only the changes in the values are recorded. Therefore, we see that, using the vertex list implementation of the vertex representation, we have an ordering of the pixels, which is analogous to a raster-scan order (i.e., the pixel values in the image are ordered by rows).

The main difference from the process of runlength encoding for the multidimensional array described earlier that was applied only to the rows is that, in the case of the vertex representation, we are not restricted to blocks of a fixed size (e.g., squares or congruent blocks). Of course, this is not quite true as we restrict ourselves to congruent blocks of infinite size (anchored at the vertices). In essence, the vertex representation is a combination of an implicit interior-based representation and an implicit boundary-based representation in the sense that both the interiors and boundaries of regions are represented implicitly through the aid of a single vertex, which is the tip of a cone.

**Exercises**

1. Assume that axis-parallel polygons are scalar fields where points inside the polygons are mapped to 1, and points outside the polygons are mapped to 0. Given a vertex representation of a two-dimensional axis-parallel polygon, prove that any vertex  $p$  at a position given by  $(x_0, y_0)$  such that no other point  $(x, y)$  on the boundary of the polygon that satisfies  $(x < x_0) \wedge (y < y_0)$  will have weight equal to +1.
2. How does the vertex representation deal with polygons containing holes?
3. In the text, we state that the vertex representation of an axis-parallel polygon is unique. How do you reconcile this statement with the fact that the object in Figure 2.168 can have two different vertex representations, depending on how its boundary is interpreted? In particular, interpreting the boundary as in (a) yields the vertex representation in (b), whereas interpreting it as in (c) results in the vertex representation given in (d).

4. It has been observed [567] that, in two dimensions, for a given simple axis-parallel polygon (i.e., non-self-intersecting), the weights of adjacent vertices along the border of the polygon always alternate between  $+1$  and  $-1$  as they are visited in clockwise or counterclockwise order. Prove that this is true.
5. Given a two-dimensional raster image represented by a vertex list, give an algorithm to determine the value associated with a location  $c$ . The algorithm should be an inverse of the procedure `RASTERTOVLIST` used to convert a raster to a vertex representation implemented as a vertex list.
6. Given an arbitrary  $d$ -dimensional raster image represented by a vertex list, give an algorithm to determine the value associated with a location  $c$ . The algorithm should be an inverse of the procedure `RASTERTOVLIST` used to convert a raster to a vertex representation implemented as a vertex list.
7. Assuming a vertex representation implemented as a vertex list, give an algorithm to perform set-theoretic operations such as union and intersection.
8. The vertex list implementation of the vertex representation orders the vertices in inverse lexicographic order. This is a variant of row order (recall the discussion in Section 2.1.1.2 and Figure 2.5(a)). Suppose that we order the vertices using another ordering, such as the Morton or the Peano–Hilbert order. How would this affect the implementation of some of the operations on vertex lists. For example, discuss the effect on the algorithm for set-theoretic operations in Exercise 7.
9. How would you extend the vertex list representation to deal with polygons whose faces are not axis parallel or not necessarily even orthogonal?

## 2.4 Historical Overview

In this section we give a brief, and very incomplete, historical overview of the method of recursive decomposition as used in the representation and processing of images and regions into blocks. There is a heavy emphasis on the quadtree and octree methods as these were the earliest and most prevalent examples of the use of this method. The origin of the principle of recursive decomposition is difficult to determine. Most likely its quadtree realization was first seen as a way of aggregating blocks of zeros in sparse matrices. Indeed, Hoare [858] attributes a one-level decomposition of a matrix into square blocks to Dijkstra. Morton [1317] used it as a means of indexing into a geographic database (i.e., it acts as a spatial index).

Warnock, in a pair of reports that serve as landmarks in the computer graphics literature [1959, 1961], described the implementation of hidden-line and hidden-surface elimination algorithms using a recursive decomposition of the picture area. The picture area is repeatedly subdivided into rectangles that are successively smaller while it is searched for areas that are sufficiently simple to be displayed.

Klinger [1035] and Klinger and Dyer [1036] applied these ideas to pattern recognition and image processing using the term *Q-tree* [1036]. Hunter [901] used them in an animation application and was the first to use the *quadtree* in such a context. In this text, we use the term *region quadtree* to describe the result, although, as we point out in Sections 1.4.2.1 and 1.4.2.2 of Chapter 1, a more precise term would be *quadtrie* as the resulting structure is really a trie [635] (recall the definition given in the opening discussion in Chapter 1).

Regardless of the terminology used, these applications were motivated by a desire to obtain a systematic way to represent homogeneous parts of an image. This resulted in what is currently known as the region quadtree. Thus, to transform the data into a region quadtree, a criterion must be chosen for deciding that an image is homogeneous (i.e., uniform). One such criterion is that the standard deviation of its gray levels is below a given threshold  $t$ . Using this criterion, the image array is successively subdivided into quadrants, subquadrants, and so on, until homogeneous blocks are obtained. This process

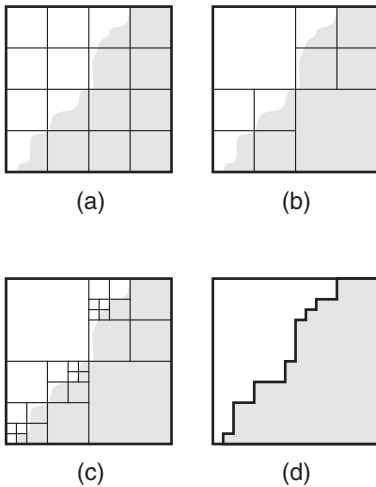

Figure 2.169  
Example illustrating the split-and-merge segmentation procedure: (a) start, (b) merge, (c) split, and (d) grouping.

leads to a regular decomposition. If one associates with each leaf node the mean gray level of its block, then the resulting region quadtree will completely specify a piecewise approximation to the image where each homogeneous block is represented by its mean. The case where  $t = 0$  (i.e., a block is not homogeneous unless its gray level is constant) is of particular interest since it permits an exact reconstruction of the image from its quadtree.

Note that the blocks of the region quadtree do not necessarily correspond to maximal homogeneous regions in the image. Often there exist unions of blocks that are still homogeneous. To obtain a segmentation of the image into maximal homogeneous regions, we must allow merging of adjacent blocks (or unions of blocks) as long as the resulting region remains homogeneous. This is achieved by a *split-and-merge segmentation algorithm* [879]. However, the resulting partition will no longer be represented by a region quadtree; instead, the final representation is in the form of an adjacency graph. Thus, the region quadtree is used as an initial step in the segmentation process.

For example, Figure 2.169(b–d) demonstrates the results of the application, in sequence, of merging, splitting, and grouping to the initial image decomposition of Figure 2.169(a). In this case, the image is initially decomposed into 16 equal-size square blocks. Next, the *merge step* attempts to form larger blocks by recursively merging groups of four homogeneous “siblings” (e.g., the four blocks in the NW and SE quadrants of Figure 2.169(b)). The *split step* recursively decomposes blocks that are not homogeneous (e.g., in the NE and SW quadrants of Figure 2.169(c)) until a particular homogeneity criterion is satisfied or a given level is encountered. Finally, the *grouping step* aggregates all homogeneous 4-adjacent black blocks into one region apiece; the 8-adjacent white blocks are likewise aggregated into white regions (see Figure 2.169(d)).

Quadtree methods have also been used in image understanding. Kelly [1015] introduced the concept of a *plan*, which is a small picture whose pixels represent gray-scale averages over  $8 \times 8$  blocks of a larger picture. Needless effort in edge detection is avoided by first determining edges in the plan and then using these edges to search selectively for edges in the larger picture. Generalizations of this idea motivated the development of multiresolution image representations, for example, the recognition cone of Uhr [1898], the preprocessing cone of Riseman and Arbib [1563], and the pyramid of Tanimoto and Pavlidis [1845]. Of these representations, the pyramid is the closest relative of the region quadtree.

Given a  $2^n \times 2^n$  image array, say  $A(n)$ , a *pyramid* is a sequence of arrays  $\{A(i)\}$  such that  $A(i - 1)$  is a version of  $A(i)$  at half the scale of  $A(i)$ , and so on, and  $A(0)$  is a single pixel. The pyramid is discussed in Section 2.1.5.1, where we observe that the pyramid is a multiresolution representation, whereas the region quadtree is a variable resolution representation. Another analogy is that the pyramid is a complete quadtree [1044]. It should be clear that a pyramid can also be defined in a more general way by permitting finer scales of resolution than the power of 2 scale.

The above conventional definition of a pyramid is based on nonoverlapping  $2 \times 2$  blocks of pixels. An alternative definition, termed an *overlapping pyramid*, uses overlapping blocks of pixels. One of the simplest schemes makes use of  $4 \times 4$  blocks that overlap by 50% in both the horizontal and vertical directions [286]. For example, Figure 2.170 is a  $2^3 \times 2^3$  array, say  $A(3)$ , whose pixels are labeled 1–64. Figure 2.171 is  $A(2)$ , corresponding to Figure 2.170, with elements labeled A–P. The  $4 \times 4$  neighborhood corresponding to element F in Figure 2.171 consists of pixels 10–13, 18–21, 26–29, and 34–37. This method implies that each block at a given level participates in four blocks at the immediately higher level. Thus, the containment relations between blocks no longer form a tree. For example, pixel 28 participates in blocks F, G, J, and K in the next higher level (see Figure 2.172, where the four neighborhoods corresponding to F, G, J, and K are drawn as squares).

To avoid treating border cases differently, each level in the overlapping pyramid is assumed to be cyclically closed (i.e., the top row at each level is adjacent to the bottom row and likewise for the columns at the extreme left and right of each level). Once again, we say that the value of a node is the average of the values of the nodes in its block on the immediately lower level. The overlapping pyramid may be compared with the Quadtree Medial Axis Transform (QMAT) [1626, 1630] (see Section 2.1.2.4) in the sense that both may result in nondisjoint decompositions of space.

Pyramids have been applied to the problems of feature detection and extraction since they can be used to limit the scope of the search. Once a piece of information of interest is found at a coarse level, the finer-resolution levels can be searched. This approach was followed by Davis and Roussopoulos [447] in approximate pattern matching. Pyramids can also be used for encoding information about edges, lines, and curves in an image [1089, 1762]. One note of caution: the reduction of resolution has an effect on the visual appearance of edges and small objects [1842]. In particular, at a coarser level of resolution, edges tend to get smeared, and region separation may disappear. Pyramids have also been used as the starting point for a “split-and-merge” segmentation algorithm [1495].

Recursive decomposition methods have also been used to facilitate control in robotics and vision systems. The SRI robot project [1378] used a three-level decomposition of space to represent a map of the robot’s world. Eastman [527] observed that recursive decomposition might be used for space planning in an architectural context and presents a simplified version of the SRI robot representation. Tucker [1894] uses quadtree refinement as a control strategy for an expert computer vision system.

The three-dimensional variant of the region quadtree—that is, the region octree—was developed independently by a number of researchers. Hunter [901] mentioned it as a natural extension of the region quadtree. Reddy and Rubin [1548] proposed the region octree as one of three representations for solid objects. The second is a three-dimensional generalization of the point quadtree of Finkel and Bentley [614]—that is, a decomposition into rectangular parallelepipeds (as opposed to cubes) with planes perpendicular to the  $x$ ,  $y$ , and  $z$  axes. The third breaks the object into rectangular parallelepipeds that are not necessarily aligned with an axis. The parallelepipeds are of arbitrary sizes and orientations. Each parallelepiped is recursively subdivided into parallelepipeds in the coordinate space of the enclosing parallelepiped. Reddy and Rubin prefer the third approach for its ease of display.

Situated somewhere in between the second and third approaches of Reddy and Rubin is the method of Brooks and Lozano-Perez [268] (see also [1206]), who use a recursive decomposition of space into an arbitrary number of rectangular parallelepipeds, with planes perpendicular to the  $x$ ,  $y$ , and  $z$  axes, to model space in solving the *findpath* or *piano movers* problem [1700] in robotics. This problem arises when, in planning the motion of a robot in an environment containing known obstacles, the desired solution is a collision-free path obtained by use of a search. Faverjon [599] discusses an approach to this problem that uses an octree, as do Samet and Tamminen [1658] and Fujimura and Samet [663]. Jackins and Tanimoto [932] adapted Hunter and Steiglitz’s quadtree translation algorithm [901, 904] to objects represented by region octrees. Meagher [1276] developed numerous algorithms for performing solid modeling operations in an environment where the region octree is the underlying representation. Yau and Srihari [2050] extended the region octree to arbitrary dimensions in the process of developing algorithms to handle medical images.

Both quadtrees and octrees are frequently used in the construction of meshes for finite-element analysis. The use of recursive decomposition for meshes was initially suggested by Rheinboldt and Mesztenyi [1561]. Yerry and Shephard [2051] adapted the quadtree and octree to generate meshes automatically for three-dimensional solids represented by a superquadric surface-based modeler. This has been extended by Kela,

Voelcker, and Goldak [1014] (see also [1013]) to mesh boundary regions directly, rather than through discrete approximations, and to facilitate incremental adaptive analysis by exploiting the spatial index nature of the quadtree and octree.

Quadtree decompositions have also found much use in solving the *N-body problem* (also known as the *multibody problem*). In particular, the solutions involve reducing the computation time from  $O(N^2)$  to  $O(N \cdot \log N)$  and  $O(N)$ . Some examples include [50, 68, 126, 297, 571, 753, 755, 1001, 1608].

## Intervals and Small Rectangles

---

The problem of how to represent the space spanned by collections of small rectangles arises in many applications. The space spanned by the rectangles can also be viewed as the  $d$ -dimensional Cartesian product of  $d$  one-dimensional intervals (i.e., spheres), and thus the problem is often cast as one of representing one-dimensional intervals. The most common application is one where rectangles are used to approximate other shapes for which they serve as the minimum enclosing objects (recall our discussion of the R-tree and other object-based hierarchical interior-based representations in Section 2.1.5.2 of Chapter 2). For example, rectangles can be used in cartographic applications to approximate objects such as lakes, forests, and hills [1258]. Of course, the exact boundaries of the object are also stored, but usually they are only accessed if a need for greater precision exists. Rectangles are also used for design rule checking in very large-scale integration (VLSI) design applications as a model of chip components for the analysis of their proper placement. Again, the rectangles serve as minimum enclosing objects. This process includes such tasks as determining whether components intersect and insuring the satisfaction of constraints involving factors such as minimum separation and width. These tasks have a practical significance in that they can be used to avoid design flaws.

The size of the collection depends on the application; it can vary tremendously. For example, in cartographic applications, the number of elements in the collection is usually small, and frequently the sizes of the rectangles are of the same order of magnitude as the space from which they are drawn. On the other hand, in VLSI design applications, the size of the collection is quite large (e.g., millions of components), and the sizes of the rectangles are several orders of magnitude smaller than the space from which they are drawn.

In this chapter, we focus primarily on how to represent a large collection of rectangles common in VLSI design applications. However, our techniques are equally applicable to other domains. We assume that all rectangles are positioned so that their sides are parallel to the  $x$  and  $y$  coordinate axes. Our presentation makes use of representations for one-dimensional intervals rooted in computational geometry as well as combines representations for multidimensional point data (see Chapter 1) and objects (see Chapter 2).

The principal tasks to be performed are similar to those described in Chapter 1. They range from basic operations, such as insertion and deletion, to more complex queries that include exact match, partial match, range, partial range, finding all objects (e.g., rectangles) in a given region, finding nearest neighbors with respect to a given metric for the data domain, and even join queries [1899]. The most common of these queries involves proximity relations and is classified into two classes by Hinrichs [839]. The first is an intersection query that seeks to determine if two sets intersect. The second is a subset relation and can be formulated in terms of enclosure (i.e., is  $A$  a subset of  $B$ ?) or of containment (i.e., does  $A$  contain  $B$ ?).

In describing queries involving these relations, we must be careful to distinguish between a point and an object. A *point* is an element in the  $d$ -dimensional space from which the objects are drawn. It is not an element of the space into which the objects may be mapped by a particular representation. For example, in the case of a collection of rectangles in two dimensions, a point is an element of the Euclidean plane and not a rectangle, even though we may choose to represent each rectangle by a point in some multidimensional space.

In this chapter, we focus on three types of proximity queries. The first, and most common, is the *point query*, which finds all the objects that contain a given point. It is important to distinguish this query from the point query discussed in Chapter 1 that seeks to determine if a given point  $p$  is actually in the dataset (more accurately described as an exact match query). The second type is a *point set query*, which, given a relation  $\oplus$  and a set of points  $Q$  (typically a region), finds the set of objects  $S$  such that  $S \oplus Q$  holds. An example is a query, more commonly known as a *window operation*, that finds all the rectangles that intersect a given region. In this example, the relation  $\oplus$  is defined by  $S \oplus Q$  if  $S \cap Q \neq \emptyset$ , and  $Q$  is the query window. The third type of query is a *geometric join query* (also known as a *spatial join query* [1415]), which, for a relation  $\oplus$  and two classes of objects  $O_1$  and  $O_2$  with corresponding subsets  $S_1$  and  $S_2$ , finds all pairs  $(P_1, P_2)$  with  $P_1 \in S_1$ ,  $P_2 \in S_2$ , and  $P_1 \oplus P_2$ . An example is a query that determines all pairs of overlapping rectangles. In such a case, both  $O_1$  and  $O_2$  correspond to the set of rectangles, and  $\oplus$  is the intersection relation. In our examples,  $S_1$  and  $S_2$  are usually the same subsets, although the more general problem can also be handled.

Initially, we present representations that are designed for use with the plane-sweep solution paradigm [119, 1511, 1740]. For many tasks, use of this paradigm yields worst-case optimal solutions in time and space. We examine its use in solving two problems:

1. Reporting all intersections between rectangles (the rectangle intersection problem—Section 3.1)
2. Computing the area of a collection of  $d$ -dimensional rectangles (the measure problem—Section 3.2)

We focus on the segment, interval, and priority search trees. They represent a rectangle by the intervals that form its boundaries. However, these representations are usually for formulations of the tasks in a static environment. This means that the identities of all the rectangles must be known if the worst-case time and space bounds are to hold. Furthermore, for some tasks, the addition of a single object to the database may force the reexecution of the algorithm on the entire database.

The remaining representations are for a dynamic environment. They are differentiated by the way in which each rectangle is represented. The first type of representation reduces each rectangle to a point in a usually higher-dimensional space and then treats the problem as if it involves a collection of points (Section 3.3). The second type is region-based in the sense that the subdivision of the space from which the rectangles are drawn depends on the physical extent of the rectangle—it does not just treat a rectangle as one point (Section 3.4). Many of these representations are variants of the quadtree. We show that these quadtree variants are very similar to the segment and interval trees that are used with the plane-sweep paradigm. Moreover, we observe that the quadtree serves as a multidimensional sort and that the process of traversing it is analogous to a plane sweep in multiple dimensions.

### 3.1 Plane-Sweep Methods and the Rectangle Intersection Problem

The term *plane sweep* is used to characterize a paradigm employed to solve geometric problems by sweeping a line (plane in three dimensions) across the plane (space in three dimensions) and halting at points where the line (plane) makes its first or last intersection

with any of the objects being processed. At these points, the solution is partially computed so that at the end of the sweep a final solution is available. In this discussion, we are dealing with two-dimensional data. Assume, without loss of generality, that the line is swept in the horizontal direction and from left to right.

To use the plane-sweep technique, we need to organize two sets of data. The first set consists of the *halting points* of the line (i.e., the points of initial or final intersection). It is usually organized as a list of  $x$  coordinate values sorted in ascending order. The second set consists of a description of the status of the objects that are intersected by the current position of the sweep line. This status reflects the information relevant to the problem to be solved, and it must be updated at each halting point.

The data structure used to store the status must be able to handle updates, but it may take advantage of characteristics of the data discovered while the data was sorted. In other words, the data structure may use knowledge about the entire batch of updates. For this reason, these data structures are sometimes called *batched dynamic* [544]. The characteristics of this data structure will determine, to a large extent, the efficiency of the solution.

The application of plane-sweep methods to rectangle problems is much studied. The solutions to many of these problems require that the data be ordered in a manner that makes use of some variant of multidimensional sorting. In such cases, the execution times of optimal algorithms are often constrained by how fast we can sort, which, for  $N$  objects, usually means a lower bound of  $O(N \cdot \log_2 N)$ . At times, an increase in speed can be obtained by making use of more storage. The text of Preparata and Shamos [1511] contains an excellent discussion of a number of problems to which such techniques are applicable.

We assume that each rectangle is specified by four values, the  $x$  coordinate values of its two vertical sides and the  $y$  coordinate values of its two horizontal sides (equivalently, these are the  $x$  and  $y$  coordinate values of its lower-left and upper-right corners). We also assume that each rectangle is closed on its left and bottom sides and open on its top and right sides. Applying the same open-closed convention to the boundaries of a rectangle finds that its horizontal (vertical) boundaries are closed on their left (bottom) ends and open on their right (top) ends. Alternatively, the boundaries can be described as being *semiclosed*.

In this section, we focus on the efficient solution of the problem of reporting all intersections between rectangles and, to a lesser extent, on some related problems. Note that a naive way to report all intersections is to check each rectangle against every other rectangle. This takes  $O(N^2)$  time for  $N$  rectangles. The plane-sweep solution of the problem consists of two passes. The first pass sorts the left and right boundaries (i.e.,  $x$  coordinate values) of the rectangles in ascending order and forms a list. For example, consider the collection of rectangles given in Figure 3.1. Letting  $O_L$  and  $O_R$  denote the left and right boundaries of rectangle object  $O$ , the result of the first pass is a list consisting of 3, 6, 8, 21, 23, 25, 26, 31, 33, 34, 35, 37, 38, and 38, corresponding to  $A_L, A_R, D_L, G_L, B_L, E_R, F_L, C_L, B_R, F_R, C_R, D_R,$  and  $G_R$ , respectively.

The second pass sweeps a vertical scan line through the sorted list from left to right, halting at each one of these points. This pass requires solving a quasidynamic version of the one-dimensional intersection problem. At any instant, all rectangles whose horizontal boundaries intersect the scan line are termed *active rectangles*. (e.g., rectangles D, E, and G for a vertical scan line through  $x = 24$  in Figure 3.1). We must report all intersections between a newly activated rectangle and currently active rectangles that lie on the scan line. The sweep process halts every time a rectangle becomes active (causing it to be inserted in the set of active rectangles) or ceases to be active (causing it to be deleted from the set of active rectangles). The key to a good solution is to organize the active rectangles so that intersection detection, insertion, and deletion are executed efficiently.

The first pass involves sorting, and thus it takes  $O(N \cdot \log_2 N)$  time. Insofar as the second pass is concerned, each rectangle is nothing more than a vertical line segment (or equivalently, a one-dimensional interval). Several data structures can be used to

Figure 3.1  
(a) A collection of rectangles. Members of the collection are designated by solid lines and labeled alphabetically (A–G). Query rectangles are designated by broken lines and labeled numerically (1–3). P and Q are the endpoints of the rectangles and the points in (a). (b) The locations of the endpoints of the rectangles and the points in (a). For a rectangle,  $x_L$  and  $x_R$  correspond to its left and right boundaries, respectively, and  $y_B$  and  $y_T$  correspond to its bottom and top boundaries, respectively. For a point,  $x_L$  and  $y_B$  are its  $x$  and  $y$  coordinate values, respectively.

represent line segments. If we care only about reporting the intersections of boundaries (i.e., vertical boundaries with horizontal boundaries), then a balanced binary search tree is adequate to represent the bottom and top boundaries (i.e.,  $y$  coordinate values) of the active rectangles [178] (see Exercise 6 in Section 3.1.4). Unfortunately, such a representation fails to account for intersections that result when one rectangle is totally contained within another rectangle.

In the rest of this section, we focus on solutions to the rectangle intersection problem that use the segment, interval, and priority search trees to represent the active line segments. We first explain the segment tree and then show how the order of the space requirements of the solution can be reduced by using either the interval or priority search trees, while still retaining the same order of execution time. Although the interval tree solution for the rectangle intersection problem requires less space than the segment tree solution, the segment tree is important due to its simplicity and finds use in a number of applications. We conclude by briefly explaining some alternative solutions and point out related problems that can be solved using the same techniques.

### 3.1.1 Segment Tree

The segment tree is a representation of a collection of line segments devised by Bentley [166]. It is useful for detecting all the intervals that contain a given point. It is best understood by first examining a simplified version that we call a *unit-segment tree*, which is used to represent a single line segment. For the moment, assume that the endpoints of the line segments of our collection are drawn from the set of integers  $\{i \mid 0 \leq i \leq 2^h\}$ . Let  $S$  be a line segment with endpoints  $l$  and  $r$  ( $l < r$ ).  $S$  consists of the set of consecutive unit intervals  $[j:j+1]$  ( $l \leq j < r$ ). The unit-segment tree is a complete binary tree of depth  $h$  such that the root is at level  $h$ , and nodes at level 0 (i.e., the bottom) represent the sequence of consecutive intervals  $[j:j+1]$  ( $0 \leq j < 2^h$ ). A node at level  $i$  in the unit-segment tree represents the interval  $[p:p+2^i]$  (i.e., the sequence of  $2^i$  consecutive unit intervals starting at  $p$ , where  $p \bmod 2^i$  is 0).

Representing line segment  $S$  in a unit-segment tree is easy. We start at the root of the tree and check if its corresponding interval is totally contained in  $S$ . If yes, then we *mark* the node with  $S$ . In such a case, we say that  $S$  *covers* the node's interval. Otherwise, we repeat the process for the left and right children of  $S$ . This process visits at most four nodes at each level, while marking at most two of them. Thus, it is easy to see that inserting a line segment into a unit-segment tree in a top-down manner can be achieved in  $O(h)$  time. An equivalent bottom-up description of this process is that a node is marked with  $S$  if all (i.e., both) the intervals corresponding to its children are totally contained in  $S$ , in which case, the children are no longer marked with  $S$ .

For an example of the unit-segment tree, consider a collection of line segments with integer endpoints that are in the range  $[0:16)$ . In this case, there are 16 possible intervals, each of unit length. The unit-segment tree for a line segment named  $A$  of length 8 whose endpoints are at 3 and 11 is given in Figure 3.2. Note that the interval  $[i:i+1)$  is represented by the node labeled  $i$ . From the figure, it is easy to observe the close analogy between the unit-segment tree and a one-dimensional region quadtree [1574] where the unit intervals are the one-dimensional analog of pixels. The analogy is completed by letting black (white) correspond to the labeled (unlabeled) nodes and merging brother nodes of the same color.

The unit-segment tree is inadequate for two reasons: it can represent only one line segment, and it is defined only for line segments with integer endpoints. The segment tree is an adaptation of the unit-segment tree that enables the use of one data structure to represent a collection of line segments with arbitrary endpoints by removing the restriction that the intervals be of uniform length and by replacing the mark at each node with a linked list of the names of the line segments that contain that node.

Figure 3.2  
 The unit-segment tree for the segment [3:11] labeled A in the range [0:16].

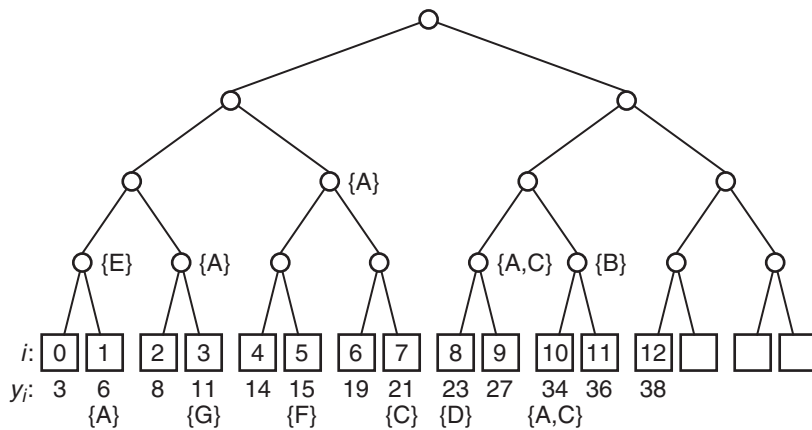

Figure 3.3  
 The segment tree for the set of line segments corresponding to the vertical boundaries of the rectangles in Figure 3.1. Terminal node  $i$  corresponds to the interval  $[y_i:y_{i+1}]$ .

This adaptation is achieved in the following manner. Given a set of  $N$  line segments, we first sort their endpoints and remove duplicates to obtain  $y_0, y_1, \dots, y_m$  ( $m < 2 \cdot N$ ). Next, we form the segment tree in the same way as the unit-segment tree with the exception that interval  $[j:j+1]$  is replaced by the interval  $[y_j:y_{j+1}]$  ( $0 \leq j < 2^h$  and  $2^{h-1} \leq m < 2^h$ ). Each line segment  $S$  with endpoints  $y_l$  and  $y_r$  consists of the sequence of consecutive intervals  $[y_j:y_{j+1}]$  ( $l \leq j < r$ ).

A node at level  $i$  in the segment tree represents the interval  $[y_p:y_{p+2^i}]$  (i.e., the sequence of  $2^i$  consecutive intervals starting at  $y_p$ , where  $p \bmod 2^i$  is 0). Each node is marked with the names of all the line segments that cover the node's corresponding interval and that do not cover the corresponding interval of the parent node. As in the case of the unit-segment tree, a node and its brother cannot both be marked with the same line segment. The set of line segments associated with each node is represented as a doubly linked list. This will be seen to facilitate deletion of line segments.

For example, Figure 3.3 is the segment tree for the set of line segments that correspond to the vertical boundaries of the rectangles in Figure 3.1. Although there are 7 line segments, the segment tree contains 12 intervals as there are only 13 different endpoints. Since the segment tree is a complete binary tree, in this case it has 4 unused intervals. Each leaf node is labeled with its corresponding interval number and the leftmost endpoint of the interval—that is, node  $i$  corresponds to the interval  $[y_i:y_{i+1}]$ . Nodes are also labeled with the sets of names of the line segments that cover their corresponding

intervals. For example, the interval [23:34) is labeled with {A,C} because it is covered by these line segments.

Inserting a line segment into the segment tree is analogous to inserting it into the unit-segment tree. The only difference is that the line segment must also be inserted into the list of line segments associated with the node. It can be placed anywhere in the list, and thus we usually attach it to the front of the list. In a domain of  $N$  line segments, insertion (into the tree and list) takes  $O(\log_2 N)$  time per line segment.

Deleting a line segment from a segment tree is somewhat more complex. We must remove the line segment from the doubly linked list associated with each node that contains it. This can be expensive since, in the worst case, it requires the traversal of  $O(\log_2 N)$  linked lists, each containing  $O(N)$  entries. This difficulty is avoided by maintaining an auxiliary table with one entry for each of the  $N$  line segments. Each table entry points to a list of pointers. Each pointer points to a list entry for the line segment in a node, say  $P$ , of the segment tree such that  $P$ 's interval is covered by the line segment (see Exercise 3).

This table is built as the line segments are entered into the segment tree. It contains at most  $N$  entries and can be accessed or updated in  $O(\log_2 N)$  time when implemented as a balanced binary search tree (or even in constant time, if implemented as an array, in which case each line segment must be represented by a unique integer in the range  $1 \dots N$ ). We can use an array instead of a dictionary because we know the identities of the rectangles in advance (i.e., it is a static environment).

A segment tree for  $N$  line segments has a maximum of  $2 \cdot N$  leaf nodes. Each line segment covers the intervals of at most  $2 \cdot \lceil \log_2 N \rceil$  nodes of the segment tree. At each of these nodes, deletion of the line segment can be performed in constant time since the segment lists that are associated with these nodes are implemented as doubly linked lists. Thus, the total cost of deleting a line segment is  $O(\log_2 N)$ . The segment tree has a total of  $O(N)$  nodes and, since each line segment can appear in (i.e., cover)  $O(\log_2 N)$  nodes, the total space required (including the auxiliary table) in the worst case is  $O(N \cdot \log_2 N)$ . Interestingly, Bucher and Edelsbrunner [277] have shown that the average space requirement for a segment tree is also  $O(N \cdot \log_2 N)$ .

Given  $F$  rectangle intersections, using a segment tree to determine the set of rectangles that intersect each other is somewhat complex [183] if we want to do it in  $O(N \cdot \log_2 N + F)$  time. In particular, it involves considerably more work than just inserting a line segment and reporting the rectangles associated with the line segments that were encountered during the insertion process. We will indicate by means of an example why this is so, after we have described our algorithm.

Conceptually, the problem is quite straightforward. For each line segment  $S$ , with starting and ending points  $l$  and  $r$ , respectively, we want the set of line segments  $A$  such that  $A_i \cap S$  is nonempty for each  $A_i \in A$ . Recalling that the segment tree is good for detecting all intervals that contain a given point, we formulate the problem as an infinite set of point queries: for each point  $p_i$  in line segment  $S$ , find all line segments that contain it. This process takes  $O(\log_2 N)$  time for each point queried. To avoid looking at every point in  $S$  (an infinite number!), we can restrict our search to the endpoints of the line segments that are overlapped by  $S$ . An obvious, but unacceptable solution, is to store explicitly with each line segment the set of segments that intersect it at a total storage cost of  $O(N^2)$ .

A more reasonable solution, which makes use of the above restriction on the search, is given by Six and Wood [1774, 1775], who decompose the search into two disjoint problems. They make use of the obvious fact that any line segment with a starting point greater than  $r$  or with an ending point less than  $l$  does not intersect the line segment  $S$ . The first problem consists of determining all line segments with starting points less than  $l$  that have a nonempty intersection with  $S$ . The second problem consists of determining

all line segments with starting points that lie between  $l$  and  $r$ . Thus, there is really a need to be concerned only with an ordering that is based on the starting points.

One way to solve the first problem is to use a balanced binary search tree to store the starting points of the line segments. Now we search for all line segments with starting points that are less than  $l$  and check if the ending points are greater than  $l$ . Unfortunately, this could require us to examine every node in the tree (if  $l$  is large). An alternative solution is to perform a point query for point  $l$  on the segment tree representation of the line segments. To determine all the line segments that contain  $l$ , we simply locate the smallest interval containing it. Since a segment tree for  $N$  line segments has a maximum of  $2 \cdot N$  leaf nodes, this search visits at most  $\lceil \log_2 N \rceil + 1$  nodes, and for each node visited, we traverse its associated list of line segments and report them as containing  $l$ . This process takes  $O(\log_2 N + F_l)$  time, where  $F_l$  is the number of line segments that contain  $l$ . Since a segment tree is used, the solution uses  $O(N \cdot \log_2 N)$  space.

The second problem is solved by performing a range query for range  $[l:r)$  on the set of starting points of the line segments. For this query, a one-dimensional range tree that stores the starting points of the line segments is ideal. Recall from Section 1.2 of Chapter 1 that a one-dimensional range tree is a balanced binary search tree where the data points are stored in sorted order in the leaf nodes that are linked in this order by use of a doubly linked list. Therefore, insertion and deletion are both  $O(\log_2 N)$  processes.

A range query consists of locating the node corresponding to the start of the range, say  $L$ , and the closest node to the end of the range, say  $R$ , and then reporting the line segments corresponding to the nodes that lie between them by traversing the linked list of nodes. This process takes  $O(\log_2 N + F_{lr})$  time, where  $F_{lr}$  is the number of line segments with starting points in  $[l:r)$ . Since a balanced binary search tree is used, it needs  $O(N)$  space.

The combination of the point and range query solution uses  $O(N \cdot \log_2 N)$  space and takes  $O(N \cdot \log_2 N + F)$  time, where  $F$  is the number of rectangle intersections. At this point, let us see if we can improve on these bounds. Since the first pass also takes  $O(N \cdot \log_2 N)$  time, the only room for improvement is in the space requirement, which is bounded from below by  $O(N)$  as a result of using the range tree (i.e., a balanced binary search tree with double links between adjacent elements) for the range query.

Suppose that, instead of using a segment tree, we use an additional one-dimensional range tree for the ending points (as well as a one-dimensional range tree for the starting points). Now we perform a range query for range  $[l:r)$  on the set of ending points of the line segments. Unfortunately, the results of the two range queries are not disjoint, so we will have to remove duplicates. The number of duplicate entries per range query can be as large as  $N$ , and we will have to sort them prior to removal. This means that the algorithm has a total worst-case execution time that can be as high as  $O(N^2 \cdot \log_2 N)$ .

Alternatively, we can try to determine the set of rectangles that intersect each other by just using a segment tree. The problem with this approach is that, upon insertion of a line segment, say  $S$ , in a segment tree, we cannot find all of the existing line segments in the tree that are totally contained in  $S$ , or partially overlap  $S$ , without examining every node in each subtree containing  $S$ . For example, consider the segment tree of Figure 3.3 without line segment A (i.e., for segments B, C, D, E, F, and G). Upon inserting line segment A into the node corresponding to interval  $[14:23)$ , the only way to determine the existence of line segment F (corresponding to the interval  $[15:19)$ ) that is totally contained in A is to descend to the bottom of the subtree rooted at  $[14:23)$ .

The problem is not restricted to the situation of total containment as it also arises in the case of partial overlap. For example, consider the segment tree of Figure 3.3 without line segment B (i.e., for segments A, C, D, E, F, and G). Upon inserting line segment B into the node corresponding to interval  $[34:38)$ , the only way to detect the partial overlap of B with line segments A and C in the interval  $[34:36)$  is to descend to the bottom of the subtree rooted at  $[34:38)$ . Checking for total containment or partial overlap in this

way takes  $O(N)$  time for each line segment, or  $O(N^2)$  for all of the line segments. Thus, we must find a more satisfactory solution since we wish to perform this task in  $O(N \cdot \log_2 N + F)$  time. This is achieved by using the interval tree and is the subject of the next section.

### Exercises

1. Under what restriction is a segment tree equivalent to a unit-segment tree?
2. Is it true that, whenever two line segments overlap, at least one node in the segment tree will have more than one line segment associated with it?
3. The implementation of the segment tree described in the text makes use of an auxiliary table that contains an entry for each line segment. This entry points to a list of pointers, each of which points to a list entry for the line segment in a node of the segment tree whose intervals are covered by the line segment. Why is this a better solution than merely pointing to the node whose intervals are covered by the line segment?
4. Why can you not formulate the sweep pass of the rectangle intersection problem as locating all line segments that start within a given line segment and those that end within the line segment? In this case, there is no need for the segment tree; instead, use two one-dimensional range trees, one for the starting points and one for the ending points.
5. Given a point  $P$  on a line, devise an algorithm to find all intervals that contain  $P$ . This is known as a *stabbing query*. Assume that the intervals are represented using a segment tree. What is the order of the execution time of the algorithm when there are  $N$  intervals?
6. Suppose that we are interested only in the number of intervals that contain  $P$ . This is known as the *stabbing counting query*. Assume that the intervals are represented using a segment tree. Given  $N$  intervals, how quickly can you determine a solution to this query, and how much space does it require?
7. Give an algorithm to insert a line segment into a segment tree.
8. Give an algorithm to delete a line segment from a segment tree.
9. Give an algorithm to determine if a line segment intersects an existing line segment in a segment tree.
10. How would you use a segment tree to determine all of the one-dimensional intervals that are totally contained within a given one-dimensional interval? Given  $N$  intervals and  $F$  contained intervals, does your algorithm run in  $O(\log_2 N + F)$  time? If not, explain why, and give an alternative solution.
11. How would you use a segment tree to determine all the one-dimensional intervals that contain a given one-dimensional interval? Given  $N$  intervals and  $F$  containing intervals, does your algorithm run in  $O(\log_2 N + F)$  time? If not, explain why.
12. Give an algorithm to determine all pairs of intersecting rectangles using a segment tree.

### 3.1.2 Interval Tree

The problem discussed at the end of Section 3.1.1 with using the segment tree as the basis of the solution to the rectangle intersection problem can be overcome, in part, by making the following modifications. Link each marked node (i.e., a node whose corresponding interval overlaps at least one line segment), say  $P$ , to some of the nodes in  $P$ 's subtrees that are marked. This can be implemented by an auxiliary binary tree with elements that are the marked nodes. Since each line segment can be associated with more than one node in the segment tree, the number of intersections that can be detected is bounded by  $2 \cdot N^2 \cdot \log_2 N$  (see Exercise 1), and the number of different intersections is bounded by  $N^2$ . Removing duplicates will require sorting, and even use of the bin method [1976], which is linear, still leaves us with an  $O(N^2 \cdot \log_2 N)$  process.

However, duplicate entries can be avoided by redefining the segment tree so that a line segment is associated only with one node: the nearest common ancestor<sup>1</sup> of all the intervals contained in the line segment (e.g., the node corresponding to the interval [3:38] for line segments A and C in Figure 3.3). The absence of duplicate entries also means that the space requirements can be reduced to  $O(N)$ .

The above modifications serve as the foundation for the development of the *interval tree* of Edelsbrunner [534, 537, 538] and the *tile tree* of McCreight [1265].<sup>2</sup> The difference between the interval tree and the tile tree is that the tile tree is based on a regular decomposition, while the interval tree is not. In the rest of this section, we discuss only the interval tree.

The interval tree is designed specifically to detect all intervals that intersect a given interval. It is motivated by the dual goals of reducing the space requirement to  $O(N)$  while maintaining an execution time of  $O(N \cdot \log_2 N + F)$ . The interval tree solution also makes use of the decomposition of the search into two disjoint tasks:

1. Determining all line segments that overlap the starting point of the query line segment
2. Determining all line segments with starting points that lie within the query line segment

Once again, assume that we are given a set of  $N$  line segments such that line segment  $S_i$  corresponds to the interval  $[l_i:r_i)$  where  $l_i$  and  $r_i$  are the left and right endpoints, respectively, of  $S_i$ . The endpoints of the  $N$  line segments are sorted (with duplicates removed) to obtain the sequence  $y_0, y_1, \dots, y_m$  ( $m < 2 \cdot N$  and  $2^{h-1} \leq m < 2^h$ ). The interval tree is a three-level structure in which the first (and principal) level is termed the *primary structure*, the second level is termed the *secondary structure*, and the third level is termed the *tertiary structure*. We shall illustrate our discussion with Figure 3.4, the interval tree for the set of line segments corresponding to the vertical boundaries of the rectangles in Figure 3.1.

The primary structure is a complete binary tree with  $m + 1$  external (i.e., leaf) nodes such that, when the tree is flattened, and the nonleaf nodes are removed, then external node  $i$  corresponds to  $y_i$ . In Figure 3.4, the primary structure is denoted by solid lines. In our example, although there are 7 line segments, the primary structure contains only 13 external nodes as there are only 13 different endpoints. Each leaf node is labeled with its corresponding endpoint (i.e.,  $y_i$  for leaf node  $i$  ( $0 \leq i < 2 \cdot N$ )). Each nonleaf node is assigned an arbitrary value, stored in the field VAL, that lies between the maximum value in its left subtree and the minimum value in its right subtree (usually their average). For example, the root node in Figure 3.4 is labeled 22.

Given a line segment corresponding to the interval  $[l:r)$ , we say that its *nearest common ancestor* in the interval tree is the nonleaf node containing  $l$  and  $r$  in its left and right subtrees, respectively. For example, in Figure 3.4, node 22 is the nearest common ancestor of line segment A, which corresponds to the interval [6,36).

Each nonleaf node in the primary structure, say  $v$ , serves as the key to a pair of secondary structures LS and RS that represent the sets of left and right endpoints, respectively, of the line segments for which  $v$  is the nearest common ancestor (i.e., they contain  $v$ 's value). Elements of the sets LS and RS are linked in ascending and descending order, respectively. In Figure 3.4, the secondary structure is denoted by dotted lines

---

<sup>1</sup> The principle of associating key information with the nearest common ancestor is also used as the basis of an efficient solution of the point location query by Lee and Preparata [1128] (see Section 2.1.3.3.1 of Chapter 2) and later improved upon by use of fractional cascading [339, 340] by Edelsbrunner, Guibas, and Stolfi [541] (see Section 2.1.3.3.2 of Chapter 2).

<sup>2</sup> Preparata and Shamos [1511, pp. 323 and 373], as well as others (e.g., Cormen, Leiserson, Rivest, and Stein [422, p. 318], quoting Preparata and Shamos [1511]), mistakenly attribute the tile tree to the technical report preprint of [1266], which, in fact, describes the priority search tree.

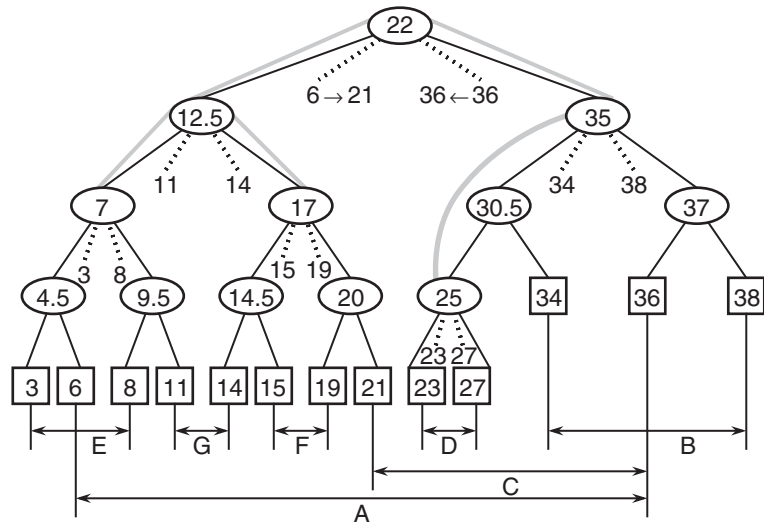

Figure 3.4

The interval tree for the set of line segments corresponding to the vertical boundaries of the rectangles in Figure 3.1. The primary structure is shown by solid lines. The secondary structure is shown by dotted lines. The tertiary structure is shown by gray lines with the active nodes circled with heavy lines. The interrelationships between the endpoints of the line segments are also shown.

emanating from each nonleaf node with a nonempty secondary structure. The sets LS and RS are distinguished by dotted lines emanating from the nonleaf node to its left and right sides, respectively.

When the sets LS and RS contain more than one entry, we show them as linked in increasing and decreasing order, respectively (e.g., LS of the root node shows 6 pointing to 21 since the corresponding intervals are  $[6:36]$  and  $[21:36]$ ). Each starting (ending) point appears in LS (RS) as many times as there are line segments that have it as a starting (ending) point. For example, 36 appears twice in RS of the root node in Figure 3.4 as it is the ending point of line segments A and C. To support rapid insertion and deletion, the sets LS and RS are implemented as balanced binary search trees (as well as doubly linked lists).

Each nonleaf node in the primary structure has eight pointers: two to its left and right subtrees in the primary structure (LP and RP), two to the roots of LS and RS in the secondary structure, one to the minimum value in LS, one to the maximum value in RS, and two (LT and RT) to its left and right subtrees in the tertiary structure. The LT and RT pointers are discussed below.

A nonleaf node in the primary structure is marked *active* if its corresponding secondary structure is nonempty or both of its children have active descendants; otherwise, it is marked *inactive*. The active nodes of the primary structure form the tertiary structure, which is a binary tree. It is rooted at the root of the primary structure and is linked via the LT and RT fields of the nonleaf nodes of the primary structure. If node  $v$  of the primary structure is inactive, then  $LT(v)$  and  $RT(v)$  are  $\Omega$  (i.e., pointers to NIL). If  $v$  is active, then  $LT(v)$  points to the closest active node in the left subtree of  $v$  (i.e., in  $LP(v)$ ), and  $RT(v)$  points to the closest active node in the right subtree of  $v$  (i.e., in  $RP(v)$ ). If there are no closest active nodes in the left and right subtrees of  $v$ , then  $LT(v)$  and  $RT(v)$ , respectively, are  $\Omega$ .

In Figure 3.4, the tertiary structure is denoted by gray lines linking all of the active nodes (e.g., nodes 22, 12.5, 7, 17, 35, and 25), also enclosed by thick ellipses. The tertiary structure is useful in collecting the line segments that intersect a given line segment. It enables us to avoid examining primary nodes with no line segments. Note that more than

half of the elements of the tertiary structure (i.e., active nodes) have nonempty secondary structures (see Exercise 4).

Inserting the line segment  $[l:r]$  in the interval tree is very simple. We start at the root and, using the primary structure, locate the first node  $v$  such that  $l < \text{VAL}(v) < r$ . In this case, we insert  $l$  into  $\text{LS}(v)$  and  $r$  into  $\text{RS}(v)$ . Both of these processes can be achieved in  $O(\log_2 N)$  time. Updating the tertiary structure requires us to traverse it in parallel with the primary structure and takes  $O(\log_2 N)$  time. Deletion of a line segment is performed in a similar manner and with the same complexity.

Reporting the rectangle intersections in an interval tree is straightforward, although there are a number of cases to consider. Again, this task is performed while inserting a vertical line segment, say  $S$  corresponding to the interval  $[l:r]$ . During this process, we search for and report the line segments that overlap  $S$  (see Exercise 11). Assume that the interval tree is rooted at  $T_1$ . The search has the following three stages:

1. Start at  $T_1$ , and find the first node  $v$  such that  $l < \text{VAL}(v) < r$ .
2. Start at  $v$ , and locate  $l$  in the left subtree of  $v$ .
3. Start at  $v$ , and locate  $r$  in the right subtree of  $v$ .

This search involves the secondary structures of the nodes in the primary structure. The tertiary structure reduces the number of nodes in the primary structure with empty secondary structures that must be examined. Note that all of the overlapping line segments will be reported, and each will be reported only once as it is associated with the secondary structure of just one node in the primary structure.

In the following, we present the main ideas of the three stages. Figure 3.5 aids in the visualization of the symbols used in the explanation for  $[l:r]$ . All secondary and tertiary structures that are visited are marked with dotted and broken lines, respectively.

Let us start with stage 1.  $\{T_i\}$  denotes the set of nodes encountered during the search for  $v$ . We use the insertion of line segment  $[6:20]$  into the interval tree of Figure 3.4 as our example. The secondary structures associated with each  $T_i$  must be checked for a possible overlap with  $S$ . This is quite simple. Either  $l < r < \text{VAL}(T_i)$  or  $\text{VAL}(T_i) < l < r$ .

If  $r < \text{VAL}(T_i)$ , then we need to report only the line segments in the secondary structure of  $T_i$  with starting points less than  $r$  (e.g., line segment A upon examining the nonleaf node with value 22). To achieve this, we visit  $\text{LS}(T_i)$  in ascending order until we encounter a line segment with a starting point exceeding  $r$ . We then search the left subtree of  $T_i$  (i.e.,  $\text{LP}(T_i)$ ).

Similarly, if  $\text{VAL}(T_i) < l$ , then we need to report only the elements of the secondary structure of  $T_i$  with ending points greater than  $l$ . To do this, we visit  $\text{RS}(T_i)$  in descending order until encountering a line segment with an ending point less than  $l$ . The search is then continued in the right subtree of  $T_i$  (i.e.,  $\text{RP}(T_i)$ ).

Both of these cases are executed in time proportional to the number of intersections reported. Once node  $v$  has been located, we report all elements of its secondary structure as intersecting  $S$ . In our example, we would report line segment G since  $v$  is the nonleaf node with value 12.5.

Now, let us understand stages 2 and 3. Since they are very similar, we just discuss stage 2. We use the insertion of line segment  $[6:34]$  into the interval tree of Figure 3.4 as our example. In this case,  $v$  is the root of the tree (the nonleaf node with value 22). Let  $\{L_i\}$  denote the set of nodes encountered during the search for  $l$  in this stage. Recall that  $l < \text{VAL}(v)$ . Either  $l < \text{VAL}(L_i)$  or  $\text{VAL}(L_i) < l$ .

If  $l < \text{VAL}(L_i)$ , then  $S$  intersects every line segment in the secondary structure of  $L_i$ .  $S$  also intersects all the line segments in the secondary structures in the right subtree of  $L_i$ . The first set consists of just the line segments in  $\text{RS}(L_i)$  (e.g., line segment G upon examining the nonleaf node with value 12.5). The second set is obtained by visiting

### Section 3.1 PLANE-SWEEP METHODS AND THE RECTANGLE INTERSECTION PROBLEM

Figure 3.5  
Example of an interval tree search for the interval  $[l:r]$ . All secondary structures that are visited are marked with dotted lines. All tertiary structures that are visited are marked with broken lines.

all of the active nodes in the right subtree of  $L_i$ ,  $RT(L_i)$  (e.g., line segment F during the processing of the nonleaf node with value 12.5 since F is associated with the active nonleaf node with value 17).

Notice the use of the pointers  $LT(L_i)$  and  $RT(L_i)$  in the tertiary structure to avoid visiting irrelevant nodes when forming the second set. Since more than half of the elements of the tertiary structure have nonempty secondary structures (see Exercise 4), the time necessary to execute this process is proportional to the number of intersections that are reported. The search is continued in the left subtree of  $L_i$ ,  $LT(L_i)$ .

If  $VAL(L_i) < l$ , then we report the line segments in the secondary structure of  $L_i$  with ending points greater than  $l$ . To do this, we visit  $RS(L_i)$  in descending order until encountering a line segment with an ending point less than  $l$ . This process is executed in time proportional to the number of intersections reported. The search is continued in the right subtree of  $L_i$ ,  $RT(L_i)$ .

Solving the rectangle intersection problem using an interval tree uses  $O(N)$  space and takes  $O(N \cdot \log_2 N + F)$  time, where  $F$  is the number of rectangle intersections.<sup>3</sup> The space requirements are obtained by observing that, for  $N$  line segments, we need at most  $2 \cdot N$  leaf nodes in the primary structure and likewise for the secondary structures. The tertiary structure is constructed from nodes in the primary structure, and thus it requires no additional space except for the pointer fields. Making use of the fact that the interval tree is a complete binary tree, the number of nonleaf nodes in the primary and secondary structures is bounded by  $2 \cdot N - 1$ .

The execution time requirements are obtained by noting that searching the primary structure for the starting and ending points of a line segment takes  $O(\log_2 N)$  time. The number of nodes visited in the secondary structure is of the same order as the number of rectangle intersections that are found. Since at least one-half of the active nodes have nonempty secondary structures, the number of nodes visited in the tertiary structure is no more than twice the number of nodes visited in the secondary structure. Constructing the interval tree takes  $O(N \cdot \log_2 N)$  time since the endpoints of the line segments forming the sides of the rectangles must be sorted.

Note that the interval tree that we have described is very different from what is termed an *interval tree* by Cormen, Leiserson, Rivest, and Stein [422, pp. 311–318], which simply stores the starting endpoint of each active vertical line segment in a balanced binary tree where each nonleaf node  $u$  also contains the maximum terminating endpoint of the vertical line segments stored in the subtree rooted at  $u$ . Thus, it is a balanced binary search tree in the starting endpoints of the active vertical line segments and a heap in the terminating endpoints of the active vertical line segments stored in each subtree. In fact, this structure is really a Cartesian tree [1944] (see Exercises 21 and 22 in Section 1.3 of Chapter 1). Unfortunately, the dual meaning of the term *interval tree* is not limited to Cormen et al. [422]. For example, this variant of the interval tree is characterized by some researchers (e.g., [89, 934]) as a *dynamic interval tree* since its use reduces the storage needed for the active list from  $O(N)$  (actually more precisely  $\Theta(N)$  due to the need to store the endpoints of all of the vertical line segments) to  $O(A)$ , where  $A$  is the maximum number of active vertical line segments at any particular moment. However, the cost of finding all intersecting pairs is now  $O(N \cdot \log_2 N + F \cdot \log_2 N)$  because detecting all intervals that intersect a given interval in a dynamic interval tree with  $n$  nodes is  $O(\min(n, k \cdot \log_2 n))$ , where  $k$  is the number of intersections of the given interval [422]. The dynamic interval tree has found use in performing a spatial join query [89, 934] (see Exercises 14 and 15).

<sup>3</sup> For the tile tree, the execution time is  $O(N \cdot \log_2(\max(N, K)) + F)$ , where the horizontal boundaries of the rectangles are integers between 0 and  $K - 1$ . The execution time becomes  $O(N \cdot \log_2 N + F)$  if the  $2 \cdot N$  y coordinate values are first sorted and then mapped into the integers from 0 to  $2 \cdot N - 1$ .

1. Suppose that you modify the definition of the segment tree so that each marked node, say  $P$ , is linked (i.e., a node with a corresponding interval that overlaps at least one line segment) to the nodes in  $P$ 's subtrees that are marked. Show that the number of intersections that can be detected is bounded by  $2 \cdot N^2 \cdot \log_2 N$ .
2. Can you implement the segment tree as a complete binary tree with  $m + 1$  external nodes as was done for the interval tree—that is, merge the leaf nodes corresponding to the unused intervals? If so, the segment tree will have the same node configuration as the primary structure of the interval tree. If this is the case, show how the nodes will be marked.
3. The text describes stage 2 of the search involved in reporting all intersections with a vertical line segment  $S$  corresponding to the interval  $[l:r)$ . Complete the description of the search by showing what will be done in stage 3.
4. Why do more than half of the elements of the tertiary structure (i.e., active nodes) of the interval tree have nonempty secondary structures?
5. Assume that a set of intervals is stored using an interval tree. Given a point  $P$  on a line, devise an algorithm to find all intervals that contain  $P$  (i.e., a stabbing query). What is the order of the execution time of the algorithm when there are  $N$  intervals?
6. Can you use the interval tree to determine the number of intervals containing  $P$  (i.e., a stabbing counting query) without storing the identities of the intervals? In other words, just store the number of intervals with each nonleaf node.
7. Prove that solution of the rectangle intersection problem based on its decomposition into a point and region query does not report an intersection more than once.
8. Give an algorithm to insert a line segment into an interval tree. Remember, you must also update the secondary and tertiary structures.
9. Give an algorithm to delete a line segment from an interval tree. Remember, you must also update the secondary and tertiary structures.
10. How would you use an interval tree to determine all of the one-dimensional intervals that are completely contained within a given one-dimensional interval? Given  $N$  intervals and  $F$  contained intervals, does your algorithm run in  $O(\log_2 N + F)$  time? If not, explain why.
11. Show that reporting the lines intersecting a line  $S$  corresponding to the interval  $[l:r)$  in an interval tree can be done concurrently while inserting  $S$  instead by first inserting it and then checking for intersections with existing line segments.
12. How would you use an interval tree to determine all of the one-dimensional intervals that contain (i.e., enclose) a given one-dimensional interval? Given  $N$  intervals and  $F$  containing intervals, does your algorithm run in  $O(\log_2 N + F)$  time? If not, explain why.
13. Give an algorithm to determine all pairs of intersecting rectangles using an interval tree. Remember that during this process you must also simultaneously traverse the tertiary structure.
14. Suppose that, instead of finding all pairs of intersecting rectangles from the same set, you want to find all pairs of intersecting rectangles from two different sets  $S_1$  and  $S_2$ —that is, a true geometric join (or spatial join) query. How would you use an interval tree to solve this problem?
15. A drawback of using the interval tree for the spatial join query in Exercise 14 is that the size of each of the interval trees for the two sets  $S_1$  and  $S_2$  is  $O(N)$  due to the need to keep track of the endpoints of all of the vertical line segments. Suppose that you have just a finite amount of memory available, say  $A$  such that  $A \ll N$ , for keeping track of the vertical line segments corresponding to the active rectangles. Devise an algorithm using the dynamic interval tree that does not fail when  $A$  is not large enough to store all of the active rectangles.

### 3.1.3 Priority Search Tree

Using an interval tree, as described in Section 3.1.2, yields an optimal worst-case space and time solution to the rectangle intersection problem. The interval tree solution requires

that we know in advance the endpoints of all of the vertical intervals as they must be sorted and stored in a complete binary tree. Thus, given  $N$  rectangles, the storage requirement is always  $O(N)$ . The solution can be slightly improved by adapting the priority search tree of McCreight [1266] to keep track of the active vertical intervals.

In this case, the storage requirements for the sweep pass depend only on the maximum number of vertical intervals that can be active at any one time, say  $M$ . Moreover, there is no need to know their endpoints in advance, and thus there is no need to sort them. This also has an effect on the execution time of the algorithm since the data structure used to keep track of the endpoints of the vertical intervals is the determinative factor in the amount of time necessary to do a search. Therefore, when using the priority search tree, the sweep pass of the solution to the rectangle intersection problem can be performed in  $O(N \cdot \log_2 M + F)$  time, rather than in  $O(N \cdot \log_2 N + F)$  time. However, sorting the endpoints of the horizontal intervals, which is the first pass of the plane sweep, still takes  $O(N \cdot \log_2 N)$  time.

The priority search tree has been described in Section 1.3 of Chapter 1. It keeps track of points in a two-dimensional space. Briefly, it is designed for solving queries involving semi-infinite ranges in such a space. A typical query has a range of the form  $([L_x:R_x],[L_y:\infty])$ . A priority search tree is built in the following manner. Sort all the points along the  $x$  coordinate, and store them in the leaf nodes of a balanced binary search tree, say  $S$ . We use a one-dimensional range tree in the following presentation so as to make the explanation easier to follow, although, as we will soon see, in order to be able to perform the sweep pass of the rectangle intersection problem in  $O(N \cdot \log_2 M + F)$  time, we will need to implement the balanced binary search tree using a representation that enables us to insert and delete items in  $O(\log_2 M)$  time (e.g., a red-black balanced binary tree [766], as described a bit more below and also in Appendix A). Continuing with the one-dimensional range tree implementation, store midrange  $x$  coordinate values in the nonleaf nodes. Next, proceed from the root node towards the leaf nodes. With each node of  $S$ , say  $I$ , associate the point in the subtree rooted at  $I$  with the maximum value for its  $y$  coordinate that has not already been stored at a shallower depth in the tree. If such a point does not exist, then the node is left empty.

Figure 3.6 is an example of the priority search tree. It is based on treating the vertical boundaries  $[y_B, y_T)$  of the rectangles in Figure 3.1 as points  $(x, y)$ . For  $N$  points, the priority search tree uses  $O(N)$  storage (see Exercise 1 in Section 1.3 of Chapter 1). The priority search tree is good for performing a semi-infinite range query  $([L_x:R_x],[L_y:\infty])$ . For  $N$  points, this process takes  $O(\log_2 N + F)$  time, where  $F$  is the number of points found (see Exercise 2 in Section 1.3 of Chapter 1). Notice that the leaf nodes of the priority search tree contain the points and are shown as linked together in ascending order of the  $y_B$  coordinate value. However, the links for the  $y_B$  coordinate values are used only if we conduct a search for all points within a given range of  $y_B$  coordinate values. They are not used in the execution of the semi-infinite range query, and thus they are frequently omitted from the implementation of the priority search tree.

It should be clear that the priority search tree in Figure 3.6 could never be realized for the example set of rectangles given in Figure 3.1. The reason is that it represents a situation in the sweep phase (i.e., a location with a particular  $x$  coordinate value) where all seven vertical intervals are simultaneously active, which is, of course, impossible given the positions of the horizontal intervals. Nevertheless, the figure does illustrate the data structure.

There are two keys to understanding the use of the priority search tree in solving the rectangle intersection problem. Assume, again, that all intervals are semiclosed (i.e., they are closed on their left ends and open on their right ends). First, each one-dimensional interval, say  $[a:b)$ , is represented by the point  $(a, b)$  in two-dimensional space. This two-dimensional space is represented by a priority search tree.

Second, we observe that the one-dimensional interval  $[a:b)$  intersects the interval  $[c:d)$  if and only if  $a < d$  and  $c < b$  (see Exercise 1). An equivalent observation is that

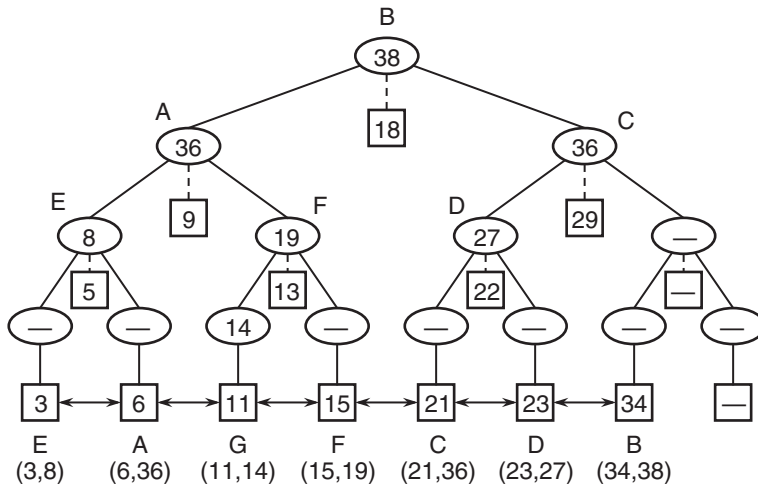

Figure 3.6  
 The priority search tree for the set of line segments corresponding to the vertical boundaries  $[y_B, y_T]$  of the rectangles in Figure 3.1. Each vertical boundary  $[y_B, y_T]$  is treated as a point  $(x, y)$  in a two-dimensional space. Each leaf node contains the appropriate  $y_B$  value in a square box. Each nonleaf node contains the appropriate  $y_B$  midrange value in a square box using a link drawn with a broken line. Circular boxes indicate the value of the  $y_T$  component of the line segment in the corresponding subtree with the maximum value for its  $y_T$  component that has not already been associated with a node at a shallower depth in the tree.

the point  $(c, d)$  lies in the range  $([-\infty:b], (a:\infty])$ . This equivalence means that to find all one-dimensional intervals that intersect the interval  $[a:b]$ , we need only perform the semi-infinite range query  $([-\infty:b], (a:\infty])$  in the priority search tree. If the priority search tree contains  $M$  one-dimensional intervals, then this operation takes  $O(\log_2 M + F)$  time, where  $F$  is the number of intersecting intervals found.

For the space and time bounds to be comparable or better than that of the interval tree, we must also show that a one-dimensional interval can be inserted and deleted from a priority search tree in  $O(\log_2 M)$  time. Unfortunately, this cannot be guaranteed when the balanced binary search tree for the  $x$  (actually  $y_B$ ) coordinate values is implemented using a one-dimensional range tree. In particular, the one-dimensional range tree is more of a static structure that requires the rearrangement of nodes and the resetting of links upon insertion and deletion, especially when  $M = 2^i$  and  $2^i + 1$ , respectively, for arbitrary values of  $i$ . This problem is overcome by implementing the balanced binary search tree for the  $y_B$  coordinate values as a red-black balanced binary tree [766] (see Appendix A). The red-black balanced binary tree has the property that, for  $M$  items, insertions and deletions take  $O(\log_2 M)$  time with  $O(1)$  rotations [1858]. McCreight [1266] shows that the priority search tree adaptation of the red-black balanced binary tree can be maintained at a cost of  $O(\log_2 M)$  per rotation (see Exercise 6). The use of a red-black balanced binary tree does not affect the  $O(M)$  storage requirements of the priority search tree. Hence, the desired time and space bounds are achieved.

When the priority search tree is implemented as a red-black balanced binary tree, its node structure differs from the way it was defined in Section 1.3 of Chapter 1. In particular, the nonleaf nodes now also contain intervals corresponding to the endpoints of the vertical intervals  $[y_B, y_T]$ . The interval associated with a nonleaf node, say  $I$ , is the one whose left endpoint, say  $L$ , is the median value of the left endpoints of the intervals in  $I$ 's subtrees. All intervals in  $I$ 's left subtree have left endpoints that are less than or equal to  $L$ , and the intervals in  $I$ 's right subtree have left endpoints that are greater than or equal to  $L$ .

Red-black trees enable the implementation of order 3 or order 4 B-trees (see Appendix A) (also known as 2-3 and 2-3-4 trees, respectively) as binary trees in a manner similar to the natural correspondence between a forest and a binary tree. Thus, all nodes are now uniform. In essence, in a red-black tree, the nodes of the order 3 and order 4 B-trees are represented as one-level binary trees consisting of zero or more red edges, while black edges are used to link up the nodes of the B-tree.

For example, Figure 3.7(a) shows a sample order 3 B-tree for the set of line segments corresponding to the vertical boundaries  $[y_B, y_T)$  of the rectangles in Figure 3.1, where the sort key is the  $y_B$  coordinate value, while Figure 3.7(b) is the corresponding red-black tree. In both cases, we have included the corresponding  $y_T$  values. The edges of the red-black tree in Figure 3.7(b) are labeled with r and b to denote their color (red and black, respectively). The red-black tree also plays the role of a heap by associating with each node of  $P$ , say,  $I$ , the point in the subtree rooted at  $I$  with the maximum value for its  $y_T$  coordinate that has not already been stored at a shallower depth in the tree. If such a point does not exist, then the node is left empty. We show these values within a circle connected to the appropriate node with a broken line.

It should be clear that the red-black tree in Figure 3.7 could never be realized for the example set of rectangles given in Figure 3.1. The reason is that it represents a situation in the sweep phase (i.e., a location with a particular  $x$  coordinate value) where all seven vertical intervals are simultaneously active, which is, of course, impossible given the positions of the horizontal intervals. Nevertheless, the figure does illustrate the data structure.

Comparing the interval and priority search tree solutions to the rectangle intersection problem, we find that the priority search tree is considerably simpler from a conceptual standpoint than the interval tree. The execution time requirements of the priority search tree are lower when the sort pass is ignored. Also, the priority search tree enables a more dynamic solution than the interval tree because, for the priority search tree, only the endpoints of the horizontal intervals need to be known in advance. On the other hand, for the interval tree, the endpoints of both the horizontal and vertical intervals must be known in advance.

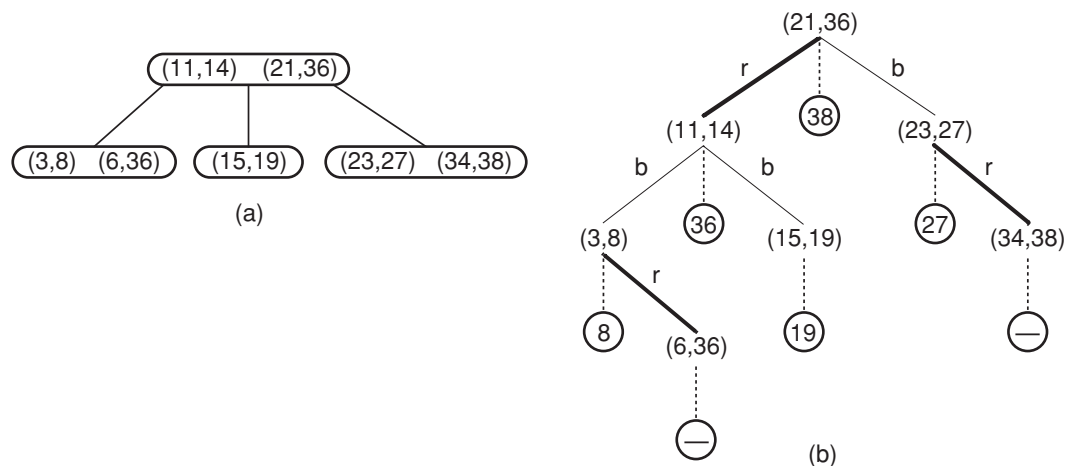

Figure 3.7  
(a) The order 3 B-tree for the left endpoints (i.e.,  $y_B$ ) of the set of line segments corresponding to the vertical boundaries  $[y_B, y_T)$  of the rectangles in Figure 3.1, and (b) its red-black tree which also shows the corresponding  $y_T$  value. Associated with each node  $I$  of the red-black tree is the value of the  $y_T$  component of the line segment in the subtree rooted at  $I$  with the maximum value for its  $y_T$  component that has not already been associated with a node at a shallower depth in the tree. This value is shown within a circle connected with a broken line.

1. Prove that the one-dimensional interval  $[a:b]$  intersects the interval  $[c:d]$  if and only if  $a < d$  and  $c < b$ .
2. The adaptation of the priority search tree as a red-black balanced binary tree differs from the version of the priority search tree described in Section 1.3 of Chapter 1) in that the data items appear in both leaf and nonleaf nodes. Show that this does not cause any problems in executing the semi-infinite range query.
3. Give an algorithm to insert the interval  $[a:b]$  into a priority search tree.
4. Give an algorithm to delete the interval  $[a:b]$  from a priority search tree.
5. Prove that a point can be deleted from a red-black balanced binary tree of  $M$  items in  $O(\log_2 M)$  time with  $O(1)$  rotations.
6. Prove that the priority search tree adaptation of the red-black balanced binary tree can be maintained at a cost of  $O(\log_2 M)$  per rotation.
7. Assume that a set of intervals is stored using a priority search tree. Given a point  $P$  on a line, devise an algorithm to find all intervals that contain  $P$  (i.e., a stabbing query). What is the order of the execution time of the algorithm when there are  $M$  intervals?
8. Give an algorithm that uses a priority search tree to find all one-dimensional intervals that partially overlap or are contained in a given one-dimensional interval.
9. Give an algorithm that uses a priority search tree to find all one-dimensional intervals  $[x:y]$  that completely contain (i.e., enclose) the one-dimensional interval  $[a:b]$ .
10. In Section 1.3 of Chapter 1 an inverse priority search tree was defined to be a priority search tree in which, with each node of  $T$ , say  $I$ , we associate the point in the subtree rooted at  $I$  with the minimum (instead of the maximum!) value for its  $y$  coordinate that has not already been stored at a shallower depth in the tree. Give an algorithm that uses an inverse priority search tree to find all one-dimensional intervals  $[x:y]$  that are completely contained in the one-dimensional interval  $[a:b]$ .
11. Repeat Exercise 10 by using a priority search tree instead of an inverse priority search tree.
12. Give an algorithm to determine all pairs of intersecting rectangles using a priority search tree.

### 3.1.4 Alternative Solutions and Related Problems<sup>4</sup>

The time requirements of the interval and priority search tree solutions of the rectangle intersection problem can be reduced further if we can make use of knowledge about the distribution of the data. Such an approach is reported by Bentley, Haken, and Hon [174]. They performed an empirical study on the distribution of components in VLSI design applications and determined that the rectangles are uniformly distributed. This distribution was used to organize the segments for the second pass so that the entire plane-sweep algorithm has a linear expected-time behavior.

Bentley et al. [174] obtained expected linear performance in the following manner. The sorting operation of the first pass takes expected linear time by use of the bin method [1976]. For the second pass, instead of using an interval tree to store the vertical segments that intersect the sweep line, bins of equal width are used. They are accessed by an array of pointers. Each bin contains a linked list of all the vertical segments that overlap it. The observed data was used to choose a bin width equal to the average width of a rectangle. This implies that each vertical segment is contained in two bins on average.

The linear expected time depends on an assumption that the expected number of rectangles per bin is a constant (i.e., independent of the number of rectangles  $N$ ). This assumption means that the total number of bins is some multiple of  $\sqrt{N}$ , which is true

<sup>4</sup> The exercises in this section are quite difficult.

as long as the data is not highly clustered (e.g., under a uniform distribution).<sup>5</sup> Under these hypotheses, initialization of the bins is an  $O(\sqrt{N})$  process. Inserting and deleting a vertical segment merely involves traversing a linked list of constant expected size. Checking a vertical segment, say  $S$ , for intersection with existing vertical segments is achieved by visiting the bins containing  $S$  and comparing  $S$  with the vertical segments stored within them. This is also achieved in constant time.

A related problem is finding the *containment set* (also known as the *inclusion* or *enclosure set*) of a collection of rectangles. The containment set is the set of all pairs of rectangles  $A$  and  $B$  such that  $A$  contains  $B$ . Variants of the segment tree are used by Vaishnavi and Wood [1910] to solve this problem in  $O(N \cdot \log_2^2 N + F)$  time and  $O(N \cdot \log_2^2 N)$  space (see Exercise 8). The space requirement is reduced to  $O(N)$  by Lee and Preparata [1129], who map each rectangle to a point in four-dimensional space and solve a point dominance problem.

As described in the opening section of this chapter, the rectangle intersection problem is closely related to the following problems:

1. Determining all rectangles that are contained in a given rectangle (a containment query)
2. Determining all rectangles that enclose a given rectangle (an enclosure query)
3. Determining all rectangles that partially overlap or are contained in a given rectangle (a window query)

The plane-sweep approach is not appropriate for these problems since, regardless of the data structures employed (e.g., segment, interval, or priority search trees), sorting is a prerequisite, and thus any algorithm requires at least  $O(N \cdot \log_2 N)$  time for  $N$  rectangles. In contrast, the naive solution of intersecting each rectangle with the query rectangle is an  $O(N)$  process.

The problems described above can be solved by segment trees and interval trees without making use of a plane sweep (e.g., Exercises 15 and 24) [1442]. The key is to adapt these representations to store two-dimensional intervals (see Exercises 9 and 20) in a manner similar to that in which the two-dimensional range tree was developed from the one-dimensional range tree (see Section 1.2 of Chapter 1) [536, 542].

For example, for  $N$  rectangles, the execution time of the solution to the window query is  $O(\log_2^2 N + F)$ , where  $F$  is the number of rectangles that satisfy the query. The difference is in their storage requirements: the segment tree solution uses  $O(N \cdot \log_2^2 N)$  space, while the interval tree solution uses  $O(N \cdot \log_2 N)$  space. For both of these structures, judicious use of doubly linked lists insures that rectangles can be inserted and deleted in  $O(\log_2^2 N)$  time (see Exercises 10 and 21). Of course, these structures must still be built, which takes  $O(N \cdot \log_2^2 N)$  time in both cases (see Exercises 11 and 22). It is not clear how to adapt the priority search tree to store two-dimensional intervals.

The plane-sweep paradigm for solving the geometric problems discussed earlier in this section (e.g., the rectangle intersection problem) assumes that the set of rectangles is processed only once. It can be shown that for many of these problems, plane-sweep methods yield a theoretically optimal solution. A disadvantage is that such solutions assume a static environment.

In contrast, in a dynamic environment where update operations occur frequently (i.e., rectangles are added and deleted), the plane-sweep approach is less attractive. Plane-sweep methods require that the endpoints of all rectangles be known a priori and that the

---

<sup>5</sup> When the data is not uniformly distributed, the hierarchical methods described in Section 3.4 may prove more attractive since the bins are of different sizes. Such methods make use of a tree traversal in the order of a space-filling curve (see Section 2.1.1.2 of Chapter 2) instead of sweeping a line across one dimension.

endpoints be sorted prior to the sweep pass. This is not a major problem as it is easy to maintain a dynamically changing set of points in sorted order. A more serious problem is that in a dynamic environment, the sweep pass of a plane-sweep algorithm will usually have to be reexecuted since there is no data structure corresponding to it. Methods based on persistent search trees [509, 1675] may be useful in avoiding the reexecution of the sweep pass.

Dynamic environments can also arise when the rectangle objects are themselves in motion, and thus their motion is what leads to the occurrence of update operations (e.g., in moving objects databases). For example, a typical query seeks the number of moving objects that are within a query window at a particular instance or interval of time (e.g., [930]). One way to answer such queries is to use some of the representations that are based on object hierarchies, such as the parametric R-tree [296], TPR-tree [1610], and TPR\*-tree [1855] mentioned in Section 2.1.5.2.3 of Chapter 2. Examples of related queries are aggregation queries such as the maximum number of moving objects that are within a query window at any time (e.g., [351, 1560]). They have received attention in constraint databases (e.g., [1559]) and spatiotemporal databases (e.g., [1203]) and are not discussed further here.

### Exercises

1. The rectangle intersection problem is a special case of the problem of determining if any two of a set of  $N$  lines in the plane intersect. Give an  $O(N \cdot \log_2 N)$  algorithm to solve the line intersection problem.
2. Suppose that you are given a set of  $N$  vertical line segments in the plane, say  $V$ , and a horizontal line segment, say  $H$ . Representing  $V$  as a segment tree, give an  $O(\log_2^2 N + F)$  algorithm to find all elements of  $V$  that intersect  $H$  that uses  $O(N \cdot \log_2 N)$  space.  $F$  is the number of intersecting elements.
3. Suppose that you are given a set of  $N$  arbitrary line segments in the plane, say  $L$ , and a rectilinear rectangle, say  $R$ . Using one-dimensional range trees and segment trees, give an  $O(\log_2^2 N + F)$  algorithm to find all elements of  $L$  that intersect  $R$  that uses  $O(N \cdot \log_2 N)$  space.  $F$  is the number of intersecting elements.
4. Suppose that, instead of reporting all intersecting rectangles, you want to report only if there is at least one pair of intersecting rectangles (including the case that a rectangle is totally enclosed in another rectangle). Once again, a plane-sweep method can be used with a scan from left to right. However, Bentley and Ottmann [177] suggest the use of a balanced binary search tree instead of a segment tree to organize the sorted list of bottom and top boundaries of the currently active rectangles during the sweep pass. Show how this technique can be used to yield a simpler  $O(N \cdot \log_2 N)$  algorithm to detect the existence of an intersection. Assume that the boundaries are stored in both leaf and nonleaf nodes in the tree.
5. Why can you not use the balanced binary search tree method of Exercise 4 instead of the segment tree to report all intersections between rectangles? Give an example in which it fails to detect an intersection.
6. Given a collection of  $N$  rectangles with  $F$  intersections between their vertical and horizontal boundaries, how would you use the balanced binary search tree method of Exercise 4 to find all the intersections in  $O(N \cdot \log_2 N + F)$  time and  $O(N)$  space? In this problem, if rectangle  $A$  is totally contained in rectangle  $B$ , then  $A$  and  $B$  do not intersect.
7. Assume that the result of Exercise 6 is used to detect all rectangles that have intersections between their horizontal and vertical boundaries. Add another pass using a segment tree to report all pairs of rectangles in which one rectangle is totally enclosed by the other in  $O(N \cdot \log_2 N + F)$  time.  $F$  is the number of pairs of rectangles that satisfy the query.
8. Using a segment tree, devise a plane-sweep algorithm to report all rectangles that are contained in other rectangles. In other words, for each rectangle in a collection of rectangles, report all the rectangles that are contained in it.
9. The segment tree can be adapted to represent rectilinear rectangles in a manner analogous to the way in which the one-dimensional range tree is extended to solve two-dimensional range

queries in Section 1.2 of Chapter 1. In particular, project the rectangles on the  $x$  axis, and store these intervals in a segment tree, say  $T$ . Let  $I$  be a nonleaf node in  $T$ , and let  $R_I$  denote the rectangles whose horizontal sides are associated with  $I$ . For each  $I$ , build a segment tree for the projections of  $R_I$  on the  $y$  axis. Show that this structure uses  $O(N \cdot \log_2^2 N)$  space for  $N$  rectangles.

10. Assuming  $N$  rectangles, prove that a rectangle can be inserted and deleted in  $O(\log_2^2 N)$  time in the two-dimensional extension of the segment tree described in Exercise 9.
11. Prove that the construction of the two-dimensional extension of the segment tree described in Exercise 9 takes  $O(N \cdot \log_2^2 N)$  time for  $N$  rectangles.
12. Using the two-dimensional extension of the segment tree described in Exercise 9, show that the two-dimensional stabbing query (i.e., find all rectilinear rectangles that contain a given point  $P$ ) can be determined in  $O(\log_2^2 N + F)$  time.  $N$  is the total number of rectangles, and  $F$  is the number of rectangles that contain  $P$ .
13. How would you generalize the solution to the two-dimensional stabbing query to  $d$  dimensions? How much storage is required, and what is the order of the execution time of the query?
14. Can you modify the two-dimensional extension of the segment tree so that the execution time of the two-dimensional stabbing query is reduced to  $O(\log_2 N + F)$  with the same space and preprocessing costs? Assume that there are  $N$  rectangles and that  $F$  is the number of rectangles that satisfy the query.
15. Suppose that you are given a set of  $N$  rectangles, say  $V$ , and a rectangle, say  $R$ . All rectangles are rectilinear. Using one-dimensional range trees and the two-dimensional extension of the segment tree described in Exercise 9, give an  $O(\log_2^2 N + F)$  algorithm to find all elements of  $V$  that intersect  $R$  that uses  $O(N \cdot \log_2^2 N)$  space.  $F$  is the number of intersecting elements.
16. How do you avoid reporting some intersections more than once in the solution to Exercise 15?
17. Suppose that you are given a set of  $N$  rectangles, say  $V$ , and a rectangle, say  $R$ . All rectangles are rectilinear. Using one-dimensional range trees and the two-dimensional extension of the segment tree described in Exercise 9, give an algorithm to find all elements of  $V$  that are contained in  $R$ .
18. Suppose that you are given a set of  $N$  rectangles, say  $V$ , and a rectangle, say  $R$ . All rectangles are rectilinear. Using one-dimensional range trees and the two-dimensional extension of the segment tree described in Exercise 9, give an algorithm to find all elements of  $V$  that enclose  $R$ .
19. Repeat Exercise 8 with an interval tree.
20. How would you use the interval tree to represent  $N$  rectilinear rectangles in a manner similar to the adaptation of the segment tree that was described in Exercise 9? Show that the storage requirement is reduced from  $O(N \cdot \log_2^2 N)$  to  $O(N \cdot \log_2 N)$ .
21. Assuming  $N$  rectangles, prove that a rectangle can be inserted into and deleted from the two-dimensional extension of the interval tree described in Exercise 20 in  $O(\log_2^2 N)$  time.
22. Prove that the construction of the two-dimensional extension of the interval tree described in Exercise 20 takes  $O(N \cdot \log_2^2 N)$  time for  $N$  rectangles.
23. Using the two-dimensional extension of the interval tree described in Exercise 20, show that the two-dimensional stabbing query (i.e., find all rectilinear rectangles that contain a given point  $P$ ) can be determined in  $O(\log_2 N + F)$  time.  $N$  is the total number of rectangles, and  $F$  is the number of rectangles that contain  $P$ .
24. Suppose that you are given a set of  $N$  rectangles, say  $V$ , and a rectangle, say  $R$ . All rectangles are rectilinear. Using one-dimensional range trees and the two-dimensional extension of the interval tree described in Exercise 20, show that all elements of  $V$  that intersect  $R$  can be determined in  $O(\log_2^2 N + F)$  time.  $F$  is the number of intersecting elements.
25. Repeat Exercise 17 with an interval tree.
26. Repeat Exercise 18 with an interval tree.
27. Repeat Exercise 8 with a priority search tree.

28. How would you adapt the priority search tree to store two-dimensional intervals? If this is not possible, explain why. If you are successful, use this data structure instead of the two-dimensional extension of the segment tree to solve Exercises 15, 17, and 18.
29. Consider a collection of  $N$  right triangles so that two of the sides are always parallel to the  $x$  and  $y$  axes, and the third side has a negative slope. Devise an algorithm to report all of the intersections between triangles. Can you get its execution time and space requirements to be  $O(N \cdot \log_2 N)$  and  $O(N)$ , respectively?
30. Repeat Exercise 29 by permitting the third side of the right triangle to have an arbitrary slope.
31. Consider a collection of  $N$  arbitrary triangles. Devise an algorithm to report all of the intersections between triangles. Can you get its execution time and space requirements to be  $O(N \cdot \log_2 N)$  and  $O(N)$ , respectively?

## 3.2 Plane-Sweep Methods and the Measure Problem<sup>6</sup>

Data structures such as the segment tree can be used with the plane-sweep paradigm to solve a number of problems other than rectangle intersection. In fact, the segment tree was originally developed by Bentley [166] as part of a plane-sweep solution to compute the area (also termed a *measure problem* [1029]) of a collection of rectangles where overlapping regions are counted only once. It can also be used to compute the perimeter, although we do not discuss it here (but see Exercise 6).

The central idea behind the use of the segment tree to compute the area is to keep track of the total length of the parts of the vertical scan line, say  $L_i$  at halting point  $X_i$ , that overlap the vertical boundaries of rectangles that are active just to the left of  $X_i$ . This quantity is adjusted at each halting point. The total area is obtained by accumulating the product of this quantity with the difference between the current halting point and the next halting point—that is,  $L_i \cdot (X_i - X_{i-1})$ .

To facilitate the computation of the area, each node  $P$  in the segment tree contains three fields, called INT, LEN, and COUNT.  $\text{INT}(P)$  is the interval consisting of the union of the intervals corresponding to the subtrees of  $P$ .  $\text{COUNT}(P)$  is the number of active rectangles whose vertical boundaries contain  $\text{INT}(P)$ .  $\text{LEN}(P)$  contains the length of the overlap of the marked<sup>7</sup> components of  $P$ 's corresponding interval with the vertical scan line.

As an example of the computation of the area, consider the collection of rectangles in Figure 3.1. When the scan line passes over  $x = 7$ , the lengths of its overlaps with the nodes corresponding to intervals [6:8), [3:8), [8:14), [3:14), [14:23), [3:23), [23:34), [34:36), [34:38), [23:38), [23:∞), and [3:∞) (i.e., the values of their LEN fields) are 2, 5, 6, 11, 9, 20, 11, 2, 2, 13, 13, and 33, respectively.

In our example, when  $x = 7$ , the nodes corresponding to the intervals [6:8), [3:8), [8:14), [14:23), [23:34), and [34:36) are marked once (i.e., their COUNT fields have a value of 1). It turns out that in this example, no node is ever marked more than once (see Exercise 3). In other words, no node's COUNT field value ever exceeds 1. The values of the LEN and COUNT fields are adjusted whenever a vertical boundary of a rectangle is inserted into, or deleted from, the segment tree—that is, at each halting point. For  $N$  rectangles, this adjustment process is performed  $O(\log_2 N)$  times per halting point for a total of  $O(N \cdot \log_2 N)$  for the area of the entire collection. The total space requirement is  $O(N)$  (see Exercise 4).

---

<sup>6</sup> This section contains some difficult material. It may be skipped on an initial reading.

<sup>7</sup> Recall from Section 3.1.1 that given a line segment  $S$ , a node  $P$  in the segment tree is *marked* with  $S$  if  $P$ 's interval is totally contained in  $S$ .

The unit-segment tree is analogous to a region quadtree in one dimension. This analogy is exploited by van Leeuwen and Wood [1145] in solving measure problems in higher-dimensional spaces (i.e.,  $d > 2$ ). A typical problem is the computation of the volume that is occupied by the union of a collection of three-dimensional rectangular parallelepipeds. In this case, they use a plane-sweep solution that sorts the boundaries of the parallelepipeds along one direction (say  $z$ ) and then sweeps a plane (instead of a line) parallel to the  $x$ - $y$  plane across it. At any instant, the plane consists of a collection of cross sections (i.e., two-dimensional rectangles). This collection is represented using a region quadtree, which is the two-dimensional analog of the segment tree.

The region quadtree, in this case, is a complete quadtree. It is built as follows. Note that there is a maximum of  $2 \cdot N$  boundaries in all directions. First, sort the  $x$  and  $y$  boundaries of the parallelepipeds (removing duplicates), obtaining  $x_0, x_1, \dots, x_p$  ( $p < 2 \cdot N$ ),  $y_0, y_1, \dots, y_q$  ( $q < 2 \cdot N$ ), and  $2^{h-1} \leq \max(p, q) < 2^h$ . Assume, without loss of generality, that the boundaries are distinct. If they are not, then there are fewer subdivisions. Also, add enough subdivision lines so that there are  $2^h$  subdivisions in each of  $x$  and  $y$ . This grid is irregular (i.e., the cells are of varying size). Next, form a fixed (termed *regular*) grid with an origin at the lower-left corner. Each cell in the regular grid with a lower-left corner at  $(i, j)$  corresponds to the cell in the irregular grid with  $(x_i, y_j)$  as its lower-left corner and is of size  $(x_{i+1} - x_i) \times (y_{j+1} - y_j)$ .

A node at level  $i$  in the region quadtree represents the two-dimensional interval corresponding to the Cartesian product of the intervals  $[x_p : x_{p+2^i})$  and  $[y_q : y_{q+2^i})$ , where  $p \bmod 2^i$  and  $q \bmod 2^i$  are 0. The presence of a cross section of a particular parallelepiped (a rectangle) is represented by *marking* the nodes that overlap it (recall the definition of marking in the discussion of the computation of area). The rectangle (corresponding to the cross section) is inserted in the quadtree in a top-down manner that is analogous to the way a line segment is inserted in a segment tree. As in the computation of the area, we only need to record how many active parallelepipeds contain a particular node (i.e., how many times it is marked) and not their identities.

The volume is computed in the same way as the area. The difference is that now we keep track of the total area of the parts of the scan plane, say  $A_i$  at halting point  $Z_i$ , that overlap the cross sections of the parallelepipeds that are active just to the left of  $Z_i$ . This quantity is adjusted at each halting point by inserting or deleting the cross sections from the quadtree. The total volume is obtained by accumulating the product of this quantity with the difference between the current halting point and the next halting point—that is,  $A_i \cdot (Z_i - Z_{i-1})$ .

Insertion and deletion of a rectangle in a region quadtree is an  $O(N)$  process, since a rectangle can appear in at most  $O(N)$  nodes (see Exercise 12 in Section 2.1.2.4 of Chapter 2). Thus, we see that a plane-sweep algorithm employing the region quadtree will execute in time  $O(N \cdot \log_2 N + N^2)$  or  $O(N^2)$  as there are  $O(N)$  halting points. The  $O(N \cdot \log_2 N)$  term is contributed by the initial sort of the boundaries of the parallelepipeds.

This is an improvement over a solution of Bentley [166] that recursively performs a plane sweep across each of the planes (i.e., it reduces the area problem to  $N$  one-dimensional subproblems) for an execution time of  $O(N^2 \cdot \log_2 N)$ . Generalizing van Leeuwen and Wood's algorithm to  $d$  dimensions reduces the time requirement of Bentley's solution from  $O(N^{d-1} \cdot \log_2 N)$  to  $O(N^{d-1})$ ; however, this increases the space requirement from  $O(N)$  to  $O(N^2)$ . The new bounds are achieved by recursively reducing the  $d$ -dimensional problem to  $N$   $(d - 1)$ -dimensional problems until we obtain the three-dimensional case and then solving each three-dimensional problem as discussed above.

The same technique is used by Lee [1126] to develop an algorithm to compute the maximum number of rectangles with a nonempty intersection (also termed a *maximum clique problem* [801]). Given  $N$  rectangles, the two-dimensional problem can be solved

using a segment tree in  $O(N \cdot \log_2 N)$  time and  $O(N)$  space. In  $d$  dimensions, an adaptation of the region quadtree is used that solves the problem in  $O(N^{d-1})$  time and  $O(N^2)$  space. Note that these algorithms only yield the cardinality of the maximum clique; they do not report its members. The algorithm can be modified to report the members of the maximum clique with the same time bound but using  $O(N \cdot \log_2 N)$  space when  $d = 2$  and  $O(N^3)$  space when  $d > 2$ . Lee points out that the solution to the maximum clique problem can be used to solve a rectangle placement problem (see Exercise 13).

Overmars and Yap [1445] have shown how to solve the  $d$ -dimensional measure problem in  $O(N^{d/2} \cdot \log_2 N)$  time with  $O(N)$  space. For  $d \geq 3$ , this is a significant improvement over the solutions of Bentley [166] and van Leeuwen and Wood [1145] described above. Below, we present Overmars and Yap's construction for three dimensions; the generalization to  $d > 3$  is relatively straightforward. They also use a plane-sweep solution that sorts the boundaries of the parallelepipeds along one direction (say  $z$ ) and then sweeps a plane parallel to the  $x$ - $y$  plane across it.

At any instant, the plane consists of a collection of cross sections (i.e., two-dimensional rectangles). Elements of the collection are termed *active rectangles*. This collection is represented as a set of cells (very much like buckets). Each halting point of the sweep pass requires inserting or deleting an active rectangle. Overmars and Yap are able to perform each insertion into and deletion from the appropriate cells in  $O(\sqrt{N} \cdot \log_2 N)$  time. This means that their algorithm runs in  $O(N \cdot \sqrt{N} \cdot \log_2 N)$  time. The key to their algorithm is to partition the space into cells of a particular size so that their contents (i.e., rectangles) form a trellis (described below) and to use the properties of a trellis in an efficient way.

A *trellis* inside a rectangular cell is a collection of rectangles such that, for each rectangle, either its left and right (i.e., vertical) boundaries coincide with the cell boundary, or its top and bottom (i.e., horizontal) boundaries coincide with the cell boundary (see Figure 3.8). A *horizontal rectangle* is a rectangle whose left and right boundaries coincide with the cell boundary (e.g., rectangle H), and a *vertical rectangle* is a rectangle whose top and bottom boundaries coincide with the cell boundary (e.g., rectangle V).

Trellises are useful because of the following property. Suppose that the cell is of width  $L_x$  and height  $L_y$ . Let  $M_x$  be the aggregate length of the projections of the union of the vertical rectangles on the  $x$  axis, and let  $M_y$  be the aggregate length of the projections of the union of the horizontal rectangles on the  $y$  axis. The area of the union of the rectangles forming the trellis is  $M_x \cdot L_y + M_y \cdot L_x - M_x \cdot M_y$  (see Exercise 15).

To keep track of the total area of the union of rectangles in a trellis, it is necessary to keep track of only the lengths of the projections on the axes (i.e., the numbers  $M_x$  and  $M_y$ ). This can be done by using two segment trees to store the two sets of projected intervals. It follows that if all the rectangles that are ever active within a cell form a trellis, and if there are  $k$  such rectangles, then the measure of the union of the rectangles can be updated at a cost of  $O(\log_2 k)$  per insertion or deletion. Thus, the geometry of the trellis enables the exploitation of the fullness of the cell (i.e., bucket).

To exploit the properties of trellises, the plane containing the rectangles is partitioned as follows. First, the horizontal range is split into  $\sqrt{N}$  intervals such that the interior of each interval contains at most  $2 \cdot \sqrt{N}$  projections of vertical boundaries of rectangles. This partitions the region into  $\sqrt{N}$  vertical *slabs*. Next, each slab is partitioned by horizontal segments into *cells*.

The partitioning within each slab makes use of the concept of a V-rectangle and an H-rectangle. If the interior of a slab contains at least one of the left and right (i.e., vertical) boundaries of a rectangle, then we call the rectangle a *V-rectangle* with respect to the slab. If the interior of the slab does not contain either of the left or right boundaries of a rectangle but does contain some portion of the rectangle's top or bottom (i.e., horizontal) boundaries, then we call the rectangle an *H-rectangle* with respect to the slab.

Figure 3.8  
A trellis.

Figure 3.9  
The partition of the collection of rectangles of Figure 3.1 into slabs and cells.

The partitioning of slabs into cells is performed as follows. Within each slab, a horizontal line is drawn through each top and bottom boundary of a V-rectangle and through every  $\sqrt{N}$ th top or bottom boundary of an H-rectangle. Since there are  $\sqrt{N}$  slabs, it can be shown that the partitioning results in a total of  $O(N)$  cells. Figure 3.9 is the result of applying this partition to the collection of rectangles in Figure 3.1, where query rectangles 1 and 3 are treated as members of the collection. The slabs are labeled S, T, and U. For example, in slab T, rectangles 1, B, D, and G are V-rectangles, while rectangle D is an H-rectangle.

To see that the partitioning does indeed yield  $O(N)$  cells, we observe that there are at most  $2 \cdot \sqrt{N}$  V-rectangles in each slab because of the way the  $x$  axis was partitioned. Therefore, there are at most  $4 \cdot \sqrt{N}$  top and bottom boundaries of V-rectangles in each slab. Moreover, at most  $2 \cdot \sqrt{N}$  top and bottom boundaries of H-rectangles are chosen to be cell boundaries within a slab. Hence, there are at most  $6 \cdot \sqrt{N}$  cells in each slab. Our desired result of  $O(N)$  cells follows since there are  $\sqrt{N}$  slabs.

It is not hard to show (see Exercise 16) that the following properties hold for the partitioning:

1. The boundary of each rectangle intersects at most  $O(\sqrt{N})$  cells.
2. Each cell intersects the boundary of at most  $O(\sqrt{N})$  rectangles.
3. For each cell, the intersection of the rectangles with the cell forms a trellis.

To exploit the cell structure efficiently, a tree having these cells as its leaf nodes is built as follows. Within each slab, vertically adjacent cells are merged (creating a father node). This process continues until there is one node per slab. Then, neighboring slabs are merged. This tree, called an *orthogonal partition tree*, is a variant of the BSP tree (see Sections 1.5.1.4 of Chapter 1 and 2.1.3.1 of Chapter 2). The  $x$  coordinate value serves as the discriminator near the root of the tree, while the  $y$  coordinate value serves as the discriminator at the deeper nodes.

Since there are  $O(\sqrt{N})$  slabs and  $O(\sqrt{N})$  cells per slab, the orthogonal partition tree has a maximum depth of  $O(\log_2 N)$ . Figure 3.10 partially illustrates the orthogonal partition tree for Figure 3.9. In the figure, we only expand the portion corresponding to slab T (containing 11 cells). The cells in each slab are numbered in sequence starting from the top. Thus, the cell labeled  $T_i$  corresponds to the  $i$ th cell from the top of slab T.

Figure 3.10  
The orthogonal partition tree for Figure 3.9. Only slab T is fully expanded.

As the plane sweep progresses, data rectangles (i.e., two-dimensional cross sections of parallelepipeds) are added to the tree (i.e., become active) and deleted from it (i.e., become inactive). Each node  $P$  in the orthogonal partition tree has associated with it five fields, called LEFT, RIGHT, RECT, COUNT, and AREA. LEFT( $P$ ) and RIGHT( $P$ ) are the left and right children, respectively, of  $P$ . RECT( $P$ ) is the rectangle consisting of the union of the cells that are descended from  $P$ . This rectangle is called the *associated rectangle* of  $P$ . COUNT( $P$ ) is the number of active data rectangles that contain RECT( $P$ ). AREA( $P$ ) is the area of the intersection of the union of the active data rectangles with RECT( $P$ ). Associated with each leaf node are two segment trees for the trellis of rectangles in the corresponding cell. These segment trees store the projection of the vertical rectangles on the  $x$  axis and the projection of the horizontal rectangles on the  $y$  axis.

Initially, all segment trees associated with leaf nodes are empty, and all AREA and COUNT fields are zero. To insert rectangle  $R$  in the tree, we start at the root and proceed recursively as follows. Assume that we are processing node  $P$ . There are three cases. If rectangle  $R$  contains RECT( $P$ ), then we increment COUNT( $P$ ). Otherwise, there are two cases, depending on whether  $P$  is a leaf node. If  $P$  is a leaf node, then, by property 3, rectangle  $R$  is either a vertical or a horizontal rectangle of a trellis, and we insert it into the appropriate segment tree. If  $P$  is not a leaf node, then we insert rectangle  $R$  into the two children of  $P$ .

In all three cases, after the insertion, if COUNT( $P$ ) is nonzero, then we set AREA( $P$ ) to the area of RECT( $P$ ). Otherwise, if COUNT( $P$ ) is zero, then we set AREA( $P$ ) to the sum of AREA(LEFT( $P$ )) and AREA(RIGHT( $P$ )) (for a nonleaf node) or to the area of the trellis of rectangles in the corresponding cell (for a leaf node). Deleting a rectangle is done similarly (see Exercise 17).

Using the above structure, inserting rectangle  $R$  (i.e., making it active) requires at most  $O(\sqrt{N} \cdot \log_2 N)$  time. To see that this is true, we observe that two classes of nodes are visited: leaf nodes and nonleaf nodes. By property 1, the boundary of any data rectangle intersects at most  $O(\sqrt{N})$  leaf nodes. Updating the two segment trees of each leaf node intersected by  $R$  requires at most  $O(\log_2 N)$  time. Therefore,  $O(\sqrt{N} \cdot \log_2 N)$  time is sufficient to update the AREA fields of all leaf nodes that intersect  $R$ . For each leaf node that is visited, the path from the root visits at most  $O(\log_2 N)$  nodes, for a total of  $O(\sqrt{N} \cdot \log_2 N)$  nodes. For each leaf node that has been visited, the children of at most  $O(\log_2 N)$  of the nodes that were encountered along the path starting from the root have their COUNT field updated. This accounts for all of the nodes that have their COUNT field updated.

The algorithm of Overmars and Yap uses  $O(N \cdot \sqrt{N})$  space since there are  $O(N)$  segment trees (one per cell), each using  $O(\sqrt{N})$  storage (see Exercise 18). Overmars and Yap [1445] show that the total storage requirement can be reduced to  $O(N)$  by using a technique called *streaming* due to Edelsbrunner and Overmars [544]. The basic idea behind streaming is to build only a portion of the tree at a time and to perform all updates to that portion of the tree together. In other words, the updates within the structure are grouped sequentially according to location within the structure, rather than according to the time at which they occur. For more details, see [544].

### Exercises

1. Devise an  $O(N \cdot \log_2 N)$  algorithm to compute the total length of a collection of  $N$  parallel line segments that can overlap. Overlapping parts should be counted only once.
2. Compute the total area spanned by the collection of rectangles in Figure 3.1. Letting  $(x_{\min}, y_{\min}, x_{\max}, y_{\max})$  represent a rectangle, rectangles A, B, C, D, E, F, and G are at (3,6,8,36), (25,34,34,38), (33,21,37,36), (21,23,38,27), (6,3,26,8), (31,15,35,19), and (23,11,38,14), respectively. Overlapping parts should be counted only once.

3. Why is no node marked more than once in the computation of the total area spanned by the collection of rectangles in Figure 3.1? In particular, what about the nodes corresponding to intervals [23,34) and [34,36)?
4. Prove that an algorithm that uses a segment tree to compute the total area spanned by a collection of  $N$  rectangles uses  $O(N)$  space.
5. Give a procedure SWEEPAREA to compute the area of a collection of possibly overlapping rectangles. Use the plane-sweep approach with a segment tree. You must code procedures to insert and delete the vertical boundaries of the rectangles into and from the segment tree.
6. Give a procedure SWEEPPERIMETER to compute the perimeter of a collection of possibly overlapping rectangles. Use the plane-sweep approach with a segment tree. You must code procedures to insert and delete the vertical boundaries of the rectangles from the segment tree.
7. Give a procedure MAX2DCLIQUE to compute the cardinality of the maximum clique of a collection of possibly overlapping rectangles. Use the plane-sweep approach with a segment tree.
8. Modify your solution to Exercise 7 so that the identities of the members of the maximum clique are also reported, not just the cardinality of the clique.
9. Give a procedure SWEEPVOLUME to compute the volume of a collection of possibly overlapping three-dimensional rectangles. Use the plane-sweep approach with a region quadtree. You must code procedures to insert and delete the  $x$ - $y$  boundaries of the rectangles into and from the region quadtree.
10. Give a procedure SWEEPSURFACEAREA to compute the surface area of a collection of possibly overlapping three-dimensional rectangles. Use the plane-sweep approach with a region quadtree. You must code procedures to insert and delete the  $x$ - $y$  boundaries of the rectangles into and from the region quadtree.
11. Give a procedure MAX3DCLIQUE to compute the cardinality of the maximum clique of a collection of possibly overlapping three-dimensional rectangles. Use the plane-sweep approach with a region quadtree.
12. Modify your solution to Exercise 11 so that the identities of the members of the maximum clique are also reported, not just the cardinality of the clique.
13. Consider the following rectangle placement problem. Given  $n$  points in a two-dimensional space and a rectangular window, say  $R$ , whose sides are parallel to the coordinate axes, find a point in the plane at which the window can be centered so that it contains a maximum number of points in its interior. The window is not permitted to be rotated; it can be translated only.
14. Consider a variation of the rectangle placement problem of Exercise 13 where the points are weighted. Find the location of  $R$  in which the sum of the weights of the points in it is maximized.
15. Consider a trellis inside a rectangular cell of width  $L_x$  and height  $L_y$ . Let  $M_x$  be the aggregate length of the projections of the union of the vertical rectangles on the horizontal axis, and let  $M_y$  be the aggregate length of the projections of the union of the horizontal rectangles on the vertical axis. Show that the area of the union of the rectangles forming the trellis is  $M_x \cdot L_y + M_y \cdot L_x - M_x \cdot M_y$ .
16. Show that properties 1, 2, and 3 used in the construction of Overmars and Yap's solution to the measure problem hold for  $d = 3$ .
17. Give an algorithm to delete a rectangle from an orthogonal partition tree when using Overmars and Yap's solution to the measure problem for  $d = 3$ .
18. Prove that each segment tree in Overmars and Yap's solution to the measure problem in three dimensions for  $N$  parallelepipeds uses  $O(\sqrt{N})$  space.
19. Can you use Overmars and Yap's approach to compute the size of the maximum clique in time  $O(N^{d/2} \cdot \log_2 N)$  with  $O(N)$  space for  $N$  rectangles in a  $d$ -dimensional space?
20. Suppose that you apply Overmars and Yap's approach to report the members of the maximum clique for  $N$  rectangles in a  $d$ -dimensional space. What are the time and space requirements? In particular, how much space is needed to store the segment trees in each of the cells?

21. Why can you not use a  $(d - 1)$ -dimensional region quadtree (e.g., an octree in three dimensions) to compute the measure of a  $d$ -dimensional space containing  $N$  rectangles in  $O(N^2)$  time—that is, why can you not represent a  $(d - 1)$ -dimensional cross section by a  $(d - 1)$ -dimensional quadtree to get the execution time of the algorithm down to  $O(N^2)$  and  $O(N^{d-1})$  space?
22. Consider a collection of  $N$  right triangles so that two of the sides are always parallel to the  $x$  and  $y$  axes, and the third side has a negative slope. Devise an algorithm to compute the area of the collection. Can you get its execution time and space requirements to be  $O(N \cdot \log_2 N)$  and  $O(N)$ , respectively?
23. Repeat Exercise 22 permitting the third side of the right triangle to have an arbitrary slope.
24. (Mark H. Overmars) Consider a collection of  $N$  arbitrary triangles. Devise an algorithm to compute the area of the collection. Can you get its execution time and space requirements to be  $O(N \cdot \log_2 N)$  and  $O(N)$ , respectively?

### 3.3 Point-Based Methods

In this section, we first discuss the representation of rectangles as points (Section 3.3.1), and then examine the representation of the collection of points (Section 3.3.2) using some of the methods described in Chapter 1. We conclude with a summary of some of the properties of the representative point method (Section 3.3.3).

#### 3.3.1 Representative Points

A common solution to the problem of representing a collection of objects is to approximate elements of the collection by simpler objects. One technique is to represent each object by using one of a number of primitive shapes that contain it. The discussion in Section 2.1.5.2 of Chapter 2 is primarily in the context of rectangle primitives; however, other shapes, such as triangles, circles, cubes, parallelepipeds, cylinders, spheres, and so on, can also be used.

This approach is motivated, in part, by the fact that it is easier to test the containing objects for intersection than it is to perform the test using the actual objects. For example, it is easier to compute the intersection of two rectangles than of two polygons for which the rectangles serve as approximations. More complex approximations can be created by composing Boolean operations and geometric transformations on instances of the primitive types. In fact, this is the basis of the constructive solid geometry (CSG) technique of representing three-dimensional objects [1555, 1935] as discussed in Section 2.2 of Chapter 2.

The advantage of using such approximations is that each primitive can be described by a small set of parameters and can, in turn, represent a large class of objects. In particular, if primitive  $P$  is described by  $d$  parameters, then each set of parameter values defines a point in a  $d$ -dimensional space assigned to the class of objects in which the members are all the possible instances of primitive  $P$ . Such a point is termed a *representative point*. Note that a representative point and the class to which it belongs completely define all of the topological and geometric properties of the corresponding object.

Most primitives can be described by more than one set of parameters. For example, using Cartesian coordinates, a circle is described by a representative point in three-dimensional space consisting of the  $x$  and  $y$  coordinate values of its center and the value of its radius. On the other hand, using polar coordinates, a circle can also be described by a representative point in three-dimensional space consisting of the  $\rho$  and  $\theta$  coordinate values of its center and the value of its radius. For other primitives, the choices are even more varied. For example, the class of objects formed by a rectangle in two dimensions

with sides parallel to the  $x$  and  $y$  coordinate axes is described by a representative point in four-dimensional space. Some choices for the parameters are as follows:

1. The  $x$  and  $y$  coordinate values of two diagonally opposite corners of the rectangle (e.g., the lower left and upper right), termed a *corner transformation* [1709]
2. The  $x$  and  $y$  coordinate values of a corner of the rectangle, together with its horizontal and vertical extents
3. The  $x$  and  $y$  coordinate values of the centroid of the rectangle, together with its horizontal and vertical extents (i.e., the horizontal and vertical distances from the centroid to the relevant sides)

The actual choice depends on the type of operations that we intend to perform on the objects formed by them.

Different parameters have different effects on the queries, and thus making the right choice is important. Hinrichs and Nievergelt [839, 841] lump the parameters into two classes: location and extension. Location parameters specify the coordinate values of a point, such as a corner or a centroid. On the other hand, extension parameters specify size, for example, the radius of a circle. This distinction is always possible for objects that can be described as Cartesian products of spheres of varying dimension.

Many common objects can be described in this way. For example, a rectangle is the Cartesian product of two one-dimensional spheres, and a cylinder is the Cartesian product of a one-dimensional sphere and a two-dimensional sphere. Whenever such a distinction between location and extension parameters can be drawn, the proximity queries described in the opening section of this chapter (i.e., intersection, containment, and enclosure) have cone-shaped search regions. The tip of the cone is usually in the subspace of the location parameters and has the shape of the query point or query object.

The importance of making the right choice can be seen by examining the class of one-dimensional intervals on a straight line. As an example, consider the collection of rectangles given in Figure 3.1. Each rectangle can be represented as the Cartesian product of two one-dimensional spheres corresponding to the sides that are given as horizontal and vertical intervals in Figure 3.11. These intervals can be represented using any of the three representations enumerated above.

Representation 1 yields an ordered pair  $(L, R)$  where  $L$  and  $R$  correspond to the left and right endpoints, respectively, of the interval. Figure 3.12 shows how the horizontal intervals are represented using this method. In most applications, the intervals are small.

Figure 3.11  
The (a) horizontal (i.e.,  $x$ ) and (b) vertical (i.e.,  $y$ ) intervals corresponding to the sides of the rectangles in Figure 3.1. Solid lines correspond to the rectangles in the collection, and dotted lines correspond to the query rectangles.

Figure 3.12  
Representation of the (a) horizontal (i.e.,  $x$ ) and (b) vertical (i.e.,  $y$ ) intervals of Figure 3.1 as ordered pairs  $(L, R)$ , where  $L$  and  $R$  are the left and right endpoints, respectively, of the interval (i.e., representation 1).

Therefore, for representation 1,  $L$  and  $R$  are very close in value.  $L < R$  means that the representative points are clustered near and above the diagonal and that the lower half of the underlying space is empty.

The clustering means that the representative points are not well distributed. Therefore, any data structure for storing the collection of the representative points that is based on organizing the embedding space from which the data is drawn (e.g., address computation) into rectangular-shaped blocks, in contrast to one based on the actual representative points that are stored (e.g., comparative search), will have to pay a price for the large empty areas in the embedding space (e.g., at least one-half below the diagonal). Faloutsos and Rego [589] use representation 1 and overcome this price for the collection of the representative points by ignoring the empty half of the underlying space (i.e., embedding space in this discussion) and decompose the isocetes triangle corresponding to the nonempty half of the underlying space with a quadtree-like regular decomposition into four congruent isocetes triangles termed *triangular cells* (or *tri-cells* for short). This process is applied recursively whenever there are too many objects associated with a particular triangular cell. Note that if all the intervals are small (or have approximately the same width), the clustering about the diagonal (or a line parallel to the diagonal) results in decomposition of all of the triangular cells through which the diagonal passes.

On the other hand, Hinrichs and Nievergelt point out that separating the location parameters from the extension parameters results in a smaller underlying space (especially when the rectangles and corresponding intervals are small) that is filled more uniformly (but see Exercise 9). For example, representation 3 is used in Figure 3.13, where the horizontal intervals are represented as an ordered pair  $(C_x, D_x)$  such that  $C_x$  is the centroid of the interval and  $D_x$  is the distance from the centroid to the end of the interval. Note that no matter which representative point is used, some part of the underlying space will be empty. In the case of representation 1, the empty space consists of half the size of the underlying space and is a direct result of the stipulation that the starting endpoints of intervals are less than the terminating endpoints. In the case of representation 3, the empty space consists of two triangular regions at the upper-left and upper-right corners of the underlying space and is a direct result of a stipulation that both the starting and terminating endpoints of intervals lie in the underlying space. Of course, we could allow intervals that extend beyond the underlying space, but they are not likely to arise in a practical setting. The advantage of representation 3 over representation 1 is that these empty regions are generally very small since the intervals are small. Thus, the effect of the presence of the empty region is negligible (see Exercise 10). Representation 2 is similar to representation 3 (see Exercise 7).

Bearing the above considerations in mind, representation 3 seems to be the most appropriate. In such a case, a rectangle is represented by the four-tuple  $(C_x, D_x, C_y, D_y)$ , interpreted as the Cartesian product of a horizontal and a vertical one-dimensional interval—that is,  $(C_x, D_x)$  and  $(C_y, D_y)$ , respectively.<sup>8</sup> This representation is used by Hinrichs and Nievergelt [839, 841], and the following examples of its utility are due to them.

Proximity queries involving point and rectangular query objects are easy to implement. Their answers are conic-shaped regions in the four-dimensional space formed by the Cartesian product of the two interval query regions. This is equivalent to computing the intersection of the two query regions but is much more efficient. It also enables us to visualize our examples since the horizontal and vertical intervals correspond to the projections of the query responses on the  $C_x$ - $D_x$  and  $C_y$ - $D_y$  planes, respectively.

We illustrate our discussion with the collection of rectangles given in Figure 3.1, along with query point P and query rectangles 1, 2, and 3. Note that when the query objects are not individual points or rectangles, then the representation of a rectangle as

### Section 3.3 POINT-BASED METHODS

Figure 3.13 Representation of the (a) horizontal (i.e.,  $x$ ) and (b) vertical (i.e.,  $y$ ) intervals of Figure 3.1 as ordered pairs  $(C_x, D_x)$  and  $(C_y, D_y)$ , where  $C_x$  and  $D_x$  are the centers and half-lengths, respectively, of the  $x$  interval, and  $C_y$  and  $D_y$  are the centers and half-lengths, respectively, of the  $y$  interval (i.e., representation 3).

<sup>8</sup> The notation  $(C_x, D_x)$  corresponds to a point in a two-dimensional space. It is *not* the open one-dimensional interval whose left and right endpoints are at  $C_x$  and  $D_x$ , respectively.

Figure 3.14 Search region for a point query on  $P$  for the (a) horizontal (i.e.,  $x$ ) and (b) vertical (i.e.,  $y$ ) intervals of Figure 3.1 when using representation 3. All intervals containing  $P$  are in the shaded regions. Intervals appearing in the shaded regions of both (a) and (b) correspond to rectangles that contain  $P$ .

Figure 3.15 Search region for a window query on query rectangle 1 of Figure 3.1 for the (a) horizontal (i.e.,  $x$ ) and (b) vertical (i.e.,  $y$ ) intervals of that figure when using representation 3. All intervals that contain points of rectangle 1 are in the shaded regions. Intervals appearing in the shaded regions of both (a) and (b) correspond to rectangles that intersect rectangle 1.

the Cartesian product of two orthogonal intervals is not that useful (e.g., query regions in the form of an arbitrary line or circle as in Exercises 13 and 14, respectively).

For a point query, we wish to determine all intervals that contain a given point, say  $p$ . These intervals form a cone-shaped region with a tip that is an interval of length zero centered at  $p$ .<sup>9</sup> For example, the horizontal and vertical intervals containing  $P$  are shown shaded in Figure 3.14(a, b), respectively. To find all of the rectangles that contain a given point, we access a specific region in the four-dimensional space defined by the Cartesian product of the horizontal and vertical point-in-interval query regions. For example,  $P$  is in the set of rectangles with representative points in the intersection of the shaded portion of Figure 3.14(a, b)—that is,  $\{C, D\}$  is the intersection of  $\{C, D, G\}$  and  $\{A, C, D\}$ .

A window query is a bit more complex than a point query. In this case, the one-dimensional analog of this query is to find all intervals that overlap a given interval, say  $I$ . Again, the set of overlapping intervals consists of a cone-shaped region with a tip that is the interval  $I$ . For example, the horizontal and vertical intervals that overlap the horizontal and vertical sides of query rectangle 1 are shown shaded in Figure 3.15(a, b), respectively. To find all of the rectangles that overlap the query window, we access a specific region in the four-dimensional space defined by the Cartesian product of the horizontal and vertical interval-in-interval query regions. For example, query rectangle 1 overlaps the intersection of the shaded portion of Figure 3.15(a, b)—that is,  $\{B, D\}$  is the intersection of  $\{B, D, E, G\}$  and  $\{A, B, C, D\}$ .

For a containment query, the one-dimensional analog is to find all the intervals that are totally contained within a given interval, say  $I$ . The set of contained intervals consists of a cone-shaped region with a tip at  $I$  that opens in the direction of smaller extent values. This makes sense as all intervals within the cone are totally contained in the interval represented by the tip. For example, the horizontal and vertical intervals contained in the horizontal and vertical sides of query rectangle 2 are shown shaded in Figure 3.16(a, b), respectively. To find all of the rectangles that are contained in the query window, we access a specific region in the four-dimensional space defined by the Cartesian product of the horizontal and vertical contained-in-interval query regions. For example, query rectangle 2 contains the intersection of the shaded portion of Figure 3.16(a, b)—that is,  $\{F\}$ .

For an enclosure query, the one-dimensional analog is to find all the intervals that enclose the given interval, say  $I$ . The set of enclosing intervals consists of a cone-shaped region with a tip at  $I$  that opens in the direction of larger extent values. This is logical because the interval represented by the tip is contained (i.e., enclosed) by all intervals within the cone. To find all of the rectangles that enclose the query window, we access a specific region in the four-dimensional space defined by the Cartesian product of the horizontal and vertical enclose-interval query regions. For example, the horizontal and vertical intervals that enclose the horizontal and vertical sides of query rectangle 3 are shown shaded in Figure 3.17 (a, b), respectively. For example, query rectangle 3 contains the intersection of the shaded portion of Figure 3.17(a, b)—that is,  $\{E\}$ .

In spite of the relative ease with which the above queries are implemented using the representative point method with representation 3, there are queries for which it is ill suited. For example, suppose that we wish to solve the rectangle intersection problem. In fact, no matter which of the three representations we use, to solve this problem we must intersect each rectangle with every other rectangle. The problem is that none of these representations is area oriented: they reduce a spatial object to a single representative point.

Although the extent of the object is reflected in the representative point, the final mapping of the representative point in the four-dimensional space does not result in the

<sup>9</sup> McCreight [1265] uses the same technique in conjunction with representation 1 to solve this problem (see Exercise 9). Note, though, that the search region is rectangle shaped in this case.

Figure 3.16 Search region for a containment query on query rectangle 2 of Figure 3.1 for the (a) horizontal (i.e.,  $x$ ) and (b) vertical (i.e.,  $y$ ) intervals of that figure when using representation 3. All intervals contained in one of the intervals forming rectangle 2 are in the shaded regions. Intervals appearing in the shaded regions of both (a) and (b) correspond to rectangles contained in rectangle 2.

preservation of nearness in the two-dimensional space from which the rectangles are drawn. In other words, two rectangles may be very close (and possibly overlap), yet the Euclidean distance between their representative points in four-dimensional space may be quite large, thereby masking the overlapping relationship between them. For example, even though rectangles B and D intersect query rectangle 1, we cannot easily tell if they intersect each other, except by checking their sizes.

So far, our discussion has emphasized representation 3. Nevertheless, of the three representations (i.e., 1, 2, and 3), representation 1 is a bit easier to work with in many applications. Recall that representations 2 and 3 have a component that indicates the extent of the rectangle (i.e., its width and height). In most applications, it is rare for this information (i.e., the extent) to be used on its own. On the other hand, it is very common (especially in geometric operations) to need to know the coordinate values of the corners of the rectangles or its sides (i.e., faces in higher dimensions).

Using representation 1, the two extreme corners specify the minimum and maximum coordinate values in the rectangle for any coordinate axis. The implementations of most geometric operations, such as point in rectangle, rectangle intersection, and distance from a point to a rectangle or between two rectangles, make use of this information. For instance, when testing whether a point is in a rectangle, we know that a point is not in the rectangle if, for any coordinate axis, the particular coordinate value of the point is outside the particular coordinate range of the rectangle (i.e., less than the minimum or greater than the maximum). This means that if we are using representations 2 and 3, then additional operations need to be performed to obtain the coordinate values of one (in the case of representation 2) or two (in the case of representation 3) corners of the rectangles. Besides making the source code implementing geometric operations less readable, this increases the number of arithmetic operations. However, in some cases, we can use clever coding tricks for representations 2 and 3 such that not many more, or even the same number of, arithmetic operations are used (see Exercise 18). In addition, we do want to point out that knowing the values of the extents is not without merit as it does make certain computations easier, such as computing areas.

Although most of our discussion has been in the context of representations 1, 2, and 3, other representative points are also commonly used. In particular, interestingly, even though a rectangle whose sides are parallel to the  $x$  and  $y$  axes requires the unique specification of four values, it is also frequently modeled by a representative point in a two-dimensional space. The representative point corresponds to the centroid of the rectangle or to one of its corners (e.g., lower left).

If rectangles are not permitted to overlap, then the above two-valued representation is sufficient to ensure that no two rectangles have the same representative point. Of course, since two values do not uniquely specify the rectangle, the remaining values are retained

Figure 3.17 Search region for an enclosure query on query rectangle 3 of Figure 3.1 for the (a) horizontal (i.e.,  $x$ ) and (b) vertical (i.e.,  $y$ ) intervals of that figure when using representation 3. All intervals that enclose one of the intervals forming rectangle 3 are in the shaded regions. Intervals appearing in the shaded regions of both (a) and (b) correspond to rectangles that enclose rectangle 3.

in the record corresponding to the rectangle that is associated with the representative point. If rectangles are permitted to overlap, then such a representation means that there may be more than one record associated with a specific representative point.

### Exercises

1. Suppose that the representative point corresponding to each rectangle is its centroid and that the collection of rectangles is represented using a PR quadtree. Moreover, rectangles are not permitted to overlap. What is the maximum horizontal or vertical separation of two rectangles with representative points that are contained in brother nodes in the PR quadtree (i.e., at level  $i$  in a  $2^n \times 2^n$  image with a root at level  $n$ )?
2. Using the same representation and assumption about no overlapping rectangles as in Exercise 1, give an algorithm to determine the rectangle associated with a given point. If the representative point is stored in a block at level  $i$ , what is the maximum size of the neighborhood that may have to be searched to perform the operation?
3. How would you adapt representation 3 to represent a region quadtree for a binary image as a collection of representative points stored as a PR quadtree?
4. Prove that storing the region quadtree using a PR quadtree, such that the black nodes are representative points that correspond to the centers of black blocks, never requires more space (i.e., more nodes) than the region quadtree.
5. How would you represent a sphere in terms of location and extension parameters?
6. How many parameters are necessary to represent a rectangle in a general position in two-dimensional space?
7. Discuss the use of representation 2 for the representative points of the horizontal and vertical intervals making up the sides of a rectangle. Draw a graph such as Figures 3.11 and 3.12 for the horizontal intervals of Figure 3.1 using this representation. What are the advantages and disadvantages in comparison to representations 1 and 3?
8. Suppose that you are using representation 1 for the representative point of each interval in a collection of one-dimensional intervals. What is the shape of the search region for a query that seeks all the intervals that contain point  $p$ ?
9. What is the relationship between representations 1 and 3?
10. The stipulation that the starting endpoints of intervals are less than their terminating endpoints means that one-half of the underlying space is empty in the case of representation 1. In the case of representation 3, the same stipulation means that the two triangular regions at the upper-left and upper-right corners of the underlying space are empty. Given that the intervals are drawn from the same space, the empty parts of the underlying space have the same area regardless of the representation. Therefore, assuming that the intervals are drawn from  $[0, w]$ , why do we say that representation 3 is superior to representation 1 when most of the intervals are very small (say of length  $s$ , where  $s$  is much smaller than  $w$ )?
11. How would you implement a point query for a collection of rectangles with a representative point that uses representation 1? Repeat for a point set query involving intersection (i.e., windowing), as well as the two subset relations (i.e., containment and enclosure).
12. How would you implement a point query for a collection of rectangles with a representative point that uses representation 2? Repeat for a point set query involving intersection (i.e., windowing), as well as the two subset relations (i.e., containment and enclosure).
13. Given a line from point  $(a, b)$  to point  $(c, d)$  and a collection of rectangles with a representative point that uses representation 3, describe the search regions for all of the rectangles intersected by the line and all the rectangles that enclose the line. Note that the line need not be horizontal or vertical.
14. Given a circle of radius  $r$  centered at point  $(a, b)$  and a collection of rectangles with a representative point that uses representation 3, describe the search regions for all of the rectangles intersected by the circle, the rectangles contained in their entirety in the circle, and the rectangles that enclose the circle.

15. Suppose that the representative point for a circle in the  $x$ - $y$  plane uses representation 3. Describe the search regions for an object intersection query in which the object is (a) a point, (b) a line, (c) a circle, or (d) a rectangle.
16. Suppose that the representative point for a circle, say  $C$ , in the  $x$ - $y$  plane uses representation 3. Describe the search regions for (a) all circles contained in  $C$  and, likewise, for (b) all circles enclosing  $C$ .
17. Consider a collection of two-dimensional objects and the implementation of a graphics editor that permits a graphical search-and-replace operation. Suppose that the objects are represented by their enclosing curves. Moreover, let each curve be approximated by a piecewise linear approximation. Give some possible representative points for the objects. Consider also the issue of translation, rotation, and scale invariance.
18. (Gísli R. Hjaltason) Compare the use of representations 1, 2, and 3 for the representative point of the horizontal and vertical intervals making up the sides of a rectangle when determining whether a point  $p$  is in rectangle  $r$ . Perform the comparison by giving the algorithms to compute the function and tabulate the number of different arithmetic and comparison operations. Note that on many CPU architectures, addition/subtraction and comparison operations are equally expensive. Note also that we ignore the cost of accessing the locations (i.e., via pointer manipulation) of the coordinate values of the point and the rectangle, which may itself involve some integer arithmetic operations, whereas the arithmetic operations on the coordinate values make use of floating-point arithmetic.

### 3.3.2 Collections of Representative Points

Once a specific representative point method is chosen for the rectangle, we can use the techniques discussed in Chapter 1 to organize the collection of representative points. Again, the choice of technique depends, to a large extent, on the type of operations that we will be performing. There are a number of techniques whose use has been proposed. In this section, we briefly describe the corner stitching method (Section 3.3.2.1) and the four-dimensional  $k$ - $d$  tree (Section 3.3.2.2), as well as use of the grid file (Section 3.3.2.3), the LSD tree (Section 3.3.2.4), and two-dimensional representations, such as the PR quadtree and the  $k$ - $d$  tree (Section 3.3.2.5).

#### 3.3.2.1 Corner Stitching

Ousterhout [1439] represents the collection of representative points using a nonhierarchical approach where each rectangle, treated as if it were a point, is connected to its neighbors by means of links. This technique is termed *corner stitching*. In particular, for each rectangle, there are two links from the lower-left corner to the two neighbors to its left and bottom and two links from the top-right corner to the two neighbors to its top and right. This is analogous to using representation 1 for the representative point of the rectangle with no indexing to speak of for the individual rectangles.

The corner stitching representation imposes a partition of the plane that resembles a mosaic consisting of two types of tiles: space and solid. The solid tiles correspond to the rectangles. The space tiles correspond to the void space, if any, between the rectangles. The space tiles are maximal horizontal strips, which means that no space tile is adjacent to a space tile immediately to its left or right. The maximality restriction implies that the decomposition into space and solid tiles is unique.

Links exist between all types of tiles: solid tiles can be linked to both solid and space tiles, and likewise for space tiles. It can be shown that, for  $N$  rectangles, there are at most  $3 \cdot N + 1$  space tiles (see Exercise 3). Figure 3.18 is an example of the space decomposition imposed by corner stitching for a nonoverlapping subset of the collection of rectangles given in Figure 3.1. The space tiles are delimited by solid and broken lines, while the rectangles are delimited by solid lines. The corner stitches (i.e., links) are also shown for some of the rectangles and space tiles. Although our discussion has been limited to the situation that the tiles are rectangles, corner stitching can also be used

Figure 3.18  
Example of the space decomposition imposed by corner stitching for a nonoverlapping subset of the collection of rectangles given in Figure 3.1. The rectangles are delimited by solid lines, while the space tiles are delimited by broken lines. Some of the corner stitches are shown.

Figure 3.19  
An example collection of rectangles A, B, C, and D illustrating the worst case of corner stitching when wishing to locate the rectangle associated with point P when the search starts at rectangle A and proceeds in an upward direction.

when the tiles are 45-degree trapezoids defined in such a way that their top and bottom sides are parallel to one of the axes while forming 45-, 90-, and 135-degree angles with the remaining sides [1245].

Corner stitching greatly facilitates operations that involve finding nearest neighbors. However, overlapping rectangles are not easily handled by it. Moreover, since the only way to move from one rectangle to another is through the links, in the worst case, accessing the rectangle associated with a given point requires that all rectangles be examined (see Exercise 5). This is a direct consequence of the fact that there is no index (i.e., none of the representations of collections of points described in Chapter 1 is used here). As an example of this worst case, consider the set of rectangles given in Figure 3.19. A is the first rectangle in the set. We wish to access the rectangle associated with point P, and we do so by traversing the up links shown in Figure 3.19. The worst case can be overcome by imposing an additional structure in the form of one of the hierarchical organizations described below while still retaining the links. However, in such a case, both the solid and space tiles must be represented in the structure. For a discussion of algorithms using corner stitching, see Shand [1741].

### Exercises

1. Give an algorithm to insert a rectangle into a corner stitching representation.
2. Give an algorithm to delete a rectangle from a corner stitching representation.
3. Prove that, for  $N$  rectangles, the corner stitching representation implies a maximum of  $3 \cdot N + 1$  space tiles.
4. Under what conditions is the number of space tiles fewer than  $3 \cdot N + 1$ ?
5. Give an algorithm to find the rectangle that covers a particular point location when the rectangles are represented using corner stitching.
6. Give an algorithm to find all rectangles that intersect a given window when the rectangles are represented using corner stitching.

### 3.3.2.2 Balanced Four-Dimensional K-d Tree

Lauther [1114] and Rosenberg [1571] use representation 1 for the representative point and then use a balanced four-dimensional k-d tree (somewhat like the adaptive k-d tree discussed in Section 1.5.1.4 of Chapter 1 with the exception that the coordinates are tested in a cyclic order) to store the collection of representative points. Lauther discusses the solution of the rectangle intersection problem using the balanced four-dimensional k-d tree. The solution is an adaptation of the  $O(N^2)$  algorithm. It first builds the tree (equivalent to a sorting process) and then traverses the tree in inorder and intersects each rectangle, say  $P$ , with the remaining unprocessed rectangles (i.e., the inorder successors of  $P$ ).<sup>10</sup>

The balanced four-dimensional k-d tree can be used to solve the rectangle intersection problem by making use of the fact that two rectangles with sides parallel to the axes intersect if their projections on the  $x$  axis intersect and their projections on the  $y$  axis intersect. The one-dimensional analog of this condition has been used in the segment and interval tree solutions to the rectangle intersection problem (see Sections 3.1.1 and 3.1.2). More formally, we can restate this condition as stipulating that in order for rectangle  $Q$  to intersect rectangle  $P$ , all four of the following conditions must be satisfied:

1.  $x_{\min}(Q) \leq x_{\max}(P)$
2.  $y_{\min}(Q) \leq y_{\max}(P)$

<sup>10</sup> In this discussion, we use  $P$  to refer to both a rectangle and its corresponding node in the tree. The correct meaning should be clear from the context.

3.  $x_{\min}(P) \leq x_{\max}(Q)$
4.  $y_{\min}(P) \leq y_{\max}(Q)$

Armed with this formulation of the condition, we see that when the collection of representative points is represented as a balanced four-dimensional k-d tree (really, any variant of a four-dimensional k-d tree), we do not always have to visit all of the inorder successors of  $P$  since, whenever one of these conditions fails to hold at a node  $Q$ , then the appropriate subtree of  $Q$  need not be searched. These conditions can be restated in the following manner, which is more compatible with the way in which the balanced four-dimensional k-d tree is traversed:

5.  $x_{\min}(Q) \leq x_{\max}(P)$
6.  $y_{\min}(Q) \leq y_{\max}(P)$
7.  $-x_{\max}(Q) \leq -x_{\min}(P)$
8.  $-y_{\max}(Q) \leq -y_{\min}(P)$

Now, we build a balanced four-dimensional k-d tree with discriminators  $K_0$ ,  $K_1$ ,  $K_2$ , and  $K_3$ , corresponding to  $x_{\min}$ ,  $y_{\min}$ ,  $-x_{\max}$ , and  $-y_{\max}$ , respectively. Whenever we encounter node  $Q$  discriminating on  $K_d$  such that  $K_d(Q) > K_{(d+2) \bmod 4}(P)$ , then no nodes in the right subtree of  $Q$  need be examined further.

Solving the rectangle intersection problem as described above has an upper bound of  $O(N^2)$  and a lower bound of  $O(N \cdot \log_2 N)$ . The lower bound is achieved when pruning is assumed to occur at every right subtree (see Exercise 6). When the rectangle intersection problem is posed in terms of conditions 5–8, the relation “ $\leq$ ” between  $Q$  and  $P$  is said to be a *dominance relation* [1511]. In such a case, the intersection problem is called the *dominance merge* problem by Preparata and Shamos [1511]. Given  $F$  rectangle intersections, the algorithm of Preparata and Shamos solves the rectangle intersection problem in  $O(N \cdot \log_2^2 N + F)$  time instead of the optimal  $O(N \cdot \log_2 N + F)$  time.

A balanced four-dimensional k-d tree takes more time to build than an ordinary four-dimensional k-d tree since medians must be computed to assure balance. The balanced four-dimensional k-d tree makes point searches and region searches quite efficient. For such operations, the balanced four-dimensional k-d tree is preferable to corner stitching because of the implicit two-dimensional sorting of the rectangles. In addition, overlapping rectangles can be handled easily with the balanced four-dimensional k-d tree, whereas this is quite complicated with corner stitching. However, for operations involving finding nearest neighbors, corner stitching is superior to the balanced four-dimensional k-d tree.

Rosenberg compares the performance of the balanced four-dimensional k-d tree, a point method in his formulation, with linked lists<sup>11</sup> and the area-based quadtree approaches discussed in Section 3.4.1 and concludes that the point methods are superior. However, he only takes into account point and window queries. Comparisons using queries, such as finding all intersecting rectangles, may lead to a different conclusion.

### Exercises

1. Can we say that whenever two rectangles intersect, then the corner of one rectangle is contained in the other rectangle?
2. By definition, each node in a balanced four-dimensional k-d tree that discriminates on key  $K_j$  serves as an upper bound for all the  $K_j$  values in the LOCHILD and as a lower bound for all the  $K_j$  values in the HICHILD. To insure that point and region searches are efficient in the balanced four-dimensional k-d tree, it is useful to know more about the region below each node. Thus, a bounds array is stored with each node to indicate the information necessary to cut

---

<sup>11</sup> The rectangles are stored in a doubly linked list.

within a conic region for a collection  
of rectangles represented by (a) a  
grid file and (b) a k-d tree.

off unproductive search. For  $d$ -dimensional data,  $2 \cdot d$  items are needed to specify completely the  $d$ -dimensional volume that is spanned by the node. Thus, for the four-dimensional trees used for the collection of rectangles, we need eight values at each node. Show that with each node, we really only need to store three values to specify the two regions (i.e., two-dimensional areas) that make up the LOCHILD and HICHILD of a node. Describe how they would be used to cut off the search. In addition, show that if the bounds array at a node only indicates the region spanned by the node, rather than the regions spanned by LOCHILD and HICHILD, then only two values are needed.

3. Give an algorithm to find all rectangles that intersect a given point (in two-dimensional space) when each rectangle is represented by a point in four-dimensional space and the collection of rectangles is organized by a balanced four-dimensional k-d tree.
4. Repeat Exercise 3 for all rectangles that intersect a rectangular window given by  $P$ .
5. Give an algorithm to determine all pairs of intersecting rectangles using a balanced four-dimensional k-d tree.
6. Prove that  $O(N \cdot \log_2 N)$  is a lower bound on solving the rectangle intersection problem when using the balanced four-dimensional k-d tree.

### 3.3.2.3 Grid File

Hinrichs and Nievergelt [839, 840, 841] make use of the grid file (see Section 1.7.2.1 of Chapter 1) to organize the rectangles whose representative point uses representation 3. In particular, each rectangle is represented by the Cartesian product of a horizontal and a vertical one-dimensional interval, each of which is represented by a representative point using representation 3. The result is that proximity queries are answered by examining all grid blocks that intersect the cone-shaped search regions. Hinrichs and Nievergelt prefer this method to one based on a tree (e.g., the k-d tree) because the relevant grid blocks are in contiguous regions, whereas, in a tree, contiguous blocks may appear in different subtrees. Hinrichs and Nievergelt are quite concerned with reducing the number of disk access operations necessary to process such queries.

Figure 3.20(a) is an example of a conic-shaped search region for a grid file organization of rectangles. Figure 3.20(b) is an example of a conic-shaped search region for a k-d tree organization of rectangles. In the case of a grid file, blocks A, B, C, D, E, and F would be examined. On the other hand, for a k-d tree, blocks G, H, I, J, K, L, and M would be examined. Note that blocks I and K are in a different subtree of the k-d tree than blocks G, H, J, L, and M. In the worst case, solving the rectangle intersection problem when using a grid file takes  $O(N^2)$  time. This is achieved by using the naive method of Section 3.1. However, the expected cost will be lower since it is assumed that the points corresponding to the rectangles are well distributed among the grid blocks.

Observe further that the conic shape of the search region resulting from the use of representation 3 for the representative points is transformed to a rectangle-shaped search region for a point query when representation 1 is used. Faloutsos and Rego [589] argue that this rectangle shape makes their method of using a quadtree-like decomposition of the underlying space into four congruent isosceles triangles (i.e., the tri-cell method discussed in Section 3.3.1) more appropriate for general queries of the nature that we have discussed. In particular, they claim that a subset of the collection of the triangular cells matches the query region better. Unfortunately, this is true only when the point query is the midpoint of the interval, in which case the search region corresponds to the middle two triangles at the top level of the decomposition. For other query points, as well as other queries (i.e., windowing and subsets), the situation is the same as for other representations of the underlying space of the collection of the representative points (e.g., the grid file).

### Exercise

1. What is the expected cost of solving the rectangle intersection problem using the grid file?

### 3.3.2.4 LSD Tree

Henrich, Six, and Widmayer [829] makes use of the LSD tree (see Section 1.7.1.3 of Chapter 1) to organize the rectangles whose representative point uses representation 1. Of special interest is the manner in which they split an overflowing bucket. In particular, the splitting strategy takes into account the fact that representation 1 is used and that part of the underlying space is empty. As mentioned in Section 1.7.1.3 of Chapter 1, two splitting strategies are proposed: data dependent and distribution dependent.

The data-dependent split strategy is simple. Given a particular coordinate  $i$  in the original space along which the bucket is to be split, the split is made at the position that corresponds to the average value of the  $i$ th coordinate for all of the objects stored in the bucket.

The distribution-dependent strategy is more complex. It is a combination of two basic strategies, each of which is designed to deal with a special extreme case of the underlying data distribution. The first, denoted by  $SP_1$ , treats the intervals as if they have zero length (i.e., points), thereby assuming that the two endpoints of the interval are identical, and thus the idea is to divide the overflowing bucket into two cells that contain approximately the same number of objects. This means that the split position is the midpoint of the part of the diagonal that runs through the underlying space that overlaps the overflowing bucket (e.g.,  $P_1$  in Figure 3.21). This strategy is designed to deal with the case that the intervals are small relative to the underlying space. The second, denoted by  $SP_2$ , treats the intervals as if their representative points are uniformly distributed in the underlying space, and thus the idea is to divide the overflowing bucket into two cells that cover approximately the same area of the nonempty portion of the underlying space that overlaps the bucket (e.g.,  $P_2$  in Figure 3.21).

The actual split position along coordinate  $i$ , denoted by  $SP$ , is a weighted sum of  $SP_1$  and  $SP_2$ :

$$SP = \alpha \cdot SP_1 + (1 - \alpha) \cdot SP_2,$$

where  $\alpha = \sqrt[10]{A_b / (u_i - l_i)^2}$ , and  $A_b$  is the area of the part of the underlying space spanned by bucket  $b$  that is above the diagonal that runs through the space, while  $u_i$  and  $l_i$  are the minimum and maximum values, respectively, of the  $i$ th coordinate value of all points that are in the bucket that is being split. Assuming, without loss of generality, that the objects are rectangles,  $\alpha$  has the property that, for large buckets (i.e., those that span a large part of the underlying space),  $SP$  approaches  $SP_1$ . On the other hand, for small buckets,  $SP$  approaches  $SP_2$ . This is appropriate: in the former case, the representative points tend to be clustered along the diagonal since their corresponding objects are much smaller than the underlying space; in the latter case, the representative points occupy a much larger portion of the underlying space as their corresponding objects are of approximately the same size as the underlying space. Not surprisingly, experiments [829] with collections of rectangles from both uniform and skewed distributions show a higher bucket utilization for the data-dependent splitting strategy than for the distribution-dependent splitting strategy, while the distribution-dependent strategy has a higher bucket utilization when the rectangles are inserted in sorted order (see Exercise 1).

#### Exercise

1. Explain why the bucket utilization for sorted data is expected to be higher for a distribution-dependent bucket-splitting strategy than for a data-dependent bucket-splitting strategy.

### 3.3.2.5 Two-Dimensional Representations

The techniques discussed in Sections 3.3.2.2 and 3.3.2.3 for organizing the collection of representative points assume that the representative point lies in four-dimensional space. Another possibility is to use a representative point in two-dimensional space and

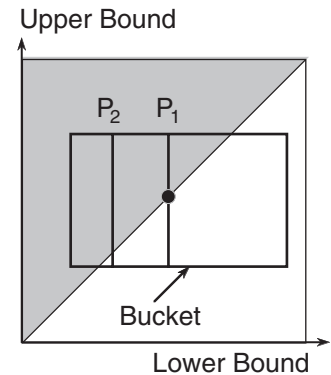

Figure 3.21  
Possible split positions in an overflowing LSD tree bucket when using a distribution-dependent bucket splitting strategy: (a)  $P_1$  corresponds to a treatment of the intervals as having zero length and (b)  $P_2$  corresponds to the assumption that the representative points of the intervals are uniformly distributed in the underlying space.

to represent the collection by one of the two-dimensional quadtree variants, such as the PR quadtree or the PR k-d tree. Recall that the PR quadtree is a regular decomposition quadtree that decomposes space until there is only one point per block (for more details, see Section 1.4.2.2 of Chapter 1).

As an example of the use of the PR quadtree, suppose that in our application we must perform a point query (i.e., determine the rectangles that contain a given point). In this case, when the representative point is the centroid, a PR quadtree requires that we search the entire data structure because the rectangle that is centered at a given point can lie in all of the quadrants. Of course, pruning can occur at deeper levels in the tree. In contrast, using the lower-left corner as the representative point may permit the pruning of up to three quadrants in the search. For instance, when the query point lies in the SW quadrant of a tree rooted at  $Q$ , then no rectangle with a representative point that lies in the NW, NE, or SE quadrants of  $Q$  can contain the query point.

One way to avoid having to search the entire data structure in the case of a point query when using a point representation, such as the PR quadtree or PR k-d tree, for the representative points that are centroids is to also associate with each block the corresponding minimum enclosing block. This approach, used by Freeston [646], stores the centroids of the objects in a BANG file, and with each block in the BANG file, he associates the minimum enclosing PR k-d tree block for the objects within it.

A similar approach serves as the basis of the *spatial k-d tree* of Ooi, McDonell, and Sacks-Davis [1404, 1407] to store the representative points that are the centroids of the objects (see also Sections 1.5.1.4 and 1.7.1.2 of Chapter 1 and Section 4.4.3 of Chapter 4).<sup>12</sup> Aside from storing the value and identity of the discriminating key, each nonleaf node, say  $P$  discriminating on key  $K_j$ , also contains information on the spatial extent of the objects stored in its two subtrees. In particular, it stores the maximum value of the  $j$  coordinate for the objects stored in  $\text{LOCHILD}(P)$  and the minimum value of the  $j$  coordinate for the objects stored in  $\text{HICCHILD}(P)$ . This information aids in reducing the number of nodes that need to be examined when executing a point query. However, in the worst case, the entire tree will still have to be searched.

### Exercise

1. Suppose that you use the spatial k-d tree [1404, 1407]. Under what circumstances will a point query require that both children of a nonleaf node  $P$  be examined?

### 3.3.3 Summary

The representative point method finds much use. In particular, it is a very attractive solution when it is desired to integrate nonstandard data such as that found in spatial and image databases into a conventional database management system (e.g., relational), where the records are analogous to points in some high-dimensional space. In this case, the entire record can be indexed by one index (treating each record as a point in a high-dimensional space), or several indexes can be used for different attributes or subsets of the attributes. In fact, most of the indexes are usually one-dimensional, where there is one index for each of the attributes of a conventional type (e.g., textual attributes, numbers).

Another argument for the use of the representative point method as a basis for an index is its perceived utility as a clustering method. In particular, it preserves clustering in the index (e.g., [1787]) in the sense that objects of similar positions and size in the original space are placed together in a region of the transformed space. This is especially

---

<sup>12</sup> In addition see the KD2-tree of van Oosterom [1410, 1412] discussed in Section 1.5.1.4 of Chapter 1, where neither the objects nor the partition lines need be axis parallel (i.e., a BSP tree is used).

true when the objects overlap. It is interesting to note that proponents of building an index based on the representative point method argue against building an index based on the distance between objects in the original space because they do not believe that it is a good basis for clustering [1787]. In particular, they claim that a distance-based index breaks down when the objects overlap in that the distance between them is zero. This implies that the degree of similarity between pairs of objects in this case is the same, regardless of the sizes of the objects or the extent of the intersection. In addition, when the objects do not overlap, then they believe that the similarity between objects should not be the same just because their separation is the same. In other words, they believe that the extent of the objects should also be taken into account. However, this argument does not take into account the possibility of using a secondary similarity measure (e.g., [244]) that corresponds to the extent of the intersection in case of overlap and the sizes of the objects in the case of nonoverlap.

Nevertheless, it is important to note that the above clustering arguments break down when the objects are not of the same or similar size (e.g., one object is large and the other one is small, as is illustrated in Figure 3.22) but are close to each other in the original space (in terms of their distance). In this case, the objects are no longer clustered in the same region of the transformed space. This means that the search regions in the transformed space will be large. Proponents of the representative point method resolve this apparent contradiction by appealing to a definition of clustering where size is deemed to be more important than separation [1787].

In addition to its utility for clustering, proponents of the representative point method [1787, 1788] also maintain that the method yields good query performance compared to other spatial indexing methods. Usually, this is measured in terms of the number of page accesses to the underlying spatial index (e.g., for range queries in [1787] and for spatial join queries in [1788], both of which use a variant of the multilevel grid file [1087, 1987], which is also discussed in Section 1.7.1.5 of Chapter 1). Unfortunately, surprisingly, the experiments used to support this claim do not index on the representative point. In particular, in [1787, 1788], when the representative point method is applied to two-dimensional objects, only two of the four dimensions are split. However, this means that the spatial index on the representative points is effectively indexing only in a two-dimensional space, using two of the four dimensions. In other words, the result is equivalent to indexing only on two of the four elements of the representative point while also storing information about the other two elements in the spatial index. Although such an approach may be worthwhile and gives good results for certain queries (e.g., the simple QSF-tree [2057]), it cannot be used as evidence of the superiority of the representative point method over methods such as the R\*-tree [152] as the index does not make use of any information about the extent of the objects. Of course, if the objects are all of approximately the same size, then the impact of this omission is lessened.

It has also been observed that the prime reason for the transformation of the query region from original space to the high-dimensional space of the representative point is to overcome the mismatch between the higher dimensionality of the data regions in the index and the lower dimensionality of the query region. This naturally leads to a mismatch in the shape of the transformed query regions and the data regions in the index (recall the discussion of the comparison of representations 1 and 3 in Section 3.3.2.3). The result is that many researchers (e.g., [822, 827, 1449]) resort to a transformation of the data regions in the index to a region in the lower-dimensional space of the query regions. As the regions in the lower-dimensional space of the query regions that correspond to the data regions in the index are generally much larger than the actual regions covered by the data, a minimum bounding box is often also associated with the data regions in the index [1449] in order to enable faster query processing. Further efficiencies can be gained in terms of the space needed to store the bounding box in the index nodes by formulating the box in terms of the original lower-dimensional space, and just using an approximation of it by virtue of quantizing the space spanned by the bounding box [822], as in the hybrid tree [317, 826] (see Sections 1.7.1.2 of Chapter 1 and 4.4.3 of Chapter 4). At this point,

Figure 3.22  
Example of two objects that are close to each other in the original space but are not clustered in the same region of the transformed space when using a transformation such as the corner transformation.

having found it beneficial to make use of the inverse transformation, it is not unnatural to question the rationale for transforming the original data into the higher-dimensional space in the first place.

## 3.4 Area-Based Methods

The problem with using trees in conjunction with representative point methods, such as those discussed in Section 3.3, is that the placement of the node in the tree (i.e., its depth) does not reflect the size (i.e., the spatial extent) of the rectangle. It primarily depends on the location of the representative point. In this section, we focus on alternative representations provided by area-based methods that associate each rectangle with the blocks containing it or the blocks that it contains. The sizes and positions of these blocks may be predetermined, as is the case in an approach based on the region quadtree. However, this need not be the case; nor must the blocks be disjoint.

As an example of a representation based on the region quadtree, suppose that we represent each rectangle by its minimum enclosing quadtree block (i.e., a square). The rectangle is associated with the center of the quadtree block. Of course, more than one rectangle can be associated with a given enclosing square, and a technique must be used to differentiate among them. Observe that in this case we do not explicitly store a representative point. Instead, there is a predefined set of representative points with which rectangles can be stored. In some sense, this is analogous to hashing where the representative points correspond to buckets. These techniques, which we term *Caltech Intermediate Form (CIF) quadtrees*, have been developed independently by Kedem [1009] (called a *quad-CIF tree*) and by Abel and Smith [8]. In this section, we focus on a variant known as the *MX-CIF quadtree* [1009], which makes use of its one-dimensional variant to distinguish between the different rectangles that have the same minimum enclosing quadtree block. The MX-CIF quadtree has been discussed briefly in Section 2.1.4 of Chapter 2.

This section is organized as follows. Section 3.4.1 describes the MX-CIF quadtree in greater detail. Section 3.4.2 discusses alternative representations based on the MX-CIF quadtree that are designed to overcome some of its drawbacks, specifically as demonstrated by some inefficiencies in search queries. Section 3.4.3 outlines some quadtree-based alternatives that permit a rectangle to be associated with more than one quadtree block. Note that analyzing the space requirements of these representations, as well as the execution time of algorithms that use them, is quite difficult, as they depend heavily on the distribution of the data. In most cases, a limited part of the tree must be traversed, and thus the execution time depends, in part, on the depth and the shape of the tree.

### 3.4.1 MX-CIF Quadtree

This section is organized as follows. We first give a definition of the MX-CIF quadtree (Section 3.4.1.1). Next, we describe how operations such as insertion, deletion, and a number of variants of searching are executed for the MX-CIF quadtree (Section 3.4.1.2). We conclude with a comparison of the MX-CIF quadtree with a number of other representations (Section 3.4.1.3).

#### 3.4.1.1 Definition

The *MX-CIF quadtree* associates each rectangle, say  $R$ , with the quadtree node corresponding to the smallest block that contains  $R$  in its entirety. Rectangles can be associated with both leaf and nonleaf nodes. Subdivision ceases whenever a node's block contains no rectangles. Alternatively, subdivision can also cease once a quadtree block is smaller

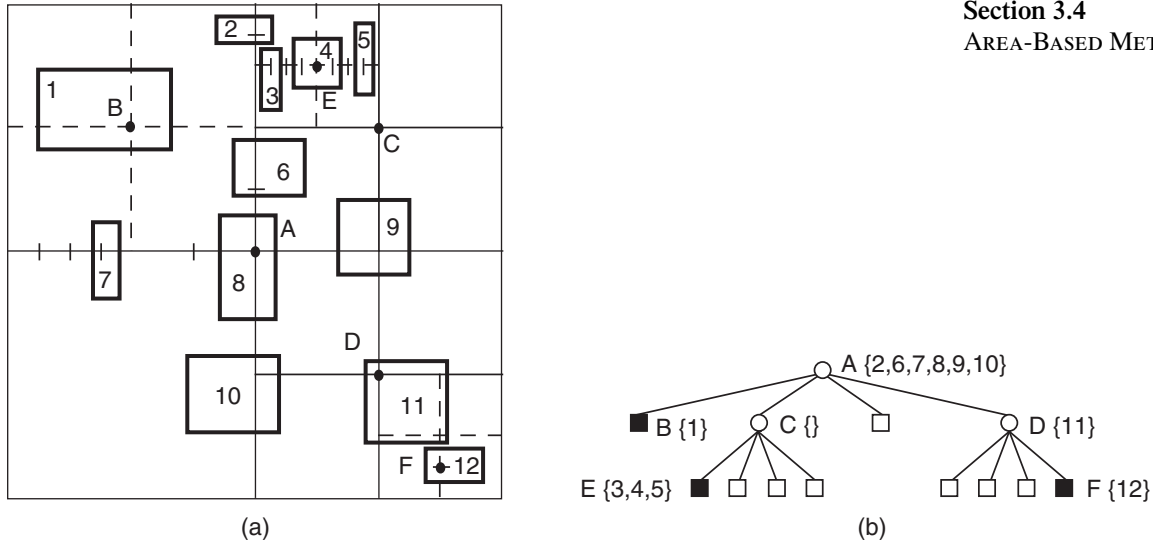

Figure 3.23

than a predetermined threshold size. This threshold is often chosen to be equal to the expected size of the rectangle [1009]. In this section, we will assume that rectangles do not overlap (but may touch), although our techniques can be modified to handle this situation. Figure 3.23 contains a set of rectangles and its corresponding MX-CIF quadtree. Once a rectangle is associated with a quadtree node, say  $P$ , it is not considered to be a member of any of the children of  $P$ . For example, in Figure 3.23, rectangle 11 overlaps the space spanned by both nodes D and F but is associated only with node D.

It should be clear that more than one rectangle can be associated with a given enclosing block (i.e., node). There are several ways of organizing these rectangles. Abel and Smith [8] do not apply any ordering. This is equivalent to maintaining a linked list of the rectangles. Another approach, devised by Kedem [1009], is described below.

Let  $P$  be a quadtree node, and let  $S$  be the set of rectangles that are associated with  $P$ . Members of  $S$  are organized into two sets according to their intersection (or the collinearity of their sides) with the lines passing through the centroid of  $P$ 's block. We shall use the terms *axes* or *axis lines* to refer to these lines. For example, consider node  $P$ , whose block is of size  $2 \cdot L_x \times 2 \cdot L_y$  and centered at  $(C_x, C_y)$ . All members of  $S$  that intersect the line  $x = C_x$  form one set, and all members of  $S$  that intersect the line  $y = C_y$  form the other set. Equivalently, these sets correspond to the rectangles intersecting the  $y$  and  $x$  axes, respectively, passing through  $(C_x, C_y)$ . If a rectangle intersects both axes (i.e., it contains the centroid of  $P$ 's block), then we adopt the convention that it is stored with the set associated with the  $y$  axis.

These subsets are implemented as binary trees (really tries), which, in actuality, are one-dimensional analogs of the MX-CIF quadtree. For example, Figure 3.24 illustrates the binary tree associated with the  $x$  and  $y$  axes passing through A, the root of the MX-CIF quadtree of Figure 3.23. The subdivision points of the axis lines are shown by the tick marks in Figure 3.23.

Note that a rectangle is associated with the shallowest node in the binary tree that contains it. For example, consider Figure 3.25, which contains the binary trees associated with the  $x$  and  $y$  axes passing through E in the MX-CIF quadtree of Figure 3.23. In particular, we see that no rectangle is stored in the left (right) subtree of node XN (XM) in Figure 3.25(a) even though rectangle 4 contains it. In this example, rectangle 4 is associated with the  $y$  axis that passes through node E (i.e., node YE in Figure 3.25(b)).

Binary trees for the (a)  $x$  axis and (b)  $y$  axis passing through node A in Figure 3.23.

Figure 3.25  
Binary trees for the (a)  $x$  axis and (b)  $y$  axis passing through node E in Figure 3.23.

### 3.4.1.2 Operations

We adopt the conventions that when rectangle  $R$  lies entirely within a block  $B$ , then  $R$  is associated with  $B$  if the left or bottom sides of  $R$  are collinear with axis lines of  $B$ . This is analogous to the open and closed conventions that we used for points in Chapter 1. Using these conventions, a rectangle is inserted into an MX-CIF quadtree by a top-down search for the position it is to occupy. As stated earlier, we assume that the input rectangle does not overlap (but may touch) any of the existing rectangles. This can be ascertained by preceding the insertion by a call to a procedure to determine if the rectangle intersects any of the existing rectangles (see procedure CIFSEARCH in Exercise 3).

The position to be occupied by a rectangle is determined by a two-step process. First, locate the first quadtree block such that at least one of its axis lines intersects the input rectangle. Second, having found such a block and an axis, say  $V$ , repeat the subdivision process for the  $V$  axis until locating the first subdivision point that is contained within the rectangle.

During the process of locating the destination position for the input rectangle, we may have to subdivide repeatedly the space spanned by the MX-CIF quadtree (termed *splitting*) and, in the process, create new nodes. As was the case for the MX quadtree, the shape of the resulting MX-CIF quadtree is independent of the order in which the rectangles are inserted into it, although the shapes of the intermediate trees are dependent on it.

Building an MX-CIF quadtree of maximum depth  $n$  for  $N$  rectangles has a worst-case execution time of  $O(n \cdot N)$ . This situation arises when each rectangle is placed at depth  $n$ <sup>13</sup>. Therefore, the worst-case storage requirements are also  $O(n \cdot N)$ . Of course, the expected behavior should be better.

Deletion of nodes from MX-CIF quadtrees is analogous to the process used for MX quadtrees. The only difference is that collapsing needs to be performed for nodes in the binary trees (i.e., one-dimensional MX-CIF quadtrees) corresponding to the axes, as well as for the nodes in the MX-CIF quadtree. As an example, to delete rectangle 9 (i.e., the rectangle associated with node XH in the binary tree for the  $x$  axis through node A in Figure 3.24(a)) from the MX-CIF quadtree of Figure 3.23, we also delete the node XH as it has no left or right children. This requires us to set the right child of XH's father node, XA, to NIL.

Deleting rectangle 5 (i.e., node XP in the binary tree for the  $x$  axis through E in Figure 3.25(a)) is slightly more complex. Again, we delete the rectangle and the node XP since it has no left or right children. However, setting the right child of XP's father node, XN, to NIL is not enough. We must also perform merging since both children of XN are now NIL. This leads to replacing the right child of XN's father, XE, by NIL and returning XN and XP to the free storage list. This process is termed *collapsing* and is the counterpart of the splitting operation that was necessary when inserting a rectangle into an MX-CIF quadtree.

Collapsing can take place over several levels in both the binary tree and in the MX-CIF quadtree. In essence, collapsing is repeatedly applied in the binary tree until the nearest ancestor that has an additional non-NIL child is encountered. If the collapsing process brings us to the root of the binary tree (e.g., after deletion of rectangles 3, 4, and 5 from the MX-CIF quadtree of Figure 3.23), then further collapsing of MX-CIF quadtree nodes is possible only if both axes are empty. This process terminates when a nearest ancestor that has an additional non-NIL child or nonempty axes is encountered.

As the collapsing process takes place, the affected nodes are returned to the free storage list. For example, suppose that after deleting rectangle 5 from Figure 3.23, we

---

<sup>13</sup>  $n$  is the sum of the maximum depths of the MX-CIF quadtree and the binary tree.

also delete rectangles 3 and 4. This means that nodes XE, XM, and YE in Figure 3.25 are subjected to the collapsing process, with the result that the axes through E are empty. Since nodes E and E's ancestor, C, have empty axes and no other non-NIL children, collapsing is applicable, with the result that the NE child of A is set to NIL and nodes C, E, XE, XM, XO, and YE are returned to the free storage list.

The execution time of the deletion algorithm is bounded by two times the maximum depth of the MX-CIF quadtree (including the binary trees for the axes). This upper bound is attained when the nearest ancestor for the collapsing process is the root node.

The simplest search query in an MX-CIF quadtree is one that determines if a given rectangle overlaps (i.e., intersects) any of the existing rectangles. Range queries can also be performed. However, they are more usefully cast in terms of finding all the rectangles in a given area (i.e., a window query). Another popular query is one that seeks to determine if one collection of rectangles can be overlaid on top of another collection without any of the component rectangles intersecting one another.

These two operations can be implemented by using variants of algorithms developed for handling set operations (i.e., union and intersection) in region-based quadtrees [901, 905, 1760]. The range query is answered by intersecting the query rectangle with the MX-CIF quadtree. The overlay query is answered by a two-step process. First, intersect the two MX-CIF quadtrees. If the result is empty, then they can be safely overlaid, and we merely need to perform a union of the two MX-CIF quadtrees. It should be clear that Boolean queries can be easily handled.

When the rectangles are allowed to overlap, reporting the pairs of rectangles that intersect each other is achieved by traversing the MX-CIF quadtree and, for each node, examining all neighboring nodes that can contain rectangles intersecting it. In the worst case, for some rectangles, we may have to examine the entire MX-CIF quadtree. However, if this is the case, then the remaining rectangles will not require this much work. Nevertheless, the worst-case execution time of this task is  $O(n \cdot N^2)$  for a tree of maximum depth  $n$  with  $N$  rectangles. The expected behavior should be better.

An alternative solution to the rectangle intersection problem can be formulated by adapting the plane-sweep method described in Section 3.1 to use the MX-CIF quadtree [1632]. This is quite straightforward and relies on the observation that a quadtree traversal is analogous to a two-dimensional plane sweep. The effect of the sort phase is obtained by the process of building the MX-CIF quadtree since a quadtree decomposition is equivalent to a multidimensional sort. The effect of the sweep phase is obtained by traversing the quadtree in some order (e.g., Morton order).

The border between the nodes that have been encountered in the traversal and those that have not is the analog of the scan line in the one-dimensional plane sweep. This border is known as the *active border* [1659, 1661] (see Sections 4.2.3 of [1636], 5.1.3 of [1636], and 6.3.3 of [1636]). The adaptation is completed by devising data structures to represent the active border with properties analogous to those of the segment and interval trees (i.e., space and time).

Note that in the plane-sweep solution described in Section 3.1, the sort was performed in one dimension, and the sweep was in the other direction. In contrast, in the MX-CIF quadtree solution, the sort and the sweep are both performed in the same direction.

The efficiency of operations such as search can be improved by associating with each node of the MX-CIF quadtree the two minimum bounding boxes of the rectangles that intersect each of the axis lines that emanate from the subdivision point. However, these additional fields will increase the complexity of the insertion and deletion procedures since these fields must always be updated.

Exercises 1–5 assume the following implementation of the MX-CIF quadtree. The basic entities are the rectangles, nodes in the MX-CIF quadtree, and the nodes in the binary trees associated with each node in the MX-CIF quadtree. Let  $P$  denote a pointer to a record. A rectangle is represented by a record of type *rectangle* that has five fields that contain the coordinate values of its centroid, the distance from the centroid to the borders of the rectangle, and its name.  $C(P, A)$  and  $L(P, A)$  indicate, respectively, the coordinate values of the centroid, and the distance from the centroid to the border of the rectangle.  $A$  takes on the values ‘X’ and ‘Y’ corresponding to the names of the coordinate axes. The NAME field contains descriptive information about the rectangle stored at a node.

Nodes in the binary trees (i.e., one-dimensional MX-CIF quadtrees) of the set of rectangles that are associated with each node of the MX-CIF quadtree are represented by records of type *bnode* with three fields. There is one node of type *bnode* for each axis subdivision point that is contained in a rectangle or has descendants that contain rectangles. Two of the fields of a *bnode* record are called  $CHILD(P, I)$  and contain pointers to the left and right children of  $P$ , distinguished by  $I$ . The third field is called RECT and points to a record of type *rectangle* whose area contains the axis subdivision point, if such a rectangle exists and is not already included in the binary tree structure associated with an ancestor node in the quadtree structure.
