Each node in the MX-CIF quadtree is represented by a record of type *cnode* that contains six fields. Four fields are termed  $CHILD(P, I)$ , in which  $I$  corresponds to one of the four principal quadrant directions. The two remaining fields represent pointers to the binary trees for the rectangles that are associated with the node. These fields are called  $BIN(P, I)$ , where  $I$  corresponds to one of the two axis names. Note that there is no need to store information about the coordinate values of nodes in the MX-CIF quadtree (in records of type *bnode* and *cnode*) since this information can be derived from the path to the node from the root of the MX-CIF quadtree. The algorithms assume that each rectangle is unique and does not overlap (but may touch) any other rectangle in the MX-CIF quadtree. In addition, an empty node is like an empty child and is represented by a NIL pointer in the direction of a quadrant that contains no rectangles.

1. Using the open and closed conventions described in this section, give an algorithm CIF-COMPARE to determine the quadrant in which the centroid of rectangle  $P$  lies relative to a grid subdivision point located at  $(C_x, C_y)$ .
2. Using the open and closed conventions described in this section, give an algorithm BIN-COMPARE to determine the axis segment in which rectangle  $P$  lies relative to axis  $V$  subdivided at the coordinate value  $V = C_V$ . Make sure that your algorithm also works properly when the specification of the rectangles and of the underlying space is constrained to using integers.
3. Give an algorithm CIFSEARCH to determine if rectangle  $P$  overlaps (i.e., intersects) any of the existing rectangles in the MX-CIF quadtree rooted at  $R$ . Also, give an auxiliary procedure CROSSAXIS that is used by CIFSEARCH to determine if rectangle  $p$  overlaps any of the rectangles that are stored in the binary trees associated with the axes that pass through the centers of the blocks corresponding to the individual nodes of the MX-CIF quadtree. Assume the existence of Boolean-valued function RECTINTERSECT to indicate whether two rectangles overlap (i.e., the intersection must have a nonzero area—that is, two rectangles that share an edge do not intersect).
4. Give an algorithm CIFINSERT to insert rectangle  $P$  into the MX-CIF quadtree rooted at  $R$ . Also, give an auxiliary procedure INSERTAXIS to insert  $P$  into the binary tree rooted in the MX-CIF quadtree node in which  $P$  belongs.
5. Give an algorithm CIFDELETE to delete rectangle  $P$  from the MX-CIF quadtree rooted at  $R$ . Assume the existence of functions OPDIRECTION and OTHERAXIS to specify the spatial relationships among directions and axes. OPDIRECTION( $D$ ) yields the direction directly opposite to  $D$ . For example, OPDIRECTION(‘LEFT’) = ‘RIGHT’, and OPDIRECTION(‘RIGHT’) = ‘LEFT’, while OPDIRECTION(‘BOTH’) is undefined. Given  $A$  as one of two coordinate axes, OTHERAXIS( $A$ ) returns the name of the second axis (i.e., OTHERAXIS(‘X’) = ‘Y’ and OTHERAXIS(‘Y’) = ‘X’).
6. Suppose that, in procedure BINCOMPARE in the solution to Exercise 2 you used the partial test “ $C(P, V) - L(P, V) \leq C_V$ ” instead of “ $C(P, V) - L(P, V) < C_V$ ” for rectangle  $P$  and coordinate axis  $V$ . What will happen when inserting two rectangles that share an edge that is

coincident with one of the coordinate axes? Assume that the specification of the rectangles and of the underlying space is constrained to using integers.

7. Suppose that, in procedure BINCOMPARE in the solution to Exercise 2 you used the partial tests " $C_V \leq C(P, V) + L(P, V)$ " for rectangle  $P$  and coordinate axis  $V$  instead of " $C_V < C(P, V) + L(P, V)$ ", and " $C(P, V) - L(P, V) \leq C_V$ " instead of " $C(P, V) - L(P, V) < C_V$ ", as described in Exercise 6. What will happen when inserting two rectangles that share an edge that is coincident with one of the coordinate axes? As in Exercise 6, assume that the specification of the rectangles and of the underlying space is constrained to using integers.

In Exercises 8–25 you are to implement functions that may be of use in an information-management system for handling a collection of small rectangles based on the MX-CIF quadtree. Assume that the rectangles do not overlap. An MX-CIF quadtree is built by a combination of procedures CREATERECTANGLE, which you are to write below, and a variant of CIFINSERT. A rectangle is created by specifying its centroid and distances to its borders and by assigning it a name for subsequent use. You will also want to keep the names in a directory so that rectangles can be retrieved by name without requiring an exhaustive search through the MX-CIF quadtree. This is useful when rectangles have not yet been inserted into the MX-CIF quadtree or after they have been removed.

8. Give a procedure CREATERECTANGLE to create a rectangle. It is invoked by a call of the form CREATERECTANGLE( $N, C_x, C_y, L_x, L_y$ ), where  $N$  is the name to be associated with the rectangle,  $C_x$  and  $C_y$  are the  $x$  and  $y$  coordinate values, respectively, of its centroid, and  $L_x$  and  $L_y$  are the horizontal and vertical distances, respectively, to its borders from the centroid.
9. What happens in procedure CIFINSERT when the rectangle being inserted is larger in width or height than the size of the root node?
10. Modify procedure CIFINSERT to take just one argument corresponding to the name of a rectangle and insert it into the MX-CIF quadtree, if it does not overlap any of the existing rectangles. To do this, you will need to invoke procedure CIFSEARCH. If two rectangles touch along a side or a corner, they are not said to overlap. You are to return TRUE if the query rectangle does not overlap any of the intersecting rectangles; otherwise, do not insert it, and return the name associated with one of the intersecting rectangles (i.e., if it intersects more than one rectangle).
11. Given the  $x$  and  $y$  coordinate values of a point, give a procedure DELETEPOINT to delete the rectangle in which the point is located. Make use of procedure CIFDELETE.
12. Given the  $x$  and  $y$  coordinate values of a point, give a procedure SEARCHPOINT to locate the rectangle, if any, that contains the point.
13. Given the  $x$  and  $y$  coordinate values of a point, say  $P$ , give a procedure NEARESTRECTANGLE to locate the rectangle, if any, whose side or corner is closest to  $P$ . Note that this rectangle could also be a rectangle that contains  $P$ , in which case the distance is 0.
14. Give a procedure DISPLAY to display the block decomposition corresponding to an MX-CIF quadtree on a screen. Assume that the space in which the rectangles are embedded is of size  $128 \times 128$ , with the origin at the lower-left corner having coordinate values (0,0). Note that the endpoints and widths of the rectangles need not be integers. Each rectangle is displayed by a rectangle with a border consisting of asterisks, while the name of the rectangle appears somewhere inside its boundary. The name is printed horizontally.
15. Give a function called LISTRECTANGLES to list all of the elements of a rectangle database in alphanumerical order. This means that, in the collating sequence, digits come before upper-case letters, which precede lower-case letters. Similarly, shorter identifiers precede longer ones. For example, a sorted list is 3DA, 5, A3D, A, AB. LISTRECTANGLES yields for each rectangle its name, the  $x$  and  $y$  coordinate values of its centroid, and the horizontal and vertical distances to its borders from the centroid. With this list, you are to include the coordinate values of each rectangle's lower-left corner and the lengths of its sides. This is of use in interpreting the display since sometimes it is not possible to distinguish the boundaries of the rectangles from the quadrant lines.
16. Give a procedure RECTINTERSECT to determine if the area of intersection of two rectangles is nonzero.

17. Give a procedure `RECTTOUCH` to determine if two rectangles touch (i.e., are adjacent along a side or a corner). Due to the limitations of a floating-point representation when checking for equality, which is needed in determining satisfaction of the touching condition, this operation is only meaningful when the specification of the rectangles and of the underlying space is constrained to using integers.
18. Give a procedure `TOUCH` to determine all of the rectangles in an MX-CIF quadtree that touch (i.e., are adjacent along a side or a corner) a given rectangle  $R$ . Note that  $R$  need not necessarily be in the MX-CIF quadtree. Due to the limitations of a floating-point representation when checking for equality, which is needed in determining satisfaction of the touching condition, this operation is only meaningful when the specification of the rectangles and of the underlying space is constrained to using integers.
19. Give a procedure `WITHIN` to determine all of the rectangles in the MX-CIF quadtree that lie within a given distance of a given rectangle, say  $R$  whose block is of size  $2 \cdot L_x \times 2 \cdot L_y$  and centered at  $(C_x, C_y)$ . This is the so-called *lambda problem* and is a variant of a range query. Given a distance  $d$ , `WITHIN` returns the names of all rectangles found to be  $\leq d$  horizontal or vertical distance units from a side or corner of the query rectangle; otherwise it returns `NIL`. In essence, `WITHIN` constructs a query rectangle  $Q$  with the same centroid as  $R$  and distances  $L_x + d$  and  $L_y + d$  to the border. Now the query returns the identity of all rectangles whose intersection with the region formed by the difference of  $Q$  and  $R$  is not empty (i.e., any rectangle  $r$  that has at least one point in common with  $Q - R$ ). In other words, we have a shell of width  $d$  around  $R$ , and we seek all the rectangles that have a point in common with this shell. Rectangle  $R$  need not necessarily be in the MX-CIF quadtree. Note that for this operation you must recursively traverse the tree to find the rectangles that overlap the query region.
20. Give a pair of procedures `HORIZNEIGHBOR` and `VERTNEIGHBOR` to find the nearest neighboring rectangle in the horizontal and vertical directions, respectively, to a given rectangle, say  $R$ . By “nearest” horizontal (vertical) neighboring rectangle, it is meant the rectangle whose vertical (horizontal) side, or extension, is closest to a vertical (horizontal) side of the query rectangle  $R$ . If the vertical (horizontal) extension of a side of rectangle  $r$  causes the extended side of  $r$  to intersect the query rectangle, then  $r$  is deemed to be at distance 0 and is thus not a candidate neighbor. In other words, the distance has to be greater than zero. `HORIZNEIGHBOR` and `VERTNEIGHBOR` return as their value the name of the neighboring rectangle if one exists; otherwise, `NIL` is returned. Rectangle  $R$  need not necessarily be in the MX-CIF quadtree. If more than one rectangle is at the same distance, then return the name of just one of them.
21. Give a procedure `NEARESTNEIGHBOR` to find the nearest rectangle, if any, to a given rectangle, say  $R$ . By “nearest,” it is meant the rectangle  $C$  with a point on its side or at a corner, say  $P$ , such that the distance from  $P$  to a side or corner of  $R$  is a minimum. Rectangle  $R$  need not necessarily be in the MX-CIF quadtree. Note that rectangles that are inside  $R$  are not considered by this query. If no such rectangle exists (e.g., when the tree is empty or all of the rectangles in the tree are in  $R$ ), then output an appropriate message. If more than one rectangle is at the same distance, then return the name of just one of them.
22. Give a pair of procedures `DRAWHORIZNEIGHBOR` and `DRAWVERTNEIGHBOR` to draw lines between the two neighbors found in Exercise 20. The difference between this procedure and `DRAWHORIZNEIGHBOR` and `DRAWVERTNEIGHBOR` is that in this case the query rectangle  $R$  must be in the MX-CIF quadtree.
23. Give a procedure `LABEL` that assigns the same label to all touching rectangles in the MX-CIF quadtree. By “touching” it is meant that the rectangles are adjacent along a side or a corner. Display the result of this operation by outputting the MX-CIF quadtree so that all touching rectangles are shown with the same label. Due to the limitations of a floating-point representation when checking for equality, which is needed in determining satisfaction of the touching condition, this operation is only meaningful when the specification of the rectangles and of the underlying space is constrained to using integers. This operation is known as *connected component labeling* (see footnote 5 in Section 2.1.1.2 of Chapter 2).
24. Give a procedure `INTERSECTWINDOW` to find all rectangles that intersect a rectangular window in an MX-CIF quadtree in which rectangles are not permitted to overlap.
25. Give a procedure `CONTAINWINDOW` to find all rectangles that are contained in a rectangular window in an MX-CIF quadtree in which rectangles are not permitted to overlap.

In Exercises 26–30, assume that the MX-CIF quadtree allows rectangles to intersect (i.e., overlap). Use an interval tree to organize the rectangles that cross the axes.

26. Give a procedure to insert a rectangle into an MX-CIF quadtree that permits overlap.
27. Give a procedure to delete a rectangle from an MX-CIF quadtree that permits overlap.
28. Give a procedure to find all rectangles that intersect a rectangular window in an MX-CIF quadtree that permits overlap.
29. Give a procedure to find all rectangles that are contained in a rectangular window in an MX-CIF quadtree that permits overlap.
30. Give a procedure to find all rectangles that enclose a rectangular window in an MX-CIF quadtree that permits overlap.
31. Analyze the expected cost of inserting a rectangle into an MX-CIF quadtree.
32. What is the expected cost of solving the rectangle intersection problem using the MX-CIF quadtree?
33. In the text, we mention that the rectangle intersection problem can be solved by using a plane-sweep technique that is based on a traversal of the MX-CIF quadtree. This requires a data structure with properties similar to the interval tree to represent the active border. Devise such a data structure. What are the space and time requirements of a solution to the rectangle intersection problem that uses it?
34. In Exercise 10 in Section 1.9 of Chapter 1, we discuss the Euclidean matching problem. Can you use a variant of the MX-CIF quadtree to try to attack this problem? You may wish to represent pairs of points as rectilinear rectangles having the two points as the extreme vertices. In particular, for each point, find the closest point and let them form a rectangle. It should be clear that a point may participate in more than one rectangle. The idea is to obtain a set of rectangles that cover all of the points, yet to have no common points (i.e., the rectangles do not touch). Give an example showing that it is not always possible to find such a set of nontouching rectangles.
35. Modify the method proposed in Exercise 34 so that it computes a solution without using the greedy-method heuristic (see Exercise 10 in Section 1.9 of Chapter 1).

### 3.4.1.3 Comparison with Other Representations

The MX-CIF quadtree is related to the region quadtree in the same way as the interval tree [534, 537, 538] is related to the segment tree [166]. The MX-CIF quadtree is the two-dimensional analog of the tile tree [1265] (see Section 3.1.2). The analogy is with the tile tree instead of the interval tree because the MX-CIF quadtree is based on a regular decomposition. In fact, the tile tree and the one-dimensional MX-CIF quadtree are identical when rectangles are not allowed to overlap.

At this point, it is also appropriate to comment on the relationship between the MX-CIF quadtree and the MX quadtree. The similarity is that the MX quadtree is defined for a domain of points with corresponding nodes that are the smallest blocks in which they are contained. Similarly, the domain of the MX-CIF quadtree consists of rectangles with corresponding nodes that are the smallest blocks in which they are contained. In both cases, there is a predetermined limit on the level of decomposition. One major difference is that in the MX-CIF quadtree, unlike the MX quadtree, all nodes are of the same type. Thus, data is associated with both leaf and nonleaf nodes of the MX-CIF quadtree. Empty nodes in the MX-CIF quadtree are analogous to white nodes in the MX quadtree.

Instead of using the one-dimensional analog of the MX quadtrees to organize the set of rectangles that are covered by a particular quadtree node, we could have adapted the one-dimensional analog of one of the other quadtree point representations discussed in Chapter 1. Not surprisingly, we find that the advantages and disadvantages are very similar to those outlined in Section 1.4.3 of Chapter 1. We briefly summarize them below. A more detailed comparison of the one-dimensional analogs of the point and

PR quadtrees is given in Section 3.4.2. Note that in this summary when we use the term *quadtree*, we are referring to the corresponding one-dimensional analog.

An advantage of the point quadtree (a binary search tree in one dimension!) is that the depth is reduced when the tree contains a small number of rectangles. This is also an advantage of the PR quadtree, although it is not necessarily true when the rectangles are very close. However, when we are using a point quadtree, deletion of a rectangle forces us to expend some work in locating a suitable replacement node. The shape of the point quadtree depends on the order in which the rectangles are inserted.

For the PR quadtree, the placement of the rectangle in the tree depends on what other rectangles are present. As rectangles are added to the PR quadtree, existing rectangles may have to be moved to positions farther away from the root (in a node distance sense). On the other hand, once a rectangle is inserted into the MX quadtree, it maintains that position forever since its position is independent of the order of insertion and of the other rectangles that are present. Another advantage of the MX and PR quadtrees over the point quadtree is that since they are based on a regular decomposition, there is no need to store the subdivision points.

Although our algorithms were generally defined under the assumption that the rectangles do not overlap (but may touch), this restriction can be removed quite easily. First, observe that when rectangles are permitted to intersect, there will often be more than one rectangle associated with a node of the one-dimensional MX-CIF quadtree that corresponds to a subdivision point. Thus, the issue becomes how to organize these rectangles. The simplest solution is to maintain a linked list of these rectangles. An even more natural solution is to use a tile tree to organize them.

Recall that the tile tree and the one-dimensional MX-CIF quadtree are identical when rectangles are not permitted to overlap. In such a case, the secondary structures of the tile tree consist of, at most, one rectangle. When the tile tree is used in this context, it is not a complete binary tree. Alternatively, the tile tree is not necessarily balanced since the subdivision points are fixed by virtue of regular decomposition rather than being determined by the endpoints of the domain of rectangles, as in the definition of the interval tree.

### 3.4.2 Alternatives to the MX-CIF Quadtree

One of the drawbacks of the MX-CIF quadtree is that region queries (e.g., a window query) are somewhat inefficient due to the possible need to examine the one-dimensional MX-CIF quadtrees stored at each node without necessarily finding any rectangles that satisfy the query. There are several problems:

1. The one-dimensional MX-CIF quadtrees that store the rectangles that overlap the partition lines may be quite deep due to the particular configuration of the rectangles that intersect the partition lines.
2. There are many empty one-dimensional MX-CIF quadtrees.
3. There is no easy way to prune the search when the query rectangle does not overlap any of the rectangles stored in the one-dimensional MX-CIF quadtrees.

One way of overcoming the first problem is to use the one-dimensional variants of the point quadtree and PR quadtree instead of the one-dimensional MX-CIF quadtree for the rectangles that overlap the partition lines. In Section 3.4.1.3, we point out that the one-dimensional variant of the point quadtree is not particularly useful as the partition points are not known in advance and deletion may be a bit more time-consuming. Moreover, partition points will depend on the order in which the data is processed, which may increase the complexity of operations between different data sets. The depth of the one-dimensional variant of the PR quadtree will in general be far less than that of the one-dimensional MX-CIF quadtree, although this is not necessarily the case when the

rectangles are very close to one another. Moreover, in the case of the one-dimensional variant of the PR quadtree, the placement of the rectangle in the tree depends on what other rectangles are present. As rectangles are added to the one-dimensional variant of the PR quadtree, existing rectangles may have to be moved to positions farther away from the root (in a node distance sense). On the other hand, once a rectangle is inserted into the one-dimensional variant of the MX-CIF quadtree, it maintains that position forever since its position is independent of the order of insertion and of the other rectangles that are present. Another advantage of the one-dimensional variant of the PR quadtree (as well as of the one-dimensional variant of the MX-CIF quadtree) over the one-dimensional variant of the point quadtree is that since it is based on a regular decomposition, there is no need to store the subdivision points. Thus, the one-dimensional variant of the PR quadtree is more useful than the one-dimensional variant of the point quadtree.

Another way of overcoming the first problem addresses the fact that the size of rectangle  $r$ 's minimum enclosing quadtree block  $b$  is not necessarily related to the size of  $r$ . In particular,  $b$  is often much larger than  $r$ , causing inefficiency in search operations due to a reduction in the ability to prune objects from further consideration. This situation arises when  $r$  overlaps the axes lines that pass through the center of  $b$ . Recalling Section 2.1.4.1 of Chapter 2, Frank and Barrera [628, 630], as well as Ulrich [1901], suggest expanding the size of the space that is spanned by each quadtree block  $b$  of width  $w$  by a factor  $p$  ( $p > 0$ ) so that the expanded block will be of width  $(1 + p) \cdot w$ . In this case,  $r$  will be associated with its minimum enclosing expanded quadtree block. The terms *cover fieldtree* [628, 630] and *loose quadtree* [1901] are used to describe the resulting structure. For example, letting  $p = 1$ , Figure 3.26 is the loose quadtree corresponding to the collection of objects in Figure 2.57(a) and their MX-CIF quadtree in Figure 2.57(b) in Section 2.1.4.1 of Chapter 2. In this example, there are only two differences between the loose and MX-CIF quadtrees:

1. Rectangle object E is associated with the SW child of the root of the loose quadtree instead of with the root of the MX-CIF quadtree.
2. Rectangle object B is associated with the NW child of the NE child of the root of the loose quadtree instead of with the NE child of the root of the MX-CIF quadtree.

Frank and Barrera [628, 630] suggest an alternative solution as well, termed the *partition fieldtree*, which shifts the positions of the centroids of blocks at successive levels of subdivision by one-half of the width of the block that is being subdivided. This guarantees that the size of the minimum enclosing quadtree block for rectangle  $r$  is bounded by eight times the maximum extent of  $r$  [630]. The loose quadtree, as well as the two fieldtree variants, is discussed in greater detail in Section 2.1.4.1 of Chapter 2.

The second problem can be overcome by adapting the k-d tree so that partitions are made along just one axis at a time, and thus we have a variant of an MX-CIF k-d tree. The third problem can be overcome by storing minimum bounding rectangles with the nodes of the one-dimensional MX-CIF quadtrees.

These problems have led to the development of a number of variants of the MX-CIF quadtree that make use of the following modifications:

1. Upon insertion of a rectangle  $r$ , instead of halting the top-level decomposition (i.e., the two-dimensional quadtree) once the minimum enclosing quadtree block of  $r$  has been found or when the subdivision will yield a block smaller than the size of the smallest possible rectangle, modify the halting condition to take into account the number of rectangles associated with each block. In particular, also halt the decomposition once a block contains no more than  $T$  rectangles. Thus, the blocks act like buckets, where  $T$  is the *bucket capacity*. This means that rectangles are no longer necessarily associated with their minimum enclosing quadtree block. The result is termed an *adaptive quadtree* [1571].
2. Omit the one-dimensional MX-CIF quadtrees used to store the rectangles that overlap the partition lines.

(a)

(b)

Figure 3.26  
(a) Block decomposition induced by the loose quadtree for a collection of rectangle objects identical to those in Figure 2.57 in Section 2.1.4.1 of Chapter 2 and (b) its tree representation.

Some of these variants are discussed in the rest of this section and also in Section 3.4.3.

Pitaksanokul, Thanawastien, and Lursinsap [1496] make use of a bucketing solution where a block  $b$  is recursively decomposed into four equal-sized quadtree blocks when there are more than  $T$  rectangles in the space spanned by  $b$ . When a rectangle  $r$  overlaps one or both of the partition lines of a block, then  $r$  is associated with the quadrant of  $b$  that contains the lower-left corner of  $r$ . In order to support search queries, the minimum bounding rectangle of the rectangles stored in each block is also stored with the block. We will refer to this representation as a *bounded quadtree* (BQT) [1100]. Note that as in the MX-CIF quadtree, each rectangle  $r$  is associated with just one node  $a$  in the BQT, even though  $a$  may be smaller than  $r$  and, likewise, smaller than  $r$ 's minimum enclosing quadtree block. Section 3.4.3 includes a discussion of more conventional adaptations of the bucketing method where the rectangles associated with the block  $b$  that is being decomposed may themselves have to be decomposed as they overlap the partition lines of  $b$ .

Lai, Fussell, and Wong [1100] overcome the above problems by employing variants of some of the proposed solutions. In particular, they use a bucket variant of an MX-CIF k-d tree with one-dimensional bucket variants of the PR k-d tree for the rectangles that intersect the partition lines in the case of a nonleaf node. In addition, they associate minimum bounding rectangles with each of the nonleaf nodes in the one-dimensional structures. They use the term *HV/VH tree* to describe their representation, although we use the term *bucket PR-CIF k-d tree* as it is more consistent with our terminology. Rectangles are allowed to overlap. There are two bucket capacities involved: one for the top-level two-dimensional bucket PR-CIF k-d tree corresponding to the maximum number of rectangles that can overlap a two-dimensional region before it must be split in two (termed a *region capacity*), and one for the one-dimensional bucket PR-CIF k-d tree corresponding to the maximum number of rectangles that can overlap a partition line (i.e., axis) before it must be split in two (termed an *axis capacity*). We use the terms *x-partition* (*y-partition*) to describe a line that partitions the underlying space at some value  $x = C_x$  ( $y = C_y$ ).

The two-dimensional bucket PR-CIF k-d tree is constructed by determining if the number of rectangles that overlap region  $r$  exceeds the region capacity. If it does not, then no further action is taken, and the rectangles are associated with the node corresponding to  $r$ . If it does, then  $r$  is split into two halves by cycling through the  $x$  and  $y$  coordinates in an alternating manner. Once  $r$  has been split (assume, without loss of generality, along the  $x$  axis at  $x = C_x$ ), then all rectangles that have a nonempty intersection with  $x = C_x$  are inserted into a one-dimensional bucket PR-CIF k-d tree that is associated with the node corresponding to  $r$ . The algorithm is applied recursively to the two sets of rectangles that do not intersect  $x = C_x$ , this time splitting the two sets along the  $y$  axis.

The one-dimensional bucket PR-CIF k-d tree is constructed by a similar process as the two-dimensional bucket PR-CIF k-d tree except that instead of determining if the number of rectangles that overlap a region exceeds the region capacity, we check if the number of rectangles that overlap the line  $l$  corresponding to the node exceeds the axis capacity. If it does not, then no further action is taken, and the rectangles are associated with the node corresponding to  $l$ . If it does, then  $l$  is split into two halves. Once  $l$  has been split into two halves, the rectangles that overlap the midpoint  $p$  of  $l$  are associated with the node corresponding to  $l$ , and the algorithm is applied recursively to the two sets of rectangles that do not overlap  $p$ .

In order to facilitate search operations, minimum bounding rectangles are associated with the nonleaf nodes of the one-dimensional bucket PR-CIF k-d trees. In particular, with each nonleaf node  $b$  of a one-dimensional bucket PR-CIF k-d tree for a  $y$ -partition ( $x$  partition), we record the minimum and maximum  $y$  ( $x$ ) coordinate values of the rectangles stored in the tree rooted at  $b$ . In addition, we also record the minimum and maximum  $x$  ( $y$ ) coordinate values of the rectangles stored in  $b$ . Moreover, in order to save execution time needed to recompute constantly the partition points by the recursive

application of a halving process to the coordinate values of the boundary of the underlying space as the tree is traversed, the coordinate values of the partition axis and point are also stored with nonleaf nodes of both the two-dimensional and one-dimensional bucket PR-CIF k-d trees [1100].

Figure 3.27 is the bucket PR-CIF k-d tree for the set of rectangles given in Figure 3.23 using region and axis bucket capacities of 3. Figure 3.27(a) is the block decomposition, and Figure 3.27(b) is the corresponding tree representation. Notice that the pairing of the one-dimensional bucket PR-CIF k-d trees and the corresponding nonleaf nodes of the two-dimensional bucket PR-CIF k-d tree is shown with a horizontal line having a diagonal sawtooth pattern to the right of the node in the two-dimensional bucket PR-CIF k-d tree. We also use the same type of a line pattern to indicate that a set of rectangles associated with a node of the one-dimensional bucket PR-CIF k-d tree overlaps the midpoint of the partition axis (e.g., the node containing rectangle 8 in Figure 3.27(b)). In contrast, rectangle 9 is a leaf node of the one-dimensional bucket PR-CIF k-d tree associated with the right child of the root of the two-dimensional bucket PR-CIF k-d tree in Figure 3.27(b).

The execution of a region query is made quite efficient by avoiding some subsequent comparison operations when we determine that both children of a node of a one-dimensional or two-dimensional bucket PR-CIF k-d tree must be visited. For example, this situation arises in the case of a rectangular query window  $w$  that intersects the line  $l$  corresponding to partition axis  $a$  of two-dimensional bucket PR-CIF k-d tree node  $b$  and also intersects the midpoint  $p$  of  $l$ . This means that the set of rectangles  $S$  stored in the node  $c$  of the one-dimensional bucket PR-CIF k-d tree associated with  $b$  intersects  $w$  as the rectangles in the set have point  $p$  in common. Thus, no comparisons are needed for the elements of  $S$ . In fact, regardless of whether  $w$  intersects both  $l$  and  $p$ , we can always determine if each element of  $S$  intersects  $w$  with fewer than four comparison operations (see Exercise 3).

Similarly, we can also avoid some subsequent comparison operations when we determine that only one child of a one-dimensional bucket PR-CIF k-d tree must be visited. For example, this situation arises in the case of a rectangular query window  $w$  that intersects the line  $l$  corresponding to partition axis  $a$  of two-dimensional bucket PR-CIF k-d tree node  $b$  and does not intersect the midpoint  $p$  of  $l$ . Assume, without loss of generality, that  $x$  ( $y$ ) is the partition axis, and let  $S$  denote the set of rectangles stored in the node  $c$  of the one-dimensional bucket PR-CIF k-d tree associated with  $b$ . When the right (top) edge of  $w$  is less than the  $x$  ( $y$ ) coordinate value of  $p$ , then only the left child of  $c$  is processed. In this case, none of the elements of  $S$  intersects  $w$  if the right (top) edge of  $w$  is less than the minimum  $x$  ( $y$ ) coordinate values of  $S$ . Similarly, when the left (bottom) edge of  $w$  is greater than the  $x$  ( $y$ ) coordinate value of  $p$ , then only the right child of  $c$  is processed. In this case, none of the elements of  $S$  intersects  $w$  if the left (bottom) edge of  $w$  is greater than the maximum  $x$  ( $y$ ) coordinate values of  $S$ .

The sets of rectangles that are associated with the leaf nodes of the two-dimensional bucket PR-CIF k-d trees and the nonleaf nodes of the one-dimensional bucket PR-CIF k-d trees are implemented as sequential lists. This is because the region and axis capacities are relatively small, and for such values, the overhead incurred by a complicated access structure is deemed not to be worthwhile [1100]. Note that it may be the case that the number of rectangles associated with a node in the one-dimensional bucket PR-CIF k-d tree may exceed the axis capacity. This situation arises when the number of rectangles that overlap the midpoint of the axis associated with the node exceeds the axis capacity. No further action is taken here.

Lai et al. [1100] conducted a number of experiments comparing the execution time for window queries and space requirements of the bucket PR-CIF k-d tree with the balanced four-dimensional k-d tree [1114, 1571], BQT [1496], and QLQT [1986] (a variant of a bucket rectangle PM quadtree, discussed in greater detail in Section 3.4.3, where the objects are rectangles instead of line segments, as in Section 2.2.2.8 of

### Section 3.4 AREA-BASED METHODS

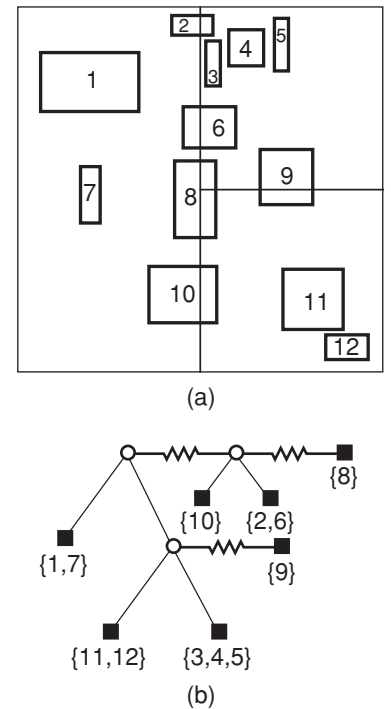

Figure 3.27  
(a) The block decomposition induced by the bucket PR-CIF k-d tree for the collection of rectangles in Figure 3.23 using region and axis bucket capacities of 3 and (b) its tree representation. Horizontal lines with a diagonal sawtooth pattern denote a link from a nonleaf node of the two- and one-dimensional structure to the corresponding one-dimensional structure and list, respectively, that includes the rectangles that overlap the respective partition axis or point.

Chapter 2). Different bucket capacities were used to obtain the best performance for each representation (i.e., 8 for the one- and two-dimensional bucket PR-CIF k-d trees, and 32 for the BQT and QLQT methods). The bucket PR-CIF quadtree was over twice as fast as the balanced four-dimensional k-d tree and somewhat less than twice as fast as the BQT method. The QLQT method took approximately the same amount of time as the bucket PR-CIF k-d tree, sometimes taking less and sometimes taking more. The bucket PR-CIF k-d tree required 20% and 40% less space than the BQT method and balanced k-d tree, respectively. Moreover, the bucket PR-CIF k-d tree required between 60% and 100% less space than the QLQT method. This difference is primarily a result of the fact that the bucket PR-CIF k-d tree represents each rectangle in just one node of the tree, while the QLQT method usually uses considerably more nodes to represent each rectangle (four in these experiments). Thus, by using the bucket PR-CIF k-d tree, we achieve approximately the same execution time performance as the QLQT method with significantly lower space requirements. These results also serve to counter those of Rosenberg [1571] (mentioned in Section 3.3), who found the performance of the balanced four-dimensional k-d tree to be better than the MX-CIF quadtree. In other words, the use of the one-dimensional bucket PR-CIF k-d tree to represent the rectangles that span both sides of the line that partitions the underlying space appears to be useful.

The bucket PR-CIF k-d tree is very similar to the R-file of Hutflesz, Six, and Widmayer [909]. The R-file differs from the bucket PR-CIF k-d tree in that when a bucket overflow occurs, instead of splitting bucket region into two halves (or four quarters in the case of a quadtree-like approach), it retains the original bucket region and creates a new bucket for just one of the two halves of the original bucket region. It then distributes the rectangle objects into the smallest of the cells within which it lies in its entirety. The choice of the half to be retained is based on which one results in approximately the same number of objects in the region that has been split and the newly created region. In fact, the process may end up splitting the newly created region again if all of the objects will lie in the same region. Note that bucket regions do overlap in this case and that an object is not necessarily associated with its minimum containing quadtree or k-d tree block. Instead, it is associated with its minimum containing quadtree or k-d tree block among the existing blocks. Of course, if all of the objects overlap the partition line, then the region corresponding to the bucket cannot be split. In this case, an R-file of one less dimension is used, as is done for the MX-CIF quadtree and the bucket PR-CIF k-d tree.

For example, Figure 3.28 is the R-file for the set of rectangles given in Figure 3.23 using a bucket capacity of 3 for both the two- and one-dimensional R-files. We assume a PR k-d tree implementation and that the  $x$  coordinate is partitioned before the  $y$  coordinate. Figure 3.28(a–c) shows the block decomposition, and Figure 3.28(d) shows a tree representation of the resulting hierarchy that also includes the one-dimensional R-file associated with the block corresponding to the entire region (shown as the root of the tree). The two-dimensional R-file contains four blocks: one corresponding to the entire region (Figure 3.28(a)), two corresponding to its two descendants (Figure 3.28(b)), and one corresponding to the descendant of the top half of the right descendant (Figure 3.28(c)). The pairing of the one-dimensional R-file and the corresponding block of the two-dimensional R-file is shown with a horizontal line having a diagonal sawtooth pattern to the right of the corresponding node in the tree representation of the two-dimensional R-file.

In this example, we find that the block corresponding to the entire region contains four rectangles (i.e., 2, 6, 8, and 10), which is more than the bucket capacity (Figure 3.28(a)). However, it cannot be decomposed further as these rectangles overlap the partition line of the block and thus we make use of a one-dimensional R-file that consists of one block corresponding to the length of the entire  $x$  partition (containing rectangles 8 and 10) and one block corresponding to the upper half of the partition (containing rectangles 2 and 6), as seen in Figure 3.28(d). Note that the empty white square nodes do not have a corresponding block in the R-file. They are only included to facilitate the visualization of which blocks are actually present in the R-file.

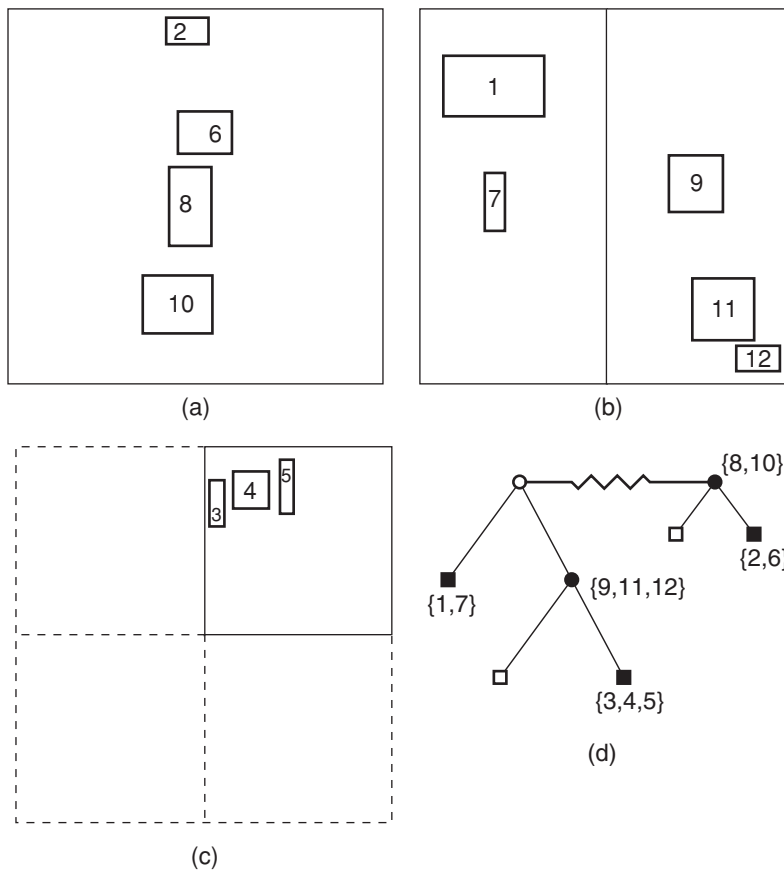

Figure 3.28  
 (a–c) The block decomposition induced by the R-file for the collection of rectangles in Figure 3.23 with a bucket capacity of 3 and (d) its tree representation. Horizontal lines with a diagonal sawtooth pattern denote the pairing of a one-dimensional R-file and the corresponding block of the two-dimensional R-file that has overflowed and whose rectangles overlap the partition axis. Empty white square nodes do not have a corresponding block in the R-file.

In order to avoid searching unoccupied space, the R-file also associates with each bucket a minimum bounding box of the objects that it contains. It is interesting to observe that the R-file is somewhat similar to the BANG file [640] (see Section 1.7.1.5 of Chapter 1) in the sense that some of the regions are nested in other regions. However, unlike the BANG file, region overlap is permitted in the R-file, and thus the nested regions are not removed from their containing regions (i.e., both the contained and containing regions are present in the R-file).

Like Abel and Smith’s implementation of the MX-CIF quadtree [2] and other methods, the R-file is implemented by storing a one-dimensional representative of the buckets (the bucket’s locational code based on the Morton number) in a B-tree. The organization and access of this B-tree that contains locational codes based on Morton numbers of overlapping blocks such as those present in the R-file, are addressed by Ouksel and Mayer [1438] in their development of the nested interpolation-based grid file (NIBGF), whose blocks overlap in much the same way as those in the R-file, although they are generated in a different manner. The motivation for the development of the NIBGF was to improve on the exhaustive search worst-case execution time of an exact match query in the BANG file. This worst-case execution time also arises for the more general, but analogous, point in the R-file.

1. Draw the cover fieldtree for the collection of rectangles given in Figure 3.23 using  $p = 1$ .
2. Draw the partition fieldtree for the collection of rectangles given in Figure 3.23.
3. Show that, regardless of whether a rectangular query window  $w$  intersects the line  $l$  corresponding to partition axis  $a$  of two-dimensional bucket PR-CIF k-d tree node  $b$  or intersects the midpoint  $p$  of  $l$ , determining if each element of the set  $S$  of rectangles stored in the node  $c$  of the one-dimensional bucket PR-CIF k-d tree associated with  $b$  intersects  $w$  can be done with fewer than four comparison operations.
4. Give an algorithm to insert a rectangle into a bucket PR-CIF k-d tree.
5. Give an algorithm to delete a rectangle from a bucket PR-CIF k-d tree.
6. Give an algorithm to find the nearest rectangle to a given point in a bucket PR-CIF k-d tree.
7. Give an algorithm to retrieve all rectangles that overlap a rectangular query window in a bucket PR-CIF k-d tree.
8. Give an algorithm to insert a rectangle into an R-file.
9. Give an algorithm to delete a rectangle from an R-file.
10. Give an algorithm to find the nearest rectangle to a given point in an R-file.
11. Give an algorithm to retrieve all rectangles that overlap a rectangular query window in an R-file.

### 3.4.3 Multiple Quadtree Block Representations

Determining how many rectangles intersect a window (e.g., in the form of a rectangle) may be quite costly when using the MX-CIF quadtree and other representations that associate each rectangle with the smallest enclosing quadtree block. The problem is that the quadtree nodes that intersect the query rectangle may contain many rectangles that do not intersect the query rectangle; yet, each one of them must be individually compared with the query rectangle to determine the existence of a possible intersection.

For example, consider the MX-CIF quadtree in Figure 3.29, corresponding to the collection of rectangles given in Figure 3.1 (excluding the query rectangles). Unlike in the examples of the MX-CIF quadtree in the previous section, we permit the rectangles to overlap. Although query rectangle 1 (see Figure 3.1) is in the NE quadrant of the root of the MX-CIF quadtree, we still have to check some of the rectangles that are stored at the root of the entire quadtree since these rectangles could conceivably overlap rectangle 1.

This work could be avoided by using a more compact (in an area sense) representation of each rectangle. Such a representation would use more, and smaller, quadtree blocks to represent each rectangle, but the total area of the blocks would be considerably less than that of the smallest enclosing quadtree block. As a result, more rectangles would be eliminated from consideration by the pruning that occurred during the search of the quadtree. A number of alternatives are available to achieve this effect. They are examined briefly below.

One possibility is to adapt the region quadtree to represent each rectangle. Such a representation leads to many nodes since its underlying decomposition rule requires that the block corresponding to each node be homogeneous (i.e., that it be totally contained within one of the rectangles or not be in any of the rectangles). Permitting rectangles to overlap forces a modification of the decomposition rule. In particular, it implies that decomposition ceases when a block is totally contained within one or more rectangles. However, if a block is contained in more than one rectangle, then it must be totally contained in all of them. We use the term *rectangle quadtree* to describe this representation.

Abel and Smith [9] present a less radical alternative. They propose that instead of using the minimum enclosing quadtree block, each rectangle be represented by a collection of enclosing quadtree blocks. They suggest that the collection contain a maximum of four blocks, although other amounts are also possible. The four blocks are obtained by determining the minimum enclosing quadtree block, say  $B$ , for each rectangle, say  $R$ , and then splitting  $B$  once to obtain quadtree blocks  $B_i$  ( $i \in \{NW, NE, SW, SE\}$ ) such that  $R_i$  is the portion of  $R$ , if any, that is contained in  $B_i$ . Next, for each  $B_i$ , we find the minimum enclosing quadtree block, say  $D_i$ , that contains  $R_i$ . Now, each rectangle is represented by the set of blocks consisting of  $D_i$ . We term such a representation an *expanded MX-CIF quadtree*. As an example of the expanded MX-CIF quadtree, consider Figure 3.30, corresponding to the collection of rectangles of Figure 3.1. Several items are worthy of note. First, each node appears at least one level lower in the expanded MX-CIF quadtree than it did in the MX-CIF quadtree. Second, some of  $D_i$  may be empty (e.g., rectangle A in Figure 3.30 is covered by blocks 2 and 4; rectangle F in Figure 3.30 is covered by block 14). Third, the covering blocks are not necessarily of equal size (e.g., rectangle E in Figure 3.30 is covered by blocks 4 and 12). It should be clear that the area covered by the collection of blocks  $D_i$  is not greater than that of  $B$ .

The worst-case execution time for building the expanded MX-CIF quadtree and the space requirements are the same as for the MX-CIF quadtree:  $O(n \cdot N)$  for a tree of maximum depth  $n$  with  $N$  rectangles. The worst-case execution time of the rectangle intersection problem is also the same as that for the MX-CIF quadtree:  $O(n \cdot N^2)$ . Abel and Smith suggest that the search process can be made more efficient by applying the splitting process again to the blocks  $D_i$ . Of course, the more times that we split, the closer we get to the region quadtree representation of the rectangles. Also, this increases the space requirement and the insertion and deletion costs.

A representation that is bit more general than the expanded MX-CIF quadtree and more closely related to the rectangle quadtree is to adapt the PM quadtree used for line segments in Section 2.2.2.6 of Chapter 2 to rectangles. We term the result a *bucket rectangle PM quadtree* (or *bucket rectangle quadtree*). This approach is used by Brown [269], who calls it a *multiple storage quadtree*. In this case, we recursively subdivide a block  $b$  into four equal-sized blocks until  $b$  contains no more than  $T$  rectangles, where  $T$  is the bucket capacity (see also [466], who subdivide  $b$  into a variable number  $c$  of blocks such that  $c$  is a power of 2 and varies from block to block, thereby reducing the ultimate depth of the tree and making accesses faster). Therefore, each rectangle can be associated with more than one node in the bucket rectangle PM quadtree. In order to avoid repeatedly storing rectangle  $r$  in all of the blocks intersected by  $r$ , the bucket rectangle PM quadtree just stores a pointer to  $r$  in these blocks. As with most PM quadtree implementations, each block contains a list of pointers to all of the rectangle objects that intersect it rather than the actual rectangles.

Numerous algorithms for operations in VLSI design applications have been developed that use the bucket rectangle PM quadtree (e.g., [887]). Weyten and De Pauw [1985] analyze the storage requirements of the bucket rectangle PM quadtree under uniform and Poisson data distribution models for the centers of the rectangles. The results of this analysis are used to predict the cost of a window query [1985].

The drawback of Brown's formulation of the bucket rectangle PM quadtree is that when executing a window query, some rectangle objects may be reported as intersecting the window several times. Brown overcomes this problem by marking each rectangle object the first time it is reported and then does not report any rectangle objects that have already been marked. Nevertheless, this solution has a shortcoming in the sense that, once the rectangle objects have been reported, the window must be processed again, and all marked rectangle objects must be unmarked.

Weyten and De Pauw [1986] avoid the need to unmark the rectangle objects that have been marked during the execution of the window query on the bucket rectangle PM

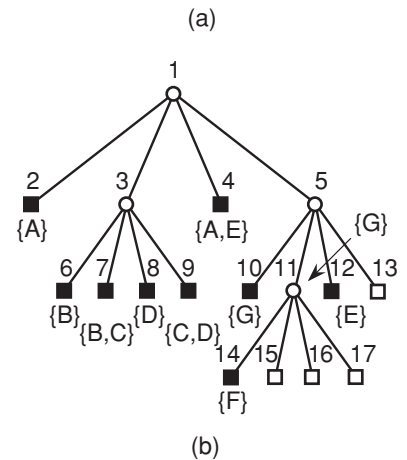

Figure 3.30  
(a) Block decomposition induced by the expanded MX-CIF quadtree for the collection of rectangles in Figure 3.1 and (b) its tree representation.

quadtree by decomposing the list of rectangle objects that intersect each block into four lists, depending on which of the left or bottom sides of the block is intersected by the objects. There are four possible list types:

1. Neither the left nor bottom side of the block is intersected.
2. Only the left side of the block is intersected.
3. Only the bottom side of the block is intersected.
4. Both the left and bottom sides of the block are intersected.

The resulting representation is termed the *quad list quadtree* (QLQT) [1986]. The QLQT has the property that each rectangle object is a member of only one list of type 1, but it can be a member of several lists of types 2–4 (see Exercise 6). A window query on window  $w$  is executed without the need to mark by applying the following steps to each block  $b$  that it overlaps (see Exercise 7):

1. If  $b$  is completely contained in  $w$ , then examine all elements of lists of type 1 as their lower-left corner is in  $b$ .
2. If only the left (bottom) side of  $w$  intersects  $b$ , then examine all elements of lists of types 1 and 2 (1 and 3).
3. If both the left and bottom sides of  $w$  intersect  $b$ , then examine the elements of all four lists (i.e., types 1–4).

Recall from Section 3.4.2 that the QLQT method was compared with the BQT and bucket PR-CIF k-d tree and was found to require considerably more space than the bucket PR-CIF k-d tree, while the execution time of a general windowing algorithm was sometimes better and sometimes worse. The space requirements of the QLQT method could be reduced somewhat by making use of a larger bucket capacity than that used by the bucket PR-CIF k-d tree at the cost of increasing the time needed for some queries due to the higher number of items that must be searched in each node. In fact, this approach of increasing the bucket capacity is used by Lai, Fussell, and Wong [1101] in their development of the hinted quadtree, which is really just an improved implementation of the QLQT method.

The hinted quadtree is motivated by a desire to increase the efficiency of nearest neighbor searching, which is a primitive operation in VLSI geometry design rule checking. Lai et al. [1101] assume that, for a rectangle object of type  $t$ , the nearest neighbor will always be found within a given distance  $h_t$  (termed the *hinted distance*). Thus, their strategy is to expand the query rectangle by its corresponding hinted distance in the four principal directions, thereby creating a new rectangle  $w$  that serves as the query window. The nearest neighbor is found by executing a window query on  $w$  in the part of the space spanned by the minimum enclosing quadtree block of  $w$ , denoted by  $b_w$ , and returning the nearest object in the window. The determination of  $b_w$  is facilitated in the hinted quadtree by also storing with each rectangle  $r$  a pointer to its minimum enclosing quadtree block  $b_r$ , termed an *owner pointer*. If  $b_r$  does not fully contain  $b_w$ , then father pointers are traversed starting at  $b_r$  until the first block whose size is greater than or equal to that of  $b_w$  is reached. It should be clear that, in fact, the owner pointer is unnecessary as the minimum enclosing quadtree block of the query window can be obtained by simply descending the QLQT from the root. Thus, there is no real difference between the hinted quadtree and QLQT.

Lai et al. [1101] conducted some experiments comparing the hinted quadtree with BQT, the balanced four-dimensional k-d tree, QLQT, and the bucket PR-CIF k-d tree, where the bucket capacity of the hinted quadtree was 56, while the bucket capacity was 8 and 16 for the one- and two-dimensional bucket PR-CIF k-d trees, respectively. Neighbor searching was about 40% faster in the hinted quadtree than in the bucket PR-CIF k-d tree, but the build times and space requirements of the hinted quadtree were still worse than those of the bucket PR-CIF k-d tree, although they were better than those for QLQT.

The speedup in the neighbor searching is a direct result of the fact that in the hinted quadtree and QLQT the only nodes that need to be inspected are the leaf nodes that overlap the query window. On the other hand, the remaining methods must also inspect nonleaf nodes with descendant leaf nodes that overlap the query window. Of course, as mentioned earlier, the large bucket capacity used in the hinted quadtree limits its utility for queries that require the examination of the individual items in the bucket (e.g., mutual intersection) rather than simply reporting the ones that are present, as is the case for the window query. Moreover, the observed superiority of the hinted quadtree over the remaining representations [1101] for the nearest neighbor query implemented as a window query does not extend to other window queries as the size of the window was constrained in their experiments to be slightly larger than the rectangle objects stored in the structure. Thus, in general, the bucket PR-CIF k-d tree is still likely to be the most attractive of the alternatives that we have explored.

### *Exercises*

1. Give a procedure called EXPANDEDINSERT to insert a rectangle  $R$  into an expanded MX-CIF quadtree. Rectangle  $R$  may overlap existing rectangles.
2. Analyze the expected cost of inserting a rectangle into an expanded MX-CIF quadtree.
3. Give a procedure called EXPANDEDWINDOW to find all rectangles that intersect a window in an expanded MX-CIF quadtree.
4. Analyze the cost of EXPANDEDWINDOW.
5. Prove that the worst-case execution time for building, the space requirements, and the worst-case execution time of the rectangle intersection problem for the expanded MX-CIF quadtree are the same as for the MX-CIF quadtree.
6. Show that the QLQT has the property that each rectangle object is a member of only one list of type 1, but it can be a member of several lists of types 2–4.
7. Show that the steps of the window query algorithm for the QLQT work properly in the sense that each rectangle object  $r$  that intersects window  $w$  is reported just once (i.e., there is no need for marking and unmarking, as in the bucket rectangle PM quadtree).
8. In order to implement the QLQT method, we need an efficient way to determine the nature of the intersection of a block and a rectangle object. How many different ways are there in which a rectangle object  $o$  intersects a block  $b$ ? Give a method of classifying them.

## High-Dimensional Data

---

Chapters 1 and 2 dealt with the representation of multidimensional points and objects, respectively, and the development of appropriate indexing methods that enable them to be retrieved efficiently. Most of these methods were designed for use in application domains where the data usually has a spatial component that has a relatively low dimension. Examples of such application domains include geographic information systems (GIS), spatial databases, solid modeling, computer vision, computational geometry, and robotics. However, there are many application domains where the data is of considerably higher dimensionality and is not necessarily spatial. This is especially true in pattern recognition and image databases where the data is made up of a set of objects, and the high dimensionality is a direct result of trying to describe the objects via a collection of features (also known as a *feature vector*). Examples of features include color, color moments, textures, shape descriptions, and so on, expressed using scalar values. The goal in these applications is often one of the following:

1. Finding objects having particular feature values (point queries).
2. Finding objects whose feature values fall within a given range or where the distance from some query object falls into a certain range (range queries).<sup>1</sup>
3. Finding objects whose features have values similar to those of a given query object or set of query objects (nearest neighbor queries). In order to reduce the complexity of the search process, the precision of the required similarity can be an approximation (approximate nearest neighbor queries).
4. Finding pairs of objects from the same set or different sets that are sufficiently similar to each other (all-closest-pairs queries). This is also a variant of a more general query commonly known as a *spatial join query*.

These queries are collectively referred to as *similarity searching* (also known as *similarity retrieval*), and supporting them is the subject of this chapter. The objective of the search can either be to find a few similar objects from a larger set or to match corresponding objects in two or more large sets of objects so that the result is a pairing of all of the objects from one set with objects in the other set. When the pairing is one-to-one (i.e., where for each distinct object in set  $A$ , we seek one nearest neighboring object in set  $B$ , which need not always be distinct), then the latter query is known as the *all nearest neighbors problem*. There is also the general problem (e.g., [226, 2030, 2066]), where  $B$  need not be the same as  $A$ , while in [297, 396, 1908],  $B$  is constrained to be

---

<sup>1</sup> When we are only interested in the number of objects that fall within the range, instead of the identity of the objects, then the query is known as a *range aggregation query* (e.g., [1853, 1203]).

the same as  $A$ ),<sup>2</sup> and the distance semijoin for  $k = 1$  [847]. An example of the utility of the latter is the *conflation problem*, which arises often in applications involving spatial data in GIS. In its simplest formulation, conflation is graph or network matching and is usually applied in a geographic setting to maps that are slightly out of alignment in a spatial sense (e.g., [155, 248, 344, 1598, 1599, 1601, 1958, 2033]). We do not deal with such searches in this book and, instead, focus on the former. Moreover, of the queries enumerated above, the nearest neighbor query also known as the *post office problem* (e.g., [1046, p. 563]), is particularly important and hence it is emphasized here. This problem arises in many different fields including computer graphics, where it is known as a *pick query* (e.g., [622]); in coding, where it is known as the *vector quantization problem* (e.g., [747]); and in pattern recognition, as well as machine learning, where it is known as the *fast nearest-neighbor classifier* (e.g., [514]). An apparently straightforward solution to finding the nearest neighbor is to compute a Voronoi diagram for the data points (i.e., a partition of the space into regions where all points in the region are closer to the region's associated data point than to any other data point) and then locate the Voronoi region corresponding to the query point. As we will see in Section 4.4.4, the problem with this solution is that the combinatorial complexity of the Voronoi diagram in high dimensions, expressed in terms of the number of objects, is prohibitive, thereby making it virtually impossible to store the structure, which renders its applicability moot. However, see the approximate Voronoi diagram (AVD) in Section 4.4.5, where the dimension of the underlying space is captured by expressing the complexity bounds in terms of the error threshold  $\varepsilon$  rather than the number of objects  $N$  in the underlying space.

The above is typical of the problems that we must face when dealing with high-dimensional data. Generally speaking, multidimensional problems such as these queries become increasingly more difficult to solve as the dimensionality increases. One reason is that most of us are not particularly adept at visualizing high-dimensional data (e.g., in three and higher dimensions, we no longer have the aid of paper and pencil). However, more importantly, we eventually run into the *curse of dimensionality*. This term was coined by Bellman [159] to indicate that the number of samples needed to estimate an arbitrary function with a given level of accuracy grows exponentially with the number of variables (i.e., dimensions) that it comprises. For similarity searching (i.e., finding nearest neighbors), this means that the number of objects (i.e., points) in the dataset that need to be examined in deriving the estimate grows exponentially with the underlying dimension.

The curse of dimensionality has a direct bearing on similarity searching in high dimensions in the sense that it raises the issue of whether or not nearest neighbor searching is even meaningful in such a domain. In particular, letting  $d$  denote a distance function that need not necessarily be a metric, Beyer, Goldstein, Ramakrishnan, and Shaft [212] point out that nearest neighbor searching is not meaningful when the ratio of the variance of the distance between two random points  $p$  and  $q$ , drawn from the data and query distributions, and the expected distance between them converges to zero as the dimension  $k$  goes to infinity—that is,

$$\lim_{k \rightarrow \infty} \frac{\text{Variance}[d(p, q)]}{\text{Expected}[d(p, q)]} = 0.$$

In other words, the distance to the nearest neighbor and the distance to the farthest neighbor tend to converge as the dimension increases. Formally, they prove that when the data and query distributions satisfy this ratio, then the probability that the farthest neighbor distance is smaller than  $1 + \varepsilon$  of the nearest neighbor distance is 1 in the limit as the dimension goes to infinity and  $\varepsilon$  is a positive value. For example, they show that this ratio holds whenever the coordinate values of the data and the query point are independent

<sup>2</sup> Some of the solutions (e.g., [226, 1908, 2030]) try to take advantage of the fact that the nearest neighbor search needs to be performed on all points in the dataset and thus try to reuse the results of efforts expended in prior searches. They arise primarily in the context of database applications, where they are known as an *all nearest neighbor join* (ANN join).

and identically distributed, as is the case when they are both drawn from a uniform distribution. This is easy to see in the unit hypercube as the variance is smaller than the expected distance.

Assuming that  $d$  is a distance metric and hence that the triangle inequality holds, an alternative way of looking at the curse of dimensionality is to observe that, when dealing with high-dimensional data, the probability density function (analogous to a histogram) of the distances of the various elements is more concentrated and has a larger mean value. This means that similarity searching algorithms will have to perform more work. In the worst case, we have the situation where  $d(x, x) = 0$  and  $d(y, x) = 1$  for all  $y \neq x$ , which means that a similarity query must compare the query object with every object of the set. One way to see why more concentrated probability densities lead to more complex similarity searching is to observe that this means that the triangle inequality cannot be used so often to eliminate objects from consideration. In particular, the triangle inequality implies that every element  $x$  such that  $|d(p, q) - d(p, x)| > \varepsilon$  cannot be at a distance of  $\varepsilon$  or less from  $q$  (i.e., from  $d(p, q) \leq d(p, x) + d(q, x)$ ). Thus, if we examine the probability density function of  $d(p, x)$  (i.e., on the horizontal axis), we find that when  $\varepsilon$  is small while the probability density function is large at  $d(p, q)$ , then the probability of eliminating an element from consideration via the use of the triangle inequality is the remaining area under the curve, which is quite small (see Figure 4.1(a) in contrast to Figure 4.1(b) where the density function of the distances is more uniform). This is not surprising because the sum of the area under the curve corresponding to the probability density function is 1. Note that use of the triangle inequality to eliminate objects from consideration is analogous to the application of the method of Friedman, Baskett, and Shustek [649] as well as Nene and Nayar [1364] for vector spaces, which eliminates a  $k$ -dimensional object  $x = (x_0, x_1, \dots, x_{k-1})$  from consideration as being within  $\varepsilon$  of  $q = (q_0, q_1, \dots, q_{k-1})$  if  $|x_i - q_i| > \varepsilon$  for one of  $x_i$  where  $0 \leq i \leq k - 1$  (see Section 1.1 in Chapter 1).

These observations mean that nearest neighbor searching may be quite inefficient as it is very difficult to differentiate between the nearest neighbor and the other elements. Moreover, as we will see, seemingly appropriate indexing methods, analogous to those described in Chapters 1 and 2, which are designed to make it easier to avoid examining irrelevant elements, may not be of great help in this case. In fact, the experiments of Beyer et al. [212] show that the curse of dimensionality becomes noticeable for dimensions as low as 10–15 for the uniform distribution. The only saving grace is that real-world high-dimensional data (say of dimension  $k$ ) is not likely to be uniformly distributed as its volume is much smaller than  $O(c^k)$  for some small constant  $c > 2$ . Thus, we can go on with our discussion despite the apparent pall of the curse of dimensionality, which tends to cast a shadow on any arguments or analyses that are based on uniformly distributed data or queries.

Assuming that the curse of dimensionality does not come into play, query responses are facilitated by sorting the objects on the basis of some of their feature values and building appropriate indexes. The high-dimensional feature space is indexed using some multidimensional data structure (termed *multidimensional indexing*) such as those described in Chapters 1 and 2 or modifications thereof to fit the high-dimensional problem environment. Similarity search that finds objects similar to a target object can be done with a range search or a nearest neighbor search in the multidimensional data structure. However, unlike applications in spatial databases where the distance function between two objects is usually Euclidean, this is not necessarily the case in the high-dimensional feature space where the distance function may even vary from query to query on the same feature (e.g., [1591]). Unless stated otherwise, we usually assume that the distance is measured directly between points in the space (i.e., “as the crow flies” in a spatial context) rather than possibly being constrained to be along a network on which the points lie, as is useful in applications such as spatial databases. Nevertheless, we do cover the situation that distance is measured along a spatial network in Section 4.1.6. We also assume that the data and query objects are static rather than in motion (e.g., [162, 296, 889, 930,

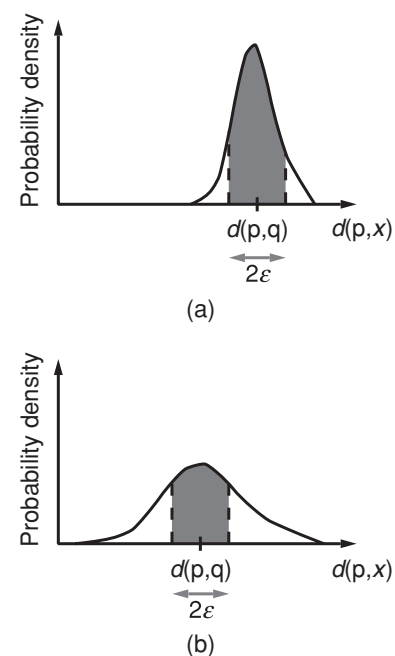

Figure 4.1  
A probability density function (analogous to a histogram) of the distances  $d(p, x)$  with the shaded area corresponding to  $|d(p, q) - d(p, x)| \leq \varepsilon$ : (a) a density function where the distance values have a small variation; (b) a more uniform distribution of distance values, thereby resulting in a more effective use of the triangle inequality to prune objects from consideration as satisfying the range search query.

931, 949, 1306, 1320, 1543, 1789, 1855, 1851, 2034, 2061], many of which make use of the TPR-tree [1610] and the TPR\*-tree [1855], which are variants of an R-tree [791] and an R\*-tree [152], respectively).

Searching in high-dimensional spaces is time-consuming. Performing point and range queries in high dimensions is considerably easier, from the standpoint of computational complexity, than performing similarity queries because point and range queries do not involve the computation of distance. In particular, searches through an indexed space usually involve relatively simple comparison tests. However, if we have to examine all of the index nodes, then the process is again time-consuming. In contrast, computing similarity makes use of distance, and the process of computing the distance can be computationally complex. For example, computing the Euclidean distance between two points in a high-dimensional space, say  $d$ , requires  $d$  multiplication operations and  $d - 1$  addition operations, as well as a square root operation (which can be omitted). Note also that computing similarity requires the definition of what it means for two objects to be similar, which is not always so obvious.

The previous discussion has been based on the premise that we know the features that describe the objects (and hence the dimensionality of the underlying feature space). In fact, it is often quite difficult to identify the features, and thus we frequently turn to experts in the application domain from which the objects are drawn for assistance in this process. Nevertheless, it is often the case that the features cannot be easily identified even by the domain experts. In this case, the only information that we have available is a distance function that indicates the degree of similarity (or dissimilarity) between all pairs of objects, given a set of  $N$  objects. Usually, it is required that the distance function  $d$  obey the triangle inequality, be nonnegative, and be symmetric, in which case it is known as a *metric* and also referred to as a *distance metric* (see Section 4.5.1). Sometimes, the degree of similarity is expressed by use of a similarity matrix that contains interobject distance values for all possible pairs of the  $N$  objects. Some examples of distance functions that are distance metrics include edit distances, such as the Levenshtein [1156] and Hamming [796] distances for strings<sup>3</sup> and the Hausdorff distance for images (e.g., [911] and footnote 45 in Section 2.2.3.4 of Chapter 2).

Given a distance function, we usually index the data (i.e., objects) with respect to their distance from a few selected objects. We use the term *distance-based indexing* to describe such methods. The advantage of distance-based indexing methods is that distance computations are used to build the index, but once the index has been built, similarity queries can often be performed with a significantly lower number of distance computations than a sequential scan of the entire dataset. Of course, in situations where we may want to apply several different distance metrics, then the drawback of the distance-based indexing techniques is that they require that the index be rebuilt for each different distance metric, which may be nontrivial. This is not the case for the multidimensional indexing methods that have the advantage of supporting arbitrary distance metrics (however, this comparison is not entirely fair since the assumption, when using distance-based indexing, is that often we do not have any feature values, as for example in DNA sequences).

There are many problems with indexing high-dimensional data. In fact, due to the complexity of handling high-dimensional data using a multidimensional index, we frequently find that the cost of performing queries using the index is higher than a sequential scan of the entire data (e.g., [212]). This is a result of the curse of dimensionality, which was discussed earlier. However, the “inherent dimensionality” of a dataset is often much lower than the dimensionality of the underlying space. For example, the values of some of the features may be correlated in some way. Alternatively, some of the features may

---

<sup>3</sup> The *Levenshtein edit distance* between two strings  $s$  and  $t$  is the number of deletions, insertions, or substitutions required to transform  $s$  into  $t$ . The *Hamming edit distance* between  $s$  and  $t$ , defined only when  $s$  and  $t$  are of the same length, is the number of positions in which  $s$  and  $t$  differ (i.e., have different characters).

not be as important as others in discriminating between objects and thus may be ignored or given less weight (e.g., [838]). Therefore, there has been a considerable amount of interest in techniques to reduce the dimensionality of the data. Another motivation for the development of many dimension reduction techniques has been a desire to make use of disk-based spatial indexes that are based on object hierarchies, such as members of the R-tree family [791]. The performance of these methods decreases with an increase in dimensionality due to the decrease in the fanout of a node of a given capacity since usually the amount of storage needed for the bounding boxes is directly proportional to the dimensionality of the data, thereby resulting in longer search paths.

In situations where no features but only a distance function are defined for the objects, there exists an alternative to using distance-based indexes. In particular, methods have been devised for deriving “features” purely based on the interobject distances [587, 886, 1181, 1950]. Thus, given  $N$  objects, the goal is to choose a value of  $k$  and find a set of  $N$  corresponding points in a  $k$ -dimensional space so that the distance between the  $N$  corresponding points is as close as possible to that given by the distance function for the  $N$  objects. The attractiveness of such methods is that we can now index the points using multidimensional data structures. These methods are known as *embedding methods*<sup>4</sup> and can also be applied to objects represented by feature vectors as alternatives to the traditional dimension reduction methods. In fact, one of these methods [587] is inspired by dimension reduction methods based on linear transformations. Embedding methods can also be applied when the features are known, in which case they can also be characterized as dimension reduction techniques (e.g., [924]).

The rest of this chapter is organized as follows. Since our main motivation is similarity searching, we start with a description of the process of finding nearest neighbors in Section 4.1. Here the focus is on finding the nearest neighbor rather than the  $k$  nearest neighbors. Once the nearest neighbor has been found, the process that we describe can be used to find the second nearest neighbor, the third, and so on. This process is incremental, in contrast to an alternative method that, given an integer  $k$ , finds the  $k$  nearest neighbors regardless of the order of their distance from the query object  $q$ . The advantage of this approach over the incremental method is that the amount of storage is bounded by  $k$ , in contrast to having possibly to keep track of all of the objects if their distance from  $q$  is approximately the same. On the other hand, the advantage of the incremental approach is that once the  $k$  nearest neighbors have been obtained, the  $(k + 1)$ -th neighbor can be obtained without having to start the process anew to obtain  $k + 1$  nearest neighbors.

Note that the problem of finding neighbors is somewhat similar to the point location query, which was discussed in Section 2.1.3. In particular, in many algorithms, the first step is to locate the query object  $q$ . The second step consists of the actual search. Most of the classical methods employ a “depth-first” *branch and bound* strategy (e.g., [836]). An alternative, and the one we describe in Section 4.1, employs a “best-first” search strategy. The difference between the two strategies is that, in the best-first strategy, the elements of the structure in which the objects are stored are explored in increasing order of their distance from  $q$ . In contrast, in the depth-first strategy, the order in which the elements of the structure in which the objects are stored are explored is a result of performing a depth-first traversal of the structure using the distance to the currently nearest object to prune the search. The depth-first approach is exemplified by the algorithm of Fukunaga and Narendra [666] and is discussed in Section 4.2, where it is also compared with the general incremental algorithm described in Section 4.1. During this comparison, we also show how to use the best-first strategy when only the  $k$  nearest neighbors are desired.

The best-first process of finding nearest neighbors incrementally yields a ranking of the objects with respect to their distance from the query object. This query has taken on an importance of its own. For example, it forms the basis of the *distance join* [847,

---

<sup>4</sup> These methods are distinct and unrelated to embedding space organization methods discussed in the opening text of Chapter 1 and throughout that chapter.

1756] query, where each element of  $A$  is paired up with elements in  $B$ , and the results are obtained in increasing order of distance. Another variant of this query is the *distance semijoin*, which arises when each element  $a$  in  $A$  can be paired up with just one element  $b$  in  $B$ , and we stipulate that  $b$  is the closest element in  $B$  to  $a$ , as well as report the results in increasing order of distance. This query is executed in a coroutine manner, obtaining as many results as necessary. When the query is executed by applying to  $A$  in its entirety, thereby letting the number of neighbors  $k = |A|$ , the result is equivalent to a discrete Voronoi diagram on  $B$  [847]. Moreover, by repeated application of the distance semijoin or distance join to the elements of one set  $A$  with respect to a second set  $B$ , and letting  $k = 1$ , the results of this query can be used as part of a process to find closest pairs (i.e., the all nearest neighbor join discussed earlier). The incremental algorithm finds use in many applications where the number of neighbors that are needed is not always known before starting the query (e.g., in forming query execution plans for query optimization in database applications).

In situations where complete accuracy is not critical, we can make use of the notion of approximate nearest neighbors. We explore two possible approaches to the problem. In the conventional approach, the approximation is the resulting quantitative error, which can be measured (Section 4.3). On the other hand, in the second, more unusual, approach, the approximation results from the assumption that “nearest neighbor” is an “equivalence” relation (Section 4.5.8), which, of course, is not generally true. For the first approach, we demonstrate how the performance of both the best-first and depth-first algorithms can be improved at the risk of having the objects reported somewhat out of order.

The presentation continues in Section 4.4, which presents some multidimensional indexing methods. Many of these methods are high-dimensional adaptations of techniques presented in Chapters 1 and 2. Section 4.5 outlines some distance-based indexing methods. Section 4.6 discusses a number of dimension reduction techniques and shows how some of them are used in conjunction with some of the indexing techniques presented in Chapters 1 and 2. Section 4.7 concludes by presenting a number of embedding methods. Note that many of the embedding methods (e.g., locality sensitive hashing [924]) could also have been discussed in the context of dimension reduction techniques. Our decision on the placement of the discussion depended on whether the emphasis was on the extent of the dimension reduction or on the satisfaction of other properties of the embedding.

## 4.1 Best-First Nearest Neighbor Finding

In this section, we present a general algorithm for finding nearest neighbors. Rather than finding the  $k$  nearest neighbors and possibly having to restart the search process should more neighbors be needed, our focus is on finding them in an incremental manner. The nature of such search is to report the objects in a dataset  $S \subset \mathbb{U}$ , one by one, in order of distance from a query object  $q \in \mathbb{U}$  based on a distance function  $d$ , where  $\mathbb{U}$  is the domain (usually infinite) from which the objects are drawn. The algorithm is a general version of the incremental nearest neighbor algorithm of [846, 848] that is applicable to virtually all hierarchical indexing methods for both spatial (point data and objects with extent) and metric data, in which case the index is based only on the distance between the objects (see Section 4.5). In order to make the discussion more concrete, we use the R-tree (recall Section 2.1.5.2 of Chapter 2) as an example data structure.

The rest of this section is organized as follows: In Section 4.1.1, we motivate the incremental nearest neighbor problem by examining some of the issues and proposed solutions. In Section 4.1.2, we introduce the basic framework for performing search in the form of a *search hierarchy*. In Section 4.1.3, we present a general incremental nearest neighbor algorithm, based on the abstract concept of a search hierarchy, as well as a discussion of its correctness. This algorithm can be adapted to virtually any data

structure by a suitable definition of a search hierarchy, and we illustrate this in the case of the R-tree. Nevertheless, this algorithm can only handle indexes where each object is represented just once (e.g., an R-tree or an arbitrary index, provided that the data are points). However, in many applications the objects may be represented more than once in the index (i.e., there are duplicate instances since the object is decomposed into several pieces, as is the case for region data that is represented by a region quadtree). Section 4.1.4 contains an adaptation of the algorithm for such an environment. In Section 4.1.5, we show how the algorithm can be extended in a variety of ways, including setting limits on the distances of the result objects or on the number of result objects, reporting the objects in reverse order of distance (i.e., finding the *farthest* neighbor first), and computing skylines. Section 4.1.6 discusses how the algorithm can be used in a spatial network—that is, an environment where objects and the space in which their proximity is being measured are constrained to lie on a network, and the distance between them is measured along this network. Section 4.1.7 concludes the discussion by reviewing some related work, thereby placing the general incremental nearest neighbor algorithm in a proper perspective.

### 4.1.1 Motivation

Frequently, it is desired to obtain the neighbors in an incremental manner as they are needed since often we do not know in advance how many neighbors will need to be examined. For example, suppose that we want to find the nearest city to Chicago that has more than one million inhabitants. There are several ways to proceed. An intuitive solution is to guess some area range around Chicago and check the populations of the cities in the range. If we find a city with the requisite population, we must make sure that there are no other cities that are closer and that meet the population condition. This approach is rather inefficient because we have to guess the size of the area to be searched. The problem with guessing is that we may choose too small or too large a region. If the size is too small, the area may not contain any cities satisfying the population criterion, in which case we need to expand the region being searched. If the size is too large, we may be examining many cities needlessly.

A radical solution is to sort all the cities by their distances from Chicago. This is not very practical as we need to resort them each time we pose a similar query with respect to another query city. Moreover, sorting requires a considerable amount of extra work, especially when all that is usually needed to obtain the desired result is to inspect the first few nearest neighbors.

A less radical solution is to retrieve the closest  $k$  cities and determine if any of them satisfy the population criterion. The problem here lies in determining the value of  $k$ . As in the area range solution, we may choose too small or too large a value of  $k$ . If  $k$  is too small, failure to find a city satisfying the population criterion means that we have to restart the search with a value larger than  $k$ , say  $m$ . The drawback of this solution is that such a search forces us to expend work in finding the  $k$  nearest neighbors (which we already did once before) as part of the cost of finding the  $m > k$  nearest neighbors. On the other hand, if  $k$  is too large, we waste work in calculating neighbors whose populations we will never check.

A logical way to overcome the drawbacks of the second and third solutions is to obtain the neighbors incrementally (i.e., one by one) as they are needed. In essence, we are browsing through the database on the basis of distance. The terms *distance browsing* [848] and *distance scan* [149]) are often used to describe this operation. The result is an incremental ranking of the cities by distance where we cease the search as soon as the secondary population condition is satisfied. The idea is that we want only a small, but unknown, number of neighbors. The incremental solution finds application in a much more general setting than our specialized query example. In particular, this includes queries that require the application of the “nearest” predicate to a subset  $s$  of the attributes

of a relation (or object class)  $r$ . This class of queries is part of a more restricted, but very common, class that imposes an additional condition  $c$  usually involving attributes other than  $s$ . This means that the “nearest” condition serves as a primary condition, and condition  $c$  serves as a secondary condition. Using an incremental solution enables such a query to be processed in a pipelined fashion.

Of course, in the worst case, we will have to examine all (or most) of the neighbors even when using an incremental approach. This may occur if few objects satisfy the secondary condition (e.g., if none of the cities have the requisite population). In this case, it may actually be better to select first on the basis of the secondary condition (the population criterion in our example) before considering the “spatially nearest” condition, especially if an index exists that can be used to compute the secondary condition. Using a  $k$ -nearest neighbor algorithm may also be preferable, provided it is more efficient than the incremental algorithm for large values of  $k$ . It makes sense to choose this solution only if we know in advance how many neighbors are needed (i.e., the value of  $k$ ), but this value can be estimated based on the selectivity of the secondary condition. These issues demonstrate the need for a query engine to make estimates using selectivity factors (e.g., [78, 1327, 1717]) involving the numbers of values that are expected to satisfy various parts of the query and the computational costs of the applicable algorithms.

### 4.1.2 Search Hierarchy

The incremental nearest neighbor algorithm is applicable whenever the search space can be represented in a hierarchical manner, provided that certain conditions hold. In this section, we define what we mean by “search hierarchy” and use the R-tree as a specific example. We assume an R-tree implementation in which each node contains an array of  $(key, pointer)$  entries, where  $key$  is a hyperrectangle that minimally bounds the data objects in the subtree pointed at by  $pointer$ . In an R-tree leaf node, the  $pointer$  is an object identifier (e.g., a tuple ID in a relational system), while in a nonleaf node, it is a pointer to a child node on the next lower level. If the geometric descriptions of the objects are simple (e.g., for points or line segments), then it is also possible to store the objects directly in the leaf nodes instead of their bounding rectangles. The maximum number of entries in each node is termed its *node capacity* or *fanout* and may be different for leaf and nonleaf nodes. The node capacity is usually chosen so that a node fills up one disk page (or a small number of them). Search operations on the R-tree are performed in a top-down manner with the bounding box serving as a filter to indicate if the tree should be descended further by following the corresponding pointer. The array of pairs associated with each node is usually not sorted and is thus searched using sequential search.

Figure 4.2  
A sample search hierarchy for objects  $A_0$  through  $N_0$ .

The algorithm operates on a finite set  $S \subset \mathbb{U}$  of objects, a query object  $q \in \mathbb{U}$ , and a data structure  $T$  that organizes the set  $S$  or provides information about it. The search hierarchy is composed of elements  $e_t$  of several different types  $t$ , with  $t = 0, \dots, t_{\max}$ . Figure 4.2 depicts the search hierarchy for a set of 14 objects,  $A_0$  through  $N_0$ , where there are three types of elements. As depicted in the figure, the search hierarchy forms a tree with the objects as leaves. Each element represents a subset of  $S$ , with an element  $e_0$  of type 0 representing a single object in  $S$ . An element  $e_t$  of type  $t$  can give rise to one or more “child” elements of types 0 through  $t_{\max}$ . Thus, the search problem for  $e_t$  is decomposed into several smaller subproblems. Often, all child elements are of the same type, but this is not a requirement. In this presentation, we assume that an element has only one “parent” in the search hierarchy and that each object is represented only once in the hierarchy. However, the algorithm can be adapted to handle multiple parents and duplicate object instances as well (see Section 4.1.4).

At this point, it may seem superfluous to use different types of elements, when they all merely represent subsets of  $S$ . However, for any particular search problem, the various element types represent different kinds of entities and therefore have different pieces of information attached to them. Furthermore, each specific search hierarchy will have

a different definition of what types of elements can be produced from each element type. In the example in Figure 4.2, for instance, elements of type 2 produce elements of types 2, 1, or 0, while elements of type 1 produce only elements of type 0. Elements of each type  $t$ , say  $e_t$ , have an associated distance function  $d_t(q, e_t)$  for measuring the distance from a query object  $q$  to the elements of that type.  $d_t(q, e_t)$  is computed when the parent element, say  $f$ , of  $e_t$  is processed, and thus its computation is based only on the specific information attached to  $f$ . Furthermore, for the algorithm to be practical, this computation must be substantially less expensive than the total cost of computing  $d_0(q, e_0)$  for all the objects  $e_0$  represented by  $e_t$ . In Section 4.1.3, it is shown that for the algorithm to be correct, it is sufficient that  $d_t(q, e_t) \leq d_0(q, e_0)$  for any object  $e_0$  in the subset represented by  $e_t$ . Some of the variants of the algorithm (e.g., farthest neighbors, as discussed in Section 4.1.5) make use of another set of distance functions,  $\hat{d}_t(q, e_t)$ , that bound from above the distances from  $q$  of the objects in a subtree (of course,  $\hat{d}_0 = d_0$ , so  $\hat{d}_0$  is not really needed). In other words,  $\hat{d}_t(q, e_t) \geq d_0(q, e_0)$  for any object  $e_0$  in the subset represented by  $e_t$ .

In most cases, the search hierarchy arises naturally from the hierarchical structure of  $T$ . In the search hierarchy for the R-tree, for instance, we have three types of elements. Elements of type 0 are the spatial objects themselves, elements of type 1 are minimum bounding rectangles for single objects, and elements of type 2 represent R-tree nodes. The reason for distinguishing between the spatial objects and their bounding rectangles will become clear later. The distance functions are typically based on a distance metric  $d_p(p_1, p_2)$  defined on points in the space, such as the Euclidean metric. Thus, for arbitrary spatial objects  $o_1$  and  $o_2$ , we define  $d(o_1, o_2) = \min_{p_1 \in o_1, p_2 \in o_2} \{d_p(p_1, p_2)\}$ .<sup>5</sup> This definition serves as a basis for the distance functions for all three types of elements of the R-tree search hierarchy, the only difference being the types of the arguments. Given an object  $o$  and any rectangle  $r$  that bounds  $o$  (i.e.,  $r$  can be the minimum bounding rectangle of  $o$  or the rectangle associated with any ancestor of the leaf node containing  $o$ ), this definition guarantees that  $d(q, r) \leq d(q, o)$ , thus ensuring correctness (according to the sufficient condition for correctness given above). In fact, according to this definition, the distance functions obey an even stricter condition, namely, that  $d_t(q, e_t) \leq d_{t'}(q, e_{t'})$  for any element  $e_{t'}$  that is a descendant of  $e_t$  in the search hierarchy.

### Exercise

1. Define a search hierarchy for an MX-CIF quadtree.

### 4.1.3 Algorithm

The key to the incremental nearest neighbor algorithm [846, 848] is that it traverses the search hierarchy in a “best-first” manner, like the classic A\*-algorithm (e.g., see [1594]), instead of the more traditional depth-first or breadth-first traversals. In other words, at any step of the algorithm, the algorithm visits the element with the smallest distances from the query object among all unvisited elements in the search hierarchy (or, more accurately, all unvisited elements whose parents have been visited). This is done by maintaining a global list of elements, organized in increasing order of their distance from the query object, with the closest element to the query object being at the front of the list (i.e., it is the most easily accessible element in the list). A data structure that supports the necessary operations (i.e., inspect, insert, and delete a minimum element) is an instance of an abstract data type termed a *priority queue*. In order to break ties among elements having the same distance, priority is given to elements with lower type numbers, and

---

<sup>5</sup> In other words, if  $o_1$  and  $o_2$  have at least one point in common, then  $d(o_1, o_2) = 0$ . Otherwise,  $d(o_1, o_2)$  equals the smallest distance between the boundaries of  $o_1$  and  $o_2$ .

among elements of the same type, priority is given to elements deeper in the search hierarchy. This allows the algorithm to report neighbors as quickly as possible.

The general incremental nearest neighbor algorithm is given by procedure INCNEAREST, where  $q$  is the query object,  $S$  is the set of objects, and  $T$  is a data structure that organizes  $S$ . Since no assumptions are made about the objects or the data structure, the algorithm is presented in terms of the search hierarchy induced by them. The algorithm starts off by initializing the priority queue with the root of the search space (lines 8–10). In the main loop, the element  $e_t$  closest to  $q$  is taken off the queue. If it is an object, we report it as the next nearest object (line 14). Otherwise, the child elements of  $e_t$  in the search hierarchy are inserted into the priority queue (line 17).

```

11 while not ISEMPY( $Queue$ ) do
12    $e_t \leftarrow$  DEQUEUE( $Queue$ )
13   if  $t = 0$  then /*  $e_t$  is an object */
14     Report  $e_t$  as the next nearest object
15   else
16     foreach child element  $e_{t'}$  of  $e_t$  do
17       ENQUEUE( $e_{t'}, d_{t'}(q, e_{t'}), Queue$ )
18     enddo
19   endif
20 enddo

```

Letting  $o_k$  be the  $k$ th object reported by the algorithm, observe that the nonobject elements on the priority queue (i.e., elements  $e_t$  with  $t > 0$ ) at the time of reporting  $o_k$  essentially represent portions of the search hierarchy that did not have to be explored to establish  $o_k$  as the  $k$ th-nearest neighbor. Thus, if  $o_k$  is the last neighbor requested, those portions are said to be *pruned* by the algorithm, and all distance computations for objects descended from the nonobject elements on the priority queue are avoided. As we show at the end of this section using the notion of  $r$ -optimality, the algorithm achieves maximal possible pruning with respect to the given search hierarchy. Of course, if more neighbors are requested, some of those elements may be processed later. Nevertheless, the fact that their processing is deferred means that  $o_k$  is reported as quickly as possible.

Interestingly, in the spatial domain,<sup>6</sup> the algorithm can be viewed as having an initial phase that corresponds to an intersect query (or, if  $q$  is a point, a point location query). In particular, the algorithm first processes all elements  $e$  in the search hierarchy with  $d(q, e) = 0$ , namely, those elements that  $q$  intersects (fully or partially). Thus, at the conclusion of this initial phase, all leaf nodes in the spatial index intersecting  $q$  have been processed and their contents inserted into the priority queue, and all objects intersecting  $q$  have been reported. A similar observation also holds for many of the search hierarchies that correspond to the representations that we present in this book, especially the ones in Section 4.5.

<sup>6</sup> The algorithm is also applicable to multimedia data where we just have distance values indicating similarity or dissimilarity between objects, as discussed in Section 4.5.

---

**Section 4.1**  
BEST-FIRST NEAREST NEIGHBOR  
FINDING

To get a better idea of how the algorithm functions, let us examine how it behaves when applied to the R-tree for spatial data objects. Initially, the root of the R-tree (representing all the data objects) is placed in the priority queue. At subsequent steps, the element at the front of the queue (i.e., the closest element not yet examined) is retrieved, and this is repeated until the queue has been emptied. Thus, the algorithm processes the elements in the priority queue in increasing order of their distance from the query object. Informally, we can visualize the progress of the algorithm for a query object  $q$  as follows (see Figure 4.3, where  $q$  is the point  $q$ ). We start by locating the leaf node(s) containing  $q$ . Next, imagine a circle centered at  $q$  being expanded from a starting radius of 0. We call this circle the *search region*. Note that for query objects other than points, the search region will have a more complex shape. Each time the circle hits the boundary of a node region, the contents of that node are put in the queue (and similarly for the bounding rectangle of an object), and each time the circle hits an object, we have found the object next nearest to  $q$ . We can characterize the contents of the priority queue based on their relationships with the search region. The elements still in the queue are outside the search region (but they all have parents that intersect the search region), while all elements that have been dequeued lie at least partially inside. Also, nodes whose bounding rectangles are fully contained in the search region will have had their entire subtrees already taken out of the priority queue. Therefore, all the queue elements are contained in nodes whose bounding rectangles intersect the boundary of the search region. Similarly, for all objects in the priority queue, their corresponding bounding rectangles intersect the boundary of the search region.

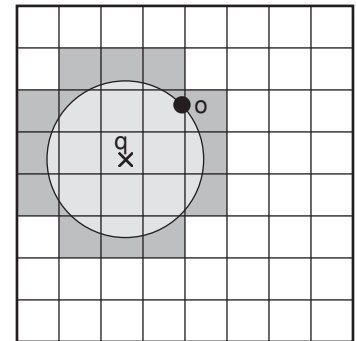

Figure 4.3  
The circle around query object  $q$  depicts the search region after reporting  $o$  as next nearest object. For simplicity, the leaf nodes are represented by a grid; in most spatial indexes, the shapes of the leaf nodes are more irregular. Only the shaded leaf nodes are accessed by the incremental nearest neighbor algorithm. The region with darker shading is where we find the objects in the priority queue.

It should be clear now why a distinction was made between the spatial objects and their bounding rectangles in the R-tree implementation of the incremental nearest neighbor algorithm. This is on account of the fact that in most R-tree implementations the precise geometry of the objects is usually stored in a separate file on disk, whereas the bounding rectangles are stored directly in the leaf nodes of the R-tree. Thus, computing the distance from the query object to the bounding rectangle of an object is much less expensive than computing the distance to the object itself. When a leaf node in the R-tree is visited by the algorithm, the bounding rectangles for the objects in the leaf node are inserted into the priority queue. The actual distance from the query object to a data object is computed only when its bounding rectangle reaches the front of the priority queue.

In fact, at times, we can report an object as a nearest neighbor without ever having to compute its distance from the query object. Such a situation can arise when using an R-tree, where we recall that elements of type 1 represent minimum bounding rectangles of objects—that is, each element  $e_1$  represents only one object. In particular, when processing such an element  $e_1$ , we can sometimes use the distance  $\hat{d}_1(q, e_1)$  to report immediately the object  $o$  represented by  $e_1$ , without computing the actual distance  $d(q, o)$ . This can be done, provided that  $\hat{d}_1(q, e_1) \leq D$ , where  $D$  is the distance of the element at the front of the queue (i.e., after  $e_1$  has been removed) since we then know that  $d(q, o)$  is also no larger than  $D$ . This principle is generally applicable any time that one (or more) of the element types  $t > 0$  represents single objects, and the upper-bound distance function  $\hat{d}_t$  can be defined. The same insight can also be applied to farthest neighbor search, reversing the roles of  $d$  and  $\hat{d}$  (see Section 4.1.5).

Deferring the computation of the actual distances usually leads to many fewer object distance computations, except when a large number of neighbors must be reported (i.e.,  $k$  neighbors are required, where  $k$  is a significant fraction of  $N$ , the size of the dataset  $S$ ). Hence, when the algorithm is terminated (i.e., enough neighbors have been obtained), any bounding rectangles present in the priority queue represent distance computations to objects that were avoided by their use. Of course, these benefits come at the cost of more priority queue operations. Similar considerations apply to other search structures.

The only drawback of the algorithm is that, in the worst case, the priority queue will be as large as the entire dataset. As an example, for an R-tree, the worst case of the

Figure 4.4  
An example of an R-tree of points with node capacity of 8, showing a worst case for the size of the priority queue for nearest neighbor search around query point  $x$ .

queue size arises when all leaf nodes are within distance  $d$  from the query object  $q$ , while all data objects are farther away from  $q$  than  $d$ . This is shown in Figure 4.4, where the query object and data objects are points. In this case, all leaf nodes must be processed by the general incremental algorithm, and all data objects must be inserted into the priority queue before the nearest neighbor can be determined. Note that any nearest neighbor algorithm that is applied to this particular R-tree has to visit all of the leaf nodes since the nearest neighbor is farther away from the query object than all the leaf nodes, and there is no other way to make sure that we have seen the nearest neighbor.

One way to prevent the priority queue from getting too large is by imposing a limit  $M$  on its size, and discarding the element with the largest distance each time an insertion causes its size to exceed  $M$ . Let  $D_{\min}$  keep track of the smallest distance associated with an element that has been discarded from the queue in this manner. Thus, the algorithm only produces a ranking for the objects with  $d(q, o) \leq D_{\min}$ . If the modified algorithm produces enough objects to satisfy the query, then no further action needs to be taken. If this is not the case (i.e., more than  $M$  objects are necessary), then the general incremental algorithm must be restarted with  $D_{\min}$  as the minimum distance. However, this is a bit more complex as we need to make use of the upper bounding distance function  $\hat{d}_i(q, e_i) \geq d_0(q, e_0)$  for any object  $e_0$  in the subset represented by  $e_i$ . In this case, we discard any element  $e_i$  that satisfies  $\hat{d}_i(q, e_i) < D_{\min}$ .

Nevertheless, a worst case like that depicted in Figure 4.4 is highly unlikely to arise in practice (as well as from a probabilistic standpoint) since it depends on a particular configuration of both the data objects and the query object. In order to provide a bound on the size of the priority queue that is more in line with observed results, Henrich [821] and Hjaltason and Samet [848] make some simplifying assumptions about the distribution of the data and the leaf nodes and obtain an expected priority queue size of  $O(\sqrt{kc})$  when finding  $k$  neighbors (see Exercise 1). They assume that the data consists of  $N$  uniformly distributed points in the two-dimensional interval  $[0, 1] \times [0, 1]$ , that the leaf nodes form a grid at the lowest level of the spatial index with average occupancy of  $c$  points per leaf node, and that the search region is completely contained in the data space.

Figure 4.3 provides an intuitive rationale for the analysis where  $o$  has just been reported as the  $k$ th-nearest neighbor of  $q$ . At this point, we know that all  $k$  objects inside the search region have already been reported by the algorithm, and all leaf nodes that intersect the boundary of the search region have been examined and their contents inserted into the priority queue. Moreover, if  $a$  is a node that is completely inside the search region, then all nodes and objects in the subtree rooted at  $a$  have already been taken out of the queue. Thus, all elements in the priority queue are contained in nodes that intersect the boundary of the search region (the dark shaded region in Figure 4.3). On the other hand, not every element in a leaf node that intersects the boundary of the search region is in the priority queue. In particular, elements of these leaf nodes that are contained in the search region are not in the priority queue as they make up some of the  $k$  neighbors that have been reported so far. Therefore, at this time, the priority queue contains exactly all of the unreported elements that intersect the boundary of the search region.

The above line of reasoning forms the basis of the expected analysis. In particular, the expected number of leaf nodes intersected by the boundary of the search region at the distance of the  $k$ th-nearest neighbor (i.e., once it has been determined) is shown to be  $O(\sqrt{k/c})$ . Moreover, using the reasonable assumption that, on the average, one-half of the  $c$  points in these leaf nodes are inside the search region, and one-half are outside, the expected number of points remaining in the priority queue once the  $k$  nearest neighbors have been reported is demonstrated to be  $O(\sqrt{kc})$ , while the fact that the  $k$  nearest neighbors have already been reported means that the expected number of leaf nodes that were accessed to obtain them is  $O(k/c + \sqrt{k/c})$ , or simply  $O(k + \sqrt{k})$ .

Roughly speaking, from the above analysis, we can say that the  $k$  term in the expected number of leaf node accesses accounts for the leaf nodes that lie completely inside the

search region, and the  $\sqrt{k}$  term accounts for the leaf nodes that are intersected by the boundary of the search region. The points in the priority queue lie outside the search region (since otherwise they would have been taken out of the queue) but inside leaf nodes intersected by the boundary of the search region. This has important ramifications for the algorithm's performance in high dimensions, where when the data is assumed to be uniformly distributed, most of the data is found to lie at or near the boundary of the space in which it is embedded (e.g., [187] and the discussion in Section 4.4.6). In particular, as the number of dimensions grows, the ratio of the number of leaf nodes intersected by the boundary of the search region to the number of leaf nodes intersected by the interior of the search region tends to grow. Thus, the size of the priority queue also tends to grow with the number of dimensions. For uniformly distributed points spread evenly among the leaf nodes, where each leaf node covers about the same amount of space, it can be shown that this ratio grows exponentially with the number of dimensions. This is true even if both the search region and leaf node regions are hypercubes (i.e., if we use the Chessboard metric  $L_\infty$ ). Of course, this is only of major significance when the number of desired neighbors is large since the volume of the search region depends on the number of neighbors.

If the average leaf node occupancy and the average node fanout are fairly high (say 50 or more), then the number of leaf node accesses dominates the number of nonleaf node accesses, and the number of objects on the priority queue greatly exceeds the number of nodes on the queue. Thus, we can approximate the total number of node accesses and total number of priority queue elements by the number of leaf node accesses and the number of objects in the priority queue. However, the traversal from the root of the spatial index to a leaf node containing the query object will add an  $O(\log N)$  term to both of these measures.

If the spatial index is disk based, then the cost of disk accesses is likely to dominate the cost of priority queue operations. However, if the spatial index is memory based, then the priority queue operations are the single largest cost factor for the algorithm. In this case, a careful implementation of the priority queue is often crucial for achieving good performance. The importance of this depends on the relative cost of priority queue operations and other operations in the algorithm, such as distance computations, with the latter taking on increasing importance as the dimension of the data increases. Typically, the algorithm performs more enqueue operations than dequeue operations, and this should guide the selection of what priority queue implementation to use (see Exercise 3). Also, it has been observed [844] that careful attention to memory allocation is an important aspect. In particular, rather than relying on dynamic allocation for each individual queue element, the implementation should manage the allocation from a pool of large memory blocks. This is made easier if each type of queue element occupies the same amount of space. Alternatively, separate pools can be kept for each type. In this way, all the elements remaining on the queue when the algorithm is terminated can be deallocated inexpensively since the pool consists only of a few blocks. In the experience of Hjaltason and Samet [848], the size of the priority queue usually remains very modest compared to the size of the dataset and thus it is unlikely that an external (i.e., disk-based) implementation is needed.

It is important to note that both visiting an element in the search hierarchy and computing distances can be expensive operations. For example, for the R-tree version of the algorithm, visiting an R-tree node involves node I/O, and computing the distances of objects may also involve I/O (if stored outside the R-tree) in addition to potentially expensive geometric computation (e.g., for polygons). Thus, the goal is to visit as few elements in the search hierarchy as possible. This goal is captured in the notion of *r-optimality* (range optimality), which is defined below.

Let  $o_k$  be the  $k$ th-nearest neighbor to a query object  $q$  reported by a nearest neighbor algorithm, which operates on a search hierarchy induced by a set of objects  $S$ , a data structure  $T$ , and the query object  $q$ , using distance functions  $d_t$ . The algorithm is said to be *r-optimal* if, for all visited elements  $e_t$  in the search hierarchy,  $d_t(q, e_t) \leq d(q, o_k)$ .

According to this definition, a nearest neighbor algorithm is  $r$ -optimal if it visits the same search hierarchy elements as would a range query with query radius  $d(q, o_k)$  implemented with a top-down traversal of the search hierarchy. The incremental nearest neighbor algorithm is  $r$ -optimal (see Exercise 5). This is based on the fact that the algorithm reports the neighbors in order of nondecreasing distance if, for any object  $e_0$  in the subtree represented by  $e_t$ , we have  $d_t(q, e_t) \leq d_0(q, e_0)$  (see Exercise 4). This is known as the *correctness criterion* [851].

A basic premise underlying the satisfaction of  $r$ -optimality is that, for any object  $e_0$  that has not been reported, there is a representative  $e_t$  in the priority queue (i.e.,  $e_t$  is an ancestor of  $e_0$  in the search hierarchy). This is clearly true initially since the root of the search hierarchy represents all the objects in  $S$ . The only actions of the algorithm are to remove objects from the priority queue and to replace search hierarchy elements with all their children. Thus, the algorithm never violates the premise.

Observe that the correctness criterion (i.e.,  $d_t(q, e_t) \leq d_0(q, e_0)$ ) does not actually guarantee that when a nonobject search hierarchy element  $e_t$  has been removed from the priority queue, no nonobject search hierarchy element  $e_{t'}$  (in the subtree represented by  $e_t$ ) with a smaller distance from the query object  $q$  can be inserted in the future and possibly removed in the future. In other words, it does not preclude the possibility that nonobject elements  $e_t$  and  $e_{t'}$ , where  $d_t(q, e_t) > d_{t'}(q, e_{t'})$ , could be processed in succession (by virtue of being removed from the priority queue in succession, although some other elements could have been inserted into the queue during this time).<sup>7</sup> The implication is that the algorithm has not necessarily visited all elements  $e_t$  with  $d_t(q, e_t) \leq d(q, o_k)$  when the  $k$ th neighbor  $o_k$  of  $q$  is reported. However, this does not change the fact that object elements are obtained from the priority queue in order of distance. Often, however, the distance functions satisfy the stricter criterion that  $d_t(q, e_t) \leq d_{t'}(q, e_{t'})$  for any element  $e_{t'}$  that is a descendant of  $e_t$  in the search hierarchy. This was the case for the distance functions defined for the R-tree in Section 4.1.2. This stricter criterion guarantees that elements are obtained from the priority queue in order of increasing distance from the query object, regardless of their type.

It is also important to note that  $r$ -optimality does not imply that the incremental nearest neighbor algorithm for the given search hierarchy is necessarily optimal in some absolute sense (regardless of whether we consider the required number of distance computations or the overall work). First, actual search performance is highly dependent on the index structure that the search hierarchy is based on. Performance can suffer if the index structure poorly captures the inherent structure of the search space. Second, it is often possible to define more than one search hierarchy for a given index structure, each with different performance characteristics. In some cases, different choices of a search hierarchy even represent a trade-off between the amount of work required to maintain the priority queue operations and to compute the various distance functions (see [851, 854] for examples using indexing methods, such as those described in Section 4.5.7, that are just based on the distance between objects). Moreover, it is sometimes possible to tailor the incremental nearest neighbor algorithm more closely to the given index structure than is achieved with our general notion of search hierarchy. Finally, even for a specific search hierarchy, it is possible that a  $k$ -nearest neighbor algorithm is more efficient for any fixed value of  $k$ . Thus, some sacrifice in performance can be expected for the flexibility offered by the incremental aspect. However, when the number of desired neighbors is unknown prior to initiating the search, an incremental algorithm provides much better performance on the average than algorithms that require fixing the number of neighbors in advance (see [851] for the results of some experiments where this was observed).

---

<sup>7</sup> Such a situation could arise, for example, for a vp-tree [2052] (see Exercise 5 in Section 4.5.2.1.2), which is a distance-based indexing method for data arising in applications where the only available information is a distance function that indicates the degree of similarity (or dissimilarity) between all pairs of objects.

1. Assuming that there are  $N$  uniformly distributed points in the two-dimensional interval  $[0, 1] \times [0, 1]$ , that the leaf nodes form a grid at the lowest level of the spatial index with average occupancy of  $c$  points per leaf node, and that the search region is completely contained in the data space, show that the expected size of the priority queue, when finding the  $k$  nearest neighbors with the general incremental algorithm, is  $O(\sqrt{kc})$ .
2. Continuing Exercise 1, show that the expected number of leaf nodes that are accessed to obtain the  $k$  nearest neighbors using the general incremental algorithm is  $O(k + \sqrt{k})$ .
3. Assume a typical priority queue implementation, such as a binary heap, for which the cost of each insertion and deletion operation is  $O(\log m)$ , where  $m$  is the size of the priority queue. Using the data model employed in Exercise 1 to analyze the expected size of the priority queue, what is the expected cost of the priority queue operations when finding the  $k$  nearest neighbors with the general incremental algorithm?
4. Let  $e_t$  be an arbitrary element in the search hierarchy. Prove that if for any object  $e_0$  in the subtree represented by  $e_t$ , we have  $d_t(q, e_t) \leq d_0(q, e_0)$  (i.e., the correctness criterion holds), then the INCNEAREST algorithm is guaranteed to report the neighbors in order of nondecreasing distance.
5. Prove that if the distance functions satisfy the correctness criterion, then the INCNEAREST algorithm is r-optimal.

#### 4.1.4 Algorithm with Duplicate Instances of Objects

The algorithm given by procedure INCNEAREST can only handle indexes where each object is represented just once (e.g., an R-tree). This is fine when the multidimensional data consists of points. However, in many applications, such as computer graphics, geographic information systems (GIS), computer vision, and so on, the multidimensional data also has extent (e.g., lines, rectangles, regions, surfaces, volumes). In this case, it may not be desirable, or even possible, to represent the objects as points or by one entity such as a minimum bounding box (as is done in the R-tree). Instead, the domain of the data (i.e., the space occupied by the objects) is decomposed into blocks, and the index is used to facilitate the identification and access of the blocks that are occupied by the objects as well as to indicate the identity of the objects. Examples of such indexes include the region quadtree, members of the PM quadtree family, the  $R^+$ -tree, and so on.

Similar issues were raised in the discussion of hierarchical object-based representations of objects based on the interior of the space occupied by the objects in Chapter 2, where we made a distinction between nondisjoint (Section 2.1.5.2) and disjoint (Section 2.1.5.3) representations. Recall that such methods employ an object hierarchy coupled with bounding boxes for the objects in order to facilitate responses to queries such as finding the identity of the object that contains location  $a$  (i.e., query 2 of Chapter 2), while also enabling responses to queries such as finding all locations associated with a particular object (i.e., query 1 of Chapter 2). A hierarchy made up of disjoint bounding boxes enables avoiding the possibility of having to examine the bounding boxes of all of the objects, which could be the case with a hierarchy made up of nondisjoint bounding boxes since they might all span location  $a$ , even though location  $a$  could lie in just one of the objects. Disjointness can be achieved by decomposing the objects into several segments. The disadvantage of disjoint bounding boxes is the presence of duplicates in the sense that some objects may be reported several times for some queries such as finding all objects in a rectangular query region  $w$  since the object could have been decomposed into several segments, each of which overlaps a part of  $w$ . Nevertheless, there has been some work on developing algorithms for spatial queries that report objects just once, even though they may be duplicated in several blocks or nodes (e.g., [76, 80, 498]).

Extending the general incremental nearest neighbor algorithm to handle indexes that represent each object in all leaf nodes whose mutually nonintersecting regions intersect

the object (e.g., the PMR quadtree,  $R^+$ -tree) means that we must be able to deal with the possible presence of duplicate instances of the objects in the search hierarchy. There are two issues here. The first is to make sure to detect all duplicate instances that are currently in the priority queue. The second is to avoid inserting duplicate instances of an object that has already been reported. Modifying the algorithm to resolve these issues involves the addition of just a few lines to procedure INCNEAREST, and the result is given by procedure INCNEARESTDUP. The resulting algorithm is also  $r$ -optimal (see Exercise 2).

```

1  procedure INCNEARESTDUP( $q, S, T$ )
2  /* A best-first incremental algorithm that returns the nearest neighbors of  $q$ 
   from the set of objects  $S$  organized using the search hierarchy  $T$  that per-
   mits duplicate instances of objects. */
3  value object  $q$ 
4  value object_set  $S$ 
5  value pointer search_hierarchy  $T$ 
6  priority_queue  $Queue$ 
7  pointer search_hierarchy  $e_t, e_{t'}$ 
8   $Queue \leftarrow$  NEWPRIORITYQUEUE()
9   $e_t \leftarrow$  root of the search hierarchy induced by  $S$  and  $T$ 
10 ENQUEUE( $e_t, 0, Queue$ )
11 while not ISEMPY( $Queue$ ) do
12    $e_t \leftarrow$  DEQUEUE( $Queue$ )
13   if  $t = 0$  then /*  $e_t$  is an object */
14     while  $e_t =$  FRONTPRIORITYQUEUE( $Queue$ ) do
15       DEQUEUE( $Queue$ ) /* Remove duplicate object instances */
16     enddo
17     Report  $e_t$  as the next nearest object
18   else /*  $e_t$  is not an object */
19     foreach child element  $e_{t'}$  of  $e_t$  do
20       if  $t' > 0$  or  $d_{t'}(q, e_{t'}) \geq d_t(q, e_t)$  then
21         ENQUEUE( $e_{t'}, d_{t'}(q, e_{t'}), Queue$ )
22       endif
23     enddo
24   endif
25 enddo

```

It is easy to see that there are two differences from the original algorithm. The first difference is the test (i.e., the **if** statement) in line 20, which ensures that objects that have already been reported are not inserted into the queue again. Such a situation can only arise if we encounter an object  $o$  as a descendant of an ancestor element  $A$  where the distance of  $o$  from query object  $q$  is smaller than that of  $A$  from  $q$ . This situation, although valid in a disjoint index, is actually a violation of the correctness criterion, which stipulates that, for any object  $e_0$  in the subtree represented by  $e_t$ , we have  $d_t(q, e_t) \leq d_0(q, e_0)$ . Thus, we modify the correctness criterion to be “for all objects  $o \in S$  (note that there could be multiple occurrences of particular objects), there exists at least one element  $e_0$  in the search hierarchy that represents  $o$  and that satisfies  $d_t(q, e_t) \leq d_0(q, e_0)$  for all ancestors  $e_t$  of  $e_0$ .” This modification ensures that each object  $o$  is detected early enough by the algorithm thereby allowing it to be reported at the appropriate time. However, duplicate instances of an object can still be inserted into the priority queue prior to the object being reported. The possibility of the occurrence of such an event is detected by the **if** statement in line 20; as a consequence, the insertion is not made. Note that the algorithm as presented assumes that elements of any type  $t$  can have objects as child elements, which is true for some structures (e.g., the PK-tree as discussed in Section 1.8 of Chapter 1). For structures in which only leaf nodes can contain objects, we can instead

use two separate **for** loops, one for leaf nodes (with the **if** statement) and another for nonleaf nodes (without the **if** statement).<sup>8</sup>

The second difference deals with the possibility that there are multiple instances of an object  $o$  in the priority queue at the same time. This is checked explicitly in the loop in lines 14–16, by making use of the primitive `FRONTPRIORITYQUEUE`, which accesses the element at the front of the priority queue (which is also the closest one to the query object) without removing it, as would be the case if we were to use the `DEQUEUE` primitive. Thus, the duplicate instances of object  $o$  be ignored. For this to work properly (i.e., in order for all duplicate instances of an object in the queue to be retrieved in sequence), we make two stipulations. First, we stipulate that the objects will be ordered in the priority queue by their identity so that when the priority queue contains duplicate instances of two or more objects with the same distance, then all duplicate instances of one of the objects appear before all duplicate instances of the remaining objects. In other words, this ensures that duplicate instances of two different objects at the same distance are not obtained from the queue in an interleaved manner.

Second, we stipulate that nodes must be retrieved from the queue before spatial objects at the same distance. Otherwise, an object  $o$  may be retrieved from the queue and reported before a node  $A$  that contains  $o$  (i.e.,  $A$  is an ancestor node, where we note that the presence of duplicate instances of objects means that an object may have more than one ancestor of a given type) that is at the same distance from the query object as  $o$ . The occurrence of such a situation means that  $o$  was contained in another node  $B$  that has already been dequeued by virtue of being an ancestor of  $o$ . Without such a stipulation, we would have the situation where when  $o$  was encountered again in node  $A$ , there would be no way of knowing that  $o$  had already been reported on account of being a descendant of  $B$ . Such situations are prevented from occurring by virtue of the fact that in order to break ties among elements having the same distance, priority is given to elements with higher type numbers (hence making objects have a lower priority than anything else). It is interesting to observe that this assignment of priorities represents a departure from the rule given in Section 4.1.3, where the emphasis was on reporting neighbors as soon as possible and thus ties among elements having the same distance were broken by giving priority to elements with lower type numbers.

Note that we explicitly check for duplicates in this manner (i.e., using the loop in lines 14–16) because, for many priority queue implementations (e.g., binary heap), it is not efficient to detect duplicates among the queue elements as these implementations only maintain a partial order among the elements. In other words, in such priority queue structures, the relative order among only some pairs of elements is represented at any given time (e.g., in a binary heap, we only know that the elements on a path from the root to a leaf are in increasing order, but two elements that are not on the same path may have any relative order). A possible alternative is to use a priority queue implementation that maintains a total order among all the queue elements (e.g., a balanced binary tree) and thus is able to detect duplicates efficiently.

### Exercises

1. The modified correctness criterion presented above states that for all objects  $o \in S$ , there exists at least one element  $e_0$  in the search hierarchy that represents  $o$  and that satisfies  $d_t(q, e_t) \leq d_0(q, e_0)$  for all ancestors  $e_t$  of  $e_0$ . Prove that the `INCNEARESTDUP` algorithm is guaranteed to report the neighbors in order of nondecreasing distance if the correctness criteria holds.
2. Prove that if the distance functions satisfy the modified correctness criterion, then the `INCNEARESTDUP` algorithm is  $r$ -optimal.

---

<sup>8</sup> In a search hierarchy formulation, we could use  $e_1$  to indicate leaf nodes (i.e., element type 1), and objects would only be children of this element type.

### 4.1.5 Algorithm Extensions ( $K$ -Nearest, $K$ -Farthest, Skylines)

The incremental nearest neighbor algorithm is easily adapted to take advantage of imposed distance bounds (as in a range query), as well as maximum result size as in a  $k$ -nearest neighbor query, notwithstanding claims to the contrary [224]. In particular, given a maximum distance bound  $D_{\max}$ , only elements having distances from  $q$  less than or equal to  $D_{\max}$  need to be enqueued. A minimum distance bound  $D_{\min}$  can be exploited in a similar way, but doing so requires the additional distance functions  $\hat{d}_t(q, e_t)$  for each element type that provide an upper bound on the distances from  $q$  of the objects in the subtree represented by  $e_t$ . Taking advantage of such distance bounds reduces the size of the priority queue (since fewer items will be enqueued) and, consequently, the average cost of priority queue operations. However, the number of distance computations or the number of search hierarchy elements visited is not decreased when using  $D_{\max}$ , and possibly not even when using  $D_{\min}$ , depending on its value (in fact, utilizing  $D_{\min}$  may even lead to worse performance as it requires computing the  $\hat{d}$  distances). Recall that  $D_{\min}$  was also mentioned in Section 4.1.3 in conjunction with a suggested method to reduce the size of the priority queue.

The simplest way of exploiting a maximum result size, say  $k$ , and performing a  $k$ -nearest neighbor query is simply to terminate the algorithm once  $k$  neighbors have been determined. Alternatively, the algorithm can be modified in such a way that the distance  $D_k$  from  $q$  of the  $k$ th candidate nearest neighbor  $o_k$  is used to reduce the number of priority queue operations. In this way, we avoid enqueueing elements with a distance greater than  $D_k$  from  $q$ , thereby pruning the search in the same way as we used  $D_{\max}$  above. However, such a modification incurs the cost of additional complexity in the algorithm. In particular, knowing  $o_k$  means that we must keep track of the set  $L$  of  $k$  candidate nearest objects that have been encountered at any moment. Moreover, we must be able to identify and remove the element in  $L$  with the largest distance. This is done most easily by implementing  $L$  as a priority queue that is distinct from *Queue*, which now contains the remaining types of elements. Thus, we see that finding the  $k$  nearest neighbors makes use of two priority queues. Such an algorithm is given by procedure BFTRAV in Section 4.2.6.

A useful extension of the algorithm is to find the farthest neighbor of a query object  $q$  (i.e., the object in  $S$  that is farthest from  $q$ ). This simply requires replacing  $d_t(q, e_t)$  as a key for any element  $e_t$  in the priority queue with  $-\hat{d}_t(q, e_t)$  (or, alternatively, ordering the elements in the priority queue in decreasing order of key values and using  $\hat{d}_t(q, e_t)$  as a key value). Thus, once an object  $o$  has reached the front of the priority queue, we know that no unreported object has a greater distance from  $q$ .

Nevertheless, using a priority queue to support finding the farthest neighbors has the drawback that the performance of the algorithm that uses it is poor as usually many nodes must be examined before the first (i.e., farthest) object can be identified and reported, thereby making the priority queue quite large. The problem is that many objects tend to be at a similar distance from the query object as the farthest one. This drawback is actually more general in the sense that it is inherent to the task of finding the farthest neighbors as the initial search region is very large due to the large distance to the farthest neighbor. In contrast, when finding the nearest neighbors, the initial search region is small and thus the priority queue is also relatively small as the number of nodes in it is proportional to the size of the search region.

The incremental nearest neighbor algorithm can be applied in the skyline query [236] as well (e.g., [1462]). Below, we first give a brief review of the problem and then outline some of the alternative solutions that have been proposed. For an analysis of their computational costs, see Godfrey, Shipley, and Gryz [713], while for an estimation of the cardinality of the result sets, see [712]. Formally, given a dataset  $P$  of points

$p_1, p_2, \dots, p_N$ , the *skyline query*<sup>9</sup> (also known as the *Pareto operator* [379]) is defined to return a subset  $S$  of  $P$  (referred to as the *skyline points*) such that any point  $p_i$  of  $S$  is not dominated by any other point  $p_j$  in  $P$ , where we say that a point  $p_j$  *dominates* another point  $p_i$  if and only if none of the attribute values of  $p_j$  are greater than the corresponding attribute values of  $p_i$  (e.g., [1511]). The Pareto operator is well known, having been first formulated in 1906 by Pareto [1468] in a treatise on political economy.

As a common and simple example of a scenario in which a skyline query is useful, let us assume that we have a hotel database where the different attributes (i.e., features) include the average room rate per night and the distance from the hotel to the nearest beach. One possible query to this database would seek the hotel  $h$  whose average nightly rate and distance from the beach are both minimums—that is,  $h$  is both the cheapest hotel and the closest to a beach (not necessarily with respect to the same beach, in this example). For this scenario, we see that if such a hotel  $h$  exists, then  $h$  dominates all of the other hotels. Of course, a hotel that meets these requirements need not necessarily exist. Thus, the scope of the set of possible responses must be broadened, and it is precisely this set of responses that is returned by a skyline query. It is called a “skyline” query because its components serve as the extreme points of a wavefront very much like the tallest buildings in a city’s skyline. The result is also similar to a convex hull, where we observe that a polygon is said to be convex if a line can be drawn between any of its constituent vertices without intersecting any of its constituent edges. Figure 4.5 is another example that shows the skyline with respect to the origin at the lower-left corner for the point data in Figure 1.1 of Chapter 1. The skyline consists of Denver, Omaha, Mobile, and Miami. We also see that Omaha dominates Chicago as well as Buffalo and Toronto. Similarly, Mobile dominates Toronto, Buffalo, and Atlanta. Denver only dominates Buffalo and Toronto, but no city is dominated by Miami.

There are many ways of computing the response to the skyline query. A simple way is to build the skyline set  $S$  as points are processed. Each time a new point  $p$  is encountered, first, remove any points in  $S$  that are dominated by  $p$ , and then insert  $p$  into  $S$  unless there exists some point  $t$  in  $S$  that dominates  $p$ , in which case  $p$  is ignored (i.e., pruned) [236]. The drawback of this solution, which is based on the well-known block-nested loop approach [733, 742], is its  $O(N^2)$  complexity for  $N$  points. Its advantages are that no index needs to be built and that its complexity is independent of the dimension of the underlying space.

Chomicki, Godfrey, Gryz, and Liang [379] improve on the block-nested loop approach by first sorting the points according to some monotonic function of their attribute values that preserves dominance among the points (i.e., if point  $p_i$  dominates point  $p_j$ , then  $p_i$  precedes  $p_j$ ) and then applying the block-nested loop algorithm. This method is known as the *sort-first strategy*. Ordering the processing of the points in this way ensures that once a point  $p$  is entered into the skyline set  $S$ , it is never dominated by any yet-to-be-processed point in the dataset, and thus  $p$  will never be removed from  $S$ . In other words, doing so improves the likelihood of pruning points and precludes the possibility of inserting them into the skyline set  $S$  only to have to remove them later. The drawback of this method is the need to sort the data before each invocation of the skyline query, which becomes readily apparent if the skyline query is invoked with respect to different reference query points. Godfrey, Shipley, and Gryz [713] further improve this approach by pruning points during the sorting phase. In essence, the sorting is now performed on a substantially smaller subset of the original data points. They show that for certain distributions of the data points, the algorithm is linear in the number of data points.

An alternative method to these two block-nested loop methods is based on a divide-and-conquer strategy of computing skylines for smaller sets and then merging

## Section 4.1

### BEST-FIRST NEAREST NEIGHBOR FINDING

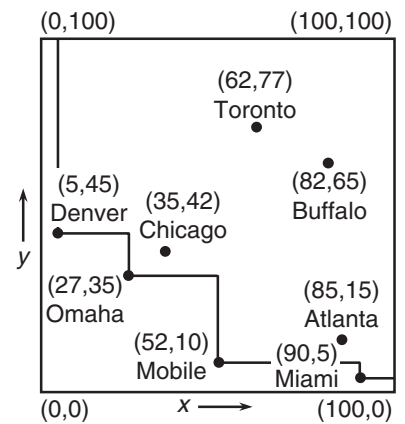

Figure 4.5  
Denver, Omaha, Mobile, and Miami form the skyline for the point data in Figure 1.1 of Chapter 1 with respect to the origin at the lower-left corner.

<sup>9</sup> See also the *skyline cube* (also termed *skycube*) [1479, 2062], which is the set of skylines of all possible nonempty subsets of a given set of dimensions—that is, the skylines for the powerset of the dimensions.

them [236]. The advantage of this strategy is that it can handle large datasets as the entire dataset need not be in memory at the same time.

Other approaches make use of applications of the plane-sweep paradigm (see, e.g., [119, 1511, 1740], and the discussion in Section 3.1 of Chapter 3), which, in the case of the skyline query, differ by the distance metric used to determine the order in which the plane-sweep algorithm processes the candidate members of the skyline. Note that all of these methods are based on the implicit assumption that the underlying dimensional units of all of the attributes are the same or that the domains of their values (i.e., their ranges) have been normalized (i.e., by the application of suitable scale factors). Thus, for example, they cannot be applied directly (i.e., without normalization) to our hotel price and distance from the beach scenario. All of these methods are progressive in the sense that they can be halted once a sufficient number of skyline points has been obtained rather than having to wait until the entire set has been determined, as is the case for the block-nested loop method [236]. Moreover, two of the methods [1462, 1838] can be used to yield a “top- $k$ ” [306] variant of the skyline query, where the results are ordered by the value of the distance metric used to order the processing of the points in the plane-sweep algorithm, and the user has placed a limit  $k$  on the cardinality of the query result set.

Tan, Eng, and Ooi [1838] use a variant of the  $L_\infty$  distance metric defined in terms of “min” instead of “max.” In particular, they process the points in increasing order of the minimum value of all of their attributes, while updating the attribute values of a fictitious point  $f$  that keeps track of the minimum value of all attributes that have been scanned so far (i.e., the halting points of the sweep process). During the sweep, for each point  $p$  that is encountered, a check is made if  $p$  is dominated by any of the existing skyline points, in which case  $p$  is discarded; otherwise,  $p$  is added to the skyline set. The process halts when all of the points have been processed or upon determining that  $f$  is dominated by one of the existing skyline points.

Kossmann, Ramsak, and Rost [1068] sweep the points in increasing order according to the  $L_2$  distance metric from the origin, although any of the  $L_i$  ( $i \geq 1$ ) Minkowski distance metrics could have been used. The first point  $p$  that is found, regardless of which of the Minkowski distance metrics is used, is guaranteed to be a skyline point. Next, the underlying space is partitioned into  $2^d$  regions at  $p$ , at which time two of the regions can be pruned immediately from further processing as one of them, say  $a$ , is guaranteed to be empty by virtue of  $p$ 's having been determined to be the closest point in  $a$  to the origin, while the other region,  $b$ , which is diametrically opposite to  $a$ , is also pruned as every point in  $b$  is dominated by  $p$ . At this point, the algorithm is applied recursively to the remaining regions. It is interesting to note that this process is equivalent to one used by Samet in a point quadtree deletion algorithm [1618] in determining which points residing in the quadrant that contains the replacement point  $p$  need to be reinserted into the newly formed quadtree rooted at  $p$  (recall the control structure of procedure NEWROOT described in Section 1.4.1.2 of Chapter 1). In fact, the points that must be reinserted are elements of the skyline. Note also that the initial process of determining  $p$  is the same as the first step in the selection process for the candidate points to replace the point to be deleted in the point quadtree.

Unfortunately, as Kossmann et al. [1068] point out, this approach does not work too well in dimensions greater than 2 as the process corresponds to a branching structure (i.e., tree) where, at each step,  $2^d$  children are generated, of which only two are pruned from further processing, and hence the number of search subspaces grows to be as large as the number of objects  $N$ . Kossmann et al. propose to overcome this shortcoming by partitioning the underlying  $d$ -dimensional space at  $p$  into two pairwise disjoint regions along each of the  $d$  dimensions, thereby resulting in  $2d$  overlapping regions. Of these  $d$  pairs of pairwise disjoint regions, retain the member of each pair that does not contain the region dominated by  $p$  (i.e.,  $b$  in the above explanation, but see also Exercise 8). This results in  $d$  overlapping regions, at which point candidate skyline points are obtained as

before for each region, and duplicate candidates are removed, although this does require search.

Papadias, Tao, Fu, and Seeger [1462] approach the problem by making use of a spatial index on the points (an R-tree) in their presentation, although in actuality any hierarchical spatial index could be used, and applying the incremental nearest neighbor algorithm described in this section to traverse the hierarchy in increasing order according to the  $L_1$  distance metric from the origin. The advantage of using a spatial index instead of sorting the points with respect to the origin, or some other suitably chosen reference point, as in the sort-first block-nested loop strategy and the methods that employ plane-sweep, is that once the index has been built (which requires a variant of a sorting process), the same index can be used to respond to a skyline query with respect to any reference point. In other words, the index need not be rebuilt, whereas the sort-first block-nested loop strategy and the methods that employ plane sweep must sort the data each time the skyline query is executed with a different reference point. The algorithm makes use of a priority queue *Queue* to keep track of all objects and spatial index blocks that have been encountered so far whose  $L_1$  distance from the origin is greater than the value of the object or block currently being processed by the algorithm.

At the outset of the algorithm, the priority queue *Queue* is initialized to the root of the search hierarchy, and the set of skyline points  $S$  is initialized to the empty set. The algorithm proceeds by removing the nearest entry  $i$  (which can be a point object or a nonobject block) to the origin in *Queue*, in terms of its  $L_1$  distance, and checks if  $i$  is dominated by any of the existing skyline points in  $S$ . If it is, then  $i$  is discarded. Otherwise, there are two cases. If  $i$  is an object, then  $i$  is inserted into  $S$ . On the other hand, if  $i$  is a nonobject, then all of the children of  $i$  are inserted into *Queue* in a position consistent with their  $L_1$  distance from the origin. Papadias et al. [1462] try to reduce the size of *Queue* by conditioning the insertion of a child  $j$  of  $i$  into *Queue* on the basis of  $j$ 's not being dominated by any of the existing skyline points. However, we point out that when  $j$  is subsequently encountered at the front of *Queue*, we must still check if  $j$  is dominated by any of the skyline points in  $S$  as, in the intervening time period, additional points could have been added to  $S$ . Thus, the algorithm may be slowed down considerably if  $j$  does indeed get inserted into *Queue* after performing this check (see Exercise 9). Note that the traversal process of the search hierarchy is analogous to a plane-sweep method where the traversal order plays the same role as the sweep order.

Needless to say, the algorithm is progressive as this is one of the distinguishing characteristics of the incremental nearest neighbor algorithm that it deploys. Papadias et al. [1462] point out that at times it is desirable to report  $k$  elements of the skyline (i.e., a top- $k$  skyline query) in a different order than that given by the distance metric  $L_1$  used to control the traversal of the search hierarchy (i.e., the analog of the plane-sweep algorithm). In other words, the top- $k$  skyline query expresses a preference [378, 1099] for an alternative weighting for the contributions of the attribute values to the equal weighting implicitly provided by the  $L_1$  distance metric. In particular, they note that the dominance relation between two points yields a preference or nonpreference between them according to some scoring function (min in our examples). They propose to extend this notion of preference to a more general *preference function* that can also be used to order (i.e., rank) the skyline points. The ordering yielded by such a scoring function is consistent with that provided by the dominance relation, and both the orders in which the points are processed and the skyline points are produced as long as the function is monotonic in all of the attributes.

Note that this type of a scoring function is also used in the sort-first block-nested loop method of Chomicki et al. [379]. However, the key advantage of its use with the spatial index is that if the preference function changes, there is no need to modify the spatial index, whereas when the preference function changes, the sort-first block-nested loop strategy must be reinvoked to sort the points. The resorting step is necessary as the change in the preference function means that the order in which the elements of the skyline will be reported will change, which is important when executing a variant of a

top- $k$  skyline query. It is interesting to observe that this preference function plays the same role as the distance metric and can also be viewed as a composition of the distance metric and the normalization function that is needed when the domains of the attribute values differ.

A drawback of the implementation of the incremental nearest neighbor algorithm of Papadias et al. [1462] is that, in order to obtain the complete set of skyline points, the algorithm must traverse the entire search hierarchy, at which time the priority queue will be empty. This is in contrast with the algorithm of Tan et al. [1838], which has a condition to be checked for early termination that is not applicable when using the  $L_1$  distance metric as done by Papadias et al. This raises the interesting point that the progressive variant of the skyline query could have also been implemented by using the incremental nearest neighbor algorithm in conjunction with any other distance metric in the Minkowski  $L_p$  family, such as  $L_2$  or, even better, the variant of the  $L_\infty$  distance metric that makes use of a minimum instead of a maximum, as done by Tan et al. [1838] (see Exercise 10).

Skyline queries are only meaningful when an ordering exists on the value domains of the various attributes. The ordering is usually presumed to be total (e.g., [1068, 1462, 1838]), although the ordering can also be partial (e.g., [319]).<sup>10</sup> However, when the ordering is partial, caution must be exercised in the manner in which the partially ordered attributes are handled so that the skyline does not consist of all of the data points in the database, which will be the case if no ordering exists on the value domains of one or more of the attributes (i.e., neither a total or a partial ordering). As an example of a scenario where a partial ordering comes into play, suppose that our hotel database also includes an attribute corresponding to the amenities provided by each hotel. Suppose that we want to determine the hotels with the best amenities and the minimum prices and distances from the beach. In this case, the only ordering-related information that we have about the values of the amenities attribute is that some amenity values are deemed preferable to others. For example, valet covered parking can be viewed as a preferred amenity to covered self-parking, which in turn is preferable to street parking. Similar relationships can be constructed for other amenities. For example, a private beach can be viewed as preferable to a public beach; also, a private beach can be viewed as preferable to a swimming pool. Different classes of amenities could also be ordered, such as a stipulation that valet parking is preferable to a private beach. It is important to note that once we have different classes of amenities, there is also the possibility that an amenity that is preferred to all other amenities may not necessarily exist, although such a situation increases the likelihood that all objects will be in the result of the skyline query.

One possible method of coping with partially ordered attribute domains is to obtain a total ordering for them as a result of applying a process such as a topological sort

---

<sup>10</sup> Briefly, an ordering on a set  $S$  is said to be a *partial ordering* if there exists a relation among the elements of  $S$ , denoted by “ $\leq$ ,” satisfying transitivity (i.e.,  $a \leq b$  and  $b \leq c$  implies  $a \leq c$ ), reflexivity (i.e.,  $x \leq x$ ), and asymmetry (i.e., if  $x \leq y$ , then  $y \leq x$  cannot hold unless  $x = y$ ). Instances of the relation  $a \leq b$  are often interpreted as indicating that  $a$  precedes or equals  $b$ . Therefore, if no such relation exists between some pair of objects  $u$  and  $v$ , then  $u$  and  $v$  can come in any order and thus  $u$  can precede  $v$  and also follow  $v$ . Partial orderings are used to describe many everyday sequences of actions and have been used to define processes such as construction and assembly where some tasks must be completed before others while other tasks can be carried out independently of each other (i.e., this is the case when no precedes relation holds between two objects). Partial orderings are to be contrasted with total orderings, where a *total ordering* is an ordering on  $S$  such that a relation  $R$  exists on  $S$  that yields a partial ordering on  $S$ , and for any two elements  $x$  and  $y$ , either  $x \leq y$  or  $y \leq x$  or  $x = y$  holds. The total ordering differs from the partial ordering in that, in the total ordering, it is impossible for one of the above three relationships not to be satisfied for every possible pair of objects in  $S$ , whereas in the partial ordering, it is possible for objects to exist where none of the three relationships is satisfied. For example, letting  $u$  and  $v$  correspond to the prices of two hotels, in a total ordering, either  $u \leq v$  or  $v \leq u$  or  $u = v$  holds. We also point out that no ordering is possible in the situation that the notion of a relation “ $\leq$ ” between objects does not exist.

(e.g., [976, 1044]). In this case, though, we must be vigilant for false negatives that would incorrectly preclude certain objects from being in the skyline. For example, letting  $a$  be a partially ordered attribute such that, after generating a total ordering via the topological sort, we have that object  $x$  dominates object  $y$ , thereby possibly precluding  $y$  from being in the skyline, when, in fact, for the partially ordered attribute  $a$ , no ordering relationship exists between  $a(x)$  and  $a(y)$ . Of course,  $x$  and  $y$  can still be prevented from being in the skyline if there exists another object  $z$  such that  $a(z)$  has priority over both  $a(x)$  and  $a(y)$ , provided that the other attribute values of  $x$  and  $y$  are also dominated by the corresponding attribute values of  $z$ . Note also that, although progressive skyline algorithms can be developed for partially ordered attribute domains, they cannot be characterized as top- $k$  algorithms as the top- $k$  objects are not unique due to the multitude of possible total orderings.

### Exercises

1. Adapt procedure INCNEAREST to execute a maximum distance query (i.e., find all elements having distance from  $q$  less than  $D_{\max}$ ) in an incremental manner as described in the text.
2. Adapt procedure INCNEAREST to execute a minimum distance query (i.e., find all elements having distance from  $q$  greater than  $D_{\min}$ ) in an incremental manner as described in the text. You will need to make use of the additional distance functions  $\hat{d}_t(q, e_t)$  for each element type that provide an upper bound on the distances from  $q$  of the objects in the subtree represented by  $e_t$ .
3. Adapt procedure INCNEAREST to execute a range query with a minimum and a maximum distance (i.e., find all elements having distance from  $q$  greater than  $D_{\min}$  and less than  $D_{\max}$ ) in an incremental manner as described in the text.
4. Adapt procedure INCNEAREST to execute a maximum result query (i.e., the  $k$  nearest neighbors) in an incremental manner as described in the text.
5. Adapt procedure INCNEAREST to execute a maximum result query (i.e., the  $k$  nearest neighbors) by making use of the distance  $D_k$  from  $q$  of the  $k$ th candidate nearest neighbor  $o_k$  to reduce the number of priority queue operations as described in the text. In particular, use two priority queues, one for the objects and one for the remaining types of elements (i.e., nonobjects).
6. Adapt procedure INCNEAREST as described in the text to obtain a procedure INCFARTHEST that returns the farthest neighbors from object  $q$  in an incremental manner.
7. Adapt procedure INCNEARESTDUP as described in Section 4.1.4 to obtain a procedure INCFARTHESTDUP that returns the farthest neighbors from object  $q$  in an incremental manner while allowing duplicate object instances.
8. The modified skyline algorithm of Kossmann et al. [1068] partitions the underlying  $d$ -dimensional space at the closest point  $p$  to the origin into two pairwise disjoint regions along each of the  $d$  dimensions, thereby resulting in  $2d$  overlapping regions. Of these  $d$  pairs of disjoint regions, the algorithm was described as retaining the member of each pair that does not contain the region dominated by  $p$  (i.e.,  $b$  in the explanation of the basic two-dimensional algorithm). Can you also implement the algorithm by retaining the member of each pair that does not contain the region for which  $p$  is the closest point to the origin (i.e.,  $a$  in the explanation of the basic two-dimensional algorithm)? If yes, which method is preferable?
9. In the text we point out that in their implementation of the incremental nearest neighbor algorithm for computing skyline queries, Papadias et al. [1462] try to reduce the size of the priority queue *Queue* by conditioning the insertion into *Queue* of a child  $j$  of a nonobject  $i$  that is not dominated by any of the elements in the set of skyline points  $S$  on the basis of  $j$ 's not being dominated by any points in  $S$ . We point out that this may slow down the algorithm considerably due to the need to check for dominance twice, once upon insertion of  $j$  into *Queue* and once when  $j$  percolates to the front of *Queue*. Evaluate the utility of this conditioning step by comparing the size of *Queue* and the execution time (i.e., extra checks for dominance) when it is used to when it is not used.
10. Implement the skyline query using the incremental nearest neighbor algorithm with the distance metric employed by Tan et al. [1838]. In other words, the distance metric  $d_T$  is the

minimum of the attribute values so that for two-dimensional points  $(x_1, y_1)$  and  $(x_2, y_2)$ ,  $d_T((x_1, y_1), (x_2, y_2)) = \min(|x_1 - x_2|, |y_1 - y_2|)$ . Compare its performance with the implementation of Papadias et al. [1462], which makes use of the  $L_1$  distance metric. In particular, what is the effect of the early termination condition on the size of the priority queue *Queue* and the execution times?

11. Develop a skyline algorithm that involves partially ordered attribute domains. Can you come up with a simpler solution than the one of Chan, Eng, and Tan [319]?

### 4.1.6 Nearest Neighbors in a Spatial Network

As mentioned in the opening section of this chapter, the nearest neighbor algorithms that we describe assume that the distance between two objects in the set of objects  $S$  is the shortest distance between them in the space in which they lie—that is, “as the crow flies.” However, in many applications such a definition of distance is of limited value because both the set of objects  $S$  and the space in which their proximity is being measured are constrained to lie on a network such as a set of roads, air corridors, sea channels, and so on. In fact, even the choice of paths through the network may be constrained due to conditions such as road widths, weight limits, trafficability, aircraft separation rules, noise constraints, security zones, water depth variations, and so on. Such naturally occurring networks can be modeled as spatial networks. In particular, spatial networks are extensions of general graphs  $G = (V, E)$ , where now the vertices in the graph have fixed spatial positions. As an example, road networks are modeled as directed weighted graphs where the vertices (i.e., road intersections) have spatial positions specified using geographical coordinates—that is, pairs of latitude and longitude values. The edges are assigned suitable weights that model other imposed constraints, such as the distance between the constituent vertices. Note that other nonspatial attributes, often reflecting constraints, could also be associated with the edges, such as road widths, weight limits, speed limits, trafficability, and so on, for the particular road network. For all practical cases, the underlying graphs that form the basis of the spatial networks are assumed to be connected planar graphs. This is not an unreasonable assumption as road networks are connected (at least within a landmass such as a continent), although they do not have to be planar as can be seen by the presence of tunnels and bridges. In the case of water networks consisting of rivers, lakes, canals, and so on, the situation is somewhat different. We do not dwell on such situations here.

It is important to note that the objects that make up the set  $S$  from which the neighbors are drawn need not be the same as the set  $V$  of vertices of the spatial network, and the size of  $S$  is usually considerably smaller than that of  $V$ . The objects in  $S$  represent entities such as restaurants, hotels, gas stations, and so on. They may be coincident with the vertices of the spatial network, lie on the edges of the network, or even be off the network, in which case the algorithms assume that they are associated with the closest vertex in the network. For the purpose of this discussion, we assume that the set  $S$  of objects of interest is a subset of the set  $V$  of vertices.

A number of different algorithms (e.g., [1464, 1672]) have been proposed that make use of the incremental nearest neighbor algorithm in an environment where the distance is measured along a spatial network such as a set of roads (e.g., Figure 4.6(a), where the heavy dots are used to denote vertices with which the objects that are to be retrieved are associated). In other words, in order for an object  $o$  to be a neighbor of object  $q$  at distance  $d$  from  $q$ , there must be some path through the spatial network between  $q$  and  $o$  of length  $d$ . This is useful for obtaining more realistic nearest neighbors, especially in the context of applications where finding  $q$ 's closest neighbor  $o$  is not an adequate answer by itself—that is, we must also actually be able to reach  $o$  on a path starting at  $q$  before reaching any other possible neighbors of  $q$  that might even be closer than  $o$  using a suitably chosen distance metric such as their Euclidean distance from  $q$ .

For example, Figure 4.6(b) is the result of the application of an incremental nearest neighbor algorithm to obtain the shortest paths between a query object associated with the vertex marked by X and its 17 nearest objects that are associated with a subset of the vertices of a spatial network in Figure 4.6(a). The objects associated with the vertices at the end of the paths in Figure 4.6(b) are labeled with a number corresponding to the relative rank of the lengths of the shortest paths to them from X, where lower numbers correspond to shorter paths. Observe that the object associated with vertex 3 is reported as a closer neighbor to X than the object associated with vertex 4, even though the spatial distance between X and 4 is less than the spatial (i.e., Euclidean) distance between X and 3.

One very simple way to use the incremental nearest neighbor algorithm to a spatial network is to note that the Euclidean distance between two objects  $q$  and  $u$  in the spatial network serves as a lower bound on the distance between them through the network (termed the *network distance*). This observation/restriction forms the basis of the *Incremental Euclidean Restriction* (IER) nearest neighbor algorithm of Papadias, Zhang, Mamoulis, and Tao [1464]. The IER algorithm uses a priority queue *Queue*, as well as an R-tree [791] to implement the search hierarchy  $T$  used to represent the set  $S$  of objects from which the neighbors are drawn (usually a subset of the vertices of the spatial network). IER starts by applying the incremental nearest neighbor algorithm to obtain a set  $L$  of  $k$  candidate nearest neighbors (recall Section 4.1.5) that are the  $k$  nearest neighbors of query object  $q$  in terms of their Euclidean distance from  $q$ . Once the  $k$  nearest Euclidean distance neighbors have been determined, IER computes the network distance from  $q$  to all of the elements of  $L$  (using a shortest-path algorithm such as Dijkstra's algorithm [491]), sorts them in increasing order of their network distance from  $q$ , and notes the farthest one  $o_k$  at network distance  $D_k$  from  $q$ . At this point, the incremental nearest neighbor algorithm is reinvoked to continue processing the remaining objects in increasing Euclidean distance from  $q$  until encountering an object  $o$  whose Euclidean distance from  $q$  is greater than  $D_k$ , at which time the algorithm terminates. Each time an object  $o$  is encountered whose Euclidean distance from  $q$  is less than  $D_k$ , then  $o$ 's network distance  $d_o$  from  $q$  is computed, and if  $o$  is closer to  $q$  than one of the elements of  $L$  (i.e.,  $d_o < D_k$ ), then  $o$  is inserted into  $L$ , thereby removing  $o_k$ , and  $o_k$  and  $D_k$  are reset as is appropriate.

IER has several drawbacks. First of all, it is not really incremental in the sense that it does not obtain the nearest neighbors of  $q$  in increasing order of their network distance from  $q$ . Instead, it is only incremental in the sense that it operates in a filter-and-refine [1416] mode where it obtains its candidate objects for the filter test in increasing order of their Euclidean distance from  $q$ . However, the actual objects that it finds are not reported in increasing order of network distance. Thus, it is more of a  $k$ -nearest neighbor algorithm that performs filtering of candidates in increasing order of their Euclidean distance from the query object. This means that once IER has found the  $k$  nearest neighbors of  $q$  in terms of their network distance, it cannot be resumed to find the  $(k + 1)$ -th nearest neighbor. The second drawback is IER's constant need to evaluate the network distance along the shortest path from  $q$  to each object that it encounters. This can be quite expensive for large graphs and entails much repeated work as the shortest paths often have common subpaths.

Sankaranarayanan, Alborzi, and Samet [1672] describe an alternative algorithm, INCNEARESTSPATIALNETWORK (given further below), that overcomes both of these drawbacks. It is truly incremental in the sense that it reports the neighbors in increasing order of their network distance from  $q$ , and once it has reported the  $k$  nearest neighbors, it can be resumed to find the  $(k + 1)$ -th nearest neighbor. Their algorithm uses an all pair shortest-path algorithm (e.g., Dijkstra's algorithm [491]) to precompute the shortest paths between all pairs of vertices  $u$  and  $v$  in  $V$  in the graph  $G = (V, E)$ , although Sankaranarayanan et al. do not store the entire paths. Instead, they store partial information about the paths (i.e., the first edge along the shortest path from source

## Section 4.1

### BEST-FIRST NEAREST NEIGHBOR FINDING

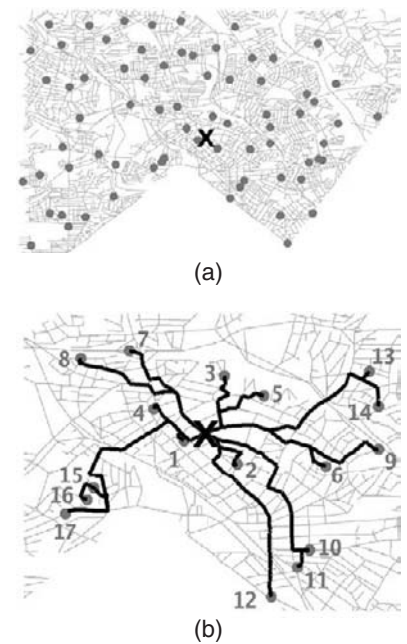

Figure 4.6  
 (a) A sample spatial network corresponding to Silver Spring, Maryland, with heavy dots denoting vertices with which the objects to be retrieved are associated and (b) the result of the application of an incremental nearest neighbor algorithm to obtain the shortest paths between a query object associated with the vertex marked by X and its 17 nearest objects that are associated with the subset of its vertices denoted by heavy dots. The objects associated with the vertices at the ends of the paths are labeled with their position number in an ordering based on increasing length of the shortest path from X to them along the spatial network.

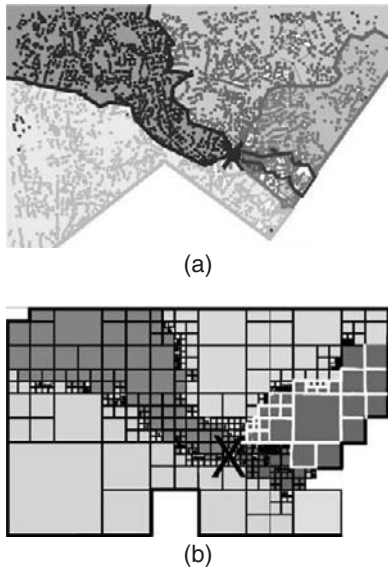

Figure 4.7  
(a) Partition of the underlying space spanned by the spatial network in Figure 4.6(a) into regions  $r_i$  such that the shortest path from the vertex marked by X to a vertex in  $r_i$  passes through the same vertex among the six vertices that are adjacent to X (i.e., the shortest-path map of X) and (b) the blocks in the shortest-path quadtree corresponding to the regions in (a).

vertex  $u$  to destination vertex  $v$ ), which enables the shortest path between  $u$  and  $v$  to be constructed in time proportional to the length of the path.

In particular, using the precomputed shortest-path information and the spatial position of the vertices, Sankaranarayanan et al. construct a map  $m_u$ , defined below, for each vertex (possible query object)  $u$  in the spatial network. Given vertex  $u_i$ , each map  $m_{u_i}$ , termed the *shortest-path map* of  $u_i$ , is a partition of the underlying space into  $M_{u_i}$  regions, where there is one region  $r_{u_i,j}$  for each vertex  $w_{u_i,j}$  ( $1 \leq j \leq M_{u_i}$ ) such that there exists an edge  $e_{u_i,j}$  from  $u_i$  to  $w_{u_i,j}$ . Region  $r_{u_i,j}$  spans the space occupied by all points  $v$  such that the shortest path from  $u_i$  to  $v$  contains edge  $e_{u_i,j}$  (i.e., the shortest path makes a transition through vertex  $w_{u_i,j}$ ). For example, Figure 4.7(a) is such a partition for the vertex marked by X in the road network of Figure 4.6(a). Sankaranarayanan et al. represent each  $m_{u_i}$  using a region quadtree (see also Exercise 5), termed a *shortest-path quadtree*, where there are  $M_{u_i}$  different disjoint regions  $r_{u_i,j}$ . Each region  $r_{u_i,j}$  consists of the disjoint quadtree blocks that it comprises. Given our assumptions that the spatial network is planar and connected, the  $M_{u_i}$  regions  $r_{u_i,j}$  for vertex  $u_i$  are connected (see Exercise 2), ignoring possible floating-point precision errors in the underlying dataset. For example, Figure 4.7(b) is the block decomposition induced by the shortest-path quadtree on the shortest-path map of Figure 4.7(a).

Given source vertex  $u$ , destination vertex  $v$ , the shortest-path map  $m_u$  and shortest-path quadtree  $s_u$  associated with  $u$ , the next vertex  $t$  in the shortest path from  $u$  to  $v$  is the vertex  $w_j$  associated with the quadtree block of  $s_u$  in region  $r_j$  of  $m_u$  that contains  $v$ . The complete path from  $u$  to  $v$  is obtained by repeating the process, successively replacing  $u$  with  $t$  and replacing  $u$ 's shortest-path quadtree with that of  $t$ , until  $u$  equals  $v$ .

There are a number of possible access structures that can be imposed on the set of blocks that make up the shortest-path quadtree. Sankaranarayanan et al. represent these blocks by their locational codes and impose a  $B^+$ -tree access structure on them. The blocks are known as Morton blocks (recall Section 2.1.2.4 of Chapter 2). This approach differs from that of Wagner and Willhalm [1945], who represent the individual regions  $r_{u_i,j}$  in map  $m_{u_i}$  for vertex  $u_i$  by their minimum bounding boxes, which must, in turn, be organized by an index for an object hierarchy such as an R-tree [791]. The drawback of the approach of Wagner and Willhalm is that the bounding boxes are not disjoint, which complicates future searches.

Sankaranarayanan et al. make use of the shortest-path quadtree representation of the shortest paths in a spatial network to facilitate finding neighbors in increasing order of their network distance along the spatial network from a query object in incremental order of network distance. Their algorithm is an adaptation of the general incremental nearest neighbor algorithm. It assumes the existence of a search hierarchy  $T$  (i.e., a spatial index) on a set of objects  $S$  (usually points in the case of spatial networks) that make up the set of objects from which the neighbors are drawn. For the sake of this discussion, we assume that  $S$ , as well as the set of query objects  $Q$ , is a subset of the vertices of the spatial network, although less restrictive definitions could also be permitted such as stipulating that elements of  $S$  and  $Q$  must lie on the network.

The algorithm of Sankaranarayanan et al. is facilitated by storing some additional information with each Morton block  $b$  to enable the computation of the range of network distances from the query object for shortest paths that pass through  $b$ . In particular, for a Morton block  $b$  in the shortest-path quadtree for the map  $m_q$  associated with a query vertex  $q$ , Sankaranarayanan et al. store a pair of values,  $\lambda^-$  ( $\lambda^+$ ), that correspond to the minimum (maximum) ratio of the network distance (i.e., through the network) to the actual *spatial distance* (i.e., “as the crow flies”) from  $q$  to all destination vertices in  $b$ .

At this point, let us elaborate on how the shortest-path quadtree is used to compute network distances. In particular, we first show how to compute the network distance between a query vertex  $q$  and a destination vertex  $v$ . We start by finding the block  $b$  in the shortest-path quadtree of  $q$  that contains  $v$  (i.e., a point location operation). By multiplying the  $\lambda^-$  and  $\lambda^+$  values associated with  $b$  by the spatial distance between

$q$  and  $v$ , we obtain an interval  $[\delta^-, \delta^+]$ , termed the *initial network distance interval*, which contains the range of the network distance between  $q$  and  $v$ . These two actions are achieved by procedure `GETNETWORKDISTINTERVAL` (not given here). Whenever it is determined that the initial network distance interval  $[\delta^-, \delta^+]$  is not sufficiently tight, an operation, termed *refinement*, is applied that obtains the next vertex  $t$  in the shortest path between  $q$  and  $v$  using procedure `NEXTVERTEXSHORTESTPATH` (not given here). Having obtained  $t$ , we retrieve the shortest-path quadtree  $s_t$  for  $t$  and then calculate a new network distance interval  $[\delta_t^-, \delta_t^+]$  by locating the Morton block  $b_t$  of  $s_t$  that contains  $v$ . The network distance interval of the shortest path between  $q$  and  $v$  is now obtained by summing the network distance from  $q$  to  $t$  (i.e., the weight of the edge from  $q$  to  $t$ ) and  $[\delta_t^-, \delta_t^+]$ . Given a pair of vertices  $q$  and  $v$  and a length  $k$  for the shortest path between them, this process can be reinvented at most another  $k - 2$  times until reaching  $v$ .

We now show how to compute the network distance between a query vertex  $q$  and a block  $b$  of the search hierarchy  $T$ . First, we point out that in the case of a block, the concept of a network distance is complicated by the fact that there are usually many vertices within the block, and thus we need to specify somehow the vertex (vertices) for which we are computing the network distance. Instead, we compute a minimum network distance for the block using procedure `MINNETWORKDISTBLOCK` (not given here). The minimum possible network distance  $\delta^-$  of  $q$  from  $b$  is computed by intersecting  $b$  with  $s_q$ , the shortest-path quadtree of  $q$ , to obtain a set of intersecting blocks  $B_q$  of  $s_q$ . For each element  $b_i$  of  $B_q$ , the associated  $\lambda_i^-$  value is multiplied by the corresponding `MINDIST( $q, b_i \cap b$ )` value to obtain the corresponding minimum shortest-path network distance  $\mu_i^-$  from  $q$  to  $b_i$ .  $\delta^-$  is set to the minimum value of  $\mu_i^-$  for the set of individual regions specified by  $b_i \cap b$ . Note that the reason that block  $b$  can be intersected by a varying number of blocks  $b_i$  of  $B_q$  is that  $s_q$  and  $T$  need not be based on the same data structure (e.g.,  $T$  can be an R-tree [791]), and even if they are both quadtree-based (e.g.,  $T$  is a PR quadtree [1413, 1637]),  $s_q$  and  $T$  do not necessarily need to be in registration (i.e., they can have different origins, as can be seen in Figure 4.8).

The incremental nearest neighbor algorithm makes use of a priority queue *Queue* that is initialized to contain the root of the search hierarchy  $T$  and the root's network distance from the query object  $q$ . The principal difference between the spatial network adaptation of the incremental nearest neighbor algorithm and the conventional incremental nearest neighbor algorithm is that, in the case of a spatial network, objects are enqueued using their network distance interval (i.e.,  $[\delta^-, \delta^+]$ ) from the query object  $q$ , instead of just their minimum spatial distance from  $q$ . However, objects and blocks are still removed from *Queue* in increasing order of their minimum network distance from  $q$  (i.e.,  $\delta^-$ ). When a nonleaf block  $b$  is removed from *Queue*, the minimum network distance is computed from  $q$  to all of the children of  $b$ , and they are inserted into *Queue* with their corresponding minimum network distances. When a leaf block  $b$  is removed from *Queue*, the objects (i.e., points) in  $b$  are enqueued with their corresponding initial network distance intervals, which are computed with the aid of the  $\lambda^-$  and  $\lambda^+$  values associated with  $b$ .

On the other hand, when the incremental nearest neighbor algorithm processes an object  $p$  (i.e., when the most recently removed element from *Queue* corresponds to an object), it determines if the maximum network distance  $\delta_p^+$  of  $p$  is less than the minimum network distance  $\delta_h^-$  of the element  $h$  that is currently at the top of the priority queue, in which case it exits because  $p$  is the desired neighbor. Otherwise, it attempts to tighten the network distance interval for  $p$  by applying one step of the refinement operation described earlier and then enqueues  $p$  with the updated network distance interval. Note that when the network distance intervals associated with an object  $p$  in *Queue* have been obtained via refinement, *Queue* must also keep track of the most recently determined intermediate vertex  $t$  on the shortest path from  $q$  to  $p$  and the network distance  $d$  from  $q$  to  $t$  along this path (see Exercise 4). Observe also that no such information need be recorded for blocks, and, in fact, each time we process a block, its associated intermediate vertex and minimum network distance are the query object  $q$  and 0, respectively.

```

It is important to note that, as we have described earlier, although the approach of Sankaranarayanan et al. does precompute the shortest paths and the corresponding network distance value ratios between all possible vertices of the spatial network, it does not store the actual paths; nor does it store the network distances between the vertex pairs, which, for spatial networks with  $N$  vertices, can require as much as  $O(N^3)$  and  $O(N^2)$  space, respectively. Instead, it stores  $N$  shortest-path quadtrees  $s_{u_i}$ , one per vertex  $u_i$  ( $1 \leq i \leq N$ ) corresponding to the various maps  $m_{u_i}$ . Assuming that each of the quadtrees  $s_{u_i}$  is embedded in a  $2^n \times 2^n$  image,  $s_{u_i}$  requires  $O(p_{u_i} + n)$  space, where  $p_{u_i}$  is the sum of the perimeters of the regions that make up  $m_{u_i}$  (recall the Quadtree Complexity Theorem in Section 2.2.2.2 of Chapter 2 [901]). This makes for a potentially considerably smaller contribution to the space requirements than the factor  $N$  associated with the methods that keep track of the network distance from each vertex to all remaining vertices as the number of different regions in the shortest-path quadtree of vertex  $v_i$  is equal to the outdegree of  $v_i$ . It is possible to obtain even lower space bounds by implementing the shortest-path map using one of the boundary-based quadtree representations such as the  $PM_1$  quadtree [1665] and PMR quadtree [1360, 1362] discussed in Sections 2.2.2.6 and 2.2.2.8, respectively, of Chapter 2 (see Exercise 5).

Both the IER algorithm and the algorithm of Sankaranarayanan et al. make use of Dijkstra's algorithm to some extent, differing in whether the shortest paths are precomputed. Both algorithms make use of a priority queue to store candidate members of the set  $S$  from which the neighbors are drawn; however, only the algorithm of Sankaranarayanan et al. reports the neighbors in increasing order of network distance from the query object. An alternative is to use Dijkstra's algorithm directly. In this case, the priority queue  $Queue$  stores the vertices  $V$  of the spatial network, along with their network distances from  $q$  on the shortest path from  $q$ , and the elements are processed in increasing order of these network distances. This alternative forms the basis of the *Incremental Network Expansion* (INE) nearest neighbor algorithm of Papadias, Zhang, Mamoulis, and Tao [1464], which also permits the objects  $S$  to lie on the edges of the network.

The INE algorithm is implemented as follows.  $Queue$  is initialized to contain the vertices of the edge  $e$  on which  $q$  lies and their network distances from  $q$ . The set of the  $k$  candidate nearest neighbors is maintained in  $L$  and is initialized to the objects that lie on  $e$  and their network distances from  $q$ . At each step of INE, the vertex  $c$  at the front of  $Queue$  is removed, and each object  $o$ , if any, associated with an edge incident at  $c$ <sup>11</sup> is inserted into  $L$  with its network distance from  $q$  via  $c$ , say  $d_o$ , provided  $d_o$  is less than the network distance of the  $k$ th nearest neighboring object in  $L$  and that  $o$  is not already in  $L$  with a smaller associated network distance value. All vertices of the edges incident at  $c$  that have not yet been visited (i.e., removed from  $Queue$ ) are inserted into  $Queue$  with their associated network distances from  $q$ . INE halts when the network distance between  $q$  and the  $k$ th nearest neighboring object in  $L$  is smaller than the network distance between  $c$  and  $q$ .

There are several differences between INE and Dijkstra's shortest-path algorithm. The first difference is that INE, as implemented above, is really a  $k$ -nearest neighbor algorithm, as is IER. INE does not obtain the  $k$  nearest neighbors of  $q$  in increasing network distance order from  $q$ , and thus it is not incremental. In contrast, the natural definition of Dijkstra's algorithm does obtain the neighbors incrementally. The second

---

<sup>11</sup> This step differs from the algorithm in [1464] which may miss some lower network distances to the objects via the closer vertex on the edge on which they lie.

Figure 4.9  
A map of Silver Spring, Maryland, and the vertices, highlighted by circles, that are visited when applying Dijkstra's algorithm in determining the shortest path from the vertex marked by X to the vertex marked by V.

difference is that INE does not attempt to remove a vertex  $v$  that has not yet been visited from *Queue* (although it could, and should, do so) when INE encounters  $v$  as a result of being incident at  $c$  when dequeuing  $c$ . This variation potentially makes INE less efficient as the size of *Queue* is larger.

As we saw above, both INE and IER make heavy use of Dijkstra's algorithm, which is good for small spatial networks where it may not be worthwhile to precompute all of the shortest paths. Papadias et al. [1464] have shown the INE algorithm to outperform the IER algorithm, which is not surprising as the IER algorithm is constantly recomputing the shortest paths from  $q$  through the vertices on the shortest paths to its  $k$  nearest neighbors. However, for large spatial networks, applications of Dijkstra's algorithm to find the shortest path between two vertices such as INE can be expensive because it will visit a large proportion of the vertices in the spatial network, unless the distribution of the objects of  $S$  around  $q$  is dense as, in this case, fewer of the vertices or edges of  $G$  need to be visited. For example, Figure 4.9 shows the vertices that would be visited when finding the shortest path from the vertex marked by X to the vertex marked by V in the spatial network of Silver Spring, Maryland, of Figure 4.6. Here we see that 75.4% of the vertices are visited in the network (i.e., 3,191 out of a total of 4,233 vertices) in the process of obtaining a shortest path of length 75 edges.

Cho and Chung [377] try to improve on INE when the distribution of objects around  $q$  is sparse by preprocessing the spatial network to find vertices with a large outdegree (e.g.,  $\geq 3$ ), termed *intersection vertices*, and computing the shortest paths from some small subset of them (elements of which are termed *condensing points*) to a predefined number  $m$  of their nearest neighboring objects. When the nearest neighbor algorithm encounters a condensing point  $c$  in the course of the search, the list  $L$  of  $k$  candidate nearest neighbors is updated with the  $m$  neighbors stored at  $c$ . Although the network distance to a neighbor  $v$  of  $c$  from  $q$ , denoted by  $d(q, v)$ , is unknown, Cho and Chung make use of the triangle inequality to approximate it with the network distance  $d(q, c) + d(c, v)$ . The result is that their algorithm encounters neighboring objects of  $q$  earlier than the INE algorithm, thereby enabling other vertices and objects to be pruned and consequently reducing the size of the priority queue. However, unfortunately, although the neighboring objects are encountered earlier, Cho and Chung do not provide a mechanism for the algorithm to terminate earlier as the network distance associated with an object  $o$  in  $L$ , such that  $o$  is a neighboring object of a condensing point, is an approximate network distance, and thus the algorithm only terminates when the search actually encounters these objects. Also, Cho and Chung's proposed improvement still does not make INE incremental. On the other hand, incremental algorithms such as the one of Sankaranarayanan et al. [1672] that we have described, which expend more time to precompute the shortest paths between

all of the vertices of the spatial network, need not be concerned with these issues, and thus are more attractive, especially when many queries are posed to the spatial network.

Of course, there have been many other attempts at improving the performance of shortest-path algorithms such as Dijkstra's algorithm on large spatial networks, and the topic remains a subject of much research. Below, we describe some of the approaches. Filho and Samet [612] propose a method to speed up shortest-path computations on graphs that correspond to spatial networks by constructing a hierarchical auxiliary structure that aids path computations on  $G$ . This approach is an improvement on an earlier method of Jing, Huang, and Rundensteiner [958]. Goldberg and Harrelson [715] propose an alternative method to speed up path computations on spatial networks by embedding a set of pivots  $P$  at known positions (termed *landmarks*) in  $G$ . The network distances between all vertices and landmarks in  $G$  are precomputed and stored. Path computation between a source vertex  $u$  and a destination vertex  $v$  in  $G$  is sped up by making use of the network distance between  $u$  and  $v$  to a landmark  $p_i \in P$ . By applying constraints based on the triangle inequality, Goldberg and Harrelson are able to avoid visiting a substantial number of infeasible edges during the search process. Recall that the approach of Cho and Chung also makes use of the triangle inequality with the vertices that are condensing points playing the role of landmarks. Interestingly, the use of landmarks by both Goldberg and Harrelson and Cho and Chung can be viewed as a special case of the approach of Filho and Samet, where only one level of the hierarchical auxiliary structure is used.

Landmarks are also used by Kolahdouzan and Shahabi [1054] in a  $k$ -nearest neighbor finding algorithm where the objects from which the neighbors are drawn (a subset of the vertices of the spatial network) serve as sites of a Voronoi diagram. Shortest paths are precomputed between the Voronoi sites and vertices whose incident edges cross the boundaries of the Voronoi regions, termed *border vertices*. In this case, the  $k > 1$  nearest neighbors of a query object  $q$  in Voronoi region  $r_q$  are obtained by making transitions to adjacent Voronoi regions of  $r_q$  with the aid of knowledge of the shortest-path network distances from the border vertices to the sites of the Voronoi regions in which they are contained. It should be clear that the border vertices play the role of landmarks. The algorithm is not incremental. Kolahdouzan and Shahabi [1053] have also adapted this method to the situation where the query object is in motion.

Linial, London, and Rabinovich [1181] describe an alternative method that constructs a Lipschitz embedding [1181] (see Section 4.7.2) consisting of a suitably chosen collection of subsets of the vertices of a general graph, where each subset serves as a coordinate. Shahabi, Kolahdouzan, and Sharifzdeh [1736] adapt this method for the special case that the general graph is a spatial network. Once the correspondence between coordinates and vertex subsets has been established, Shahabi et al. map each of the vertices in the spatial network into the high-dimensional vector space  $H$  formed by these coordinates. An approximate network distance between source vertex  $u$  and destination  $v$  is obtained by using the  $L_\infty$  Minkowski distance (i.e., the Chessboard metric) between their corresponding representations in  $H$ . Observe that Shahabi et al. do not compute the shortest path between  $u$  and  $v$ , although they claim that the approximate network distance that they obtain can be used as an estimate to guide the search for an approximate shortest path between them. However, it is important to point out that the distortion of the embedding (see Section 4.7.1) is  $O(\log N)$ , where  $N$  is the number of vertices in the spatial network. Gupta, Kopparty, and Ravishankar [781] describe a related approach that also makes use of embeddings in a high-dimensional space, which obtains exact network distances and shortest paths but requires that the edge weights be integers.

### Exercises

1. Compare the performance of the incremental nearest neighbor algorithm in a spatial network when using a region quadtree [1672] and an R-tree [1945] for the regions of the shortest-path map of the query objects.

2. Recall that, for a given vertex  $u$ , its shortest-path map  $m_u$  is a partition of the underlying space into  $M_u$  regions where there is one region  $r_{uj}$  for each vertex  $w_j$  ( $1 \leq j \leq M_u$ ) such that there exists an edge  $e_{uj}$  from  $u$  to  $w_j$ . Region  $r_{uj}$  contains the space occupied by all vertices  $v$  such that the shortest path from  $u$  to  $v$  contains edge  $e_{uj}$  (i.e., makes a transition through vertex  $w_j$ ). Assuming that the spatial network is planar, prove that each of the  $M_u$  regions  $r_{uj}$  is connected.
3. How would you handle spatial networks that are both nonplanar and disconnected?
4. In the text, we mention that when the network distance intervals associated with a point  $p$  in *Queue* have been obtained via refinement, *Queue* must also keep track of the most recently determined intermediate vertex  $t$  on the shortest path from  $q$  to  $p$  and of the network distance from  $q$  to  $t$  along this path. Alternatively, instead of storing the network distance from  $q$  to  $t$  in *Queue*, suppose you stored the network distance interval from the intermediate vertex  $t$  to  $p$ . Is there any advantage to using this alternative?
5. Discuss the ramifications of representing the shortest-path map by imposing a variant of a PM quadtree such as the  $PM_1$  quadtree [1665] or the PMR quadtree [1360, 1362] on the underlying subdivision of space instead of a region quadtree.
6. Given a spatial network, one way to store it is to build a spatial data structure such as one of the PM quadtree variants discussed in Sections 2.2.2.6 and 2.2.2.8, respectively, of Chapter 2. An alternative is to decompose the underlying space into regions so that the number of unconnected vertices in the region is kept low. Discuss how you would construct such a decomposition.

### 4.1.7 Related Work

Numerous algorithms exist for answering nearest neighbor and  $k$ -nearest neighbor queries. They are motivated by the importance of these queries in fields including geographical information systems (GIS), databases, pattern recognition, document retrieval, and learning theory. Almost all of these algorithms, many of them originating from the fields of pattern recognition and computational geometry, are for points in a  $d$ -dimensional vector space (e.g., [264, 530, 650, 666, 986, 1586, 1797]), but some allow for arbitrary spatial objects (e.g., [821, 863, 864]), although most of them restrict the query object to be a point.

Many of the above algorithms require specialized search structures (e.g., [100, 202, 666, 986]), but some employ commonly used spatial indexes such as those described in this book. For example, algorithms exist for the  $k$ -d tree (e.g., [264, 530, 650, 1331, 1797]), quadtree-related structures (e.g., [846, 848, 863]), the R-tree (e.g., [848, 1586, 1989]), the LSD tree [821], and others. In addition, many of the algorithms can be applied to other spatial indexes, some of which are discussed in Section 4.4. A number of approximate nearest neighbor algorithms have also been developed (e.g., [100, 202, 346, 387, 517, 608, 1226, 1229, 1230, 1286, 1971, 1989]). Some are discussed in Section 4.3 (i.e., [100, 346, 387, 517]), while others are discussed in Section 4.4.4 (i.e., [387, 1226, 1229, 1230]), Section 4.4.5 (i.e., [97, 98, 799]), and briefly in Section 4.4.8 (i.e., [387, 608, 1971]).

As we have pointed out in this section, frequently it is desired to obtain the neighbors in an incremental manner as they are needed since we often do not know in advance how many neighbors will have to be examined. Only a few of the above algorithms are incremental [821, 846, 848]. All of these incremental algorithms employ priority queues to organize the objects and to allow reporting the neighbors one by one. In addition, the algorithms of [821, 846, 848] also use a priority queue for the nodes of the index, enabling them to perform “best-first” traversal (i.e., at each step of the algorithms, the next node or object to visit is taken as the closest one to the query object that has yet to be visited).

The algorithm of [264] was developed for the  $k$ -d tree [164]. It is considerably different from the other algorithms [821, 846, 848] in that the algorithm of [264] stores

only the data objects in the priority queue and uses a stack to keep track of the subtrees of the spatial data structure that have yet to be processed completely. This makes it necessary to use an elaborate mechanism to avoid processing the contents of a node more than once.

The algorithm of [821] was developed for the LSD tree [829]. It is very similar to the algorithm that we describe in Section 4.1.3 (presented in [846]) and was published at about the same time. The principal difference between [821] and the method that we have presented is that the LSD tree algorithm uses two priority queues, one for the data objects and another for the nodes of the spatial index, while our algorithm does not distinguish between the data objects and the nodes—that is, both nodes and data objects are stored in the same priority queue. This makes the algorithm of [821] a bit more complicated than the algorithm that we have presented, while the use of two priority queues does not offer any performance benefits according to experiments [848].

The incremental algorithm [846] that we have described in this section was initially developed for the PMR quadtree [1360], although its presentation was general and was easily adapted to an R-tree [848]. It was also recently adapted to be used with an MX-CIF quadtree in a peer-to-peer (P2P) setting [1848]. In addition, [848] has shown how an existing  $k$ -nearest neighbor algorithm [1586] can be transformed into a special case of the algorithm that we have presented. A byproduct of the transformation process is that the  $k$ -nearest neighbor algorithm has been simplified considerably.

Nearest neighbor algorithms have also been developed for general objects where the only restriction is that they reside in a metric space—that is, a distance metric is defined between any two objects. Methods for indexing such objects (e.g., [118, 241, 255, 283, 334, 389, 666, 851, 854, 1292, 1347, 1383, 1743, 1897, 1930, 1951, 2052]) are discussed in greater detail in Section 4.5. Most existing  $k$ -nearest neighbor algorithms for such distance-based indexes use a depth-first *branch and bound* strategy (e.g., [836]) as discussed in Section 4.2. A few algorithms employ best-first search, much like the general incremental nearest neighbor algorithm that we have described, but the full power of best-first search is not always exploited. Section 4.5 contains a detailed discussion of how to adapt the search hierarchies proposed in Section 4.1.2 and the general incremental nearest neighbor algorithm INCNEAREST to a number of the distance-based indexes.

## 4.2 The Depth-First $K$ -Nearest Neighbor Algorithm

Perhaps the most common strategy for nearest neighbor finding employs the depth-first *branch and bound* method (e.g., [836]). Nearest neighbor finding algorithms that incorporate this strategy can be easily extended to find the  $k$  nearest neighbors, and this is how we describe them here. These algorithms are generally applicable to any index based on hierarchical clustering. The idea is that the data is partitioned into clusters that are aggregated to form other clusters, with the total aggregation being represented as a tree. The search hierarchies used by these algorithms are partly specific to vector data (e.g., [202, 530, 650, 666, 955, 986, 1103, 1199, 1331, 1374, 1586, 1797, 1989]), but they can be easily adapted to nonvector data (e.g., [118, 241, 255, 283, 334, 389, 851, 854, 1292, 1347, 1383, 1743, 1897, 1930, 1951, 2052]), as discussed in Section 4.5), and this is how we present them here. This means that many of our derivations, unless stated otherwise, only make use of the triangle inequality rather than make an implicit assumption that the underlying space is a vector space with the Euclidean distance metric.

This section is organized as follows. The basic depth-first  $k$ -nearest neighbor algorithm is described in Section 4.2.1. Section 4.2.2 contains a detailed presentation of a number of pruning rules to avoid processing some of the clusters, as well as individual objects, when they can be shown to be farther from the query object  $q$  than any of the current  $k$  nearest neighbors of  $q$ . Section 4.2.3 discusses the effects of the manner in which the search hierarchy is formed on the pruning rules. Section 4.2.4 examines the effects of the order in which the clusters are processed on the performance of the

algorithm. Section 4.2.5 incorporates some of the observations made in Sections 4.2.3 and 4.2.4 to yield a new and improved depth-first  $k$ -nearest neighbor algorithm. Besides using an estimate of the minimum distance at which a nearest neighbor can be found to eliminate some of the remaining clusters and objects from further consideration (referred to as MINDIST), the algorithm also makes use of an estimate of the maximum possible distance at which a nearest neighbor is guaranteed to be found in a cluster (referred to as MAXNEARESTDIST), which is new. Section 4.2.6 shows how to incorporate the MAXNEARESTDIST estimate into a best-first algorithm. Section 4.2.7 gives an example where use of the MAXNEARESTDIST estimate does indeed improve the performance of both the depth-first and best-first  $k$ -nearest neighbor algorithms. Section 4.2.8 concludes with a comparison of the depth-first algorithm with the best-first algorithm with a particular emphasis on the use of the MAXNEARESTDIST estimate.

### 4.2.1 Basic Algorithm

A very general and basic depth-first  $k$ -nearest neighbor algorithm is given by procedures KNEAREST and DFTRAV, where  $q$  is the query object,  $k$  is the number of neighbors sought,  $S$  is the set of objects, and  $T$  is a data structure that organizes  $S$ . Since no assumptions are made about the objects or the data structure used to store them, the algorithm is presented in terms of the search hierarchy induced by them. The algorithm makes use of a set  $L$  that contains the  $k$  current candidate nearest neighbors along with their corresponding distance from  $q$ .  $L$  is implemented using a priority queue so that accessing the farthest of the  $k$  nearest neighbors, as well as updates (i.e., insertions and deletions of the  $k$  nearest neighbor), can be performed without needless exchange operations, as would be the case if  $L$  were implemented using an array. Each element  $e$  in  $L$  has two data fields E and D corresponding to the object  $o$  that  $e$  contains and  $o$ 's distance from  $q$  (i.e.,  $d(q, o)$ ), respectively, and a number of fields corresponding to control information that is specific to the data structure used to implement the priority queue (e.g., a binary heap).

The algorithm is invoked by calling KNEAREST, which starts off by initializing  $L$  to be empty, thereby indicating that we have no candidate neighbors.  $D_k$  corresponds to an upper bound on the distance to the farthest of the  $k$  nearest neighbors (i.e., the  $k$ th-nearest neighbor) of  $q$ .  $D_k$  is initialized to  $\infty$  because we have no candidate neighbors initially.  $D_k$  retains this initial value until either  $k$  actual neighbors have been found, or upper bounds on the distances to  $k$  distinct neighbors have been determined, in which case  $D_k$  is the maximum of these upper bounds. Thus, initially the algorithm is equivalent to a range query with the search range  $\varepsilon$  of  $\infty$ . The actual algorithm to find the  $k$  nearest neighbors of  $q$  is realized by the recursive procedure DFTRAV, which is invoked with  $e$  set to the root of the search hierarchy and the parameters  $L$  and  $D_k$  initialized as described above.

In DFTRAV, if the nonobject element  $e$  being visited is at the deepest level of the search hierarchy (usually referred to as a *leaf* or *leaf element*), then every object  $o$  in  $e$  that is nearer to  $q$  than the current  $k$ th-nearest neighbor of  $q$  (i.e.,  $d(q, o) < D_k$ ) is inserted into  $L$  using procedure INSERTL. If there are fewer than  $k$  candidate neighbors (determined with the aid of the function SIZE, which is not given here), then INSERTL invokes procedure ENQUEUE (not given here) to perform the actual insertion. Otherwise, if there are  $k$  candidate neighbors, then INSERTL dequeues the current farthest member (i.e., the  $k$ th-nearest member) from  $L$  using DEQUEUE (not given here)<sup>12</sup> and invokes ENQUEUE to perform the actual insertion. Next, if there are  $k$

---

<sup>12</sup> Note the asymmetry between DEQUEUE, which removes the item at the front of the queue, and ENQUEUE, which inserts an item in its appropriate position in the queue. Procedure REMOVEPRIORITYQUEUE (not given here) is the complement of ENQUEUE in that it removes a specified element from the queue, which may involve a search.

candidate nearest neighbors after the insertion, then INSERTL resets  $D_k$  to the distance of the current farthest nearest neighbor, accessed by MAXPRIORITYQUEUE (not given here but equivalent to FRONTPRIORITYQUEUE when priority is given to elements at a maximum distance). Otherwise (i.e.,  $e$  is not a leaf element), DFTRAV generates the immediate successors of  $e$ , places them in a list  $A$  known as the *active list* of child elements of  $e$ , and then proceeds to process them one by one by calling itself recursively.

---

## Section 4.2

### THE DEPTH-FIRST K-NEAREST NEIGHBOR ALGORITHM

```

1  priority_queue procedure KNEAREST( $q, k, S, T$ )
2  /* A depth-first algorithm that returns a priority queue with the  $k$  nearest
   neighbors of  $q$  from the set of objects  $S$  organized using the search
   hierarchy  $T$ . */
3  value object  $q$ 
4  value integer  $k$ 
5  value object_set  $S$ 
6  value pointer search_hierarchy  $T$ 
7  priority_queue  $L$ 
8  pointer search_hierarchy  $e$ 
9  integer  $D_k$ 
10  $L \leftarrow$  NEWPRIORITYQUEUE() /*  $L$  is the priority queue containing the  $k$ 
   nearest objects */
11  $D_k \leftarrow \infty$  /*  $D_k$  denotes the distance of  $q$ 's current  $k$ th candidate nearest
   object in  $L$  */
12  $e \leftarrow$  root of the search hierarchy induced by  $S$  and  $T$ 
13 DFTRAV( $q, k, e, L, D_k$ )
14 return  $L$ 

1  recursive procedure DFTRAV( $q, k, e, L, D_k$ )
2  /* Depth-first algorithm that recursively processes element  $e$  of a search hi-
   erarchy to determine the  $k$  nearest neighbors of  $q$  while using  $L$  to keep
   track of these neighbors with  $D_k$  as the distance of  $q$ 's current  $k$ th candi-
   date nearest object in  $L$ . */
3  value object  $q$ 
4  value integer  $k$ 
5  value pointer search_hierarchy  $e$ 
6  reference pointer priority_queue  $L$ 
7  reference integer  $D_k$ 
8  object  $o$ 
9  pointer search_hierarchy  $e_p$ 
10 pointer active_list  $A$ 
11 if ISLEAF( $e$ ) then /*  $e$  is a leaf with objects */
12   foreach object child element  $o$  of  $e$  do
13     Compute  $d(q, o)$ 
14     if  $d(q, o) < D_k$  then
15       INSERTL( $o, d(q, o), k, L, D_k$ )
16     endif
17   enddo
18 else
19   Generate active list  $A$  containing the child elements of  $e$ 
20   foreach element  $e_p$  of  $A$  do
21     DFTRAV( $q, k, e_p, L, D_k$ )
22   enddo
23 endif

1  procedure INSERTL( $e, s, k, L, D_k$ )
2  /* Insert object  $e$  at distance  $s$  from query object  $q$  into the priority queue
    $L$  using ENQUEUE where  $D_k$  is the distance of  $q$ 's current  $k$ th candidate
   nearest object in  $L$ . */
3  value pointer search_hierarchy  $e$ 

```

```

4  value integer  $s, k$ 
5  reference pointer priority_queue  $L$ 
6  reference integer  $D_k$ 
7  if SIZE( $L$ ) =  $k$  then
8    DEQUEUE( $L$ )
9  endif
10 ENQUEUE( $e, s, L$ )
11 if SIZE( $L$ ) =  $k$  then
12    $D_k \leftarrow D(\text{MAXPRIORITYQUEUE}(L))$ 
13 endif

```

The general algorithm is a simple depth-first traversal of the treelike search structure. It visits every element of the search hierarchy. Clearly, better performance could be obtained by not visiting every element and its objects when it can be determined that it is impossible for an element to contain any of the  $k$  nearest neighbors of  $q$ . For example, this is true if we know that for every nonobject element  $e$  of the search hierarchy,  $d(q, e) \leq d(q, e_0)$  for every object  $e_0$  in  $e$  and that the relation  $d(q, e) > D_k$  is satisfied.<sup>13</sup> In this case, line 21 of the **for** loop in DFTRAV is replaced by the following condition statement:

```

1  if  $d(q, e_p) > D_k$  then skip processing  $e_p$ 
2  else DFTRAV( $q, k, e_p, L, D_k$ )
3  endif

```

Furthermore, given that  $d(q, e) \leq d(q, e_0)$  for every object  $e_0$  in  $e$  for all nonobject elements  $e$ , if we process the elements  $e_p$  of the active list  $A$  of  $e$  in order of increasing values of  $d(q, e_p)$ , then once we have found one element  $e_i$  in  $A$  such that  $d(q, e_i) > D_k$ , then  $d(q, e_j) > D_k$  for all remaining elements  $e_j$  of  $A$ . This means that none of these remaining elements need to be processed, and we simply exit the loop and backtrack to the parent of  $e$  or terminate if  $e$  is the root of the search hierarchy. In this case, line 21 of the **for** loop in DFTRAV is replaced by the following condition statement:

```

1  if  $d(q, e_p) > D_k$  then exit_for_loop
2  else DFTRAV( $q, k, e_p, L, D_k$ )
3  endif

```

These modifications to DFTRAV and the rationale for making them should be familiar as they were used in our development of the general algorithm for finding the nearest neighbors of  $q$  in increasing order of their distance from  $q$  (i.e., INCNEAREST in Section 4.1.3). Recall that they enabled INCNEAREST to visit the various elements of the search hierarchy in increasing order of their distance from  $q$ , using a suitably defined distance metric. In particular, we saw that given a nonobject element  $e$  of the search hierarchy, using INCNEAREST we were able to avoid (actually only delay if we want all of the neighbors rather than just the  $k$  nearest neighbors) visiting all of the objects in  $e$  if  $d(q, e) \leq d(q, e_0)$  for every object  $e_0$  in  $e$  (termed the *correctness criterion* [851] in Section 4.1.3). Of course, INCNEAREST differs from the method discussed in this section in a significant manner by not being required to be depth first.

### Exercises

1. Why is it worth sorting the elements  $e_p$  of the active list  $A$  of  $e$  in increasing order of  $d(q, e_p)$  even though each one is only processed once?
2. Suppose that you want to find the  $k$  farthest neighbors instead of the  $k$  nearest neighbors. The basic idea is to keep track of the distance  $D_k$  to the current  $k$ th-farthest neighbor and, each

<sup>13</sup> This stopping condition ensures that all objects at the distance of the  $k$ th-nearest neighbor are examined. Of course, if the size of  $L$  is limited to  $k$  and if there are two or more objects at distance  $D_k$ , then some of them may not be reported in the set of  $q$ 's  $k$  nearest neighbors.

time we encounter an object  $o$ , to check if  $d(q, o) > D_k$ , in which case  $o$  becomes one of the  $k$  farthest neighbors. In the case of a nonobject element  $e$ , if we know that the upper bound on the distance to  $q$ 's farthest neighbor in  $e$  is less than  $D_k$ , then we can ignore  $e$  (i.e.,  $e$  is pruned from further consideration), thereby enabling us to avoid visiting every nonobject element of the search hierarchy. Give a set of procedures KFARTHEST and DFTRAVFARTHEST corresponding to KNEAREST and DFTRAV, respectively, to achieve this. You may also have to modify procedure INSERTL.

3. Suppose that you use an alternative adaptation of the  $k$ -nearest neighbor algorithm that replaces all distances by their negation (recall the discussion in Section 4.1.5 of finding the  $k$  farthest neighbors using a best-first algorithm), while still making use of the definition of distance in terms of the upper bounds. Show how procedures and DFTRAV are affected by this change vis-à-vis the changes proposed in the solution to Exercise 2.
4. Suppose that you use a distance measure, as in Exercise 2, such that  $d(q, e) \geq d(q, e_0)$  for every object  $e_0$  in  $e$  for all nonobject elements  $e$ . How can you process the elements of the active list so that once we prune one element, all remaining elements need not be processed?

## 4.2.2 Pruning Rules

Fukunaga and Narendra [666] propose to use similar considerations to those outlined at the conclusion of Section 4.2.1, as well as others, to enhance the performance of the general depth-first  $k$ -nearest neighbor algorithm, although they do not require that the neighbors be reported in increasing order. These enhancements are based on observations similar to those that we use in Section 4.5.1 (as set forth in the various lemmas) to improve the efficiency of search algorithms in an environment that employs distance-based indexes, albeit in a somewhat different form.

Fukunaga and Narendra [666] achieve these enhancements by associating additional information with each element of the search hierarchy about its subelements. Their presentation assumes that the data is drawn from a vector space. In particular, with each element  $e_p$ , they associate its mean  $M_p$  and the distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$ . On the other hand, a dataset may consist of general objects where the only restriction is that the objects reside in a metric space—that is, a distance metric is defined between all pairs of objects, but no coordinate values are known. In this case, we propose to associate each element  $e_p$  with a representative object  $M_p$  that may or may not be in the dataset (although it usually is) and need not necessarily be in  $e_p$ . The distance  $r_{p,max}$  from  $M_p$  to the farthest object in  $e_p$  is also stored. In the literature,  $M_p$  is known as a *pivot* [1897] or, less commonly, as a *routing object* [389]. While the work of Fukunaga and Narendra, as well as that of other researchers (e.g., Kamgar-Parsi and Kanal [986] and Larsen and Kanal [1103]), focuses on vector spaces, many of their conclusions are equally applicable to metric spaces. Thus, we present the following discussion in the more general context of metric spaces.<sup>14</sup>

Regardless of the interpretation placed on  $M_p$ , Fukunaga and Narendra [666] retain the results of the distance computations that were performed when obtaining the means (or pivots) and  $r_{p,max}$  values of the clusters associated with the leaf elements of the search hierarchy. In other words, for each object  $o$  in leaf element  $e_p$ ,  $d(o, M_p)$  is stored with  $e_p$ . This is useful because knowledge of  $d(o, M_p)$ , in conjunction with the known distance of  $M_p$  from  $q$  and  $D_k$  (i.e., the distance from  $q$  to the current  $k$ th-nearest neighbor), will enable us to take advantage of the failure of satisfying the triangle inequality to show that  $o$  is too far from the query object  $q$  and thereby avoid computing  $d(q, o)$ .

Fukunaga and Narendra [666] define the distance  $d(o, e_p)$  between an object  $o$  (as well as the query object  $q$ ) and a nonobject element  $e_p$  with representative object

---

<sup>14</sup> In the rest of the discussion, although we refer to the distinguished element  $M_p$  as the *mean*, it should be clear that the discussion is equally applicable when the only restriction on the data is that it resides in a metric space, in which case the term *pivot* would be more appropriate.

Figure 4.10  
Examples illustrating that an object  $o$  is not necessarily associated with the element whose mean is closest to  $o$ . In particular,  $o$  is associated with element  $e_a$ , whose mean  $M_a$  is farther away from  $o$  than the mean  $M_b$  of element  $e_b$ .

$M_p$  and maximum radius  $r_{p,max}$  as  $d(o, M_p)$ . We use the term MEANORPIVOTDIST to describe this distance function—that is,  $\text{MEANORPIVOTDIST}(o, e_p) = d(o, e_p) = d(o, M_p)$ . Note that with this definition it is not generally true that  $d(q, e_p) \leq d(q, e_0)$  for every object  $e_0$  in  $e_p$  for all  $e_p$  that are not objects. However, on the other hand, with this definition,  $d(o, e_p) = d(o, M_p)$  is not necessarily 0 when  $o$  or  $q$ , or both, are in  $e_p$ . Instead,  $d(o, e_p) = d(o, M_p) = 0$  only holds if  $o = M_p$ .

We make the following observations:

1. The principal difference between the way vector data and metric data are handled is that, in the case of vector data,  $M_p$  usually does not correspond to one of the objects in the dataset, whereas for metric data,  $M_p$  usually corresponds to an object in the dataset, although, as we pointed out before,  $M_p$  need not be an element of  $e_p$ .
2. In the case of vector data, a representative other than the mean could be used (e.g., median).
3. Regardless of the nature of the underlying data, an object  $o$  is not necessarily associated with the element (e.g., cluster) whose representative object is the closest to  $o$ . In other words,  $o$  can be associated with element  $e_a$  with mean  $M_a$  while  $o$ 's distance from the mean  $M_b$  of another element  $e_b$  is less—that is,  $d(o, M_b) < d(o, M_a)$  (e.g., Figure 4.10). In the case of vector data, this means that the decomposition of the underlying space that is induced by the search hierarchy is not necessarily disjoint—that is, the blocks corresponding to the elements may overlap. Thus, when trying to insert a new object  $o$ , there could be several choices for the element in the search hierarchy that could contain  $o$ .

This information is used in five pruning rules that are described below. They are all presented here in a more general fashion than that used by Fukunaga and Narendra [666], Kamgar-Parsi and Kanal [986], and Larsen and Kanal [1103]. In particular, we consider the case of pruning a search for the  $k$  nearest neighbors; the others (i.e., [666, 986, 1103]) only consider the case of pruning a search for the nearest neighbor, although they do mention that the extension for the more general case can be made. In fact, as we see, often, although not always (i.e., for Pruning Rule 5), the modification is straightforward and usually only involves the replacement in the rules of the distance  $D_1$  to the nearest neighbor with the distance  $D_k$  to the  $k$ th-nearest neighbor.

The pruning rules are motivated by a desire to prune some of the nonobject elements (and all of the objects that they contain) from further consideration when all of the objects that they contain are farther from the query object  $q$  than the distance  $D_k$  of the farthest of the current  $k$  candidate nearest neighbors. Similarly, in the case of an individual object  $o$ ,  $o$  is pruned from further consideration by virtue of knowledge of  $o$ 's distance from  $M_p$  (which was stored with the nonobject element  $e_p$  at the time of its formation), thereby rendering it farther from the query object than  $D_k$ . Pruning these elements and objects means that we can avoid needless distance computations between them and  $q$  given that we know that they cannot be members of the final set of the  $k$  nearest neighbors of  $q$ . Note that regardless of whether the pruned element is a nonobject element  $e_p$  or an object in  $e_p$ , the distance from  $q$  to  $M_p$  is computed (i.e.,  $d(q, M_p)$ ).

The pruning rules are embedded in procedure FNDFTRAV, given below, which is invoked by procedure KNEAREST instead of invoking DFTRAV. FNDFTRAV differs from DFTRAV in two main ways. First, naturally, it includes the various pruning rules proposed by Fukunaga and Narendra [666], as well as others proposed by Kamgar-Parsi and Kanal [986] and Larsen and Kanal [1103]. Second, following Fukunaga and Narendra [666], the algorithm processes elements in the active list in increasing order of  $\text{MEANORPIVOTDIST}(q, e_p)$ —that is, the distance of their representative objects from  $q$ . This is achieved by sorting the active list (line 26) prior to testing for the applicability of the pruning rules and processing the remaining elements (lines 35–40). Fukunaga and Narendra in their formulation of the algorithm repeatedly check if each element of

the active list can be pruned prior to recursively invoking FNDFTRAV on a particular element (line 38) on the current member of the active list. This is not needed. Thus, we check if an element  $e_p$  can be pruned just once, and this is done immediately before processing it (lines 36 and 37).

40 enddo
41 endif

```

Fukunaga and Narendra [666] suggest that the search be sped up by applying the following pair of related pruning rules. The first rule prunes elements of the active list, and the second rule is used to prune individual objects.

Figure 4.11  
Example illustrating Pruning Rule 1, which eliminates element  $e_p$  and all its objects when  $D_k + r_{p,max} < d(q, M_p)$ .

Figure 4.12  
Examples illustrating Pruning Rule 2, which eliminates any object  $o$  in element  $e_p$  when  $D_k + d(o, M_p) < d(q, M_p)$ . Positioning of query object  $q$  so that (a)  $q$  is outside  $e_p$ , and (b)  $q$  is inside  $e_p$ .

- Rule 1: Element  $e_p$  in the active list with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  cannot contain the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + r_{p,max} < d(q, M_p)$  (see Exercise 1).
- Rule 2: Object  $o$  in element  $e_p$  at the deepest level of the search hierarchy with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  cannot be the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + d(o, M_p) < d(q, M_p)$  (see Exercise 2).

Rule 1 is illustrated by Figure 4.11 and is invoked in line 36. Rule 1 amounts to computing the minimum distance from the query object  $q$  to an object in  $e_p$  (referred to as MINDIST) and determining if it is greater than  $D_k$ , the distance from  $q$  to the farthest of the current  $k$  candidate nearest neighbors of  $q$ . In this case, there is no need to process any of the elements of  $e_p$ . Rule 1 is only meaningful when the distance of  $q$  from  $M_p$  renders it outside  $e_p$ —that is,  $d(q, M_p) > r_{p,max}$ .

Rule 2 is illustrated by Figure 4.12 and is invoked in lines 13–14. Rule 2 is related to Rule 1 in that it corresponds to the situation that, although some of the objects in  $e_p$  are sufficiently far from  $M_p$  to make them candidates for being the  $k$  nearest neighbors of  $q$ , object  $o$  is close enough to  $M_p$  to eliminate  $o$  from being one of the  $k$  nearest neighbors of  $q$ . Rule 2 is only meaningful when  $q$  is further from  $M_p$  than  $o$ —that is, when  $d(q, M_p) > d(o, M_p)$  and also only when  $d(q, M_p) > D_k$ . However, given these constraints (i.e.,  $d(q, M_p) > d(o, M_p)$  and  $d(q, M_p) > D_k$ ), for Rule 2 to be applicable,  $q$  can be both outside (Figure 4.12(a)) and inside (Figure 4.12(b))—that is,  $d(q, M_p)$  has an arbitrary value (i.e., it is independent of  $r_{p,max}$ ).

Kamgar-Parsi and Kanal [986] improve the algorithm of Fukunaga and Narendra [666] by proposing an additional pair of related pruning rules, one of which is applied to elements of the active list (Pruning Rule 3), while the other is applied to the individual objects (Pruning Rule 4). They differ from Pruning Rules 1 and 2 by also associating with each element  $e_p$  the distance  $r_{p,min}$  from the mean  $M_p$  to the closest object within  $e_p$ . This means that  $e_p$  has the shape of a multidimensional spherical shell, where  $r_{p,min}$  and  $r_{p,max}$  are the distances from  $M_p$  to  $e_p$ 's internal and external spherical faces, respectively—that is,  $r_{p,min}$  is the radius of  $e_p$ 's inner spherical face, and  $r_{p,max}$  is the radius of  $e_p$ 's outer spherical face. Thus, whereas Pruning Rules 1 and 2 pertain to the outer spherical face of the spherical shell, Pruning Rules 3 and 4 pertain to the inner spherical face of the spherical shell.

- Rule 3: Element  $e_p$  in the active list with mean  $M_p$  and distance  $r_{p,min}$  from  $M_p$  to the closest object within  $e_p$  cannot contain the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + d(q, M_p) < r_{p,min}$  (see Exercise 6).
- Rule 4: Object  $o$  in element  $e_p$  at the deepest level of the search hierarchy with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  cannot be the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + d(q, M_p) < d(o, M_p)$  (see Exercise 7).

Rule 3 is illustrated by Figure 4.13 and is invoked in line 37. Rule 3 amounts to computing the minimum distance from the query object  $q$  to an object in  $e_p$  and determining if it is greater than  $D_k$ , the distance from  $q$  to the farthest of the current candidate  $k$  nearest neighbors of  $q$ . In this case, there is no need to process any of the elements of  $e_p$ . The difference from Rule 1 is that, for Rule 3,  $e_p$  has the shape of a multidimensional spherical shell, and Rule 3 is only meaningful if  $q$  is inside the inner sphere of the spherical shell corresponding to  $e_p$ , whereas for Rule 1, regardless of whether  $e_p$  is a multidimensional spherical shell,  $q$  is outside the outer sphere of the spherical shell.

Rule 4 is illustrated by Figure 4.14 and is invoked in lines 15–16. Rule 4 is only meaningful when  $q$  is closer to  $M_p$  than  $o$ —that is,  $d(q, M_p) < d(o, M_p)$ . However, given this constraint (i.e.,  $d(q, M_p) < d(o, M_p)$ ), for Rule 4 to be applicable,  $q$  can be either inside  $e_p$  (Figures 4.14(b) and 4.14(d)) or inside the inner sphere of the spherical shell

corresponding to  $e_p$  (Figures 4.14(a) and 4.14(c))—that is,  $d(q, M_p)$  has an arbitrary value (i.e., it is independent of  $r_{p,\min}$ ).

Rule 4 is related to Rule 3 when  $q$  is inside the spherical shell or its inner sphere in a way analogous to that in which Rule 2 was determined to be related to Rule 1. In particular, Rule 4 corresponds to the situation that even though some of the objects in  $e_p$  are sufficiently close to  $M_p$  to make them candidates for being the  $k$  nearest neighbors of  $q$ , the distance of object  $o$  in  $e_p$  from  $M_p$  is far enough to eliminate  $o$  from being one of the candidates—that is,  $o$  cannot be one of the  $k$  nearest neighbors of  $q$ . Note that both Rules 3 and 4 are applicable regardless of whether  $D_k < d(q, M_p)$  (See Figures 4.13(a) and 4.14(a, b)) or  $D_k \geq d(q, M_p)$  (see Figures 4.13(b) and 4.14(c, d)). This is in contrast to Pruning Rules 1 and 2, where  $D_k < d(q, M_p)$  must always hold.

When  $M_p$  is one of the objects in  $e_p$ , which means that  $r_{p,\min} = 0$ , and  $q$  is in  $e_p$ , then Pruning Rule 4 is related to a well-known principle for nearest neighbor searching given by Feustel and Shapiro [610] (see also [1199]). This principle, which they call Lemma 2.1, states that, given the distance  $d(q, p)$  from the query object  $q$  to some other object  $p$ , the distance from  $p$  to  $q$ 's nearest neighbor  $o$  cannot be greater than  $2d(q, p)$  (see Exercises 8–12). Feustel and Shapiro [610] use this principle as a heuristic to minimize the number of distance calculations in a metric space for a computer vision model matching application.

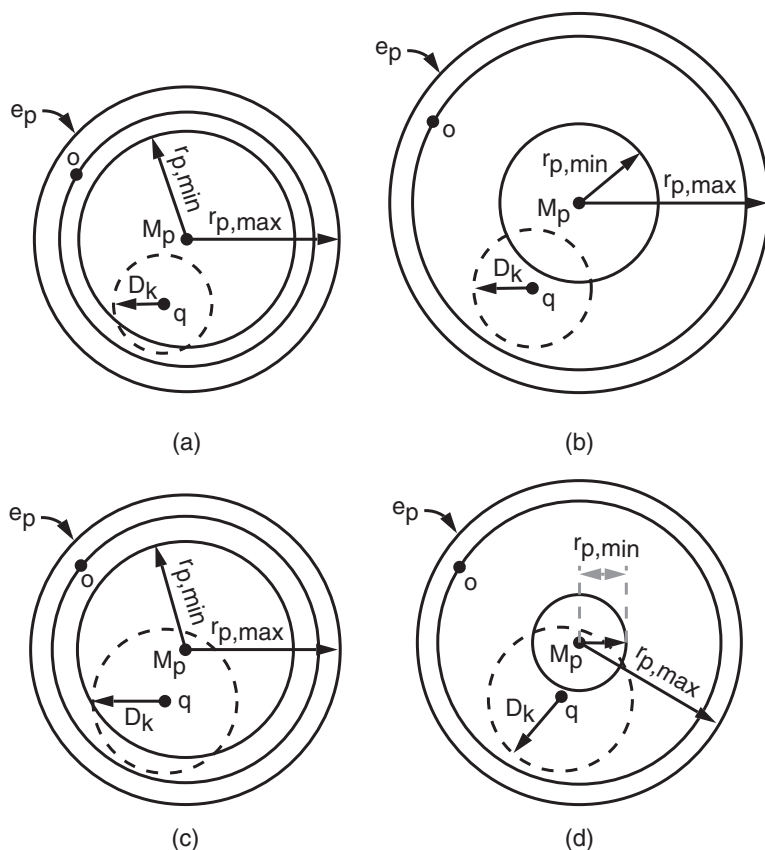

Figure 4.14

Examples illustrating Pruning Rule 4, which eliminates any object  $o$  in element  $e_p$  when  $D_k + d(q, M_p) < d(o, M_p)$ . Query object  $q$  is positioned so that (a) and (b) correspond to  $d(q, M_p) > D_k$ , while (c) and (d) correspond to  $d(q, M_p) \leq D_k$ .  $q$  is inside the inner sphere of the spherical shell corresponding to  $e_p$  in (a) and (c);  $q$  is in the spherical shell corresponding to  $e_p$  in (b) and (d).

## Section 4.2

### THE DEPTH-FIRST K-NEAREST NEIGHBOR ALGORITHM

Figure 4.13

Examples illustrating Pruning Rule 3, which eliminates element  $e_p$  and all its objects when  $D_k + d(q, M_p) < r_{p,\min}$ . Query object  $q$  is positioned so that (a) corresponds to  $d(q, M_p) > D_k$ , while (b) corresponds to  $d(q, M_p) \leq D_k$ .

Figure 4.15  
Example illustrating a nearest neighbor searching principle that given objects  $p$  and  $q$  and the distance  $d(q, p)$  between them, the distance from  $p$  of  $q$ 's nearest neighbor  $o$  cannot be greater than  $2d(q, p)$ .

Obviously, the usefulness of this principle, as seen in Figure 4.15, depends heavily on the choice of  $p$ —that is,  $d(q, p)$  must be small. If we choose  $p$  to be  $M_p$ , then we make the following four observations:

1. The pruning condition of Lemma 2.1 implies the pruning condition of Pruning Rule 4 (see Exercise 9).
2. In general, Lemma 2.1 is more widely applicable than pruning Rule 4 because it holds for any object  $p$  instead of just for  $M_p$ .
3. Whenever Pruning Rule 4 is applicable, then it has more pruning power than Lemma 2.1 (see Exercise 10).
4. For Lemma 2.1 to be applicable,  $q$  need not be inside  $e_p$ . However, in this case, Pruning Rules 1 and 2 provide tighter pruning.

Pruning Rules 1–4 make use of estimates of the minimum possible distance at which the nearest neighbor in nonobject element  $e$  can be found to avoid examining some nonobject elements of the search hierarchy. For  $k = 1$ , Fukunaga and Narendra [666] proposed one more pruning rule, which they characterize as a minor optimization, to be applied while constructing the active list  $A$  of child elements of  $e$ . In particular, assuming only the knowledge that  $r_{p,max}$  is the distance from  $M_p$  to the farthest object in  $e_p$ , they point out that the distance from the query object  $q$  to its nearest neighbor cannot exceed  $d(q, M_p) + r_{p,max}$ . Thus, they suggest resetting  $D_1$ , the distance from  $q$  to its current nearest neighbor  $x$ , to the minimum of  $D_1$  and  $d(q, M_p) + r_{p,max}$  (see Exercise 13). In other words, the distance from  $q$  to the farthest possible object  $i$  of  $e_p$  is calculated (referred to as MAXDIST), and it is noted whether  $i$  can possibly serve as the nearest neighbor of  $q$  by virtue of being closer to  $q$  than  $x$ . Figure 4.16(a) illustrates a situation where this pruning rule, which we call Rule 5, is applicable. It is interesting to observe that at the time we find that Rule 5 is applicable to element  $e_p$ , the actual object in  $e_p$  that could serve as the nearest neighbor has not yet been identified. Instead, we are only setting an upper bound on the distance  $D_1$  from  $q$  to it.

Larsen and Kanal [1103] improve upon Fukunaga and Narendra's [666] formulation of Pruning Rule 5 by taking advantage of the knowledge that  $r_{p,min}$  is the distance from  $M_p$  to the closest object within  $e_p$ . In particular, they point out that the distance from the query object  $q$  to its nearest neighbor cannot exceed  $d(q, M_p) + r_{p,min}$ . Thus, they suggest resetting  $D_1$ , the distance from  $q$  to its current nearest neighbor  $x$ , to the minimum of  $D_1$  and  $d(q, M_p) + r_{p,min}$  (see Exercise 14).

In other words, the maximum possible distance from  $q$  to its nearest neighbor  $i$  in  $e_p$  is calculated (referred to as MAXNEARESTDIST), and it is checked whether  $i$  can possibly serve as the nearest neighbor of  $q$  by virtue of being closer to  $q$  than  $x$ —that is, we have determined the distance from  $q$  to its farthest possible nearest neighbor in  $e_p$  (i.e., MAXNEARESTDIST) instead of the distance to the farthest possible object in element  $e_p$  (i.e., MAXDIST) as in Fukunaga and Narendra's [666] formulation of this rule. Figure 4.16(b) illustrates a situation where this pruning rule, which from now on we refer to as Rule 5, is applicable. Again, as in the formulation of Fukunaga and Narendra [666], we observe that at the time we find that Rule 5 is applicable to element  $e_p$ , the actual object in  $e_p$  that could serve as the nearest neighbor has not yet been identified. Instead, we are only setting a minimum on the upper bound on the distance  $D_1$  from  $q$  to it.

The extension of Pruning Rule 5 to find the  $k$  ( $k > 1$ ) nearest neighbors is not immediate, although neither Fukunaga and Narendra [666] nor Larsen and Kanal [1103] give it any mention. In particular, note that we cannot simply reset  $D_k$  to  $d(q, M_p) + r_{p,min}$  whenever  $d(q, M_p) + r_{p,min} < D_k$ . The problem is that the distance  $s$  from  $q$  to some of its  $k$  nearest neighbors may lie within the range  $d(q, M_p) + r_{p,min} < s \leq D_k$ , and thus resetting  $D_k$  to  $d(q, M_p) + r_{p,min}$  may cause them to be missed, especially if child element  $e_p$  contains just one object. In other words, we must also examine the values of  $D_i$  ( $1 \leq i < k$ ).

Figure 4.16  
Examples illustrating the applicability of Pruning Rule 5, which resets the distance  $D_1$  from  $q$  to its nearest neighbor during the insertion into the active list of element  $e_p$ , with  $M_p$  as the mean and  $r_{p,max}$  and  $r_{p,min}$  as the distances from  $M_p$  to the farthest and closest, respectively, objects within  $e_p$ : (a) if  $d(q, M_p) + r_{p,max} < D_1$  and (b) if  $d(q, M_p) + r_{p,min} < D_1$ .

The problem is that, given the way in which Pruning Rule 5 is stated, its primary role is to set an upper bound on the distance from the query object to its nearest neighbor in a particular cluster. It is important to observe that this is not the same as saying that the upper bound computed by Pruning Rule 5 is the minimum of the maximum possible distances to the  $k$ th-nearest neighbor of the query object, which is not true. As we will see in Section 4.2.5, incorporating Pruning Rule 5 correctly for  $k > 1$  requires a significant change in the algorithm. In particular, the way in which Pruning Rule 5 is used in  $k$ -nearest neighbor finding is to provide bounds for a number of different clusters. Once we have obtained  $k$  distinct such bounds, we have an estimate on the distance to the  $k$ th-nearest neighbor. Thus, we find that, as presented here using procedure FNDFTRAV, the depth-first  $k$ -nearest neighbor algorithm of Fukunaga and Narendra [666], even with the modification of Larsen and Kanal [1103], can make use of Pruning Rule 5 directly only for  $k = 1$ .

It should be clear that Pruning Rules 1–4 enable us to avoid the explicit computation of the distance from  $q$  to the individual subelements and objects of  $e_p$ . Moreover, these rules make use of existing distance computations that were performed when obtaining the means (or pivots) and  $r_{p,max}$  values of the various elements (i.e., clusters). Thus, there is no need for additional distance computations. It is interesting to observe that Rules 1 and 2 prune objects from consideration on the basis of an upper bound on their distance from  $M_p$ , and Rules 3 and 4 prune objects from consideration on the basis of a lower bound on their distance from  $M_p$ . An alternative way of looking at this interpretation is to recall our characterization of nonobject element  $e_p$  as a multidimensional spherical shell, in which case Pruning Rules 1 and 2 are for a query object  $q$  that is not inside the inner sphere of the spherical shell corresponding to  $e_p$ , while Pruning Rules 3 and 4 are for a  $q$  that is either in the spherical shell or inside the inner sphere of the spherical shell corresponding to  $e_p$ . Pruning Rules 1 and 3 apply only when  $q$  is not in the spherical shell (i.e., Rule 1 for  $q$  outside the outer sphere of the spherical shell and Rule 3 for  $q$  inside the inner sphere of the spherical shell), while Pruning Rules 2 and 4 apply regardless of the position of  $q$  (i.e., Rule 2 for  $q$  in the spherical shell or outside the outer sphere of the spherical shell, and Rule 4 for  $q$  in the spherical shell or inside the inner sphere of the spherical shell). Note that Pruning Rule 5 also applies, regardless of the position of  $q$ . Finally, observe that Pruning Rule 5 can never be satisfied if either Pruning Rule 1 or 3 is applicable, and thus it need not be tested when either of them holds (see Exercise 16).

Rules 1 and 3 appear as part of Lemma 4.2, discussed in Section 4.5.1, where they serve as lower bounds on the distance from  $q$  to any object  $o$  such that  $r_{p,lo} \leq r_{p,min} \leq d(o, M_p) \leq r_{p,max} \leq r_{p,hi}$ , given  $d(q, M_p)$ . In addition, the formulation of Rule 5 given by Fukunaga and Narendra [666] (i.e., in terms of  $d(q, M_p) + r_{p,max}$ ) also appears as part of this lemma, where the quantity  $d(q, M_p) + r_{p,max}$  serves as an upper bound on the distance from  $q$  to an object  $o$  in the same range. In fact, Rules 1 and 3 and Fukunaga and Narendra's [666] formulation of Rule 5 could also be expressed in terms of the looser upper and lower bounds  $r_{p,hi}$  and  $r_{p,lo}$  instead of  $r_{p,max}$  and  $r_{p,min}$ , respectively, as the proofs are identical. Similarly, Rules 2 and 4 also appear as part of Lemma 4.1, discussed in Section 4.5.1, where they serve as lower bounds on the distance from  $q$  to an arbitrary object  $o$  by knowing the distances  $d(q, M_p)$  and  $d(o, M_p)$ . In fact, Rules 2 and 4 can be combined, as they are in Lemma 4.1, using the absolute value of the difference between  $d(q, M_p)$  and  $d(o, M_p)$ —that is,  $o$  cannot be the  $k$ th-nearest neighbor of  $q$  if  $D_k < |d(q, M_p) - d(o, M_p)|$ . These lemmas are used to facilitate range searching and nearest neighbor finding with different indexing methods in a metric space.

### Exercises

1. Prove that element  $e_p$  in the active list with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  cannot contain the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + r_{p,max} < d(q, M_p)$ , where  $D_k$  is the distance from  $q$  to the farthest of the current candidate  $k$  nearest neighbors—that is, prove that Pruning Rule 1 is correct.

2. Prove that object  $o$  in element  $e_p$  at the deepest level of the search hierarchy with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  cannot be the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + d(o, M_p) < d(q, M_p)$ , where  $D_k$  is the distance from  $q$  to the farthest of the current candidate  $k$  nearest neighbors—that is, prove that Pruning Rule 2 is correct.
3. Feustel and Shapiro [610] make use of an alternative formulation of Pruning Rule 2 (which they call Lemma 2.2) that does not depend on the identification of a particular object to serve the role of  $M_p$  for the set of objects. In other words, the role of  $M_p$  is played by an arbitrary object rather than by the mean of a set or a pivot in the case of some metric data structures. Again, it makes use of the distance  $d_1$  from query object  $q$  to some object  $n$ , and the distance  $d_2$  from  $q$  to some other object  $p$  that plays the role of  $M_p$  in Rule 2, and that  $d_1 < d_2$ . The stipulation that  $d_1 < d_2$  ensures that  $n$  plays the role of  $q$ 's current nearest neighbor in the equivalence to Rule 2. Based on these distances, Lemma 2.2 stipulates that an arbitrary object  $o$  cannot be the nearest neighbor of  $q$  if  $o$ 's distance from  $p$  is less than  $d_2 - d_1$ —that is,  $d(o, p) < d_2 - d_1$ . Prove this lemma.
4. Prove that Lemma 2.2 of Feustel and Shapiro [610], described in Exercise 3, is a special case of Pruning Rule 2 for  $k = 1$ . In other words, show that Rule 2 can be instantiated with the appropriate parameter bindings so that Lemma 2.2 holds.
5. Lemma 2.2 of Feustel and Shapiro [610], described in Exercise 3, is designed for use in pruning object  $o$  from further consideration as the nearest neighbor of query object  $q$ . In contrast, Pruning Rule 2 is designed for use in pruning object  $o$  from further consideration as the  $k$ th-nearest neighbor of query object  $q$ . How would you modify Lemma 2.2 so that it can also be used to prune object  $o$  from further consideration as the  $k$ th-nearest neighbor of query object  $q$ ?
6. Prove that element  $e_p$  in the active list with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  cannot contain the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + d(q, M_p) < r_{p,min}$ , where  $r_{p,min}$  is the distance from  $M_p$  to the closest object within  $e_p$ , and  $D_k$  is the distance from  $q$  to the farthest of the current candidate  $k$  nearest neighbors—that is, prove that Pruning Rule 3 is correct.
7. Prove that object  $o$  in element  $e_p$  at the deepest level of the search hierarchy with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  cannot be the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + d(q, M_p) < d(o, M_p)$ , where  $D_k$  is the distance from  $q$  to the farthest of the current candidate  $k$  nearest neighbors—that is, prove that Pruning Rule 4 is correct.
8. In the text, we point out that Pruning Rule 4 is related to Lemma 2.1 of Feustel and Shapiro [610] when  $M_p$  is one of the objects in  $e_p$ , which means that  $r_{p,min} = 0$ , and  $q$  is in  $e_p$ . In particular, Lemma 2.1 states that, given the distance  $d(q, p)$  from the query object  $q$  to some other object  $p$ , if the distance from  $p$  to some other object  $o$  is greater than  $2d(q, p)$ , then  $o$  cannot be  $q$ 's nearest neighbor. Prove this lemma.
9. Consider query object  $q$  in element  $e_p$  and  $M_p$  as an actual object in  $e_p$ , which means that  $r_{p,min} = 0$ . Prove that if Lemma 2.1 of Feustel and Shapiro [610], described in Exercise 8, holds, then so does Pruning Rule 4 of Kamgar-Parsi and Kanal [986]. In other words, Lemma 2.1 stipulates that  $o$  cannot be the nearest neighbor of  $q$  if  $d(o, M_p) > 2d(q, M_p)$ . You need to prove that, in this case,  $d(o, M_p) > D_1 + d(q, M_p)$ , which is the condition that must hold for Pruning Rule 4 to be applicable.
10. In the text, we stated that for  $k = 1$ , if  $M_p$ ,  $o$ , and  $q$  are objects in  $e_p$  (which means that  $r_{p,min} = 0$ ), and if  $p$  in Lemma 2.1 is chosen to be  $M_p$ , then Pruning Rule 4 has more pruning power than Lemma 2.1. Explain why this is true.
11. Lemma 2.1 of Feustel and Shapiro [610], described in Exercise 8, is designed for use in pruning object  $o$  from further consideration as the nearest neighbor of query object  $q$ . In contrast, Pruning Rule 4 is designed for use in pruning object  $o$  from further consideration as the  $k$ th-nearest neighbor of query object  $q$ . How would you modify Lemma 2.1 so that it can also be used to prune object  $o$  from further consideration as the  $k$ th-nearest neighbor of query object  $q$ ?
12. A similar principle to Lemma 2.1 of Feustel and Shapiro [610], described in Exercise 8, is used to bound the maximum distance between any pair of objects  $a$  and  $b$  given the object  $p$  at a maximum distance from another object  $q$ —that is,  $d(a, b) \leq 2d(q, p)$  (see the discussion in Section 4.7.3.2). Prove it.

13. Justify the correctness of Fukunaga and Narendra's [666] formulation of Pruning Rule 5—that is, resetting the distance  $D_1$  from  $q$  to its nearest neighbor to  $d(q, M_p) + r_{p,max}$  whenever  $D_1 > d(q, M_p) + r_{p,max}$  while constructing the active list  $A$  of child elements of  $e$  for finding the nearest neighbor to query object  $q$ . Assume that  $M_p$  is the mean of the elements of child element  $e_p$ , and  $r_{p,max}$  is the distance from  $M_p$  to the farthest object within  $e_p$ .
14. Justify the correctness of Larsen and Kanal's [1103] formulation of pruning Rule 5—that is, resetting the distance  $D_1$  from  $q$  to its nearest neighbor to  $d(q, M_p) + r_{p,min}$  whenever  $D_1 > d(q, M_p) + r_{p,min}$  while constructing the active list  $A$  of child elements of  $e$  for finding the nearest neighbor to query object  $q$ . Assume that  $M_p$  is the mean of the elements of child element  $e_p$ , and  $r_{p,min}$  and  $r_{p,max}$  are the distances from  $M_p$  to the closest and farthest, respectively, objects within  $e_p$ .
15. Assuming that KNEAREST using FNDFTRAV processes the elements  $e_p$  in the active list in increasing MEANORPIVOTDIST order, give an example that shows that Pruning Rule 5 can indeed be applied.
16. Consider nonobject element  $e_p$  with mean  $M_p$  and  $r_{p,min}$  and  $r_{p,max}$  as the distances from  $M_p$  to the closest and farthest, respectively, objects within  $e_p$ . Show that the condition for the applicability of Pruning Rule 5 (i.e.,  $d(q, M_p) + r_{p,min} < D_1$ ) can never be satisfied if either of Pruning Rules 1 or 3 are applicable, and thus Pruning Rule 5 need not be tested when they hold.
17. How would you adapt Pruning Rules 1–5 to facilitate finding the  $k$  farthest neighbors, as in Exercises 2 and 3 of Section 4.2.1?
18. Give the analog procedure FNDFTRAVFARTHEST of FNDFTRAV for finding the  $k$  farthest neighbors using the approach outlined in Exercise 2 in Section 4.2.1. Incorporate the modified Pruning Rules 1–5 given in Exercise 17.
19. Repeat Exercise 18 using the approach outlined in Exercise 3 of Section 4.2.1.

### 4.2.3 Effects of Clustering Methods on Pruning

Pruning Rules 1–5 have been presented in the context of a clustering method that clusters objects with respect to a cluster center  $M$  and the minimums and maximums on their distance values from  $M$ . In this section, we briefly examine some related clustering methods and their effect on the pruning rules.

First of all, we point out that Rules 3 and 4 are particularly useful when the partitions induced by the various cluster elements are such that an object  $o$  is not necessarily associated with the element whose cluster center (e.g., mean) is the closest to  $o$ . In other words,  $o$  can be associated with element  $e_a$  with mean  $M_a$  while  $o$ 's distance from the mean  $M_b$  of another element  $e_b$  is less—that is,  $d(o, M_b) < d(o, M_a)$  (e.g., recall Figure 4.10). Figure 4.17 is a more vivid illustration of such a scenario where  $M_b$  is an element of  $e_a$  and  $M_a$  is an element of  $e_b$ , and we see that  $e_b$  and all of its objects are eliminated by application of Rule 3 with respect to the given values of  $q$  and  $D_k$ , even though  $M_b$  is definitely one of the possible  $k$  nearest neighbors of  $q$ . Such a scenario can arise in the  $M$ -tree [389] (see Section 4.5.4.1), but it cannot arise in GNAT [255] (see Section 4.5.3.2). In the vector (and also spatial) domain, this scenario is analogous to a stipulation that the regions are not necessarily disjoint—that is, the region spanned by one cluster  $e_a$  can contain objects that are associated with another cluster  $e_b$  (e.g., the shaded area in Figure 4.17, assuming that each object is associated with just one cluster).

As we saw in Section 4.2.2, the cluster  $e_p$  is analogous to a bounding object, and the quantity  $d(q, M_p) - r_{p,max}$  in Pruning Rule 1 can be interpreted as the minimum distance from the query object  $q$  to the bounding object, assuming that  $q$  is outside  $e_p$ . In the formulation of Rule 1, the bounding object is a ball centered at  $M_p$  of radius  $r_{p,max}$ . Similarly, recalling our analogy between  $e_p$  and a multidimensional spherical shell-like bounding object, the quantity  $r_{p,min} - d(q, M_p)$  in Pruning Rule 3 can be interpreted as the minimum distance from  $q$  to the interior face of the bounding object, assuming that  $q$  is inside the inner sphere of the spherical shell corresponding to  $e_p$ . In both of these

Figure 4.17  
Example of the utility of Pruning Rules 3 and 4 when objects (including pivots) are not necessarily associated with the element, whose mean (pivot) is the closest. In particular, objects  $o$  and  $M_a$  are associated with element  $e_b$ , whose mean  $M_b$  is farther away from  $o$  than the mean  $M_a$  of element  $e_a$ . Similarly,  $M_b$  is associated with element  $e_a$ , whose mean  $M_a$  is farther away than  $M_b$ . Here,  $e_b$  and all of its objects are eliminated by application of Rule 3 with respect to the given values of  $q$  and  $D_k$ , even though  $M_b$  is definitely one of the possible  $k$  nearest neighbors of  $q$ . Area common to both elements  $e_a$  and  $e_b$  is shown shaded.

cases, we refer to the distance from  $q$  to  $e_p$  as MINDIST. These analogies hold for both a vector and a metric space.

It is important to note that the clusters above are not true minimum bounding objects due to the dependence on the cluster center  $M_p$ . For the cluster to be a true minimum bounding object, the cluster center  $M_p$  must be determined by the objects in the cluster and is not necessarily the sample mean. Moreover, the cluster must contain at least two distinct objects, as otherwise  $r_{p,max}$  and  $r_{p,min}$  are both zero, in which case the minimum bounding box is a point.

When the minimum bounding objects are hyperspheres (see Exercise 4 in Section 4.4.2) centered at an appropriately determined cluster center  $M_p$ , Pruning Rules 1–4 are applicable as stated. When the minimum bounding objects have other shapes such as hyperrectangles, then Pruning Rules 2 and 4 are applicable as stated with an appropriately determined cluster center, while Pruning Rules 1 and 3 must be reformulated in terms of the minimum distances from the query object to the minimum bounding hyperrectangles as  $r_{p,min}$  and  $r_{p,max}$  are not part of the definition of the minimum bounding object in this case (e.g., minimum bounding hyperrectangles).

On the other hand, in the same context (i.e., when the minimum bounding objects are hyperspheres), the issue of the applicability of Pruning Rule 5 is more complex. In particular, all of the statements that we make about the ramifications of Pruning Rule 5 are restricted to the case that  $k = 1$ —that is, to the situation that we are seeking the nearest neighbor as this is how the rule was presented in Section 4.2.2. However, as we will see in Section 4.2.5, the depth-first  $k$ -nearest neighbor algorithm of Fukunaga and Narendra [666] can be modified so that Pruning Rule 5 can be used for arbitrary values of  $k$ .

As we saw earlier, Pruning Rule 5 is considerably different from Pruning Rules 1–4 since its use does not result in pruning any elements in the active list. Instead, it is used to set an upper bound on the distance to the nearest neighbor, thereby enabling more elements and objects to be pruned by subsequent invocation of Pruning Rules 1–4. The upper bound computed by Pruning Rule 5 is the minimum of the maximum possible distances to the nearest neighbor of the query object. When the clusters are minimum bounding objects, sometimes it is possible to tighten Pruning Rule 5 even more than the form given by Larsen and Kanal [1103]—that is, to obtain a lower value for MAXNEARESTDIST than  $d(q, M_p) + r_{p,min}$ . Note that our discussion of Pruning Rule 5 is in terms of finding the nearest neighbor rather than the  $k$  nearest neighbors as its primary role is to set a bound on the distance from the query object to its nearest neighbor in a particular cluster. Its use for finding the  $k$  nearest neighbors is independent of the nature of the clustering method, and hence is not discussed further here.

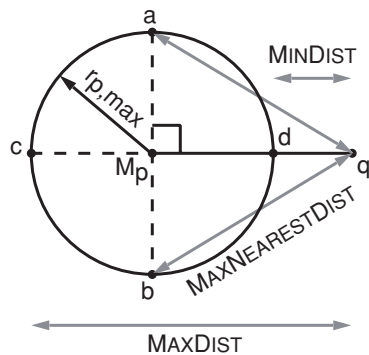

Figure 4.18 Example showing the calculation of MINDIST, MAXDIST, and MAXNEARESTDIST when the minimum bounding object is the minimum bounding hypersphere (e.g., an SS-tree) centered at  $M_p$  with radius  $r_{p,max}$  and an unknown value of  $r_{p,min}$ , assuming a query point  $q$  and a Euclidean distance metric.

When the minimum bounding objects are hyperspheres, we first consider the situation that  $r_{p,min}$  is unknown. In this case, let  $r_{p,max}$  be the radius of the minimum bounding hypersphere of the objects in  $e_p$  whose center has been determined to be  $M_p$ . Assuming a Euclidean distance metric, it is easy to see that the maximum possible distance from the query object  $q$  to an object  $o$  in  $e_p$  that serves as the nearest neighbor of  $q$  arises when  $o$  lies in one of two positions  $a$  and  $b$  located diametrically opposite each other on the surface of the hypersphere so that the  $(d - 1)$ -dimensional hyperplane passing through  $a$ ,  $b$ , and  $M$  is perpendicular to the line joining  $M$  and  $q$ . Observe that  $a$  and  $b$  are equidistant from  $q$  and that the distance from  $q$  to either one of them is  $\sqrt{d(q, M_p)^2 + r_{p,max}^2}$ , the value of MAXNEARESTDIST (see Exercise 10). This quantity is clearly less than or equal to  $d(q, M_p) + r_{p,max}$  (e.g., by the triangle inequality), which was the upper bound used by Fukunaga and Narendra [666] in their formulation of Pruning Rule 5 (i.e., MAXDIST). Figure 4.18 illustrates these concepts.

Now, suppose that  $r_{p,min}$  is known, which corresponds to the situation that the minimum bounding object is a multidimensional spherical shell. We assume that the minimum bounding hypersphere with radius  $r_{p,max}$  and centered at  $M_p$  coincident with

the outer sphere of the spherical shell is formed first. Next, given the above value of  $M_p$ , we determine the maximum bounding hypersphere with radius  $r_{p,min}$  and centered at  $M_p$  coincident with the interior face of the spherical shell (i.e., the inner sphere) so that the interior is empty. From our earlier presentation of Pruning Rule 5, we know that the maximum possible distance from  $q$  to an object  $o$  of  $e_p$  that is on the interior face of  $e_p$  and that is to serve as the nearest neighbor of  $q$  is  $d(q, M_p) + r_{p,min}$ . In addition, from the immediately preceding derivation when  $r_{p,min}$  was unknown, we also know that, assuming a Euclidean distance metric, the maximum possible distance from  $q$  to an object  $o$  of  $e_p$  that is on the exterior face of  $e_p$  and that is to serve as the nearest neighbor of  $q$  is  $\sqrt{d(q, M_p)^2 + r_{p,max}^2}$ . Thus, the maximum possible distance from  $q$  to an object  $o$  of  $e_p$ , which is a multidimensional spherical shell, that is to serve as the nearest neighbor of  $q$  is the minimum of  $d(q, M_p) + r_{p,min}$  and  $\sqrt{d(q, M_p)^2 + r_{p,max}^2}$ , the value of MAXNEARESTDIST for the minimum bounding hypersphere, assuming a Euclidean distance metric. Note that the object that satisfies this minimum may in fact lie on the exterior face of the spherical shell (i.e., the outer sphere) when  $r_{p,min}$  is not much different from  $r_{p,max}$ . On the other hand, the object that satisfies this minimum may lie on the interior face of the spherical shell (i.e., the inner sphere) when  $r_{p,min}$  is much smaller than  $r_{p,max}$ .

It is interesting to observe that if the maximum bounding hypersphere with radius  $r_{p,min}$  and centered at  $M_p$  coincident with the interior face of the spherical shell (i.e., the inner sphere) so that the interior is empty is formed first, then the maximum possible distance from  $q$  to its nearest neighbor on the interior face of the spherical shell is  $\sqrt{d(q, M_p)^2 + r_{p,min}^2}$ , assuming a Euclidean distance metric, which is always less than the maximum possible distance from  $q$  to its nearest neighbor on the exterior face (i.e., outer sphere) of the spherical shell. Thus, when forming the maximum bounding hypersphere corresponding to the interior face of the spherical shell first, there is no need to take the minimum bounding hypersphere corresponding to the outer face into account in determining the maximum possible distance to the nearest neighbor of  $q$ .

When the minimum bounding objects are hyperrectangles, and assuming that they are axis aligned, we take advantage of the fact that every face of the minimum bounding hyperrectangle  $b$  must contain at least one object. Thus, the farthest possible object from the query object  $q$  lies at the farthest corner  $f$  of  $b$  from  $q$  (i.e., MAXDIST). On the other hand, to obtain the minimum of the maximum possible distances from  $q$  to an object  $o$  in  $b$  that is to serve as the nearest neighbor we must determine the distances to the farthest points on each face of  $b$  from  $q$  and choose their minimum, the value of MAXNEARESTDIST. An alternative definition of MAXNEARESTDIST( $q, b$ ) is as the distance from  $q$  to the closest corner of  $b$  that is “adjacent” to the corner  $f$  farthest from  $q$ .

When the objects have extent (rather than point objects), then the clusters are often formed in terms of their minimum bounding hyperrectangles. MINDIST, MAXDIST, and MAXNEARESTDIST are defined in the same manner as for the point objects. Once again, we take advantage of the fact that every surface of the minimum bounding hyperrectangle  $b$  must contain at least one point of the corresponding object’s boundary. Figure 4.19 shows two examples of the calculation of MINDIST and MAXNEARESTDIST in two dimensions, which are depicted with a solid and a broken line, respectively. In both cases,  $f$  is the farthest corner from  $q$  and MAXDIST is the distance from  $q$  to it. However, notice that for the minimum bounding rectangle in Figure 4.19(a), the distance from  $q$  to  $a$  is less than the distance from  $q$  to  $b$ , thereby accounting for the value of MAXNEARESTDIST being equal to the former rather than to the latter, while the opposite is true for Figure 4.19(b).

It is important to observe that the complexity of the computation of MINDIST, MAXDIST, and MAXNEARESTDIST is heavily dependent on the nature of the clustering process used to form the search hierarchy, as well as the domain of the data. For example, in  $d$  dimensions, the complexity of computing MAXNEARESTDIST is the same as that of MINDIST and MAXDIST when the cluster elements are minimum bounding

## Section 4.2

### THE DEPTH-FIRST K-NEAREST NEIGHBOR ALGORITHM

Figure 4.19

A pair of examples showing the relationship between MINDIST(solid line) and MAXNEARESTDIST(broken line) for a minimum bounding axis-aligned rectangle  $r$ . The distance of the object  $o$  from  $q$  is bounded from below by MINDIST( $q, r$ ) and from above by MAXNEARESTDIST( $q, r$ ). (a) Point  $a$  is closer to  $q$  than point  $b$  and in (b) point  $b$  is closer to  $q$  than point  $a$ . In both examples  $f$  is the farthest corner from  $q$ , and MAXDIST is the distance to it.

hyperspheres (i.e.,  $O(d)$ ), whereas when the cluster elements are minimum bounding hyperrectangles, the complexity of MAXNEARESTDIST is  $O(d^2)$ , while the complexity of MINDIST and MAXDIST in this case is just  $O(d)$ .

The above clustering methods can be viewed as making use of object hierarchies in the sense that when the data is drawn from a vector space, it is not necessarily the case that every point in the underlying space is guaranteed to be contained in one of the clusters; nor is it necessarily the case that each point in the underlying space is contained in just one cluster. In other words, they are not based on a disjoint decomposition of the underlying space, and possibly an aggregation of the regions resulting from the decomposition that satisfy these properties (i.e., disjointness and coverage). This is especially true in light of the nature of the aggregation method, which ensures that the aggregate clustering shapes are formed in the same way as the base clusters.

Other clustering methods can be devised that make use of a disjoint decomposition of the underlying space (e.g., a grid [955, 1374]). Again, all of the pruning rules are applicable with appropriate modifications similar to those made when using minimum bounding objects. Note that Pruning Rule 3 will not be applicable if the regions resulting from the decomposition do not have holes or voids (i.e., there are no regions whose shape is topologically equivalent to a spherical shell).

It is interesting to observe that, if for every nonobject element  $e_p$  the ball of radius  $r_{p,min}$  centered at  $M_p$  is empty (i.e., besides not containing any objects of  $e_p$  by definition, this ball also does not contain any objects belonging to any other element  $e_o$ ), then Pruning Rule 3 will never be invoked. This is a more general (and hence broader) specification than the one given by Larsen and Kanal [1103], who rely on the satisfaction of the following conditions in order to guarantee that Pruning Rule 3 cannot be applied:

1. The existence of a tessellation of the underlying space into regions (i.e., a partition into disjoint regions such that every point in the underlying space is in one of the regions), where
2. For each nonobject element  $e_p$ , its corresponding region contains the empty ball of radius  $r_{p,min}$  centered at  $M_p$ , and
3. The members of the active list are visited in such an order so that all the elements that are visited on the first descent of the depth-first process (assuming that the clustering process results in a tree) contain the query object.

Although it seems that Pruning Rule 3 can never be invoked if the partition of the underlying space is disjoint, this is not the case because the ball of radius  $r_{p,min}$  centered at  $M_p$  can contain an object that is not in  $e_p$  while still being empty with respect to  $e_p$  (i.e., locally empty by not containing any objects of  $e_p$ ). In fact, as we stated before, all that is required for Pruning Rule 3 to be inapplicable is for the maximal empty balls (defined by  $r_{p,min}$  for each  $e_p$ ) to be globally empty.

Note also that in the case of data drawn from a metric space, the situation under which Pruning Rule 3 can be applied only arises when  $M_p$  does not correspond to an object in  $e_p$ , as otherwise  $r_{p,min} = 0$ . Moreover, if in such a case  $M_p$  is required to be an object in the dataspace, then our conclusions about the impossibility of invoking Pruning Rule 3 are inapplicable as the balls centered at  $M_p$  cannot be empty, whereas, in contrast, when the data is drawn from a vector space,  $M_p$  is not required to be an object in the dataspace.

Experiments by Kamgar-Parsi and Kanal [986] on finding the nearest neighbor for random two-dimensional data from both a Gaussian and uniform distribution showed that the number of distance computations that were eliminated by Rules 2 and 4 were about the same, and they were much greater than the number eliminated by Rules 1 and 3. In fact, use of each of Rules 2 and 4 resulted in eliminating approximately 40% of the distance computations, while use of each of Rules 1 and 3 resulted in eliminating between 1% and 3% of the distance computations. This is not surprising because Rules 2 and 4 involve elements at the deepest level of the search hierarchy (i.e., leaf elements

and objects), and there are generally many more leaf elements than nonleaf elements and, likewise, more objects than nonobjects. Note that in these experiments, the random data was not sorted—that is, the first  $n$  samples that were generated were assigned to the first cluster, the second  $n$  samples to the second cluster, and so on. The rationale was to measure the performance of the four pruning rules in a manner independent of the clustering method. For example, Fukunaga and Narendra [666] used a hierarchical 3-means clustering method. In this way, Kamgar-Parsi and Kanal [986] demonstrated that their additional pruning rules (i.e., Rules 3 and 4) resulted in almost doubling the number of distance computations eliminated by Fukunaga and Narendra’s algorithm, which only used Pruning Rules 1 and 2.

On the other hand, experiments by Larsen and Kanal [1103] with data that was clustered using clustering methods that satisfied the above conditions that ensure that Pruning Rule 3 will not be invoked also found that Pruning Rule 4 was invoked relatively rarely in comparison with Pruning Rule 2. Nevertheless, Pruning Rules 3 and 4 are important as they are general and formulated in a manner that is independent of the clustering method. In particular, recall the utility of these rules when the data is clustered, as in the example illustrated in Figure 4.17.

### Exercises

1. Give an algorithm to compute the MINDIST function when the minimum bounding object is an axis-aligned hyperrectangle.
2. Give an algorithm to compute the MAXDIST function when the minimum bounding object is an axis-aligned hyperrectangle.
3. Give an algorithm to compute the MAXNEARESTDIST function when the minimum bounding object is an axis-aligned hyperrectangle.
4. How would you modify the MINDIST cost estimate function for an object hierarchy in the spatial domain where the minimum bounding object is the intersection of the minimum bounding hyperrectangle and the minimum bounding hypersphere of the objects (e.g., an SR-tree [999] as discussed in Section 4.4.2) instead of a hyperrectangle?
5. Repeat Exercise 4 for the MAXDIST cost-estimate function.
6. Repeat Exercise 4 for the MAXNEARESTDIST cost-estimate function.
7. How would you apply the depth-first  $k$ -nearest neighbor algorithm to an object hierarchy in an arbitrary metric space (e.g., an M-tree [389] as discussed in Section 4.5.4)?
8. Suppose you choose an arbitrary set of points in a vector space as cluster centers and then apply a clustering method that associates each point with its nearest cluster center. Show with an example that Pruning Rule 3 is applicable.
9. Can you prove that pruning Rule 3 is never invoked for data in a vector space that is clustered using a  $k$ -means algorithm (e.g., [1174, 1219])? Try this for one-dimensional data first. Can you prove this for arbitrary dimensions?
10. Consider the case that the minimum bounding object is a hypersphere. Formally, we say that  $B$  is the minimum enclosing hypersphere of  $P$ , a set of  $d$ -dimensional points, if and only if  $B$  is an enclosing hypersphere of  $P$ , and any hypersphere containing  $P$  has a radius greater than or equal to the radius of  $B$ . It can be shown easily that the minimum enclosing hypersphere  $B$  of a point set  $P$  is uniquely defined. Armed with this definition, given hypersphere  $B$  centered at  $c$  with radius  $r$  and query point  $q$ , and assuming a Euclidean distance metric, prove that  $\text{MAXNEARESTDIST}(q, B)$ , the distance of the closest point  $p \in P$  to  $q$ , cannot be greater than  $\sqrt{d(q, c)^2 + r^2}$ .
11. Suppose that the cluster centers  $M_i$  are chosen as the centroids of the clusters  $e_i$  and that  $r_i$  is the maximum distance from  $M_i$  to an object in  $e_i$ . Assuming a Euclidean distance metric, prove that  $\text{MAXNEARESTDIST}(q, e_i)$  is  $\sqrt{d(q, M_i)^2 + r_i^2}$ .

Exercises 12–16 consider the computation of the minimum distance from query object  $q$  to its farthest neighbor in minimum bounding object  $b$  (referred to as MINFARTHESTDIST) for

different types of minimum bounding objects. Note that whereas the MAXNEARESTDIST function corresponds to the minimum of the maximum possible distances to the object  $o$  in  $b$  that is to serve as  $q$ 's nearest neighbor, MINFARTHESTDIST is the maximum of the minimum possible distances from  $q$  to an object  $o$  in  $b$  that is to serve as  $q$ 's farthest neighbor (see also Exercise 17 in Section 4.2.2 and its solution).

12. Give an algorithm to compute the MINFARTHESTDIST function when  $b$  is a minimum bounding object that is an axis-aligned hyperrectangle?
13. In the text, for the case that the minimum bounding object  $b$  is an axis-aligned hyperrectangle, we give an alternative definition of MAXNEARESTDIST( $q, b$ ) as the distance from  $q$  to the closest corner of  $b$  that is "adjacent" to the corner  $f$  farthest from  $q$ . It would seem that the analogous alternative definition of MINFARTHESTDIST( $q, b$ ) would be the distance from  $q$  to the farthest corner of  $b$  that is "adjacent" to the corner  $f$  nearest to  $q$ . Explain why this definition holds or fails to hold.
14. Assuming a Euclidean distance metric, what is MINFARTHESTDIST when the minimum bounding object  $b$  is the hypersphere  $e_p$  of radius  $r_{p,max}$  whose center has been determined to be  $M_p$ , and  $r_{p,min}$  is unknown?
15. Assuming a Euclidean distance metric, what is MINFARTHESTDIST when the minimum bounding object  $b$  is a multidimensional spherical shell  $e_p$ ? Distinguish between the case that the minimum bounding hypersphere with radius  $r_{p,max}$  and centered at  $M_p$  coincident with the exterior face of the spherical shell (i.e., outer sphere) is formed first and the case that the maximum bounding hypersphere with radius  $r_{p,min}$  and centered at  $M_p$  coincident with the interior face of the spherical shell (i.e., inner sphere) so that the interior is empty is formed first.
16. Repeat Exercise 4 for the MINFARTHESTDIST cost-estimate function.

#### 4.2.4 Ordering the Processing of the Elements of the Active List

As we pointed out before, generally speaking, regardless of the clustering method that is used, Fukunaga and Narendra's algorithm [666] processes the child elements  $e_p$  (which are not objects) in the active list in increasing MEANORPIVOTDIST order—that is, the distance from the query object to their means (i.e.,  $M_p$ ). The drawback of such an ordering is that the distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  is not taken into account. In other words, a MEANORPIVOTDIST ordering results in giving priority to nearby elements whose  $r_{p,max}$  values may be small over elements with larger  $r_{p,max}$  values that are farther from the query object  $q$ —that is, for  $d(q, M_a) > d(q, M_b)$ , element  $e_a$  with mean  $M_a$  and farthest object at distance  $r_{a,max}$  is deemed farther from query object  $q$  than element  $e_b$  with mean  $M_b$  and farthest object at distance  $r_{b,max}$ , even though  $e_a$  may contain an object  $o$  that is closer to  $q$  than any other object in  $e_b$  (e.g., see Figure 4.20). Alternatively, even though the elements  $e_p$  of the active list are processed in order of increasing values of  $d(q, M_p)$ , just because element  $e_b$  is processed before element  $e_a$  does not mean that  $e_a$  may not contain an object that is closer to  $q$  than any object in  $e_b$ . This means that the pruning of one element  $e_b$  of the active list cannot lead to the pruning of all remaining elements of the active list at the given level as they may contain objects that are in fact closer to  $q$  than any of the objects in the pruned element  $e_b$ . This is a direct consequence of the fact that when  $d(q, e_p)$  is defined as MEANORPIVOTDIST,  $d(q, e_p) \leq d(q, e_0)$  is not satisfied for every object  $e_0$  in  $e_p$ .

Figure 4.20  
Example where element  $e_a$  contains an object  $o$  that is closer to  $q$  than any other object in element  $e_b$ . The ordering of Fukunaga and Narendra [666] deems  $e_b$  to be closer to  $q$  than  $e_a$ , while  $e_a$  is deemed closer using an ordering based on a distance  $d(q, e_p)$  between query object  $q$  and a nonobject element  $e_p$  of  $d(q, M_p) - r_p$ .

Ideally, we would like to process the child elements in the active list in an order that is correlated with the likelihood of finding the  $k$  nearest neighbors. In particular, when the search hierarchy formed by the clustering method is a tree, which is the case in our discussion, we want to process the subtrees that are most likely to contain the  $k$  nearest neighbors (i.e., those closer to the query object) before those that are less likely to contain them and possibly to prune them from further consideration by virtue of being farther away from the query object than any of the members of the set  $L$  of the current candidate  $k$  nearest neighbors. This can be done with the aid of the pruning rules discussed in

Section 4.2.2. This approach is analogous to a limited version of the  $A^*$ -algorithm (e.g., see [1594]) used in heuristic search for a minimum-cost solution path from a start state to a goal state. In this case, an estimate is made of the cost of the solution (i.e., to the problem of finding the  $k$  nearest neighbors), and if the estimate is a lower bound on the total cost, then we are guaranteed to find the optimal solution.

Two other possible orderings for processing the child elements of an element of the active list that spring to mind are based on the cost-estimate functions `MINDISTOBJECT` and `MAXDISTOBJECT`. In particular, given cluster element  $n$  in the active list, estimate `MINDISTOBJECT( $q, n$ )` is a lower bound on the distance between  $q$  and an object in the tree rooted at the search hierarchy element corresponding to  $n$  that is to serve as  $q$ 's nearest neighbor. Similarly, estimate `MAXDISTOBJECT( $q, n$ )` is an upper bound on the distance between  $q$  and an object in the tree rooted at the search hierarchy element corresponding to  $n$  that is to serve as  $q$ 's nearest neighbor. Note that if  $n$  is not a leaf element, then we can define `MAXDISTOBJECT( $q, n$ )` as the minimum value attained by `MAXDISTOBJECT` over all of the subtrees of  $n$ . `MINDISTOBJECT( $q, n$ )` can also be defined recursively in the same manner. Unlike `MEANORPIVOTDIST`, `MINDISTOBJECT` and `MAXDISTOBJECT` are good estimates of where the nearest neighbor is to be found, but, unfortunately, the time needed to calculate them for  $n$  and its subtrees is proportional to the number of objects in  $n$  and its subtrees, which means that by the time we compute the ordering, we could have already found the closest neighbor. Thus, a better solution is needed.

The two additional orderings proposed above are easily improved upon by modifying the cost-estimate functions `MINDISTOBJECT` and `MAXDISTOBJECT` to yield `MINDIST` and `MAXNEARESTDIST`, respectively, so that given cluster element  $n$  in the active list, they are based only on the cluster associated with  $n$  instead of also being based on the objects in the subtrees of  $n$ . `MINDIST` and `MAXNEARESTDIST` are defined exactly in the same manner as they were in Section 4.2.3 in conjunction with Pruning Rule 5. In particular, for cluster  $c$ , `MINDIST( $q, c$ )` is the least possible distance from the query object  $q$  to an object in  $c$  that can serve as  $q$ 's nearest neighbor. Observe that `MINDIST( $q, c$ ) = 0` when  $q$  is in  $c$ . Similarly, `MAXNEARESTDIST( $q, c$ )` is the greatest possible distance between  $q$  and an object in  $c$  that can serve as  $q$ 's nearest neighbor.

The orderings based on the `MINDIST` estimate have been used by a number of researchers (e.g., [955, 1374]) in conjunction with modifications of the clustering methods proposed by Fukunaga and Narendra [666] that replace the hierarchical treelike clustering by a multidimensional array so that the cluster elements are the array elements. Of course, using the array reduces the significance of the depth-first algorithm as the search hierarchy usually has either just one level or its depth is bounded by the dimensionality of the underlying dataspace. Roussopoulos, Kelley, and Vincent [1586] proposed using orderings based on the `MINDIST` and `MAXNEARESTDIST` estimates for an R-tree search hierarchy where the clusters are hyperrectangle minimum bounding objects, although, as we have seen, they are also applicable to other clustering methods.<sup>15</sup> The utility of these estimates lies in that often their calculation for an appropriate distance metric only requires knowledge of the size and shape of  $c$  rather than an examination of

---

<sup>15</sup> Roussopoulos et al. [1586] used the term `MINMAXDIST` instead of `MAXNEARESTDIST` as they were primarily concerned with objects that have extent and were trying to minimize the distance from the query object  $q$  to the farthest possible point on the  $(d - 1)$ -dimensional faces of the  $d$ -dimensional minimum bounding hyperrectangles of the objects as each face must contain at least one point of the object—that is, they were trying to minimize the upper bound on the distance of the farthest possible point on the object, which accounts for the use of the term `MINMAXDIST`. On the other hand, a case could also be made for using the term `MAXMINDIST` to denote this quantity as we have an upper bound on the distance from  $q$  to the closest possible point of the object. However, in the more general context, when we disregard the nature of the data objects, Roussopoulos et al. [1586] were actually determining the maximum possible distance to the nearest neighbor, and this is why we use instead the term `MAXNEARESTDIST` in the rest of the discussion.

$c$ 's actual contents.<sup>16</sup> Note again that MAXNEARESTDIST is conceptually different from MAXDIST in that MAXDIST indicates the greatest possible distance from  $q$  to an object in  $c$  that need not necessarily be  $q$ 's nearest neighbor. Nevertheless, MAXNEARESTDIST and MAXDIST sometimes have the same value in some domains, such as when the data is drawn from a metric space that is organized using a ball partitioning search hierarchy and the only information known about the balls is their radii (i.e., we do not know if the pivot objects are members of the balls).

In some sense, the MINDIST ordering represents the optimistic choice, MAXNEARESTDIST represents the pessimistic choice, and MEANORPIVOTDIST behaves like a compromise. To see this, observe that if the active list is ordered in order of increasing value of MINDIST, and if cluster  $c_1$  precedes cluster  $c_2$  (i.e.,  $\text{MINDIST}(q, c_1) \leq \text{MINDIST}(q, c_2)$ ), then, at best,  $c_1$  contains an object  $o_1$  at a distance close to its MINDIST value, such that  $\text{DISTANCE}(q, o_1) \leq \text{MINDIST}(q, c_2)$ . However, there is no guarantee that this will indeed be the case as  $c_2$  may contain an object  $o_2$  that is closer to  $q$  than  $o_1$ . On the other hand, if the active list is ordered in order of increasing value of MAXNEARESTDIST so that  $\text{MAXNEARESTDIST}(q, c_1) \leq \text{MAXNEARESTDIST}(q, c_2)$ , then, in the worst case, the object in  $c_1$  nearest to  $q$  is at distance  $\text{MAXNEARESTDIST}(q, c_1)$ , which is no larger than  $\text{MAXNEARESTDIST}(q, c_2)$ .

Regardless of which of the cost-estimate functions MINDIST and MAXNEARESTDIST is used for ordering the processing of the elements of the active list, they sometimes have other uses in the depth-first  $k$ -nearest neighbor algorithm. In particular, since MINDIST represents the minimum distance at which an object could be found in a cluster  $c$ , MINDIST yields a means of pruning elements from the search, provided that a bound on the maximum distance to the  $k$ th-nearest neighbor is available. In particular, given the value of  $D_k$ , the distance from the query object  $q$  to the farthest of the  $k$  current candidate nearest neighbors, knowing that MINDIST is larger than  $D_k$  has the same effect as using Pruning Rule 1 of Fukunaga and Narendra [666], described in Section 4.2.2.

On the other hand, for any nonobject element  $e$ ,  $\text{MAXNEARESTDIST}(q, e)$  is an upper bound on the distance of the object  $o$  in  $e$  nearest to  $q$ . In particular, MAXNEARESTDIST can be used to tighten the search by resetting  $D_1$  to the value of  $\text{MAXNEARESTDIST}(q, e)$  whenever  $\text{MAXNEARESTDIST}(q, e) < D_1$ . This has the same effect as using Pruning Rule 5. However, this technique, as well as Pruning Rule 5, can only be used in conjunction with a MINDIST ordering since the fact that MINDIST only provides a lower bound on  $D_1$  makes it possible for elements of the active list that are subsequently processed to have MAXNEARESTDIST values that are lower than  $D_1$ . In contrast, when using the MAXNEARESTDIST ordering, we know that once we have processed element  $e$  and obtained  $D_1$ , then  $D_1 \leq \text{MAXNEARESTDIST}(q, e)$ , and thus Pruning Rule 5 is inapplicable as all remaining unprocessed elements of the active list have higher MAXNEARESTDIST values. Moreover, as we point out in Sections 4.2.2 and 4.2.3, it should be clear that MAXNEARESTDIST by itself does not help in pruning the search, as objects closer to  $q$  could be found in child elements of element  $e$  at positions in the ordering with higher MAXNEARESTDIST values. In this respect, MAXNEARESTDIST has the same drawback as MEANORPIVOTDIST.

Roussopoulos et al.'s [1586] implementation of the  $k$ -nearest neighbor algorithm uses MAXNEARESTDIST to prune any element  $e_1$  in the active list such that  $\text{MINDIST}(q, e_1) > \text{MAXNEARESTDIST}(q, e_2)$ , where  $e_2$  is some other element in the active list. However, this pruning method is only useful for  $k = 1$ . Moreover, it can be shown (e.g., [360, 848]) that regardless of how the active list is ordered, the facts that  $\text{MINDIST}(q, e) \leq \text{MAXNEARESTDIST}(q, e)$  and that  $D_1 \leq \text{MAXNEARESTDIST}(q, e)$  mean that this pruning method is of no use as these clusters will not be examined any-

<sup>16</sup> Of course, this statement is not completely true as the actual contents of  $c$  were examined at the time that  $c$  was originally formed.

way on account of the application of Pruning Rule 1, which will result in at least as much pruning (see Exercise 2).

At this point, let us summarize our observations about the utility of the MINDIST, MAXNEARESTDIST, and MEANORPIVOTDIST orderings. An advantage of ordering the elements  $e_p$  of the active list  $A$  of  $e$  according to increasing values of  $\text{MINDIST}(q, e_p)$  is that, by the definition of MINDIST, we have that  $\text{MINDIST}(q, e_p) \leq d(q, e_0)$  for every object  $e_0$  in  $e_p$ . Therefore, once we prune one element  $e_i$  in  $A$  of  $e$  on account of determining that  $\text{MINDIST}(q, e_i) > D_k$ , then we will know that  $\text{MINDIST}(q, e_j) > D_k$  for all remaining elements  $e_j$  of the active list  $A$  of  $e$ . This means that none of these elements needs to be processed, and we simply exit the loop and backtrack to the parent of  $e$  or terminate if  $e$  is the root of the search hierarchy.

Therefore, from the above discussion, it does not appear that a MAXNEARESTDIST (as well as MEANORPIVOTDIST) ordering is as useful as a MINDIST ordering. It is interesting to observe that if we are willing to forgo the use of Pruning Rule 5 (as is done in Roussopoulos et al.'s [1586] implementation of the depth-first  $k$ -nearest neighbor algorithm), then not using MAXNEARESTDIST for ordering the processing of the elements of the active list means that the CPU cost of the depth-first  $k$ -nearest neighbor algorithm is reduced since there is no need to compute the MAXNEARESTDIST value of each cluster. This is especially important because MAXNEARESTDIST is usually more expensive to compute than MINDIST.

Notwithstanding the above, of course, examples can be constructed where using a MAXNEARESTDIST ordering leads to the examination of fewer minimum bounding objects than a MINDIST ordering (see Exercise 3), and vice versa (see Exercise 4), when finding the  $k$ th-nearest neighbor. This is true even if the depth-first  $k$ -nearest neighbor algorithm makes use of Pruning Rule 5 with the MINDIST ordering (i.e., for the case that  $k = 1$ ), although the implementation of Roussopoulos et al. [1586] did not make use of Pruning Rule 5. The reason for the occasional superior performance of the MAXNEARESTDIST ordering is the better initial estimates of  $D_1$  and its subsequent refinement, which can lead to some additional initial pruning.

Nevertheless, experiments reported by Roussopoulos et al. [1586], using a search hierarchy where the clusters are minimum bounding hyperrectangles organized in an R-tree, support the preference for the MINDIST ordering by finding that ordering the active list using MINDIST consistently performed better than using MAXNEARESTDIST. This was also confirmed in experiments reported by Hjaltason and Samet [848], who conclude that these results indicate that the optimism inherent in MINDIST usually provides a better estimate of the distance of the nearest object than the pessimism inherent in MAXNEARESTDIST, so a MINDIST order will, in general, lead to finding the nearest object(s) earlier in the active list. Thus, the MINDIST order is the one that is usually used [848].

### Exercises

1. Assume that KNEAREST using FNDFTRAV processes the elements  $e_p$  in the active list in increasing MINDIST order, and prove that Pruning Rule 5 can indeed be applied.
2. Roussopoulos et al. [1586] use the following three pruning strategies in their implementation of the depth-first  $k$ -nearest neighbor algorithm regardless of which of the cost-estimate functions MINDIST and MAXNEARESTDIST is used for ordering the processing of the elements of the active list. Roussopoulos et al. [1586] differentiate the strategies, in part, on the basis of whether they are applied before or after processing an element on the active list and term them *downward pruning* or *upward pruning*, respectively. Note that it can be shown [848] that it is not necessary to distinguish between downward and upward pruning in the sense that there is no need to remove items explicitly from the active list. Instead, we just test each element on the active list when its turn comes. Although these strategies were proposed for an R-tree search hierarchy that makes use of minimum bounding hyperrectangles, they are also applicable for arbitrary clusters, even though we do not present them here in this way.

- (a) Strategy 1 is used in downward pruning. It allows pruning an element from the active list whose minimum bounding hyperrectangle  $r_1$  is such that  $\text{MINDIST}(q, r_1) > \text{MAXNEARESTDIST}(q, r_2)$ , where  $r_2$  is the minimum bounding hyperrectangle of some other element in the active list. This strategy, as formulated here, is only useful for  $k = 1$ .
- (b) Strategy 2 prunes an object  $o$  when its distance from  $q$  is greater than  $\text{MAXNEARESTDIST}(q, r)$ , where  $r$  is some minimum bounding hyperrectangle. Again, this strategy is only applicable when  $k = 1$ . Roussopoulos et al. [1586] claim that this strategy is of use in downward pruning, but Hjaltason and Samet [848] point out that its inclusion is somewhat puzzling since it does not help in pruning elements in the active list from the search. It is possible that the intent of Roussopoulos et al. [1586] is for Strategy 2 to be used to prune objects in leaf elements [848]. However, this does not appear to be particularly fruitful since it still requires that the objects be accessed and their distances from  $q$  be calculated [848]. Another possible explanation given by Hjaltason and Samet [848] for the inclusion of this strategy is that it can be used to discard the nearest object found in an element  $s$  in the active list after  $s$  has been processed. However, as Hjaltason and Samet [848] point out, the purpose of this is not clear since a better candidate will replace this object later on anyway.
- (c) Strategy 3 prunes any element from the active list whose minimum bounding hyperrectangle  $r$  is such that  $\text{MINDIST}(q, r) > D_k$ . It is applicable for any value of  $k$  and in both downward and upward pruning.

As pointed out above, Strategy 2 is not a useful strategy. Show that even though Strategy 1 is only applicable when  $k = 1$ , applying Strategy 3 in upward pruning eliminates at least as many elements of the active list as applying Strategy 1 in downward pruning. In other words, show that there is no need to make use of Strategy 1.

- 3. Assume a search hierarchy where the clusters are minimum bounding hyperrectangles organized in a structure such as an R-tree. Letting  $k = 1$ , give an example of the depth-first algorithm where use of  $\text{MAXNEARESTDIST}$  to order the processing of elements of the active list for finding the  $k$  nearest neighbors of query point  $q$  examines the contents of fewer minimum bounding hyperrectangles than the use of  $\text{MINDIST}$ .
- 4. Assume a search hierarchy where the clusters are minimum bounding hyperrectangles organized in a structure such as an R-tree. Letting  $k = 1$ , give an example of the depth-first algorithm where use of  $\text{MINDIST}$  to order the processing of elements of the active list for finding the  $k$  nearest neighbors of query point  $q$  examines the contents of fewer minimum bounding hyperrectangles than the use of  $\text{MAXNEARESTDIST}$ .
- 5. How would you apply a depth-first  $k$ -nearest neighbor algorithm to a  $k$ -d tree representation of points?
- 6. Suppose that you want to find the  $k$  farthest neighbors instead of the  $k$  nearest neighbors. Discuss the relative merits of using  $\text{MAXDIST}$  and  $\text{MINFARTHESTDIST}$  to order the processing of the elements of the active list.
- 7. Assume a search hierarchy where the clusters are minimum bounding hyperrectangles organized in a structure such as an R-tree. Give an example of the depth-first algorithm where use of  $\text{MINFARTHESTDIST}$  to order the processing of elements of the active list for finding the  $k$ th-farthest neighbor of query point  $q$  examines the contents of fewer minimum bounding hyperrectangles than the use of  $\text{MAXDIST}$ .
- 8. Assume a search hierarchy where the clusters are minimum bounding hyperrectangles organized in a structure such as an R-tree. Give an example of the depth-first algorithm where use of  $\text{MAXDIST}$  to order the processing of elements of the active list for finding the  $k$ th-farthest neighbor of query point  $q$  examines the contents of fewer minimum bounding hyperrectangles than the use of  $\text{MINFARTHESTDIST}$ .

## 4.2.5 Improved Algorithm

In this section we make use of some of the observations made in Sections 4.2.3 and 4.2.4 to modify procedures  $\text{FNDFTRAV}$  and  $\text{INSERTL}$ , thereby yielding  $\text{OPTDFTRAV}$  and  $\text{OPTINSERTL}$ , respectively, which are given below. First, we incorporate a modified definition of  $\text{MINDIST}$  and use a  $\text{MINDIST}$  ordering to process the elements of the active

list. We also indicate how to apply Pruning Rules 2 and 4 to nonobjects instead of just to objects. Next, we show how to modify the control structure of the original depth-first  $k$ -nearest neighbor algorithm of Fukunaga and Narendra [666] to enable the use of Pruning Rule 5 for arbitrary values of  $k$ . The result is a new algorithm that lies somewhere between the depth-first and best-first approaches, which we call the *maxnearest depth-first  $k$ -nearest neighbor algorithm*.

The discussion of MINDIST in Section 4.2.4 was for the most part silent about the shape of the nonobject cluster element  $e_p$ . Recall that in its most general form,  $e_p$  has the shape of a multidimensional spherical shell, where  $r_{p,min}$  and  $r_{p,max}$  are the distances from  $M_p$  to  $e_p$ 's internal and external faces, respectively. Thus, we should have two bounding objects (hyperspheres) in this situation—one for the interior face of the element and one for the exterior face. In this case, we redefine  $d(q, e_p) = \text{MINDIST}(q, e_p)$  to be

$$\text{MINDIST}(q, e_p) = \begin{cases} r_{p,min} - d(q, M_p) & 0 \leq d(q, M_p) \leq r_{p,min} \\ 0 & r_{p,min} \leq d(q, M_p) \leq r_{p,max} \\ d(q, M_p) - r_{p,max} & r_{p,max} \leq d(q, M_p). \end{cases}$$

Making this modification enables us to combine Pruning Rules 1 and 3. Note that for this definition, the hyperspheres are not necessarily minimum bounding objects of the objects within them as we do not specify how  $M_p$  is chosen.

Despite the advantages cited above for using MINDIST to order the processing of elements of the active list, MEANORPIVOTDIST is still useful. In particular, when  $q$  is in a nonobject cluster element  $e_p$  of the search hierarchy, then we define  $d(q, e_p) = \text{MINDIST}(q, e_p) = 0$ , while this is not necessarily the case when we use the definition  $d(q, e_p) = \text{MEANORPIVOTDIST}(q, e_p) = d(q, M_p)$ . Thus, retaining MEANORPIVOTDIST enables us to distinguish between the different nonobject elements that contain  $q$ . In particular, we do this by using MEANORPIVOTDIST as a secondary order on all elements  $e_p$  in the active list such that  $d(q, e_p) = \text{MINDIST}(q, e_p) = 0$ . We also use MEANORPIVOTDIST as a secondary key when two elements have the same MINDIST values.

Recall that the tests for the applicability of Pruning Rules 2 and 4 are made when processing the objects in a leaf element  $e_p$ . In particular, for each object  $o$  in  $e_p$ , we examine the distance  $d(o, M_p)$  from  $o$  to the mean or pivot  $M_p$  and try to apply the appropriate pruning rule to avoid computing the distance between  $o$  and  $q$ . The rationale for this is to make use of the distances from each  $o$  in  $e_p$  to  $M_p$ , which were computed when the cluster represented by  $e_p$  was formed.

In fact, there is no need to apply these tests for all of the objects. Instead, we propose to sort the objects in  $e_p$  in increasing order of their distance from  $M_p$  (i.e., using MEANORPIVOTDIST( $o, M_p$ )) and to prune all objects  $o$  from consideration whose distance  $d(o, M_p)$  from  $M_p$  is less than  $d(q, M_p) - D_k$  (Pruning Rule 2) and greater than  $d(q, M_p) + D_k$  (Pruning Rule 4), given that  $D_k$  is the distance from  $q$  to the farthest of its current  $k$  candidate nearest neighbors. In other words, any object  $o$  that is one of the  $k$  nearest neighbors of  $q$  must lie in the range  $d(q, M_p) - D_k \leq d(o, M_p) \leq d(q, M_p) + D_k$ . Notice that although  $D_k$  may change as more objects are examined, the fact that  $D_k$  is nonincreasing means that as more objects are processed, the new range is always a subrange of the original range (i.e., it decreases in size), and thus we are assured that we will not miss any objects. The objects are sorted in increasing MEANORPIVOTDIST order—that is, with respect to their distance from  $M_p$ . Note that there is no need to sort the objects in procedure OPTDFTRAV as the sort need only be performed once, and this is best done when the cluster represented by  $e_p$  is formed.

It is also interesting to observe that by ordering the objects  $o$  in  $e$  in terms of their distance from their mean or pivot object  $M$  (i.e., MEANORPIVOTDIST( $o, M$ )), we are using an analogous principle to prune the processing of objects in a leaf element as we did to prune the processing of the child nonobject elements  $e_p$  in the active list  $A$  of

nonleaf element  $e$ . Recall that this was done by ordering them using their distance from  $q$  (i.e.,  $\text{MINDIST}(q, e_p)$ ). The difference lies in the nature of the reference object for the sort—that is, with respect to  $M$  instead of  $q$ . Implementing this improvement requires that we find the first object  $o'$  such that  $d(o', M) \geq d(q, M) - D_k$ . This can be achieved by implementing the set of objects in leaf element  $e$ , say  $O(e)$ , as an array and executing a binary search on the set of object distances from  $M$  for the objects in  $e$ . Once the appropriate  $o'$  has been found, the distance between  $q$  and all other objects  $o$  in  $O(e)$  is computed by stepping through  $O(e)$  using  $\text{NEXT}(O(e))$ , and  $D_k$  is reset if necessary, until an object  $o''$  is encountered such that  $d(o'', M) > d(q, M) + D_k$ , at which time we cease processing objects in  $e$  as none of the unprocessed objects can be one of the  $k$  nearest neighbors of  $q$ .

Note that when processing the child elements  $e_p$  of a nonleaf element  $e$  we did not need to find the first element of the active list whose distance from  $q$  was less than a given value as the distances (expressed in terms of  $\text{MINDIST}$ ) are all lower bounds on  $D_k$ , and any nonleaf element whose distance from  $q$  is less than  $D_k$  can contain potential  $k$ th-nearest neighbor candidates. In particular, in the case of the active list of a nonleaf element, the pruning condition (i.e., the combination of Pruning Rules 1 and 3) only makes use of the ordering of the elements  $e_p$  of the active list (i.e.,  $\text{MINDIST}(q, e_p)$ ) with respect to their distances from  $q$ , whereas in the case of a leaf element  $e$ , the pruning condition (i.e., the combination of Pruning Rules 2 and 4) makes use of both the ordering of the objects (i.e.,  $\text{MEANORPIVOTDIST}(o, e) = d(o, M)$ ) with respect to their distances from the mean or pivot object  $M$  and the distance of the query object from  $M$  (i.e.,  $\text{MEANORPIVOTDIST}(q, e) = d(q, M)$ ).

Ciaccia, Patella, and Zezula [389] suggest that Pruning Rules 2 and 4 can also be applied to nonobject elements, instead of just to objects, in their adaptation of a best-first  $k$ -nearest neighbor algorithm for the M-tree. Below, we apply these rules to the depth-first algorithm as well. The idea is to prune some of the nonobject elements from the active list without having to compute their distances from  $q$ . In particular, for each nonobject element  $e$  with mean  $M$  whose elements  $e_p$  are also nonobjects with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$ , this is achieved by storing the distance from  $M$  to the farthest and nearest object within  $e_p$ —that is,  $\text{MAXDIST}(M, e_p) = d(M, M_p) + r_{p,max}$  and  $\text{MINDIST}(M, e_p) = d(M, M_p) - r_{p,max}$ , respectively. With this information at hand, while generating the active list  $A$  containing the nonobject child elements  $e_p$  of  $e$ ,  $e_p$  is pruned if  $d(q, M) - D_k > \text{MAXDIST}(M, e_p)$  when  $M$  is closer to the object at distance  $\text{MAXDIST}(M, e_p)$  (and hence  $M_p$  as  $d(M, M_p) < \text{MAXDIST}(M, e_p)$ ) than to  $q$ , and if  $\text{MINDIST}(M, e_p) > D_k + d(q, M)$  when  $M$  is closer to  $q$  than to the object at distance  $\text{MINDIST}(M, e_p)$  (and hence  $M_p$  as  $d(M, M_p) > \text{MINDIST}(M, e_p)$ ). Notice that, in effect, the former corresponds to replacing Pruning Rule 2 for objects with  $o, M_p, d(M_p, o)$ , and  $M_p$  being closer to  $o$  than to  $q$  (Figure 4.12) with  $e_p, M, \text{MAXDIST}(M, e_p)$ , and  $M$  being closer to the object at distance  $\text{MAXDIST}(M, e_p)$  than to  $q$  (Figure 4.21(a)), respectively. Similarly, the latter corresponds to replacing Pruning Rule 4 for objects with  $o, M_p, d(M_p, o)$ , and  $M_p$  being closer to  $q$  than to  $o$  (Figure 4.14) with  $e_p, M, \text{MINDIST}(M, e_p)$ , and  $M$  being closer to  $q$  than to  $e_p$  (i.e., the object at distance  $\text{MINDIST}(M, e_p)$ ) (Figure 4.21(b)), respectively. Observe that the formulation of the rules in terms of  $\text{MAXDIST}$  and  $\text{MINDIST}$  leads to a more generalized formulation than the one of Ciaccia et al. [389] as it is applicable to a broader range of search hierarchies than the M-tree.

$\text{OPTDFTRAV}$  has also been enhanced so that it need not apply the tests corresponding to Pruning Rules 2 and 4 to all nonobjects in a nonleaf node  $e$  with mean  $M$  when forming the active list. In this way, it can possibly avoid computing the distance from  $q$  to some of the individual nonobjects in  $e$ . In particular, the nonobjects in  $e$  are sorted in increasing  $\text{MAXDIST}$  order with respect to  $M$  (this is done when the search hierarchy is initially formed). This enables pruning all nonobjects  $e_p$  from consideration for which  $\text{MAXDIST}(e_p)$  is less than  $d(q, M) - D_k$  (Pruning Rule 2). The remaining nonobjects

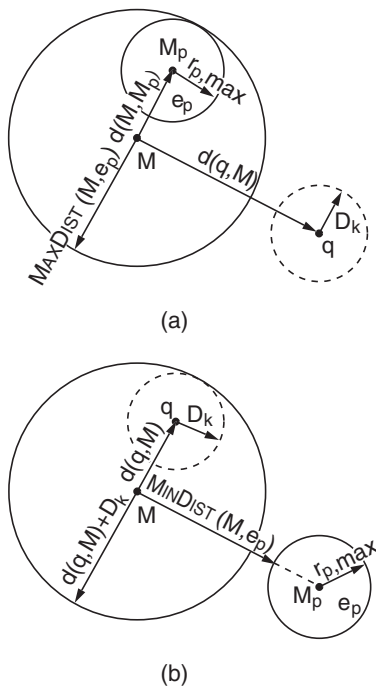

Figure 4.21  
Examples illustrating Pruning Rules 2 and 4 for nonobject elements  $e_p$  in  $e$  with mean  $M$ : (a) Pruning Rule 2 eliminates any nonobject  $e_p$  in  $e$  when  $D_k + \text{MAXDIST}(M, e_p) < d(q, M)$ , for the case that  $M$  is closer to the object at distance  $\text{MAXDIST}(M, e_p)$  than to  $q$  and (b) Pruning Rule 4 eliminates any nonobject  $e_p$  in  $e$  when  $D_k + d(q, M) < \text{MINDIST}(M, e_p)$ , for the case that  $M$  is closer to  $q$  than to  $e_p$ .

are only pruned if  $\text{MINDIST}(M, e_p) > d(q, M) + D_k$  (i.e., Pruning Rule 4); otherwise, they are inserted into the active list.

As we pointed out in Section 4.2.2, it is not immediately clear how to adapt Pruning Rule 5 to deal with  $k > 1$  neighbors. In order to visualize better the following discussion, we assume, without loss of generality, that the nonobject element  $e_p$  has the shape of a multidimensional spherical shell. Note that these hyperspheres are not necessarily minimum bounding objects of the objects within them as we do not specify how  $M_p$  is chosen. Therefore, in our examples,  $\text{MAXNEARESTDIST}(q, e_p) = d(q, M_p) + r_{p,\min}$ , although the results also hold when using other values of  $\text{MAXNEARESTDIST}$ . One possible solution is that whenever we find that  $d(q, M_p) + r_{p,\min} < D_k$ , we reset  $D_k$  to  $d(q, M_p) + r_{p,\min}$  if  $D_{k-1} \leq d(q, M_p) + r_{p,\min}$  (Figure 4.22(a)); otherwise, we reset  $D_k$  to  $D_{k-1}$  (Figure 4.22(b)). Nevertheless, this solution is problematic when  $D_{k-1} > d(q, M_p) + r_{p,\min}$  since, at this point, both  $D_k$  and  $D_{k-1}$  are the same (i.e.,  $D_k = D_{k-1}$ ), and from now on we will never be able to obtain a lower bound on  $D_k$  than  $D_{k-1}$ . The remedy is to add another explicit check to determine if  $D_{k-2} \leq d(q, M_p) + r_{p,\min}$ , in which case we reset  $D_{k-1}$  to  $d(q, M_p) + r_{p,\min}$ ; otherwise, we reset  $D_{k-1}$  to  $D_{k-2}$ . Nevertheless, this remedy is only temporary as it will break down again if  $D_{k-2} > d(q, M_p) + r_{p,\min}$ . However, we can just repeatedly apply the same method again until we find the smallest  $i \geq 1$  such that  $D_i > d(q, M_p) + r_{p,\min}$ . Once this value of  $i$  has been located, we set  $D_i$  to  $d(q, M_p) + r_{p,\min}$  after resetting  $D_j$  to  $D_{j-1}$  ( $k \geq j > i$ ).

Unfortunately, the solution described above does not guarantee that the objects that are associated with the different  $D_j$  ( $1 \leq j \leq k$ ) values are unique. The problem is that the same object  $o$  may be responsible for the  $\text{MAXNEARESTDIST}$  value associated with both elements  $e_p$  and  $e_a$  of the search hierarchy that caused  $d(q, M_p) + r_{p,\min} < D_k$  and  $d(q, M_a) + r_{a,\min} < D_k$ , respectively, at different times. Of course, this situation can only occur when  $e_p$  is an ancestor of  $e_a$ . However, it must be taken into account as, otherwise, the results of the algorithm are wrong.

In order to avoid this problem and to be able to make use of Pruning Rule 5, we expand the role played by the set  $L$  of the  $k$  nearest neighbors encountered so far so that it also contains nonobject elements corresponding to the elements of the active list along with their corresponding  $\text{MAXNEARESTDIST}$  values, as well as objects with their distance values from  $q$  [1639, 1643]. In particular, each time we process a nonobject element  $e$  of the search hierarchy, we insert in  $L$  all of  $e$ 's child elements that make up  $e$ 's active list, along with their corresponding  $\text{MAXNEARESTDIST}$  values (i.e., this replaces lines 28–33 in procedure `FNDFTRAV`). Moreover, in order to ensure that no ancestor-descendent relationship could possibly hold for any pair of items in  $L$ , before we process a nonobject element  $e$  of the search hierarchy (line 38 in procedure `FNDFTRAV`), we remove  $e$ 's corresponding element from  $L$  using procedure `REMOVEPRIORITYQUEUE` (not given here). Therefore, the object  $o$  associated with the nonobject element  $u$  of  $L$  at a distance of  $\text{MAXNEARESTDIST}$  is guaranteed to be unique. In other words,  $o$  is not already in  $L$ ; nor is  $o$  associated with any other nonobject element in  $L$ . It is also important to note that each of the entries  $u$  in  $L$  ensures that there is at least one object in the dataset whose maximum possible distance from  $q$  is the one associated with  $u$ .

```

We also retain the minimum of the distances that have been associated with the entry in  $L$  corresponding to  $q$ 's  $k$ th-nearest neighbor, which we denote by  $D_k$ . Note that  $D_k$  is not necessarily the same as the value currently associated with the entry in  $L$  corresponding to  $q$ 's  $k$ th-nearest neighbor, which we denote by  $D(L_k)$  (i.e.,  $D(\text{MAXPRIORITYQUEUE}(L))$ ). The reason is that we cannot guarantee that the  $\text{MAXNEARESTDIST}$  values of all of  $e$ 's immediate descendents (i.e., the elements of the active list of  $e$ ) are smaller than the  $\text{MAXNEARESTDIST}$  value of  $e$ . All we know for sure is that the distance from  $q$  to the nearest object in  $e$  and its descendents is bounded from above by the  $\text{MAXNEARESTDIST}$  value of  $e$ . In other words,  $D_k$  is nonincreasing, but  $D(L_k)$  can increase and decrease as items are added and removed from  $L$ . For example, when  $e$  is a multidimensional spherical shell comprising two bounding hyperspheres (not necessarily minimum), we see that  $D(L_k)$  must increase when element  $E(L_k)$  has just two children  $e_a$  and  $e_b$ , both of whose  $\text{MAXNEARESTDIST}$  values are greater than  $D(L_k)$ . Such an example in two dimensions is easy to construct, as can be seen in Figure 4.23.

Figure 4.23  
Example illustrating how  $D(L_k)$  increases when the  $\text{MAXNEARESTDIST}$  values of the two children  $e_a$  and  $e_b$  of  $e_p$  are greater than the current value of  $D(L_k)$ , which is the  $\text{MAXNEARESTDIST}$  value of  $e_p$ .

We implement Pruning Rule 5 by resetting  $D_k$  to  $D(L_k)$  whenever, upon insertion of a nonobject element  $e_p$  into  $L$  with its corresponding MAXNEARESTDIST value, we find that  $L$  has at least  $k$  entries and that  $D(L_k)$  is less than  $D_k$  as this corresponds to the situation that  $d(q, M_p) + r_{p,min} < D_k$  (i.e., assuming that the nonobject element  $e_p$  contained in  $L_k$  has mean  $M_p$  and  $r_{p,min}$  as the distance from  $M_p$  to the closest object within  $e_p$ ). Recall that the same action of resetting  $D_k$  was also taken in procedures FNDFTRAV and INSERTL upon insertion of an object into  $L$  when  $L$  has  $k$  entries as can be seen by noting that MAXNEARESTDIST of an object  $o$  is just  $d(q, o)$  as  $r_{p,min} = 0$ . Thus, we are able to use the unexplored nonobject elements of the active list for pruning in the sense that the distances from  $q$  of the farthest objects within them that can serve as the nearest neighbors enable us to calculate an upper bound  $D_k$  on the distance of the  $k$ th-nearest neighbor. Observe that it is important to distinguish between  $D_k$ , which is used in Pruning Rules 1–4 and  $D(L_k)$ , which serves as the basis of Pruning Rule 5. In particular, we see that defining  $D_k$  in terms of the minimum of  $D_k$  and  $D(L_k)$  ensures that there are  $k$  distinct objects (even though they may not all have been identified) whose maximum distance from  $q$  is less than or equal to  $D_k$ . Of course, we do not reset  $D_k$  upon explicitly removing a nonobject element from  $L$  because  $D_k$  is already a minimum and thus cannot decrease further as a result of the removal of a nonobject element, although it may decrease upon the subsequent insertion of an object or nonobject.

Note that nonobjects can only be pruned after the successful application of Pruning Rules 1 or 3 (i.e., on the basis of their MINDIST values), in which case they should also be removed from  $L$ . Moreover, the fact that we are using the MINDIST ordering means that once we prune one of the child elements of nonobject element  $e$  in the active list  $A$  of  $e$ , we can prune all remaining elements in  $A$  since they all have larger MINDIST values as  $A$  is sorted in increasing MINDIST order. Therefore, all of these elements should be removed from  $L$  as well since each of their MAXNEARESTDIST values is greater than its corresponding MINDIST value and hence also greater than  $D_k$ . However, there is really no harm in not removing any of the pruned nonobjects from  $L$  as neither the pruned nonobjects nor their descendants will ever be examined again. Nevertheless, the pruned nonobjects take up space in  $L$ , which is why it may be desirable to remove them anyway.

The drawback of the solution that we have described is that the maximum size of  $L$  has grown considerably since it is no longer  $k$ . Instead, assuming that pruned nonobjects have been removed from  $L$ , the maximum possible size of  $L$  is  $k$  plus the maximum number of possible active list elements over all levels of the search hierarchy. For example, assuming  $N$  data items and that the clustering method makes use of a treelike search hierarchy with  $m$  as the branching factor, then the maximum size of  $L$  is  $O(k + m \cdot \log N)$  and is attained when the depth-first search algorithm first encounters an object at the maximum depth, which is  $O(\log N)$ . Actually, it is interesting to note that the cost of increasing the size of  $L$  to include the maximum number of possible active list elements is not such a drawback as this amount of storage is needed by the recursion anyway due to the unexplored paths that remain at each level while descending to the deepest level of the search hierarchy.

Nevertheless, the facts that only nonobject elements with MINDIST values less than or equal to  $D_k$  are ever processed by the algorithm and that all of these nonobject elements have the same or larger corresponding MAXNEARESTDIST values mean that any nonobject element  $e$  whose MAXNEARESTDIST value is greater than the current value of  $D_k$  should not be inserted in  $L$  as  $D_k$  is nonincreasing, and thus were  $e$  to be inserted in  $L$ , it would never be examined subsequently, thereby implying that there will never be an explicit attempt to remove it. In fact, there is also no need to insert  $e$  in  $L$  when its MAXNEARESTDIST value is equal to the current value of  $D_k$ , regardless of how many elements are currently in  $L$ , as such an insertion will not enable us to lower the known value of  $D_k$  so that more pruning will be possible in the future (see Exercise 1). Otherwise, there is no reason to use  $L$  to keep track of the MAXNEARESTDIST values of the nonobjects.

Moreover, the fact that only the first  $k$  elements of  $L$  are ever examined by the algorithm (i.e., retrieved from  $L$ ) when updating  $D_k$  in the case of an insertion into  $L$  means that there is no need for  $L$  ever to contain more than  $k$  elements. This simplifies the algorithm considerably. However, it does mean that when it comes to needing to remove a nonobject element  $e$  explicitly from  $L$  just before inserting into  $L$  all of  $e$ 's child elements that make up  $e$ 's active list along with their corresponding MAXNEARESTDIST values, it could be the case that  $e$  is no longer in  $L$ . This is because  $e$  may have been implicitly removed as a byproduct of the insertion of closer objects or nonobject elements whose corresponding MAXNEARESTDIST values are smaller than that of  $e$  and thereby resulted in the resetting of  $D_k$ .

The only tricky case is ensuring that a nonobject  $e$  is actually in  $L$  when we are about to attempt to remove  $e$  explicitly from  $L$ . In other words, we want to ensure that  $e$  has not already been removed implicitly. Of course, if  $e$ 's MAXNEARESTDIST value is greater than  $D_k$ , then there is no need for any action because it is impossible for  $e$  to be in  $L$ , and thus we are guaranteed that  $e$  was implicitly removed from  $L$ . However, when  $e$ 's MAXNEARESTDIST value is less than or equal to  $D_k$ , and there are several elements in  $L$  with distance  $D_k$ , we do not want to search needlessly for  $e$ , as may be the case if  $e$  had already been implicitly removed from  $L$  by virtue of the insertion of a closer object or a nonobject with a smaller MAXNEARESTDIST value. This needless search can be avoided by adopting some convention as to which element of  $L$  at distance  $D_k$  should be removed when there are several nonobjects in  $L$  having  $D_k$  as their MAXNEARESTDIST value, as well as objects at distance  $D_k$ .

We adopt the convention that objects have priority over nonobjects in the sense that, in terms of nearness, objects have precedence over nonobjects in  $L$ . This means that when nonobjects and objects have the same distance, the nonobjects appear closer to the maximum entry in the priority queue  $L$ , denoted by MAXPRIORITYQUEUE( $L$ ), which corresponds to the  $k$ th-nearest candidate neighbor. In particular, we stipulate that whenever insertion into a full priority queue results in dequeuing a nonobject element  $b$ , we check if the new MAXPRIORITYQUEUE( $L$ ) entry  $c$  corresponds to a nonobject with the same MAXNEARESTDIST value  $d$ , in which case  $c$  is also dequeued. This loop continues until the new MAXPRIORITYQUEUE( $L$ ) entry corresponds to an object at any distance including  $d$  or to a nonobject at any other distance  $d'$ , or until  $L$  is empty. Note that  $D_k$  can only be reset if exactly one entry has been dequeued, and the distance of the new MAXPRIORITYQUEUE( $L$ ) entry is less than  $D_k$ . Otherwise, if we dequeue more than one entry, then, even though the distance of the new MAXPRIORITYQUEUE( $L$ ) entry may now be less than  $D_k$ , it cannot be used to reset  $D_k$  as  $L$  now contains fewer than  $k$  entries. In fact, it should be clear that  $D_k$  should not be reset because  $D_k$  has not been decreased since the only reason for the removal of the multiple nonobject entries is to avoid subsequent, possibly needless, searches when explicitly removing nonobject elements with MAXNEARESTDIST value  $D_k$ .

Following this convention, when a nonobject  $e$  is to be removed explicitly from  $L$  and  $e$ 's MAXNEARESTDIST value is less than  $D_k$ , then  $e$  has to be in  $L$  because it is impossible for  $e$  to have been removed implicitly as  $D_k$  is nonincreasing. Therefore, we remove  $e$  and decrement the size of  $L$ . On the other hand, the situation is more complicated when  $e$ 's MAXNEARESTDIST value is equal to  $D_k$ . First, if the maximum value in  $L$  (i.e., the one associated with MAXPRIORITYQUEUE( $L$ )) is less than  $D_k$ , then  $e$  cannot be in  $L$ , and we do not attempt to remove  $e$ . Such a situation arises, for example, when we dequeue more than one nonobject because there are several nonobjects at distance  $D_k$ . Second, if the maximum value in  $L$  (i.e., the one associated with MAXPRIORITYQUEUE( $L$ )) is equal to  $D_k$ , then there are two cases, depending on whether the entry  $c$  in MAXPRIORITYQUEUE( $L$ ) corresponds to an object or a nonobject. If  $c$  corresponds to an object, then nonobject  $e$  cannot be in  $L$  as we have given precedence to objects, and all nonobjects at the same distance are either in  $L$  or they are all not in  $L$ . If  $c$  corresponds to a nonobject, then nonobject  $e$  has to be in  $L$  as all of the nonobjects at the same distance have either been removed implicitly together

or retained, and, in this case, by virtue of the presence of  $c$  in  $L$ , we know that they have been retained in  $L$ . Note that when we explicitly remove a nonobject at distance  $D_k$  from  $L$ , we do not remove all remaining nonobjects at the same distance from  $L$  as this needlessly complicates the algorithm with no additional benefit because they will all be removed implicitly together later if at least one of them must be implicitly removed due to a subsequent insertion into a full priority queue.

The advantage of expanding the role of  $L$  to contain nonobjects as well, instead of just containing objects, is that without this expanded role, when  $L$  contains  $h$  ( $h < k$ ) objects, then the remaining  $k - h$  entries in  $L$  are  $\infty$ . Therefore, as long as there are at least  $k - h$  other entries in  $L$  that correspond to some nonobjects, we have a lower bound  $D_k$  than  $\infty$ . Moreover, the nonobjects in  $L$  often enable us to provide a lower bound  $D_k$  than if all entries in  $L$  were objects. In particular, this is the case when we have nonobjects with smaller MAXNEARESTDIST values than the  $k$  objects with the  $k$  smallest distance values encountered so far.

It is interesting to observe that the manner in which we incorporate Pruning Rule 5 in OPTDFTRAV enables the use of its result at a deeper level than the one at which it is calculated. In particular, the use of  $L$  to store the MAXNEARESTDIST values of some active nonobject elements means that a MAXNEARESTDIST value of an unexplored nonobject at depth  $i$  can be used to help in pruning objects and nonobjects at depth  $j > i$ . This is a significant improvement over the depth-first algorithm in FNDFTAV, where the MAXNEARESTDIST value of a nonobject element at depth  $i$  could only be used to tighten the distance to the nearest neighbor (i.e., for  $k = 1$ ) and prune nonobject elements at larger MINDIST values at the same depth  $i$ .

Unlike procedure FNDFTAV, OPTDFTRAV incorporates Pruning Rule 5 in terms of MAXNEARESTDIST (lines 31–37) instead of  $r_{p,min}$ . This is preferable as we no longer need to be concerned about whether the data is drawn from a metric space rather than from a vector space, whether  $r_{p,min}$  is known, or about the nature of the clustering method. Using MAXNEARESTDIST also enables us to distinguish between the use of  $r_{p,min}$  in the definition of MINDIST where an unknown value of  $r_{p,min}$  is equivalent to setting  $r_{p,min}$  to 0, while when the value of  $r_{p,min}$  is unknown in Pruning Rule 5, it is wrong to set  $r_{p,min}$  to 0. In fact, when  $r_{p,min}$  is unknown in Pruning Rule 5, then  $r_{p,min}$  is set to  $r_{p,max}$ .

Notice that OPTDFTRAV is considerably different from Roussopoulos et al.'s [1586] implementation of the depth-first algorithm. Besides permitting a more general cluster element than a hyperrectangle minimum bounding object, OPTDFTRAV also incorporates Pruning Rules 2–5 instead of just Pruning Rule 1. In addition, OPTDFTRAV also tries to apply pruning to the objects in each of the leaf elements of the search structure and to the nonobjects in each of the nonleaf elements of the search structure, which is not done in the implementation of Roussopoulos et al. [1586].

Moreover, we observe that OPTDFTRAV is quite different from the original algorithm of Fukunaga and Narendra [666] in that OPTDFTRAV incorporates Pruning Rules 2–5 rather than just Pruning Rules 1, 2, and 5; it is also different from the enhanced version proposed by Kamgar-Parsi and Kanal [986], which incorporates Pruning Rules 1–4. OPTDFTRAV also differs from previous approaches including that of Larsen and Kanal [1103] by handling the  $k$  nearest neighbors instead of just the nearest neighbor (i.e.,  $k = 1$ ) in all of the pruning rules (especially Pruning Rule 5). Furthermore, use of the MINDIST ordering in conjunction with the MEANORPIVOTDIST ordering, as well as the application of the tighter pruning criteria, represents an improvement in terms of the number of objects that can eventually be pruned.

OPTDFTRAV processes each nonobject element  $e_p$  as a unit. This means that Pruning Rule 3 is inapplicable when the mean or pivot  $M_p$  is an element of  $e_p$  as then  $r_{p,min} = 0$ . This situation can be avoided, although we do not do so here, by modifying OPTDFTRAV to process the means or pivots  $M_p$  separately from the rest of the elements of nonobject element  $e_p$  (see Exercise 8 and Exercise 1 in Section 4.2.6). In particular, this will permit

us to try to take advantage of the value of  $r_{p,min}$ , even when  $M_p$  is an element of  $e_p$  (i.e., permitting the use of Pruning Rule 3).

### Exercises

1. How can a situation arise that there are two or more nonobjects in  $L$  with the same MAX-NEARESTDIST value?
2. Suppose that the search hierarchy is such that each cluster  $e_p$ , besides having a mean  $M_p$ , also has a maximum distance  $r_{p,max}$ , as is the case for the M-tree. Can you formulate the condition for the application of Pruning Rules 2 and 4 to be in terms of  $r_{p,max}$ ,  $d(q, M)$ ,  $d(M, M_p)$ , and  $D_k$ , instead of in terms of  $\text{MINDIST}(M, e_p)$ ,  $\text{MAXDIST}(M, e_p)$ ,  $d(q, M)$ ,  $d(M, M_p)$ , and  $D_k$  so that there is no need to make an explicit distinction between whether  $M$  is closer to  $M_p$  than to  $q$ ?
3. Prove that nonobject element  $e_p$  in the active list of nonobject element  $e$  with mean  $M$  and distance  $\text{MAXDIST}(M, e_p)$  from  $M$  to the farthest object within  $e_p$ , where  $M$  is closer to the object at distance  $\text{MAXDIST}(M, e_p)$  than to  $q$ , cannot contain the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + \text{MAXDIST}(M, e_p) < d(q, M)$ , where  $D_k$  is the distance from  $q$  to the farthest of the current candidate  $k$  nearest neighbors—that is, prove that Pruning Rule 2 for nonobjects is correct.
4. Prove that nonobject element  $e_p$  in the active list of nonobject element  $e$  with mean  $M$  and distance  $\text{MAXDIST}(M, e_p)$  from  $M$  to the farthest object within  $e_p$  and distance  $\text{MINDIST}(M, e_p)$  from  $M$  to the nearest object within  $e_p$ , where  $M$  is closer to  $q$  than to the object at distance  $\text{MINDIST}(M, e_p)$ , cannot contain the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + d(q, M) < \text{MINDIST}(M, e_p)$ , where  $D_k$  is the distance from  $q$  to the farthest of the current candidate  $k$  nearest neighbors—that is, prove that Pruning Rule 4 for nonobjects is correct.
5. Can you incorporate Pruning Rules 2 and 4 for nonobjects in OPTDFTRAV by sorting the nonobjects in nonleaf node  $e$  with mean  $M$  in  $\text{MINDIST}$  order with respect to  $M$  instead of  $\text{MAXDIST}$  order? If yes, then explain how this can be achieved; otherwise, explain why it cannot.
6. In the case of objects, Pruning Rules 2 and 4 are incorporated in OPTDFTRAV by first sorting the objects in  $e$  with mean  $M$  in increasing order of their distances from  $M$ , which are computed once and stored with  $e$ , and then only computing the distance  $d(q, o)$  for the objects  $o$  whose distance from  $M$  lies between  $d(q, M) - D_k$  and  $d(q, M) + D_k$ . In the case of nonobjects, they are incorporated by sorting the nonobjects in  $e$  with mean  $M$  in increasing  $\text{MAXDIST}$  order and only computing the distance  $d(q, e_p)$  for the nonobjects  $e_p$  whose  $\text{MAXDIST}$  from  $M$  is greater than or equal to  $d(q, M) - D_k$  and for which  $\text{MINDIST}$  from  $M$  is less than or equal to  $d(q, M) + D_k$ . Thus, there is no upper bound on the  $\text{MAXDIST}(M, e_p)$  values that must be checked, which is different from the incorporation of these rules for objects where there is both a lower and upper bound on the range. Explain why we cannot have both a lower and upper bound on the range in the case of nonobjects.
7. Suppose that we support the incorporation of Pruning Rules 2 and 4 for nonobjects in OPTDFTRAV by using two sorted lists in order to overcome the drawbacks of the current solution embodied by OPTDFTRAV as pointed out in Exercise 6. In particular, sort all nonobjects  $e_p$  in  $e$  in increasing and decreasing order with respect to  $M$  using  $\text{MAXDIST}$  and  $\text{MINDIST}$ , and store them in  $\text{MX}(e)$  and  $\text{MN}(e)$ , respectively. The solution has two parts. First, find the first object  $e_p$  in  $\text{MX}(e)$  such that  $\text{MAXDIST}(M, e_p) \geq d(q, M) - D_k$  and then insert each of the ensuing nonobjects  $e_i$  with mean  $M_i$  into the active list as long as  $d(M_i, M) \leq d(q, M)$ , which is equivalent to requiring that  $M$  be closer to  $e_i$  than to  $q$ . Next, find the first object  $e_p$  in  $\text{MN}(e)$  such that  $\text{MINDIST}(M, e_p) \leq d(q, M) + D_k$  and then insert each of the ensuing nonobjects  $e_i$  with mean  $M_i$  into the active list as long as  $d(M_i, M) > d(q, M)$ , which is equivalent to requiring that  $M$  be closer to  $q$  than to  $e_i$ . Give a code fragment to implement this strategy by replacing lines 24–30 in OPTDFTRAV. Will this method work? In other words, is it guaranteed to insert all relevant nonobjects into the active list?
8. (Daniel DeMenthon) Modify procedure OPTDFTRAV to process the means or pivots  $M_p$  of nonobject element  $e_p$  separately from the rest of the elements of  $e_p$  so that you can take

advantage of  $r_{p,min}$  even when  $M_p$  is an element of  $e_p$  (i.e., enabling the use of Pruning Rule 3).

9. Implement procedure KNEAREST with OPTDFTRAV and run it on some test data using an R-tree search hierarchy with minimum bounding hyperrectangles (e.g., an R\*-tree [152]). Perform the comparison using different values of  $k$ . Is there a qualitative difference in performance comparable to that reported by Kamgar-Parsi and Kanal [986] with respect to the use of the various pruning rules? Also, compare its performance with that of an implementation that just makes use of Pruning Rule 1, as done by Roussopoulos et al. [1586].
10. Implement procedure KNEAREST with OPTDFTRAV as in Exercise 9, and compare its performance with that of the general incremental algorithm using an R-tree search hierarchy with minimum bounding hyperrectangles (e.g., an R\*-tree [152]). Perform the comparison using different values of  $k$ . Is there a difference from the results reported in [848], which perform the comparison with the implementation of Roussopoulos et al. [1586], which only makes use of Pruning Rule 1?
11. How would you adapt Pruning Rules 2 and 4 so that each one can be applied to nonobject elements when finding the  $k$  farthest neighbors?
12. Give the analog procedure OPTDFTRAVFARTHEST of OPTDFTRAV for finding the  $k$  farthest neighbors using the approach outlined in Exercise 2 in Section 4.2.1. Incorporate the modified Pruning Rules 1–5 given in Exercise 17 of Section 4.2.2 as well as Pruning Rules 2 and 4 for nonobjects as in Exercise 11.
13. Repeat Exercise 12 using the approach outlined in Exercise 3 of Section 4.2.1.

## 4.2.6 Incorporating MAXNEARESTDIST in a Best-First Algorithm

Incorporating Pruning Rule 5 (i.e., MAXNEARESTDIST) in the depth-first  $k$ -nearest neighbor algorithm, resulting in what we call the maxnearest depth-first algorithm, can be viewed as providing a middle ground between a pure depth-first and a best-first  $k$ -nearest neighbor algorithm. In particular, assuming  $N$  data items, the priority queue  $L$  in the maxnearest depth-first algorithm behaves in a similar manner as the priority queue *Queue* in the incremental implementation of the best-first  $k$ -nearest neighbor algorithm (i.e., so that it returns the  $k$  nearest neighbors while also enabling continuing the algorithm to obtain more neighbors, such as the  $(k + 1)$ -th, etc.), except that the upper bound on  $L$ 's size is  $k$ , whereas the upper bound on the size of *Queue* is  $O(N)$ . In contrast, in all of the versions of the depth-first algorithms that we have presented, the worst-case total storage requirements only depend on the nature of the search hierarchy (i.e., the maximum height of the search hierarchy, which is  $O(\log N)$ ), instead of on the size of the dataset, as is the case for the best-first algorithm.

The difference in the maximum storage requirements of the depth-first and best-first algorithms is caused by several factors. First of all, in the incremental implementation of the best-first  $k$ -nearest neighbor algorithm, no objects or nonobjects can ever be deleted from the priority queue *Queue* as they may eventually be needed. Second, even if the best-first algorithm is implemented to return only the  $k$  nearest neighbors, then *Queue* may still be as large as the entire dataset. For example, recall from Figure 4.4 and the discussion in Section 4.1.3 that such a situation can arise when all of the leaf nonobject elements of the search hierarchy are within distance  $d$  from the query object  $q$ , while all of the data objects are farther away from  $q$  than  $d$ .

The best-first algorithm can be implemented to return only the  $k$  nearest neighbors by keeping track of the  $k$  nearest objects in a separate data structure, say  $C$ , and modifying the algorithm so that no objects are inserted into *Queue* that are farther from  $q$  than the farthest of the current  $k$  candidate nearest neighbors.<sup>17</sup> As the  $k$  nearest objects must eventually be inserted into  $C$  when they reach the front of *Queue*, we might as well

---

<sup>17</sup> It should be clear that no nonobjects farther from  $q$  than the farthest of the current  $k$  candidate nearest neighbors should be inserted into *Queue* since the fact that the nonobjects are processed in order

insert them into  $C$  immediately when they are first encountered and possibly remove them from  $C$  if closer objects are eventually encountered. This means that  $Queue$  now contains only nonobject elements, and, in fact,  $C$  is the same as  $L$  and thus we just make use of  $Queue$  and  $L$ . Such a solution was proposed by Hjaltason and Samet [851] and is described briefly in Section 4.1.5.

Procedure BFTRAV corresponds to this solution, with  $D_k$  again indicating the distance of the current  $k$ th-nearest neighbor of  $q$  (initialized to  $\infty$ ). BFTRAV has a structure that combines features from both INCNEAREST in Section 4.1.3 and DFTRAV in Section 4.2.1. In this case,  $Queue$  is implemented in the same way as  $L$ , which means that each element  $e$  in  $Queue$  has two fields E and D, corresponding to the nonobject  $i$  that  $e$  contains and the value of  $MINDIST(q, i)$ , respectively.  $Queue$  is initialized with the root of the search hierarchy and a  $MINDIST$  value of 0. Notice the use of INSERTL to insert objects in the priority queue  $L$  instead of ENQUEUE as in procedure INCNEAREST since  $L$  has a fixed size, which means that a check for  $L$  being full must be performed before the insertion is actually made.

```

1  priority_queue procedure BFTRAV( $q, k, S, T$ )
2  /* A best-first nonincremental algorithm that returns a priority queue contain-
   *   ing the  $k$  nearest neighbors of  $q$  from the set of objects  $S$  organized using
   *   the search hierarchy  $T$ . */
3  value object  $q$ 
4  value integer  $k$ 
5  value object_set  $S$ 
6  value pointer search_hierarchy  $T$ 
7  integer  $D_k$ 
8  priority_queue  $L, Queue$ 
9  priority_queue_entry  $t$ 
10 object  $o$ 
11 pointer search_hierarchy  $e, e_p$ 
12  $L \leftarrow NEWPRIORITYQUEUE()$  /*  $L$  is the priority queue containing the  $k$ 
   *   nearest objects */
13  $Queue \leftarrow NEWPRIORITYQUEUE()$ 
14  $e \leftarrow$  root of the search hierarchy induced by  $S$  and  $T$ 
15 ENQUEUE( $e, 0, Queue$ )
16  $D_k \leftarrow \infty$ 
17 while not ISEMPY( $Queue$ ) do
18    $t \leftarrow$  DEQUEUE( $Queue$ )
19    $e \leftarrow E(t)$ 
20   if  $D(t) > D_k$  then
21     return  $L$  /*  $k$  nearest neighbors were found, and exit */
22   elseif ISLEAF( $e$ ) then /*  $e$  is a leaf with objects */
23     foreach object child element  $o$  of  $e$  do
24       Compute  $d(q, o)$ 
25       if  $d(q, o) < D_k$  then
26         INSERTL( $o, d(q, o), k, L, D_k$ )
27       endif
28     enddo
29   else
30     foreach child element  $e_p$  of  $e$  do
31       ENQUEUE( $e_p, MINDIST(q, e_p), Queue$ )
32     enddo
33   endif
34 enddo

```

---

of increasing  $MINDIST$  values means that they will never be removed from  $Queue$  should they ever have been inserted.

Thus, we see that the best-first algorithm given by BFTRAV uses the current  $k$  candidate nearest neighbors to prune objects from further consideration by not inserting them into *Queue* or  $L$ . On the other hand, the maxnearest depth-first algorithm (as implemented by OPTDFTRAV) also employs the estimate MAXNEARESTDIST to enable the use of the nonobject elements of the search hierarchy to speed up the convergence of  $D_k$  to its final value, thereby helping to prune the set of  $k$  candidate nearest neighbors instead of pruning only with the aid of the  $k$  nearest objects, as in the implementation of the best-first algorithm given by BFTRAV. It should be clear that the facts that a best-first algorithm examines the nonobject elements in increasing MINDIST order and that every nonobject element with MINDIST less than  $D_k$  must be examined together mean that no matter how fast the value of  $D_k$  converges to its final value, a best-first algorithm will never examine any extra nonobject elements. Therefore, use of an estimate such as MAXNEARESTDIST cannot have the same effect on a best-first algorithm as it can on a depth-first algorithm.

However, as we show below, the best-first algorithm given by BFTRAV can be adapted to use the estimate MAXNEARESTDIST to speed up the convergence of  $D_k$  to its final value and thereby reduce the size of *Queue* when finding the  $k$  nearest neighbors by checking if the MAXNEARESTDIST estimate for a given nonobject element  $e$  is less than  $D_k$ , in which case an entry corresponding to  $e$  is inserted in  $L$ . We characterize the result as a *maxnearest best-first  $k$ -nearest neighbor algorithm*. Such an algorithm is realized by procedure OPTBFTRAV as given below. It is a combination of BFTRAV and OPTDFTRAV and also incorporates Pruning Rules 1–4.

```

1  priority_queue procedure OPTBFTRAV( $q, k, S, T$ )
2  /* A best-first nonincremental algorithm that returns a priority queue contain-
   ing the  $k$  nearest neighbors of  $q$  from the set of objects  $S$  organized using
   the search hierarchy  $T$ . The algorithm makes use of the MAXNEAREST-
   DIST estimate and Pruning Rules 1–4. */
3  value object  $q$ 
4  value integer  $k$ 
5  value object_set  $S$ 
6  value pointer search_hierarchy  $T$ 
7  integer  $D_k$ 
8  priority_queue  $L, Queue$ 
9  priority_queue_entry  $t$ 
10 object  $o$ 
11 pointer search_hierarchy  $e, e_p$ 
12  $L \leftarrow$  NEWPRIORITYQUEUE() /*  $L$  is the priority queue containing the  $k$ 
   nearest objects */
13 ENQUEUE( $e, \text{MAXNEARESTDIST}(q, e), L$ )
14  $Queue \leftarrow$  NEWPRIORITYQUEUE()
15  $e \leftarrow$  root of the search hierarchy induced by  $S$  and  $T$ 
16 ENQUEUE( $e, 0, Queue$ )

```

OPTBFTRAV processes all nonobject elements in *Queue* in the order in which they appear in *Queue* (i.e., the element  $e$  at the front is processed first). We first remove  $e$  from *Queue* (lines 19–20) and also check if  $e$  should be explicitly removed from  $L$  using the same method as in OPTDFTRAV (lines 23–28). Recall that this step ensures that the objects that are associated with the different entries in  $L$  are unique. This removal step is missing in a variant of a best-first algorithm that uses MAXNEARESTDIST proposed by Ciaccia, Patella, and Zezula for the M-tree [389], thereby possibly leading to erroneous results. Next, we check if  $e$  is a leaf element, in which case we test for the applicability of Pruning Rules 2 and 4 using the same method as in OPTDFTRAV (lines 31–38). Otherwise, we examine each of  $e$ 's child elements  $e_p$  that is not pruned by Pruning Rules 2 and 4 (lines 41–44) and insert  $e_p$  and its associated MINDIST( $q, e_p$ ) value into *Queue* (line 51) if MINDIST( $q, e_p$ ) is less than or equal to  $D_k$ , which is equivalent to determining that Pruning Rules 1 and 3 do not hold (line 46). Note that Pruning Rules 1–4 are used here to reduce the size of the priority queue *Queue* rather than for pruning nonobject elements from further processing, as in the depth-first algorithm OPTDFTRAV. When MINDIST( $q, e_p$ )  $\leq D_k$ , we also check if  $e_p$ 's associated MAXNEARESTDIST( $q, e_p$ ) value is less than  $D_k$  (line 48), in which case we use OPTINSERTL to insert  $e_p$  and MAXNEARESTDIST( $q, e_p$ ) into  $L$  and possibly reset  $D_k$  (line 49). As in OPTDFTRAV, this action may cause some elements (both objects and nonobjects) to be implicitly

removed from  $L$ . Thus, the MAXNEARESTDIST estimate is used here to tighten the convergence of  $D_k$  to its final value.

As OPTBFTRAV proceeds, we find that the distances of the farthest object in  $L$  and the closest nonobject in  $Queue$  converge toward each other from  $\infty$  and 0, respectively. OPTBFTRAV halts (line 21) once it encounters an element at the front of  $Queue$  whose associated distance value (i.e., MINDIST) is greater than  $D_k$ , the distance value associated with the object at the front of  $L$  (i.e., MAXDIST). This is another instance where Pruning Rules 1 and 3 are invoked, but this time it is done implicitly as their deployment is an inherent part of OPTBFTRAV by virtue of the use of MINDIST to order the processing of the nonobject elements. It is interesting to compare the use of Pruning Rules 1 and 3 in OPTBFTRAV with their use in the depth-first algorithm given by OPTDFTRAV, where they are used in conjunction with MINDIST to order the processing of the nonobject elements of the active list. However, the ordering in OPTDFTRAV is only local in the sense that it only involves the nonobject elements of the current active list, and thus once the pruning rules are found to be applicable, we only cease to process the nonobject elements of the current active list. In contrast, in OPTBFTRAV the ordering is global in the sense that it involves all of the nonobject elements, and thus once the pruning rules are found to be applicable, the algorithm terminates.

Notice that, in contrast to the depth-first algorithm OPTDFTRAV (recall Exercise 1 in Section 4.2.1), in the best-first algorithm OPTBFTRAV, the nonobject child elements  $e_p$  of nonobject element  $e$  (i.e., analogous to the elements of the active list of  $e$  in the case of the depth-first algorithm) need not be (and are not) sorted with respect to their distance (MINDIST or MAXNEARESTDIST) from  $q$  before we test for the possibility of insertion into  $L$  and enqueueing into  $Queue$  (lines 41–55). In particular, assuming that the active list contains  $T$  elements, there is no advantage to incurring the extra time needed to sort the child elements (i.e., an  $O(T \log T)$  process) since all that the sort can accomplish is avoiding the tests (which is an  $O(T)$  process). However, the nonobject child elements of  $e$  are sorted in increasing MAXDIST order with respect to the mean  $M$  of  $e$  in order to support the use of Pruning Rules 2 and 4 for nonobjects in both OPTDFTRAV and OPTBFTRAV.

Observe also that the facts that each time a nonobject element  $e$  is removed from the priority queue  $Queue$ ,  $e$  is also removed from  $L$  if it is in  $L$  by virtue of its MAXNEARESTDIST value's being less than  $D_k$  and that  $\text{MINDIST}(q, e) \leq \text{MAXNEARESTDIST}(q, e)$  together ensure that there are no nonobject elements left in  $L$  when the best-first algorithm terminates (i.e., when the distance value associated with the first element in the priority queue  $Queue$  is greater than  $D_k$ ), and thus the elements in  $L$  are the  $k$  nearest neighbors of  $q$ . This is of interest because, when the best-first algorithm terminates, it is quite likely that the priority queue  $Queue$  is not empty as we do not constantly check it for the presence of nonobject elements with associated distance values greater than  $D_k$  each time the value of  $D_k$  decreases.

In addition, we point out that in the maxnearest depth-first algorithm, the nonobject elements are inserted into  $L$  with their corresponding MAXNEARESTDIST values, whereas in any best-first algorithm (including the maxnearest best-first algorithm), the nonobject elements are inserted into the priority queue  $Queue$  with their corresponding MINDIST values. Moreover, note that for the best-first nearest neighbor algorithm to be correct, the MINDIST value of any nonobject element  $e$  must be less than or equal to the distance from the query object  $q$  to any object in  $e$ 's descendants (recall Section 4.1.3), but in the maxnearest depth-first algorithm, neither is it the case that such a relationship holds between the MAXNEARESTDIST value of  $e$  and the objects in its descendants, nor is it required to hold for the correctness of the algorithm.

### Exercises

1. (Daniel DeMenthon) Modify procedure OPTBFTRAV to process the means or pivots  $M_p$  of nonobject element  $e_p$  separately from the rest of the elements of  $e_p$  so that you can take

Figure 4.24  
Example query object  $q$  and search hierarchy illustrating the ability of the MAXNEARESTDIST estimate to lead to additional pruning in the depth-first algorithm and to a reduction in the size of the priority queue in the depth-first algorithm.

advantage of  $r_{p,min}$  even when  $M_p$  is an element of  $e_p$  (i.e., enabling the use of Pruning Rule 3).

2. Give the analog procedure BFTRAVFARTHEST of BFTRAV for finding the  $k$  farthest neighbors in a best-first nonincremental manner using the approach outlined in Exercise 2 of Section 4.2.1.
3. Repeat Exercise 2 using the approach outlined in Exercise 3 of Section 4.2.1.
4. Give the analog procedure OPTBFTRAVFARTHEST of OPTBFTRAV for finding the  $k$  farthest neighbors in a best-first nonincremental manner using the approach outlined in Exercise 2 of Section 4.2.1. Incorporate the modified Pruning Rules 1–5 given in Exercise 17 of Section 4.2.2, as well as Pruning Rules 2 and 4 for nonobjects as in Exercise 11 of Section 4.2.5.
5. Repeat Exercise 4 using the approach outlined in Exercise 3 of Section 4.2.1.

## 4.2.7 Example

In this section we show with the aid of an example a situation where use of the MAXNEARESTDIST estimate can lead to additional pruning in the depth-first algorithm and, likewise, to a reduction in the size of the priority queue in the best-first algorithm. In particular, we use query point  $q$  and the search hierarchy given in Figure 4.24 consisting of three clusters A, B, and C with MINDIST values 5, 7, and 8 and MAXNEARESTDIST values 25, 13, and 16.55, respectively. We determine the two nearest neighbors (i.e.,  $k = 2$ ). We assume that the data is embedded in a two-dimensional Euclidean space. The search hierarchy could be realized by an index such as the M-tree [389].

The depth-first algorithm as encoded by procedure OPTDFTRAV starts with  $D_2$  and  $e$  initialized to  $\infty$  and the nonobject element corresponding to the universe, respectively. It first generates the active list, consisting of A, B, and C, in this order due to the associated MINDIST values and the fact that none of A, B, and C have been pruned by Pruning Rules 2 and 4. Next, it examines the elements of the active list and constructs  $L$ , which contains  $\{(B, 13), (A, 25)\}$  after processing the first two elements A and B. Once C has been processed,  $L$  contains  $\{(B, 13), (C, 16.55)\}$  as the MAXNEARESTDIST value associated with A (i.e., 25) is greater than the MAXNEARESTDIST value associated with C (i.e., 16.55), and thus  $D_2 = 16.55$ . Next, the active list, which is unchanged, is processed in order of increasing MINDIST values. Therefore, cluster A, containing clusters D, E, and F, with MINDIST values 17.36, 23, and 18.82, and MAXNEARESTDIST values 22.91, 29.61, and 23.17, respectively, is processed first. Since A is not a leaf, we process its child elements in increasing MAXDIST order with respect to the mean of cluster A and

generate the active list with all of them since none of them are pruned by Pruning Rule 2 (as they all have the same MAXDIST value of 15 and are all closer to the mean of cluster A than to  $q$ ). The active list is sorted in increasing MINDIST order, which leads to D, F, and E. However,  $\text{MINDIST}(q, D)$  is 17.36, which is greater than  $D_2 = 16.55$ , and thus we do not process further any of the elements of A's active list, which means that D, E, and F have been pruned. Clearly, the two nearest neighbors of  $q$  cannot be in cluster A. However, if we had not used the MAXNEARESTDIST estimate to set the value of  $D_2$ , then we would have had to examine further elements or objects in D, E, and F. The algorithm continues by processing cluster B.

Applying the best-first algorithm as encoded by procedure OPTBFTRAV starts out with  $D_2$  initialized to  $\infty$  and the priority queue *Queue* initialized to the universe. At this point, it dequeues the universe from *Queue* and examines all of its constituent clusters in increasing MAXDIST order with respect to the mean of the universe (which is an arbitrary value, say 0, without loss of generality) as Pruning Rules 2 and 4 do not yield any pruning due to  $D_2$ 's having an initial value of  $\infty$ . Assume, without loss of generality, that the initial order is A, B, and C. During this process, OPTBFTRAV constructs  $L$ , which contains  $\{(B, 13), (A, 25)\}$  after processing the first two elements A and B, while entering them into *Queue* with their corresponding MINDIST values. Once C has been processed,  $L$  contains  $\{(B, 13), (C, 16.55)\}$  as the MAXNEARESTDIST value associated with A (i.e., 25) is greater than the MAXNEARESTDIST value associated with C (i.e., 16.55), and thus  $D_2 = 16.55$ , while *Queue* contains A, B, and C in this order. Next, the closest element of *Queue* to  $q$ , which is A, is removed from *Queue*, but there is no need to adjust  $D_2$  as the MAXNEARESTDIST value associated with A (i.e., 25) is greater than that of  $D_2$ , which is 16.55. Since A is not a leaf, we process its child elements in increasing MAXDIST order with respect to the mean of cluster A. As they all have the same MAXDIST value of 15, which means that none of them are pruned by Pruning Rule 2 (as they are all closer to the mean of cluster A than to  $q$ ), we process them in arbitrary order, say D, E, and F, and check if their corresponding MINDIST values are greater than  $D_2$ . The fact that they are all greater than  $D_2$  means that they could never contain the two nearest neighbors of  $q$ , and thus they are not enqueued in *Queue*. However, if we had not used the MAXNEARESTDIST estimate, then we would have had to enqueue D, E, and F as  $D_2 = \infty$  initially, even though we would never dequeue them and hence never further examine elements or objects in them. Thus, the maximum possible size of the priority queue has been decreased by the use of the MAXNEARESTDIST estimate. The algorithm continues by processing cluster B, which is the closest element in *Queue* to  $q$ .

From this example, we see that use of the MAXNEARESTDIST estimate has enabled us to satisfy our goal of enhancing the performance of both the depth-first and best-first  $k$ -nearest neighbor algorithms. In particular, in the case of the depth-first algorithm, we have pruned elements from further processing, and in the case of the best-first algorithm, we have reduced the maximum possible size of the priority queue.

## 4.2.8 Comparison

In Sections 4.2.5 and 4.2.6, we have shown how to incorporate an estimate of the maximum possible distance at which a nearest neighbor is guaranteed to be found (termed MAXNEARESTDIST) to enhance the performance of both a depth-first branch and bound and a best-first  $k$ -nearest neighbor finding algorithm by virtue of yielding tighter initial estimates of  $D_k$ . Thus, we can start pruning elements of the search hierarchy (both objects and nonobjects) without having to wait until we have encountered the first  $k$  objects as this is the first time that  $D_k$  is reset from its initial value of  $\infty$  in the traditional algorithms.

In the case of the depth-first algorithm, the enhancement lies in not having to process some of the nonobject elements of the search hierarchy, thereby making the algorithm faster with no increase in the storage requirements. On the other hand, in the case of the best-first algorithm, the enhancement lies in reducing the size of the priority queue *Queue*

as the tighter initial estimates of  $D_k$  result in the insertion of fewer nonobject elements into *Queue*. The motivation for this is the observation that the nonobject elements that have not been inserted into *Queue* never would have been expanded anyway since their MINDIST values are greater than  $D_k$ , and thus there cannot be any reduction in execution time, which means that space in *Queue* should not be wasted to store them. An alternative rationale for this is to recall that, in the best-first algorithm, because the nonobject elements are examined in increasing order of  $D_k$  and because every nonobject element with MINDIST less than  $D_k$  must be examined no matter how fast the value of  $D_k$  is reduced, the algorithm will never examine any extra nonobject elements. Thus, use of an estimate such as MAXNEARESTDIST cannot have the same effect on a best-first algorithm as it can on a depth-first algorithm.

In general, it is well-known that depth-first  $k$ -nearest neighbor algorithms may achieve less pruning of the search space and therefore perform worse, as measured by the number of visited search hierarchy elements, than algorithms that apply best-first search on the same search hierarchy. The problem is that a depth-first algorithm must make local decisions about the next element to be visited, choosing among the children of a single element (the elements in the active list  $A$  of  $e$  that have not yet been visited) based on the current value of  $D_k$ . In contrast, a best-first algorithm makes global decisions about the next element to be visited. In particular, the global set of unvisited elements sorted by their distance from the query object that is maintained by the best-first algorithm essentially corresponds to the union of the unvisited portions of the active lists  $A$  in the depth-first algorithm for all elements  $e$  on the path from the root to the element that is currently being visited. Thus, while the best-first algorithm visits an element  $e$  only if  $d(q, e) \leq d(q, o_k)$ , where  $o_k$  is the  $k$ th-nearest neighbor 5 (since the elements are visited in order of distance), the depth-first algorithm may visit an element  $e_p$  with  $d(q, e_p) > d(q, o_k)$ , since  $D_k$  may be much larger than  $d(q, o_k)$  for much of the duration of the search, especially early on.

Notice that these observations are also true for variants of the depth-first algorithms that attempt to improve performance by introducing aggressive pruning (effectively by reducing  $D_k$ ), such as those described for the vp-tree by Chiueh [376].<sup>18</sup> Although such strategies can narrow the performance gap of a depth-first algorithm vis-à-vis a best-first algorithm, they cannot visit fewer elements in the search hierarchy than a best-first algorithm without taking the risk of missing some of the  $k$  nearest neighbors of  $q$ . In fact, when such an aggressive algorithm detects that too much pruning has taken place (which may well be a common occurrence), the search hierarchy must be traversed again, this time with less aggressive pruning. Hence, the average performance gain of aggressive pruning may be modest.

The manner in which we incorporated the MAXNEARESTDIST estimate in the maxnearest depth-first  $k$ -nearest neighbor algorithm (i.e., OPTDFTRAV) enables us to overcome the lower pruning power of the depth-first algorithm vis-à-vis the best-first algorithm as it enables the use of its result at a deeper level than the one at which it is calculated. In particular, the use of  $L$  to store the MAXNEARESTDIST values of some active nonobject elements means that a MAXNEARESTDIST value of an unexplored nonobject at depth  $i$  can be used to help in pruning objects and nonobjects at depth  $j > i$ . This is a significant improvement over the depth-first algorithm DFTRAV, where the MAXNEARESTDIST value of a nonobject element at depth  $i$  could only be used to tighten the distance to the nearest neighbor (i.e., for  $k = 1$ ) and to prune nonobject elements at larger MINDIST values at the same depth  $i$ . Thus, we see that the manner

---

<sup>18</sup> Chiueh [376] suggested using an estimate of the upper bound on the distance to the nearest neighbor in each subtree to bound the search in that subtree, thus yielding an algorithm that performs a “bounded” nearest neighbor search of each subtree (in the reported experiments, a simpler strategy was employed that made use of an estimate of the maximum upper bound over all nodes of the vp-tree). Of course, if the upper bound estimate is too low, it may be necessary to apply the algorithm with a higher estimate.

in which MAXNEARESTDIST is used in OPTDFTRAV can be viewed as providing a middle ground between a pure depth-first and a best-first  $k$ -nearest neighbor algorithm by enabling more nonobject elements to be used in tightening the value of  $D_k$ .

On the other hand, the drawback of any best-first algorithm (including ours with the MAXNEARESTDIST estimate) is the need for the priority queue *Queue*, which, in the worst case, may be as large as the entire dataset. In contrast, as we pointed out, any implementation of the depth-first algorithm (including ours with the MAXNEARESTDIST estimate) only requires storage for  $L$  (which is  $k$ ) and the recursive calls of the algorithm corresponding to the depth of the search hierarchy, which is  $O(\log N)$  for a dataset of size  $N$ . Note, however, that for  $k$ -nearest neighbor computation, when data is stored on disk, which is often the case in practical applications, the priority queue *Queue* is relatively small because it only contains pairs of disk page addresses and distances.

Of course, in the case of a ranking operation (i.e., when we must report the neighbors in an incremental manner without knowledge of the number of neighbors that will ultimately be required), this size drawback of best-first algorithms is irrelevant as no implementations of the depth-first algorithm (including one that makes use of OPTDFTRAV) can be used since they all prune some of the elements of the search hierarchy from further consideration. In other words, in order to be able to perform ranking, any implementation of the depth-first algorithm (including one that makes use of OPTDFTRAV) would need to retain these elements for possible further processing.

The manner in which we incorporate the MAXNEARESTDIST estimate in the max-nearest best-first  $k$ -nearest neighbor algorithm (i.e., OPTBFTRAV) enables us to reduce some of the storage requirements of the algorithm, thereby lessening the storage penalty incurred by using the best-first algorithm vis-à-vis the depth-first algorithm. Thus, we see that use of the MAXNEARESTDIST estimate enhances the performance of both the depth-first and best-first algorithms by addressing their shortcomings—that is, by reducing the execution time of the former and reducing the storage requirements of the latter, at no cost in extra execution time for the latter or extra storage requirements for the former.

It is important to note that the above comparison of the effects of the use of the MAXNEARESTDIST estimate in the depth-first and best-first  $k$ -nearest neighbor algorithms does not address the relative performance of the two algorithms, which is a more general issue and beyond the scope of this discussion. Nevertheless, experiments conducted by Hjaltason and Samet [848] showed that for an R-tree spatial index, a best-first  $k$ -nearest neighbor algorithm implemented using procedure INCNEAREST performed better in terms of execution time than a depth-first algorithm implemented using the method of Roussopoulos et al. [1586]. In fact, Berchtold, Böhm, Keim, and Kriegel [186] have proved that the best-first algorithm is I/O optimal in terms of the number of disk page accesses when the query object and the data objects are points and  $k = 1$ . In particular, they show that the number of disk accesses is generally smaller than that needed by the depth-first algorithm (see Exercise 1). The I/O optimality of the general incremental algorithm is not surprising given our prior demonstration in Section 4.1.3 that it is r-optimal.

The depth-first  $k$ -nearest neighbor algorithm that we have presented, as embodied by procedure OPTDFTRAV, is very different from that of previous work. It differs considerably from Roussopoulos et al.'s [1586] implementation of the depth-first algorithm, which, like that of Larsen and Kanal [1103], only incorporates the MAXNEARESTDIST estimate for  $k = 1$  instead of for arbitrary values of  $k$ . Moreover, besides being formulated in terms of a more general cluster element than a hyperrectangle minimum bounding object, OPTDFTRAV also applies pruning to the objects and nonobjects in each of the leaf and nonleaf elements, respectively, of the search structure (i.e., Pruning Rules 2 and 4), which is not done in the implementation of Roussopoulos et al. [1586]. Furthermore, we observe that OPTDFTRAV is very different from the original algorithm of Fukunaga and Narendra [666], as well as from the enhancements of Kamgar-Parsi and Kanal [986], neither of which make use of the MAXNEARESTDIST estimate.

The best-first  $k$ -nearest neighbor algorithm that we have presented as embodied by procedure OPTBFTRAV is different from a previous adaptation of INCNEAREST to the M-tree by Ciaccia et al. [389] (see Section 4.5.4.2) in the following respects. First, it incorporates the MAXNEARESTDIST estimate correctly for  $k > 1$ . Second, it is more general in that it is applicable to more search hierarchies, instead of being limited to the M-tree. Third, it contains a more efficient implementation of Pruning Rules 2 and 4 for both objects and nonobjects by sorting them with respect to the mean in each cluster. Finally, it takes advantage of the priority queue of nonobjects that remain to be visited by making the nonobject element with the smallest MINDIST value immediately accessible and by not having to remove explicitly previously enqueued nonobject elements with MINDIST values greater than  $D_k$ , as done by Ciaccia et al. [389].

*Exercise*

1. Give an example of a situation for point data where use of the general incremental algorithm to find the  $k$  nearest neighbors performs fewer page accesses than using an implementation of the depth-first algorithm that makes use of a MINDIST ordering (e.g., the one of Roussopoulos et al. [1586]). In order to simplify your task, use a minimum bounding hyperrectangle search hierarchy, and assume that each page is a minimum bounding hyperrectangle.

### 4.3 Approximate Nearest Neighbor Finding

In many applications, obtaining exact results is not critical. Therefore, users are willing to trade accuracy for improved performance. There are two principal methods of proceeding. The first method, and the one discussed in this section, is based on the use of an approximation error tolerance  $\varepsilon$ . In particular, the approximation criterion is that the distance between the query object  $q$  and the resulting candidate nearest neighbor  $o'$  is within a factor of  $1 + \varepsilon$  of the distance to the actual nearest neighbor  $o$ —that is,  $d(q, o') \leq (1 + \varepsilon) \cdot d(q, o)$  (see Exercise 1). This is the basis of the bulk of the work on approximate nearest neighbor search (e.g., [100]).

An alternative method is one where the approximation criterion is the result of treating the nearest neighbor relation as an “equivalence” relation, which is generally not true because the nearest neighbor relation is not necessarily symmetric or transitive and because of the absence of equivalence classes. This type of an approximation is the basis of the Spatial Approximation Sample Hierarchy (SASH) approximate search strategy [883, 884], which has been successfully deployed in applications involving very high dimensions, as well as those where only a similarity/dissimilarity measure is available that need not be a distance metric. This is discussed in more detail in Section 4.5.8.

Both the depth-first and best-first  $k$ -nearest neighbor algorithms can be adapted to return the approximate nearest neighbors using the first method, although it is more common to adapt the best-first algorithms, and this is the focus of this section (but see Exercises 3–5). The reason is that the motivation behind loosening the criterion as to what constitutes a nearest neighbor is to speed up the process, which is more in the spirit of the best-first algorithms that are inherently designed to cease processing as soon as the desired number of neighbors is found rather than possibly exploring the entire search hierarchy, as is the case for some of the depth-first algorithms. Regardless of whether the approximate  $k$ -nearest neighbor algorithm is an adaptation of the best-first or depth-first  $k$ -nearest neighbor algorithm, it is important to observe that, as a result, some of  $q$ 's exact  $k$  nearest neighbors that are within a factor of  $1 + \varepsilon$  of the distance  $D_k$  of  $q$ 's approximate  $k$ th-nearest neighbor (including the exact  $k$ th-nearest neighbor  $o_k$ ) may be missed (i.e., those neighbors  $o$  where  $D_k/(1 + \varepsilon) \leq d(q, o) < D_k$ ).

A number of approximate  $k$ -nearest neighbor algorithms make use of a priority queue *Queue* to support a “best-first” traversal. Most of these algorithms (e.g., [100, 387, 1286])

only store the nonobject elements of the spatial index in *Queue* (of course, sorted in the order of their distance from  $q$ ). In particular, they do not store the objects (usually points) in *Queue*. Thus, these algorithms have the same control structure as the basic best-first  $k$ -nearest neighbor algorithm BFTRAV given in Section 4.2.6. Procedure ANNBFTAV, given below, is an example of one such adaptation.

```

1  priority_queue procedure ANNBFTAV( $q, k, \varepsilon, S, T$ )
2  /* A best-first nonincremental algorithm that returns a priority queue contain-
   ing the  $k$  approximate nearest neighbors of  $q$  within a factor of  $1 + \varepsilon$  of the
   distance to the actual  $k$ th-nearest neighbor from the set of objects  $S$  orga-
   nized using the search hierarchy  $T$ . */
3  value object  $q$ 
4  value integer  $k, \varepsilon$ 
5  value object_set  $S$ 
6  value pointer search_hierarchy  $T$ 
7  integer  $D_k$ 
8  priority_queue  $L, Queue$ 
9  priority_queue_entry  $t$ 
10 object  $o$ 
11 pointer search_hierarchy  $e, e_p$ 
12  $L \leftarrow \text{NEWPRIORITYQUEUE}()$  /*  $L$  is the priority queue containing the  $k$ 
   nearest objects */
13  $Queue \leftarrow \text{NEWPRIORITYQUEUE}()$ 
14  $e \leftarrow \text{root of the search hierarchy induced by } S \text{ and } T$ 
15  $\text{ENQUEUE}(e, 0, Queue)$ 
16  $D_k \leftarrow \infty$ 
17 while not  $\text{ISEMPTY}(Queue)$  do
18    $t \leftarrow \text{DEQUEUE}(Queue)$ 
19    $e \leftarrow \text{E}(t)$ 
20   if  $\text{D}(t) > D_k / (1 + \varepsilon)$  then
21     return  $L$  /* Found  $k$  approximate nearest neighbors and exit */
22   elseif  $\text{ISLEAF}(e)$  then /*  $e$  is a leaf with objects */
23     foreach object child element  $o$  of  $e$  do
24       Compute  $d(q, o)$ 
25       if  $d(q, o) < D_k$  then
26          $\text{INSERTL}(o, d(q, o), k, L, D_k)$ 
27       endif
28     enddo
29   else
30     foreach child element  $e_p$  of  $e$  do
31       if  $\text{MINDIST}(q, e_p) < D_k / (1 + \varepsilon)$  then
32          $\text{ENQUEUE}(e_p, \text{MINDIST}(q, e_p), Queue)$ 
33       endif
34     enddo
35   endif
36 enddo
37 return  $L$ 

```

These algorithms work by shrinking the distance  $D_1$  ( $D_k$ ) from  $q$  to the closest ( $k$ th-nearest, in which case the  $k$  objects are maintained in  $L$ ) object  $o$  by a factor of  $1 + \varepsilon$  and by only inserting the nonobject element  $e_p$  into *Queue* if the minimum distance from  $q$  to an object in  $e_p$  (i.e.,  $\text{MINDIST}(q, e_p)$ ) is less than this shrunken distance (lines 31–32).  $D_1$  ( $D_k$ ) and  $o$  ( $L$ ) are updated as nonobject leaf elements are removed from *Queue*.

The algorithms process the elements in *Queue* in increasing order of their distance from  $q$  and halt when the element  $t$  corresponding to nonobject element  $e$  with distance  $\text{D}(t)$  (i.e.,  $\text{MINDIST}(q, e)$ ) is removed from *Queue*, where  $\text{D}(t)$  is greater than the shrunken distance (i.e., lines 20–21) as all remaining nonobject elements in *Queue* are

at the same or greater distance, and thus the objects that they contain are too far away from  $q$ . Of course, letting  $\varepsilon = 0$  means that this approach can also be used to find the exact  $k$  nearest neighbors, in which case it is equivalent to procedure BFTRAV (but see Exercise 2). Arya, Mount, Netanyahu, Silverman, and Wu [100] have shown that the use of this algorithm with a BBD-tree (see Section 1.5.2.7 of Chapter 1) enables finding the  $\varepsilon$ -nearest neighbor in time inversely proportional to  $\varepsilon$ .

The drawback of implementations that make use of the shrinking approach (e.g., [100, 387, 1286]) is that they can only be used to find the approximate nearest neighbor or the  $k$  approximate nearest neighbors. In particular, such implementations cannot obtain the neighbors incrementally (regardless of whether or not they are approximate) because, once a closer object than the object  $o'$  currently deemed to be the closest has been found, or once it has been decided not to enqueue a nonobject element  $a$ , we cannot go back and process  $o'$  or  $a$  later when more neighbors are needed.

Hjaltason and Samet [851] observe that instead of shrinking distances (e.g.,  $D_k$ ) by a factor of  $1 + \varepsilon$  as in ANNBFTAV, the distances of the nonobject elements  $e_p$  (i.e.,  $\text{MINDIST}(q, e_p)$ ) could be expanded by a factor of  $1 + \varepsilon$  and used in all comparisons with  $D_k$  rather than the shrunken distances. In other words, they suggest multiplying the key values for all nonobject elements in the priority queue *Queue* by  $1 + \varepsilon$ —that is, for a nonobject element  $e_p$ , use  $(1 + \varepsilon) \cdot \text{MINDIST}(q, e_p)$  as a key. The advantage of using this simple and equivalent approximation mechanism is that it enables them to transform an incremental exact nearest neighbor algorithm that uses it into an incremental approximate nearest neighbor algorithm, where  $k$  need not be known in advance, by simply always also enqueueing the objects with their true distance, as well as always enqueueing a nonobject element with its expanded distance. Procedure ANNINCNEAREST, given below, is the incremental approximate nearest neighbor variant of the incremental nearest neighbor algorithm INCNEAREST presented in Section 4.1.3 that incorporates this approach. The only difference is in line 19, where the distance of a nonobject  $e_{t'}$  (i.e.,  $t' \neq 0$ ) from  $q$  is multiplied by  $1 + \varepsilon$  prior to enqueueing it, and, of course, the presence of an additional parameter  $\varepsilon$  corresponding to the approximation error tolerance.

```

1  procedure ANNINCNEAREST( $q, \varepsilon, S, T$ )
2  /* A best-first incremental algorithm that returns the approximate nearest
   neighbors of  $q$  within a factor of  $1 + \varepsilon$  of the distance to the actual
   nearest neighbor from the set of objects  $S$  organized using the search
   hierarchy  $T$ . */
3  value object  $q$ 
4  value integer  $\varepsilon$ 
5  value object_set  $S$ 
6  value pointer search_hierarchy  $T$ 
7  priority_queue  $Queue$ 
8  pointer search_hierarchy  $e, e_{t'}$ 
9   $Queue \leftarrow \text{NEWPRIORITYQUEUE}()$ 
10  $e_t \leftarrow$  root of the search hierarchy induced by  $S$  and  $T$ 
11 ENQUEUE( $e_t, 0, Queue$ )
12 while not ISEMPY( $Queue$ ) do
13    $e_t \leftarrow$  DEQUEUE( $Queue$ )
14   if  $t = 0$  then /*  $e_t$  is an object */
15     Report  $e_t$  as the next nearest object
16   else
17     foreach child element  $e_{t'}$  of  $e_t$  do
18       if  $t' = 0$  then ENQUEUE( $e_{t'}, d_{t'}(q, e_{t'}), Queue$ )
19       else ENQUEUE( $e_{t'}, d_{t'}(q, e_{t'}) \cdot (1 + \varepsilon), Queue$ )
20       endif
21     enddo
22   endif
23 enddo

```

From a practical point of view, in the incremental algorithm, enqueueing a nonobject element  $e_t$  with a larger distance value (i.e., by a factor of  $1 + \varepsilon$  in this case) means that we delay its processing, thereby allowing objects to be reported “before their time.” In particular, once  $e_t$  is finally processed, all of the objects  $o$  that we have reported satisfy  $d(q, o) \leq (1 + \varepsilon) \cdot d_t(q, e_t)$  (which is greater than  $d_t(q, e_t)$  if  $\varepsilon > 0$ ). Therefore, it could be the case that there exists an object  $c$  in  $e_t$  with a distance  $d(q, c) \leq d(q, o)$ , yet  $o$  is reported before  $c$ . It should be clear that in this case the algorithm does not necessarily report the resulting objects in strictly increasing order of their distance from  $q$ . With this modification, for the object  $o'_k$  returned as the  $k$ th-nearest neighbor by the algorithm and the actual  $k$ th-nearest neighbor  $o_k$ , we have  $d(q, o'_k) \leq (1 + \varepsilon) \cdot d(q, o_k)$ .

The same technique of expanding all distances by a factor of  $1 + \varepsilon$  can also be applied to the nonincremental best-first  $k$ -nearest neighbor algorithm given by procedure OPTBFTRAV to yield a best-first approximate  $k$ -nearest neighbor algorithm ANNOPTBFTRAV. In this case, we must also properly accommodate the MAXNEARESTDIST estimate. The solution is to expand the distances (i.e., estimates and hence both MINDIST and MAXNEARESTDIST) of nonobject elements from  $q$  by  $1 + \varepsilon$ . These expanded distances are used in all comparisons with  $D_k$ , and the algorithm is simplified by also associating these expanded distances with the nonobjects in both  $L$  and  $Queue$ . In particular, the test for the applicability of Pruning Rules 1 and 3 becomes  $\text{MINDIST}(q, e_p) \cdot (1 + \varepsilon) > D_k$  (line 46), the test for the applicability of Pruning Rules 2 and 4 for nonobjects becomes  $\text{MAXDIST}(M, e_p) \geq d(q, M) - D_k/(1 + \varepsilon)$  (line 41) and  $\text{MINDIST}(M, e_p) \leq d(q, M_p) + D_k/(1 + \varepsilon)$  (line 44), and the test for the insertion of nonobjects (i.e., Pruning Rule 5) in  $L$  by OPTINSERTL becomes  $\text{MAXNEARESTDIST}(q, e_p) \cdot (1 + \varepsilon) < D_k$  (line 48). The distances associated with the nonobjects  $e_p$  that are inserted in  $Queue$  and  $L$  become  $\text{MINDIST}(q, e_p) \cdot (1 + \varepsilon)$  (line 51) and  $\text{MAXNEARESTDIST}(q, e_p) \cdot (1 + \varepsilon)$  (line 49), respectively. The conditions involving MAXNEARESTDIST to determine whether it is necessary to remove a nonobject from  $L$  when processing its immediate descendants become  $\text{MAXNEARESTDIST}(q, e) \cdot (1 + \varepsilon) < D_k$  (line 23) and  $\text{MAXNEARESTDIST}(q, e) \cdot (1 + \varepsilon) = D_k$  (line 24). Observe that the depth-first  $k$ -nearest neighbor algorithm as given by procedures DFTRAV, FDNDFTRAV, and OPTDFTRAV can be modified in the same way as OPTBFTRAV to yield depth-first approximate  $k$ -nearest neighbor algorithms ANNDNFTRAV (see Exercise 3), ANNFDNFTRAV (see Exercise 4), and ANNOPTDFTRAV (see Exercise 5), respectively.

It is important to note that we must expand the values of both the MINDIST and MAXNEARESTDIST estimates rather than just that of the MINDIST estimate as otherwise we could have the situation that the ANNOPTBFTRAV algorithm terminates with some nonobjects in  $L$  where for some of these nonobjects, say  $b$ ,  $\text{MINDIST}(q, b) \leq \text{MAXNEARESTDIST}(q, b) < D_k < \text{MINDIST}(q, b) \cdot (1 + \varepsilon)$ . In this case, the fact that  $\text{MINDIST}(q, b) \cdot (1 + \varepsilon) > D_k$  results in  $b$  being pruned, and the fact that  $\text{MAXNEARESTDIST}(q, b) < D_k$  means that  $b$  is still in  $L$ . Thus, if the algorithm terminates at this point in the sense that  $\text{MINDIST}(q, e) \cdot (1 + \varepsilon) > D_k$  for all remaining nonobjects  $e$  in  $Queue$ , then  $L$  may still contain some nonobjects. This means that the search hierarchy elements corresponding to each of these nonobjects, say  $b$ , will have to be searched to find the object  $o_b$  for which  $d(q, o_b) \leq \text{MAXNEARESTDIST}(q, b) < D_k$ , which may be a time-consuming process, thereby defeating the purpose of finding the  $k$  approximate nearest neighbors instead of the exact  $k$  nearest neighbors. On the other hand, when the values of both the MINDIST and MAXNEARESTDIST estimates are expanded by  $1 + \varepsilon$ , then we know by virtue of  $\text{MINDIST}(q, b) \leq \text{MAXNEARESTDIST}(q, b)$  that  $\text{MINDIST}(q, b) \cdot (1 + \varepsilon) \leq \text{MAXNEARESTDIST}(q, b) \cdot (1 + \varepsilon)$ . Thus, the fact that  $\text{MINDIST}(q, b) \cdot (1 + \varepsilon) > D_k$  means that  $\text{MAXNEARESTDIST}(q, b) \cdot (1 + \varepsilon) > D_k$ , and therefore  $b$  is not in  $L$ . In other words,  $L$  contains the  $k$  approximate nearest neighbors of  $q$  (which are objects).

As we pointed out, the key idea behind all of the methods that we have described is to delay the processing of nonobject elements (in the case of the incremental nearest

neighbor algorithm and the best-first  $k$ -nearest neighbor algorithm) or avoid (in the case of the depth-first  $k$ -nearest neighbor algorithm) the processing of nonobject elements that are within a factor of  $1 + \varepsilon$  of the distance of the actual  $k$ th-nearest neighbor of  $q$ . These methods can be viewed as enhancing Pruning Rules 1 and 3, as well as the nonobject variants of Pruning Rules 2 and 4, to deal with approximate nearest neighbors. The same principle could also be applied with similar results to objects that are within a factor of  $1 + \varepsilon$  of the distance of the actual  $k$ th-nearest neighbor of  $q$  (see Exercises 3, 7, and 8). Moreover, we could also use this principle for pruning objects by incorporating it into the tests for the applicability of the object variants of Pruning Rules 2 and 4 (see Exercise 9).

Other methods for performing approximate nearest neighbor search can also be integrated into the general incremental nearest neighbor algorithm by similarly modifying the distances used in the priority queue. For example, the method of Chen, Bouman, and Dalton [346] is applicable to spatial and metric indexing methods that make use of spherical node regions (e.g., the SS-tree [1991] and the M-tree [389]). In particular, if  $b$  is a node in the structure having a reference object  $p$  and an associated radius of  $r$ , then for every object  $o$  stored in the subtree rooted at  $b$ , we have  $d(p, o) \leq r$ . Observe that if  $q$  is the query object,  $d(p, q) - r$  is a lower bound on the distance  $d(q, o)$  for  $o$  in the subtree rooted at  $b$ , and that this lower bound can be considered the distance between  $q$  and  $b$  when performing queries (see also the discussion of the vp-tree and Exercise 6 in Section 4.5.2.1.2).<sup>19</sup>

Like Arya et al. [100], Chen et al. [346] propose that the processing of  $b$  in best-first nearest neighbor algorithms (such as our incremental algorithm) be delayed by “inflating” the distance value  $d(q, b)$ , thus delaying or avoiding the processing of  $b$ . However, in the case of Chen et al., the distance is inflated by shrinking the radius of  $b$  by a factor of  $\lambda$  ( $0 < \lambda \leq 1$ ), resulting in the modified distance function  $d'(q, b) = d(p, q) - \lambda \cdot r$ . Notice that the extent to which the processing of  $b$  (and hence the objects in  $b$ ) will be delayed depends on the radius of  $b$ , and thus nodes at the same distance will be processed in increasing order of their radii. In fact, it is not inconceivable that a small node  $b_s$  will be processed before a larger node  $b_l$ , even though  $b_l$  is closer to  $q$  than  $b_s$ . This is in contrast to the method of Arya et al. [100], where nodes are always processed in the order of their distance from  $q$ , even after their distances from  $q$  have been expanded. Observe that the approximation error is unbounded when using the method of Chen et al. (see Exercise 12).

From an intuitive standpoint, the two methods can be compared by noting that they differ in how they evaluate the likelihood that a particular bounding region will contain the nearest neighbor. In particular, the method of Chen et al. deems larger nodes as less likely to contain the nearest neighbor than smaller nodes at the same distance. On the other hand, the method of Arya et al. deems nodes that are farther away as less likely to contain the nearest neighbor than closer nodes, regardless of their size.

In some applications, even the willingness to settle for an approximate answer rather than an exact answer does not yield a solution procedure that is sufficiently fast. In particular, as we saw earlier, in high dimensions the effects of the curse of dimensionality come into play (i.e., for some data and query distributions, such as the uniform distribution, the difference between the distance to the nearest and the farthest neighbor approaches zero as the dimensionality increases), so that the approximate nearest neighbor algorithm (as does the exact nearest neighbor algorithm) spends most of the time deciding whether a particular candidate is good enough in comparison to the time it spends to locate it.

This consideration has led to a proposal to relax slightly the approximate nearest neighbor condition by stipulating a maximum probability  $\delta$  for tolerating failure, thereby

---

<sup>19</sup> Note that  $d(p, q) - r$  is a lower bound on  $d(q, o)$  regardless of whether  $q$  is inside or outside  $b$ . Nevertheless, when  $q$  is inside  $b$ , then 0 is a tighter lower bound since  $d(p, q) - r$  is then negative whereas distances are always nonnegative.

enabling the decision process to halt sooner at the risk  $\delta$  of being wrong. This is the basis of the *probably approximately correct* (PAC) nearest neighbor method of Ciaccia and Patella [387]. Formally, an object  $o'$  is considered a PAC nearest neighbor of  $q$  if the probability that  $d(q, o') \leq (1 + \varepsilon) \cdot d(q, o)$ , where  $o$  is the actual nearest neighbor, is at least  $1 - \delta$ . In other words, given values of  $\varepsilon$  and  $\delta$ ,  $1 - \delta$  is the minimum probability that  $o'$  is the  $(1 + \varepsilon)$ -approximate nearest neighbor of  $q$ . Equivalently, the probability that the effective error, defined as  $d(q, o')/d(q, o) - 1$ , is greater than  $\varepsilon$  is no more than  $\delta$ . Ciaccia and Patella [387] show that, given some information about the distances between  $q$  and the data objects, we can derive an upper bound  $s$  on the distance between  $q$  and a PAC nearest neighbor  $o'$ . The distance bound  $s$  is then used during the actual nearest neighbor search as a preestablished halting condition—that is, the search can be halted once an object  $o'$  with  $d(q, o') \leq s$  is located.

It is interesting to observe that using the PAC nearest neighbor method is analogous to executing a variant of a range query, where the range is defined by the distance bound  $s$ , which halts on the first object in the range. If no object is in the range, then the nature of the nearest neighbor algorithm that is used is important. In particular, if the objects are not indexed, then a sequential scan will end up examining all of the objects. In this case, it will either return no object or the closest one if it keeps track of the closest object found so far, which is the natural course of action. In contrast, if the objects are indexed, then a “best-first” nearest neighbor algorithm, regardless of whether it is incremental as ours is or nonincremental such as the one of Arya et al. [100] described above, will halt once it encounters the object at the minimum distance from the query object, subject to the approximation error tolerance  $\varepsilon$ . Thus, in this case, the range simply provides an additional stopping condition that is independent of the distance from the query point to the object that is currently the closest, which changes as the algorithm is executed.

The main difficulty in computing the PAC nearest neighbor lies in determining a relationship between  $\delta$  and the distance bound  $s$ . Ciaccia and Patella assume that the relative distance distribution  $F_q(x)$  of the query object  $q$  from an arbitrary object  $p$  is known—that is,  $F_q(x) = \text{Prob}\{d(q, p) \leq x\}$ . In other words,  $F_q(x)$  is the probability that an object  $p$  is within distance  $x$  of  $q$ , which means that  $1 - F_q(x)$  is the probability that  $p$  does not lie within distance  $x$  of  $q$ . Therefore, the probability that none of the  $N$  objects lies within distance  $x$  of  $q$  is  $(1 - F_q(x))^N$ , and thus the probability that at least one of the objects lies within distance  $x$  of  $q$  is  $1 - (1 - F_q(x))^N$ . This results in  $G_q(x) = \text{Prob}\{d(q, NN(q)) \leq x\} = 1 - (1 - F_q(x))^N$  being the probability distribution for the distance to the nearest neighbor of  $q$  denoted by  $NN(q)$ . At this point, we define  $r$  as the distance bound so that  $G_q(r) = \delta$ . If  $G_q$  is invertible, then  $r = G_q^{-1}(\delta)$  (see Exercises 14 and 15).

From the above, we have that the maximum probability that the nearest neighbor of  $q$  is closer than  $r$  is  $\delta$ , and thus an algorithm that makes use of  $r$  as a halting condition can be said to be *probably correct* (PC), with  $r$  being a probably correct distance bound. However, we are interested in a probably approximately correct (PAC) distance bound. We now show that  $s = (1 + \varepsilon) \cdot r$  is such a bound. Assume that  $d(q, o') \leq s$  for some object  $o'$ , and let  $o$  be the actual nearest neighbor of  $q$ . We now must show that  $\text{Prob}\{d(q, o') \leq (1 + \varepsilon) \cdot d(q, o)\} \geq 1 - \delta$ . In other words, we need to show that  $1 - \delta$  is the minimum probability that  $o'$  is the  $(1 + \varepsilon)$ -approximate nearest neighbor of  $q$ . Rearranging terms, this goal can be rewritten as trying to show that  $1 - \text{Prob}\{d(q, o') \leq (1 + \varepsilon) \cdot d(q, o)\} \leq \delta$ . Appealing to the fact that  $\text{Prob}\{X\} = 1 - \text{Prob}\{\text{not}(X)\}$ , we have that  $1 - \text{Prob}\{d(q, o') \leq (1 + \varepsilon) \cdot d(q, o)\} = \text{Prob}\{d(q, o') > (1 + \varepsilon) \cdot d(q, o)\}$ . The right-hand side can be rewritten as  $\text{Prob}\{d(q, o) < d(q, o')/(1 + \varepsilon)\}$ , which equals  $\text{Prob}\{d(q, o) \leq d(q, o')/(1 + \varepsilon)\}$  since the probability of real-valued variables being equal is zero (i.e.,  $\text{Prob}\{d(q, o) = d(q, o')/(1 + \varepsilon)\} = 0$ ). However,  $\text{Prob}\{d(q, o) \leq d(q, o')/(1 + \varepsilon)\} = G_q(d(q, o')/(1 + \varepsilon))$ , which is less than or equal to  $G_q(r) = \delta$ , and thus  $s = (1 + \varepsilon) \cdot r$  can be used as the distance bound for the PAC nearest neighbor method. Note that  $G_q(d(q, o')/(1 + \varepsilon)) \leq G_q(r)$  is a direct result of  $d(q, o')/(1 + \varepsilon) \leq r$  and the fact that  $G_q$  is a nondecreasing function.

As we saw above,  $F_q(x)$  is the probability distribution of the distance from  $q$  to a random point, and  $G_q(x)$  is the probability distribution of the distance from  $q$  to its closest point. Observe that as the number of points  $N$  goes to  $\infty$ ,  $G_q(x)$  approaches the constant function 1, while  $F_q(x)$  is unchanged. On the other hand, as the dimension  $d$  goes to  $\infty$ , both  $F_q(x)$  and  $G_q(x)$  converge to the same value by virtue of the curse of dimensionality (i.e., the distance from the query point to a random point has the same distribution as the distance from the query point to the nearest point), assuming a uniform data and query distribution.

At this point, let us briefly review the PAC method. Earlier, we pointed out that use of the PAC method is similar to executing a range query on the basis of the distance bound that has been obtained. The effect of increasing  $\varepsilon$  is to increase the range. Thus, a probably correct nearest neighbor algorithm (i.e., with  $\varepsilon = 0$ ) has the minimum range. Note that in the case of a probably correct nearest neighbor algorithm,  $\delta$  is the maximum probability that the object  $o$  being reported as the nearest neighbor of query object  $q$  is wrong. In contrast, for a PAC nearest neighbor,  $\delta$  is the maximum probability that the distance from  $q$  to  $o$  is more than a factor of  $1 + \varepsilon$  of the distance to the real nearest neighbor. Note that neither  $\varepsilon$  nor  $\delta$  indicates the effective error (i.e., the extent to which  $o$  is not the nearest neighbor), which has usually been found to be much smaller than  $\varepsilon$ . It is also important to observe that, in reality, it is difficult to make use of the PAC nearest neighbor algorithm as it is rare to have explicit knowledge of the distribution  $F_q(x)$  and  $G_q(x)$ . This difficulty may be overcome by sampling the dataset [387]. For an alternative application of the PAC concept, see the discussion in Section 4.4.4 of the os-tree and the use of training sets to approximate a Voronoi diagram in high dimensions to find PAC nearest neighbors [1226, 1229].

There are a number of ways of adapting these methods for approximate farthest neighbor search. In this case, the approximation criterion is that the distance between the query object  $q$  and the resulting candidate farthest neighbor  $o'$  is within a factor of  $1 + \varepsilon$  of the distance to the actual farthest neighbor  $o$ —that is,  $d(q, o') \geq d(q, o)/(1 + \varepsilon)$  (notice the slight difference from the definition of the approximate nearest neighbor). For example, the incremental farthest neighbor algorithm (see Exercise 6 in Section 4.1.5) can be modified so that a nonobject element  $e_{i'}$  is always enqueued after shrinking its distance value by a factor of  $(1 + \varepsilon)$  (in contrast to expanding it by this value, as in the approximate variant of the incremental nearest neighbor algorithm). Again, as in the case of approximate nearest neighbor finding, this has the effect of delaying its processing, thereby allowing objects to be reported “before their time.” In particular, for the approximate  $k$ th-farthest neighbor, we have that the distance between the query object  $q$  and the resulting candidate  $k$ th-farthest neighbor  $o'_k$  is within a factor of  $1 + \varepsilon$  of the distance to the actual  $k$ th-farthest neighbor  $o_k$ —that is,  $d(q, o'_k) \geq d(q, o_k)/(1 + \varepsilon)$ . Note that this method works even when we use the incremental nearest neighbor algorithm with distance  $-\hat{d}_t(q, e_t)$  instead of  $d_t(q, e_t)$  for any element  $e_t$ , as discussed in Section 4.1.5 (see Exercises 17–21).

The drawback of using a relative error bound, such as the one described above, for finding approximate farthest neighbors is that all of the points in  $S$  would tend to be the approximate farthest neighbor if all of the points in  $S$  were relatively close to each other, while the query object is far from them. Such a situation is common for high-dimensional point data. This has led Duncan, Goodrich, and Kobourov [517] to suggest an alternative criterion that stipulates that  $o'$  is an approximate farthest neighbor of  $q$  if  $d(q, o') \geq d(q, o) - \varepsilon D$ , where  $o$  is the actual farthest neighbor and  $D$  is the *diameter* of the point set  $S$  (i.e., the distance between the two farthest points in  $S$ ). As we can see, this criterion is in terms of an *absolute error bound* based on  $D$  and, in the farthest neighbor case, can give a tighter bound than a *relative error bound* based on  $d(q, o)$ . This criterion can also be incorporated into the incremental nearest neighbor algorithm in a straightforward manner (see Exercise 23).

1. An alternative definition of approximate nearest neighbor search is that the distance between the query object  $q$  and the resulting candidate nearest neighbor  $o'$  is within a factor of  $1/(1 - \varepsilon)$  of the distance to the actual nearest neighbor  $o$ —that is,  $d(q, o') \leq d(q, o)/(1 - \varepsilon)$ . What is the drawback of using such a definition?
2. In the text, we claim that procedures BFTRAV and ANNBFTTRAV are equivalent when  $\varepsilon = 0$ . However, when we examine them more closely, we see that, whereas BFTRAV has line 31, ANNBFTTRAV makes use of lines 31–32 to achieve this task. Explain the significance of this difference.
3. How would you adapt the basic depth-first  $k$ -nearest neighbor algorithm given by procedure DFTRAV in Section 4.2.1 to return the  $k$  approximate nearest neighbors, thereby yielding procedure ANNDFTRAV?
4. How would you modify procedure FNDFTTRAV to return the  $k$  approximate nearest neighbors, thereby yielding procedure ANNFNDFTTRAV?
5. How would you modify procedure OPTDFTRAV to return the  $k$  approximate nearest neighbors, thereby yielding procedure ANNOPTDFTRAV? Make sure to pay attention to the proper usage of MAXNEARESTDIST.
6. Suppose that Pruning Rule 5 is implemented in procedure OPTBFTRAV using the MAXDIST estimate instead of the MAXNEARESTDIST estimate. Suppose further that, in the approximate  $k$  nearest neighbor adaptation of OPTBFTRAV given by ANNOPTBFTRAV, only the value of the MINDIST estimate is expanded by  $1 + \varepsilon$  (i.e., the value of the MAXDIST estimate is not expanded). How would you resolve the situation where ANNOPTBFTRAV terminates with some nonobjects in  $L$ ?
7. The key idea behind the approximate nearest neighbor algorithms is to shrink the distances  $D_1$  ( $D_k$ ) from  $q$  to the closest ( $k$ th-nearest) object by a factor of  $1 + \varepsilon$  and to ignore a nonobject element  $e_p$  and the objects it contains if the minimum distance from  $q$  to an object in  $e_p$  (i.e.,  $\text{MINDIST}(q, e_p)$ ) is greater than this shrunken distance. An alternative formulation of this idea is to expand the minimum distance  $\text{MINDIST}(q, e_p)$  from  $q$  to an object in  $e_p$  and to ignore  $e_p$  and its objects if the expanded distance is greater than  $D_1$  ( $D_k$ ). Can you also apply this idea at the object level in procedure ANNBFTTRAV in the sense that an object  $o$  is ignored if the distance from  $q$  to  $o$  is greater than the shrunken distance  $D_1$  ( $D_k$ ) from  $q$  to the closest ( $k$ th-nearest) object (line 25)? Alternatively, can we ignore  $o$  in ANNBFTTRAV if the expanded distance from  $q$  to  $o$  is greater than the distance  $D_1$  ( $D_k$ ) from  $q$  to the closest ( $k$ th-nearest) object (line 25)? Discuss the effect of adding these tests on the results of ANNBFTTRAV.
8. Suppose that you apply the modification outlined in Exercise 7 to objects as well as nonobjects in variants of the approximate  $k$ -nearest neighbor algorithm that make use of the MAXNEARESTDIST estimate, such as the adaptations of FNDFTTRAV (line 19), OPTDFTRAV (line 17), and OPTBFTRAV (line 34) given by ANNFNDFTTRAV (see Exercise 4), ANNOPTDFTRAV (see Exercise 5), and ANNOPTBFTRAV (see the text), respectively. From an initial glance, it would appear that this modification could cause the algorithm to terminate with some nonobjects in  $L$ —that is, not all of the elements in  $L$  are objects. For FNDFTTRAV,  $k$  must be 1 for such a termination to arise. On the other hand, for OPTDFTRAV and OPTBFTRAV, it could arise when  $k \neq 1$ , and initially some of the  $k$  entries in  $L$  correspond to nonobjects. In particular, if we know that  $d(q, o) > D_k/(1 + \varepsilon)$  for all subsequently processed objects  $o$ , then the algorithms could terminate with  $L$  containing some nonobjects. This would mean that each of the individual nonobject elements  $b$  of  $L$  would have to be searched to find the object  $o_b$  for which  $d(q, o_b) \leq \text{MAXNEARESTDIST}(q, b) < D_k$ , which may be a time-consuming process, thereby defeating the purpose of finding the  $k$  approximate nearest neighbors instead of the exact  $k$  nearest neighbors. Prove or disprove that these modifications can cause these algorithms to terminate with some nonobjects in  $L$ —that is, not every element in  $L$  is an object.
9. How would you adapt Pruning Rules 2 and 4 (see Section 4.2.2) so that they can be used in the different approximate  $k$ -nearest neighbor algorithms to prune some objects from further consideration? Recall that the approximate  $k$ -nearest neighbor algorithms that we presented already incorporate Pruning Rules 1–4 to prune a nonobject and the objects it contains.

10. Suppose that you modify the incremental nearest neighbor algorithm INCNEAREST by expanding the key values of both the object and nonobject elements in the priority queue by a factor of  $1 + \varepsilon$  instead of just expanding the key values of the nonobject elements as in ANNINCNEAREST. What is the resulting effect?
11. Suppose that you modify the incremental nearest neighbor algorithm INCNEAREST by expanding the key values of just the object elements in the priority queue by a factor of  $1 + \varepsilon$  while leaving the key values for the nonobject elements unchanged. What is the resulting effect?
12. Show that the maximum approximation error  $\varepsilon$  when using the method of Chen et al. [346], so that the processing of a spherical minimum bounding box  $b$  centered at  $p$  is delayed by shrinking its radius  $r$  by  $\lambda$  ( $0 < \lambda \leq 1$ ), is unbounded.
13. As discussed in the text, Chen et al. [346] propose that the processing of a block (i.e., nonobject element)  $b$  be delayed by shrinking  $b$ 's radius by a factor of  $\lambda$  ( $0 < \lambda \leq 1$ ) prior to evaluating its distance from  $q$ , which effectively increases the distance value for  $b$  (i.e.,  $d(q, b)$ ) used by the algorithm. We have given a number of possible rationales for this strategy. Can you give a theoretical justification for these rationales?
14. Consider a set of points uniformly distributed over the  $d$ -dimensional unit hypercube. Using the  $L_\infty$  distance metric, derive  $F_q(x)$ ,  $G_q(x)$ , and  $\delta = G_q^{-1}(x)$  to be used in the PAC nearest neighbor algorithm for a query point that coincides with the center of the hypercube and also for a query point that coincides with one of the  $2^d$  corners.
15. Continuing Exercise 14 involving the PAC nearest neighbor algorithm, let  $\delta = 0.01$ ,  $N = 1,000,000$ , and  $d = 50$ , and solve for  $x$  when the query point is in the center of the hypercube.
16. How would you extend the PAC nearest neighbor algorithm to finding the  $k$  nearest neighbors so that the exact search would retrieve the  $k$  best matches for the query object. This will require an estimate of the distance to the  $k$ th-nearest neighbor. Exercises 17–21 deal with adapting the specified procedures to obtain the  $k$  approximate farthest neighbors using the approach outlined in Exercise 3 of Section 4.2.1. All of the procedures use the relative error bound for finding the approximate  $k$ th-farthest neighbor. In other words, the distance between the query object  $q$  and the resulting candidate  $k$ th-farthest neighbor  $o'_k$  is within a factor of  $1 + \varepsilon$  of the distance to the actual  $k$ th-farthest neighbor  $o_k$ —that is,  $d(q, o'_k) \geq d(q, o_k)/(1 + \varepsilon)$ . Note that in these exercises, this approximation criterion becomes  $d(q, o'_k) \leq d(q, o_k)/(1 + \varepsilon)$  when all distances are replaced by their negation as in the approach in Exercise 3 of Section 4.2.1.
17. Adapt procedure ANNBFTRAV to obtain the  $k$  approximate farthest neighbors, thereby yielding procedure ANNBFTRAVFARTHEST.
18. Adapt procedure ANNINCNEAREST to obtain the approximate farthest neighbors in an incremental manner, thereby yielding procedure ANNINCFARTHEST.
19. Adapt procedure ANNOPTBFTRAV to obtain the  $k$  approximate farthest neighbors in a nonincremental best-first manner, thereby yielding procedure ANNOPTBFTRAVFARTHEST.
20. Adapt the depth-first procedure ANNFNDFTRAV in Exercise 4 to obtain the  $k$  approximate farthest neighbors in a depth-first manner, thereby yielding procedure ANNFNDFTRAVFARTHEST.
21. Adapt the depth-first procedure ANNOPTDFTRAV in Exercise 5 to obtain the  $k$  approximate farthest neighbors, thereby yielding procedure ANNOPTDFTRAVFARTHEST.
22. Adapt procedure INCNEAREST to obtain the approximate farthest neighbors in an incremental manner using the criterion proposed by Duncan et al. [517]. In particular,  $o'$  is an approximate farthest neighbor of  $q$  if  $d(q, o') \geq d(q, o) - \varepsilon D$ , where  $o$  is the actual farthest neighbor, and  $D$  is the diameter of the point set (i.e., the distance between the two farthest points).
23. Repeat Exercise 22 for obtaining the approximate nearest neighbors in an incremental manner. You will need to modify the criterion for the approximate farthest neighbor to the case of an approximate nearest neighbor. In other words, devise an absolute error bound.

## 4.4 Multidimensional Indexing Methods

In this section we discuss the issues that must be dealt with when trying to adapt the multidimensional indexing methods presented in Chapters 1 and 2 to high-dimensional data. Section 4.4.1 describes the X-tree, which attempts to address problems that arise if we cannot find a good partition (i.e., one that does not result in too much overlap) when using an indexing method that makes use of an object hierarchy (e.g., an R-tree). Section 4.4.2 presents indexing methods that make use of an object hierarchy where the bounding objects are spheres rather than rectangles. This is based on the premise that the bounding spheres are preferable for nearest neighbor queries that use the Euclidean distance metric. The efficiency of indexing methods that consist of a tree structure can be improved by reducing the number of levels in the tree. This can be achieved by increasing the fanout in each node and is the subject of Section 4.4.3. Sections 4.4.4 and 4.4.5 discuss indexing methods that try to take advantage of the partitioning of the underlying space provided by a Voronoi diagram to facilitate finding nearest neighbors in high dimensions.

Sections 4.4.6 and 4.4.7 present techniques to overcome the problem that most query regions overlap a high proportion of the leaf blocks that result from the index since it can be shown, at least for a uniform distribution, that most of the data lies at or near the surface. It is assumed that part of the data lies in external memory. Nevertheless, in this case, it is often preferable to scan the entire database sequentially instead of incurring the random access overhead costs associated with using the hierarchy of an index. In other words, in sequential access, we amortize the seek time over many disk blocks, but in random access, we must pay the price of a disk seek each time we access a disk block. In particular, using an index may be more costly than sequential access if as little as 15% of the data blocks are accessed [212]. Section 4.4.8 describes a number of indexing methods that are designed to work with a sequential scan of the database. They usually involve a reduction in the amount of data that is retrieved by reducing the size of the representative of each data object.

### 4.4.1 X-Tree

As we have observed in earlier chapters, there are two types of multidimensional objects: points having zero volume (Chapter 1) and objects with extent, such as spatial data (Chapter 2). The X-tree [190] is a variant of an object hierarchy such as an R-tree that is designed to handle high-dimensional point data as well as spatial data (i.e., with extent). In the X-tree, node splits are avoided if they will result in a high degree of overlap among the resulting nodes. In particular, if a node overflows and an appropriate split position cannot be found, then the node is enlarged such that it occupies two disk blocks. Such a node is termed a *supernode*. Supernodes can be further enlarged (i.e., if an appropriate split does not exist), so supernodes may consist of an arbitrary number of disk blocks. In fact, in an extreme case, the directory consists of a single supernode.

The X-tree applies two kinds of node-splitting policies, both of which result in splitting along a single dimension (in two approximately equal halves, if we assume uniformly distributed point data). The first policy is based on topological considerations—that is, attempts to minimize a combination of perimeter and overlap, such as the traditional R\*-tree node-splitting policies. If the overlap among the nodes resulting from the split exceeds some threshold, a second node-splitting policy is applied instead. This policy splits the node along the dimension that was used when the first two children of the node were created. If this split is unbalanced (i.e., one child contains many more elements than the other), a supernode is created instead of performing the split. For point data, it can be shown that such a split is overlap free [190]. Furthermore, the likelihood of an overlap-free split existing for any other dimension decreases rapidly as the dimension of the underlying data increases [190]. A split history in the form of a binary tree is maintained for each nonleaf node to facilitate determining the overlap-free split dimension.

When two nodes resulting from a split have excessive overlap, it becomes highly likely that most queries end up accessing both nodes. Thus, the advantage of creating a supernode instead of splitting is that sequential access can be used to read all the blocks making up the supernode, instead of the random accesses that would be required to access the nodes resulting from a split. The result is a compromise between an index that makes use of a hierarchy and a sequential access. Such an approach enables the index to adapt gracefully between the R-tree, which is good for low-dimensional data, and a sequential access of the entire dataset when the dimensionality of the data is high. The X-tree was shown to outperform the R\*-tree significantly for data of increasing dimensionality as high as 16 [190].

The notion of a supernode in the X-tree is similar to the concept of *oversized shelves* [771, 777, 778], which is used with representations that are based on a disjoint decomposition of the underlying space for representing data with extent to deal with the situation that the decomposition causes an object to be split too many times. In this case, the objects get stored in the oversized shelves that are associated with nonleaf nodes in the structure. This is in contrast with the X-tree, where all the data objects are stored in the leaf nodes, and only pointers to nodes at the next level and their corresponding minimum bounding boxes are stored in the nonleaf nodes.

#### 4.4.2 Bounding Sphere Methods: Sphere Tree, SS-Tree, Balltree, and SR-Tree

In the above discussion (Section 4.4.1 and Chapter 2), we assume the use of bounding boxes in the form of minimum bounding hyperrectangles, although these can be extended to bounding boxes of arbitrary shapes. As we saw earlier, in applications that involve high-dimensional data, among the most common queries are those that find the nearest neighbors to a given object  $o$  or find all objects within a given distance from  $o$ . These queries usually use the Euclidean distance metric. In this case, the query region is a hypersphere rather than a hyperrectangle. This has led some researchers (e.g., [1991]) to argue that using bounding boxes in the shape of hyperspheres is preferable to ones shaped like hyperrectangles in spatial indexes that are object hierarchies (e.g., as the R-tree). This is based on the observation that the number of hyperrectangular data regions that are intersected by a hyperspherical query region tends to increase sharply as the dimensionality of the underlying space increases, regardless of the indexing method (i.e., the way in which the data regions are determined). For example, assuming that the data space is tiled by hypercubes of volume  $V$ , a hypersphere query region  $r$  with volume  $V$  will intersect at least 5 of the hypercube tiles for dimension 2 and 19 for dimension 3 (assuming that the hypersphere is fully inside the data space). In general, as the dimension  $d$  of the underlying space increases, the number of hypercube tiles with volume  $V$  of the underlying space intersected by  $r$  increases very rapidly in  $d$  (see Exercise 1).

The SS-tree of White and Jain [1991] is a representation that is similar in spirit to the R\*-tree, which makes use of minimum bounding hyperspheres instead of minimum bounding hyperrectangles. The center of each minimum bounding hypersphere is the centroid of the points that have been aggregated to form it. The centroids are used in both the insertion and split algorithms. Each SS-tree node has a minimum of  $m$  and a maximum of  $M$  children. The SS-tree is equivalent to the sphere tree of van Oosterom and Claassen [1410, 1412], which was developed for representing objects with extent. They both use minimum bounding hyperspheres with the only difference between them being that the sphere tree is based on an R-tree while the SS-tree is based on an R\*-tree. The SS-tree is also similar to the balltree of Omohundro [1399], which is based on a binary tree. The sphere tree of Hubbard [895, 896] also makes use of a hierarchy of spheres constructed in a somewhat different manner for collision detection among moving objects. One of the motivations for using the sphere as a minimum bounding box in this application is its rotation invariance [895].

The SS-tree insertion algorithm combines aspects of both the R-tree [791] and the R\*-tree [152]. In particular, initially, an object  $o$  is inserted into the node whose centroid is the closest to the centroid of  $o$ . This step is similar to the first step of the R-tree insertion algorithm and is motivated by the desire to minimize the coverage of the existing nodes (but see Exercise 2).

Overflow in an existing SS-tree node is resolved in a similar manner to the way it is handled in an R\*-tree in that forced reinsertion is used. In particular, if a node  $A$  is full, then a fraction of the elements in  $A$  are reinserted (e.g., 30% [1991]). The elements to reinsert are the ones farthest from the centroid. These elements are removed from  $A$ , the centroid and radius of  $A$  are adjusted, and the elements are inserted again into the SS-tree starting from the root. If  $A$  overflows again during the reinsertion,  $A$  is split rather than attempting reinsertion again. Note that this is different from the reinsertion convention of the R\*-tree, where reinsertion is invoked on only one node at any given level (i.e., any node at the same level of  $A$  that overflows during the reinsertion process is split).

As in some implementations of the R-tree [750] and the R\*-tree [152], a two-step process is used for splitting a node  $A$ . The first step is to find a split dimension. The dimension  $i$  that is split is the one with the highest variance for component  $i$  of the centroids of the elements in  $A$ . This process takes  $O(M)$  time. The actual split position along dimension  $i$  is chosen by minimizing the variances for the  $M + 2 - 2 \cdot m$  possible split positions with respect to the values of component  $i$  of the centroid of the resulting region. This process takes  $O(M^2)$  time as computing the variance is an  $O(M)$  process, and it must be done for each of the  $O(M)$  possible split positions.<sup>20</sup> Of course, there are many other possible options for the way in which the split position or objects can be chosen. For example, we could take into account the variance of the centroid coordinate values along all of the dimensions as well as taking overlap and coverage into account (see Exercise 3).

Another advantage of using minimum bounding hyperspheres over minimum bounding hyperrectangles is that specifying a minimum bounding hypersphere requires slightly more than half the storage needed to describe a minimum bounding hyperrectangle. In fact, this was one of the motivations mentioned for the development of the sphere tree [1410, 1412]. In particular, in  $d$  dimensions, we need  $d + 1$  values to specify a minimum bounding hypersphere (the  $d$  coordinate values of its centroid plus the radius) versus  $2 \cdot d$  values to specify the minimum bounding hyperrectangle (the  $d$  coordinate values of two of its diagonally opposite corners). This means that the nodes in the SS-tree have a greater fanout, thereby reducing the height of the tree, which speeds up search. Nevertheless, the time needed to compute the minimum bounding hypersphere should be taken into account as it is considerably more complex than computing the minimum bounding hyperrectangles, especially as the dimension  $d$  increases (see Exercise 4) and when the faces of the hyperrectangles are parallel to the coordinate axes (see Exercise 1 in Section 2.1.5.2.1 of Chapter 2).

In experiments [999] on different datasets using a  $k$ -nearest neighbor algorithm [1586] for 16-dimensional data, the SS-tree performed better than the R\*-tree in terms of CPU time and lower I/O operations (i.e., disk reads). Interestingly, in these experiments, the heights of the SS-tree and the R\*-tree were usually the same, and thus the superiority of the SS-tree here was not a result of its lower fanout. Comparison with the VAMSplit R-tree [1989] (see Section 1.7.1.7 of Chapter 1) showed that the SS-tree performed slightly worse, but this was deemed a positive result given that the SS-tree is a dynamic method while the VAMSplit R-tree is a static method. However, in these comparisons, the height of the SS-tree was almost always one less than that of the VAMSplit R-tree, and thus the lower fanout of the SS-tree could have been the mitigating factor.

---

<sup>20</sup> White and Jain [1991] claim that this process takes  $O(M)$  time instead of  $O(M^2)$  time by virtue of restricting  $M$  to be equal to  $2 \cdot m$ . However, this need not be the case in general.

From the experiments [999], it was also observed that the average volume of the minimum bounding hyperrectangles in the  $R^*$ -tree was much smaller than that of the minimum bounding hyperspheres in the SS-tree (approximately 2%), while the average diameter of the minimum bounding hyperspheres in the SS-tree was about 60% of that of the minimum bounding hyperrectangles in the  $R^*$ -tree (i.e., the lengths of their diagonals). Although at a first glance it seems odd that regions with large diameters have small volumes, upon further reflection, this is not surprising. In particular, we note that in high dimensions, the length of the diagonal of a  $d$ -dimensional unit hypercube is  $\sqrt{d}$ , which is also the maximum diameter of the hypercube. For example, when  $d = 16$ , the maximum diameter of the unit hypercube is 4. Thus, given a set of points in the unit  $d$ -dimensional hypercube, the diameters of both the minimum bounding hypersphere and hyperrectangle range between 1 and  $\sqrt{d}$ . In contrast, the volume of the minimum bounding hyperrectangle ranges between 0 and 1, while the volume of the minimum bounding hypersphere ranges between 0 and

$$\left(\frac{\sqrt{d}}{2}\right)^d \frac{\pi^{d/2}}{\Gamma(d/2 + 1)}.$$

This is a considerably larger range of values. This means that there is less potential for overlap when using minimum bounding rectangles than minimum bounding spheres, and thus point location queries are faster when using minimum bounding hyperrectangles.

These observations mean that the SS-tree groups points into regions with short diameter, while the  $R^*$ -tree groups points into regions with small volumes, which is to be expected given the node insertion and split policies that are being used. Katayama and Satoh [999] explain these results by appealing to their belief that the smallness of the diameter of the minimum bounding hyperspheres has a greater effect on the performance of nearest neighbor queries than their volume. This is especially true when using the Euclidean distance metric.

The drawback of using hyperspheres as bounding boxes is that it is impossible to completely cover the underlying space with a finite set of hyperspheres of arbitrary volume without overlap. This means that if hyperspheres are used as bounding boxes, it is highly likely there will be significant overlap among them no matter how hard we try to minimize it. This overlap will have negative effect on the efficiency of range queries and nearest neighbor queries.

The SR-tree [999] was motivated by the belief that the performance of the SS-tree for both search and nearest neighbor queries could be improved if the volume of the minimum bounding boxes (which are hyperspheres in the SS-tree) could be reduced because this would lead to less overlap between nodes. Results of experiments with a uniformly distributed set of 16-dimensional points [999] showed that the average volume of the minimum bounding hyperrectangles for the points in the minimum bounding hyperspheres was approximately 0.1% of the average volume of the minimum bounding hyperspheres themselves. Moreover, the average volume of the minimum bounding hyperrectangles for the points in the minimum bounding hyperspheres was approximately 5% of the average volume of the minimum bounding hyperrectangles obtained when using an  $R^*$ -tree. The SR-tree takes advantage of these results by defining the bounding boxes to be the intersection of minimum bounding hypersphere and the minimum bounding hyperrectangle of the points, while it is constructed in basically the same way as the SS-tree with a few minor differences. The effect is to reduce significantly the volume of the bounding boxes. Thus, the SR-tree is a combination of an  $R^*$ -tree (rather than the  $R$ -tree due to the use of forced reinsertion) and an SS-tree.

The main difference in the construction of the SR-tree from that of the SS-tree is in the way the minimum bounding boxes are updated upon insertion of a point. In particular, both the minimum bounding hypersphere and the minimum bounding hyperrectangle must be updated, and this information must be propagated upward toward the root. The

minimum bounding hyperrectangles are updated in the same way as in the R-tree and R\*-tree. The minimum bounding hypersphere of a parent node is updated by examining both the minimum bounding hyperspheres and hyperrectangles of the child nodes. The center of the minimum bounding hypersphere is computed in the same way as in the SS-tree—that is, each coordinate value is a weighted average of the corresponding coordinate value of the center of the child nodes. The weight is the number of elements in the child node. The radius of the minimum bounding hypersphere  $s$  of a parent node  $u$  is the minimum of the maximum distance from the center of  $s$  to a point on the minimum bounding hyperspheres of its children and the maximum distance from  $s$  to a point on the minimum bounding hyperrectangles of its children. In this way, the radii of the minimum bounding hyperspheres in the SR-tree are smaller than those in the SS-tree, thereby reducing the extent of the overlap of the minimum bounding hyperspheres.

The idea of letting the intersection of the minimum bounding hypersphere and hyperrectangle serve as the minimum bounding box is similar to the idea that forms the basis of the P-tree [939]. In this case, instead of using a minimum bounding hyperrectangle whose faces are parallel to the coordinate axes, the P-tree is based on the observation that the volume of a minimum bounding hyperrectangle can be reduced by dropping the restriction that it be axis aligned (i.e., that its faces be parallel to the coordinate axes). The cost of such a solution is the addition of  $d - 1$  orientation parameters corresponding to the dimension of the data. Even further reductions in the volume can be achieved by making use of the intersection of several bounding hyperrectangles with different orientations. The result is a polygonal bounding box that serves as the basis of the P-tree. It is easy to see that the SR-tree corresponds to an adaptation of the P-tree without the restriction that the constituent bounding boxes be hyperrectangles (i.e., it uses the intersection of a hypersphere and a hyperrectangle). However, it is limited to two bounding boxes (of different type) rather than an arbitrary number as in the P-tree.

Notice that the SR-tree achieves a reduction in the volume of the bounding box in the SS-tree without having to increase the diameter, which is advantageous in the performance of nearest neighbor queries. However, there is a small price to pay in that the search for the nearest neighbors in the SR-tree must be modified so that the minimum distance from a query point  $p$  to a region  $q$  is no longer the minimum distance from  $p$  to the minimum bounding hypersphere of  $q$ . Instead, it is the longer of the minimum distance from  $p$  to the minimum bounding hypersphere of  $q$  and the distance from  $p$  to the minimum bounding hyperrectangle of  $q$ .

Searching for a point in an SR-tree is performed by using the minimum bounding hypersphere and minimum bounding hyperrectangle as filters. Notice that the object formed by the intersection is not used explicitly in the search, and thus there is no need to store it explicitly in the tree as it is too hard to compute and requires much storage. Thus, the minimum bounding boxes are stored implicitly in the SR-tree. In fact, the need to store both the minimum bounding hyperrectangle and the minimum bounding hypersphere for each node is one of the drawbacks of the SR-tree. In particular, the SR-tree requires almost 3 times the storage needed by the SS-tree and slightly more than 1.5 times the storage needed by the R-tree. This means that the fanout of intermediate nodes in the SR-tree is much smaller than that of the R-tree and the SS-tree, which leads to an increased height in the trees. This increase in height should lead to more I/O operations for the SR-tree in comparison with the SS-tree. Experiments [999] with 16-dimensional points showed that the number of nonleaf node I/O operations was indeed higher for the SR-tree than for the SS-tree. However, the number of leaf node I/O operations was much lower for the SR-tree than for the SS-tree, thereby resulting in an overall reduction in the total number of I/O operations for the SR-tree.

The same experiments also showed that the cost of creating an SR-tree was higher than that for an SS-tree while being lower than that for an R\*-tree. The performance of the SR-tree for nearest neighbor queries resulted in the SR-tree's having a lower CPU time and number of I/O operations (i.e., disk reads) than the SS-tree for both uniformly distributed data and real data. For uniformly distributed data, the VAMSplit R-tree had

better performance, but for real data, the SR-tree had slightly better performance. Again, as in the comparison of the SS-tree with the VAMSplit R-tree, the lack of degradation in the performance of the SR-tree vis-à-vis the VAMSplit R-tree is of importance as the SR-tree is a dynamic method while the VAMSplit R-tree is a static method. Nevertheless, in the case of uniformly distributed data of higher dimensionality (e.g., 32 and 64), the SR-tree (as well as the SS-tree) did not perform very well as they ended up accessing all of the leaf nodes in the tree. This is another case where sequential scan may be preferable to using an index.<sup>21</sup> The behavior of the SR-tree was better when the data was more clustered.

### Exercises

1. Suppose that the underlying space is tiled with hypercubes of volume  $v$ . We have observed that a hypersphere query region  $r$  of the same volume (i.e.,  $v$ ) will intersect at least 5 of the hypercube tiles of the underlying space for dimension 2 and 19 for dimension 3. Can you generalize these observations in terms of  $d$ , the dimension of the underlying space? Assume that  $r$  is always inside the data space.
2. The initial step in the SS-tree insertion algorithm routes the object  $o$  to a leaf node of the tree, starting from the root. When choosing among the children of a nonleaf node  $n$  during the traversal, the algorithm selects the child node whose centroid is the closest to the centroid of  $o$ . This technique is motivated by a desire to reduce the coverage of the nodes. However, unfortunately, this is not always the result, and the use of this strategy may in fact increase the coverage and the overlap as compared to alternatives. In particular, suppose that the centroid of  $o$  is within the minimum bounding hypersphere of child node  $a$  of  $n$  while being closer to the centroid of child node  $b$  but not being within the minimum bounding hypersphere of  $b$ . In this case, the algorithm will descend to child node  $b$ , which will have to be expanded to contain  $o$ , and, as a result, overlap the minimum bounding hypersphere of  $a$  as well as increase the total coverage. In contrast, if we had chosen child node  $a$ , depending on the radii of the minimum bounding hyperspheres of  $o$  and  $a$ , then perhaps we would not have had to expand the minimum bounding hypersphere of  $a$  and thus not increase the overlap or coverage. In light of this observation, can you still give an explanation for the rationale of inserting  $o$  in the node whose centroid is closest to the centroid of  $o$ ?
3. Devise alternative methods for partitioning an overflowing node  $A$  in the SS-tree, and compare their performance with the method of White and Jain [1991] that splits along the dimension  $i$  that has the highest variance and then chooses the split position with the minimum variance of component  $i$  of the centroids of the resulting region. In particular, devise methods that minimize overlap and coverage as in the conventional R-tree (see Section 2.1.5.2.3 of Chapter 2). This means trying to find two elements to serve as seeds and assigning the remaining elements to them so that the overlap or coverage, or both, of their minimum bounding spheres is minimized.
4. How would you compute the minimum bounding sphere for  $N$  points in a  $d$ -dimensional space?
5. Given a set of  $N$  uniformly distributed points in a unit  $d$ -dimensional hypercube, compute the expected diameter of the minimum bounding hypersphere for the points as a function of  $d$  and  $N$ .
6. Given a set of  $N$  uniformly distributed points in a unit  $d$ -dimensional hypercube, compute the expected volume of the minimum bounding hypersphere for the points as a function of  $d$  and  $N$ .
7. Given a set of  $N$  uniformly distributed points in a unit  $d$ -dimensional hypercube, can you prove that the minimum bounding hypersphere for the points has a smaller expected diameter than that of the minimum bounding hyperrectangle (defined as the length of the longest diagonal)? An intuitive explanation is that, as long as at least one point lies on each face of the unit hypercube, the minimum bounding hyperrectangle is identical to the unit hypercube. In

---

<sup>21</sup> However, it has been noted [212] that nearest neighbor search in uniformly distributed data may not make sense in high-dimensional spaces since there tends to be little difference in the distances to the various objects.

contrast, in order for the minimum bounding hypersphere to have a maximum diameter, there must be at least two points at a pair of diagonally opposite corners. In order for the claim to hold, you need to show that the latter event is less likely to occur than the event leading to the minimum bounding hyperrectangle being equivalent to the hypercube.

8. Given a set of  $N$  uniformly distributed points in a unit  $d$ -dimensional hypercube, can you prove that the minimum bounding hypersphere for the points has a larger expected volume than that of the minimum bounding hyperrectangle?

### 4.4.3 Increasing the Fanout: TV-Tree, Hybrid Tree, and A-Tree

As mentioned earlier, multidimensional indexing methods are attractive only if they result in better performance than using a sequential scan, which is fairly simple to execute as it only requires that we check the individual items one by one in sequence. Some of the bad performance of methods that are based on the use of an object hierarchy, such as the R-tree, SS-tree, SR-tree, and so on, for high-dimensional data can be attributed to the small fanout in each node of the structure. This is due to the increasing amount of information that must be stored in each node for the minimum bounding box as the dimensionality increases, which in turn causes the tree to get deeper, thereby resulting in more disk accesses.

One way to increase the fanout in each node is to limit the number of attributes that are tested at each level of the index hierarchy. The TV-tree (denoting *telescoping vector*) of Lin, Jagadish, and Faloutsos [1171] is an example of such an approach. In this case, the number of attributes that are tested at each level is fixed, although their identities can be varied from level to level, as well as from node to node at the same level. The same philosophy is used in the X-Y tree [1334] and the equivalent treemap [1758] and puzzletree [480] (see Section 2.1.2.9 of Chapter 2) with the difference that minimum bounding boxes are associated with each node in the TV-tree. The minimum bounding boxes are not restricted to hyperrectangles and, in fact, can be spheres constructed with any Minkowski distance metric  $L_p$  (where given the points  $(x_1, y_1)$  and  $(x_2, y_2)$ , the distance is defined as  $d_{L_p}((x_1, y_1), (x_2, y_2)) = ((x_1 - x_2)^p + (y_1 - y_2)^p)^{1/p}$ ). Note that when all the attributes are tested, then the TV-tree reduces to being equivalent to the SS-tree (which uses  $L_2$  but could also use any other metric) in structure.

The attributes (i.e., features) that are tested in the TV-tree are termed *active* and are deemed to enable the best discrimination among the data. They are used for the initial discrimination phase. At some point, these features do not provide further discriminatory power, which occurs when all the feature vectors in a node share the same value in the first active attribute(s). In order to provide additional discriminatory power, other features are shifted into the active set while the currently active features are made inactive—hence the use of the term *telescoping*. Experiments have shown that the TV-tree leads to fewer disk accesses than the R\*-tree for some datasets [1171].

The utility of the TV-tree is based on the assumption that features can be ordered according to “importance.” It also depends on the assumption that sets of feature vectors will be likely to match exactly on some of the features, especially the “important” ones, as this is what will cause the shifting of features into and out of the active set. The first assumption is reasonable as an appropriate transform can be applied to some of the dimensions to obtain the most important ones (such as with principal component analysis or the discrete cosine transform [587] in the case of dynamic data; see Section 4.6). Unfortunately, the second assumption does not always hold in applications such as those in image databases where the feature values are real numbers and thus an exact match for these features is rare. This means that the TV-tree reduces to be an index on just the first few dimensions.

More significant reduction in the fanout in each node can be achieved by using the hybrid tree of Chakrabarti and Mehrotra [317] (see Section 1.7.1.2 of Chapter 1). The hybrid tree is a variant of the k-d-B-tree [1567] that shares some of the features of the R-tree [791]. In the hybrid tree, the partition regions in nonleaf nodes (i.e., the regions for the child nodes) are represented with a variant of the k-d tree [164] that allows overlap while minimum bounding boxes are associated with the child nodes. In particular, instead of representing the child node regions in a nonleaf node  $a$  with a list of minimum bounding boxes as is the case for an R-tree, the hybrid tree represents them as the leaf nodes of the k-d tree for  $a$ . Such a representation is much more compact than a list of bounding boxes, especially in high-dimensional spaces, as the same amount of fanout is obtained regardless of the dimensionality of the underlying space. In contrast, in the R-tree, the fanout is inversely proportional to the dimensionality of the underlying space.

However, the hybrid tree representation has the drawback that the child node regions are no longer minimal, in the sense that they may be larger than the minimum bounding box of the points in the subtree rooted at the child node. The extraneous area is termed *dead space* and can lead to reduced query performance. In particular, while during a query that has query region of  $r$ , a child node  $b$  may be accessed even though  $r$  only covers the dead space of  $b$ 's region (as determined by the “k-d tree” in  $b$ 's parent). The hybrid tree addresses this drawback by approximating the minimum bounding box of each child node region of a nonleaf node in a very compact form that is based on a quantization of the underlying space, thereby enabling it to be represented with fewer bits (this method was first proposed by Henrich [826]). Experiments with real data with dimension as high as 64 showed that the hybrid tree outperforms the SR-tree and sequential scan [317]. Nevertheless, as the dimension of the underlying space increases further, the advantage of the hybrid tree over sequential scan will vanish (at around dimension 100 [315]).

The A-tree of Sakurai, Yoshikawa, Uemura, and Kojima [1607] also uses a quantized approximation of the bounding boxes to reduce the space requirements in an R-tree for high-dimensional data. The idea is to modify the format of an internal node  $a$  so that instead of storing the bounding box of each of  $a$ 's children, it stores an approximation of the bounding box of each child  $b$  where the approximation is a quantized bounding box relative to the location of the bounding box of  $a$ . The advantage is that at deeper nodes in the tree, the corresponding bounding boxes are smaller and thus their quantized approximation can be encoded with just a small number of bits. Such bounding boxes are characterized as being *virtual*: the complete bounding box of the set of objects in the space spanned by  $a$  is still stored with  $a$ , while the virtual bounding box of  $a$  is only associated with the node that points to  $a$  as one of its children.

#### 4.4.4 Methods Based on the Voronoi Diagram: OS-Tree

One straightforward method of adapting the Voronoi diagram for nearest neighbor searching is to approximate each Voronoi region by its minimum bounding rectangle and then to construct an index in the form of an object hierarchy such as one of the variants of the R-tree as discussed in Section 2.1.5.2 of Chapter 2 [189]. We do not discuss this approach here. Instead, we focus on the os-tree (denoting *overlapped-split tree*) [1226, 1229], which is an adaptation of the BSP tree to provide both a hierarchical approximation of the  $d$ -dimensional Voronoi diagram and an index to it in order to facilitate finding nearest neighbors in high dimensions. The idea is to associate with each node  $a$  a bounding box in the form of a convex polyhedron, termed a *cover*, that contains every point in the  $d$ -dimensional space whose nearest data point is in the space spanned by  $a$ . Therefore, the cover of  $a$  is really the  $d$ -dimensional polyhedron formed by the union of the Voronoi regions of the data points in  $a$ . This polyhedron is quite expensive to compute, and thus there are a number of alternatives that can be used. For example, one choice is the minimum convex bounding region—that is, the convex hull of the vertices of the union of the Voronoi regions. It should be clear that the covers of

the children of a node will usually overlap (i.e., they are not disjoint), unless the node has only two data points (assuming a bucket size of 1) as the Voronoi bisector of two points is just a hyperplane. In other words, due to the requirement that the cover be convex, the cover of  $a$  can also contain points in the  $d$ -dimensional space whose nearest data point is not in  $a$ . In essence, the os-tree is an adaptation of an object hierarchy such as that used in the R-tree to the Voronoi diagram where the objects are the individual Voronoi regions (instead of the points) and the BSP tree is used like a skeleton to guide both the process of forming the bounding boxes, which are  $d$ -dimensional polyhedra, as well as the search.

Searching for the nearest neighbor to query point  $q$  in the os-tree is straightforward. Descend the tree and at each node visit the children whose covers contain  $q$ . Since the covers are not disjoint, both children may need to be visited. The efficiency of the solution depends on how tightly the covers surround the union of the Voronoi regions of the points in each node. Notice that the solution is simpler than one that uses the incremental nearest neighbor algorithm given in Section 4.1.3. In particular, it is analogous to the first component of that algorithm, which finds the block (i.e., leaf node) containing the query point. The difference is that the nondisjointness of the covers may result in more than one node's being visited at each level of the tree. An advantage is that actual distances between points are only computed when processing a leaf node. Of course, if more than one neighbor is sought, then the incremental nearest neighbor algorithm should be applied to the os-tree, which is possible.

The os-tree is constructed by recursively partitioning the cell corresponding to node  $a$ , containing point set  $S_a$  with cover  $c_a$  and bounded by the set of  $(d - 1)$ -dimensional hyperplanes  $U_a$ , into two new cells using some partitioning hyperplane  $H_a$ . This results in the creation of two new nodes  $al$  and  $ar$  containing disjoint point sets  $S_{al}$  and  $S_{ar}$ , respectively, whose union is  $S_a$  and whose corresponding covers  $c_{al}$  and  $c_{ar}$  are computed as follows. At each partitioning step, compute the Voronoi bisector between  $S_{al}$  and  $S_{ar}$  (e.g., a sequence of connected line segments in two dimensions) and the corresponding Voronoi regions,  $v_{al}$  and  $v_{ar}$ , respectively, each of which is the union of the Voronoi regions of the individual points. Obtain covers  $c_{al}$  and  $c_{ar}$  by finding two parallel  $(d - 1)$ -dimensional hyperplanes  $L$  and  $R$  having the property that  $v_{al} \subset c_{al}$ , where  $c_{al} = U_a \cap L$ , and  $v_{ar} \subset c_{ar}$ , where  $c_{ar} = U_a \cap R$  (where the set operation  $\cap$  is performed on the halfspaces induced by the hyperplanes).<sup>22</sup> The actual covers  $c_{al}$  and  $c_{ar}$  are the regions bounded by the subsets of  $(d - 1)$ -dimensional hyperplanes  $U_a \cup L$  and  $U_a \cup R$ , respectively. Note that  $L$  and  $R$  need not necessarily be parallel to the BSP partitioning hyperplane  $H_a$ ; nor must they be parallel to each other. However, as we shall see below, making  $L$  and  $R$  parallel enables the detection of the children whose covers contain  $q$  with the same operation (i.e., the dot product of  $q$  and their normals, which are the same since they are parallel). Figure 4.25(a) shows the BSP tree node corresponding to a sample set of points and their Voronoi regions, as well as the node's cover, partitioning hyperplane, and Voronoi bisector. Figure 4.25(b) shows the result of partitioning the node in (a), including the covers of the resulting nodes that are induced by the additional hyperplanes  $L$  and  $R$ . The actual regions spanned by the nodes (in contrast to those spanned by the covers) are shaded.

Figure 4.25  
(a) The BSP tree node corresponding to a sample set of points and their Voronoi regions (shown with broken lines), as well as the node's cover, partitioning hyperplane  $H_a$ , and Voronoi bisector. (b) The result of partitioning the node in (a), including the covers of the resulting nodes that are induced by the additional hyperplanes  $L$  and  $R$ . The actual regions spanned by the nodes (in contrast to those spanned by the covers) are shaded.

A critical shortcoming of the above solution is that it requires knowledge of the Voronoi diagram. This is a serious flaw as the combinatorial complexity of the  $d$ -dimensional Voronoi diagram grows exponentially with its dimension  $d$ —that is, for  $N$  points, the time to build and the space requirements can grow as rapidly as  $\Theta(N^{d/2})$  as an example can be constructed that attains this bound [112]. In particular, the time to build is the storage cost plus the cost of sorting. In two dimensions, this cost is dominated

<sup>22</sup> The addition of two arbitrary hyperplanes to bound the area spanned by the objects in the two subtrees is also used in the KD2-tree [1410, 1412] (see Section 1.5.1.4 of Chapter 1). In addition, it is used in the spatial k-d tree [1404, 1407] (see Sections 1.5.1.4 and 1.7.1.2 of Chapter 1 and Section 3.3.2.5 of Chapter 3) and the hybrid tree [317] (see Section 4.4.3 and Section 1.7.1.2 of Chapter 1) where the hyperplanes are restricted to being axis parallel.

by the time to sort, which is  $O(N \log N)$ . Therefore, the os-tree, as presented above, is impractical for high dimensions (even for moderate dimensions as low as  $d = 10$ ) and not really usable. In order to overcome this shortcoming, Maneewongvatana and Mount [1230] modify the os-tree so that the covers correspond to unions of approximations of the Voronoi regions of the points rather than the unions of the actual Voronoi regions. This is achieved by the use of training points,<sup>23</sup> which are sample nearest neighbor queries whose results are used to delineate the boundaries of an approximate Voronoi diagram, where the approximate Voronoi diagram consists of approximate covers. For example, Figure 4.26 shows the result of forming an approximate cover for the set of sample points and node in Figure 4.25(a) using a set of training points. The broken line denotes the cover corresponding to the true Voronoi regions, the thick line denotes the cover corresponding to the approximate Voronoi regions, and the thin line denotes the boundary of the BSP tree node. Of course, the number of training points must be considerably larger than the number of data points as the training points are used to approximate boundaries that are already quite complex from a combinatorial standpoint. The result is termed a *probably correct os-tree*.

- Data points (S)
- Training points (T)

Figure 4.26  
The approximate cover, drawn with a thick line, for the set of sample points and the node in Figure 4.25(a) obtained using the specified training points. The broken line corresponds to the cover for the true Voronoi regions, and the thin line is the boundary of the node. The shaded regions correspond to locations where the query points will be associated with the wrong nearest neighbor as they lie outside the approximate cover of the node.

The drawback of this modification is that it can lead to errors: a query point  $q$  could be associated with the wrong nearest neighbor. This is the case when  $q$  is in the Voronoi region of a point  $p$  while not being in the approximate cover of the node containing  $p$  (e.g., whenever  $q$  is in any of the shaded regions in Figure 4.26). Let  $f$ , termed the *failure probability*, be the maximum probability of the occurrence of such an event. It can be shown that if the cover of each node in a probably correct os-tree contains the covers of its children, then  $f$  is the failure probability for search in the probably correct os-tree (see Exercise 1) [1226]. The result is an approximation of a Voronoi diagram, and an index is provided for it in the form of a BSP tree without ever actually having to construct the Voronoi diagram. This is an important point.

The probably correct os-tree is constructed in a similar manner to the conventional os-tree but with some key differences. Start at the root node, which corresponds to the entire set  $S$  of data points. For each node  $a$  corresponding to the point set  $S_a$ , determine if the number of data points in  $S_a$  is less than some threshold  $b$  (analogous to a bucket capacity), in which case the points are stored in a leaf node. Otherwise, split the cell corresponding to  $a$  into two new cells, thereby creating two new nodes  $al$  and  $ar$  containing disjoint data point sets  $S_{al}$  and  $S_{ar}$  whose union is  $S_a$ , where  $S_{al}$  and  $S_{ar}$  are of approximately equal size so that the resulting tree is balanced. Splitting the cell is actually a two-step process:

1. Choose the points that make up subsets  $S_{al}$  and  $S_{ar}$ .
2. Choose a partitioning plane  $I_a$  for the cell corresponding to  $a$ .

The first step introduces a partitioning plane  $H_a$  whose orientation is orthogonal to the direction of the greatest variation of the data points. This is achieved by using Principal Component Analysis (PCA) (e.g., [665]). In particular, the covariance matrix is computed for  $S_a$ , and the points are sorted according to their projection onto the eigenvector corresponding to the largest eigenvalue.  $S_{al}$  and  $S_{ar}$  are formed by the first and second halves, respectively, of the sequence. The eigenvalues are the variances along the directions of the corresponding eigenvector and indicate the relative strength of the correlation along that direction. Thus, without additional information about the distribution of the data points, separating the points on the basis of the first eigenvector is reasonable. For example, Figure 4.27 is an example of the result of applying PCA to a sample set of points. PCA is frequently used in dimension reduction (see Section 4.6.4.1) because the actual high-dimensional data does not usually span the entire space but, instead, is of some lower dimension. Use of this method for obtaining the partitioning

<sup>23</sup> The use of training points was inspired by Clarkson [400], who used them in a randomized (e.g., [1318, 1325]) nearest neighbor algorithm in a metric space, which, at times, with very low probability, may return the wrong answer.

Figure 4.27  
Example of the result of applying PCA to a sample set of points.

plane was first suggested by Sproull [1797] in a discussion of a k-d tree whose partitioning planes have an arbitrary orientation, a variant of a BSP tree for points (see Section 1.5.1.4 of Chapter 1).

It should be clear that once the points in  $S_a$  have been partitioned as described above, if the maximum of the projections of the elements in  $S_{al}$  is less than the minimum of the projections of the elements in  $S_{ar}$ , then there is an infinite number of possible choices for the separating hyperplane  $I_a$ . The second step tries to find a more appropriate orientation for  $I_a$  than the one used for the first step (i.e.,  $H_a$ ). The goal is to minimize the extent to which the Voronoi regions of the elements of  $S_{al}$  ( $S_{ar}$ ) (measured by their  $d$ -dimensional volume) overlap the right (left) side of  $I_a$ . This will enable the covers to be tighter, thereby resulting in a more efficient search. The ideal solution is for  $I_a$  to coincide with the Voronoi bisector of the two sets  $S_{al}$  and  $S_{ar}$ , in which case there is zero overlap. This is generally impossible, so the next best solution is for  $I_a$  to be as close as possible in position and orientation to the Voronoi bisector of the two sets  $S_{al}$  and  $S_{ar}$ . However, as we do not know the Voronoi regions for the data points, we can try to find the position and orientation of  $I_a$  that minimizes the number of training points on the right side of  $I_a$  whose nearest neighbors are elements of  $S_{al}$  and the number of training points on the left side of  $I_a$  whose nearest neighbors are elements of  $S_{ar}$  (see Exercise 2).

This requires quite a bit of work as the number of training points is expected to be large. Thus, we need an alternative solution that is less complex. Maneewongvatana and Mount [1230] observe that most of the overlap can be accounted for by the data points that are closest to  $I_a$ . Therefore, they propose to position  $I_a$  so that it is coincident with the bisector of the edge that separates the two points  $p_{al}$  and  $p_{ar}$  in  $S_{al}$  and  $S_{ar}$ , respectively, which are the farthest apart subject to the additional constraints that all other points in  $S_{al}$  ( $S_{ar}$ ) are to the left (right) of  $I_a$  and even farther from  $I_a$  than  $p_{al}$  ( $p_{ar}$ ) (see also Exercise 3). Such a choice means that we are in essence ignoring the points that are far apart from  $I_a$ . They suggest that  $I_a$  be computed using the support vector machines (SVM) method [281, 1917] as it leads to a hyperplane that is farthest from the closest points on its two sides.

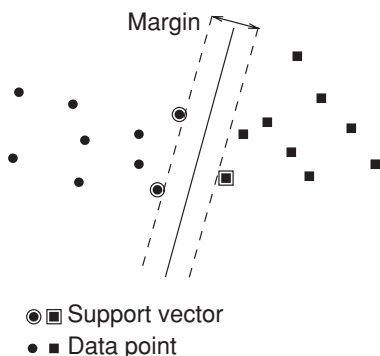

Figure 4.28  
Sample dataset and the resulting separating hyperplane and support vectors resulting from use of the SVM method.

Formally, given the sets  $S_{al}$  and  $S_{ar}$ , the SVM method finds the hyperplane  $I_a$  with the highest margin, where the *margin* is defined as the sum of the distance from  $I_a$  to the nearest point  $p_{al}$  in  $S_{al}$  and the distance from  $I_a$  to the nearest point  $p_{ar}$  in  $S_{ar}$ , subject to the constraints that all points in  $S_{al}$  ( $S_{ar}$ ) are to the left (right) of  $I_a$ . The SVM method formulates this as a nonlinear optimization problem and returns a set of points termed *support vectors*, as well as other coefficients that are used to determine  $I_a$ . The support vectors are the points that have a direct influence on the result. In particular, if a support vector is removed or modified, then the result may change, and thus other points in the original dataset may be removed with no change in the resulting hyperplane. For example, Figure 4.28 shows the resulting hyperplane and the support vectors for a small dataset. It is important to observe that one of the reasons for basing the choice of the separating hyperplane  $I_a$  on the SVM method rather than the PCA method is that the hyperplane resulting from the SVM method is more heavily influenced by the points that lie near it (i.e., it is local) while the one resulting from the PCA method is influenced by all of the points (i.e., it is global).

The SVM method may take quite a bit of time to execute due to the need to satisfy the constraints on the relative positions of the points in  $S_{al}$  and  $S_{ar}$  with respect to  $I_a$ . This is generally much more complex than finding the distance between each point in one set and its nearest point in a second set (known as the *nearest foreign neighbor problem* [2047]).

One way to speed up the SVM method is to partition  $S_{al}$  and  $S_{ar}$  into smaller subsets, apply the SVM method to pairs of subsets, find the resulting support vectors, and then reapply the SVM method to sets making up the support vectors. The final application of the SVM method takes place once there are just two sets left [1226]. Of course, the result is an approximation of the hyperplane that would be obtained had the SVM method been applied to sets  $S_{al}$  and  $S_{ar}$  in their entirety rather than their partitions.

Earlier we stated that our goal in the choice of  $I_a$  is to minimize the extent to which the Voronoi regions of the elements of  $S_{al}$  ( $S_{ar}$ ) (measured by their  $d$ -dimensional volume) overlap the right (left) side of  $I_a$ . This assumes that the distribution of the query points is uniform in the regions where misclassification occurs. If this is not the case, then we may want to have an alternative way to measure the extent of the misclassification by enumerating the number of training points that are misclassified and minimizing it instead of the  $d$ -dimensional volume of the extent of the Voronoi regions that overlap the wrong side of  $I_a$ . This can be achieved by incorporating the minimization of the misclassification of training points into the constraints taken into account by the SVM method. Of course, this will result in a significant increase in the complexity of the SVM method due to the large number of training points, and hence this alternative is not used.

Once  $I_a$  has been determined, compute the nearest neighbor for each of the query points in the training set  $T_a$ , and partition  $T_a$  into two sets  $T_{al}$  and  $T_{ar}$ , depending on whether the nearest neighbor is in  $S_{al}$  or  $S_{ar}$ , respectively. Next, calculate the covers for the cells corresponding to nodes  $al$  and  $ar$  by computing two cover hyperplanes  $B_{al}$  and  $B_{ar}$  parallel to  $I_a$  that serve to bound the regions containing  $T_{al}$  and  $T_{ar}$ , respectively. These three hyperplanes (i.e.,  $I_a$ ,  $B_{al}$ , and  $B_{ar}$ ) are stored with node  $a$ . Notice that the training points were not used in the determination of  $I_a$ , although they may provide some additional information, as discussed earlier. For example, Figure 4.29 shows the result of splitting a node in a probably correct os-tree corresponding to the set of data points and node in Figure 4.25. The shaded area in the root node corresponds to the overlap of the covers of the left and right children.

Figure 4.29  
 The result of splitting a node in a probably correct os-tree corresponding to the set of data points and the node in Figure 4.25. The shaded area in the root node corresponds to the overlap of the covers of the left and right children. The shaded areas in the left and right children correspond to locations where the query points will be associated with the wrong nearest neighbor as they lie outside the approximate cover of the node.

Figure 4.30  
Sample query point  $q$  whose closest neighbor  $p$  is closer than the partitioning plane  $I_a$ , thereby precluding the need to visit the node that does not contain  $q$ .

Searching for the nearest neighbor to point  $q$  in the probably correct os-tree is done in a similar manner to that described earlier for the conventional os-tree. The search starts at the root node. At any internal node  $a$  (with hyperplanes  $I_a$ ,  $B_{al}$ , and  $B_{ar}$ ), find the location of the query point  $q$  with respect to the separating hyperplane  $I_a$  and the two cover hyperplanes  $B_{al}$  and  $B_{ar}$  (which define the covers of  $a$ 's child nodes). This is done by taking the dot product of  $q$  and the normal to  $I_a$ , yielding  $v$ , and examining whether  $v$  is greater than or equal to the constant term of the equation corresponding to  $I_a$ , or if it is smaller. The fact that all three hyperplanes are parallel means that they all have the same normal, and thus only one dot product is needed for determining the location of  $q$  with respect to  $I_a$ ,  $B_{al}$ , and  $B_{ar}$ , which can be done in  $O(d)$  time. The only difference is in the comparand of the test. Armed with the result of the test, node  $al$  ( $ar$ ) is visited first if  $q$  lies to the left (right) of  $I_a$ , while  $ar$  ( $al$ ) is not visited unless  $q$  is in the cover region of  $ar$  ( $al$ ), in which case it is visited next.

A minor optimization can avoid visiting  $ar$  ( $al$ ) even if  $q$  is in the cover region of  $ar$  ( $al$ ). This depends on the distance to  $q$ 's current candidate nearest neighbor in the region corresponding to  $al$  ( $ar$ ) being smaller than the distance from  $q$  to  $I_a$ . In this case, every point in  $S_{ar}$  ( $S_{al}$ ) is on the other side of  $I_a$  and thus even farther from  $q$ . Therefore, no point in  $S_{ar}$  ( $S_{al}$ ) can be a candidate nearest neighbor, which precludes visiting  $ar$  ( $al$ ). Figure 4.30 illustrates such a situation.

The only way in which the above search can fail is if the query point  $q$  lies in the Voronoi region  $v_p$  of some point  $p$ , where  $p$  is in node  $b$  while the cover of  $b$  does not contain  $q$ . This is a direct result of the absence of training points in the neighborhood of  $q$ , thereby causing the covers to fail to capture properly the Voronoi regions of the data points. For example, the search will fail for any query point  $q$  that lies in the shaded regions in Figure 4.26 and in the left and right children in Figure 4.29. Maneewongvatana [1226] shows that if the set  $S$  of data points and the set  $T$  of training points are independent and identically distributed, then the probability of such a failure is approximately  $|S|/|T|$  when  $|T|$  is relatively large. Remarkably, this probability estimate is quite tight and was attained in a wide range of experiments [1230]. This is in contrast to most estimates in approximate nearest neighbor searching where the actual error was much less than the approximation error tolerance [387, 1226] (for more details, see below).

The  $|S|/|T|$  failure probability means that the training set must be quite large in order to reduce it below some reasonable threshold when the volume of the data is of reasonable size with respect to the dimensionality of the underlying space, which somehow lessens the attractiveness of this method. Nevertheless, although the number of necessary training points seems large in comparison with the number of data points, it should be realized that the training points serve to approximate the Voronoi diagram, which is considerably more complex. Recall that the combinatorial complexity of the Voronoi diagram for  $N$   $d$ -dimensional points can grow as rapidly as  $\Theta(N^{d/2})$ . For example, for  $d = 30$  and  $N = 4,000$ , the combinatorial complexity is  $4,000^{30}$ , which is a huge number. In contrast, Maneewongvatana and Mount [1230] used training sets that were approximately 200 times the size of the datasets. Thus, the os-tree reduces the complexity from exponential to linear.

It is difficult to compare the os-tree with other representations as the concept of a failure probability is not present. However, finding the nearest neighbor with a failure probability is somewhat similar to approximate nearest neighbor finding. The idea is to find an approximation error tolerance  $\epsilon$  that yields a failure error roughly equal to the failure probability. Note that the failure error is usually far less than the approximation error tolerance. Maneewongvatana and Mount [1229, 1230] conducted such a comparison of the os-tree with the sliding-midpoint  $k$ - $d$  tree (see Section 1.5.2.2) for finding the nearest neighbor. The result when the failure error of approximate nearest neighbor finding for the sliding-midpoint  $k$ - $d$  tree was roughly equal to that of the os-tree was comparable performance in terms of query time and number of nodes visited for 10 and 20 dimensions. On the other hand, the sliding-midpoint  $k$ - $d$  tree usually performed better

for 30 dimensions. Moreover, they found that the failure error was often as much as two orders of magnitude smaller than the approximation error tolerance (e.g., 0.0044 failure probability versus an epsilon value of 0.55 [1226]). Of course, the sliding-midpoint k-d tree was much faster to build.

These results show that the os-tree did reasonably well at approximating the Voronoi diagram in the lower dimensions (e.g., 10 and 20) but not so well in the higher dimensions (e.g., 30). The query time of the os-tree was hampered by the need to test the query point with respect to the partitioning hyperplane, which is an  $O(d)$  operation, in contrast to a simple comparison of one coordinate value in the case of the sliding-midpoint k-d tree. This suggests that the idea of incorporating the approximation of the Voronoi diagram into the index is worthwhile, but perhaps better performance could be obtained if the index made use of partition planes that were parallel to the coordinate axes, as is usually done with a conventional k-d tree, while still retaining the notion of a cover that would also make use of axis-parallel boundaries (very similar to an R-tree). Of course, the trade-off is that the covers may not be as tight, thereby leading to larger overlap regions and more nodes being searched.

Maneewongvatana and Mount [1229] also examined the amount of overlap in the nodes, which they found to be surprisingly high. This is not really surprising when we realize that the amount of overlap is directly related to the number of training points. In particular, the greater the number of training points, the larger the cover associated with the node. However, the failure probability decreases with an increase in the number of training points. Thus, we have the seemingly contradictory result that the greater the overlap, the smaller is the failure probability. Actually, this is not surprising as the greater the amount of overlap, the smaller the chance of missing a nearest neighbor when descending the tree in the search process as the larger cover ensures that we descend both subtrees if necessary. Although the overlap ranged from 0.3 to 0.7, the maximum was attained at most of the levels of the tree, and it did not show a great variation with respect to the failure probability. This suggests that the work expended in the SVM method in choosing a good partitioning may not be worth the effort, thereby leading to faster construction of the os-tree. Moreover, it provides further confirmation of the hypothesis that a more computationally tractable bounding box (e.g., whose sides are axis parallel) may lead to performance improvements with possibly a small degradation in the accuracy as measured by the theoretical failure probability if a smaller number of training points is found to be needed. It should be clear that the utility of the os-tree needs to be investigated further.

Note that the idea of permitting the search to fail via the introduction of a failure probability is similar to that proposed by Ciaccia and Patella [387] for the computation of what are termed probably approximately correct (PAC) nearest neighbors (see Section 4.3). However, the difference is that Ciaccia and Patella assumed that the distribution of the distance between the query and data points is known. Moreover, they did not actually execute a nearest neighbor search. Instead, they used the knowledge of the distance distribution, approximation error tolerance, and a failure probability  $f$  to predict an expected distance  $d_f$  for which the probability that the nearest neighbor is closer than  $d_f$  is at most  $f$ , and then they proceeded to find a point within this distance of  $q$  that is deemed the nearest neighbor. Thus, they actually executed a variant of a range query where they stopped on the first object in the range.

Their approach has several drawbacks. First of all, the nearest neighbor distance is usually not independent of the position of the query point; nor is it independent of boundary effects. Second, notwithstanding the criticism of the above independence assumption, the distribution of the distance between the query and the data points is not generally known, thereby making the failure probability, which depends on it, difficult to compute. In contrast, in the method of Maneewongvatana and Mount [1229], the failure probability is shown to be a function of the ratio of the volume of the data and the number of training points, provided these two sets are independent and identically distributed.

1. Given a probably correct os-tree where  $f$  holds for the leaf nodes, prove that if the cover of each node contains the covers of its children, then  $f$  is the failure probability for search in the tree.
2. When constructing the probably correct os-tree, once the points in  $S_a$  have been partitioned with the hyperplane  $H_a$  resulting from the use of the PCA method, it was proposed to find a more appropriate separating hyperplane  $I_a$  that minimizes the number of training points on the right side of  $I_a$  whose nearest neighbors are elements of  $S_{al}$  and the number of training points on the left side of  $I_a$  whose nearest neighbors are elements of  $S_{ar}$ . Would it not be more appropriate to choose the separating hyperplane  $I_a$  that minimizes the  $d$ -dimensional volume spanned by the training points on the right side of  $I_a$  whose nearest neighbors are elements of  $S_{al}$  and the volume spanned by the training points on the left side of  $I_a$  whose nearest neighbors are elements of  $S_{ar}$ ? If yes, what are the drawbacks of such a choice?
3. When constructing the probably correct os-tree, what is the rationale for choosing the hyperplane that is farthest from the closest points on its two sides rather than one that is closer to the same two points?

Figure 4.31  
Partitions of the underlying space induced by the  $\varepsilon$ -nearest neighbor sets corresponding to the sites of the Voronoi diagram given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2 for (a)  $\varepsilon=0.10$ , (b)  $\varepsilon=0.30$ , and (c)  $\varepsilon=0.50$ . The darkness of the shading indicates the cardinality of the  $\varepsilon$ -nearest neighbor sets, with white corresponding to 1.

### 4.4.5 Approximate Voronoi Diagram (AVD)

Har-Peled [799] addresses the  $\Theta(N^{d/2})$  space requirements of the  $d$ -dimensional Voronoi diagram of a point set  $S$  by approximating it with an implicit representation that he terms an *approximate Voronoi diagram* (AVD). The idea is to partition the underlying space using some arbitrary block decomposition rule so that, given a  $\varepsilon \geq 0$ , every block  $b$  is associated with some element  $r_b$  in  $S$  such that  $r_b$  is an  $\varepsilon$ -nearest neighbor for all of the points in  $b$ . The motivation for the AVD is to reduce the space requirements for a  $d$ -dimensional Voronoi diagram from  $\Theta(N^{d/2})$  for  $N$  points to a quantity closer to linear, although not necessarily linear. In particular, Har-Peled [799] shows that, for a given value of  $\varepsilon$ , it is possible to construct an AVD in  $O((N/\varepsilon^d)(\log N)(\log(N/\varepsilon)))$  time, taking up the same amount of space (i.e., the number of blocks is also  $O((N/\varepsilon^d)(\log N)(\log(N/\varepsilon)))$ ) and to determine the  $\varepsilon$ -nearest neighbor of a query point  $q$  in  $O(\log(N/\varepsilon))$  time.

Note that the Voronoi diagram is only implicitly represented in the AVD in the sense that the boundaries of the Voronoi regions are not explicitly stored in the blocks. This implicit representation is also a characteristic of using the mb-tree [1383] (see Section 4.5.3.3) to represent data drawn from either a vector or a metric space where the data are objects, termed *pivots*, with associated regions so that all objects that are associated with a pivot  $p$  are closer to  $p$  than to any other pivot. In this case, the boundaries of the regions are also represented implicitly (see Section 4.5.3.3 for more details).

There are many possible block decomposition rules. Regardless of the rule that is chosen for each block, the only requirement is that the intersection of the  $\varepsilon$ -nearest neighbor sets of all of the points in each block be nonempty. For example, Figure 4.31(a–c), corresponds to the partitions of the underlying space induced by the  $\varepsilon$ -nearest neighbor sets corresponding to the sites of the Voronoi diagram given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2 for  $\varepsilon = 0.10, 0.30$ , and  $0.50$ , respectively. The darkness of the shading indicates the cardinality of the  $\varepsilon$ -nearest neighbor sets, with white corresponding to 1. The space requirements and the time complexity of nearest neighbor queries are reduced when the block decomposition rule yields blocks that are sufficiently “fat” (i.e., they have a good aspect ratio as discussed in Section 1.5.1.4 of Chapter 1). One possibility, for which the “fat” requirement holds, is to use a rule, such as the PR quadtree [1413, 1637] (see Section 1.4.2.2), that for multidimensional point data recursively decomposes the underlying space into congruent blocks (i.e., squares in two dimensions) until each block is either empty or contains at most one point.

In the case of the AVD, the decomposition rule is such that the underlying space is recursively decomposed into congruent blocks until the space spanned by each block  $b$  is associated with an element  $r_b$  in  $S$  (also known as the *sites* of the Voronoi diagram) such that  $r_b$  is an  $\varepsilon$ -nearest neighbor for every point in the space spanned by  $b$ . In this case,  $r_b$  is said to be associated with  $b$ . Of course, the same site  $r_b$  can be associated with several different blocks in the PR quadtree. Similarly, a particular block  $b$  can be associated with more than one site of the Voronoi diagram, say  $r_c$  in  $S$ , as well as  $r_b$ . This means that  $r_c$  is also an  $\varepsilon$ -nearest neighbor for every point in the space spanned by  $b$ . Naturally, the decomposition rule tries to avoid such multiple associations by stipulating that the blocks resulting from the decomposition be maximal. However, this stipulation can only reduce the likelihood of a multiple association; it cannot guarantee its absence.

For example, Figure 4.32(a) is the block decomposition induced by the AVD for a suitably chosen value of  $\varepsilon$  (e.g., 0.25) using a PR quadtree-like block decomposition rule for the Voronoi diagram given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2 and also shown using broken lines in the figure. Notice that due to space limitations, Figure 4.32(a) does not show the site that is associated with each block except for the block that contains the actual site, which is labeled with the site's name. One important difference from the PR quadtree is that there are no empty blocks in the block decomposition of the underlying space that is induced by the AVD. This is not surprising as each block must indicate the identity of its associated site.

Given a block decomposition rule, an access structure must be specified for the blocks. This is usually a tree of out degree 4 as in the tree representation of the PR quadtree in Figure 1.31(b) of Chapter 1. One shortcoming of such a tree representation is that its maximum depth may be high due to the need for a large number of empty blocks when much decomposition is required in order to separate the sites associated with a particular block or when the value of  $\varepsilon$  is very small so that much decomposition is needed to ensure that the entire space spanned by a block that straddles a boundary between adjacent regions of two sites can be associated with one of the relevant sites. In this case, Har-Peled [799] suggests using what he terms a “compressed quadtree” that avoids transitions through nonleaf nodes where the blocks corresponding to three of the child nodes are associated with the same site and no boundary of the Voronoi diagram passes through them. Many of these nodes and their corresponding blocks are eliminated from the data structure, and the blocks that remain are identified by recording the appropriate transitions to them from the root block via the use of suitably valued bit patterns. The exact number of nodes and blocks eliminated in this way depends on the value of  $\varepsilon$  and the minimum separation  $\delta$  between the sites on the opposite sides of an edge of the Voronoi diagram. Thus, the blocks that remain are either squares or the differences between two squares, assuming, without loss of generality, two-dimensional data. This is analogous to the *path-compressed PR k-d tree* discussed in Section 1.5.2.4 of Chapter 1, except that here the tree has an out degree of 4 instead of 2. The same principle is used in other data structures discussed in Chapter 1, such as the BD-tree [1386, 1387] (Section 1.5.2.6), hB-tree [575, 1201] (Section 1.7.1.4), BANG file [640, 641, 645, 646] (Section 1.7.1.5), and balanced box-decomposition tree (BBD-tree) [100] (Section 1.5.2.7).

Arya, Malamatos, and Mount [97, 98] generalized the result of Har-Peled [799] to yield what they term a  $(t, \varepsilon)$ -AVD by allowing up to  $t \geq 1$  elements  $r_{ib} (1 \leq i \leq t)$  of  $S$  to be associated with each block  $b$  for a given  $\varepsilon$ , where each point in  $b$  has one of the  $r_{ib}$  as its  $\varepsilon$ -nearest neighbor. When the underlying space decomposition rule is based on a regular decomposition, the result is analogous to a bucket variant of the PR quadtree (i.e., the *bucket PR quadtree* discussed in Section 1.4.2.2 of Chapter 1) with bucket capacity  $t$ , where now, instead of halting the decomposition process whenever there are  $t$  or fewer points in a block  $b$ , we halt the decomposition process whenever the total number of different  $\varepsilon$ -nearest neighbors of the points in the space spanned by  $b$  is  $t$  or fewer. As long as the underlying space decomposition rule yields blocks that are sufficiently “fat,” which is the case for the bucket PR quadtree, Arya et al. [98] are able to obtain AVDs that are more space efficient than the ones of Har-Peled [799], where

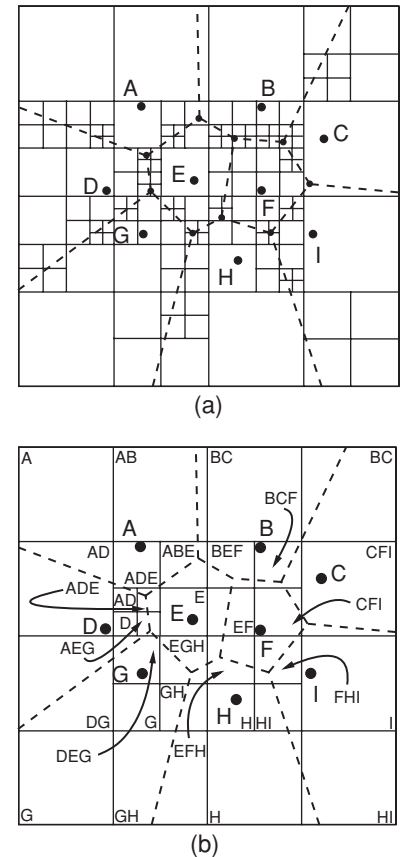

Figure 4.32  
(a) The block decomposition induced by the AVD according to the definition of Har-Peled [799] for a suitably chosen value of  $\varepsilon$  (e.g., 0.25) using a PR quadtree-like block decomposition rule for the point set  $\{A, B, C, D, E, F, G, H, I\}$  whose Voronoi diagram is given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2 and also shown here using broken lines and (b) the corresponding block decomposition induced by the  $(3,0)$ -AVD of Arya, Malamatos, and Mount [97, 98].

$t = 1$ . In particular, for  $N$  objects with dimension  $d$ , and considering the extreme cases of  $t$  (i.e., minimum value of 1 and maximum value of  $1/\varepsilon^{(d-1)^2}$ ), Arya et al. [98] have shown that when  $t = 1$ , their structure requires  $O(N/\varepsilon^{d-1})$  space and answers queries in  $O(\log(N/\varepsilon^{d-1}))$  time, and when  $t = 1/\varepsilon^{(d-1)^2}$ , their structure requires  $O(N)$  space and answers queries in  $O(t + \log N)$  time. Notice that the dimension of the underlying space enters into these bounds (also those of Har-Peled [799]) in terms of the error threshold  $\varepsilon$  rather than the number of objects  $N$  in the underlying space. For example, Figure 4.32(b) is the block decomposition induced by a (3,0)-AVD using a bucket PR quadtree-like block decomposition rule for the Voronoi diagram given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2 and also shown using broken lines in the figure.

Of course, there are many other ways of defining an AVD. In particular, any of the point data representations discussed in Chapter 1 could have been used to organize the sites of the Voronoi diagram. For example, Zheng and Lee [2070] use what they term a *grid-partition index* to decompose the underlying space into disjoint equal-sized grid cells, where each grid cell  $b$  keeps track of the  $t \geq 1$  elements  $r_{ib} (1 \leq i \leq t)$  of  $S$  (i.e., the sites of the Voronoi diagram) so that each point in  $b$  has one of the  $r_{ib}$  as its nearest neighbor. Note that  $\varepsilon = 0$  in the grid-partition index.

One of the problems with our constructive definition of the  $(t, \varepsilon)$ -AVD (and likewise for the AVD that is a  $(1, \varepsilon)$ -AVD) is that it is circular. In other words, we must bear in mind that these are structures for determining nearest neighbors (more precisely, approximate nearest neighbors), yet a construction that implements their recursive definition assumes that we have access to this approximate nearest neighbor information. In particular, we have defined the block decomposition as halting when, for a given  $\varepsilon$ , every point in the space spanned by each block  $b$  has at least one of  $t$  of the elements of  $S$  as its  $\varepsilon$ -nearest neighbor—that is, the  $\varepsilon$ -nearest neighbor is an element of a subset of size  $t$  of  $S$ . Actually, this definition of  $(t, \varepsilon)$ -AVD is really more a property of the decomposition of the underlying space that makes up the data structure than of the process of obtaining it. The circularity in the definition of  $(t, \varepsilon)$ -AVD that we have observed is not unique to this structure. For example, it also arises in the definition of the kNN graph [1704] (see Section 4.5.6), which is a graph where there is a link from each object  $o$  to its  $k$  nearest neighbors. On the other hand, the Spatial Approximation Sample Hierarchy (SASH) [884] (see Section 4.5.8) is unusual in that it is defined so that it can be constructed in an incremental manner where objects at each successively deeper level of the hierarchy are linked to neighbors that are determined on the basis of the neighbor relationships recorded at the shallower levels of the hierarchy.

The circularity is avoided by making use of the principle of *well-separation* in the construction of the  $(t, \varepsilon)$ -AVD. In particular, letting  $S$  be a set of  $N$   $d$ -dimensional points, we say that two sets of points  $X$  and  $Y$  are *well-separated* if they can be enclosed within two disjoint  $d$ -dimensional balls of radius  $r$  such that the distance between the centers of these balls is at least  $\alpha r$ , where  $\alpha \geq 2$  is a real parameter called the *separation factor*. The motivation for this restriction on  $\alpha$  is to ensure that  $X$  and  $Y$  are disjoint.

The construction algorithm requires a *well-separated pair decomposition* (WSPD) of the  $N$  objects in  $S$ , which is a partition of  $S$  so that each of the elements of the  $\binom{N}{2}$  subsets of the  $N$  objects in  $S$  of size 2 is a member of a well-separated pair. Formally, a WSPD of  $S$  is a set  $P_{S, \alpha} = \{(X_1, Y_1), \dots, (X_m, Y_m)\}$  of pairs of subsets of  $S$  such that

1. For  $1 \leq i \leq m$ ,  $X_i$  and  $Y_i$  are well-separated.
2. For any distinct points  $x, y \in S$ , there exists a unique pair  $(X_i, Y_i)$  such that either  $x \in X_i$  and  $y \in Y_i$  or  $x \in Y_i$  and  $y \in X_i$ .

We say that the pair  $(X_i, Y_i)$  *separates*  $x$  and  $y$ . Callahan and Kosaraju [297] have shown that we can construct a WSPD containing  $O(\alpha^d N)$  pairs in  $O(N \log N + \alpha^d N)$  time. For example, Figure 4.33 is an example of a WSPD for the sites of the Voronoi diagram given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2 using  $\alpha = 4$ . Figure 4.33(a) shows the nontrivial pairs (i.e., the ones that are not singletons), while Figure 4.33(b) consists of the

trivial singleton pairs (i.e., the ones for which it is not possible to do any aggregation). The trivial singleton pairs in Figure 4.33(b) are depicted using both a tabular format and a graph format (not necessarily planar), where the existence of the pair is denoted by the presence of an edge between two nodes corresponding to the appropriate sites. Note that this WSPD is not necessarily unique; other WSPDs are possible, and likewise other values of  $\alpha$  could have been used.

Arya et al. [98] construct the quadtree corresponding to the  $(t, \epsilon)$ -AVD by a process that is analogous to digitizing (i.e., rasterizing) the bisector between a pair of well-separated points, say  $p_1$  and  $p_2$ . The rasterization results in the approximation of the bisector by a set of cells  $c_j$  that are sufficiently small so that each cell  $c_j$  can be associated with one of  $p_1$  or  $p_2$ , such that for all points within  $c_j$ , the associated point is an  $\epsilon$ -nearest neighbor drawn from the set  $\{p_1, p_2\}$ . The remaining cells are associated with one of  $p_1$  or  $p_2$ , depending on which serves as the  $\epsilon$ -nearest neighbor. The key to the utility of this approach is that the number of cells that would be produced by such a digitization is a function of  $\epsilon$  but does not depend on the number of sites  $N$ . Of course, the length of the bisector does impact the number of cells.

Clearly, we cannot afford to apply this process to every pair of points as there are  $O(N^2)$  such pairs. Instead, Arya et al. apply the process to the  $O(N)$  well-separated pairs. To understand how this works, it is useful to think of nearest neighbor searching as a tournament, where every pair of points  $p_1$  and  $p_2$  competes to see who is closer to the given query point. Of course, nearest neighbor searching algorithms do not simulate such a tournament explicitly. Instead, the tournament is implicit in the choices that the algorithm makes in eliminating all the  $N - 1$  “other” points from consideration so that the remaining victorious point is the nearest neighbor. Arya et al. take advantage of the fact that the well-separated pairs cover all the pairs of points, thereby making it sufficient for each well-separated pair  $(X, Y)$  to determine whether the nearest neighbor to the query point is in  $X$  or in  $Y$ . In particular, they apply this digitization process to each of the well-separated pairs so that a set of cells  $C$  is generated for each pair, and for any cell  $c$  in  $C$ , all query points in  $c$  agree in their response to the query “Is my  $\epsilon$ -nearest neighbor in  $X$  or in  $Y$ ?” In other words, they agree on the answer to whether the tournament winner is in  $X$  or in  $Y$ . By overlaying these digitizations for all the well-separated pairs, it follows that for every cell in the resulting spatial decomposition, every query point in this cell agrees on the outcomes of *all* the pairwise competitions. In other words, all the query points of the cell share a common  $\epsilon$ -nearest neighbor.

The algorithm proceeds by overlaying all of these digitizations and merging them into a single quadtree-like decomposition, which is stored as a balanced box-decomposition

Figure 4.33 The (a) nontrivial pairs and (b) singleton pairs of a WSPD for the sites of the Voronoi diagram given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2 using  $\alpha = 4$ .

Figure 4.34  
The block decompositions induced by the (a)  $PM_1$ , (b)  $PM_2$ , and (c)  $PM_3$  quadtrees for the Voronoi diagram of the set of sites  $\{A, B, C, D, E, F, G, H, I\}$  whose Voronoi diagram is given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2 and shown here using broken lines.

tree (BBD-tree) [100]. All that remains is for each cell of the decomposition to select its representative. This can be done by running any existing algorithm for approximate nearest neighbor searching (e.g., the algorithm of Arya et al. [100]) applied to any point in the cell (e.g., its midpoint). The overall execution time is on the order of the product of the number of cells of the decomposition and the time needed to answer these approximate nearest neighbor queries using this auxiliary approximate nearest neighbor data structure (i.e., the BBD-tree). Har-Peled did not make use of well-separated pairs in his construction of the AVD [799] (i.e., for  $t = 1$ ). Instead, he viewed the Voronoi diagram as a tournament, involving “spheres of influence” growing around each point. He used an approximation to the minimum spanning tree to determine the number of spheres and then used these spheres to guide the process of subdividing space.

For two-dimensional data, the block decomposition resulting from the bucket PR quadtree construction of Arya et al., using suitably chosen parameter values, is equivalent to an implicit variant of the PM quadtree [1665] family of hierarchical spatial data structures when the underlying data is a polygonal map (see Section 2.2.2.6 in Chapter 2). We use the qualifier *implicit* because the line segments are not explicitly present in the  $(t, \epsilon)$ -AVD. For example, Figure 4.34(a–c) shows the block decompositions induced by the  $PM_1$ ,  $PM_2$ , and  $PM_3$  quadtrees,<sup>24</sup> respectively, for the Voronoi diagram given in Figure 2.110(a) in Section 2.2.1.4 of Chapter 2. From the figures, we see that the block decomposition induced by the  $(3, 0)$ -AVD data structure (e.g., Figure 4.32(b)) is very similar to an implicit version of a  $PM_2$  quadtree [1665]. A key difference is that the  $(t, \epsilon)$ -AVD data structure is designed to represent only the special case of a polygonal map  $M$  that is a Voronoi diagram, whereas members of the PM quadtree family can be used to represent arbitrary polygonal maps, including the Delaunay triangulation, which is the dual of the Voronoi diagram. Moreover, the  $(t, \epsilon)$ -AVD data structure only keeps track of the Voronoi sites (which are points) associated with each block. In contrast, members of the PM quadtree family keep track of the edges that make up the polygonal subdivision (i.e., the boundaries of the Voronoi regions), or, equivalently, the vertices of the polygonal map (i.e., the vertices of the Voronoi regions).

More specifically, recall that the  $PM_2$  quadtree is a member of the PM quadtree family where the underlying space is recursively partitioned into four congruent blocks so that at most one edge of the polygonal map passes through each block  $b$ , unless all the edges that pass through  $b$  are incident at the same vertex  $v$ , regardless of whether  $v$  is in  $b$ . The  $PM_2$  quadtree is usually implemented by keeping track of the set of edges that pass through each block. However, alternatively, as we pointed out in Section 2.2.2.6 of Chapter 2, the  $PM_2$  quadtree can also be implemented in such a way that each leaf block  $b$  stores the vertex, if any, that is common to the edges that pass through  $b$ . If only one edge passes through  $b$ , then one of its vertices is arbitrarily chosen to be stored in  $b$ . In any case, regardless of how many edges pass through  $b$ , the vertices are usually part of an auxiliary data structure (e.g., a triangle table or some other variant of the winged-edge data structure) that keeps track of the topological properties of the polygonal map. When the polygonal map  $M$  is a Voronoi diagram where no four elements of  $S$  are cocircular, it is easy to see that the block decomposition of the underlying space induced by the  $(3, 0)$ -AVD of  $M$  is equivalent to the block decomposition of the underlying space induced by the  $PM_2$  quadtree for the edges of the Voronoi diagram (see Exercise 2). In other words, the set of blocks in the  $PM_2$  quadtree and the  $(3, 0)$ -AVD are identical, although they do contain different information. In particular, in the  $(3, 0)$ -AVD, the blocks store the sites  $S$  of the Voronoi diagram, while in the  $PM_2$  quadtree, the blocks store the vertices  $V$  of the Voronoi diagram (i.e., the circumcenters of the Delaunay triangulation of the underlying point set  $S$ , which is the dual of the Voronoi diagram). Thus, in this case, the

<sup>24</sup> There is no decomposition in the SW quadrant of the  $PM_3$  quadtree in Figure 4.34(c) because in this example we assume that the Voronoi edges are semi-infinite lines. An alternative is to treat the Voronoi diagram as having pseudo vertices wherever the Voronoi edges intersect the boundary of the underlying space. In our example, this will cause the SW quadrant for the  $PM_3$  quadtree to be decomposed once.

$PM_2$  quadtree of the Voronoi diagram of the point set  $S$  can be viewed as the dual of the  $(3,0)$ -AVD of  $S$ .

Notice that when the polygonal map  $M$  is a Voronoi diagram, the implementation in terms of the blocks of the  $PM_2$  quadtree of  $M$  is more efficient spacewise than the implementation in terms of the blocks of the  $(3,0)$ -AVD of  $M$  as the  $(3,0)$ -AVD may need to store as many as three points of  $S$  in each block, whereas the  $PM_2$  quadtree only needs to store at most one of the vertices of the Voronoi diagram in each block. Moreover, none of the blocks in the  $(3,0)$ -AVD of  $M$  are empty, but all blocks of the  $PM_2$  quadtree through which no edges pass are empty. In many quadtree implementations (e.g., pointerless representations that make use of locational codes as described in Section 2.1.2.4 of Chapter 2), there is no need to keep track of the empty blocks as their identity can be derived from knowledge of the nonempty blocks (see Exercise 24 in Section 2.3.1 of Chapter 2, which shows how the locational codes of the empty blocks can be obtained from the locational codes of the nonempty blocks).

Of course, using such a pointerless implementation, given an arbitrary point  $q$ , determining the closest point of  $S$ , in the case of the  $PM_2$  quadtree, will be more complex because this information is not explicitly present in the  $PM_2$  quadtree data structure and thus can be most easily obtained by first constructing  $S$  by a process analogous to solving a linear system (see Exercises 5 and 6 in Section 2.2.1.4 of Chapter 2). An alternative, and more practical, solution is to augment the  $PM_2$  quadtree data structure to store also the sites of the Voronoi diagram if they lie in a particular block. In this case, each block of the  $PM_2$  quadtree will contain up to four points where at most three of the points correspond to sites, provided that we have a nondegenerate Voronoi diagram. Finding the site  $s$  associated with a particular point  $q$  requires locating the block  $b$  containing  $q$  and then searching  $b$ 's adjacent blocks for a block  $c$  such that  $c$  contains a site  $s$  whose associated region also contains  $q$ . This search guarantees finding  $s$  as long as the search paths do not cross blocks that are associated with edges of the Voronoi diagram. This solution is not very efficient if there are many empty blocks. This drawback is overcome by reverting to a solution that associates a site with each block  $b$  of the  $PM_2$  quadtree, which is essentially what is done in the  $(3,0)$ -AVD, except we now also keep track of the vertices of the Voronoi diagram. Of course, still another alternative is to make use of the auxiliary structure that may be present that captures the topological properties of the polygonal map.

### Exercises

1. Show how to construct a  $(t, \varepsilon)$ -AVD for a  $d$ -dimensional Voronoi diagram of  $N$  sites that uses  $O(N)$  space and that can be used to answer an  $\varepsilon$ -nearest neighbor query in  $O(\log N + (1/\varepsilon)^{(d-1)/2})$  time.
2. Prove that, in the case of a two-dimensional polygonal map  $M$  that is a Voronoi diagram where no four elements of  $S$  are cocircular, the  $(3,0)$ -AVD of  $M$  yields the same block decomposition of the underlying space as the  $PM_2$  quadtree for the edges of  $M$ .
3. How would you adapt the analogy between the PM quadtree family and the  $(3,0)$ -AVD to three and more dimensions? In particular, devise an analog of the  $PM_2$  quadtree in higher dimensions.

## 4.4.6 Avoiding Overlapping All of the Leaf Blocks

Most of the index structures that we have discussed are based on the principle that the data regions are recursively split into two when the data regions contain too many points—that is, each data region contains some maximum number of points. Such a splitting strategy can be implemented within many different structures (e.g., k-d tree, R-tree, hybrid tree, LSD tree). Berchtold, Böhm, and Kriegel [187] claim that one of the main reasons for the performance gaps of these index structures when dealing with high-dimensional data

vis-à-vis the sequential scan is the fact that a typical query region usually overlaps all of the leaf node regions. Note that their focus is only on the data regions, whereas they ignore the directory (i.e., the nonleaf nodes),

They observe that when the data consists of uniformly distributed points in a sufficiently high-dimensional space (e.g., 20), most of the points lie near the boundary of the space or node that is being split (see Exercise 1). In addition, they point out that in high dimensions the number of data points is rarely so large as to require that all of the dimensions will have to be split, even once. To see why this is so, suppose that we have  $d$  dimensions, a bucket capacity of  $M$ , and at least  $M/2$  points in each leaf node. If there is at least one split on each dimension, then the total number of points  $N$  must be at least  $2^d M/2$ . For example, if  $d = 20$  and  $M = 10$ , then  $N$  must be at least 5 million. Thus, if  $N$  is less than 5 million, then we cannot have a split on all of the dimensions.

Given that the data is uniformly distributed, we know that each split results in decomposing the underlying space into approximately equal-sized halves. This is based on the premise that the splits are performed in such a manner that one-half of the points lie on each side of the split axis. Furthermore, given that for most reasonable amounts of data, in the case of high-dimensional data, each dimension is split at most once, it can be easily shown that query regions will typically overlap nearly all leaf node regions. On the other hand, it is not inconceivable that the data may be distributed in such a manner that none of the points will lie in the query region in the sense that the part of the leaf node region that overlaps the query region happens to be empty while the data is in the remaining part of the leaf node region.

We now make an additional observation. In particular, assume that the query region is a hypercube  $q$  with volume  $V$ , where the entire dataspace is the unit cube. Given our uniform data distribution assumption,  $V$  is proportional to the number of points in  $q$  and is equivalent to the selectivity of the region query when the underlying dataspace is the unit hypercube. This means that the side length of the hypercube  $q$  corresponding to the query region is  $\sqrt[d]{V}$ . Observe that for a hypercube query region  $q$  with a fixed volume  $V$ , the side length of  $q$  increases as  $d$  increases as long as the volume  $V$  is less than 1.

The above observation has a direct ramification on searching as the volume of the hypercube search region is analogous to the query selectivity, as pointed out above. For example, for a selectivity of 0.01% (i.e., 0.01% of the points fall into  $q$ , or equivalently,  $V = 0.0001$ ) and  $d = 20$ , the side length of  $q$  is 0.63. This means that  $q$  will overlap all of the leaf node regions, given our assumptions that the underlying space has been split at most once along each of the dimensions since the minimum side length of each of the hyperrectangles resulting from the splits is close to one-half of the side length of the underlying space that has been split. Note that it could be argued that this problem is irrelevant because, in most high-dimensional data applications, the primary query is usually a  $k$ -nearest neighbor query rather than a range query. However, the  $k$ -nearest neighbor query is analogous to a range query, where  $k$  represents the desired selectivity, and thus the query region  $q$  corresponds to the region that contains the  $k$  desired points.

In order to avoid the situation that typical query regions overlap all of the leaf node regions, Berchtold, Böhm, and Kriegel [187] propose to split a region in an unbalanced manner into two or more regions, instead of the typical half-and-half splitting strategy usually used in many representations (e.g., in the VAMSplit R-tree; but see the R\*-tree, which uses a split ranging between 40% and 60% on each side). In particular, Berchtold et al. [187] suggest that once a split dimension has been chosen, the data be split into three parts, two of which are relatively small at the extreme ends of the value range of the split dimension, each containing a ratio  $r$  of the dataset, with the remaining portion (i.e.,  $1 - 2r$ ) of the dataset in the middle part. This principle conforms with the observation made earlier that, in the case of uniformly distributed data, most of the points lie near the boundary of the space or node that is being split. Use of this splitting technique for 16-dimensional data (both synthetic and real) [187] resulted in significant speedup in the

execution time of range queries and also in the initial construction of an X-tree [190] when compared with use of the Hilbert packed R-tree [983].

### Exercises

1. Show that in the case of uniformly distributed point data in high dimensions (e.g., 20), most of the points lie at or near the boundary of the high-dimensional hypercube that is being split.
2. Consider a unit hypercube of  $d$  dimensions centered at  $c = (0.5, 0.5, \dots, 0.5)$ . Can you prove that every  $d$ -dimensional hypersphere that touches or intersects the  $(d - 1)$ -dimensional boundaries of the dataspace formed by the unit hypercube also contains  $c$ ? If not, give a counterexample.

## 4.4.7 Pyramid Technique

The *pyramid technique* of Berchtold, Böhm, and Kriegel [188] is a representation for high-dimensional data that takes advantage of the observation made in Section 4.4.6 that most of the data lies close to the boundary of the dataspace (see Exercise 1 in Section 4.4.6) and subdivides it in such a way that a typical window query will not overlap all of the nodes, as is the expected case for uniformly distributed data. In particular, the dataspace is subdivided as if it were an onion by peeling off hypervolumes that are close to its boundary. This is achieved by first dividing the hypercube corresponding to the  $d$ -dimensional dataspace into  $2d$  pyramids having the center of the data space as their top point. Each of the  $2d$  pyramids has one of the faces of the hypercube as its base. These pyramids are subsequently cut into slices that are parallel to their base.

The *Spherical Pyramid Technique* (SPY-TEC) [1124, 1125] is an equivalent method that partitions a sphere into spherical pyramids (i.e., cones) that are subsequently subdivided into spherical slices. The rationale for this method is that it is more in keeping with the nature of the search regions used in similarity search, assuming a Euclidean distance metric.

The utility of the pyramid technique can be seen easily when we examine the situation where the side length of the query window  $q$  is greater than 0.5. This means that, using a conventional splitting method that recursively splits the dataspace into equally filled regions at the 50% quantile (termed *balanced splits*),  $q$  will overlap all of the leaf node regions, assuming that the underlying space has been split at most once along each of the dimensions. For example, in two dimensions, this results in four regions (Figure 4.35(a)), all of which are overlapped by  $q$  no matter how  $q$  (shown shaded) is positioned. In contrast, when using the pyramid technique, as illustrated in the two-dimensional space in Figure 4.35(b), where each pyramid has been partitioned into four pieces, we have 16 regions and query region  $q$  (shown shaded) overlaps just 10 of them.

The advantage of the pyramid technique becomes more evident in higher dimensions. For example, in six dimensions,  $q$  overlaps  $2^6 = 64$  regions when using balanced splits (assuming the dataspace has been split once in each dimension). In contrast, the pyramid technique yields  $2d = 12$  pyramids, and if each pyramid is partitioned into four pieces, then  $q$  overlaps half of the pyramids completely (i.e.,  $6 \cdot 4 = 24$  regions), while overlapping only 1 out of 4 regions in each of the remaining pyramids (i.e., 6 regions). Thus, out of a total of 48 regions, only 30 regions are accessed. Notice that no matter how we position  $q$ , we will not overlap all of the regions when using the pyramid technique, but no such guarantee can be made for balanced splits.

Berchtold, Böhm, and Kriegel [188] propose to represent the high-dimensional point data using locational codes (see Section 2.1.2.4 of Chapter 2) and to store the result in a  $B^+$ -tree. In this way, all of the  $2d$  pyramids are represented in the same data structure. Furthermore, this means that the pyramid regions are not explicitly represented. Instead, each leaf node of the  $B^+$ -tree implicitly forms a pyramid region based on the locational

Figure 4.35 Regions overlapped by a query window (shown shaded), each of whose side lengths are greater than half the width of the underlying space when using (a) balanced splits and (b) the pyramid technique.

codes of the objects residing in it (however, as we shall see below, a  $B^+$ -tree leaf node can contain objects from two or more pyramids).

Figure 4.36  
Correspondence of regions and pyramids in two-dimensions (coordinates  $c_0$  and  $c_1$ ) when using the pyramid numbering method of the pyramid technique.

The pyramid technique transforms a point  $v$  in  $d$ -dimensional space to a locational code (essentially a point in a one-dimensional space) as follows. The  $2d$  pyramids forming the unit hypercube are numbered from 0 to  $2d - 1$  in such a way that pyramids  $p_j$  and  $p_{j+d}$  have the property that all points on their base have a value of 0 and 1, respectively, for dimension  $j$  (recall that the base of each pyramid is a  $(d - 1)$ -dimensional surface of the unit hypercube). Put another way, the base of pyramid  $p_i$  has 0 values along dimension  $i$  if  $i < d$  and 1 values along dimension  $i - d$  if  $i \geq d$ . For example, Figure 4.36(a) shows the result of numbering the four pyramids  $p_1, p_2, p_3,$  and  $p_4$ , in two dimensions  $c_0$  and  $c_1$ , using this method.

Given a point  $v$  in  $d$ -dimensional space, it is easy to identify the pyramid  $p_i$  that contains  $v$ . In particular, all points in  $p_i$  have the common property that the distance in the  $(i \bmod d)$ -th coordinate from the center point is greater than the distance of all other coordinates from the center point. In addition, the  $(i \bmod d)$ -th coordinate value of all points in  $p_i$  is less than that of the center point (i.e., 0.5) if  $i < d$  and greater than or equal to that of the center point (i.e., 0.5) if  $i \geq d$ . More precisely, for a point  $v = (v_0, v_1, \dots, v_{d-1})$ , let  $j$  be the dimension along which  $|v_j - 0.5|$  is maximized. Then,  $v$  belongs to pyramid  $p_i$ , where  $i = j$  if  $v_j$  is less than 0.5 and  $i = j + d$  otherwise. Furthermore, the *height* of a point  $v$  in  $p_i$  is defined as  $h_v = |v_{i \bmod d} - 0.5|$ —that is, the distance from the center point along coordinate  $i \bmod d$ . The locational code, termed a *pyramid value* [188], for point  $v$  in pyramid  $p_i$  has the value  $i + h_v$ . For example, the values  $h_a$  and  $h_b$  for points a and b in Figure 4.36(b) are indicated by the arrows. Since  $h_v$  ranges from 0 to 0.5, the pyramid values of all points in pyramid  $p_i$  span the interval  $[i, i + 0.5]$ , so the ranges of pyramid values in different pyramids are disjoint.

Each point  $v$  is stored in a leaf node of the  $B^+$ -tree using the pyramid value  $i + h_v$  as a key, along with the actual coordinate values of  $v$ . As mentioned above, the pyramid regions are implicitly represented by the ranges of values that fall into a particular  $B^+$ -tree leaf node. However, there is nothing to prevent values from adjacent pyramids from residing in the same  $B^+$ -tree leaf node. For example, in Figure 4.36(b), the points a–e might be stored in the same  $B^+$ -tree leaf node, even though some of the points reside in pyramid  $p_0$  and some in pyramid  $p_1$ . Note that the pyramid value transformation is not a one-to-one correspondence, as two different points  $v_1$  and  $v_2$  may have the same pyramid value. However, there is no need for an inverse transformation since the coordinate values are represented in the  $B^+$ -tree.

Insertion and deletion are relatively simple when using the pyramid technique. However, range (i.e., window) queries are more complex since a  $d$ -dimensional range query must be translated into as many  $2d$  one-dimensional range queries on the pyramid values in the  $B^+$ -tree, one for each pyramid. In particular, for each pyramid  $p_i$ , this involves determining the interval  $[i + h_{l_i}, i + h_{h_i}]$  that is guaranteed to contain the pyramid value of all points in  $p_i$  that intersect the query rectangle. Deriving the smallest such interval is rather involved, but as an approximation, we can use  $[j, j + (0.5 - l_j)]$  and  $[j + d, j + d + (h_j - 0.5)]$  for pyramids  $p_j$  and  $p_{j+d}$ , respectively, assuming a range of  $[l_j, h_j]$  along coordinate  $j$ . Notice that some of these ranges are empty (i.e., when the query region does not intersect some of the pyramids), in which case the corresponding one-dimensional query in the  $B^+$ -tree can be avoided. Observe that a point  $v$  that results from one of the one-dimensional  $B^+$ -tree queries does not necessarily fall into the  $d$ -dimensional query range. Thus, the results from the  $B^+$ -tree queries must be further refined based on the actual coordinate values.

The pyramid technique as presented above is designed to deal with uniformly distributed data. In particular, when the data is clustered at a corner (Figure 4.37(a)), then many of the pyramids will be almost empty (Figure 4.37(b)), which leads to a suboptimal partitioning with respect to the distribution of the data in the individual pyramids. This

will lead to poor query performance as the queries can be expected to be distributed in a similar manner to the data.

When the data is not uniformly distributed, Berchtold, Böhm, and Kriegel [188] propose to transform the dataspace so that the data cluster is located at the center point of the transformed space (Figure 4.37(c)). This technique is termed the *extended pyramid technique*. The transformation should map the  $d$ -dimensional median of the data to the center point. Notice that the transformation is applied only in the process of determining the pyramid value of the  $d$ -dimensional data points and query rectangles. The data points themselves are not transformed, and thus there is no need to be concerned about an inverse transformation for the answer set.

Unfortunately, computing the  $d$ -dimensional median is not a simple process. Thus, it is computed with the aid of a heuristic that maintains a histogram for each dimension  $i$  to keep track of the median along  $i$ . The  $d$ -dimensional median is approximated by a combination of the  $d$  one-dimensional medians. Of course, it is possible that the approximated  $d$ -dimensional median may be located outside the convex hull of the data cluster, although this did not arise in experiments [188]. One problem is that the median is not known in advance of building the representation, and thus the construction process is started with the existing center point as an approximation of the median, which serves as the center point while maintaining a histogram for each dimension in order to compute the true median. If the distance of the current median from the center point is greater than some threshold (e.g.,  $(\sqrt{d})/4$  since the maximum distance from any point to the center point for  $d$ -dimensional data is  $(\sqrt{d})/2$ ), then the representation is rebuilt with the current median.

Experiments [188] with range queries of 0.01% selectivity for uniformly distributed data of dimension as high as 24 showed that the pyramid technique significantly outperformed the X-tree (by a factor as high as 2,500 for total elapsed time) and by even more for the Hilbert R-tree [984]. It also outperformed the sequential scan but by smaller factors. For the pyramid technique, the percentage of accessed pages with respect to all data pages was about 8% and, as expected, decreased as the dimension of the underlying space increased to a value as high as 100. Similar results were obtained for real data of dimension 16.

As we saw, in the pyramid technique, the key factor in determining the pyramid that contains a query point  $q = (q_1, q_2, \dots, q_d)$  is the coordinate  $i$ , whose distance from the center point of the unit underlying space is greater than that of all other coordinates. The *iMinMax method* of Ooi, Tan, Yu, and Bressan [1408] is similar, with the difference that it associates  $q$  with the  $(d - 1)$ -dimensional surface that is closest to  $q$ . This is done by determining the coordinate whose distance from all of the edges of the unit underlying space is smaller than that of all other coordinates. Thus, iMinMax is very similar to employing a representative point method that uses projection, where instead of projecting all points onto the same coordinate (e.g., [649]), each point is projected along its most dominant (i.e., discriminatory) coordinate, where dominance (i.e., discriminance) is defined as being closest to the outer surface.

It should be clear that both the pyramid technique and iMinMax partition the  $d$ -dimensional underlying space into  $2d$  pyramids. The difference is in the format of the representative point that is used (i.e., the locational code). In particular, in iMinMax the locational code of a point  $p$  consists of the concatenation of the identity of the coordinate that is closest to the  $(d - 1)$ -dimensional surface of the underlying space and its magnitude, while in the pyramid technique, the locational code of  $p$  consists of the concatenation of the identity of  $p$ 's containing pyramid and the distance from  $p$  to the center  $c$  of the underlying space along the coordinate of  $p$  that is the farthest from  $c$ . Note also that, for  $d$  dimensions, the locational codes for both the pyramid technique and iMinMax have the same range of values. In particular, in the pyramid technique, the locational codes span a one-dimensional space consisting of  $2d$  noncontinuous regions where the range of each region is from 0 to 0.5. On the other hand, in iMinMax, the

locational codes span a one-dimensional space consisting of  $d$  continuous regions where the range of each region is from 0 to 1. For a discussion of an implementation of both iMinMax and the pyramid technique in the spirit of the Generalized Search Tree (GiST) [66, 817] and the spatial partitioning generalized search tree (SP-GiST) [70] discussed in Section 1.9 of Chapter 1, see Ooi, Kalnis, Tan, and Zhang [1403].

The definition of the iMinMax mapping given by Ooi et al. [1408] is slightly more general than the one given above in that the resulting one-dimensional locational code is in terms of a parameter  $\theta$  that tries to account for data that is not uniformly distributed (i.e., with some skewness). Given a point  $v = (v_1, v_2, \dots, v_d)$  in  $d$ -dimensional space, letting  $v_{max} = \max_{i=1}^d v_i$  and  $v_{min} = \min_{i=1}^d v_i$  be the maximum and minimum values, respectively, among the  $d$  coordinate values of  $v$ , and letting  $d_{max}$  and  $d_{min}$  denote the coordinates at which the maximum and minimum values, respectively, occur, the locational code  $l(v)$  is defined in terms of the parameter  $\theta$  as follows:

$$l(v) = \begin{cases} d_{min} + v_{min} & \text{if } v_{min} + \theta < 1 - v_{max} \\ d_{max} + v_{max} & \text{otherwise} \end{cases}$$

Figure 4.38  
Result of partitioning a two-dimensional space with iMinMax for (a)  $\theta = 0$ , (b)  $\theta = 0.25$ , and (c)  $\theta = -0.25$ .

The effect of a negative  $\theta$  value is to attach more significance to the 0 (i.e., minimum) faces along each coordinate. On the other hand, a positive  $\theta$  value attaches more significance to the 1 (maximum) faces along each coordinate. In other words, a value of  $\theta = 0$  is analogous to assuming a uniform distribution. Moreover, a value of  $\theta \leq -1.0$  projects onto the coordinate with the minimum value, and a value of  $\theta \geq 1.0$  always projects onto the coordinate with the maximum value. Thus,  $\theta$  can be said to reflect the skewness of the data. One immediate problem in making use of the skewness of the data is that we do not necessarily know the extent of the skewness of the data a priori. This means that we must resort to some kind of sampling to determine the extent of the skewness and then rebuild the index using a different value of  $\theta$ .

Ooi et al.'s [1408] motivation for using  $\theta \neq 0$  in iMinMax is similar to Berchtold et al.'s [188] motivation for using the extended pyramid technique in that they both try to deal with skewed data. In fact, we could make an analogy between using  $\theta \neq 0$  in iMinMax and shifting the center of the underlying space (i.e., the point common to all of the pyramids) in the extended pyramid from  $(0.5, 0.5, \dots, 0.5)$  to  $((1 - \theta)/2, (1 - \theta)/2, \dots, (1 - \theta)/2)$  (see Exercise 3). However, the key difference is that, in the extended pyramid technique, the  $d$ -dimensional underlying space is still partitioned into pyramids, although they are no longer congruent. In contrast, using  $\theta \neq 0$  in iMinMax means that the  $d$ -dimensional underlying space is no longer partitioned into  $2d$  pyramids. Instead, the resulting partition is best described as yielding truncated pyramids, where the truncation is a result of clipping along the  $(d - 1)$ -dimensional faces of the underlying space. For example, Figure 4.38(a–c) shows the result of the partitioning of a two-dimensional space for  $\theta = 0$ ,  $\theta = 0.25$ , and  $\theta = -0.25$ , respectively.

Ooi et al. [1408] conducted a number of experiments comparing the I/O cost of iMinMax with the pyramid technique, as well as sequential scan for range queries with a number of different selectivities and data distributions. For uniformly distributed data, both iMinMax and the pyramid technique significantly outperformed sequential scan using dimensions ranging up to 100, with a slight edge for the iMinMax method. In this case,  $\theta = 0$ . It is important to observe that the difference in the performance of iMinMax and the pyramid technique is probably more a reflection of the nature of the algorithms used for the range queries, as the methods are fundamentally the same. In particular, for iMinMax, Ooi et al. [1408] perform a range query by using a filter-and-refine query processing strategy [1416]. They decompose the query into  $d$  one-dimensional subqueries, one for each transformed range of coordinate values, and the result set is the union of all of the points that satisfy the ranges once the extraneous ones have been filtered out based on the actual point data (see Exercise 2). Berchtold et al. [188] apply the same filter-and-refine strategy—that is, they use one-dimensional range queries to filter and refine based on the actual  $d$ -dimensional points. The difference is in the nature

and number (i.e.,  $2 \cdot d$ ) of subqueries due to the different encoding that is used for the data points.

For nonuniformly distributed data, the performance of iMinMax depended greatly on the value of  $\theta$  that was used, with some instances of dramatic performance improvement. However, the results of these experiments are colored by the fact that the comparisons were made with the conventional pyramid technique instead of with the extended pyramid technique, which may have yielded significantly different results as the extended pyramid technique is specifically designed to deal with nonuniformly distributed data. At present, iMinMax uses just one value for  $\theta$ . The performance of iMinMax could be enhanced further by making use of a different value of  $\theta$  for each coordinate, or even better, a separate value of  $\theta$  for each possible pair of coordinates as the locational code depends on both a minimum and a maximum coordinate value.

It should be clear that iMinMax is very similar to employing a representative point method that uses projection, where instead of projecting all points onto the same coordinate (e.g., [649]), each point is projected along its most dominant (i.e., discriminatory) coordinate, where dominance (i.e., discriminance) is defined as being closest to the outer surface. Note that we are using the concept of discriminance in a very different way than the conventional use in methods such as Principal Component Analysis (PCA) [665] and the equivalent methods of Singular Value Decomposition (SVD) [721] and the Karhunen-Loève Transform (KLT) [665], where the goal is to find the most discriminating dimension (by either locating an existing one or creating a new one) based on the minimization of the mean square error (for more details, see Section 4.6.4.1).

A more general characterization of the iMinMax method is that it provides a transformation that partitions a dataspace into different partitions based on some property of the data that is maximized or minimized. In this section, we have assumed that the underlying space is a vector space formed by the unit  $d$ -dimensional cube, and we have sought to minimize the distance to one of its  $(d - 1)$ -dimensional faces. The method can be generalized further for an arbitrary dataspace that need not be a vector space (but that has a distance function) by replacing the minimum distance from a face by the minimum distance to one of  $d$  reference objects  $O_i$  ( $1 \leq i \leq d$ ) that play a role analogous to that of the coordinates [940, 2059]. This is a common technique in dealing with such data and results in embedding it in a vector space (for more details, see Section 4.7). Thus, for a given object  $v$ , the locational code  $l(v)$  resulting from the transformation becomes

$$l(v) = i \cdot c + \text{dist}(v, O_i),$$

where  $\text{dist}(v, O_i)$  is the distance function that returns the distance from  $v$  to the nearest reference object  $O_i$  ( $1 \leq i \leq d$ ), and  $c$  is some constant that ensures that the distance ranges are sufficiently large so that the nearest regions for the reference objects are disjoint. The result of the transformation also resembles the top-level of GNAT [255] (see Section 4.5.3.2), where the reference objects are termed *split points*, and the result is a partition of the objects into subsets, one per split point, where the elements of each subset are closer to the subset's split point than to any of the other split points (see Exercise 6).

### Exercises

1. Give an algorithm to perform a window query using the pyramid technique.
2. Give an algorithm to perform a window query using iMinMax for a given value of  $\theta$ .
3. Show that using  $\theta \neq 0$  in iMinMax results in shifting the center of the underlying space (i.e., the point common to all of the regions—that is, pyramids) from  $(0.5, 0.5, \dots, 0.5)$  to  $((1 - \theta)/2, (1 - \theta)/2, \dots, (1 - \theta)/2)$ .
4. The iMinMax method as defined in the text assumes that the underlying space is the unit  $d$ -dimensional cube. One way to extend it to deal with an arbitrary, but bounded,  $d$ -dimensional space is by introducing a multiplicative factor  $c$  that corresponds to the maximum extent (i.e.,

variability) along the different coordinates. Thus, for a given point  $v$ , the locational code  $l(v)$  resulting from the transformation becomes

$$l(v) = \begin{cases} d_{\min} \cdot c + v_{\min} & \text{if } v_{\min} + c \cdot \theta < c - v_{\min} \\ d_{\max} \cdot c + v_{\max} & \text{otherwise} \end{cases}$$

What are the disadvantages of such an approach?

5. Can you define a variant of iMinMax that results in a partition of the  $d$ -dimensional underlying space into pyramids analogous to the extended pyramid technique rather than truncated pyramids. You will need to modify the definition of  $\theta$  so that there is at least one variant for each coordinate.
6. In the text, we pointed out that the generalization of iMinMax to an arbitrary dataspace that need not be a vector space (but that has a distance function) resembles the top level of GNAT [255] (see Section 4.5.3.2). Does it also resemble the M-tree [389] (see Section 4.5.4)?

#### 4.4.8 Methods Based on a Sequential Scan

As we pointed out in the previous subsections, as the dimensionality of the underlying space increases, the indexing methods that we have described become increasingly worse<sup>25</sup> and are often eventually outperformed by a simple sequential scan (also referred to as a *linear scan*) of the underlying data. The key advantage of sequential scan over hierarchical indexing methods is that the actual I/O cost for query algorithms (e.g., finding the nearest neighbor or the  $k$  nearest neighbors) is reduced because we can scan the data sequentially instead of at random. Accessing disk pages at random is likely to incur a disk seek overhead for each access, whereas sequential access only incurs one seek time overhead. Recall that the main reason for the poor performance of the hierarchical indexing methods is the fact that they do not discriminate well on high-dimensional data.

This has led a number of researchers to investigate methods that speed up the sequential scan method [185, 607, 1973]. Clearly, sequential scan must examine all of the data. Thus, the only way to reduce the work involved in the sequential scan is to reduce the proportion of the amount of each data object that is examined—that is, by not examining all of the features that characterize each object or each data point in its entirety. There are two principal methods of achieving this. The first way, which is quite simple, is to use a partial distance search (e.g., [356]). In this case, if the partial sum of the square differences (assuming Euclidean distance) of the features for a candidate exceeds the distance to the nearest neighbor found so far, then the candidate is rejected. In this case, we avoid examining some of the features completely.

The second way is a more general application of the idea. It takes all of the features into account at once, rather than sequentially, and then just examines a predefined part of each feature. This is the key to the efficiency of methods that scan the entire file, such as the VA-file [1973], the VA<sup>+</sup>-file [607], and, in a more local manner, the IQ-tree [185]. These methods are the subject of the rest of this section. This idea has also been used in conventional indexing methods such as the hybrid tree [317] and the LSD<sup>h</sup> tree [826] (see Section 4.4.3 and Section 1.7.1.2 in Chapter 1) to obtain a more compact, but less precise, representation of a minimum bounding box so that the fanout of a nonleaf node can be increased.

The *vector approximation file* (denoted *VA-file*) [1973] represents each object (i.e., a data point  $p$  in  $d$ -dimensional space) by a pair of values:

---

<sup>25</sup> More precisely, as the dimensionality of the underlying space increases, for some query and data distributions, such as the uniform distribution, the curse of dimensionality comes into play, and the performance of the indexing methods worsens.

1. An approximation of the  $d$  feature values using a bitstring of width  $b_i$  bits per feature  $i$
2. A pointer to the tuple corresponding to  $p$  in the actual data file

Thus, the range of values of feature  $i$  is subdivided into  $2^{b_i}$  slices. The boundaries of the slices are determined in such a way that all slices are approximately equally populated. Note that the boundaries of the slices are kept fixed as updates, such as insertions and deletions, are made to the data. However, periodic reorganizations can be performed when the distribution among slices becomes bad. The actual bitstrings for the individual feature are concatenated to form a larger bitstring of width  $b = \sum_{i=1}^d b_i$  bits. The result is an approximation (actually a lossy compression) of the feature vector and hence the rationale for the use of the name *vector approximation* to describe the representation. Alternatively, we say that the vector is quantized.

The VA-file is a simple array or list of pairs with no particular order (i.e., the order of entries is simply the order in which the points were inserted). There is no spatial index imposed on it. Thus, the VA-file is nothing more than a representation of the original data that takes up less space. Nevertheless, it is important to observe that the VA-file is not a replacement for the original data, but, instead, it is an additional representation much like an index in the sense that it requires additional storage beyond that needed to store the original data.

In essence, the VA-file imposes a  $d$ -dimensional grid with  $2^b$  hyperrectangular grid cells on the underlying dataspace, and each data point is represented by its grid cell. As we pointed out above, the actual representation of the grid cell is the concatenation of the bit values that it comprises, but, of course, it could also be represented by interleaving the corresponding bit values. The disadvantage of using bit interleaving is that this usually requires that each feature be approximated by the same number of bits, although it could be defined with a variable number of bits per feature, as done is in the BANG file [640]. Nevertheless, the fact that the VA-file is completely unordered means that the issue of using bit concatenation or some other encoding is most likely irrelevant.

Queries are processed using a two-stage procedure that, in essence, is a filter-and-refine algorithm [1416]. The first stage, corresponding to the filter step, applies a sequential scan to the VA-file instead of the original data file. During this process, candidate data points are generated that could satisfy the query. In particular, the grid cell  $c$  associated with each data point  $p$  is used to compute a lower bound on the distance from a query point  $q$  to  $p$ . This is the distance from  $q$  to the nearest boundary of  $c$ , or 0 if  $q$  is inside  $c$ . Similarly, an upper bound on the distance from  $q$  to  $p$  is the distance from  $q$  to the farthest point on the farthest boundary of  $c$ .

For example, for a range search (i.e., all points within radius  $r$  of query object  $q$ ), a point  $p$  with grid cell  $c$  is a candidate if the lower bound on  $p$ 's distance from  $q$ , based on  $c$ , falls within the range. Similarly, for a  $k$ -nearest neighbor query, a list is maintained of the  $k$  points that have been processed so far with the smallest upper bounds on their distance from  $q$  (again, based on their grid cells). Let  $D$  be the greatest of these  $k$  upper bounds.  $D$  is also an upper bound on the distance of the actual  $k$ th-nearest neighbor of  $q$ , and thus we ignore any grid cell  $c$  for which the lower bound on its distance from  $q$  is greater than  $D$  (i.e., the corresponding point  $p$  is not a candidate). This approach to finding nearest neighbors in a grid has been attributed to Elias by Rivest [1566] and is known as the *Elias algorithm* [403, 1566]. The Elias algorithm is typically only presented for the  $k = 1$  case, but generalizing it to arbitrary  $k$  is not hard, as we saw above.

In the second stage, corresponding to the refine step, the elements in the candidate set obtained in the first stage are processed in increasing order of their lower-bound distances (i.e., using a priority queue mechanism such as a heap; see Exercise 1). For each element, the corresponding actual point representation  $p$  is accessed from disk, its distance from  $q$  is computed, and  $p$  is added to a (candidate) result set based on the query criteria. In the case of range searching, all of the points corresponding to the

candidates must be examined, and those points satisfying the range criteria are added to the result set. However, for a  $k$ -nearest neighbor query, we can avoid examining all of the points corresponding to the candidates. In particular, the  $k$ -nearest neighbor query is implemented by again maintaining a candidate set, this time comprising the  $k$  points seen so far with the smallest actual distances from  $q$ . Let  $D$  be the greatest of these distances. The search is stopped as soon as a candidate element is encountered for which the lower bound on its distance from  $q$  is greater than  $D$ . Note that the nearest neighbor is obtained by letting  $k = 1$ . The same process is also used in many range and nearest neighbor query processing algorithms when we do not have easily identifiable features, and thus the indexing is based solely on the value of a distance function that indicates the similarity or dissimilarity between the pairs of objects (see Section 4.5).

Empirical studies [1973] show that the VA-file outperforms the X-tree, R\*-tree, and the sequential scan methods for nearest neighbor searches on both random data as well as real datasets for dimensions ranging as high as 45. The performance of the VA-file was already better in all cases for dimensions greater than six.

The VA-file bears a close resemblance to the grid file [839, 840, 1376] (see Section 1.7.2.1 of Chapter 1). They both impose a grid on the underlying dataspace, and queries are processed by inspecting data that falls into relevant grid cells. Nevertheless, there are some important differences. First, in the VA-file, the relevant grid cells are obtained by a sequential scan of all of the grid cells, while in the grid file, the relevant grid cells are obtained by random access via the aid of the  $d$  linear scales (one per feature). Thus, the linear scales provide the index for the grid file. On the other hand, the VA-file has no index. Second, in contrast to the VA-file, in the grid file, the boundaries of the slices are modified as the underlying data changes (i.e., due to updates). Thus, the dynamic behavior of the VA-file may be bad, which means that, at times, the VA-file may have to be rebuilt. Actually, the VA-file need not necessarily be rebuilt as we may only need to move the points that are affected by the change in relevant slice boundaries. However, in order to determine these points, we will need to scan the VA-file in its entirety, which is somewhat time-consuming. Nevertheless, given the fact that the entire VA-file is always scanned for each query, the cost of this additional scan is less of an issue. In contrast, the same actions of moving points as a result of the change in the grid cell boundaries can be performed in the grid file via random access, and thus the grid file has good dynamic behavior.

The design of the VA-file makes the implicit assumption that the features are independent, or at least uncorrelated, as the number of bits used to represent each feature, as well as the boundaries of the slices corresponding to the grid cells, are obtained independently. Ferhatosmanoglu, Tuncel, Agrawal, and El Abbadi [607] address the situation where these assumptions do not hold—that is, when some of the features are less discriminatory than others or exhibit less variability, and so on. They propose to decorrelate the data by using the Karhunen-Loève Transform (KLT) [665]. Based on the KLT, they then examine the new features and allocate a varying number of bits to them, depending on their discriminating range. In addition, instead of dividing each range into equally populated or equally sized intervals, they use an optimal quantizer such as Lloyd's algorithm [1194], which is nothing more than a greedy heuristic for solving the  $k$ -means problem, thereby resulting in clustering (e.g., [1174, 1219]) that is adapted for one-dimensional data.

Ferhatosmanoglu et al. use the term *VA<sup>+</sup>-file* to describe the result of these modifications and show that the VA<sup>+</sup>-file is a significant improvement over the VA-file for a number of real datasets. This improvement is in terms of the I/O cost and is achieved due to having better approximations of the distances of the points to the queries. In other words, the lower and upper bounds are tighter, which means better filtering in the first stage of range and nearest neighbor algorithms (i.e., fewer candidates are obtained). Moreover, according to their experiments, the nearest neighbors are obtained by examining fewer candidates in the second stage of the algorithm, which must perform random

disk I/O as the data objects are accessed in the order of their lower bound distances as determined from their grid cells.

The IQ-tree of Berchtold, Böhm, Jagadish, Kriegel, and Sander [185] also attempts to apply a more optimal quantization process, albeit based on a different philosophy. It is distinguished from the VA-file in several respects, with the most important being that the sequential scan is applied on a local basis, which has the consequence that a feature need not be quantized in the same way for the entire file. This enables a more optimal form of quantization to be used.

The IQ-tree is a three-level hierarchy. The first level contains an unordered list of minimum bounding rectangles (MBRs) of subsets of the dataset, obtained through a partitioning scheme described below. The second level consists of quantized data pages corresponding to the partitions at the first level. These quantized data pages are like mini VA-files for the data points in the MBR of each partition. These pages are of a fixed size, and the number of data points that they contain depends on the extent of the quantization (i.e., the number of bits allocated to each dimension). The third level consists of data pages that contain the full representation of the data points whose quantized representation is found on the second level. These data pages are of variable size. These pages are accessed only if the approximation at the second level is not enough to evaluate the query. Thus, we see that, in principle, when using the IQ-tree to respond to a query, the IQ-tree enables replacing the sequential scan of the VA-file corresponding to the entire dataset by a sequential scan of the file of MBRs of partitions of the underlying space and of the corresponding VA-file of the data points in the relevant MBRs. Therefore, the IQ-tree can be characterized as a hybrid of the VA-file and of hierarchical indexing methods such as the R-tree.

One of the main goals of Berchtold et al. [185] is to determine the optimal number of bits that should be assigned to the points in each partition. The partitions are formed by using a partitioning scheme such as that described by Berchtold, Böhm, and Kriegel [187] (see Section 4.4.6), originally proposed for fast bulk loading of high-dimensional indexes like the X-tree [190] (see Section 4.4.1). The initial step partitions the underlying data into  $s$  partitions using 1-bit quantization (i.e., each feature is quantized with 1 bit for a total of  $m$  bits for  $m$  features). Therefore, for  $d$  feature dimensions, each quantized data point occupies  $d$  bits. Thus, if a disk page can hold  $M$  such  $d$  bit-quantized values, then the initial partitioning is into  $s = \lceil N/M \rceil$  partitions of approximately  $M$  points each, where  $N$  is the number of data points. Hence, we obtain a partitioning of the data points into the minimum number of nearly full data pages based on 1-bit quantization of each dimension (i.e., feature).

Next, each partition  $t$  is considered in turn, to see whether it is worthwhile to split  $t$  into two parts, each with an equal number of points. Observe that after such a split, each part will only fill half a disk block if we still use 1-bit quantization. Therefore, we can double the number of bits for each dimension (i.e., feature), thus nearly filling two disk blocks to capacity. The decision as to whether or not to split the partition is made with the aid of a cost model. The idea is to find an appropriate trade-off between the increased accuracy obtained by splitting (since we have twice the number of bits per dimension) and the increased I/O cost of possibly accessing two disk blocks instead of one (i.e., depending on the likelihood of both parts being involved in a single query). The actual quantization is always performed with respect to the MBR of the partition that is being split, and all features are split the same number of times (i.e., the same number of bits is assigned to each feature). The splitting process is applied recursively with the number of bits of quantization per object doubled at each stage. The total number of splits is determined by the cost model, which also takes into account the costs of loading and processing the various levels of the directory [185].

The borders of the quantization cells in the IQ-tree are determined in the same way they are in the VA-file in that each range of a feature's quantized values has the same number of points. However, unlike in the VA-file, a feature need not be quantized using

the same number of bits for the entire dataset; instead, in the IQ-tree, a different number of quantization bits can be used in each partition. However, all the features in a partition must be quantized using the same number of bits.

The query processing algorithms such as nearest neighbor finding are the same as for an R-tree or other spatial indexes (e.g., [846, 848]) with the exception that, instead of always resorting to the exact representation of a point, a quantized representation is used that plays the same role as the minimum bounding box of an object with extent, such as a line, surface, or volume. Furthermore, Berchtold et al. [185] adapt the algorithms to yield sequential access to disk blocks where possible. For nearest neighbor search, this involves estimating the access probabilities of disk pages. Note that, unlike the algorithms for the VA-file, instead of applying a sequential scan to the entire data file, for the IQ-tree, sequential scan is only applied to the file containing the MBRs of the partitions. Of course, a sequential scan is also used when examining the elements of a quantized data page. This is usually done for many spatial indexes, such as R-trees, where the elements of a leaf node have not been organized to permit fast access. Note that the quantized data page in the IQ-tree is similar to a VA-file with the difference that only the quantized representations of the points are stored, with no explicit pointer to the disk page at the third level that contains the full representation of the point.

Empirical studies [185] have shown the IQ-tree outperforming the VA-file, sequential scan, and the X-tree. These studies have demonstrated the benefit of indexing, which is something not really done in the VA-file. However, the dimensions of the data were generally low (up to 16) in contrast to those reported in studies of the VA-file [1973]. The effect of increasing the dimension of the data is an interesting subject for further study. Note that the performance of the IQ-tree could be improved upon by using the same methods employed by the VA<sup>+</sup>-file [607] to improve on the VA-file. In particular, a different number of bits could be assigned to each feature in each partition, and an optimal quantizer could be used based on clustering instead of partitioning each range into equally populated regions.

The sequential scan can also be applied to the computation of approximate nearest neighbors. One of the simplest methods is to scan the actual objects sequentially and terminate once finding an object within some predefined distance  $s$  of the query object  $q$ . This is the basis of the sequential variant of the probably approximately correct (PAC) nearest neighbor method of Ciaccia and Patella [387] (see Section 4.3). Of course, deriving an appropriate value for  $s$  is challenging: with too small a value, the entire file must be scanned (i.e., no object is within distance  $s$  of  $q$ ), and with too large a value, the object that is found is a poor candidate (e.g., if all objects are within distance  $s$  of  $q$ ). Unfortunately, this method does not easily extend to finding the  $k$  nearest neighbors as we only have the estimate of the distance from the query object to the nearest neighbor and not to the  $k$ -nearest neighbor, thereby limiting its utility.

In the case of the VA-file, Weber and Böhm [1971] propose to obtain an approximate nearest neighbor by simply omitting the second step of the algorithm. However, this means that there is no need even to compute the upper-bound distances as they are only used to reduce the number of candidates for the second step. Thus, in order to determine the approximate  $k$  nearest neighbors, only the first pass needs to be performed, and the  $k$  elements with the  $k$  smallest lower bounds are retained.

A more drastic alternative to computing the approximate  $k$  nearest neighbors is limiting the number of pages that are scanned in sequence, retaining the  $k$  elements with the smallest distances from the query object, and deeming them the  $k$  nearest neighbors. Ferhatosmanoglu et al. [608] compare this approach with a number of other approaches that are based on limiting the amount of information (i.e., bits) that is available about each element (i.e., the number of bits per dimension), thereby also limiting the number of page accesses. These approaches include the VA-file, VA<sup>+</sup>-file, and the result of decorrelating the data using the Karhunen-Loève Transform (KLT) [665]. In addition, the result is compared to a new method that makes use of clustering once the data has been decorrelated using the KLT. The method partitions the new features into groups of

$d/s$  features according to the variance along each new feature axis (the variance, which is obtained as a byproduct of KLT, indicates the “spread” in data values along the axes) and applies a  $k$ -means clustering algorithm (e.g., [1174, 1219]) to all the data, but only in terms of the values of the group of the  $s$  most significant features. The closest cluster  $c$  to query point  $q$  is determined, and the  $k$  nearest elements in  $c$  to  $q$  are obtained. Next, the  $k$  elements in  $c$  are refined by including the values of the next  $s$  most significant features. These newly refined  $k$  elements are compared with the elements in the second closest cluster to  $q$  (using  $2 \cdot s$  features this time), and, once again, the  $k$  nearest elements are determined. This process of increasing the number of clusters by one and the number of features by  $s$  is applied repeatedly until the quality of the result is deemed good enough.

One of the difficulties with applying any of the above approaches (except for PAC [387], which is only applicable for  $k = 1$  and was not one of the approaches studied by Ferhatosmanoglu et al. [608]) to the determination of the approximate  $k$  nearest neighbors is that we have no a priori control over the quality of the resulting approximation. In particular, in contrast to conventional approximate  $k$ -nearest neighbor techniques, given an approximation error tolerance  $\varepsilon$ , we cannot stipulate that, as a result, all of the  $k$  elements are within a factor of  $(1 + \varepsilon)$  of the distance to the real nearest neighbors. Thus, we need other measures of quality. One possible measure of quality is the number of elements in the set of  $k$  approximate nearest neighbors that should not have been returned (i.e., *false hits*) or the number of elements that should have been in the result but were not (i.e., *false dismissals*).

However, when computing the approximate  $k$  nearest neighbors, the number of false hits is always equal to the number of false dismissals. Thus, the quality of the result can be measured using either of these measures. For example, we could use the ratio of the number of false hits over  $k$ . Unfortunately, this ratio does not provide a good evaluation of the quality of the approximate  $k$ -nearest neighbor process. In particular, false hits that are far from the  $k$  nearest neighbors are less desirable than false hits that are close to the  $k$  nearest neighbors; yet, the ratio does not reflect this. Thus, a better measure is to compute a relative approximation error

$$D = \sum_{i=1}^k \|q - a_i\|^2 / \|q - r_i\|^2,$$

where  $q$  is the query point, and  $a_i$  and  $r_i$  ( $1 \leq i \leq k$ ) are the corresponding approximate and exact result sets, respectively.

Using this quantity  $D$ , Ferhatosmanoglu et al. [608] show that, for a given number of pages that are accessed, the new method outperforms all three other methods, with the VA<sup>+</sup>-file being second best, followed by the VA-file, and the method that applies no data reduction. In other words, to attain a given value of  $D$ , the new method requires that far fewer pages be accessed than the other methods. The same behavior also holds when the value of  $D$  is kept fixed while the volume of the dataset is allowed to grow. Nevertheless,  $D$  still depends on knowledge of the nearest neighbors, and thus it cannot be used to determine when enough pages have been accessed to obtain a good approximation. There is no obvious solution to this problem except possibly to use a distribution of  $D$  versus the number of pages that have been accessed for some prior queries to obtain an expected value of  $D$  and to use that value to choose the number of pages to be accessed.

### Exercises

1. Queries on the VA-file, such as finding the  $k$  nearest neighbors, make use of a two-stage procedure such as a filter-and-refine algorithm. Why is it not necessary to sort the elements obtained in the first stage prior to starting to process them in the second stage?
2. Modify the IQ-tree by using some of the methods employed by the VA<sup>+</sup>-file [607] to improve on the VA-file.
3. Adapt the IQ-tree to compute the  $k$  approximate nearest neighbors.

## 4.5 Distance-Based Indexing Methods

In many applications, we do not have easily identifiable features. In this case, the only available information is a distance function that indicates the degree of similarity (or dissimilarity) between all pairs of objects. Thus, searching is facilitated by indexing objects with respect to their distances from other objects. A number of such methods have been proposed over the past few decades, some of the earliest being due to Burkhard and Keller [283]. These methods generally assume that we are given a finite set  $S$  of  $N$  objects and a distance metric  $d$  indicating the distance values between them (collectively termed a *finite metric space*; for more details, see Section 4.5.1). Typical of distance-based indexing structures are *metric trees* [1896, 1897], binary trees that result in recursively partitioning a dataset into two subsets at each node. Uhlmann [1897] identified two basic partitioning schemes: *ball partitioning* and *generalized hyperplane partitioning*.

Figure 4.39  
Possible top-level partitionings of a set of objects (depicted as two-dimensional points) in a metric tree using (a) ball partitioning and (b) generalized hyperplane partitioning.

In ball partitioning, the dataset is partitioned based on distances from one distinguished object, sometimes called a *vantage point* [2052], into the subset that is inside and the subset that is outside a ball around the object (e.g., see Figure 4.39(a)). In generalized hyperplane partitioning, two distinguished objects  $p_1$  and  $p_2$  are chosen, and the dataset is partitioned based on which of the two distinguished objects is the closest—that is, all the objects in subset  $A$  are closer to  $p_1$  than to  $p_2$ , while the objects in subset  $B$  are closer to  $p_2$  (e.g., see objects  $p_1$  and  $p_2$  in Figure 4.39(b)). The asymmetry of ball partitioning (which is evident from Figure 4.39(a)) is a potential drawback of this method as the outer shell tends to be very narrow for metric spaces typically used in similarity searching (e.g., see [255]). In contrast, generalized hyperplane partitioning is more symmetric, in that both partitions form a “ball” around an object (see Figure 4.39(b)).

An alternative way of distinguishing between some of the different distance-based indexing methods is on the basis of whether they are pivot based or clustering based (e.g., [332]). Pivot-based methods choose a subset of the objects in the dataset to serve as distinguished objects, termed *pivot objects* (or more generally *pivots*), and classify the remaining objects in terms of their distances from the pivot objects. Pivot-based similarity searching algorithms make use of the known distances from the objects to different pivot objects to reduce the number of distance computations involving the query object that will be needed to respond to the query. The pivot objects, assuming without loss of generality that there are  $k$  of them, can often be viewed as coordinates in a  $k$ -dimensional space, and the result of the distance computation for object  $x$  is equivalent to a mapping of  $x$  to a point  $(x_0, x_1, \dots, x_{k-1})$ , where coordinate value  $x_i$  is the distance  $d(x, p_i)$  of  $x$  from pivot  $p_i$ . The result is very similar to embedding methods discussed in Section 4.7. Ball partitioning methods are examples of pivot-based methods. In addition, methods that make use of distance matrices that contain precomputed distances between some or all of the objects in the dataset [1292, 1930, 1951] are also examples of pivot-based methods. Note that the distance matrix methods differ from the ball partitioning methods in that they do not form a hierarchical partitioning of the dataset.

Clustering-based methods partition the underlying dataset into spatial-like zones called *clusters* that are based on proximity to a distinguished object known as the *cluster center*. In particular, once a set of cluster centers has been chosen, the objects that are associated with each cluster center  $c$  are those that are closer to  $c$  than to any other cluster center. Although the cluster centers play a similar role to the pivot objects, the principal difference is that an object  $o$  is associated with a particular pivot  $p$  on the basis of the distance from  $o$  to  $p$ , and not because  $p$  is the closest pivot to  $o$ , which would be the case if  $p$  were a cluster center. This distinction was already made in Figure 4.10 in conjunction with the discussion of the pruning methods used with the depth-first  $k$ -nearest neighbor algorithm in Section 4.2. Generalized hyperplane partitioning methods are examples of clustering-based methods. The *sa-tree* [1347], inspired by the Voronoi diagram, is another example of a clustering-based method. It records a portion of the Delaunay graph of the dataset, which is a graph whose vertices are the Voronoi cells,

with edges between adjacent cells. Although many of the clustering-based methods that we describe are hierarchical, this need not necessarily be the case.

It is interesting to observe that both pivot-based and clustering-based methods achieve a partitioning of the underlying dataset into spatial-like zones. However, the difference is that the boundaries of the zones are better defined in the case of pivot-based methods in the sense that they can be expressed explicitly using a small number of objects and a known distance value. In contrast, in the case of clustering-based methods, the boundaries of the zones are usually expressed implicitly in terms of the cluster centers, instead of explicitly, which may require quite a bit of computation to determine. In fact, very often, the boundaries cannot be expressed explicitly, as, for example, in the case of an arbitrary metric space (in contrast to a Euclidean space) where we do not have a direct representation of the “generalized hyperplane” that separates the two partitions.

Note that often the terms *cluster*, *cluster center*, and *pivot object* are used loosely without much attention to the nature of the indexing method with which they are being deployed (i.e., whether it is pivot based or clustering based). In particular, recall Section 4.2, where the cluster centers and cluster elements are actually pivots and collections of objects within a given distance of the pivots, respectively, in the context of the above discussion. Thus, in the rest of this section we usually use the term *pivot* in a collective sense to refer to any type of distinguished object that can be used during search to achieve pruning of other objects, following the convention of Chávez, Navarro, Baeza-Yates, and Marroquín [334]. In other words, a pivot  $p \in S$  is an object for which we have some information about its distance from some or all objects in  $S$ . For example, for all objects  $o \in S' \subseteq S$ , we know one of the following:

1. The exact value of  $d(p, o)$
2. That  $d(p, o)$  lies within some range  $[r_{lo}, r_{hi}]$  of values
3. That  $o$  is closer to  $p$  than to some other object  $p' \in S$

In this section, we describe a number of distance-based indexing methods with an emphasis on how they can be used to find similar objects (i.e., range searching and nearest neighbors). The focus is on understanding the basic ideas behind the methods and on differentiating between them. Thus, we do not provide much detail about construction algorithms or devote much effort to comparing or contrasting the different methods. This section is organized as follows. In Section 4.5.1, we discuss properties of the distance metric useful for search pruning. This section is rather technical, and the reader may wish to skim over this section on first reading and refer back to it as needed. In Section 4.5.2, we describe the *vp-tree* [2052] and other variants of metric trees that employ ball partitioning. In Section 4.5.3, we present the *gh-tree* [1897] and other variants of metric trees that employ generalized hyperplane partitioning. In Section 4.5.3.3, we focus on the bisector tree [978] and the mb-tree [1383], which are representations based on generalized hyperplane partitioning that are analogous to classical space partitioning methods, such as the PR quadtree [1413, 1637] (see Section 1.4.2.2 in Chapter 1) with implicit rather than explicit boundaries of the regions formed by the partitions. In Section 4.5.4, we describe the *M-tree* [389], a dynamic and balanced metric tree variant suitable for disk-based implementation, which has features common to both pivot-based and clustering-based indexing methods. In Sections 4.5.5 and 4.5.6, we introduce the *Spatial Approximation tree (sa-tree)* [1347] and the *kNN graph* [1704], respectively, which are a pair of clustering-based methods. In Section 4.5.7, we describe *AESA* [1930] and *LAESA* [1292], methods that rely on distance matrices, which are variants of pivot-based methods. Finally, in Section 4.5.8, we present Spatial Approximation Sample Hierarchy (SASH), which enables distance-based indexing without requiring the triangle inequality. In this respect, it is similar to the kNN graph; however, it is much faster to construct, at the cost of having edges to objects that are likely to be nearest neighbors rather than to exact nearest neighbors, as in the kNN graph. In particular, indexing methods such as the kNN graph must compute the nearest neighbors as part of the process of forming the index, which will speed up the calculation of nearest neighbors in the

future. In contrast, SASH constructs the index in an incremental manner by using the existing index for a set of objects to determine the approximate nearest neighbors of newly added objects.

### 4.5.1 Distance Metric and Search Pruning

As mentioned earlier, the indexed objects must reside in a finite metric space  $(S, d)$ . This means that the distance function  $d$  must satisfy the following three properties, where  $o_1, o_2, o_3 \in S$ :

1.  $d(o_1, o_2) = d(o_2, o_1)$  (symmetry)
2.  $d(o_1, o_2) \geq 0$ ,  $d(o_1, o_2) = 0$  iff  $o_1 = o_2$  (nonnegativity)
3.  $d(o_1, o_3) \leq d(o_1, o_2) + d(o_2, o_3)$  (triangle inequality)

When the distance function  $d$  satisfies these three properties, then  $d$  is said to be a *metric* as well as a *distance metric*. The indexing methods discussed in the remaining subsections are often applicable even when these three properties are relaxed. For example, it rarely matters if  $d(o_1, o_2) = 0$  for some pairs of distinct objects  $o_1$  and  $o_2$  (in this case,  $d$  is often termed a *pseudometric*). Furthermore, adequate performance can often be attained even if the triangle inequality is occasionally violated,<sup>26</sup> but this leads to approximate results (i.e., we cannot guarantee that the nearest neighbors are obtained in strictly nondecreasing order of distance).

Of the distance metric properties, the triangle inequality is the key property for pruning the search space when processing queries. However, in order to make use of the triangle inequality, we often find ourselves applying the symmetry property. Furthermore, the nonnegativity property allows the discarding of negative values in formulas. Below, we enumerate a number of results that can be derived based on the metric properties. Our goal is to provide a foundation for use in later sections when we explain how to perform operations such as range searching and finding nearest neighbors. In particular, we provide lower and upper bounds on the distance  $d(q, o)$  between a query object  $q$  and some object  $o$ , given some information about distances between  $q$  and  $o$  and some other object(s).

Recall that  $S \in \mathbb{U}$ , where  $\mathbb{U}$  is some underlying set, usually infinite, and we assume that  $(\mathbb{U}, d)$  is also a metric space (i.e., that  $d$  also satisfies the above properties on  $\mathbb{U}$ ). For generality, we present our results in terms of  $(\mathbb{U}, d)$  since a query object is generally not in  $S$ . In the first lemma, we explore the situation where we know the distances from an object  $p$  to both  $q$  and  $o$  (while the distance between  $q$  and  $o$  is unknown).

**Lemma 4.1** *Given any three objects  $q, p, o \in \mathbb{U}$ , we have*

$$|d(q, p) - d(p, o)| \leq d(q, o) \leq d(q, p) + d(p, o) \quad (4.1)$$

Thus, knowing  $d(q, p)$  and  $d(p, o)$ , we can bound the distance of  $d(q, o)$  from both below and above.

*Proof* The upper bound is a direct consequence of the triangle inequality. For the lower bound, notice that  $d(p, o) \leq d(p, q) + d(q, o)$  and  $d(q, p) \leq d(q, o) + d(o, p)$ , according to the triangle inequality. The first inequality implies  $d(p, o) - d(p, q) \leq d(q, o)$ , and the second implies  $d(q, p) - d(o, p) \leq d(q, o)$ . Therefore, combining these inequalities and making use of symmetry, we obtain  $|d(q, p) - d(p, o)| \leq d(q, o)$ , as desired. ■

Figure 4.40(a) illustrates the situation where the lower bound  $|d(q, p) - d(p, o)|$  established in Lemma 4.1 is nearly attained. Clearly, in the figure,  $d(q, o)$  is nearly as small as  $d(q, p) - d(p, o)$ . The opposite relationship (i.e.,  $d(q, o)$  being nearly as small as  $d(p, o) - d(q, p)$ ) is obtained by exchanging  $q$  and  $o$  in the figure. Similarly,

Figure 4.40  
Illustration of distance bounds. Given  $d(q, p)$  and  $d(p, o)$ , a lower bound (a) and an upper bound (b) can be established for  $d(q, o)$ .

<sup>26</sup> Distance functions for DNA data that are based on edit distance are usually of this nature [1780].

Figure 4.40(b) illustrates the situation where the upper bound  $d(q, p) + d(p, o)$  is nearly attained.

The lower bound on  $d(q, o)$  in Lemma 4.1 is also used in Pruning Rule 2 of Fukunaga and Narendra [666] and in Pruning Rule 4 of Kamgar-Parsi and Kanal [986], discussed in Section 4.2.2, to eliminate object  $o$  from consideration as  $q$ 's  $k$ th-nearest neighbor in a depth-first  $k$ -nearest neighbor finding algorithm. We show this for  $k = 1$ , but the argument for arbitrary values of  $k$  is the same. To see this, we recall that both Rules 2 and 4 apply the triangle inequality to obtain a lower bound of  $d(q, p) - d(p, o)$  and  $d(p, o) - d(q, p)$ , respectively, on the distance from  $q$  to  $o$ , with the difference depending on whether  $o$  is closer to  $p$  than  $q$  (Rule 2) or whether  $q$  is closer to  $p$  than  $o$  (Rule 4). This lower bound is used to eliminate  $o$  from being considered as the nearest neighbor of  $q$  when we know that a candidate nearest neighbor  $o'$  of  $q$  is at a distance of  $D_1$  from  $q$  and that  $D_1$  is less than  $|d(q, p) - d(p, o)|$ . In particular, in this case it is impossible for  $o$  to be a better candidate nearest neighbor of  $q$  than  $o'$  as  $o$  is farther from  $q$  than  $o'$ . Thus, we see that the lower bound on  $d(q, o)$  given in Lemma 4.1 is also a lower bound on the distance to the nearest neighbor of  $q$  if  $o$  is to serve as  $q$ 's nearest neighbor.

Use of the lower bound on  $d(q, o)$  in Lemma 4.1 to eliminate objects from consideration is analogous to the application of the method of Friedman, Baskett, and Shustek [649], as well as that of Nene and Nayar [1364], for vector spaces who eliminate a  $k$ -dimensional object  $x = (x_0, x_1, \dots, x_{k-1})$  from consideration as being within  $\varepsilon$  of  $q = (q_0, q_1, \dots, q_{k-1})$  if  $|x_i - q_i| > \varepsilon$  for one of  $x_i$ , where  $0 \leq i \leq k - 1$  (see Section 1.1 in Chapter 1). A variant of this method is also advocated by Chávez, Marroquín, and Baeza-Yates [330]. It is interesting to note that all of these search strategies make an implicit assumption that the  $k$ -dimensional space is indexed with a set of inverted lists, one for the distance of the objects from each of the pivots. This is in contrast with a search strategy that assumes the existence of a more general multidimensional point access method such as those discussed in Chapter 1. Other instances where this technique is used include AESA [1930] (Section 4.5.7.1), LAESA [1292] (Section 4.5.7.2), the fixed-queries tree [118] (Section 4.5.2.4), and the fixed-queries array [331] (Section 4.5.2.4), which can all be viewed as variations of embedding methods (see Section 4.7) that map the distances between the objects into a  $k$ -dimensional space by finding  $k$  objects  $p_i$  known as *pivots*, and the result of the mapping of an object  $x$  is a point  $(x_0, x_1, \dots, x_{k-1})$  whose coordinate value  $x_i$  is the distance  $d(x, p_i)$  of  $x$  from pivot  $p_i$ . An object  $x$  is pruned from further consideration as being within  $\varepsilon$  of query object  $q$  when  $|d(q, p_i) - d(x, p_i)| > \varepsilon$  for some pivot  $p_i$  ( $0 \leq i \leq k - 1$ ).

In the next lemma, we assume that we know the distance between  $q$  and  $p$  but that the distance between  $p$  and  $o$  is known only to be within some range. This is illustrated in Figure 4.41, where we show three different positions of the query object  $q$ . The lower bounds on the distances  $d(q_1, o)$  and  $d(q_2, o)$  are indicated with gray arrows, and the upper bound on  $d(q_2, o)$  is indicated with a gray broken arrow. It should be clear that the lower bound on  $d(q_3, o)$  is 0.

**Lemma 4.2** *Let  $o$  and  $p$  be objects in  $\mathbb{U}$  such that  $r_{lo} \leq d(o, p) \leq r_{hi}$ . The distance  $d(q, o)$  from  $q \in \mathbb{U}$  to  $o$  can be bounded as follows, given  $d(q, p)$ :*

$$\max\{d(q, p) - r_{hi}, r_{lo} - d(q, p), 0\} \leq d(q, o) \leq d(q, p) + r_{hi} \quad (4.2)$$

*Proof* Again, we use the triangle inequality to prove these bounds. In particular, from the inequality  $d(q, p) \leq d(q, o) + d(o, p)$  and the upper bound  $d(o, p) \leq r_{hi}$ , we obtain  $d(q, p) - d(q, o) \leq d(o, p) \leq r_{hi}$ , which implies that  $d(q, p) - r_{hi} \leq d(q, o)$  (e.g., see  $q_1$  in Figure 4.41). Similarly, we can combine the triangle inequality and the lower bound on  $d(o, p)$  to obtain  $r_{lo} \leq d(o, p) \leq d(q, o) + d(q, p)$ , which implies that  $r_{lo} - d(q, p) \leq d(q, o)$  (e.g., see  $q_2$  in Figure 4.41). Either or both of these lower bounds can be negative (e.g., for  $q_3$  in Figure 4.41), whereas distance values are required to be nonnegative. Thus, the overall lower bound in Equation 4.2 is obtained by taking the maximum of zero and these two lower bounds. The upper bound in Equation 4.2 is obtained by a

Figure 4.41  
Illustration of distance bounds. Given that  $r_{lo} \leq d(p, o) \leq r_{hi}$ , we can establish lower and upper bounds on  $d(q, o)$ . Three positions are shown for  $q$ , demonstrating three cases that can arise.

straightforward application of the triangle inequality and the upper bound on  $d(o, p)$ —that is,  $d(q, o) \leq d(q, p) + d(o, p) \leq d(q, p) + r_{hi}$  (e.g., see the broken arrow from  $q_2$  through  $p$  to the outer boundary in Figure 4.41). ■

The lower bounds on  $d(q, o)$  in Lemma 4.2 are also used in Pruning Rule 1 of Fukunaga and Narendra [666] and in Pruning Rule 3 of Kamgar-Parsi and Kanal [986], discussed in Section 4.2.2, to eliminate object  $o$  from consideration as  $q$ 's  $k$ th-nearest neighbor in a depth-first  $k$ -nearest neighbor finding algorithm. We show this for  $k = 1$ , but the argument for arbitrary values of  $k$  is the same. To see this, we recall that Pruning Rule 1 makes use of the fact that, given any object  $o$  whose distance from object  $p$  is less than  $r_{hi}$ , the distance from  $o$  to another object  $q$  must be at least  $d(q, p) - r_{hi}$ , provided that the distance from  $q$  to  $p$  is larger than  $r_{hi}$ . This means that if we know that a candidate nearest neighbor of  $q$  is at a distance of  $D_1$  from  $q$  and that  $D_1$  is less than  $d(q, p) - r_{hi}$ , then it is impossible for  $o$  to be a better candidate nearest neighbor, and, in fact, no object  $o$  whose distance from  $p$  is less than  $r_{hi}$  can be the nearest neighbor of  $q$ .

Similarly, we recall that Pruning Rule 3 makes use of the fact that, given any object  $o$  whose distance from object  $p$  is greater than  $r_{lo}$ , the distance from  $o$  to another object  $q$  must be at least  $r_{lo} - d(q, p)$ , provided that the distance from  $q$  to  $p$  is smaller than  $r_{lo}$ . This means that if we know that a candidate nearest neighbor of  $q$  is at a distance of  $D_1$  from  $q$  and that  $D_1$  is less than  $r_{lo} - d(q, p)$ , then it is impossible for  $o$  to be a better candidate nearest neighbor, and in fact no object  $o$  whose distance from  $p$  is greater than  $r_{lo}$  can be the nearest neighbor of  $q$ . Thus, we see that the lower bounds on  $d(q, o)$  given in Lemma 4.2 are also lower bounds on the distance to the nearest neighbor of  $q$  if  $o$  is to serve as  $q$ 's nearest neighbor.

In addition, observe that the upper bound on  $d(q, o)$  in Lemma 4.2 is also used in Fukunaga and Narendra's [666] formulation of Pruning Rule 5 discussed in Section 4.2.2 to bound the distance to the  $k$ th-nearest neighbor of  $q$  if  $o$  is to serve as  $q$ 's  $k$ th-nearest neighbor in a depth-first  $k$ -nearest neighbor finding algorithm. To see this, we recall that Fukunaga and Narendra's [666] formulation of Pruning Rule 5 makes use of the fact that, given any object  $o$  whose distance from object  $p$  is less than  $r_{hi}$ , the distance from  $o$  to another object  $q$  must be no greater than  $d(q, p) + r_{hi}$ .

Note that Pruning Rules 1, 3, and 5 are formulated in terms of  $r_{p,max}$  and  $r_{p,min}$  instead of  $r_{hi}$  and  $r_{lo}$ , respectively. This means that objects  $o_{max}$  and  $o_{min}$  must exist at the maximum and minimum distances  $r_{p,max}$  and  $r_{p,min}$ , respectively, from  $p$ . However, this is not a problem as the proof of Lemma 4.2 is identical as are the proofs of Pruning Rules 1, 3, and 5 with the alternative definitions.

In some situations, the distance  $d(q, p)$  in Lemma 4.2 may not be known exactly. The next lemma establishes bounds on the distance from  $q$  to  $o$  in such circumstances.

**Lemma 4.3** *Let  $o, p,$  and  $q$  be objects in  $\mathbb{U}$  for which  $d(o, p)$  is known to be in the range  $[r_{lo}, r_{hi}]$  and  $d(q, p)$  is known to be in the range  $[s_{lo}, s_{hi}]$ . The distance  $d(q, o)$  can be bounded as follows:*

$$\max\{s_{lo} - r_{hi}, r_{lo} - s_{hi}, 0\} \leq d(q, o) \leq r_{hi} + s_{hi} \quad (4.3)$$

*Proof* Substituting  $s_{lo}$  for the first instance of  $d(q, p)$  in Equation 4.2 can reduce only the lower bound. Thus, we find that  $s_{lo} - r_{hi} \leq d(q, o)$ . The same is true when substituting  $s_{hi}$  for the second instance of  $d(q, p)$  in the equation as this instance is subtractive, which shows that  $r_{lo} - s_{hi} \leq d(q, o)$ . Similarly, substituting  $s_{hi}$  for the last instance of  $d(q, p)$  in the equation increases the upper bound, so we obtain  $d(q, o) \leq r_{hi} + s_{hi}$ . ■

Clearly, the roles of the two ranges in Lemma 4.3 are symmetric. For an intuitive understanding of the lower bound, imagine two shells around  $p$ , one with radius range  $[r_{lo}, r_{hi}]$  (where  $o$  is allowed to reside) and the other with radius range  $[s_{lo}, s_{hi}]$  (where  $q$  is allowed to reside). This is illustrated by the shaded arrow in Figure 4.42(a) where the minimum distance between  $q$  and  $o$  is equal to the space between the shells, if there is

Figure 4.42  
(a) The lower bound on  $d(q, o)$  for the case when  $d(p, o)$  is in the range  $[r_{lo}, r_{hi}]$  and  $d(p, q)$  is in the range  $[s_{lo}, s_{hi}]$  and (b) illustration of how the upper bound on  $d(q, o)$  can be attained when  $d(p, o)$  and  $d(p, q)$  are in these ranges.

any. Similarly, the upper bound can be understood by visualizing shells around  $q$  and  $o$ , with  $p$  at the outer edge of each shell, as illustrated in Figure 4.42(b).

In some distance-based indexes, such as those that use generalized hyperplane partitioning (see Section 4.5.3), objects are partitioned based on the relative closeness to two or more objects. Lemma 4.4 provides a result that we can use in such situations.

**Lemma 4.4** *Let  $o \in \mathbb{U}$  be an object that is closer to  $p_1$  than to  $p_2$  or equidistant from both (i.e.,  $d(p_1, o) \leq d(p_2, o)$ ). Given  $d(q, p_1)$  and  $d(q, p_2)$ , we can establish a lower bound on  $d(q, o)$ :*

$$\max \left\{ \frac{d(q, p_1) - d(q, p_2)}{2}, 0 \right\} \leq d(q, o) \quad (4.4)$$

*Proof* From the triangle inequality, we have  $d(q, p_1) \leq d(q, o) + d(p_1, o)$ , which yields  $d(q, p_1) - d(q, o) \leq d(p_1, o)$ . When combined with  $d(p_2, o) \leq d(q, p_2) + d(q, o)$  (from the triangle inequality) and  $d(p_1, o) \leq d(p_2, o)$ , we obtain  $d(q, p_1) - d(q, o) \leq d(q, p_2) + d(q, o)$ . Rearranging yields  $d(q, p_1) - d(q, p_2) \leq 2d(q, o)$ , which yields the first component of the lower bound in Equation 4.4; the second component is furnished by nonnegativity. ■

There are several ways of obtaining intuition about this result. One way is to observe that it is directly applicable to determining which Voronoi regions to examine when performing a range search in a Voronoi diagram (i.e., find all objects within  $\varepsilon$  of query object  $q$ ). In essence, we compute the distance from  $q$  to each of the sites  $s_i$  of Voronoi region  $v_i$  and then choose the closest site  $s$  to  $q$  and eliminate every Voronoi region whose site  $s_i$  satisfies  $(d(q, s_i) - d(q, s)) > 2 \cdot \varepsilon$  as the intersection of the Voronoi region  $v_i$  of  $s_i$  with the query range of radius  $\varepsilon$  centered at  $q$  is empty.

An alternative illustration of this result is obtained by considering the situation shown in Figure 4.43(a) where  $q$  lies on the line between  $p_1$  and  $p_2$  in a two-dimensional Euclidean space, closer to  $p_2$ . If  $o$  is closer to  $p_1$ , then  $o$  is to the left of the horizontal line midway between  $p_1$  and  $p_2$  that separates the regions in which objects are closer to  $p_1$  or to  $p_2$ . Thus,  $d(q, o)$  is lower bounded by the distance from  $q$  to the dividing line, which equals  $(d(q, p_1) - d(q, p_2))/2$  for the particular position of  $q$  in the figure. If we move  $q$  up or down parallel to the dividing line (e.g., up in Figure 4.43(b) to position  $q'$ ), then the distance from  $q'$  to the line is clearly unchanged (i.e., it is still  $d(q, p_1) - d(q, p_2)$ ). However, the difference between  $d(q', p_1)$  and  $d(q', p_2)$  can be shown to decrease as both  $d(q', p_1)$  and  $d(q', p_2)$  increase, so the value of  $(d(q', p_1) - d(q', p_2))/2$  will also decrease (see Exercise 3). In other words, we see that the distance from  $q$  to the dividing line in the figure is exactly  $(d(q, p_1) - d(q, p_2))/2$ , whereas  $(d(q', p_1) - d(q', p_2))/2$  decreases as  $q'$  is moved while keeping the distance from  $q'$  to the dividing line constant. Therefore, the value  $(d(q, p_1) - d(q, p_2))/2$  is indeed a lower bound on the distance from  $q$  to any point on the dividing line or from any point  $q'$  on the line parallel to the dividing line that passes through  $q$ , and thus it is also a lower bound on the distance between  $q$  and  $o$ . Note that this argument holds for all positions of  $q$  that are closer to  $p_2$  than to  $p_1$  as the initial position of  $q$  can be anywhere on the line between  $p_1$  and  $p_2$ . Observe that without additional information, an upper bound on  $d(q, o)$  cannot be established as  $o$  may be arbitrarily far away from  $p_1$  or  $p_2$ .

Figure 4.43  
(a) Lower bound on  $d(q, o)$  illustrated in a two-dimensional Euclidean space when  $q$  is on the line between  $p_1$  and  $p_2$ , closer to  $p_2$ , while  $o$  is closer to  $p_1$  and (b) the lower bound is shown to decrease when  $q$  is moved off the line (e.g., to  $q'$ ).

### Exercises

1. Recall from footnote 3 of this chapter that the Hamming edit distance between two strings  $s$  and  $t$ , is defined only when  $s$  and  $t$  are of the same length, and is the number of positions in which  $s$  and  $t$  differ (i.e., have different characters). Show that the Hamming edit distance is a distance metric.
2. Recall from footnote 3 of this chapter that the Levenshtein edit distance between two strings  $s$  and  $t$  is the number of deletions, insertions, or substitutions required to transform  $s$  into  $t$ . Show that the Levenshtein edit distance is a distance metric.

- Suppose that you are given points  $p_1$ ,  $p_2$ ,  $q$ , and  $o$  in a two-dimensional Euclidean space, where  $q$  is on the line between  $p_1$  and  $p_2$ , closer to  $p_1$ , while  $o$  is closer to  $p_2$ , as shown in Figure 4.43(a). Move  $q$  in a direction parallel to the dividing line between  $p_1$  and  $p_2$  (e.g., up in Figure 4.43(a) as shown by  $q'$  in Figure 4.43(b)). Show that the difference between  $d(q, p_1)$  and  $d(q, p_2)$  is decreasing as both  $d(q, p_1)$  and  $d(q, p_2)$  increase—that is, show that  $(d(q', p_1) - d(q', p_2))/2 < (d(q, p_1) - d(q, p_2))/2$ , while  $d(q', p_1) \geq d(q, p_1)$  and  $d(q', p_2) \geq d(q, p_2)$ .

## 4.5.2 Ball Partitioning Methods

In this section, we discuss ball partitioning methods. Recall that in this case the dataset is partitioned based on distances from one distinguished object  $p$  into one subset that is inside and the subset that is outside a ball around the object (recall Figure 4.39(a)). The rest of this section is organized as follows. Section 4.5.2.1 describes the vp-tree. Section 4.5.2.2 presents the  $vp^{sb}$ -tree, which is a variant of the vp-tree that keeps track of additional distance information, as well as makes use of buckets in the leaf nodes. Section 4.5.2.3 introduces the mvp-tree, which increases the fanout of the nodes in the vp-tree by splitting the region corresponding to each node into more than two regions corresponding to more than two subsets. Section 4.5.2.4 contains a brief discussion of additional methods based on ball partitioning.

Figure 4.44  
(a) Example set of objects that are points in the two-dimensional Euclidean space and (b) one possible vp-tree corresponding to them. The circles in (a) correspond to the balls, and the objects that serve as pivots are also surrounded by circles.

### 4.5.2.1 Vp-Tree

The *vantage point tree* (vp-tree) [2052] is the most commonly used ball partitioning method. In this section, we first describe the structure of the vp-tree and a number of ways of constructing it (Section 4.5.2.1.1). Next, we discuss how to perform range searching and how to find nearest neighbors incrementally (Section 4.5.2.1.2).

#### 4.5.2.1.1 Structure

The vp-tree is an example of an indexing method that uses ball partitioning (and thus is a variant of the metric tree [1896, 1897]). In this method, we pick a pivot  $p$  from  $S$  (termed a *vantage point* in [2052]), compute the median  $r$  of the distances of the other objects to  $p$ , and then divide the remaining objects into roughly equal-sized subsets  $S_1$  and  $S_2$  as follows:

$$S_1 = \{o \in S \setminus \{p\} \mid d(p, o) < r\}$$

$$S_2 = \{o \in S \setminus \{p\} \mid d(p, o) \geq r\}$$

Thus, the objects in  $S_1$  are *inside* the ball of radius  $r$  around  $p$ , while the objects in  $S_2$  are *outside* this ball. Applying this rule recursively leads to a binary tree, where a pivot object is stored in each internal node, with the left and right subtrees corresponding to the subsets inside and outside the corresponding ball, respectively. In the leaf nodes of the tree, we would store one or more objects, depending on the desired capacity. An example of such a partition is shown in Figure 4.39(a). A more complex example is given by Figure 4.44(b), which is one possible vp-tree for a set of data objects that are points in a two-dimensional Euclidean space given in Figure 4.44(a). The circles in Figure 4.44(a) correspond to the balls, and the objects that serve as pivots are also surrounded by circles.

Note that the ball regions play a role somewhat similar to that of the bounding rectangles in the R-tree. In fact, we can define *bounding values* for each subset  $S_1$  and  $S_2$ . In particular, for  $o \in S_i$ , we have  $d(p, o) \in [r_{i,lo}, r_{i,hi}]$ , for some bounding values  $r_{i,lo}$  and  $r_{i,hi}$ . Given only the radius  $r$ , the known bounds are  $[r_{1,lo}, r_{1,hi}] = [0, r]$  and  $[r_{2,lo}, r_{2,hi}] = [r, \infty]$  (or, more accurately,  $[0, r - \delta]$  and  $[r, M]$ , respectively, where  $\delta \leq d(o, o_1) - d(o, o_2)$  and  $M \geq d(o_1, o_2)$  for all  $o, o_1, o_2$  in  $S$ ). For the tightest bounds possible, all four bounding values can be stored in the node corresponding to  $p$ . This may yield improved search performance, but perhaps at the price of excessive storage

cost. Below, we use  $r_{lo}$  and  $r_{hi}$  to denote bounding values of  $S_1$  or  $S_2$  for statements or equations that apply to either subset.

The easiest method of picking pivots is simply to select at random. Yianilos [2052] argues that a more careful selection procedure can yield better search performance (but at the price of a higher construction cost). The method he proposes is to take a random sample from  $S$  and choose the object among the sample objects that has the best spread (defined in terms of the variance) of distances from a subset of  $S$ , also chosen at random. For a dataset drawn from a Euclidean space for which the data points are relatively uniformly spread over a hypercube  $c$ , this would tend to pick points near corners as pivots (the observation that such pivots are preferable was first made by Shapiro [1743]). Choosing such points as pivots can be shown to minimize the boundary of the ball that is inside  $c$  (e.g., the length of the boundary in Figure 4.45(a) is greater than that in Figure 4.45(b)), which Yianilos [2052] argues increases search efficiency. Some intuitive insight into the argument that the boundary is reduced as the pivot is moved farther from the center of  $c$  can be gained by considering that if we are allowed to pick points outside  $c$  as pivots, the resulting partitioning of the hypercube increasingly resembles a partitioning by a hyperplane (e.g., see Figure 4.45(c)). Notice that the areas of the two regions inside  $c$  formed by the partitioning tend to be about the same when the points are uniformly distributed, and the length of the partitioning arc inside  $c$  is inversely proportional to the distance between the pivot point and the center of  $c$  (see Figure 4.45). Observe also that the length  $l$  of the partitioning arc decreases even more as the pivot is moved farther away from  $c$  (e.g., see Figure 4.45(c)).

In the vp-tree, the ball radius is always chosen as the median  $r$  of the distances of the other objects to the pivot  $p$  so that the two subsets are roughly equal in size. Another possibility would be to split at the midpoint between the distances of the objects in  $S \setminus \{p\}$  that are closest and farthest from  $p$ , as proposed by Chávez et al. [334] (and inspired by Burkhard and Keller [283]). This yields a partition into equal-width “shells” around  $p$ . Chávez et al. [334] argue that splitting at the midpoint yields better partitions for datasets whose “inherent dimensionality” is high as the objects outside the ball may reside in a thin “shell” when always splitting at the median [334]. However, the disadvantage of splitting at the midpoint is that the resulting tree is not balanced, as is the case when splitting at the median. Nevertheless, even when splitting at the median, the tree can become unbalanced if we support dynamic insertions, but this can be alleviated with periodic reorganization. For a discussion of how to handle dynamic datasets, see Fu, Chan, Cheung, and Moon, [656].

### Exercises

1. Give an algorithm to insert an object in a vp-tree.
2. Give an algorithm to delete an object from a vp-tree.
3. Give an algorithm to construct a vp-tree. Use one of the pivot and radius value selection methods described in the text.
4. Compare a number of different methods of constructing a vp-tree by varying the radius  $r$ :
  - (a)  $r$  is the median of the distances of all objects to the pivot object  $p$ .
  - (b)  $r$  is the midpoint of the distances of the objects in  $S \setminus \{p\}$  that are closest and farthest from  $p$ .
  - (c)  $r$  is the average of the distances of the objects in  $S \setminus \{p\}$  from  $p$ .
5. In ball partitioning, the surface of the sphere of radius  $r$  centered at  $p$  serves as a partitioning surface in the sense that the data has been partitioned into two sets, depending on whether it is inside the sphere or either on the surface of the sphere or outside it. Uhlmann [1896] suggests that the partition surface can be chosen according to the application at hand. How would you incorporate a generalized elliptical surface where the ellipse has pivots at  $p_1$  and  $p_2$  and a principal (i.e., major) axis  $r$ ?

---

## Section 4.5

### DISTANCE-BASED INDEXING METHODS

Figure 4.45  
Depiction of partitions of a set of points in a two-dimensional Euclidean space, assumed to be uniformly distributed in a cube  $c$ , for pivot points (a) in the center of  $c$ , (b) in a corner of  $c$ , and (c) outside  $c$ .

6. Suppose that the partition surface in Exercise 5 is chosen so that it is the set of all objects whose distance from one of two pivots, say  $p_1$ , is  $r$  plus the distance from the other pivot, say  $p_2$ . What is the intuitive definition of this method?

### 4.5.2.1.2 Search

Clearly, search algorithms are fundamentally the same, regardless of how the pivot and ball radius are determined, since the basic structure is the same. For example, a range query for a query object  $q$  and query radius  $\varepsilon$ —that is, we wish to determine all objects  $o$  such that  $d(q, o) \leq \varepsilon$ —is most easily implemented with a depth-first traversal of the tree. In particular, when visiting a node  $n$  with pivot  $p$  and ball radius  $r$ , we must decide whether to visit the left or right child of  $n$  or both. Lemma 4.2 enables us to establish lower bounds on the distances from  $q$  to objects in the left and right subtrees. If the query radius is less than the lower bound for a subtree, there is no need to visit that subtree. For example, in Figure 4.46(a), the left subtree (for the objects inside the ball) need not be visited, but in Figure 4.46(b), the left subtree must be visited. Formally, from Equation 4.2 in Lemma 4.2, with  $r_{lo} = 0$  and  $r_{hi} = r$ , we know that the distance from  $q$  to an object in the left subtree of  $n$  is at least  $\max\{d(q, p) - r, 0\}$ . Similarly, by applying the equation with  $r_{lo} = r$  and  $r_{hi} = \infty$ , we know that the distance from  $q$  to an object in the right subtree of  $n$  is at least  $\max\{r - d(q, p), 0\}$ . Thus, we visit the left child if and only if  $\max\{d(q, p) - r, 0\} \leq \varepsilon$  and the right child if and only if  $\max\{r - d(q, p), 0\} \leq \varepsilon$ . For a probabilistic analysis of the search process in a vp-tree, see Tasan and Özsoyoglu [1861].

Figure 4.46 During a range query with query radius  $\varepsilon$ , the subtree corresponding to the inside of the ball need not be visited in (a) while it must be visited in (b).

Figure 4.47 (a) An example vp-tree for three objects  $p$ ,  $o_1$ , and  $o_2$  and (b) the search hierarchy induced by the vp-tree.

We can also use a similar approach to design an incremental nearest neighbor algorithm for the vp-tree, by specifying the search hierarchy according to the framework presented in Section 4.1.2. Being that the vp-tree is hierarchical, the search hierarchy essentially falls out of the existing hierarchical structure. Thus, the elements of the search hierarchy correspond to the objects (type 0) and the nodes in the vp-tree (type 1). Again, we observe that the ball regions for the vp-tree nodes play the same role as bounding rectangles in the R-tree. The resulting search hierarchy for a small sample vp-tree is depicted in Figure 4.47. Note that elements of type 1 can produce elements of type 0 and 1.

We now define the distance functions  $d_t$  for the distance between the query object  $q$  and elements  $e_t$  of type  $t$ ,  $t = 0, 1$ . Since elements  $e_0$  of type 0 represent objects,  $d_0$  is simply equal to  $d$ . As for  $d_1$ , recall that the value of  $d_1(q, e_1)$  should be a lower bound on the distance  $d(q, o)$  for any object  $o$  in the subhierarchy rooted at  $e_1$ . The information we have on hand to derive such a lower bound is the value of  $d(q, p)$  and the fact that  $d(p, o)$  is in the range  $[r_{lo}, r_{hi}]$ , where  $p$  is the pivot of the parent  $e_1$ , and  $[r_{lo}, r_{hi}]$  defines the shell around  $p$  containing the objects in the subtree rooted at  $e_1$  (i.e.,  $[0, r]$  if  $e_1$  is a left child and  $[r, \infty]$  if  $e_1$  is a right child, where  $r$  is the ball radius). Thus, as we saw above for the range query, we can make use of Lemma 4.2, which gives lower and upper bounds on  $d(q, o)$  based on exactly such information. In particular, the definition of  $d_1$  as obtained from the lemma is

$$d_1(q, e_1) = \max\{d(q, p) - r_{hi}, r_{lo} - d(q, p), 0\}.$$

This definition of  $d_1$  is general in that it accounts for  $e_1$  being either a left child (in which case  $r_{lo} = 0$  and  $r_{hi} = r$ ) or a right child (in which case  $r_{lo} = r$  and  $r_{hi} = \infty$ ).<sup>27</sup> Furthermore, for either case, it also accounts for  $q$  being either inside or outside the region for  $e_1$  (i.e., inside or outside the ball around  $p$  of radius  $r$ ). Since the lemma guarantees that  $d_1(q, e_1) \leq d(q, o)$  for any object  $o$  in the subtree rooted at  $e_1$ , we are

<sup>27</sup> As we pointed out before, tight distance bounds for each subtree could be stored in each vp-tree node instead of just the median [2052], thereby causing  $d_1$  and  $\hat{d}_1$  to yield improved bounds. This can improve search performance but at the cost of an increase in the storage requirement (i.e., four distance values in each node instead of just one).

assured that the incremental nearest neighbor algorithm is correct when applied to the vp-tree search hierarchy that we have defined (see Section 4.1.3).

The upper-bound distance function  $\hat{d}_1$  can also be derived from the result in Lemma 4.2 (i.e., by Equation 4.2):

$$\hat{d}_1(q, e_1) = d(q, p) + r_{hi}$$

where  $p$  and  $r_{hi}$  are defined as above. Recall that upper-bound distance functions are used when performing farthest-neighbor queries and when a minimum distance bound is imposed on the query results (see Section 4.1.5). The correctness of such algorithm variants is guaranteed by the lemma—that is, since  $\hat{d}_1(q, e_1) \geq d(q, o)$  for any object  $o$  in the subtree rooted at  $e_1$ .

Given the search hierarchy defined above, incremental nearest neighbor search proceeds as described in Section 4.1.3. In particular, when the element obtained from the queue represents an object (i.e., is of type 0), we report it as the next nearest neighbor. Otherwise, the element is of type 1, representing a node  $n$ . If  $n$  is a nonleaf node with pivot  $p$  and ball radius  $r$ , we compute  $d(q, p)$  and insert  $p$  into the priority queue as an element of type 0. Furthermore, the left and right children of  $n$  are inserted into the priority queue as elements of type 1 using the distance function defined above. If  $n$  is a leaf node, we perform the same action as for pivots of nonleaf nodes for the object(s) in the node.

### Exercises

1. Implement the algorithm described in the text for a range query with query radius  $\varepsilon$  in a vp-tree.
2. Implement the algorithm described in the text to find the nearest neighbors in an incremental manner to a query object  $q$  in a vp-tree.
3. Implement the algorithm described in the text to find the farthest neighbors in an incremental manner to a query object  $q$  in a vp-tree.
4. Give an algorithm to find all objects within a range of distance values in an incremental manner from a query object  $q$  in a vp-tree (i.e., find all elements having distance from  $q$  greater than  $D_{\min}$  and less than  $D_{\max}$ ).
5. In the discussion of the incremental nearest neighbor algorithm in Section 4.1.3, we pointed out that the correctness criterion (i.e.,  $d_t(q, e_t) \leq d_0(q, e_0)$  for any object  $e_o$  in the subtree represented by  $e_t$ ) does not actually guarantee that when a nonobject search hierarchy element  $e_t$  has been removed from the priority queue, no nonobject search hierarchy element  $e_{t'}$  (in the subtree represented by  $e_t$ ) with a smaller distance from the query object  $q$  can be inserted in the future, and possibly be removed in the future. In other words, it does not preclude the occurrence of the situation that nonobject elements  $e_t$  and  $e_{t'}$ , where  $d_t(q, e_t) > d_{t'}(q, e_{t'})$ , could be processed in succession (by virtue of being removed from the priority queue in succession, although some other elements could have been inserted into the queue during this time). Give an example of how this situation can arise in a vp-tree.
6. In Section 4.3 we discuss the method of Chen et al. [346] for finding approximate nearest neighbors, which delays the processing of a node  $b$  by shrinking  $b$ 's radius by a factor of  $\lambda$  ( $0 < \lambda \leq 1$ ), thereby increasing the effective distance  $d(b, q)$  between query object  $q$  and  $b$  as measured by the distance between  $q$  and the closest point in  $b$  (after its radius has been shrunk). How would you apply this idea to the vp-tree?

#### 4.5.2.2 Vp<sup>sb</sup>-Tree

When the vp-tree is constructed, we must compute the distances of an object  $o$  from each of the pivots on the path from the root to the leaf containing  $o$ . This information is useful as it can often be used during search either to prune  $o$  from the search or to include it in the search result without computing its distance. Based on this insight, Yianilos [2052] proposed a version of the vp-tree, termed the *vp<sup>s</sup>-tree*, where we store, for each object (whether it functions as a pivot or is stored in a leaf node), its distance from all ancestral

pivots (i.e., those higher in the tree on the path from the root). In the related  $vp^{sb}$ -tree, the leaf nodes can store more than one object, thus serving as “buckets.”

Knowledge of the distances to the ancestral pivots is useful in performing a range query. In particular, consider an object  $o$ , one of its ancestral pivots  $p$ , and the query object  $q$ . Given  $d(q, p)$  and  $d(p, o)$ , Lemma 4.1 allows us to bound the distance between  $q$  and  $o$ —that is,  $|d(q, p) - d(p, o)| \leq d(q, o) \leq d(q, p) + d(p, o)$ . Thus, when performing a range query with radius  $\varepsilon$ , we can safely discard  $o$  if  $|d(q, p) - d(p, o)| > \varepsilon$  or directly include it in the result if  $d(q, p) + d(p, o) \leq \varepsilon$ .

In order to take full advantage of all ancestral pivots, we define two functions  $d_{lo}(q, o)$  and  $d_{hi}(q, o)$  that provide upper and lower bounds on  $d(q, o)$ , respectively, for any object  $o$ :

$$d_{lo}(q, o) = \max_i \{ |d(q, p_i) - d(p_i, o)| \} \text{ and}$$

$$d_{hi}(q, o) = \min_i \{ d(q, p_i) + d(p_i, o) \}$$

where  $p_1, p_2, \dots$  are the ancestral pivots of  $o$ . Observe that when we evaluate these functions, no new distance computations are needed, as  $d(q, p_i)$  will have been computed earlier in the query evaluation, and  $d(p_i, o)$  is stored with  $o$  in its  $vp$ -tree node. Clearly, a straightforward application of Lemma 4.1 yields  $d_{lo}(q, o) \leq d(q, o) \leq d_{hi}(q, o)$ . Therefore, knowing that  $d_{lo}(q, o) > \varepsilon$  means that we can discard object  $o$  from the result of a range query with radius  $\varepsilon$ , even if there exist several pivot objects  $v$  for which  $|d(q, v) - d(v, o)| \leq \varepsilon$ . Similarly, knowing that  $d_{hi}(q, o) \leq \varepsilon$ , we can include object  $o$  in the result, even if there exist several pivot objects  $v$  for which  $d(q, v) + d(v, o) > \varepsilon$ .

Incidentally, there is an interesting connection between  $d_{lo}$  and a class of mapping methods termed *Lipschitz embeddings* (see Section 4.7.2). In particular, the  $m$  ancestral pivots  $p_1, \dots, p_m$  of an object  $o$  can be regarded as  $m$  singleton sets, each of which corresponds to a coordinate axis, forming the mapping  $h : S \rightarrow \mathbb{R}^m$ , where  $h(o)$  is the vector  $(d(p_i, o))_i$ . If we now map  $q$  and  $o$  according to  $h$ , the  $L_\infty$  distance  $d_M(h(q), h(o))$  between  $h(q)$  and  $h(o)$  is equal to  $d_{lo}(q, o)$ .

### Exercises

1. Give an algorithm to construct a  $vp^{sb}$ -tree with a bucket capacity  $b$ .
2. Give an algorithm to perform a range query for a query object  $q$  and query radius  $\varepsilon$  in a  $vp^{sb}$ -tree.
3. Give an algorithm to find the nearest neighbors in an incremental manner to a query object  $q$  in a  $vp^{sb}$ -tree.

### 4.5.2.3 Mvp-Tree

A potential criticism of  $vp$ -tree and related metric tree variants is that the fanout is low (i.e., just 2). As pointed out by Yianilos [2052], the  $vp$ -tree can gain higher fanout by splitting  $S$  into  $m$  subsets of roughly equal size instead of just two, based on  $m + 1$  bounding values  $r_0, \dots, r_m$  (alternatively, we can let  $r_0 = 0$  and  $r_m = \infty$ ). In particular,  $S$  is partitioned into  $S_1, S_2, \dots, S_m$ , where  $S_i = \{o \in S \setminus \{p\} \mid r_{i-1} \leq d(p, o) < r_i\}$ . Observe that objects in the subsets lie on spherical “shells” around  $p$ . Applying this partitioning process recursively yields an  $m$ -ary tree. Range searching is performed in the same way as in the  $vp$ -tree using Equation 4.2 in Lemma 4.2, with  $r_{lo}$  and  $r_{hi}$  set to the proper values—that is,  $r_{lo} = r_{i-1}$  and  $r_{hi} = r_i$  for the child corresponding to  $S_i$  (unless tighter bounds are maintained).

Another variant of  $vp$ -trees that achieves a higher fanout, termed the *mvp-tree*, was suggested by Bozkaya and Özsoyoglu [241]. Each node in the *mvp-tree* is essentially equivalent to the result of collapsing the nodes at several levels of a  $vp$ -tree. There is one crucial difference between the *mvp-tree* and the result of such collapsing: only one

pivot is used for each level inside an mvp-tree node (although the number of different ball radius values is unchanged). Thus, in an mvp-tree that corresponds to collapsing a vp-tree over every two levels, two pivots are used in each mvp-tree node with three ball radius values. An example of one possible top-level partitioning for such an mvp-tree is shown in Figure 4.48 which corresponds to the set of objects that are points in the two-dimensional space given in Figure 4.44(a). Figure 4.48(a) shows the partitioning of the underlying space, and Figure 4.48(b) shows the corresponding mvp-tree node. Range searching in an mvp-tree is performed in a manner analogous to that in the vp-tree with the difference that the search is decomposed into  $j$  stages, where there is one stage per pivot value.

The motivation for the mvp-tree is that fewer distance computations are needed for pivots during search since there are fewer pivots (e.g., for an mvp-tree node with two pivots, three pivots would be needed in the corresponding vp-tree). Observe that some subsets are partitioned using pivots that are not members of the sets, which does not occur in the vp-tree (e.g.,  $p$  is used to partition the subset inside the ball around  $i$  in Figure 4.48(a)).

Bozkaya and Özsoyoglu [241] describe a number of modifications to the basic definition of the mvp-tree given above. First, they suggest using multiple partitions for each pivot, as discussed above. Hence, with  $k$  pivots per node and  $m$  partitions per pivot, the fanout of the nonleaf nodes is  $m^k$ . Furthermore, they propose storing, for each data object in a leaf node, the distances to some maximum number  $n$  of ancestral pivots (by setting a maximum  $n$  on the number of ancestral pivots, the physical size of all nodes can be fixed). This is analogous to the use of ancestral pivots in the  $vp^{sb}$ -tree, as described above, except that this distance information is maintained only in leaf nodes in the mvp-tree. Another minor departure from the vp-tree that enables additional pruning to take place is that each leaf node in the mvp-tree also contains  $k$  pivots (whereas pivots are not used in leaf nodes in the vp-tree). In addition, the distances between these pivots and the data objects are stored in the node (a version of the mvp-tree in which pivots are not used in leaves is also considered in [241]). Thus, the leaf node pivots essentially function like the ancestral pivots. The mvp-tree has found use in applications in bioinformatics databases (e.g., [1299]) when the data is on disk, and found to perform well when the pivots are chosen in a judicious manner (e.g., [1235]) in comparison to methods based on general hyperplane partitioning such as the gh-tree [1897] and more general methods such as the M-tree [389].

### Exercises

1. Give an algorithm to construct an mvp-tree.
2. Give an algorithm to perform a range query for a query object  $q$  and query radius  $\varepsilon$  in an mvp-tree.
3. Give an algorithm to find the nearest neighbors in an incremental manner to a query object  $q$  in an mvp-tree.

#### 4.5.2.4 Other Methods Related to Ball Partitioning

A number of additional proposals of search structures that employ some form of ball partitioning have been made. Below, we summarize some of these ball partitioning methods. Unless otherwise mentioned, finding similar objects (i.e., range searching and nearest neighbors) can be performed in these structures using similar techniques to those described in Sections 4.5.2.1 to 4.5.2.3.

The vp-tree, one of the most common instances of ball partitioning, is actually a special case of what Knuth terms a *post office tree*, whose proposal he attributes to Bruce McNutt in 1972 [1046, p. 563]. The difference is that each node in the post office tree is a vp-tree node  $(p, r)$  with the addition of a tolerance  $\delta$  that is associated with the radius

### Section 4.5 DISTANCE-BASED INDEXING METHODS

Figure 4.48 (a) Possible top-level partitioning for the set of objects that are points in the two-dimensional space given in Figure 4.44(a) in an mvp-tree where two pivots are used in each node and (b) a depiction of the corresponding mvp-tree node. The second pivot,  $p$ , partitions the inside of the ball for pivot  $i$  into subsets  $S_1$  and  $S_2$  and the outside of the ball into subsets  $S_3$  and  $S_4$ .

Figure 4.49  
 (a) Example set of objects that are points in the two-dimensional Euclidean space with broken circular lines denoting the boundaries of partitions around pivot objects  $a$  and  $g$  and (b) one possible  $bk$ -tree corresponding to them with bucket capacity 2.

$r$  of the ball centered at  $p$ . In particular, given a value of  $\delta$ , once pivot  $p$  and radius  $r$  have been chosen, the remaining objects are subdivided into two subsets  $S_1$  and  $S_2$  as follows:

$$S_1 = \{o \in S \setminus \{p\} \mid d(p, o) \leq r + \delta\}$$

$$S_2 = \{o \in S \setminus \{p\} \mid d(p, o) \geq r - \delta\}$$

Thus, the objects in  $S_1$  are inside the ball of radius  $r + \delta$ , while the objects in  $S_2$  are outside a ball of radius  $r - \delta$ . Of course, some objects lie both in  $S_1$  and  $S_2$ —that is, all objects  $o$  where  $|d(o, p) - r| \leq \delta$ .<sup>28</sup>

Among the earliest published work on distance-based indexing is that of Burkhard and Keller [283]. One of the three structures they proposed employs ball partitioning and is frequently referenced as a *bk-tree*. However, the distance function was assumed to be discrete so that only a few different distance values are possible, say  $m$ . At the top level, some distinguished object  $p \in S$  is chosen, and the remaining objects are partitioned into  $m$  subsets  $S_1, S_2, \dots, S_m$  based on their distance from  $p$ . Applying this process recursively yields an  $m$ -ary tree. The decomposition stops whenever the partition yields a set with  $b$  or fewer elements ( $b$  is a bucket capacity). For example, Figure 4.49(b) is one possible  $bk$ -tree for the set of data objects that are points in a two-dimensional Euclidean space given in Figure 4.44(a) with  $b = 2$ . The set of data objects is redrawn in Figure 4.49(a) with a pair of possible initial partitions around pivot objects  $a$  and  $g$  with broken circular lines, denoting the boundaries of the various subsets with respect to the pivot objects.

Clearly, in the  $bk$ -tree,  $p$  has the same role as a pivot in the  $vp$ -tree, and the result of the partitioning process is analogous to that of an  $m$ -ary  $vp$ -tree (see Section 4.5.2.3). In fact, as pointed out by Chávez et al. [334], a natural adaptation of the  $bk$ -tree to continuous distance functions is to choose the partition values  $r_0, r_1, \dots, r_m$  such that the objects are partitioned into  $m$  equiwidth shells around  $p$ . In other words,  $r_0$  and  $r_m$  are chosen as the minimum and maximum distances, respectively, between  $p$  and objects in  $S \setminus \{p\}$ , and  $r_i = \frac{i}{m}(r_m - r_0) + r_0$  for  $i = 1, \dots, m - 1$ .

<sup>28</sup> The idea of a loose partition so that the children of a node are not disjoint is also used in the  $os$ -tree [1229, 1230] (see Section 4.4.4), the  $KD2$ -tree [1410, 1412] (see Section 1.5.1.4 of Chapter 1), the spatial  $k$ -d tree [1404, 1407] (see Sections 1.5.1.4 and 1.7.1.2 of Chapter 1 and Section 3.3.2.5 of Chapter 3), and the hybrid tree [317] (see Section 4.4.3 and Section 1.7.1.2 of Chapter 1).

Figure 4.50  
The fixed-queries tree corresponding to the set of objects that are points in the two-dimensional Euclidean space given in Figure 4.49(a). All branches at the root of the tree are with respect to pivot object  $a$ , and all branches at nodes that are sons of the root are with respect to pivot object  $g$ .

Figure 4.51  
The fixed-height fixed-queries tree corresponding to the fixed-queries tree in Figure 4.50.

Baeza-Yates, Cunto, Manber, and Wu [118] proposed a variant of the *bk-tree* that they termed the *fixed-queries tree* (also known as an *fq-tree*). In this variant, all nodes at the same level in the tree use the same pivot, and the pivot objects also appear as data objects in leaf nodes of the tree (unlike the *vp-tree* or the *bk-tree*). For example, Figure 4.50 is the fixed-queries tree corresponding to the set of objects that are points in the two-dimensional Euclidean space given in Figure 4.49(a). All branches at the root of the tree are with respect to pivot object  $a$ , and all branches at nodes that are sons of the root are with respect to pivot object  $g$ . The rationale for using just one pivot per level is the same as in the *mvp-tree* [241] (see Section 4.5.2.3, although these two trees are quite different, as pointed out in Exercise 10)—that is, so that fewer distance computations are needed during search since only one distance computation is needed for visiting all nodes at a given level (as is the case when the search backtracks). The drawback is that the quality of the partitioning may suffer as a result of using fewer pivots.

Fixed-height variants of the fixed-queries tree were also proposed (termed the *fixed-height fixed-queries tree*) [118], where all leaf nodes are at the same level  $h$ . Thus, some internal nodes have only one child node (in cases where the node would otherwise have been a leaf node), and leaf nodes may contain arbitrary numbers of objects. For example, Figure 4.51 is the fixed-height fixed-queries tree corresponding to the fixed-queries tree in Figure 4.50.

Each object in the fixed-height fixed-queries tree has the same number of ancestral pivots, and thus requires the same number of distance computations when constructing the tree. This insight led to the proposal of the *fixed-queries array* (also known as an *fq-array*) [331], which is essentially a compact representation of the distances in a fixed-height fixed-queries tree in the form of an array of  $h$  numbers corresponding to the branches taken in the tree to reach the appropriate elements in the tree from the root.

The  $h$  numbers are the distances to the  $h$  pivots. For example, Figure 4.52 is the fixed-queries array corresponding to the fixed-height fixed-queries tree in Figure 4.51. The representation is made compact by encoding each of these numbers as a bitstring of  $b$  bits, which are concatenated to form a single number so that the most significant digits correspond to the pivots closer to the root. In the fixed-queries array, movements in the equivalent fixed-height fixed-queries tree are simulated with binary search.

It is interesting to repeat our observation (made in conjunction with the discussion of Lemma 4.1 that all three of the fixed-queries tree, fixed-height fixed-queries tree, and fixed-queries array methods can be viewed as variations of embedding methods (see Section 4.7) that map the distances between the objects into a  $k$ -dimensional space by using  $k$  pivots (i.e., the pivots at the different levels of these trees) as coordinates and the distances of the objects from the pivots as the coordinate values of the objects. In other words, the result of the mapping of an object  $x$  is a point  $(x_0, x_1, \dots, x_{k-1})$  whose coordinate value  $x_i$  is the distance  $d(x, p_i)$  of  $x$  from pivot  $p_i$ . Lemma 4.1 enables pruning an object  $x$  from further consideration as being within  $\varepsilon$  of query object  $q$  when  $|d(q, p_i) - d(x, p_i)| > \varepsilon$  for some coordinate corresponding to pivot  $p_i$  ( $0 \leq i \leq k - 1$ ). Note that a similar observation was made in the discussion of the  $vp^{sb}$ -tree in Section 4.5.2.2, which is similar to these methods.

Yianilos [2053] proposed a variant of the  $vp$ -tree termed the *excluded middle vantage point forest* (see also [699]) that is intended for radius-limited nearest neighbor search—that is, where the nearest neighbor is restricted to being within some radius  $r^*$  of the query object. This method is based on the insight that most of the complexity of performing search in methods based on binary partitioning, such as the  $vp$ -tree, is due to query objects that lie close to the partition values, thereby causing both partitions to be processed. For example, in the  $vp$ -tree, these are objects  $q$  for which  $d(q, p)$  is close to  $r$ , the partitioning value for a pivot  $p$ . The proposed solution is to exclude all data objects whose distances from a pivot are within  $r^*$  of the partition value (i.e., the ball radius). This process is applied to all pivots in the tree, and a new tree is built recursively for the set of all excluded objects. Thus, the final result is a forest of trees. Since the width of all exclusion regions is at least  $2r^*$ , nearest neighbor search limited to a search region of radius  $r^*$  can be performed with no backtracking, but at the price of having to search all the trees in the forest. The fact that no backtracking is needed enables determining a worst-case bound on the search cost, based on the heights of the trees in the forest. Unfortunately, the method appears to provide good performance only for very small values of  $r^*$  [2053], which is of limited value in most similarity search applications.

**Exercises**

1. Give an algorithm to construct Burkhard and Keller’s variant of the  $m$ -ary  $vp$ -tree (i.e., the  $bk$ -tree).
2. Give an algorithm to perform a range query for a query object  $q$  and query radius  $\varepsilon$  in the  $bk$ -tree.
3. Give an algorithm to find the nearest neighbors in an incremental manner to a query object  $q$  in the  $bk$ -tree.
4. Give an algorithm to construct a fixed-queries tree.

Object	a	h	i	r	j	s	p	c	q	m	d	g	o	t	v	f	u	l	n	k	e	b
Level 0	0	1	1	2	2	2	3	3	3	3	3	4	4	4	4	4	5	5	5	6	6	6
Level 1	4	3	4	4	5	5	1	2	2	3	5	0	1	2	4	5	3	4	5	2	3	5

The fixed-queries array corresponding to the fixed-height fixed-queries tree in Figure 4.51.

5. Give an algorithm to perform a range query for a query object  $q$  and query radius  $\varepsilon$  in a fixed-queries tree.
6. Give an algorithm to find the nearest neighbors in an incremental manner to a query object  $q$  in a fixed-queries tree.
7. Give an algorithm to construct a fixed-height fixed-queries tree.
8. Give an algorithm to perform a range query for a query object  $q$  and query radius  $\varepsilon$  in a fixed-height fixed-queries tree.
9. Give an algorithm to find the nearest neighbors in an incremental manner to a query object  $q$  in a fixed-height fixed-queries tree.
10. Compare the fixed-queries tree with the.mvp-tree [241] (see Section 4.5.2.3).
11. Give an algorithm to construct a fixed-queries array.
12. Give an algorithm to perform a range query for a query object  $q$  and query radius  $\varepsilon$  in a fixed-queries array.
13. Give an algorithm to find the nearest neighbors in an incremental manner to a query object  $q$  in a fixed-queries array.
14. Chávez and Navarro [332] propose a linear variant of the vp-tree that only applies recursive decomposition to the subset outside the ball rather than to the subsets that are both inside and outside the ball as in the vp-tree. In particular, it initially picks a pivot  $p$  from  $S$  and a value  $r$  and divides the remaining objects into two subsets  $I$  and  $E$  corresponding to the objects inside and outside the ball, respectively, as follows:

$$I = \{o \in S \setminus \{p\} \mid d(p, o) < r\}$$

$$E = \{o \in S \setminus \{p\} \mid d(p, o) \geq r\}$$

This rule is applied recursively only to  $E$ . Thus, any search algorithm that is applied will process the objects in  $I$  exhaustively while being recursively invoked on the objects in  $E$ . The main rationale for this method is to take advantage of the fact that most of the objects will lie outside  $I$  for most reasonably chosen values of  $r$ , and thus there is no need to decompose  $I$  recursively. Give an algorithm to perform a range query on a set  $R$  for a query object  $q$  and query radius  $\varepsilon$  using this structure.

### 4.5.3 Generalized Hyperplane Partitioning Methods

In this section, we discuss generalized hyperplane partitioning methods. Recall that in this case two distinguished objects are chosen, and the dataset is partitioned based on which of the distinguished objects is the closest (recall Figure 4.39(b)). The rest of this section is organized as follows. Section 4.5.3.1 describes the gh-tree. Section 4.5.3.2 presents the Geometric Near-neighbor Access Tree (GNAT), which is a generalization of the gh-tree where more than two pivots may be chosen to partition the dataset in each node. Section 4.5.3.3 describes the bisector tree and the mb-tree, and Section 4.5.3.4 contains a brief discussion of additional methods based on generalized hyperplane partitioning.

#### 4.5.3.1 Gh-Tree

Uhlmann [1897] defined a metric tree using generalized hyperplane partitioning, which has been termed a *generalized hyperplane tree* (*gh-tree*) by later authors [241, 255, 656]. Instead of picking just one object for partitioning, as in the vp-tree, this method picks two pivots  $p_1$  and  $p_2$  (e.g., the objects farthest from each other; see Exercise 3) and splits the set of remaining objects based on the closest pivot (see Figure 4.39(b)):

$$S_1 = \{o \in S \setminus \{p_1, p_2\} \mid d(p_1, o) \leq d(p_2, o)\} \text{ and}$$

$$S_2 = \{o \in S \setminus \{p_1, p_2\} \mid d(p_2, o) < d(p_1, o)\}$$

In other words, the objects in  $S_1$  are closer to  $p_1$  than to  $p_2$  (or equidistant from both), and the objects in  $S_2$  are closer to  $p_2$  than to  $p_1$ . This rule is applied recursively, resulting in

Figure 4.53 (a) A possible space partitioning produced by the gh-tree for a set of points in a two-dimensional Euclidean space and (b) its tree representation.

Figure 4.54 (a) An example gh-tree for four objects  $p_1$ ,  $p_2$ ,  $o_1$ , and  $o_2$  and (b) the search hierarchy induced by the gh-tree.

a binary tree where the left child of a nonleaf node corresponds to  $S_1$  and the right child corresponds to  $S_2$ . This rule can be restated as stipulating that  $S_1$  contains all objects  $o$  such that  $d(p_1, o) - d(p_2, o) \leq 0$ . Clearly, the two subsets  $S_1$  and  $S_2$  can be very different in size. Uhlmann [1897] actually suggested partitioning based on a median value  $m$ , so that  $d(p_1, o) - d(p_2, o) \leq m$  applies to roughly half the objects in  $S$ . For simplicity, we assume below that  $m$  is fixed at 0; the discussion is easily generalized to other values. Note also that the decomposition process is halted once the number of objects in each leaf node (corresponding to a cluster) is less than the desired capacity (which may be one). A sample gh-tree is shown in Figure 4.53 that makes use of the same data as in Figure 4.44(a). It is interesting to note, although it is beyond the scope of our discussion, that there have also been recent attempts to implement the gh-tree in a peer-to-peer (P2P) setting (e.g., [136]).

The term *generalized hyperplane partitioning* is derived from the fact that if the objects are points in an  $n$ -dimensional Euclidean space, then the resulting partitioning is equivalent to one based on an  $(n - 1)$ -dimensional hyperplane like that used in a k-d tree (in a k-d tree, however, the partitioning planes are axis aligned). This hyperplane is the set of all points  $o$  that satisfy  $d(p_1, o) = d(p_2, o)$ . Consider how to compute a lower bound on the distance from a query object  $q$  to an object in one of the partitions, say, that for  $S_1$ . If  $q$  is in the partition (i.e., is closer to  $p_1$ ), the lower bound is clearly zero. Otherwise, the lower bound is equal to the distance from  $q$  to the partitioning hyperplane, which is easy to compute in Euclidean spaces. For arbitrary metric spaces, however, we cannot form a direct representation of the “generalized hyperplane” that divides the two partitions since we assume that the interobject distances are the only available information.

Fortunately, even given the limited information available in the gh-tree, Lemma 4.4 shows that it is possible to derive a lower bound on the distance from  $q$  to some object in a partition<sup>29</sup> (though an upper bound cannot be determined since objects can be arbitrarily far from  $p_1$  and  $p_2$ ). In particular, for a range query with query radius  $\epsilon$ , the left subtree (i.e., for  $S_1$ ) must be visited if and only if

$$\frac{d(q, p_1) - d(q, p_2)}{2} \leq \epsilon$$

and the right subtree (i.e., for  $S_2$ ) must be visited if and only if

$$\frac{d(q, p_2) - d(q, p_1)}{2} \leq \epsilon$$

We can also use a similar approach to design an incremental nearest neighbor algorithm for the gh-tree by specifying the search hierarchy according to the framework presented in Section 4.1.2. Our treatment is analogous to that used for the vp-tree in Section 4.5.2.1. Because the gh-tree is hierarchical, the search hierarchy essentially falls out of the existing hierarchical structure. Thus, the elements of the search hierarchy correspond to the objects (type 0) and the nodes in the gh-tree (type 1). Note that the ball regions for the gh-tree nodes play the same role as bounding rectangles in the R-tree. The resulting search hierarchy for a small sample gh-tree is depicted in Figure 4.54. Note that elements of type 1 can produce elements of type 0 and 1.

We now define the distance function  $d_1$  for the distance between the query object  $q$  and elements  $e_1$  of type 1. Recall that the value of  $d_1(q, e_1)$  should be a lower bound on the distance  $d(q, o)$  for any object  $o$  in the subhierarchy rooted at  $e_1$ . The information we have on hand to derive such a lower bound is the distance from  $q$  to the pivot value associated with  $e_1$  and the distance from  $q$  to the pivot value associated with the brother of  $e_1$ . Thus, we can make use of Lemma 4.4, which gives a lower bound on  $d(q, o)$  based on exactly such information. In particular, assuming that the parent of  $e_1$  is pivoted at objects  $p_1$  and  $p_2$  so that the left child is associated with  $p_1$  and the right child is associated with

<sup>29</sup> The bound in the lemma is clearly much weaker than that which would be obtained in a Euclidean space by using the hyperplane directly.

$p_2$ , the definition of  $d_1$  as obtained from the lemma is

$$d_1(q, e_1) = \begin{cases} \max \left\{ \frac{d(q, p_1) - d(q, p_2)}{2}, 0 \right\}, & \text{if } e_1 \text{ is a left child} \\ \max \left\{ \frac{d(q, p_2) - d(q, p_1)}{2}, 0 \right\}, & \text{if } e_1 \text{ is a right child} \end{cases}$$

This definition of  $d_1$  is general in that, for either case, it also accounts for  $q$ 's being either inside or outside the region for  $e_1$ . Since the lemma guarantees that  $d_1(q, e_1) \leq d(q, o)$  for any object  $o$  in the subtree rooted at  $e_1$ , we are assured that the incremental nearest neighbor algorithm is correct when applied to the gh-tree search hierarchy that we have defined (see Section 4.1.3).

Note that Lemma 4.4 does not provide an upper bound on the distance from  $q$  to any point  $o$  in a hyperplane-bounded region  $e_1$  since objects can be arbitrarily far from  $p_1$  and  $p_2$  (recall Figure 4.43). However, by modifying the gh-tree data structure so that, in addition to the two pivots  $p_1$  and  $p_2$ , each node also stores the radius of the balls around  $p_1$  and  $p_2$  that contain  $S_1$  and  $S_2$  [978] (i.e.,  $r_1 = \max_{o \in S_1} \{d(p_1, o)\}$  and  $r_2 = \max_{o \in S_2} \{d(p_2, o)\}$ ), we can then use these radii in conjunction with Lemma 4.2 to define  $\hat{d}_1$ —that is,

$$\hat{d}_1(q, e_1) = \begin{cases} d(q, p_1) + r_1, & \text{if } e_1 \text{ is a left child} \\ d(q, p_2) + r_2, & \text{if } e_1 \text{ is a right child} \end{cases}$$

Observe that the addition of the radii of the balls around the pivots to the data structure means that we can also take them into account in the following definition of  $d_1(q, e_1)$ :

$$d_1(q, e_1) = \begin{cases} \max \{ (d(q, p_1) - d(q, p_2)) / 2, d(q, p_1) - r_1, 0 \}, & \text{if } e_1 \text{ is a left child} \\ \max \{ (d(q, p_2) - d(q, p_1)) / 2, d(q, p_2) - r_2, 0 \}, & \text{if } e_1 \text{ is a right child} \end{cases}$$

The rationale for the two choices for the lower bounds and taking their maximum is that the balls, which correspond to minimum bounding hyperspheres of the objects in the two partitions, are not necessarily disjoint. Thus, it could be the case that an object  $o$  lies in the hypervolume spanned by both balls, yet  $o$  is associated with just one of them. Observe that the query object  $q$  may itself lie in the ball corresponding to the objects in partition  $e_1$ , thereby accounting for the presence of 0 as one of the choices for  $d_{min}$ .

Given the search hierarchy defined above, incremental nearest neighbor search proceeds as described in Section 4.1.3. In particular, when the element obtained from the queue represents an object (i.e., is of type 0), we report it as the next nearest neighbor. Otherwise, the element is of type 1, representing a node  $n$ . If  $n$  is a nonleaf node with pivots  $p_1$  and  $p_2$ , we compute  $d(q, p_1)$  and  $d(q, p_2)$  and insert both  $p_1$  and  $p_2$  into the priority queue. Furthermore, the left and right children of  $n$  are inserted into the priority queue as elements of type 1 using the distance function defined above. If  $n$  is a leaf node, we perform the same action as for pivots of nonleaf nodes for the object(s) in the node.

Note that Merkwirth, Parlitz, and Lauterborn [1286] make use of a similar, but nonincremental, approach to find the  $k$  nearest neighbors in a variant of a gh-tree that also stores the radii of the balls centered at the pivots that contain the objects associated with the pivots. The difference from our suggested approach is that Merkwirth et al. [1286] only store the nonleaf nodes in the priority queue sorted by a more precise, but equivalent (see Exercise 7), definition of  $d_1(q, e_1)$  and sequentially scan the objects in the leaf nodes using Lemma 4.1 to try possibly to eliminate the need to compute their distance from  $q$ .

### Exercises

1. Give an algorithm to insert an object in a gh-tree.
2. Give an algorithm to delete an object from a gh-tree.
3. Give an algorithm to construct a gh-tree. You need to come up with ways of choosing the pivots. Use the method described in the text that selects the objects farthest from each other.

4. One of the drawbacks of using the objects  $a$  and  $b$  that are the farthest apart as the pivot objects is that the resulting clusters may have a much larger radius (i.e.,  $d(a, b)/2$ ) than if other objects were chosen. Devise an alternative method of selecting the pivot objects besides the pair that are the farthest apart.
5. Implement the algorithm described in the text for a range query with query radius  $\varepsilon$  in a gh-tree.
6. Implement the algorithm described in the text to find the nearest neighbors in an incremental manner to a query object  $q$  in a gh-tree.
7. Merkwirth, Parlitz, and Lauterborn [1286] use a variant of a gh-tree that also stores the radii of the balls centered at the pivots that contain the objects associated with the pivots, and they make use of the following definition of  $d_1(q, e_1)$ :

$$d_1(q, e_1) = \begin{cases} \max\{(d(q, p_1) - d(q, p_2))/2, d(q, p_1) - r_1, d_1(q, e_a), 0\}, & e_1 \text{ a left child of } e_a \\ \max\{(d(q, p_2) - d(q, p_1))/2, d(q, p_2) - r_2, d_1(q, e_a), 0\}, & e_1 \text{ a right child of } e_a \end{cases}$$

The difference from our definition in the text lies in also taking  $e_a$ , the parent of  $e_1$ , into account. Show that the nearest neighbor process is not affected by this modification. In other words, its use does not result in the pruning of more objects or nodes from the search process. Equivalently, failing to use it does not cause additional objects or nodes to be visited during the search process.

8. Give an algorithm to find all objects within a range of distance values from a query object  $q$  in a gh-tree (i.e., find all elements having distance from  $q$  greater than  $D_{\min}$  and less than  $D_{\max}$ ). The algorithm should be incremental and report the objects in order of increasing distance from  $o$ .

### 4.5.3.2 GNAT

Geometric Near-neighbor Access Tree (GNAT) [255], devised by Brin, is a generalization of the gh-tree, where more than two pivots (termed *split points* in [255]) may be chosen to partition the dataset at each node. In particular, given a set of pivots  $P = \{p_1, \dots, p_m\}$ , we split  $S$  into  $S_1, \dots, S_m$  based on which of the objects in  $P$  is the closest. In other words, for any object  $o \in S \setminus P$ ,  $o$  is a member of  $S_i$  if  $d(p_i, o) \leq d(p_j, o)$  for all  $j = 1, \dots, m$ . In case of ties,  $i$  is the lowest index among the ones that participate in the tie. Thus, applying such a partitioning process recursively yields an  $m$ -ary tree. Brin [255] left the value of  $m$  as a parameter and also suggested a way to choose a different number of pivots at each node adaptively, based on the cardinalities of the partition sets. The method Brin [255] describes for choosing the pivot objects is based on a philosophy similar to that of Yianilos [2052] for the vp-tree (and also suggested by others [241, 1743]). In particular, initially, randomly pick  $3m$  candidate pivot objects from  $S$ . Next, pick the first pivot object at random from the candidates, pick as the second the candidate farthest away from the first one, pick as the third the candidate farthest away from the first two, and so on.

Figure 4.55

Depiction of the bounds for two pivots  $p_i$  and  $p_j$  in a GNAT. The broken line indicates the hyperplane between the pivots (here, it is a line, but, in general, there may be no such simple characterization), and the filled circles denote objects associated with  $p_j$ . Query object  $q_1$  with query radius  $\varepsilon_1$  results in eliminating  $p_j$  and its subset from the search since  $d(q_1, p_i) - \varepsilon_1 > r_{hi}^{(i,j)}$ . Similarly, query object  $q_2$  with query radius  $\varepsilon_2$  eliminates  $p_j$  from the search since  $d(q_2, p_i) + \varepsilon_2 < r_{lo}^{(i,j)}$ .

In addition to pivots and child pointers, the nodes in GNAT also store information about the ranges of distances between the pivots and objects in the subtrees, which enables more pruning during search. In particular, for each pair of pivots  $p_i$  and  $p_j$  in a node  $n$ , we store the range  $[r_{lo}^{(i,j)}, r_{hi}^{(i,j)}]$  of  $d(p_i, o)$  over all objects  $o \in S_j \cup \{p_j\}$  (i.e.,  $r_{lo}^{(i,j)} = \min_{o \in S_j \cup \{p_j\}} \{d(p_i, o)\}$  and  $r_{hi}^{(i,j)} = \max_{o \in S_j \cup \{p_j\}} \{d(p_i, o)\}$ ). Although not mentioned by Brin [255], it may also be advantageous to store the range  $[r_{lo}^{(j,j)}, r_{hi}^{(j,j)}]$  for  $d(p_j, o)$  over all  $m$  objects  $o \in S_j$ , bringing the total number of ranges to  $m^2$  (as there are  $m \cdot (m - 1) + m$  ranges altogether). This approach should be contrasted with the approach of Kamgar-Parsi and Kanal [986] and Larsen and Kanal [1103] (see Section 4.2.2), who store  $r_{lo}^{i,i}$  and  $r_{hi}^{i,i}$ , while in the augmented gh-tree [978, 1286, 1383] (see Section 4.5.3.1), only  $r_{hi}^{i,i}$  is stored. Figure 4.55 illustrates the distance bounds for two pivots  $p_i$  and  $p_j$ , where the dots clustered around  $p_j$  depict the objects in  $S_j$ .

If the objects are points in an  $n$ -dimensional Euclidean space, the objects in  $S_i$  are exactly the objects in  $S \setminus P$  that fall into the Voronoi cell with  $p_i$  as a site. For Euclidean spaces, it is relatively straightforward to represent the Voronoi cells directly (although this becomes increasingly impractical as the dimensionality grows) and thus compute a lower bound on the distance from a query point to the points inside a given cell (i.e., based on the geometry of the cell). Unfortunately, for arbitrary metric spaces, computing a lower bound in this way is not feasible since, as we saw for the gh-tree, we do not have a direct representation of the “generalized Voronoi cells” formed by the pivots (also known as *Dirichlet domains* in [255]). Clearly, we could simply apply Lemma 4.4, as we did for the gh-tree, which would yield the lower bound  $(d(q, p_i) - d(q, p_j))/2$  on  $d(q, o)$  for an object  $o$  in  $S_i$  (i.e.,  $o$  is closer to  $p_i$  than to  $p_j$ ), where  $p_j$  is the object in  $P$  closest to  $q$  (since this choice of  $p_j$  maximizes the lower bound). However, as shown below, tighter bounds can be obtained by using the distance ranges  $[r_{lo}^{(i,j)}, r_{hi}^{(i,j)}]$  (based on Lemma 4.2), thus achieving better search performance. We can think of the distance bounds as effectively constraining the “shape” of the region represented by the child nodes so as to approximate the corresponding Voronoi cells. For example, in Euclidean spaces, the distance bounds represent spherical shells around the pivots, and the Voronoi cell for  $p_i$  is approximated by the intersection of the shells for all other pivots  $p_j$  (i.e.,  $j \neq i$ ). Of course, two approximate Voronoi cell regions may intersect each other, unlike actual Voronoi cells (which at most share a boundary).

The range query algorithm for GNAT described by Brin [255], for a query object  $q$  and query radius  $\varepsilon$ , proceeds in a depth-first manner. When processing a node  $n$ , the distances between  $q$  and the pivots are computed one by one, gradually eliminating subtrees when possible. The children of  $n$  are visited only after the distances are computed for all pivots that could not be eliminated using the distances of pivots that were considered earlier. In particular, the process is initiated with the set  $P$  consisting of all pivots for  $n$ . At each step, we remove one of the objects  $p_i \in P$  whose distance from  $q$  has not been computed and compute  $d(q, p_i)$ . If  $d(q, p_i) \leq \varepsilon$ , we add  $p_i$  to the query result. Next, for all  $p_j \in P$ , we remove  $p_j$  from  $P$  if  $d(q, p_i) - \varepsilon > r_{hi}^{(i,j)}$  or  $d(q, p_i) + \varepsilon < r_{lo}^{(i,j)}$  (or, equivalently, if  $\max\{d(q, p_i) - r_{hi}^{(i,j)}, r_{lo}^{(i,j)} - d(q, p_i)\} > \varepsilon$ , based on Lemma 4.2). Figure 4.55 depicts two sample query objects  $q_1$  and  $q_2$  and associated query radii  $\varepsilon_1$  and  $\varepsilon_2$ , respectively, both of which would cause  $p_j$  to be removed from  $P$  since  $d(q_1, p_i) - \varepsilon_1 > r_{hi}^{(i,j)}$  and  $d(q_2, p_i) + \varepsilon_2 < r_{lo}^{(i,j)}$ . After the distances from  $q$  for all the pivots in  $P$  have been computed (or  $P$  becomes empty), the children of  $n$  that correspond to the remaining pivots in  $P$  are searched recursively. Notice that a pivot  $p_j$  may be discarded from  $P$  before its distance from  $q$  is computed.

### Exercises

1. Give an algorithm to construct GNAT.
2. Give an algorithm to find the nearest neighbors in an incremental manner to a query object  $q$  in GNAT.

#### 4.5.3.3 Bisector Tree and Mb-Tree

The gh-tree is almost identical to the bisector tree (also known as a bs-tree) of Kalantari and McDonald [978]. In particular, the bisector tree is a gh-tree that also stores the radii of the smallest balls (termed *covering balls*) centered at the pivots that contain the objects associated with the pivots, as discussed in Section 4.5.3.1. The principal difference between the bisector tree and the gh-tree is the algorithm used for searching. For example, assuming radii  $r_1$  and  $r_2$  for the covering balls associated with pivots  $p_1$  and  $p_2$ , respectively, in element  $e_a$ , for a range query with query object  $q$  and radius  $\varepsilon$ , the left (right) subtree of  $e_a$  (i.e.,  $e_1$ ) corresponding to  $S_1$  ( $S_2$ ) of the bisector tree is processed only if  $d(q, p_1) - r_1 \leq \varepsilon$  ( $d(q, p_2) - r_2 \leq \varepsilon$ ). In contrast, the left (right) subtree of  $e_a$

(i.e.,  $e_1$ ) corresponding to  $S_1$  ( $S_2$ ) of the gh-tree is processed only if  $\frac{d(q,p_1)-d(q,p_2)}{2} \leq \varepsilon$  ( $\frac{d(q,p_2)-d(q,p_1)}{2} \leq \varepsilon$ ).

The advantage of the bisector tree over the gh-tree is that, at times, the lower bound  $d(q, p_1) - r_1$  ( $d(q, p_2) - r_2$ ) on  $d(q, o)$  for all objects  $o$  in  $e_1$  (i.e.,  $d(q, e_1)$ , where we assume that  $e_1$  is a nonobject element) is greater than the lower bound  $\frac{d(q,p_1)-d(q,p_2)}{2}$  ( $\frac{d(q,p_2)-d(q,p_1)}{2}$ ), which means that the bisector tree provides a tighter lower bound on the search in  $e_1$  (i.e.,  $d(q, e_1)$ ). However, this is not always the case. In particular, when the covering balls associated with pivots  $p_1$  and  $p_2$  are not disjoint, the lower bound provided by the gh-tree is greater than the lower bound provided by the bisector tree. Both of these cases may result in some of the subtrees being descended needlessly. In fact, it is exactly for this reason that we use the following definition for  $d_1(q, e_1)$  at the conclusion of the presentation of the gh-tree in Section 4.5.3.1:

$$d_1(q, e_1) = \begin{cases} \max\{(d(q, p_1) - d(q, p_2))/2, d(q, p_1) - r_1, 0\}, & \text{if } e_1 \text{ is a left child} \\ \max\{(d(q, p_2) - d(q, p_1))/2, d(q, p_2) - r_2, 0\}, & \text{if } e_1 \text{ is a right child} \end{cases}$$

The motivation for adding the covering balls to the gh-tree is to speed up the search by enabling the pruning of elements whose covering balls are farther from the query object than the current candidate nearest neighbor (the farthest of the  $k$  candidate nearest neighbors) or are outside the range for a range query. Naturally, the utility of the covering balls for pruning increases as their radii decrease. Thus, as the search hierarchy is descended, it is desirable for the covering balls to become smaller, thereby leading to more pruning. Unfortunately, the radii of the covering balls of the children are not necessarily smaller than the radii of the covering balls of their ancestors. For example, consider a two-dimensional space with a Euclidean distance metric as shown in Figure 4.56. Let  $p_a$  be at the origin,  $p_1$  be at  $(-2, 3)$ ,  $p_2$  be at  $(-2, -3)$ ,  $o_1$  be at  $(4, 3)$ , and  $o_2$  be at  $(4, -3)$ . Let  $o_1$  and  $o_2$  be the farthest objects from  $p_a$ . Moreover, let  $o_1$  be the farthest object from  $p_1$ , and let  $o_2$  be the farthest object from  $p_2$ . We now see that the radii of the covering balls around  $p_1$  and  $p_2$  are both 6 and are larger than the radius of the covering ball of  $p_a$ , which is 5.

Dehne and Noltmeier [473] characterize a child element in the bisector tree as *eccentric* when the radius of its covering ball is larger than the radius of the covering ball of its ancestor element. Eccentricity of children is disadvantageous for pruning because the radii of the covering balls increase as the search hierarchy is descended. The potential for having eccentric children is viewed by some (e.g., [473, 1383]) as a drawback of the bisector tree. Hence, it has been proposed to modify the definition of the bisector tree so that one of the two pivots in each nonleaf node  $n$ , except for the root, is inherited from its parent node—that is, of the two pivots in the parent of  $n$ , the one that is inherited is the one that is closer to each object in the subtree rooted at  $n$ . In other words, each pivot will also be a pivot in the child node corresponding to that pivot. Since this strategy leads to fewer pivot objects, its use can be expected to reduce the number of distance computations during search (provided the distances of pivot objects are propagated downward during search), at the possible cost of a worse partitioning and a deeper tree if the decomposition process is only halted when each mb-tree leaf node contains just one object. Of course, the radius of the covering ball around the pivots (i.e., the maximum distance to objects in the corresponding subtree) is also stored and used for pruning. The result is termed the *monotonous bisector tree* (abbreviated below as *mb-tree*) and was proposed by Noltmeier, Verbarg, and Zirkelbach [1383] (and used by Bugnion, Fei, Roos, Widmayer, and Widmer [278]). The mb-tree is a simpler form of the Voronoi tree [473], which is a ternary tree where each node contains between two and three pivot objects instead of just two objects, as in the mb-tree (see Exercises 6–8).

Mb-trees were originally intended for use with point data and Minkowski metrics. However, the mb-tree can be used with arbitrary metrics. An extension of the mb-tree, the *mb\*-tree* [1383], accommodates complex objects, such as lines and polygons. The TLAESA method of Micó, Oncina, and Carrasco [1291] also uses an mb-tree-like search

Figure 4.56  
Example where the radii of the covering balls around pivots  $p_1$  and  $p_2$  in element  $e_a$  are greater than the radius of the covering ball around the pivot  $p_a$  in the ancestor element  $e$  of  $e_a$ .

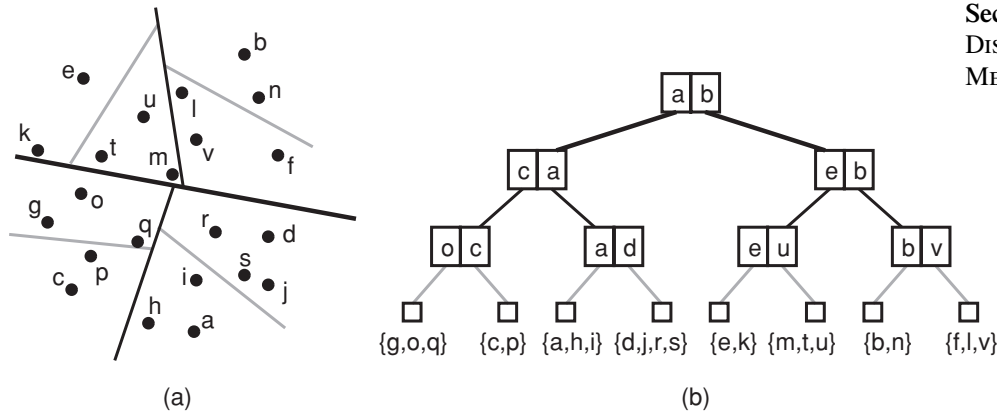

Figure 4.57  
 (a) A possible space partitioning produced by the mb-tree for the set of points in a two-dimensional Euclidean space of Figure 4.53 and (b) its tree representation.

structure in conjunction with a distance matrix to provide lower bounds on the distance from  $q$  to the pivot objects during search (see Section 4.5.7.3 for more details).

Figure 4.57(a) is an example of the space partitioning produced by an mb-tree corresponding to the set of points in the two-dimensional space stored in the gh-tree in Figure 4.53, and Figure 4.57(b) is its tree representation, where the same number of partitions were made at each level as in the corresponding gh-tree. Notice that two points are associated with each nonleaf node of the tree representation, thereby defining the partition of the underlying space, while each of the points is repeated in the next level of the tree. However, in the interest of saving storage, all of the points are actually stored in the leaf nodes of the mb-tree. Nonleaf nodes store pointers to their corresponding leaf node entries.

It should be clear that many different configurations are possible when constructing an mb-tree for a set of objects. This is because there are many options for which objects to choose as pivots at each step of the decomposition. In constructing our example mb-tree, we have followed a strategy that tries to associate approximately the same number of objects with each leaf node, while using the same initial partition as in the example gh-tree (i.e., using pivots  $a$  and  $b$ ). Note also that if we decomposed the underlying space so that every leaf node contained just one point, then the resulting mb-tree would be considerably deeper than the corresponding gh-tree. In particular, for a set of  $N$  ( $N > 1$ ) objects, the fully decomposed mb-tree always requires  $N - 1$  nonleaf nodes, but the corresponding gh-tree may need as few as  $N/2$  nodes in total because each node can contain as many as two objects, and there is no need to distinguish between leaf and nonleaf nodes in a gh-tree as they are both used to store the points.

It is interesting to observe that the decomposition rule on which the mb-tree is based is analogous to a classical decomposition rule in applications involving vector space data, such as points, where a region is decomposed if it contains more than one point. This is the case for a PR quadtree [1413, 1637] (see Section 1.4.2.2 in Chapter 1) and the PR k-d tree [1413] (see Section 1.5.2 in Chapter 1). In particular, the analogy becomes more apparent when the comparison is made with the path-compressed PR k-d tree (see Section 1.5.2.4 in Chapter 1), as the mb-tree does not have any empty nodes, whereas both the PR k-d tree and its PR quadtree ancestor can have empty nodes that arise when all remaining nodes lie on the same side of the partitioning plane. For example, Figure 4.58(a, b) illustrates the block and tree representations of the mb-tree corresponding to the two-dimensional point data in Figure 1.1 of Chapter 1. Notice that the nonleaf nodes are labeled with the identity of the points whose partitioning line is captured by the node.

In the case of vector space data, the decomposition of the underlying space that is induced by the mb-tree is similar to that induced by variants of k-d trees [164], such as the adaptive k-d tree [650] and the BSP tree [658] (see Section 1.5.1.4 in Chapter 1). The BSP tree analogy is probably the easiest to compare as the partitioning planes in the BSP tree are not necessarily orthogonal. In particular, this similarity becomes very clear when we compare the BSP tree for the point data in Figure 1.1 of Chapter 1 given in Figure 1.47 (see Section 1.5.1.4 of Chapter 1) with the corresponding mb-tree in Figure 4.58. The analogy also holds for bucket variants of these structures where the decomposition is based on the region containing  $k > 1$  points. In all of these examples, the pivot objects play the same role as the points. The principal difference is that the boundaries of the regions associated with the points are represented explicitly, while they are implicit in the mb-tree, and thus it is easy to use the mb-tree with data from an arbitrary metric space. In particular, in the latter, each partition is defined by two pivots and the set of objects that are closer to one of them than to the other. Thus, the pivot objects play a similar role to control points in Bézier methods in modeling curves and surfaces in computer-aided design applications (e.g., [622]) in the sense that just as the curve in the latter is implicitly defined by the control points, the partitioning hyperplanes in the former are also implicitly defined by the pivot points.

Sharing a pivot with an ancestor, as proposed for the mb-tree, has the effect of guaranteeing that children are not eccentric (i.e., that the radii of the covering balls around pivots  $p_1$  or  $p_2$  in element  $e_a$ , which form  $e_1$ , are not greater than the radius of the covering ball around the pivot  $p_a$  in the ancestor element  $e$  of  $e_a$ ; see Exercise 1). This noneccentricity constraint on the radii of the covering balls is also satisfied when the more general stipulation that the distance from  $q$  to a nonobject element  $e_1$  (i.e.,  $d(q, e_1)$ ) must be greater than or equal to the distance from  $q$  to an ancestor of  $e_1$  (i.e.,  $d(q, e_a)$ ) holds—that is, they form a containment hierarchy and hence are monotonically nondecreasing.

It is important to note that, although it is impossible to have a containment hierarchy when the children are eccentric, a containment hierarchy may also fail to exist when the children are not eccentric and even when the hierarchy is formed by sharing a pivot with

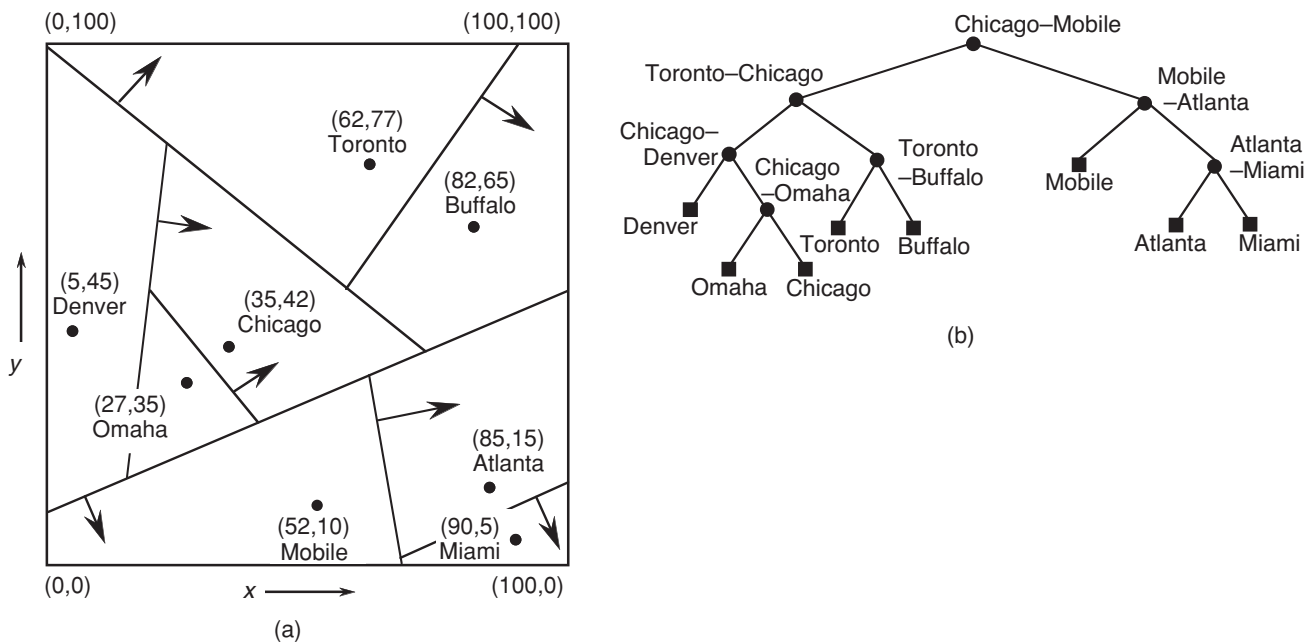

Figure 4.58  
(a) A possible space partitioning produced by the mb-tree for the set of points corresponding to the data in Figure 1.1 of Chapter 1 and (b) its tree representation.

an ancestor, as in the mb-tree. For example, consider Figure 4.59, where the radius of the covering ball of child  $e_1$  is smaller than the radius of the covering ball of its ancestor  $e_a$ , yet the covering ball of  $e_1$  is not completely contained in the covering ball of  $e_a$ .

Merkwirth, Parlitz, and Lauterborn [1286] (see Exercise 7 in Section 4.5.3.1) ignore the issue of eccentricity and, instead, force a containment hierarchy to exist by basing the lower bound  $d(q, e_1)$  on the maximum of the distance of  $q$  from the children and the distance of  $q$  from the parent (i.e.,  $d(q, e_a)$ ). They use a conventional bisector tree (also referred to as an augmented gh-tree in Section 4.5.3.1). Nevertheless, it can be shown (see Exercise 7 in Section 4.5.3.1) that for queries such as finding the nearest neighbors of  $q$  using the best-first method, the fact that the covering balls of the children do not contain any objects that are not in the covering balls of the ancestors means that taking the distance of the parent (i.e.,  $d(q, e_a)$ ) into account when computing  $d(q, e_1)$  does not result in the pruning of more objects or nodes from the search process. Equivalently, failing to take the distance of the parent into account, and thus just using the distance from  $q$  of the children, does not cause additional objects or nodes to be visited during the search process. A similar statement can be made about range searching. The only requirement that must be met is that the distances of the nonobject elements be lower bounds for the distances of the object elements (as pointed out in Section 4.1.3). Thus, we can also safely ignore the issue of whether or not a containment hierarchy exists. In particular, whenever we process a nonobject element  $e_a$  and determine that the radius of the covering ball around the pivot in the ancestor (i.e., parent) element of  $e_a$  means that  $e_a$ 's children must be visited, then whether or not the radii of the covering balls around the pivots of the children are larger than those of the covering balls around the pivot in the ancestor element of  $e_a$  has no effect on the extent of the pruning as the covering balls of the parent and the children contain the same objects (i.e., there are no additional objects in the hypervolume corresponding to the set difference of the covering balls of the child and its parent).

From the above we observe that the presence or absence of eccentric children is not really an issue in the bisector tree (and the suitably modified gh-tree). The real issue is similar to one that was raised earlier in our discussion of the incremental nearest neighbor algorithm in Section 4.1.3, where we pointed out that the correctness criterion (i.e.,  $d_t(q, e_t) \leq d_0(q, e_0)$  for any object  $e_0$  in the subtree represented by  $e_t$ ) does not actually guarantee that when a nonobject search hierarchy element  $e_t$  has been removed from the priority queue, no nonobject search hierarchy element  $e_{t'}$  (in the subtree represented by  $e_t$ ) with a smaller distance from the query object  $q$  can be inserted, and possibly removed, in the future. In other words, it does not preclude the occurrence of the situation that nonobject elements  $e_t$  and  $e_{t'}$ , where  $d_t(q, e_t) > d_{t'}(q, e_{t'})$ , could be processed in succession (by virtue of their being removed from the priority queue in succession, although some other elements could have been inserted into the queue during this time). The latter situation arises in the bisector tree (and in a gh-tree that is augmented with covering balls) when eccentric children are present; it can also arise in a vp-tree (see Exercise 5 in Section 4.5.2.1.2). Note that, as we pointed out earlier, this situation is not limited to eccentric children in the bisector tree.

Figure 4.59  
Example illustrating that the covering ball of a descendant of a node may extend past the ball element of its ancestor.

### Exercises

1. Prove that none of the children in an mb-tree are eccentric.
2. Prove that, given  $N > 1$  objects, the mb-tree requires  $N - 1$  nodes.
3. Give an algorithm to construct an mb-tree.
4. Give an algorithm to perform a range query for a query object  $q$  and query radius  $\varepsilon$  in an mb-tree.
5. Give an algorithm to find the nearest neighbors in an incremental manner to a query object  $q$  in an mb-tree. Exercises 6–8 deal with the Voronoi tree [473], which is closely related to the mb-tree. Assuming a set of objects  $S$ , its Voronoi tree  $T$  is a ternary tree where each node

represents at least two, and at most three, objects of  $S$ , termed *pivots*. Of course, the root may represent just one object of  $S$  if  $S$  has just one object. The Voronoi tree is built in a manner analogous to that of the mb-tree. We first search for the node in which the new object  $o$  is to be inserted, starting at the root. If the current node  $U$  is not full, then insert  $o$ . If  $U$  is full and has no children, then create a new node  $V$  and insert  $o$  into  $V$ , as well as a redundant copy of the closest pivot  $p$  in  $U$ . Otherwise, determine the closest pivot  $p$  to  $o$  in  $U$  and descend to  $p$ 's corresponding child.

6. Show that the Voronoi tree has no eccentric children.
7. Prove that the Voronoi tree is transitive in the sense that, given an object  $o$  stored in node  $U$  and letting  $f(o, U)$  denote  $o$ 's closest pivot in the immediate ancestor of  $U$ ,  $d(o, f(o, U)) = \min\{d(o, f(o, U'))\}$ , where  $U'$  is in the set of ancestors of  $U$ .
8. Prove that a search for the nearest neighbor of an object stored in the root node of a Voronoi tree of height  $h$  can be done in  $O(h)$  time.

#### 4.5.3.4 Other Methods Related to Generalized Hyperplane Partitioning

The gh-tree and GNAT (as well as the M-tree, described in Section 4.5.4) can be considered special cases of a general class of hierarchical clustering methods, as described by Burkhard and Keller [283] and Fukunaga and Narendra [666] (recall Section 4.2.2). Using the description given by Burkhard and Keller [283], a set  $S$  of objects is clustered into  $m$  subsets  $S_1, S_2, \dots, S_m$  using some criterion usually based on proximity. Next, a pivot object  $p_i$  is chosen for each  $S_i$ , and the radius  $r_i = \max_{o \in S_i} \{d(p_i, o)\}$  is computed.<sup>30</sup> This process is applied recursively to each  $S_i$ , possibly with a different number  $m$  of clusters each time. Observe that for performing search (e.g., range search), a lower bound on the distances from a query object  $q$  to all objects in  $S_i$  can be derived based on  $p_i$  and  $r_i$  according to Lemma 4.2, as was done for the vp-tree in Section 4.5.2.1.2 (i.e., letting  $r_{lo} = 0$  and  $r_{hi} = r_i$ ). Besides the above general formulation, Burkhard and Keller also described a specific method of clustering, where each cluster is a *clique*, which they define to be a set of objects  $R$  such that the greatest distance between any two objects in  $R$  is no more than some value  $D$ .<sup>31</sup> The clique property was found to reduce the number of distance computations and allow more pruning during search [283], at the price of high preprocessing cost (for determining the cliques).

The manner in which we described the hierarchies that make up the gh-tree, GNAT, monotonous bisector tree (mb-tree), and so on, implies that they are built in a top-down manner. For example, recall that the hierarchy in GNAT is built by initially choosing  $m$  of the objects to serve as pivots and then forming  $m$  sets, each of which contains the objects that are closest to the corresponding pivot. Each of these  $m$  sets are recursively processed to yield  $m$  or some other number of subsets. Alternatively, the hierarchy can also be built in a bottom-up manner. In this case, the algorithms generally assume that the objects are initially processed using some clustering method to obtain  $k$  clusters with  $k$  cluster centers. These clusters are subsequently processed by applying a hierarchical clustering method (e.g., [445, 666, 1311]). These methods are very similar to those used to obtain object hierarchies, such as the R-tree (Section 2.1.5.2 in Chapter 2), and, more specifically, object hierarchies that make use of minimum bounding hyperspheres, such as the SS-tree [1991], balltree [1399], and sphere tree [895, 896, 1410, 1412] (see Section 4.4.2).

There are many possible ways to perform the initial clustering at the bottom level of the hierarchy. For example, given a dataset  $S$  and an integer  $k$ , one way to proceed is to determine the  $k$  objects in  $S$  such that the maximum radius of the covering balls centered

---

<sup>30</sup> GNAT [255] maintains more comprehensive distance information in each node.

<sup>31</sup> If we consider the objects to be nodes in a graph with edges between objects whose distance is no more than  $D$ , a graph-theoretic clique in this graph corresponds to Burkhard and Keller's definition of a clique.

at these objects is minimized, assuming that each object is associated with its closest of these  $k$  objects. These  $k$  objects are known as  $k$ -centers. In other words, the process of finding the  $k$ -centers is equivalent to finding the  $k$  pivot objects so that the maximum distance from a  $k$ -center to an object in  $S$  is minimized.

Note that the pivots used by GNAT are not necessarily  $k$ -centers. The  $k$ -centers act like sites in a Voronoi diagram in the sense that all objects in each covering ball are closer to the corresponding  $k$ -center than to any other  $k$ -center. However, the converse is not generally true—that is, the sites in a Voronoi diagram are not necessarily  $k$ -centers. Observe also that the  $k$ -centers are not the same as the  $k$ -means, which are the  $k$  objects, not necessarily in  $S$ , that minimize the sum of the squares of the distances (usually using the Euclidean distance for objects in a vector space) of the individual objects from their closest  $k$ -mean. The  $k$ -median problem is similar to the  $k$ -center problem, with the difference that, in the former, it is the average radius of the covering balls that is minimized, and, in the latter, it is the maximum radius of the covering balls that is minimized.

Obtaining the  $k$ -centers is computationally complex (i.e., NP-hard [203]), and thus there is interest in obtaining what are termed *approximate  $k$ -centers*. In particular, assuming  $N$  objects, Gonzalez [723] describes an  $O(N \cdot k)$  algorithm that yields the approximate  $k$ -centers such that the maximum radius is at most twice the optimum maximum radius resulting from the use of the actual  $k$ -centers (see Exercise 1). Hochbaum and Shmoys [859] proved that a better guarantee than twice the optimum maximum radius cannot be obtained in polynomial time (unless  $P = NP$ ), while Feder and Greene [601] reduced the time bound for the algorithm of Gonzalez to  $O(N \log k)$  in low dimensions by using a more efficient implementation. Dasgupta [445] and Moore [1311] address the issue of building the cluster hierarchy once the bottom level of the hierarchy has been built using methods similar to those of Gonzalez [723]. Moore uses the term *anchors hierarchy* to describe the resulting structure, which is similar to the balltree [1399] (see Section 4.4.2).

Micó, Oncina, and Vidal [1292] apply a variant of the Gonzalez [723] algorithm to find the  $k$ -medians (termed *base prototypes*) that are used in LAESA, where they behave like coordinates in a distance-based indexing method that makes use of a distance matrix that is similar in spirit to an embedding method (see Section 4.5.7.2). The difference is that, in this variant, it is the average distance from each object to the pivot set at each pivot selection step that is maximized; in the original formulation, it is the minimum distance from each object to the pivot set that is maximized. Charikar, Guha, Tardos, and Shmoys [325] also give an algorithm to obtain the approximate  $k$ -medians and prove that their average radius is at most eight times the optimum average radius from use of the actual  $k$ -medians (see Exercise 2).

### Exercises

1. Assuming  $n$  objects, Gonzalez [723] proposed the following simple greedy algorithm called *farthest-point clustering* to determine the set  $C$  of approximate  $k$ -centers  $c_1, \dots, c_k$ , which is initially empty, and to construct the corresponding sets  $S_1, \dots, S_k$ .
  - (a) Initially, pick an object  $v_0$  in  $S$  at random to serve as the first approximate  $k$ -center and add it to  $C$ .
  - (b) For  $i = 1$  to  $k - 1$  do the following:
    - i. For every object  $v \in S$ , compute the distance from  $v$  to the current approximate  $k$ -center set  $C = \{v_0, v_1, \dots, v_{i-1}\}$ —that is,  $d_i(v, C) = \min_{c \in C} \|v - c\|$ .
    - ii. From the set of objects  $S - C$ , find an object  $v_i$  that is farthest away from the current approximate  $k$ -center set  $C$ —that is,  $d_i(v_i, C) = \max_{v \in S - C} \min_{c \in C} \|v - c\|$ .
    - iii. Add  $v_i$  to  $C$ .
  - (c) Return the set  $C = \{v_0, v_1, \dots, v_{k-1}\}$  as the set of  $k$  approximate  $k$ -centers.

Prove that the maximum radius obtained by this approximate algorithm is at most twice the optimum maximum radius resulting from the use of the actual  $k$ -centers. Your proof should make use of the following properties of the algorithm, letting  $C_i = \{v_0, v_1, \dots, v_{i-1}\}$  be the set of approximate  $k$ -centers after  $i$  iterations.

- (a) The distance from each object to  $C$  does not increase as the approximate  $k$ -center algorithm progresses—that is,  $d_j(v_j, C_j) \leq d_i(v_j, C_i)$  for  $j \geq i$ .
  - (b) For  $j \geq i$ , by definition, we have that  $d_i(v_j, C_i) \leq d_i(v_i, C_i)$  as  $v_i$  at distance  $d_i(v_i, C_i)$  is always the farthest object from an element of  $C_i$  after  $i$  iterations of the approximate  $k$ -center algorithm.
2. Show that the average radius obtained by the approximate  $k$ -medians algorithm of Charikar et al. [325] is at most eight times the optimum average radius from use of the actual  $k$ -medians.
  3. Can you derive a bound on the quality of the bound obtained by the algorithm of Mico et al. [1292] for the  $k$ -medians similar to that obtained by Charikar et al. [325].

## 4.5.4 M-Tree

The distance-based indexing methods described in Sections 4.5.2 and 4.5.3 are either static, unbalanced, or both. Hence, they are unsuitable for dynamic situations involving large amounts of data, where a disk-based structure is needed. The M-tree [388, 389] is a distance-based indexing method designed to address this deficiency. Its design goal was to combine a dynamic, balanced index structure similar to the R-tree with the capabilities of static distance-based indexes. Below, we first describe the structure of the M-tree (Section 4.5.4.1) and then show how to perform search in it (Section 4.5.4.2)

### 4.5.4.1 Structure

In the M-tree, as in the R-tree, all the objects being indexed are referenced in the leaf nodes,<sup>32</sup> while an entry in a nonleaf node stores a pointer to a node at the next lower level, along with summary information about the objects in the subtree being pointed at. Recall that, in an R-tree, the summary information consists of minimum bounding rectangles for all the objects in the subtree. For arbitrary metric spaces, we cannot explicitly form the “regions” that enclose a set of objects in the same manner. Instead, in the M-tree, “balls” around pivot objects (termed *routing objects* in [389]) serve the same role as the minimum bounding rectangles in the R-tree. Clearly, the pivots in the M-tree have a function similar to that of the pivots in GNAT (see Section 4.5.3). However, unlike GNAT, all objects in  $S$  are stored in the leaf nodes of the M-tree, so an object may be referenced multiple times in the tree (once in a leaf node and as a pivot in one or more nonleaf nodes). For an object  $o$  in the subtree of a node  $n$ , the pivot  $p$  of that subtree is not always the one closest to  $o$  among all the pivots in  $n$  (i.e., we may have  $d(p, o) > d(p', o)$  for some other pivot  $p'$  in  $n$ ). In addition to this summary information, the entries in M-tree nodes also contain distance values that can aid in pruning during search, as is done in the  $vp^{sb}$ -tree (see Section 4.5.2.2).

More precisely, for a nonleaf node  $n$ , the entries are  $(p, r, D, T)$ , where  $p$  is a pivot,  $r$  is the corresponding *covering radius*,  $D$  is a distance value (defined below), and  $T$  is a reference to a child node of  $n$ . For all objects  $o$  in the subtree rooted at  $T$ , we have  $d(p, o) \leq r$ . For each nonroot node, let *parent object* denote its associated pivot (i.e., the pivot in the entry pointing to it in its parent). The distance value stored in  $D$  is the distance  $d(p, p')$  between  $p$  and the parent object  $p'$  of  $n$ . As we shall see, these parent distances allow more pruning during search than would otherwise be possible. Similarly, for a leaf node  $n$ , the entries consist of  $(o, D)$ , where  $o$  is a data object, and  $D$  is the distance between  $o$  and the parent object of  $n$ . Clearly, the root has no parent, so  $D = \infty$  for all the

---

<sup>32</sup> The objects can either be stored directly in the leaf nodes or externally to the M-tree, with object IDs stored in the leaf nodes.

entries in the root. Observe that the covering radius for a nonleaf entry is not necessarily the minimum radius for the objects in the corresponding subtree (except when the M-tree is bulk-loaded [386]).

Being a dynamic structure, the M-tree can be built gradually as new data arrives [389]. The insertion procedure first “routes” a new data object to a leaf node  $n$ , for each nonleaf node on the path, picking a child node that “best matches” the data object, based on heuristics. For example, a heuristic might first look for a pivot object whose “ball” includes the data object and pick the one closest to the data object if there is more than one such pivot. The insertion into  $n$  may cause overflow, causing  $n$  to be split and a new pivot to be selected. Thus, overflow may cascade up to the root, in which case the tree will actually grow in a bottom-up fashion. Ciaccia et al. [389] considered a number of heuristics for choosing the child node to route an object into and for splitting overflowing nodes. Bulk loading strategies [386, 1236] have also been developed for use when an M-tree must be built for an existing set of data objects. An example of root node partitioning in an M-tree for a set of objects is shown in Figure 4.60, where we have three pivot objects,  $p_1$ ,  $p_2$ , and  $p_3$ . Notice that the regions of some of the three subtrees overlap. This may give rise to a situation where an object can be inserted into more than one subtree, such as the object marked  $o$ , which can be inserted into the subtree of either  $p_1$  or  $p_3$ .

As pointed out above, the balls around the pivot objects in the M-tree play the same role as the minimum bounding rectangles in the R-tree. In fact, a more precise analogy is to the SS-tree [1991] and the sphere tree [1410, 1412] (see Section 4.4). There are a number of differences, though. In particular, the SS-tree and the sphere tree do not store parent distances as is done in the M-tree. In addition, the SS-tree and the sphere tree make use of geometric properties for some of the operations such as node splitting upon overflow, whereas this is not the case for the M-tree.

The M-tree has features common to both pivot-based and clustering-based indexing methods. The routing objects and the associated covering radii play the same role as the pivots in the pivot-based methods. On the other hand, the fact that an object is inserted into the ball of its closest pivot object when it is contained in the covering balls of more than one pivot object is a reminiscent of clustering-based methods. Nevertheless, when the object is not in the covering balls of any of the pivot objects, it is usually associated with the pivot whose covering is increased the least. This is reminiscent of techniques that minimize the coverage when inserting into an R-tree node. However, such a policy will not necessarily result in associating the new object with the closest pivot object. Therefore, it is not always a clustering-based strategy. Thus, we see that the M-tree is really a hybrid method combining features common to both pivot-based and clustering-based indexing methods.

Traina, Traina, Seeger, and Faloutsos [1888, 1889] introduced the *Slim-tree*, a variant of the M-tree with faster node-insertion and node-splitting algorithms. More importantly, the Slim-tree also features improved storage utilization, which is achieved, in part, by applying a postprocessing step, termed the *Slim-down* algorithm. This algorithm attempts to reduce the overlap among node regions by moving entries between sibling nodes in iterative fashion. In particular, in the case of slimming down leaf nodes, an object  $o$  stored in a leaf node  $n$  is a candidate for being moved if (1)  $o$  is the object in  $n$  that is farthest from  $n$ 's parent object  $p$ , and (2) the region of a sibling  $n'$  of  $n$  also covers  $o$ . Having identified such a candidate  $o$ ,  $o$  is moved from  $n$  to  $n'$ , and the covering radius of  $n$  is reduced, if possible, depending on the distance between  $p$  and the next farthest object in  $n$ . An empirical study showed that these modifications led to a reduction in the number of disk accesses as compared to the original M-tree [1888].

### Exercise

1. Give an algorithm to construct an M-tree.

## Section 4.5 DISTANCE-BASED INDEXING METHODS

Figure 4.60  
Possible top-level partitionings of a set of objects (depicted as two-dimensional points) in an M-tree. Objects that fall into more than one ball, like  $o$ , can be inserted into any of the corresponding subtrees.

### 4.5.4.2 Search

Range queries for query object  $q$  and query radius  $\varepsilon$  can be performed on the M-tree with a straightforward depth-first traversal, initiated at the root. Let  $n$  be a node that is being visited, and let  $p'$  be its parent pivot—that is,  $p'$  is the pivot for the entry in  $n$ 's parent that points to  $n$ . In order to exploit the parent distance  $D$  stored in the entries of  $n$  (i.e., to avoid as much as possible the computation of the distances from  $q$  to the pivots  $p$  stored in the entries of  $n$ ), the value of  $d(q, p')$  must be propagated downward in the depth-first traversal as  $n$  is visited (since the root has no parent, we use  $d(q, p') = \infty$  when processing the root and assume that  $\infty - \infty$  evaluates to 0). Assume that  $n$  is a nonleaf node. We consider each entry  $(p, r, D, T)$  in turn. There are two cases:

1. If  $|d(q, p') - D| - r > \varepsilon$ , then the subtree pointed at by  $T$  need not be traversed, and thus the entry is pruned. In other words, we have found a lower bound on the distance from  $q$  to an object in the subtree pointed at by  $T$  and note that if this lower bound is greater than  $\varepsilon$ , then no object in this subtree can be in the range. This can be seen by making use of Lemmas 4.1 and 4.3. Lemma 4.1 yields a lower bound from  $q$  to any of the pivots (e.g.,  $p$ ) in node  $n$ . In this case,  $p$  and  $p'$  play the roles of  $o$  and  $p$ , respectively, in the lemma, which stipulates that  $|d(q, p') - d(p', p)| = |d(q, p') - D| \leq d(q, p)$ . The upper bound on the distance from  $q$  to any of the pivots (e.g.,  $p$ ) in node  $n$  is  $\infty$ . The distance from pivot  $p$  to any of the objects in the corresponding subtree  $T$  lies between 0 and  $r$ . We now apply Lemma 4.3 to obtain a lower bound on the distance from  $q$  to any object  $o$  in the subtree pointed at by  $T$ —that is,  $r_{lo} = 0$ ,  $r_{hi} = r$ ,  $s_{lo} = |d(q, p') - D|$ , and  $s_{hi} = \infty$  yield  $|d(q, p') - D| - r \leq d(q, o)$ . Thus, as long as  $\varepsilon < |d(q, p') - D| - r$ , the subtree pointed at by  $T$  need not be traversed.
2. Otherwise,  $|d(q, p') - D| - r \leq \varepsilon$ . In this case, we can no longer avoid computing  $d(q, p)$ . However, having computed  $d(q, p)$ , we can still avoid visiting the node pointed at by  $T$  if the lower bound on the distance from  $q$  to any object  $o$  in  $T$  is greater than  $\varepsilon$ . This is the case if  $d(q, p) - r > \varepsilon$  and is a direct result of applying Lemma 4.2, noting that the distance from  $p$  to  $o$  lies between 0 and  $r$ .

Leaf nodes are processed in a similar way: For each entry  $(o, D)$  in  $n$  with parent pivot  $p'$ , we first check if  $|d(q, p') - D| \leq \varepsilon$  (since we know from Lemma 4.1 that  $|d(q, p') - d(p', o)| = |d(q, p') - D| \leq d(q, o)$ , so if  $\varepsilon < |d(q, p') - D| \leq d(q, o)$ , we can immediately discard  $o$  without computing its distance), and only for such entries do we compute  $d(q, o)$  and check whether  $d(q, o) \leq \varepsilon$ . Observe that, once again, we see that the parent distances sometimes allow us to prune node entries from the search based on the query radius  $\varepsilon$ , without computing the actual distances of the corresponding objects.

Finding nearest neighbors is more complicated. For  $k$ -nearest neighbor search, Ciaccia et al. [389] propose using the distance of the farthest candidate  $k$ th-nearest neighbor in place of  $\varepsilon$  in the pruning conditions.<sup>33</sup> This technique is discussed further below once we describe the more general incremental approach where the number of desired neighbors is not known in advance. In particular, for incremental nearest neighbor search, not knowing the number of desired neighbors in advance means that the search radius is unbounded, and thus the pruning condition used by Ciaccia et al. [389] is inapplicable. Hjaltason and Samet [851] overcome this drawback in their implementation of incremental nearest neighbor searching by introducing two new element types corresponding to approximate objects and approximate nodes to the search hierarchy. These new element types serve the same role as bounding rectangles in the case of an R-tree. Thus, they provide a simple way to order the subsequent processing of elements of both a leaf and nonleaf node without having to compute the actual distances of these elements from the

<sup>33</sup> This is a standard approach for solving this problem. For example, see Exercise 10 in Section 4.6.1.2, which deals with its use by Seidl and Kriegel [1716] to find nearest neighbors in an environment that employs dimensionality reduction.

query object. As we will see, this method can also be applied to obtain a more efficient solution to the  $k$ -nearest neighbor problem than the algorithm of Ciaccia et al. [389].

In particular, four types of elements are defined. Type 0 represents objects, type 1 represents approximate objects, type 2 represents nodes, and type 3 represents approximate nodes. Elements of type 1 and 3 are generated as a result of processing leaf nodes and nonleaf nodes, respectively. In particular, when processing a leaf (nonleaf) node  $n$  (i.e., when it reaches the front of the priority queue as an element of type 2), an element of type 1 (3) is generated from each of the entries in  $n$ . An element of type 0 is generated as a result of processing an element of type 1, and, similarly, each element of type 2 derives from an element of type 3. The distance functions for elements of type 1 through 3 are defined as follows:

$$\begin{aligned} d_1(q, e_1) &= \max\{|d(q, p') - D|, 0\} \\ d_2(q, e_2) &= \max\{d(q, p) - r, 0\} \\ d_3(q, e_3) &= \max\{|d(q, p') - D| - r, 0\} \end{aligned} \quad (4.5)$$

where  $p'$  is the parent object,  $D$  is the corresponding distance for the node entry from which  $e_1$  and  $e_3$  were generated, and  $p$  and  $r$  are the pivot and covering radius for the node corresponding to  $e_2$  and  $e_3$ . Using the same definitions, the upper-bound distance functions for types 1 through 3 are

$$\begin{aligned} \hat{d}_1(q, e_1) &= d(q, p') + D \\ \hat{d}_2(q, e_2) &= d(q, p) + r \\ \hat{d}_3(q, e_3) &= d(q, p') + D + r \end{aligned}$$

To support distance computations for descendants, we must associate certain information with each element. In particular, an element of type 1 must include the identity of the corresponding object; an element of type 2 must include a pointer to the corresponding node  $n$  and the distance  $d(q, p')$ , where  $p'$  is the parent object of  $n$ ; and an element of type 3 must include  $p$ ,  $r$ , and  $T$ , where  $(p, r, D, T)$  is the nonleaf node entry that gave rise to it. Note that a depth-first range search on this search hierarchy is equivalent to the range query algorithm described above.

The correctness of incremental nearest neighbor search with these definitions can be shown by applying the results in Section 4.5.1. In particular, for an element  $e_1$  and the corresponding object  $o$ ,  $d_1(q, e_1) = |d(q, p') - D| = |d(q, p') - d(p', o)| \leq d(q, o) \leq d(q, p') + d(p', o) = |d(q, p') + D| = \hat{d}_1(q, e_1)$  follows from Lemma 4.1. For an element  $e_2$  and an object  $o$  in its subtree, we have

$$d_2(q, e_2) = \max\{d(q, p) - r, 0\} \leq d(q, o) \leq d(q, p) + r = \hat{d}_2(q, e_2)$$

from Lemma 4.2. Finally, for an element  $e_3$  and an object  $o$  in the subtree,

$$\begin{aligned} d_3(q, e_3) &= \max\{|d(q, p') - D| - r, 0\} \\ &= \max\{|d(q, p') - d(p', p)| - r, 0\} \leq d(q, o) \leq d(q, p') + d(p', p) + r \\ &= |d(q, p') + D| + r \\ &= \hat{d}_3(q, e_3) \end{aligned}$$

follows from Lemmas 4.1, 4.2 and 4.3.

Observe that when  $d_1(q, e_1)$  and  $d_3(q, e_3)$  are computed for elements  $e_1$  and  $e_3$ , respectively, the distance information that they are based on is already available, so no additional computation of actual distances is necessary. In particular,  $D$  is a distance value computed during the construction of the M-tree, and  $d(q, p')$  was computed earlier in the processing of the query and stored in  $e_2$ , the node element from which  $e_1$  or  $e_3$  is generated (i.e.,  $p'$  is the parent object of the node corresponding to  $e_2$ ). Thus, assuming that incremental nearest neighbor search is terminated after object  $o_k$  has been reported, any element of type 1 that still remains on the priority queue represents an object that

we were able to prune without computing its actual distance from  $q$ . A similar statement applies to elements of type 3.

The above general incremental algorithm can also be adapted to compute the  $k$  nearest neighbors, thereby obtaining an algorithm similar to one used by Ciaccia et al. [389] to solve the same problem. The  $k$ -nearest neighbor algorithm of Ciaccia et al. makes use of a priority queue containing the nodes of the M-tree (not the objects or the additional approximate elements introduced in the general incremental algorithm) and processes them in increasing order of their distance from the query object  $q$ . It uses the distance function  $d_c(q, e) = \max\{d(q, p) - r, 0\}$ , where  $p$  and  $r$  are the pivot and covering radius for node  $e$ , and  $d_c$  is the same as  $d_2$  in Equation 4.5. As the algorithm obtains the actual neighbors (i.e., the objects) one by one, it computes the actual distance of each object using  $d$  and inserts the objects into a list  $L$  of the  $k$  candidate nearest neighbors. If the insertion causes  $L$  to contain more than  $k$  objects, then the object farthest from  $q$  is discarded.<sup>34</sup> Clearly, if all the objects in  $S$  were inserted into  $L$  in this way,  $L$  would eventually contain the actual  $k$  nearest neighbors. However, the algorithm can usually be terminated long before inserting all of the objects into  $L$  since an object is only inserted into  $L$  once the M-tree leaf node  $n$  that contains it is obtained from the priority queue—that is, when  $n$  is the unprocessed leaf node closest to  $q$ . In particular, the condition for terminating the search is  $d_c(q, e) \geq D_k$ ,<sup>35</sup> where  $e$  represents the node that was most recently retrieved from the priority queue, and  $D_k$  is the distance of the current candidate  $k$ th-nearest neighbor in  $L$  (or  $\infty$  if  $|L| < k$ ). The reason that the search can be terminated at this point is that we know from Lemma 4.2 that  $D_k \leq d_c(q, e) = \max\{d(q, p) - r, 0\} \leq d(q, o)$  for an M-tree node  $e$  and an object  $o$  in its corresponding subtree, and thus  $o$  cannot be one of the  $k$  nearest neighbors.

The way in which the algorithm of Ciaccia et al. makes use of a candidate list is analogous to placing the objects on the priority queue and terminating the search once the  $k$ th object has been retrieved from the priority queue. The primary difference is that, in the candidate list approach, at most  $k$  objects are remembered at any given time, whereas the priority queue can contain any number of objects in the general incremental algorithm. Note that the algorithm of Ciaccia et al. also uses  $D_k$  to prune entries locally as it processes nodes obtained from the priority queue. This local pruning takes the place of the approximate node and object elements used in the general incremental algorithm, which, as we recall, stores both the nodes and the objects in the priority queue. In particular, when processing a node  $n$ , using the distance functions in Equation 4.5, the algorithm of Ciaccia et al. prunes an entry in  $n$  if  $d_1(q, e_1) \geq D_k$  or  $d_3(q, e_3) \geq D_k$ , depending on whether  $n$  is a leaf or a nonleaf node, respectively. Nevertheless, it should be clear that despite the use of such local pruning, the algorithm of Ciaccia et al. still results in more distance computations than in the general incremental algorithm, since  $D_k$  may converge slowly to its final value (i.e.,  $d(q, o_k)$ , where  $o_k$  is the  $k$ th-nearest neighbor of  $q$ ).

As an example of how use of the algorithm of Ciaccia et al. results in more distance computations than the general incremental algorithm, suppose that  $D_k = 6$  for the current candidate  $k$ th-nearest neighbor. Moreover, suppose that we are currently processing a leaf node  $n$  with two objects  $a$  and  $b$  and that the “parent” object of  $n$  is  $p$ . Therefore, we know  $d(q, p)$  (since it was computed when  $n$  was inserted into the priority queue), and we know  $d(p, a)$  and  $d(p, b)$  (since they are stored in the entries of M-tree node  $n$ ). Furthermore, we know that  $|d(q, p) - d(p, a)|$  and  $|d(q, p) - d(p, b)|$  are lower bounds on  $d(q, a)$  and  $d(q, b)$ , respectively. Let us assume that  $|d(q, p) - d(p, a)| = 5$ ,  $|d(q, p) - d(p, b)| = 3$ ,

<sup>34</sup> Of course, this distance is based on  $d$  rather than  $d_c$  as here we are dealing with an object rather than a node.

<sup>35</sup> This condition means that the algorithm will report exactly  $k$  neighbors regardless of how many objects are at the same distance from  $q$  as the  $k$ th-nearest neighbor. If it is desired to report all of the objects that are at the same distance from  $q$  as the  $k$ th-nearest neighbor, then the condition for terminating the search is modified to be  $d_c(q, e) > D_k$ .

$d(q, a) = 7$ , and  $d(q, b) = 4$ . We first examine the execution of the general incremental algorithm. It inserts the “approximate” versions of  $a$  and  $b$  into the priority queue and uses the lower bound distance values 5 and 3, respectively. Assume that the next element that is removed from the priority queue is the “approximate”  $b$ , which would lead to computing  $d(q, b)$  and inserting  $b$  on the priority queue. Next, the algorithm removes  $b$  from the queue, which is the next neighbor. If the search is now terminated, then the computation of  $d(q, a)$  has been avoided.

To see why the general incremental algorithm is better in this example, we point out that, at the time the leaf node  $n$  was processed, the algorithm of Ciaccia et al. would compute both  $d(q, a)$  and  $d(q, b)$  since their lower bounds are both smaller than  $D_k = 6$ . In essence, Ciaccia et al.’s use of the lower-bound distances is local (as they are used to make an immediate decision about whether to compute the actual distance), whereas the general nearest neighbor algorithm makes a global use of them (by putting them on the priority queue, and only computing the actual distance once they are removed from the queue). In other words, the general incremental algorithm defers the computation of the distances via the use of the approximate objects and nodes. Nevertheless, both the general incremental algorithm and the algorithm of Ciaccia et al. explore the same number of M-tree nodes because, in both algorithms, these nodes are only explored once they reach the head of the priority queue, which happens in the same way in the two algorithms. However, use of the approximate node for  $n$  does result in deferring the computation of  $d(q, p)$  and replacing it with a quantity that involves  $|d(q, p') - D|$ , which has already been computed before processing  $n$ . Thus, a distance computation has also been possibly avoided.

### Exercises

1. Discuss the process of splitting an overflowing M-tree node and how to distribute the objects into the newly created nodes. Can you derive some techniques analogous to those used in the R\*-tree [152] (see Section 2.1.5.2.4 in Chapter 2) to split an overflowing R-tree node?
2. Implement the algorithm described in the text to find the  $k$  nearest neighbors to a query object  $q$  in an M-tree.
3. Implement the algorithm described in the text to find the nearest neighbors in an incremental manner to a query object  $q$  in an M-tree.

## 4.5.5 Sa-Tree

The Voronoi diagram is a widely used method for nearest neighbor search in point data. For each “site”  $p$ , the Voronoi cell or region of  $p$  identifies the area closer to  $p$  than to any other site. Thus, given a query point  $q$ , nearest neighbor search simply involves identifying the Voronoi cell that contains  $q$ . In other words, we are given an underlying space  $\mathbb{U}$  and a set of objects  $S \subset \mathbb{U}$  (i.e., the “sites”) such that, for each query object  $q$  into  $\mathbb{U}$ , we wish to find the nearest object in  $S$  to  $q$  (more generally the nearest  $k$  objects to or the objects within  $\varepsilon$  of  $q$ ).

As we saw in Section 2.2.1.4 of Chapter 2, a somewhat indirect way of constructing a search structure for nearest neighbor search based on the Voronoi diagram is to build a graph termed a *Delaunay graph*, defined as the graph where each object is a node, and two nodes have an edge between them if their Voronoi cells have a common boundary.<sup>36</sup>

---

<sup>36</sup> In a conference version of [1347], Navarro used the term *Voronoi graph*, but the term *Delaunay graph* is a more appropriate term as it is closely related to the use of this concept in Section 2.2.1.4 of Chapter 2 (e.g., Delaunay triangulations), except that in the problem setting at hand, the edges in the Delaunay graph merely indicate that the Voronoi regions have a common boundary but do not have an associated geometric shape (e.g., they do not correspond to a particular curve or  $(d - 1)$ -dimensional hyperplane, assuming that the objects are drawn from a  $d$ -dimensional space).

In other words, the Delaunay graph is simply an explicit representation of neighbor relations that are implicitly represented in the Voronoi diagram.

Searching a Delaunay graph for the nearest neighbor in  $S$  of a query point  $q$  in  $\mathbb{U}$  starts with an arbitrary point in  $S$  and proceeds to a neighboring point in  $S$  that is closer to  $q$  as long as this is possible. Once we reach a point  $o$  in  $S$  where the points in its neighbor set  $N(o)$  in  $S$  (i.e., the points connected to  $o$  by an edge) are all farther away from  $q$  than  $o$ , we know that  $o$  is the nearest neighbor of  $q$ . The reason this search process works on the Delaunay graph of a set of points is that the Delaunay graph has the property that if  $q$  is closer to a point  $p$  than to any of the neighbors of  $p$  in the Delaunay graph, then  $p$  is the point in  $S$  closest to  $q$ . The same search process can be used on any graph that satisfies this *Voronoi property*. In fact, for an arbitrary metric space  $(\mathbb{U}, d)$ , a Delaunay graph for a set  $S \subset \mathbb{U}$  is a minimal graph that satisfies the Voronoi property (i.e., removing any edge would cause violation of the property). Thus, any graph that satisfies the Voronoi property must include a Delaunay graph as a subgraph. Note, however, that the Delaunay graph is not necessarily unique as there can be several such minimal graphs (possibly even with a different number of edges). In the rest this section, we define the sa-tree (Section 4.5.5.1), a data structure based on the Delaunay graph, and then show how to search it (Section 4.5.5.2).

### 4.5.5.1 Definition

The Voronoi diagram serves as the inspiration for the sa-tree [1347], a distance-based indexing method. Recall that in Section 4.5.3 we defined two other methods, the gh-tree and GNAT, that are also based on Voronoi cell-like partitioning. However, these structures make use of a hierarchical partitioning, where at each level the space is partitioned into two or more Voronoi cell-like regions. In contrast, the sa-tree attempts to approximate the structure of the Delaunay graph—hence its name, which is an abbreviation for *Spatial Approximation Tree*.

As we saw in Section 4.5.3.2, Voronoi cells (or, perhaps more accurately, Dirichlet domains [255]) for objects cannot be constructed explicitly (i.e., their boundaries specified) if only interobject distances are available. Moreover, it is possible to show [1347] that, without more information about the structure of the underlying metric space  $(\mathbb{U}, d)$ , just knowing the set of interobject distances for a finite metric space  $(S, d)$ ,  $S \subset \mathbb{U}$ , is not enough to enable the construction of a valid Delaunay graph for  $S$  based on  $d$ —that is, we also need information about the distances between the elements of  $S$  and the elements of  $\mathbb{U}$ . In other words, for the two sets  $S \subset \mathbb{U}$  and  $S' \subset \mathbb{U}'$  with identical interobject distances (i.e.,  $(S, d)$  and  $(S', d')$  are isometric), possibly drawn from different underlying spaces  $\mathbb{U}$  and  $\mathbb{U}'$ ,  $(S, d)$  may have a Delaunay graph  $D$  that is not a Delaunay graph for  $(S', d')$ , or vice versa (see Exercise 1). Moreover, for any two objects  $a$  and  $b$ , a finite metric space  $(S, d)$  exists whose Delaunay graph contains the edge between  $a$  and  $b$ . Hence, given only the interobject distances for a set  $S$ , the only way to construct a graph  $G$  such that  $G$  satisfies the Voronoi property for all potential query objects in  $\mathbb{U}$  (i.e., contains all the edges in the Delaunay graph) is for  $G$  to be the complete graph—that is, the graph containing an edge between all pairs of nodes (each of which represents an object in  $S$ ). However, such a graph is useless for search as deciding on what edge to traverse from the initial object in  $S$  requires computing the distances from the query object to all the remaining objects in  $S$  (i.e., it is as expensive,  $O(N)$ , as brute-force search). The idea behind the sa-tree is to approximate the proper Delaunay graph with a tree structure that retains enough edges to be useful for guiding search, but not so many that an excessive number of distance computations is required to decide what node to visit next.

The sa-tree is defined as follows for a finite metric space  $(S, d)$  (see the example in Figure 4.61 to clarify some of the questions that may arise). An arbitrary object  $a$  is chosen as the root node of the tree (since each object is associated with exactly one node, we use the terms *object* and *node* interchangeably in this discussion). Next, a smallest possible set  $N(a) \subset S \setminus \{a\}$  is identified, such that  $x$  is in  $N(a)$  if and only if for all

Figure 4.61  
(a) A set of points in a two-dimensional Euclidean space and (b) its corresponding sa-tree constructed using the algorithm of [1347] when  $a$  is chosen as the root.

$y \in N(a) \setminus \{x\}$ ,  $d(x, a) < d(x, y)$  (see Exercise 2). The set  $N(a)$  is termed the *neighbor set* of  $a$ , by analogy with the Delaunay graph, and the objects in  $N(a)$  are said to be the neighbors of  $a$ . Intuitively, for a legal neighbor set  $N(a)$  (i.e., not necessarily the smallest such set), each object in  $N(a)$  is closer to  $a$  than to the other objects in  $N(a)$ , and all the objects in  $S \setminus N(a)$  are closer to one of the objects in  $N(a)$  than to  $a$ . For example, the minimum neighbor set of  $a$  in Figure 4.62 is  $N(a) = \{d\}$ . The objects in  $N(a)$  then become children of  $a$ . The remaining objects in  $S$  are associated with the closest child of  $a$  (i.e., the closest object in  $N(a)$ ), and the subtrees are defined recursively in the same way for each child of  $a$ . As we shall see below, for the efficient implementation of search algorithms, it is useful to store in each node  $b$  the distance  $d_{\max}(b)$  to the farthest object in the subtree rooted at  $b$ . More precisely,  $d_{\max}(b) := \max_{o \in S_b} d(o, b)$ , where  $S_b$  denotes the set of objects in the subtree rooted at  $b$ . Figure 4.61(b) shows a sample sa-tree for the set of two-dimensional points  $a$ – $w$  given in Figure 4.61(a), with  $a$  chosen as the root. In this example,  $N(a) = \{b, c, d, e\}$ . Note that  $h$  is not in  $N(a)$  as  $h$  is closer to  $b$  than to  $a$ .

Figure 4.62  
An example of four points  $a$ ,  $b$ ,  $c$ , and  $d$  where the sa-tree construction algorithm does not find the minimal neighbor set  $N(a)$ .

It should be clear that the definition of the sa-tree given above does not yield a unique solution. For example, such a situation arises when  $a$  is far from two of its neighbors  $b$  and  $c$ , which are close to each other, thereby resulting in the situation that both  $N(a) = \{b\}$  and  $N(a) = \{c\}$  satisfy the definition. Moreover, the fact that the neighbor set  $N(a)$  is used in its definition (i.e., in a sense, the definition is self-referential) makes constructing a minimal set  $N(a)$  expensive, and Navarro [1347] argues that its construction is an NP-complete problem. Thus, Navarro [1347] resorts to a heuristic for identifying the set of neighbors. This heuristic considers the objects in  $S \setminus \{a\}$  in the order of their distance from  $a$  and adds an object  $o$  to  $N(a)$  if  $o$  is closer to  $a$  than to the existing objects in  $N(a)$  (see Exercise 3). In fact, for the points in Figure 4.61(a), the heuristic actually identifies the correct neighbor sets, and the sa-tree in Figure 4.61(b) was constructed using the heuristic with  $a$  chosen as the root. Nevertheless, the heuristic sometimes fails to find the minimal set of neighbors. An example of a situation where the heuristic would not find the minimal set of neighbors is shown in Figure 4.62, where approximate distances between four points  $a$  through  $d$  are labeled. The minimum neighbor set of  $a$  in this case is  $N(a) = \{d\}$  (and  $N(d) = \{b, c\}$ ), whereas use of the heuristic would lead to  $N(a) = \{b, c\}$  (and  $N(b) = \{d\}$ ).

Although the heuristic does not necessarily find the minimal neighbor set, it is deterministic in the sense that, for a given set of distance values, the same neighbor set is found (except for possible ties in distance values). Therefore, using the heuristic, the structure of the sa-tree is uniquely determined once the root has been chosen. In fact, Navarro [1347] formally redefines the sa-tree as the result of the application of this heuristic construction procedure. Thus, the initial minimality requirement in the sa-tree definition on the sizes of the individual neighbor sets seems to have been discarded.

Observe that different choices of the root lead to different tree structures. As an example, consider the distance matrix representing the interobject distances for the 18 objects  $a$ – $r$  given in Figure 4.63. Figure 4.64(a) is the result of embedding these objects in the two-dimensional plane, assuming that the distance metric is the Euclidean distance, and assigning them a consistent set of coordinate values so that these distance values hold, while Figure 4.64(b) is the corresponding Delaunay graph, which for this particular embedding is a plane graph (e.g., [196, Theorem 9.5]) known as the Delaunay triangulation (DT) (i.e., the graph representation of the neighbor structure of the Voronoi diagram of the suitably embedded point set given by Figure 4.64(c)—see Section 2.2.1.4 of Chapter 2 for more details). Of course, it bears noting that for another embedding, not necessarily in the two-dimensional Euclidean plane, the Delaunay graph, in this case, is not necessarily a Delaunay triangulation. Figure 4.65(a–d) shows the sa-trees corresponding to the Delaunay graph realized by the planar embedding of Figure 4.64 when using objects  $r$ ,  $a$ ,  $d$ ,  $b$ , respectively, as the roots. It is interesting to note that, from this example, we see that the sa-tree is not necessarily a subgraph of the Delaunay graph. In particular, when the sa-tree is rooted at  $a$  in Figure 4.65(b), we find the presence of edge  $hq$ , which is not present in the Delaunay graph in Figure 4.64(b).

Figure 4.63  
Example distance matrix showing the interobject distance values for 18 objects a–r in an arbitrary metric space.

Figure 4.64  
(a) The result of embedding the objects and the corresponding interobject distances in Figure 4.63 into the two-dimensional plane using the Euclidean distance, (b) the corresponding Delaunay graph, which is the Delaunay triangulation, and (c) the corresponding Voronoi diagram.

The sa-tree, as described above, is a static structure, in that the entire dataset must be known in order to build it. Navarro and Reyes [1348] introduce a dynamic version of the sa-tree that supports both insertions and deletions. In order to yield adequate performance, the dynamic version must relax the definition of neighbor sets. In particular, for a given object  $o$  inserted into the tree at time  $t$ , the properties described above for ancestors and siblings of ancestors of  $o$  only hold for those inserted before time  $t$ . The implication of this relaxed definition of neighbor sets is that, when evaluating the lower-bound distances for objects in the subtree rooted at a node  $b$ , we can only make use of those ancestors and ancestor siblings of  $b$  that were inserted before  $b$ .

### Exercises

1. Give an example to illustrate that, without more information about the structure of the underlying space  $\mathbb{U}$ , the set of interobject distances for a finite metric space  $(S, d)$ ,  $S \subset \mathbb{U}$ , does not uniquely determine the Delaunay graph for  $S$  based on  $d$ . In other words, two sets  $S \subset \mathbb{U}$  and  $S' \subset \mathbb{U}'$ , with identical interobject distances (i.e.,  $(S, d)$  and  $(S', d')$  are isometric) but possibly drawn from different underlying spaces  $\mathbb{U}$  and  $\mathbb{U}'$ , may have different Delaunay graphs.
2. Investigate the effect of changing the definition of the sa-tree to be based on finding a smallest possible set  $N(a) \subset S \setminus \{a\}$  such that  $x$  is in  $N(a)$  if and only if for all  $y \in N(a) \setminus \{x\}$ ,  $d(x, a) \leq d(x, y)$ , instead of  $d(x, a) < d(x, y)$ .
3. Give a detailed description of Navarro's [1347] heuristic algorithm to construct the sa-tree.
4. The presence of edge  $hq$  in the sa-tree in Figure 4.65(b) demonstrates that the sa-tree is not necessarily a subgraph of the Delaunay graph as edge  $hq$  is not present in the corresponding Delaunay graph in Figure 4.64(b) (which is actually a Delaunay triangulation). Can you give some necessary or sufficient conditions for the sa-tree to be a subgraph of the Delaunay graph that it approximates?

Figure 4.65  
 The sa-trees corresponding to the Delaunay graph realized by the planar embedding of Figure 4.64 when using objects (a)  $r$ , (b)  $a$ , (c)  $d$ , and (d)  $b$  as the roots.

### 4.5.5.2 Search

Using the sa-tree, it is easy to perform exact match queries (i.e., to search for an object in  $S$ ) with the same procedure as in the Delaunay graph, as described above. Of course, this is not very useful, as the query object is typically not in  $S$  in most actual queries. Nearest neighbor and range search can be performed in the sa-tree for arbitrary query objects  $q$  by using Lemma 4.4. In particular, if  $a$  is the object corresponding to a root node, let  $c$  be some object in  $\{a\} \cup N(a)$ . Letting  $b$  be an arbitrary object in  $N(a)$  and  $o$  be an object in the subtree associated with  $b$  (i.e., rooted at  $b$ ), we know that  $o$  is closer to  $b$  than to  $c$  (or equidistant, e.g., if  $c = b$ ). Thus, we can apply Lemma 4.4 to yield the lower bound  $(d(q, b) - d(q, c))/2$  on  $d(q, o)$ —that is,  $o$  is at a distance of at least  $(d(q, b) - d(q, c))/2$  from  $q$ . Since  $o$  does not depend on  $c$ , we can select  $c$  in such a way that the lower bound on  $d(q, o)$  is maximized, which occurs when  $d(q, c)$  is as small as possible—that is,  $c$  is the object in  $\{a\} \cup N(a)$  that is closest to  $q$ .

When performing range search with query radius  $\varepsilon$ , we can use the lower bound on the distances derived above to prune the search. In particular, the search is realized with a depth-first traversal of the tree, starting at the root. When at node  $a$ , we first find the object  $c \in \{a\} \cup N(a)$  for which  $d(q, c)$  is minimized. Next, the search traversal visits each child  $b \in N(a)$ , except those for which  $(d(q, b) - d(q, c))/2 > \varepsilon$  (or, equivalently,  $d(q, b) > d(q, c) + 2\varepsilon$ , as used in [1347]) since in this case we know that  $d(q, o) > \varepsilon$  for any object  $o$  in the subtree rooted at  $b$ .

Recalling our observations in Section 4.5.1 about Lemma 4.4, we note that this strategy is the same as the one that we would use in determining which Voronoi regions to examine when performing a range search in a Voronoi diagram (i.e., find all objects within  $\varepsilon$  of query object  $q$ ). In essence, we compute the distance from  $q$  to each of the sites  $s_i$  of Voronoi region  $v_i$ , and then choose the closest site  $s$  to  $q$ . Next, we eliminate every Voronoi region whose site  $s_i$  satisfies  $(d(q, s_i) - d(q, s)) > 2 \cdot \varepsilon$  as the intersection of the Voronoi region  $v_i$  of  $s_i$  with the query range of radius  $\varepsilon$  centered at  $q$  is empty. In this case, the set  $N(a)$  plays the role of the sites of the Voronoi regions, and  $c$  plays the role of the site that is closest to  $q$ .

In addition, the search traversal can also make use of  $d_{\max}(b)$  (the maximum distance from  $b$  of the objects in the subtree rooted at  $b$ ) for pruning, thus discarding subtrees for which  $d(q, b) - d_{\max}(b) > \varepsilon$ . To see why this can be done, we observe that, from the triangle inequality, we know that  $d(q, o) \geq d(q, b) - d(b, o)$  for any object  $o$ , including any object  $o$  in the subtree rooted at  $b$ . We also know that for every object  $o$  in the subtree rooted at  $b$ , we have that  $d_{\max}(b) \geq d(b, o)$ . Substituting this inequality into  $d(q, o) \geq d(q, b) - d(b, o)$  shows that

$$d(q, o) \geq d(q, b) - d_{\max}(b) \quad \text{for all objects } o \text{ in the subtree rooted at } b. \quad (4.6)$$

Therefore, whenever  $d(q, b) - d_{\max}(b) > \varepsilon$ , we have that  $d(q, o) > \varepsilon$  as well, and thus any object  $o$  in the subtree rooted at  $b$  can be pruned in this case.

It should be clear that the search process that we have described usually descends several of the subtrees of  $a$  in the process of determining the objects that satisfy the range query, and thus it will require backtracking. This is because, unlike exact match search in an sa-tree, where the fact that we know in advance the identity of the object  $q$  that we are seeking means that we only pursue one path to find it, in the range searching query we do not know in advance the identity of the objects that will satisfy the range and thus more paths in the tree must be pursued.

Hjaltason and Samet [851, 853] have identified a slight optimization over the search strategy presented in [1347] (which is equivalent to what we described above). In particular, instead of basing the selection of  $c$  on the set  $\{a\} \cup N(a)$  (i.e., based on their distances from  $q$ ), we can use the larger set  $A_N(b)$ , where  $b$  is an arbitrary element of  $N(a)$ . We define  $A_N(b) = \bigcup_{a' \in A(b)} (\{a'\} \cup N(a'))$ , where  $A(b)$  is defined to be the set of ancestors of  $b$ . Note that  $A_N(b)$  is the same for all  $b \in N(a)$ . In other words,  $c$  is the closest to  $q$  among  $b$ 's ancestors and all of their immediate children (see Exercise 1). We call the objects in  $A_N(b)$  the *ancestor neighbors* of  $b$ , where we define the ancestor neighbor of the root to be the root itself. Since a larger set is used to select  $c$ , this may possibly provide a larger value for the lower bound  $(d(q, b) - d(q, c))/2$  on  $d(q, o)$ .

Recalling that the search in the sa-tree proceeds in a top-down manner starting at the root of the sa-tree, it may appear that the expansion of the set from which  $c$  is chosen requires us to examine the ancestors and all of their immediate children each time that a node is visited. However, this is not necessary as we can simply keep track of the “ancestor neighbor”  $c$  that is closest to  $q$  as the tree is descended. Thus, when visiting a new node  $a$ , we evaluate  $d(q, b)$  for all  $b \in N(a)$  and replace  $c$  as the closest to  $q$  if  $d(q, b) < d(q, c)$  for some  $b$ . In fact, instead of keeping track of the identity of  $c$ , all we need to do is to keep track of the distance value  $d(q, c)$ .

Finding nearest neighbors employs a similar strategy to that used for range searching in terms of using the same type of lower bounds to prune the search. Hjaltason and Samet [853] adapt the general incremental nearest neighbor algorithm [848, 854] as given in procedure SATREEINCNEAREST below. SATREEINCNEAREST makes use of a priority queue *Queue* and proceeds in a similar manner as procedure INCNEAREST in Section 4.1.3. In particular, SATREEINCNEAREST is initialized in lines 9–11, after which the newly created priority queue, *Queue*, contains as its only element the object at the root of the sa-tree  $T$ . In each iteration of the **while** loop, starting at line 12, the element  $e$  with the smallest key is removed from *Queue* (with DEQUEUE) and processed appropriately. Notice that the sa-tree is not represented explicitly in SATREEINCNEAREST. In particular, the action of traversing the link structure of the sa-tree, as is the case when the children of a nonleaf node with  $a$  as its associated object are descended, is implicit in the sense that it is part of the formation of the neighbor set of  $a$  (i.e.,  $N(a)$ ) in line 21.

```

1  object procedure SATREEINCNEAREST( $q, T$ )
2  /* Return the nearest neighbors of  $q$  from the set of objects organized using
   the sa-tree  $T$ . */
3  value object  $q$ 
4  value pointer sa_tree  $T$ 
5  priority_queue  $Queue$ 
6  priority_queue_entry  $e$ 
7  object  $a, b$ 
8  integer  $d_a, d_{10}, MinAncestorDist$ 
9   $Queue \leftarrow$  NEWPRIORITYQUEUE()
10  $a \leftarrow$  object at the root of the sa-tree  $T$ 
11 ENQUEUE( $Queue, [a, d(q, a), d(q, a)]$ : 'node', 0)
12 while not ISEMPY( $Queue$ ) do
13    $e \leftarrow$  DEQUEUE( $Queue$ )

```

```

14  if ISOBJECT( $e$ ) then /*  $e$  is an object element */
15      [ $a$ ]  $\leftarrow e$ 
16      Report  $a$  as the next nearest neighbor
17  else /*  $e$  is a node element */
18      [ $a, d_a, MinAncestorDist$ ]  $\leftarrow e$ 
19      ENQUEUE( $Queue, [a]: \text{'object'}, d_a$ )
20       $MinAncestorDist \leftarrow \min\{MinAncestorDist, \min_{b \in N(a)}\{d(q, b)\}\}$ 
21      foreach  $b \in N(a)$  do
22           $d_{lo} = \max\{d(q, b) - d_{\max}(b), (d(q, b) - MinAncestorDist)/2\}$ 
23          ENQUEUE( $Queue, [b, d(q, b), MinAncestorDist]: \text{'node'}, d_{lo}$ )
24      enddo
25  endif
26  enddo

```

SATREEINCNEAREST differs from other adaptations of the general incremental nearest neighbor algorithm that we discussed in that each object  $a$  that is associated with a nonleaf node  $A$  in the sa-tree may be enqueued twice. The first time is when  $A$  is first encountered either as the root of the sa-tree (line 11) or as the child of another nonleaf node that has been dequeued (line 23). At this time, an entry  $e$  corresponding to  $A$  containing  $a$  and some additional information is enqueued along with the lower bound on the distance from  $a$  to an object  $o$  in the subtree associated with  $A$  (i.e., the key forming the basis of the priority queue), as well as the label ‘node’ indicating that  $e$  corresponds to a node rather than an object. The second time is when  $A$  is dequeued from the priority queue. At this time, the actual object  $a$  associated with  $A$  is enqueued along with  $a$ ’s distance from  $q$  (i.e., the key forming the basis of the priority queue), as well as the label ‘object’ indicating that  $A$  corresponds to an object rather than a node (line 19). This is followed by enqueueing  $A$ ’s children with appropriate distance values as keys.

The actual format of an element  $e$  in the priority queue depends on the nature of  $e$  (i.e., whether it is labeled ‘object’ or ‘node’). If  $e$  represents an object  $a$ , then  $e$  is of the form  $[a]$ . On the other hand, if  $e$  represents a nonleaf node  $A$  in the sa-tree whose associated object is  $a$ , then  $e$  is also used to keep track of both  $d(q, a)$  and the distance  $d(q, c)$  from  $q$  to the closest object  $c$  among the ancestor neighbors of  $a$ . Thus,  $e$  has the form  $[a, d(q, a), d(q, c)]$ . Note that, although the formulation of SATREEINCNEAREST suggests that some distances must be computed many times, it is easy to reuse distance values such that  $d(q, a)$  is computed only once for each object  $a$  that has a corresponding element on the priority queue; that is,  $d(q, a)$  for the root  $a$  need be computed only once in line 11, and the distances  $d(q, b)$  for the neighbors  $b$  of  $a$  computed in line 20 can be reused in lines 22 and 23. Reusing the distance values is also facilitated by keeping track of  $d(q, a)$  in the priority queue entry for each nonleaf node.

As pointed out above, the key for an element  $e$  should be a lower bound on the distance from  $q$  of all objects that are in the subset of  $S$  represented by  $e$ . Furthermore, to facilitate good performance of the algorithm, this lower bound should be as tight as possible (i.e., as close to the actual minimum distance from  $q$  to the objects in the subset). For an ‘object’ element  $e = [a]$ , this subset consists of the single object  $a$ , so the key equals  $d(q, a)$ . For a ‘node’ element  $e = [a, d(q, a), d(q, c)]$ , the subset represented by  $e$  equals  $a$  and all objects that are descendants of the node corresponding to  $a$ . The lower bound for this subset is computed in the same manner as when performing range search and makes use of both  $d_{\max}(a)$  (the maximum distance between  $a$  and the objects in its subtree) and  $d(q, c)$  (the minimum distance between  $q$  and “ancestor siblings” of  $a$ ). Thus, to obtain the greatest possible lower bound, we use the maximum of both  $d(q, a) - d_{\max}(a)$  and  $(d(q, a) - d(q, c))/2$  (line 22). The lower-bound property of  $d(q, a) - d_{\max}(a)$ , stated in Equation 4.6, follows from the triangle inequality in a straightforward manner, while the lower-bound property of  $(d(q, a) - d(q, c))/2$  is guaranteed by Lemma 4.4 and the fact that we can base the selection of  $c$  on the larger set  $A_N(a)$  and use  $c$  in the lemma (see Exercise 1).

In procedure SATREEINCNEAREST, the value of  $d(q, c)$  is propagated down the sa-tree as the search progresses by recording (i.e., storing) it in priority queue elements (i.e., as the third component). It is initialized to  $d(q, a)$  for the root  $a$  in line 11 (since the root  $a$  is the only ancestor neighbor of itself), while it is computed “incrementally” when processing a node element  $e$ , namely, for the elements  $b$  of the neighbor set of the object  $a$  associated with  $e$ . In particular, in line 18, the variable *MinAncestorDist* is set to  $d(q, c)$  for  $c$  among the ancestor neighbors of  $a$  (i.e.,  $A_N(a)$ ). Then, in line 20 *MinAncestorDist* is decreased if one or more of the elements of the neighbor set of  $a$  is found to be closer to  $q$ , thus ensuring that *MinAncestorDist* takes into account the ancestor neighbors of each  $b \in N(a)$ , even though we pointed out that they are all the same.

It is interesting to observe that an ‘object’ element for an object  $a$  is inserted into the queue when the associated ‘node’ element  $e$  is processed (line 19) instead of when  $e$  is originally enqueued (i.e., line 23). The rationale for postponing the enqueueing of ‘object’ elements in this manner is that this results in a smaller priority queue. In particular, if the corresponding ‘node’ and ‘object’ were enqueued at the same time (i.e., in line 23), then, in the worst case, the priority queue size could be nearly twice as large as when postponing the enqueueing of ‘object’ elements, as many objects may have both types of corresponding elements on the queue. Having a smaller priority queue is an advantage because the cost of priority queue operations is related to the queue size  $s_q$ —that is, at best, the cost of ENQUEUE, DEQUEUE, or both is at least proportional to  $\log s_q$ .

Procedure SATREEINCNEAREST is closely related to the  $k$ -nearest neighbor algorithm of Navarro [1347] in that both algorithms use a best-first traversal of the hierarchical sa-tree and a priority queue. One difference is that Navarro uses an additional separate fixed-size data structure to keep track of the  $k$  candidate nearest neighbors. In essence, Navarro’s algorithm is an adaptation of procedure BFTRAV in Section 4.2.6 and also discussed in Section 4.1.5.

Another more important difference is that, unlike Navarro’s algorithm, procedure SATREEINCNEAREST does not take the unnecessary steps to ensure that the keys of the ‘node’ elements are monotonically nondecreasing as the tree is traversed downward, which may appear to be a flaw. In particular, in SATREEINCNEAREST for  $b \in N(a)$ , the lower-bound  $d_{l_0}$  value for  $b$ , as computed in line 22, may be smaller than that for its parent  $a$ . In other words, the fact that  $b$  is in the neighbor set of  $a$  does not represent a sufficient criterion to ensure that the lower-bound properties used in line 22 (that is, the ones stated by Equations 4.6 and 4.4, respectively) provide a value for  $b$  that is greater than or equal value to that for  $a$ .<sup>37</sup> An example that demonstrates this for the lower bound of Equation 4.6, which makes use of the bound on ancestor distances (i.e.,  $d_{\max}(a) \geq d(a, b)$  for all descendants  $b$  of  $a$ ), is shown in Figure 4.66. Given a Euclidean space such as that in the figure, the lower bound for an object  $p$  (e.g., points  $a$  and  $b$  in Figure 4.66) equals the distance to the “ball” (i.e., solid circle in two dimensions) around  $p$  of radius equal to  $d_{\max}(p)$ . Thus, this lower bound is clearly smaller for  $b$  than for  $a$  in the figure. In fact, if the query object  $q$  were moved inside the dark shaded area, the value of  $d(q, b) - d_{\max}(b)$  would be negative.

It is easy to modify procedure SATREEINCNEAREST so that monotonicity is guaranteed on the keys of ‘node’ elements, as defined above (see Exercise 4). It is also easy to prove that SATREEINCNEAREST is correct even without the monotonic modification in the sense that both versions of the procedure traverse the exact same portion of the sa-tree  $T$  (i.e., dequeuing the same set of ‘node’ elements, albeit possibly in different order) as the modified procedure when invoked to produce the same number of

Figure 4.66  
An sa-tree for three points  $a$ ,  $b$ , and  $c$ , rooted at  $a$ , assuming the Euclidean distance metric. The circles around  $a$  and  $b$  denote their  $d_{\max}$  balls, beyond which we know there to be no descendants.

<sup>37</sup> The same situation arises for other metric indexing methods that also use these lower-bound properties, such as the vp-tree [1896, 2052] (see Exercise 5 in Section 4.5.2.1.2) and the gh-tree [1897] (see Exercise 7 in Section 4.5.3.1).

neighbors,<sup>38</sup>thereby guaranteeing that the neighbors of  $q$  are produced in the proper nondecreasing order of distance (see Exercise 5).

### Exercises

1. Prove that in the formation of the lower bound  $(d(q, b) - d(q, c))/2$  on  $d(q, o)$  for the sa-tree search algorithm, instead of basing the choice of  $c$  on the set  $\{a\} \cup N(a)$ , we can use the larger set  $A_N(b) = \bigcup_{a' \in A(b)} (\{a'\} \cup N(a'))$ , where  $A(b)$  is the set of ancestors of  $b$ . In other words, given a node  $a$  in an sa-tree and an object  $b'$  in a subtree  $b$  such that  $b \in N(a)$  (i.e.,  $b$  is a child of  $a$ ), prove that  $b'$  is closer to  $b$  (or equidistant) than to any of the ancestors of  $b$  or their children—that is,

$$\forall c \in A_N(b) \equiv \bigcup_{a' \in A(b)} \{a'\} \cup N(a'), d(b', b) \leq d(b', c)$$

Therefore, the object  $c$  that maximizes the lower bound  $d(q, o)$  can be chosen from any of  $b$ 's ancestors or immediate children.

2. Having succeeded in enlarging the set of objects from which  $c$  is selected during the search from  $\{a\} \cup N(a)$  to the larger set  $\bigcup_{a' \in A(a)} (\{a'\} \cup N(a'))$ , where  $A(a)$  is the set of ancestors of  $a$  (with the understanding that  $a$  is an ancestor of itself), can an even larger set be used to find an even closer object to  $q$ ? If such a larger set exists, show how it is defined. Otherwise, with the aid of an example, show why this is not possible.
3. Each time procedure SATREEINCNEAREST encounters a nonleaf node  $A$ , it enqueues the object associated with  $A$  as an element of type 'object' as well as enqueueing  $A$ 's children as elements of type 'node'. In this case, it appears that SATREEINCNEAREST will never terminate when  $A$ 's children are leaf nodes as they are enqueued as elements of type 'node'. Prove that SATREEINCNEAREST works correctly in this case in the sense that it will terminate.
4. Modify procedure SATREEINCNEAREST so that monotonicity is guaranteed on the keys of 'node' elements.
5. Prove that SATREEINCNEAREST is correct even without the monotonic modification (Exercise 4) in the sense that the two versions traverse the exact same portion of the sa-tree  $T$  (i.e., dequeuing the same set of 'node' elements, albeit possibly in different order) when invoked to produce the same number of neighbors, thereby guaranteeing that the neighbors of  $q$  are produced in the proper nondecreasing order of distance.
6. How would you modify the strategy for performing range search to use the optimization of Hjaltason and Samet [851, 853] for expanding the size of the set from which  $c$ , the closest object to  $q$ , is chosen?
7. Figure 4.65 demonstrates that the structure of the sa-tree differs considerably on the basis of which object is chosen as the root node. In particular, the trees have different maximum depths. For example, the maximum depth when  $r$  serves as the root (Figure 4.65(a)) is 4, while it is 6 when  $d$  serves as the root (Figure 4.65(d)) and 7 when  $a$  and  $d$  serve as the root (Figure 4.65(b, c), respectively), assuming that the root is at depth 0. How does the maximum depth of the sa-tree affect the efficiency of the range search query?
8. Repeat Exercise 7 for the incremental nearest neighbor query given by procedure SATREEINCNEAREST.

### 4.5.6 kNN Graph

Sebastian and Kimia [1704] suggest replacing the approximation of the Delaunay graph provided by the sa-tree [1347] (see Section 4.5.5) by what they term a *kNN graph*. In particular, the kNN graph contains as many vertices as there are objects in  $S$ , and each

---

<sup>38</sup> This statement is somewhat imprecise as it disregards the possibility of ties in the key values of priority queue elements. However, by giving 'node' elements priority over 'object' elements, the claims made here can all be shown to be true, even in the presence of ties.

Figure 4.67  
The kNN graphs for  $k = 1 \dots 5$  corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64(a): (a)  $k = 1$ , (b)  $k = 2$ , (c)  $k = 3$ , (d)  $k = 4$ , and (e)  $k = 5$ . Edges that are shown undirected correspond to bidirectional edges, which means that both vertices are in the  $k$ -nearest neighbor sets of each other.

vertex with corresponding object  $o$  has an edge to each of the vertices that correspond to the  $k$  nearest neighbors of  $o$ . As an example, consider the distance matrix representing the interobject distances for the 18 objects a–r in Figure 4.63 discussed in Section 4.5.5.1. Recall that Figure 4.64(a) is the result of embedding these objects in the two-dimensional plane, assuming that the distance is the Euclidean distance and assigning them a consistent set of coordinate values so that these distance values hold. In addition, Figure 4.64(b) is the corresponding Delaunay graph, which for this particular planar embedding is a plane graph known as the Delaunay triangulation. Figure 4.67(a–e) shows the kNN graphs for  $k = 1 \dots 5$ , respectively, corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64. Edges in the graphs that are shown as undirected correspond to bidirectional edges, which means that both vertices are in the  $k$  nearest neighbor sets of each other.

Finding the nearest neighbor in  $S$  ( $S \subset \mathbb{U}$ ) of query object  $q$  in  $\mathbb{U}$  using the kNN graph can be achieved by using the same algorithm used in the Delaunay graph. In particular, start at an arbitrary object in  $S$  and proceed to a neighboring object in  $S$  that is closer to  $q$  as long as this is possible. Upon reaching an object  $o$  in  $S$  where the objects in its neighbor set  $N(o)$  in  $S$  (i.e., the objects connected to  $o$  by an edge) are all farther away from  $q$  than  $o$ , we know that  $o$  is the nearest neighbor of  $q$ . Unfortunately, as can be seen from the different kNN graphs in Figure 4.67, there are situations where this algorithm will fail to yield the nearest neighbor. In particular, just because we found an object  $p$  whose  $k$  nearest neighbors are farther from the query object  $q$  than  $p$  does not necessarily mean that  $p$  is  $q$ 's nearest neighbor, whereas this is the case in the Delaunay graph whenever we have found an object  $p$ , all of whose nearest neighbors (rather than just  $k$ ) are farther from  $q$ .

There are several reasons for this failure. The first can be seen by examining Figure 4.67(a–c) where for low values of  $k$  (i.e.,  $k \leq 3$ ), the kNN graphs are not connected, as is the case when the kNN graph consists of disconnected subgraphs corresponding to clusters. These clusters have the same effect on the search process as local minima or maxima in optimization problems. This shortcoming can be overcome by increasing  $k$ . However, this action does have the effect of increasing the storage requirements of the data structure by a factor of  $N$  for each unit increase in the value of  $k$ .

Nevertheless, even if we increase  $k$  so that the resulting kNN graph is connected, the algorithm may still fail to find the nearest neighbor. In particular, this is the case when the search halts at an object  $p$ , that is closer to  $q$  than any of  $p$ 's  $k$  nearest neighbors but not necessarily closer to  $q$  than any of the objects that are in  $p$ 's neighbor set but are farther from  $p$  than the  $k$  nearest neighbors of  $p$ . For example, consider the query object X in the kNN graph for  $k = 4$  in Figure 4.67(d) positioned two-thirds of the way between k and r so that r is its nearest neighbor. Also consider a search that starts out at any one of objects e, f, j, k, l, m, n. In this case, assuming the planar embedding of Figure 4.64, the search will return k as the nearest neighbor instead of r. Again, this shortcoming can be overcome by further increasing the value of  $k$ . However, we do not have a guarantee that the true nearest neighbor will be found.

Sebastian and Kimia [1704] propose to overcome this drawback by extending the search neighborhood around the arbitrary object that is used as the starting point (termed a *seed*) of the search, as well as its closest neighbors obtained through use of the kNN graph, by a factor of  $\tau \geq 1$ . In particular, an object  $p_i$  is said to be  $\tau$ -closer to  $q$  with respect to  $p$  if  $d(p_i, q) \leq \tau \cdot d(p, q)$ . Armed with this definition, given an arbitrary object  $p$ , an element  $p_n$  belongs to the extended neighborhood  $EN(p, q)$  of  $p$  with respect to query object  $q$  if there exists a path  $p_0, p_1, \dots, p_n$ , where  $p = p_0$  and  $p_i$  is  $\tau$ -closer to  $q$  with respect to  $p$  for all  $i = 1, \dots, n - 1$ . An object  $p$  is now reported as the nearest neighbor of  $q$  if it is closer to  $q$  than any other object in  $EN(p, q)$ . In essence, use of the extended neighborhood enables us to be able still to get to the nearest neighbor of  $q$  when the search is at an object  $p$  that is closer to  $q$  than any of  $p$ 's  $k$  nearest neighbors but not necessarily closer to  $q$  than some of the objects that are reachable by transitioning via one of the  $k$  nearest neighbors of  $p$ . Note that the quality and performance of the

search depends directly on the value of  $\tau$ . In particular, if  $\tau$  is sufficiently large, then the extended neighborhood will contain all of the objects, in which case there is no advantage to using the method over a search that involves all of the objects. Similarly, if  $\tau$  is too small, then the extended neighborhood is small, and thus it may be the case that the true nearest neighbor will not be reported for some queries.

Unfortunately, use of the extended neighborhood will still not overcome the problem caused by the failure of the kNN graph to be connected. In particular, starting the search at a seed in a cluster, it is impossible to make a transition to the remaining clusters, even if the extended neighborhood factor  $\tau$  is set to  $\infty$ . Thus, Sebastian and Kimia [1704] propose to use a multiple number of seeds chosen to be well separated and then to retain the closest neighbor of the objects that are returned as the nearest neighbor.

The notions of an extended neighborhood and multiple seeds are combined by Sebastian and Kimia [1704] to find the nearest neighbor by making use of a variant of the best-first search algorithm described in Section 4.1. In essence, they place the elements of the extended neighborhood in a priority queue *Queue*, sorted in increasing order of their distance from  $q$ , and at each step they pick the first element in *Queue* and attempt to move towards its neighbors that are  $\tau$ -closer with respect to  $q$  than the current nearest neighbor of  $q$ . The search halts when the element at the front of *Queue* is not  $\tau$ -closer to the current nearest neighbor of  $q$ . In order to minimize the effect of a possibly poor starting object, which is the case when the data is clustered so that the kNN graph is not connected, several starting objects are used as the seeds by initializing *Queue* with a few well-separated objects from the database, thereby increasing the likelihood that all of the components of the graph will be explored.

In experiments with synthetic and real data [1704], the true nearest neighbor was usually found by the algorithm, which was also relatively insensitive to the number of seeds for a given range of neighborhood extension parameter  $\tau$  values, while also saving a good number of distance computations over a search that involved all objects. Note that, regardless of these experiments, this method may still yield an approximate nearest neighbor search (see Section 4.3) instead of an exact nearest neighbor search, as is the case in the sa-tree. Of course, exact nearest neighbor search in the sa-tree comes at the cost of some backtracking. However, there is also an element of backtracking involved in the kNN graph due to the use of a multiple number of seed objects.

Observe that the nearest neighbor search algorithm for the kNN graph does not make use of any of the properties of a metric space such as the triangle inequality (see Exercise 6). Thus, the algorithm would work correctly even if the distances between the objects were chosen arbitrarily. This is in contrast to the sa-tree, where the triangle inequality is an integral part of the search algorithm. Note also that using multiple seeds in the kNN graph nearest neighbor finding algorithm is somewhat similar to using different objects for the root in the sa-tree. For example, recall Figure 4.65(a–d), which shows the sa-trees corresponding to the Delaunay graph realized by the planar embedding of Figure 4.64 when using objects  $r$ ,  $a$ ,  $d$ , and  $b$ , respectively, as the roots.

At this point, let us repeat that the motivation for the development of the kNN graph is to provide an approximation of the Delaunay graph. As we saw, one of the principal drawbacks of the kNN graph is that it is not necessarily connected, especially for low values of  $k$ . In the case of an embedding in the Euclidean plane, we can take advantage of some well-known properties of other approximations of the Delaunay graph, which are known to be connected by virtue of being supersets of the minimal spanning tree (MST) (e.g., [836]) of the vertices, while simultaneously being subsets of the Delaunay graph (i.e., the Delaunay triangulation in the Euclidean plane). For example, Figure 4.68(a) is the minimal spanning tree corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64.

One such approximation is the relative neighborhood graph (RNG) [1883], where there is an edge between vertices  $u$  and  $v$  if, for all vertices  $p$ ,  $u$  is closer to  $v$  than is  $p$  or  $v$  is closer to  $u$  than is  $p$ —that is,  $d(u, v) \leq \max\{d(p, u), d(p, v)\}$  (see also Exercises 8–15).

Figure 4.68  
 The (a) minimal spanning tree, (b) relative neighborhood graph, and (c) Gabriel graph corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64(a).

Figure 4.69  
Example showing the criterion for the existence of an edge between vertices  $u$  and  $v$  in a relative neighborhood graph for a two-dimensional Euclidean embedding.

Figure 4.70  
(a) Some of the empty lunes in the relative neighborhood graph and (b) some of the empty circles in the Gabriel graph corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64(a).

In a practical sense, assuming an  $n$ -dimensional Euclidean embedding, edge  $uv$  exists if the “lune” formed by the intersection of two spheres centered at  $u$  and  $v$ , each having radius  $d(u, v)$ , is empty (e.g., Figure 4.69 for a two-dimensional Euclidean embedding). For example, Figure 4.68(b) is the relative neighborhood graph corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64.

Another approximation is the Gabriel graph (GG) [667], where there is an edge between vertices  $u$  and  $v$  if, for all other vertices  $p$ , we have that  $d(u, p)^2 + d(v, p)^2 \geq d(u, v)^2$ . In other words, the square of the distance between them is less than or equal to the sum of the squares of their distances to any other vertex (see also Exercises 18–22). In a practical sense, assuming an  $n$ -dimensional Euclidean embedding, edge  $uv$  exists if the “sphere” having diameter  $d(u, v)$  centered at the midpoint of  $uv$  is empty. For example, Figure 4.68(c) is the Gabriel graph corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64.

Clearly, both of the approximations resulting from use of the relative neighborhood graph and the Gabriel graph can be applied to an arbitrary metric space—that is, they are not restricted to the Euclidean plane or to one of the Minkowski metrics  $L_i$ . In fact, both the relative neighborhood graph and the Gabriel graph can be viewed as variants of the Minkowski metrics when using a bidistance function that is defined in terms of a distance  $d_i(p, (u, v))$  from an arbitrary object  $p$  to two fixed objects  $u$  and  $v$  so that  $d_i(p, (u, v)) = (d(p, u)^i + d(p, v)^i)^{1/i}$ . Using this definition, an edge  $uv$  is in the relative neighborhood graph if and only if  $d(u, v) \leq d_\infty(p, (u, v)) = \max\{d(p, u), d(p, v)\}$ , and in the Gabriel graph if and only if  $d(u, v) \leq d_2(p, (u, v)) = \sqrt{d(p, u)^2 + d(p, v)^2}$ . In other words, the condition for the existence of an edge between  $u$  and  $v$  using distance metric  $d_i(p, (u, v))$  is one that stipulates that the locus of all objects  $p$ , at a distance  $d_i(p, (u, v))$  from  $u$  and  $v$  that is less than  $d(u, v)$ , must be empty. The similarity between the relative neighborhood graph and the Gabriel graph, with their corresponding bidistance functions  $d_\infty(p, (u, v))$  and  $d_2(p, (u, v))$  to the  $L_\infty$  and  $L_2$  norms, respectively, should be clear (see also Exercise 16). For example, Figure 4.70(a–b) shows some of the empty lunes and circles in the relative neighborhood graph and Gabriel graph, respectively, corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64. Notice that the graph implied by the  $d_1$  bidistance function contains an edge between  $u$  and  $v$  if for all other objects  $p$ , we have  $d(u, p) + d(p, v) \geq d(u, v)$ . Thus, if the objects are drawn from a metric space, then the graph is a complete graph. Conversely, if the objects are drawn from a nonmetric space, and for three of the drawn objects  $u$ ,  $v$ , and  $p$ , the triangle equality does not hold, then the graph implied by the  $d_1$  bidistance function is not a complete graph.

We now note that we can similarly define multidistance functions from an arbitrary object  $p$  to an arbitrary number  $k$  of objects referenced as  $\langle u_j \rangle$  (where  $j$  runs from 1 to  $k$ ) so that  $d_i(p, \langle u_j \rangle) = (\sum_{j=1}^k (d(p, u_j)^i)^{1/i}$ . At this point, the analogy with the  $L_i$  metrics can be seen further by noting that the  $L_i$  metrics are multidistance functions from an object to each of the  $k$  axes. It is also interesting to observe that use of the multidistance function is somewhat like a process of embedding a vector space in a metric space and hence is the inverse of the conventional use of embedding methods where a distance function is given for a set of  $N$  objects, and a set of  $k$ -dimensional points is obtained so that the distance between these points is as close as possible to the original distance between their corresponding objects (see Section 4.7 for more details).

For a given embedding in the Euclidean plane with edges  $E$ , it can be shown that  $\text{MST}(E) \subset \text{RNG}(E) \subset \text{GG}(E) \subset \text{DT}(E)$  (e.g., [947, 1883]). In fact, by defining DT using the disc property,<sup>39</sup> this subset hierarchy has been shown to hold for all Minkowski

<sup>39</sup> Recall Section 2.2.1.4 of Chapter 2, where, using the notation of this section, an edge between two vertices  $q$  and  $r$  corresponding to objects in  $S$  is an edge of the DT of  $S$  if and only if there exists at least one sphere (i.e., a circle in two dimensions)  $c$  with respect to the metric being used so that its boundary contains  $q$  and  $r$  such that no other point in  $S$  lies inside  $c$ .

metrics  $L_p$  and arbitrary dimension [1422, 947]. It should be clear that the definitions of the RNG and the GG are applicable in any metric space, and  $\text{RNG} \subset \text{GG}$  holds in any space, even with nonmetric distances (as long as the distances are positive). However, for these graphs to be a subset of DT, we need to redefine DT as well as GG (see Exercise 23) and RNG (see Exercise 24).

We can also use these approximations for nearest neighbor searching in an analogous manner to that which we described for the Delaunay graph and the kNN graph—that is, we start at an arbitrary object in  $S$  and proceed to a neighboring object in  $S$  that is closer to  $q$  as long as this is possible. Again, unless the graph of the approximation is a superset of the DT (which it is not), we will need to be able to force the algorithm to make a transition to other neighbors of the current object, even if they are farther from the query object  $q$  than the current object. Recall that Sebastian and Kimia [1704] achieve this in the kNN graph by making use of the extended neighborhood. In the sa-tree, this is achieved by pruning the search whenever it can be shown (usually with the aid of the triangle inequality) that it is impossible to reach the nearest neighbor via a transition to the current neighbor or set of neighbors. The advantage of approximations such as the RNG and the GG over the kNN graph is that there is no need to be concerned about the lack of connectedness and thus there is no need to introduce the seeds. On the other hand, the kNN graph has the property that the  $k$  nearest neighbors are precomputed and represented as edges in the graph. We can take advantage of this when the query object is close to one of the vertices of the kNN graph as further search is not needed (see Exercise 7).

It should be clear that the greater the number of edges of the Delaunay graph that are present in the approximation, the greater is the extent of the pruning that is achievable as there are more possible transitions and thus there are more possible transitions to be pruned. On the other hand, if we cannot use all of the information about the properties and relations of distances of the neighbors of a vertex, then working with a smaller subset of the edges of the Delaunay graph will be advantageous, as there will be fewer transitions to consider pruning.

### Exercises

1. Is the kNN graph a directed graph?
2. Given a set of objects and their interobject distances, prove that the set of edges of the minimal spanning tree (MST) (e.g., [836]) of the corresponding complete graph is a superset of the edges of the corresponding kNN graph for  $k = 1$ .
3. Modify the nearest neighbor algorithm of Sebastian and Kimia [1704] described in the text to return the  $k$  nearest neighbors to query object  $q$  when the distances are indexed using a kNN graph.
4. Modify the nearest neighbor algorithm of Sebastian and Kimia [1704] described in the text to return the nearest neighbors to query object  $q$  in an incremental manner when the distances are indexed using a kNN graph.
5. Modify the nearest neighbor algorithm of Sebastian and Kimia [1704] described in the text to find all objects within a distance  $\varepsilon$  of query object  $q$  when the distances are indexed using a kNN graph.
6. Can you make the nearest neighbor algorithm of Sebastian and Kimia [1704] described in the text more efficient by making use of any of the properties of a metric space such as the triangle inequality to avoid computing the distances from the query object to some of the objects that are the  $k$  nearest neighbors of the objects in the kNN graph?
7. Suppose that you want to find the  $k$  nearest neighbors of query object  $q$  using the kNN graph and that one of the seeds  $s$  is very close to  $q$ . What conditions must the distances between  $q$ ,  $s$ , and the  $k$  nearest neighbors of  $s$  satisfy in order to be able to stop the search and report the  $k$  nearest neighbors of seed  $s$  as the  $k$  nearest neighbors of  $q$ ? In other words, how far can  $q$  be from  $s$  so that we can guarantee that  $q$ 's  $k$  nearest neighbors are the same as the  $k$  nearest neighbors of  $s$ ? The solution should give an upper bound for a value of  $\varepsilon$  so that  $d(q, s) < \varepsilon$

Figure 4.71  
The (a) union neighborhood graph and (b) difference neighborhood graph corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64(a).

The augmented Gabriel graph corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64(a).

guarantees that the  $k$  precomputed nearest neighbors of  $s$  are in fact the  $k$  nearest neighbors of  $q$  as well.

8. Prove that the RNG is always connected. Hint: prove that it is a superset of the MST.
9. One way to visualize the RNG is to note that there is an edge between  $u$  and  $v$  if the lune formed by the two spheres centered at  $u$  and  $v$  of radius  $d(u, v)$  is empty. In particular, the area defined by the points  $p$  such that  $\max\{d(p, u), d(p, v)\} < d(u, v)$  must be empty. In other words, the intersection of the two spheres is empty. Using this analogy, let us define another graph, which we term the *union neighborhood graph* (UNG), where there is an edge between  $u$  and  $v$  if the union of the two spheres centered at  $u$  and  $v$  of radius  $d(u, v)$  is empty—that is,  $u$  and  $v$  are closer to each other than to any other vertex. In particular, the area defined by the objects  $p$  such that  $\min\{d(p, u), d(p, v)\} \leq d(u, v)$  must be empty. For example, Figure 4.71(a) shows the UNG corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64. Prove that the UNG is not connected except for the trivial case that there are just two objects in the data.
10. Devise a way to use the UNG defined in Exercise 9 for clustering.
11. Using the same set operations analogy as in Exercise 9, define another graph, which we term the *difference neighborhood graph* (DNG), where there is an edge between  $u$  and  $v$  if the union minus the lune of the two spheres centered at  $u$  and  $v$  of radius  $d(u, v)$  is empty while the lune may or may not be empty. In particular, the area specified by the objects that satisfy  $\min\{d(p, u), d(p, v)\} \leq d(u, v) < \max\{d(p, u), d(p, v)\}$  must be empty. For example, Figure 4.71(b) shows the DNG corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64. When this DNG is used, an edge indicates that, with respect to the vertices of the edge, either all other objects in the dataset are close to both of the vertices or far from both vertices. The DNG is naturally a superset of UNG as the existence of an edge only requires that the area excluding the lune be empty. Can you prove that the DNG is not connected? If not, give an example of a connected DNG.
12. Prove that there is always an edge in the DNG between the two vertices having the largest distance from each other.
13. Devise a way to use the DNG defined in Exercise 11 for clustering.
14. In Exercise 11, we point out that the UNG is a subset of the DNG. Prove that the UNG is also a subset of the RNG.
15. Can you prove that  $\text{RNG} \cap \text{DNG} = \text{UNG}$ ? If not, then provide a counterexample and discuss the situations when it would hold.
16. In the text we point out that both the RNG and the GG can be viewed as variants of the Minkowski metrics by using a bidistance function that is defined in terms of a distance  $d_i(p, (u, v))$  from an arbitrary object  $p$  to two fixed objects  $u$  and  $v$  so that  $d_i(p, (u, v)) = (d(p, u)^i + d(p, v)^i)^{1/i}$ . In this case,  $i = \infty$  yields the RNG, and  $i = 2$  yields the GG. In particular, we noted the similarity between the RNG and the GG with their corresponding bidistance functions  $d_\infty(p, (u, v))$  and  $d_2(p, (u, v))$  to the  $L_\infty$  and  $L_2$  norms, respectively. Devise a graph in an analogous manner whose bidistance function  $d_1(p, (u, v))$  is similar to the  $L_1$  (i.e., City Block or Manhattan) norm.
17. Prove that the RNG is always a subset of the GG.
18. (Houman Alborzi) Define yet another alternative to the kNN graph in the spirit of the GG, termed an *augmented Gabriel graph* (AGG), which implicitly assumes Euclidean distance, although not restricted to the plane. In particular, given two vertices  $u$  and  $v$ , let  $\alpha$  denote the largest angle from a vertex  $p$  to  $u$  and  $v$ —that is,  $\alpha = \angle u, p, v$ . We now say that there is an edge between  $u$  and  $v$  if, for all other vertices  $w$  in the graph, the angle formed by  $w$  to  $u$  and  $v$  is less than or equal to  $\pi - \alpha$ —that is,  $\angle u, w, v \leq \pi - \alpha$ . For example, Figure 4.72 shows the AGG corresponding to the data in Figure 4.63 using the planar embedding depicted in Figure 4.64. Prove that an equivalent condition for the formation of the AGG is that an edge exists between  $u$  and  $v$  in the AGG if and only if  $\alpha \leq \pi/2$  or, for all other vertices  $w$  in the graph,  $\angle u, w, v \leq \pi - \alpha$ .
19. (Houman Alborzi) Using the definition of the AGG given in Exercise 18, show that, assuming a Euclidean distance, although not restricted to the plane, an alternative definition for the GG is that there is an edge between  $u$  and  $v$  if and only if  $\alpha \leq \pi/2$ .

20. Suppose that the AGG is defined so that, given two vertices  $u$  and  $v$ ,  $\alpha$  still denotes the largest angle from a vertex  $p$  to  $u$  and  $v$ —that is,  $\alpha = \angle u, p, v$ . However, we now say that there is an edge between  $u$  and  $v$  if, for all other vertices  $w$  in the graph that are not on the same side of edge  $uv$  as  $p$  is, the angle formed by  $w$  to  $u$  and  $v$  is less than or equal to  $\pi - \alpha$ ; that is,  $\angle u, w, v \leq \pi - \alpha$ . Show that this slight modification yields the Delaunay triangulation (DT).
21. The modification in Exercise 20 to obtain the DT is only valid in two dimensions. Provide an example in three-dimensional Euclidean space where the modification does not yield a DT.
22. Prove that the AGG with edges  $E$  fit into the hierarchy of embeddings in the Euclidean plane discussed in the text in the following manner:  $\text{MST}(E) \subset \text{RNG}(E) \subset \text{GG}(E) \subset \text{AGG}(E) \subset \text{DT}(E)$ .
23. One of the drawbacks of the definition of the GG using squared distances is that, for some non-Euclidean  $L_p$  metrics or dimensions, the resulting graph does not satisfy the property that  $\text{GG} \subset \text{DT}$ . As we observed in the text, an alternative way of defining the GG is to make use of the observation that in Euclidean space the edge  $uv$  between vertices  $u$  and  $v$  is in the GG if the minimum disc containing  $u$  and  $v$  (i.e., the disc with  $uv$  as its diameter) does not contain any other vertices. How would you generalize this property to define the GG for other metrics or dimensions?
24. Can you show that  $\text{RNG} \subset \text{GG}$  still holds when the GG is redefined as in Exercise 23—that is, that there is no need to redefine the RNG?
25. Give a definition of the AGG that can be applied to any metric or dimension.
26. Devise a nearest neighbor algorithm for the MST.
27. Devise a nearest neighbor algorithm for the RNG.
28. Devise a nearest neighbor algorithm for the GG.
29. Devise a nearest neighbor algorithm for the AGG.
30. Compare the performance of the RNG, GG, AGG, kNN graph, and the sa-tree for finding the nearest neighbor.

## 4.5.7 Distance Matrix Methods

The distance-based index methods that we have considered in the previous sections impose a hierarchy on the set of objects that guides the order of distance computations during query evaluation. In this section, we examine a number of methods that make use of a matrix that contains the interobject distances between some or all of the objects in the dataset. The rest of this section is organized as follows. Section 4.5.7.1 describes AESA (Approximating and Eliminating Search Algorithm), which precomputes the interobject distances between all objects. Section 4.5.7.2 presents LAESA (Linear AESA), which precomputes the interobject distances between a subset of the objects. Section 4.5.7.3 contains a brief discussion of additional methods based on distance matrices.

### 4.5.7.1 AESA

AESA (Approximating and Eliminating Search Algorithm) [1929, 1930]<sup>40</sup> is a nearest neighbor algorithm that has a preprocessing step that computes all  $O(N^2)$  interobject distances for the  $N$  objects in  $S$  and stores them in a matrix. At query time, the distance matrix is used to provide lower bounds on distances to objects whose distances have not yet been computed, based on object distances already computed. The process is initiated by computing the distance from the query object to an arbitrary data object, thereby allowing the establishment of the initial lower-bound distances of the remaining

---

<sup>40</sup> The difference between [1929] and [1930] lies in the presentation of the algorithm and in the order in which the objects are chosen whose distance from the query object is computed—that is, in the “approximating” step (see footnote 43 below).

data objects. The algorithm uses these lower bounds to guide the order in which objects are chosen to have their distances from the query object  $q$  computed and to eliminate objects from consideration (hopefully without computing their actual distances from  $q$ ). In other words, AESA treats all  $N$  data objects as pivot objects when performing search. Although designed for finding nearest neighbors, AESA can also be used with almost no modification to perform range searching.

According to experiments presented in [1930], nearest neighbors can be obtained with AESA using remarkably few distance computations. In particular, AESA was observed to require at least an order of magnitude fewer distance computations than competing methods and was argued to have constant-time behavior with respect to the size of the dataset [1930]. These benefits are obtained at the expense of quadratic space complexity, quadratic time preprocessing cost, and linear time and storage overhead during search. Thus, although promising, the method is practical only for relatively small datasets of at most a few thousand objects. For example, for 10,000 data objects, the distance matrix occupies about 400 MB, assuming 4 bytes per distance value. Nevertheless, if distances are expensive to evaluate and if we can afford the large preprocessing cost, the search performance is hard to beat with other methods.

Of course, we could ask if it is really worthwhile to perform  $N \cdot (N - 1)/2$  distance computations between the objects, when by using brute force we can always find the nearest object to  $q$  using  $N$  distance computations. The payoff occurs when we can be sure that the set of objects is static, and that there will be many queries (more than  $N$ , assuming that preprocessing time and query time are of equal importance), and that most of these queries will be nearest neighbor queries for low numbers of neighbors or range queries with small query radii (otherwise, AESA will tend to require  $O(N)$  distance computations, like the brute-force approach). The complexity arguments made in favor of AESA must also bear in mind that the constant-time claim refers to the number of distance computations, while the distance matrix has to be accessed many times for each query ( $\Omega(N)$  for each nearest neighbor query<sup>41</sup>), although the distance computations are usually many orders of magnitude more complex than the operation of accessing the distance matrix.

The key to the use of AESA [1930] in performing range searching and finding nearest neighbors is the property described in Lemma 4.1: for any objects  $o$  and  $p$  in the dataset  $S$  and any query object  $q \in \mathbb{U}$ , the following inequality holds:

$$|d(q, p) - d(p, o)| \leq d(q, o)$$

Thus, if  $S_c \subset S$  is the set of objects whose distances from  $q$  have been computed, the greatest known lower bound  $d_{lo}(q, o)$  on  $d(q, o)$  for any object  $o \in S \setminus S_c$  is

$$d_{lo}(q, o) = \max_{p \in S_c} \{|d(q, p) - d(p, o)|\} \quad (4.7)$$

An example of this computation is illustrated in Figure 4.73 for query object  $q$  and two objects  $o_1$  and  $o_2$  based on distances to three other objects,  $p_1$ ,  $p_2$ , and  $p_3$ , in  $S_c$ , which serve as pivots. There are three directed lines emanating from each object  $o_1$  and  $o_2$  to the closest possible object position on the ball of radius  $d(q, p_j)$  centered at each of the three different pivots  $p_j (j = 1 \dots 3)$  and passing through the query object  $q$ . The lines are labeled with these distance values (i.e.,  $|d(q, p_j) - d(p_j, o_i)|$ ) in parentheses. For each object  $o_i$ , the solid directed line is the longest, and its corresponding distance value is the one that is used in computing the lower-bound distance  $d_{lo}(q, o_i)$ .

<sup>41</sup> To see why the number of accesses is at least proportional to  $N$  (i.e.,  $\Omega(N)$  instead of  $O(N)$ , which denotes at most), observe that even if the first object picked at random as the candidate nearest neighbor turns out to be the actual nearest neighbor, we still must access the distances between that object and all the other objects in order to establish that this is indeed the case.

Figure 4.73  
An example of the computation of the lower-bound distance  $d_{lo}$  for query object  $q$  and two objects  $o_1$  and  $o_2$  based on three pivots,  $p_1$ ,  $p_2$ , and  $p_3$ . Three directed lines emanate from each object  $o_i$  to the closest possible object position on the ball of radius  $d(q, p_j)$  centered at each of the three different pivots  $p_j (j = 1 \dots 3)$  and passing through the query object  $q$ . The lines are labeled with these distance values (i.e.,  $|d(q, p_j) - d(p_j, o_i)|$ ) in parentheses. For each object  $o_i$ , the solid directed line is the longest, and its corresponding distance value is the one that is used in computing the lower-bound distance  $d_{lo}(q, o_i)$ .

AESA uses this lower bound in the algorithm for range searching with query radius  $\varepsilon$  to eliminate objects  $o$  in  $S \setminus S_c$  whose lower-bound distances from  $q$  are greater than  $\varepsilon$ —that is,  $d_{lo}(q, o) > \varepsilon$ . For finding the nearest neighbor, the elimination criterion is objects  $o$  whose lower bound distances from  $q$  are greater than the distance from  $q$  of the nearest neighbor candidate  $o_n$ —that is,  $d_{lo}(q, o) > d(q, o_n)$ .<sup>42</sup> Hence, it maintains the set  $S_u \subset S$  of objects whose distances from  $q$  have not been computed and that have not been eliminated based on their lower-bound distances.

Initially, the algorithm sets  $S_c$  to the empty set,  $S_u$  to  $S$ , and  $d_{lo}(q, p)$  to 0 for all  $p \in S$ . At each step of the algorithm, the next object  $p \in S_u$  whose distance is to be computed is chosen as the one whose lower-bound distance  $d_{lo}(q, p)$  is smallest, with ties in lower-bound distances broken arbitrarily. Next, the algorithm computes  $d(q, p)$  (which, we point out, may be very expensive), adds  $p$  to the result set if  $d(q, p) \leq \varepsilon$  (in the case of finding the nearest neighbor, it instead updates the nearest neighbor candidate  $o_n$  if necessary), and then eliminates objects from  $S_u$  that cannot be within the range being searched (or that cannot be the nearest neighbor in the case of finding the nearest neighbor) as described above. The algorithm is terminated once  $S_u$  becomes empty—that is, once the greatest known lower-bound distance  $d_{lo}(q, o)$  for each object  $o \in S \setminus S_c$  is greater than  $\varepsilon$  (or  $d(q, o_n)$  in the case of finding the nearest neighbor).

Observe that in the above algorithm, the lower-bound distance,  $d_{lo}(q, o)$ , for an object  $o \in S_u$  need not be computed from scratch based on all  $p \in S_c$  each time the algorithm makes use of it. Rather, the algorithm stores the current lower-bound distance for each object  $o \in S_u$  and incrementally updates  $d_{lo}(q, o)$  in each iteration as a new distance value is computed. Storing and maintaining this information accounts for the linear space and time overhead of the algorithm, besides the quadratic space and time cost for constructing and storing the distance matrix, respectively.

The rationale for picking the object  $p$  to process next based on the smallest lower bound  $d_{lo}(q, p)$  is that, hopefully, such a choice ensures that  $p$  is relatively close to  $q$ . As pointed out by Vidal [1929], the closer  $p$  is to  $q$ , the greater the tendency is for  $|d(p, o) - d(q, p)|$  to be large, which means that the lower bound  $d_{lo}(q, o)$  is larger and hence the potential for pruning increases. Of course, other strategies for picking the next object are also possible.<sup>43</sup> Some possible strategies include picking the object at random, choosing the object with the greatest value of  $d_{lo}(q, p)$ , or even basing the choice on the upper bound  $d_{hi}(q, p)$ , where  $d_{hi}(q, p) = \min_{o \in S_c} \{d(q, o) + d(p, o)\}$ . Wang and Shasha [1951] explored several different strategies, which are described briefly in Section 4.5.7.3.

AESA is easily extended to a  $k$ -nearest neighbor algorithm by maintaining a list of the  $k$  candidate nearest neighbors seen so far and by using the largest distance among the  $k$  candidates for the elimination step. Unfortunately, this is not applicable for finding the nearest neighbors incrementally as the search radius is typically not bounded. Hjaltason and Samet [851] discuss a number of ways to define a search hierarchy based on the AESA framework so that the incremental nearest neighbor search algorithm in Section 4.1.3 can be applied. Of course, applying a range query algorithm to such a hierarchy should be equivalent to the algorithm presented above, in terms of the number of distance computations. Hjaltason and Samet [851] outline the definition of three search hierarchies, each of which has somewhat different characteristics. Conceptually, all three approaches involve the maintenance of two sets,  $S_c$  and  $S_u$ , of data objects, where

---

<sup>42</sup> If  $d_{lo}(q, o) > \varepsilon$  is satisfied, we know that  $d(q, o) > \varepsilon$ ; similarly, in the case of finding the nearest neighbor,  $d_{lo}(q, o) > d(q, o_n)$  means that  $d(q, o) > d(q, o_n)$  since  $d_{lo}(q, o) \leq d(q, o)$ .

<sup>43</sup> In the original formulation of AESA [1930], the selection criterion was actually based on picking the object  $p \in S_u$  that minimizes the value of  $\sum_{s \in S_c} \{|d(q, s) - d(s, p)|\}$  rather than that of  $d_{lo}(q, p) = \max_{s \in S_c} \{|d(q, s) - d(s, p)|\}$ , which Vidal [1929] later claimed was a better “approximation.” One possible rationale for the claimed improvement is that the former minimizes the average lower bound, while the latter minimizes the maximum of the lower bounds, which yields a tighter lower bound.

$S = S_c \cup S_u$ , whose distances from the query object have and have not been computed, respectively. Notice that in the case of incremental nearest neighbor search,  $S_u$  is larger than when it was used for range searching as no objects can be eliminated; instead, their reporting is deferred. In essence, they differ in the way in which  $S_u$  is represented, which has implications for the cost of maintaining the lower-bound distance,  $d_{lo}(q, o)$ , associated with each object  $o \in S_u$ .

### Exercise

1. Give an algorithm to find the nearest neighbors in an incremental manner using AESA.

### 4.5.7.2 LAESA

Recall that AESA is impractical for all but the smallest datasets due to the large pre-processing and storage costs. LAESA (Linear AESA) [1292] alleviates this drawback by choosing a fixed number  $M$  of pivots (termed *base prototypes* by Micó, Oncina, and Vidal [1292]), whose distances from all other objects are computed. Thus, for  $N$  data objects, the distance matrix contains  $N \cdot M$  entries rather than  $O(N^2)$  for AESA (or more precisely  $N(N - 1)/2$  entries, assuming that only the lower triangular portion of the matrix is stored). An algorithm for choosing the  $M$  pivots is presented by Micó et al. [1292]. Essentially, this algorithm attempts to choose the pivots such that they are *maximally separated*—that is, as far away from each other as possible (a similar procedure was suggested by Brin [255] for GNAT, which is described in Section 4.5.3.2).

The LAESA search strategy is very similar to that of AESA, except that some complications arise from the fact that not all objects in  $S$  serve as pivot objects in LAESA (and the distance matrix does not contain the distances between nonpivot objects). In particular, as before, let  $S_c \subset S$  be the set of objects whose distances from  $q$  have been computed, and let  $S_u \subset S \setminus S_c$  be the set of objects whose distances from  $q$  have yet to be computed and that have not been eliminated.

The distances between the query object  $q$  and the pivot objects in  $S_c$  are used to compute a lower bound on the distances of objects in  $S_u$  from  $q$ , and these lower bounds allow eliminating objects from  $S_u$  whose lower-bound distances from  $q$  are greater than  $\varepsilon$  for range searching with query radius  $\varepsilon$  (for finding the nearest neighbor, the elimination criterion is objects whose lower-bound distances from  $q$  are greater than the distance from  $q$  of the current nearest neighbor candidate  $o_n$ ). The difference here is that nonpivot objects in  $S_c$  do not help in tightening the lower-bound distances of the objects in  $S_u$ , as the distance matrix stores only the distances from the nonpivot objects to the pivot objects and not to the remaining objects. Thus, Micó et al. [1292] suggest treating the pivot objects in  $S_u$  differently from nonpivot objects when

1. selecting the next object in  $S_u$  to have its distance from  $q$  computed (since computing the distances of pivot objects early will help in tightening distance bounds) and
2. eliminating objects from  $S_u$  (since eliminating pivot objects that may later help in tightening the distance bounds is undesirable).

A number of possible policies can be established for this purpose. The policies explored by Micó et al. [1292] are simple and call for

1. selecting a pivot object in  $S_u$  over any nonpivot object and
2. eliminating pivot objects from  $S_u$  only after a certain fraction  $f$  of the pivot objects has been selected into  $S_c$  ( $f$  can range from 0% to 100%; note that if  $f = 100\%$ , pivots are never eliminated from  $S_u$ ).

As with AESA, several possible strategies can be pursued for defining a search hierarchy within the framework of LAESA, as shown in [851]. However, since LAESA is practical for much larger datasets than AESA, some of the approaches that are feasible

for AESA are too inefficient. Nevertheless, it is possible to define search hierarchies in which the use of the incremental nearest neighbor search algorithm in Section 4.1.3, without a priori knowledge of the result size, has the same cost as the LAESA nearest neighbor search strategy [851]. See Chávez et al. [330] for another search strategy that is in the spirit of the method of Nene and Nayar [1364].

It is interesting to repeat our observation (made in conjunction with the discussion of Lemma 4.1 in Section 4.5.1) that LAESA, and to a lesser extent AESA, can be viewed as variations of embedding methods (see Section 4.7) that map the distances between the objects into a  $k$ -dimensional space by using  $k$  pivots (i.e., the base prototypes in LAESA and all of the objects in AESA) as coordinates and the distances of the objects from the pivots as the coordinate values of the objects. In other words, the result of the mapping of an object  $x$  is a point  $(x_0, x_1, \dots, x_{k-1})$  whose coordinate value  $x_i$  is the distance  $d(x, p_i)$  of  $x$  from pivot  $p_i$ . Lemma 4.1 enables pruning an object  $x$  from further consideration as being within  $\varepsilon$  of query object  $q$  when  $|d(q, p_i) - d(x, p_i)| > \varepsilon$  for some coordinate corresponding to pivot  $p_i$  ( $0 \leq i \leq k - 1$ ).

### Exercise

1. Give an algorithm to find the nearest neighbors in an incremental manner using LAESA.

### 4.5.7.3 Other Distance Matrix Methods

Shapiro [1743] described a nearest neighbor algorithm, that is also applicable to range searching with query radius  $\varepsilon$  and is closely related to LAESA in that it also uses an  $N \cdot M$  distance matrix based on  $M$  pivot objects. The order in which the data objects are processed in the search is based on their positions in a list  $(o_1, o_2, \dots)$  sorted by distance from the first pivot object  $p_1$ . Thus, the search is initiated at the object whose distance from  $p_1$  is most similar to  $d(q, p_1)$ , where  $q$  is the query object—that is, the element at the position  $j$  (i.e.,  $o_j$ ) for which  $|d(q, p_1) - d(p_1, o_j)|$  is minimized (this value is a lower bound on  $d(q, o_j)$ , as shown in Lemma 4.1). The goal is to eliminate object  $o_i$  from consideration as soon as possible, thereby hopefully avoiding the need to compute its distance from  $q$ . Therefore, assuming range searching, when object  $o_i$  is processed during the search, we check whether the pruning condition  $|d(q, p_k) - d(p_k, o_i)| > \varepsilon$  (or  $|d(q, p_k) - d(p_k, o_i)| > d(q, o_n)$  for finding the nearest neighbor, where  $o_n$  is the current candidate nearest neighbor) is satisfied for each pivot object  $p_1, p_2, \dots$  in turn until  $o_i$  can be eliminated; otherwise, we compute  $d(q, o_i)$  and add  $o_i$  to the result set if  $d(q, o_i) \leq \varepsilon$  (in the case of finding the nearest neighbor, it instead updates the nearest neighbor candidate  $o_n$  if necessary). The search continues alternating in the two directions—that is, for  $i = j + 1, j - 1, j + 2, j - 2, \dots$ , stopping in either direction when the pruning condition  $|d(q, p_1) - d(p_1, o_i)| > \varepsilon$  (or  $|d(q, p_1) - d(p_1, o_i)| > d(q, o_n)$  for finding the nearest neighbor) is satisfied.

Observe that Shapiro’s algorithm is less sophisticated than LAESA in two ways:

1. The order used in the search is based on position in the sorted list ordered by distance from  $p_1$ .
2. Only the first pivot  $p_1$  affects the order in which the data objects are processed.

In contrast, LAESA uses the lower-bound distances as determined by *all* pivot objects that have been applied so far to guide the search (i.e., to choose the pivot to use next and to decide when to compute the actual distances of data objects). In other words, rather than applying all pivots for each object in turn as done by Shapiro, LAESA applies each pivot in turn for all objects. Therefore, the difference can be characterized roughly in terms of processing the pivot-object distance matrix in row-major or column-major order.

Wang and Shasha [1951] have described a general search method based on distance matrices that is similar to AESA, which is applicable to a number of problems, including

range searching and finding nearest neighbors. However, they allow for the case where only some of the distances have been precomputed, as in LAESA. In contrast to LAESA, Wang and Shasha make no assumptions about the pairs of objects for which the distance is precomputed (so that no distinction is made between pivot and nonpivot objects). In other words, we are given a set of interobject distances for arbitrary pairs of objects in  $S$ . Search is facilitated by the use of two matrices  $D_{lo}$  and  $D_{hi}$  (called *ADM* and *MIN* in [1951]), constructed on the basis of the precomputed distances, where  $D_{lo}[i, j] \leq d(o_i, o_j) \leq D_{hi}[i, j]$ , given some enumeration  $o_1, o_2, \dots, o_N$  of the objects in  $S$ .<sup>44</sup> In other words, all entries in  $D_{lo}$  and  $D_{hi}$  are initialized to 0 and  $\infty$ , respectively, except that the entries on their diagonals are set to 0, and if  $d(o_i, o_j)$  has been precomputed, then  $D_{lo}[i, j]$  and  $D_{hi}[i, j]$  are both set to  $d(o_i, o_j)$ .

A dynamic programming algorithm is described by Wang and Shasha [1951] that utilizes a generalized version of the triangle inequality<sup>45</sup> to derive values for the entries of  $D_{lo}$  and  $D_{hi}$ , whose distance values are missing, in such a way that they provide as tight a bound as possible, based on the precomputed distances that are available. In particular, the generalized triangle inequality property was used by Wang and Shasha to derive rules for updating  $D_{lo}[i, j]$  and  $D_{hi}[i, j]$  based on the values of other entries in  $D_{lo}$  and  $D_{hi}$  (some of these rules use entries in  $D_{lo}$  to update entries in  $D_{hi}$ , and others do the opposite). At search time, the matrices  $D_{lo}$  and  $D_{hi}$  are augmented so that the query object  $q$  is treated as if it were object  $o_{N+1}$ . In particular,  $D_{lo}[i, N+1]$  and  $D_{hi}[i, N+1]$  are initialized to 0 and  $\infty$ , respectively. Observe that the values of  $D_{lo}[i, N+1]$  and  $D_{hi}[i, N+1]$  correspond to the definitions of  $d_{lo}(q, o_i)$  and  $d_{hi}(q, o_i)$ , respectively, given in Section 4.5.7.1.

The range searching (as well as nearest neighbor) algorithm presented by Wang and Shasha [1951] follows the same general outline as AESA. Thus, any object  $o_i$  satisfying  $D_{lo}[i, N+1] > \varepsilon$  (or  $D_{lo}[i, N+1] > d(q, o_n)$  for finding the nearest neighbor, where  $o_n$  is the current candidate nearest neighbor) can be pruned from the search. The difference here is that when  $d(q, o_k)$  is computed for some candidate object  $o_k$ , their method attempts to update  $D_{lo}[i, j]$  and  $D_{hi}[i, j]$  (by applying their generalized triangle inequality property) for all pairs of objects  $o_i, o_j \in S$  whose actual distances are not available (i.e., they are either precomputed or computed during the search), thereby possibly yielding a tighter bound on  $d(o_i, o_j)$ . In contrast, in AESA, only the values of  $d_{lo}(q, o_i)$  and  $d_{hi}(q, o_i)$  are updated for all objects  $o_i \in S$ , corresponding to  $D_{lo}[i, N+1]$  and  $D_{hi}[i, N+1]$ , respectively.

Since updating the entire matrices  $D_{lo}$  and  $D_{hi}$  can be expensive if done for all pairs at each stage of the algorithm, Wang and Shasha [1951] describe two alternatives, one of which is almost equivalent to the updating policy used in AESA. The difference is that in AESA, upper-bound distances are not maintained, whereas such upper bounds can be used to update the values of  $d_{lo}(q, o)$  in the same way as is done for  $D_{lo}[N+1, i]$  in the method of Wang and Shasha [1951]. Wang and Shasha [1951] identify four heuristics for picking the next candidate object during search. The next object  $o_i$  for which to compute  $d(q, o_i)$  is chosen as the object in  $S_u$  (as defined in Section 4.5.7.1) having one of the following:

1. The least lower bound  $D_{lo}[i, N+1]$
2. The greatest lower bound  $D_{lo}[i, N+1]$
3. The least upper bound  $D_{hi}[i, N+1]$
4. The greatest upper bound  $D_{hi}[i, N+1]$

<sup>44</sup> Note that the matrices are symmetric and that their diagonals are 0. Thus, only the lower triangular part of each matrix is actually maintained.

<sup>45</sup> For example, based on  $d(o_1, o_4) \geq d(o_1, o_3) - d(o_3, o_4)$  and  $d(o_1, o_3) \geq d(o_1, o_2) - d(o_2, o_3)$ , we can conclude that  $d(o_1, o_4) \geq d(o_1, o_2) - d(o_2, o_3) - d(o_3, o_4)$ .

According to their experiments, the best choice is the object with the least lower-bound distance estimate (i.e., heuristic 1), which is the same as is used in AESA. Incremental nearest neighbor search in this setting is implemented in the same manner as is done for AESA [851].

Micó et al. [1291] have proposed a hybrid distance-based indexing method termed *TLAESA* that makes use of both a distance matrix and hierarchical clustering, thereby combining aspects of LAESA [1292] (see Section 4.5.7.2) and the monotonous bisector tree (mb-tree) [1383] (see Section 4.5.3.3). The hierarchical search structure used by TLAESA applies the same variation on the gh-tree as is used in the monotonous bisector tree (mb-tree): two pivots are used in each node for splitting the subset associated with the node (based on which pivot is closer), where one of the pivots in each nonroot node is inherited from its parent. The search algorithm proposed by Micó et al. uses a partial distance matrix as in LAESA, thus introducing a second set of pivots (termed *base prototypes* by Micó et al. [1291]). Initially, the algorithm computes the distances between  $q$  and all distance matrix pivots. Next, when traversing the tree structure, TLAESA uses the distance matrix pivots to compute lower bounds on the distances of the tree pivots from  $q$ , rather than computing their actual distances from  $q$ . In other words, if  $p_1, p_2, \dots, p_M$  are the distance matrix pivots, and  $p$  is a tree pivot, a lower bound  $d_{lo}(q, p)$  on  $d(q, p)$  is obtained by applying Lemma 4.1 to all the distance matrix pivots. Therefore,  $d_{lo}(q, p) \leq d(q, p)$ , where

$$d_{lo}(q, p) = \max_i \{|d(q, p_i) - d(p_i, p)|\}$$

Now, if  $r$  is the ball radius corresponding to the tree pivot  $p$ ,  $d_{lo}(q, p) - r$  is the lower bound on the distances between  $q$  and all the objects in the subtree rooted at the child node corresponding to  $p$  (via Lemma 4.3, setting  $r_{lo} = 0$ ,  $r_{hi} = r$ ,  $s_{lo} = d_{lo}(q, p)$ , and  $s_{hi} = \infty$ ). The actual distances of data objects (other than distance matrix pivots) are then computed only when reaching leaf nodes of the tree.

Several other variants of AESA and LAESA have been developed (e.g., [1533, 1932]). For example, Ramasubramanian and Paliwal [1533] have presented a variant of AESA that is tailored to vector spaces, allowing them to reduce the preprocessing cost and space complexity to  $O(nN)$ , where  $n$  is the dimensionality of the vector space (thus, there are significant savings compared to  $O(N^2)$  since  $n \ll N$ ). This algorithm appears to be quite related to LAESA.

Although both AESA and LAESA usually lead to a low number of distance computations when searching, they do have an overhead of  $O(N)$  in terms of computations other than distance. Vilar [1932] presents a technique termed *Reduced Overhead AESA* (or ROAESA for short), which is applicable to both AESA and LAESA, and reduces this overhead cost by using a heuristic to limit the set of objects whose lower-bound distances  $d_{lo}$  are updated at each step of the algorithm. In particular, rather than updating  $d_{lo}$  for all objects in  $S_u$  (to use the notation in Section 4.5.7.1), ROAESA partitions  $S_u$  into two subsets that are termed *alive* ( $S_a$ ) and *not alive* ( $S_d$ ), and only updates the  $d_{lo}$  values of the objects in  $S_a$ . ROAESA starts by picking an object  $o_1$  whose distance from  $q$  is computed, and  $o_1$  is entered into  $S_c$ . Next, it computes  $d_{lo}$  for all objects in  $S_u = S \setminus S_c$  on the basis of  $o_1$  and makes the object  $o_a$  in  $S_u$  with the lowest  $d_{lo}$  value alive—that is, initially,  $S_a = \{o_a\}$  and  $S_d = S \setminus \{o_a\}$ .

In the main loop that constitutes the search, the object in  $S_a$  with the smallest  $d_{lo}$  value is picked as the next object whose distance is computed, and the  $d_{lo}$  values of the objects in  $S_a$  are updated. Then, in an inner loop, the objects in  $S_d$  are considered in order of their  $d_{lo}$  value (i.e., which was based on the initial object  $o_1$ ) and made alive (i.e., moved from  $S_d$  to  $S_a$ ) if their  $d_{lo}$  value is lower than the minimum of  $d_n$  and  $d_a$ , where  $d_n$  is the distance of the current candidate nearest neighbor and  $d_a$  is the minimum

$d_{i_0}$  of an object in  $S_a$  (note that  $d_a$  may change in each iteration of the inner loop).<sup>46</sup> Note that ROAESA has no effect for range searching as in this case  $d_n$  is replaced by  $\varepsilon$ , and now  $S_a$  is the set of all elements of  $S_u$  that have not been eliminated by virtue of their  $d_{i_0}$  values being greater than  $\varepsilon$ .

Interestingly, some of the search hierarchies devised by Hjaltason and Samet [851] for finding nearest neighbors in an incremental manner using AESA and LAESA are related to Vilar's technique, as they also aim at reducing the amount of updating in a somewhat analogous, but more powerful, manner. In particular, in some of the search hierarchies that they proposed,  $S_u$  is partitioned into any number of subsets rather than just two (i.e., the alive and not alive objects in ROAESA), where a different number of objects in  $S_c$  are used to define  $d_{i_0}$  for each subset.

### Exercises

1. Give an algorithm to find the nearest neighbors in an incremental manner using Shapiro's algorithm.
2. Give an algorithm to find the nearest neighbors in an incremental manner using Wang and Shasha's algorithm.
3. Give an algorithm to find the nearest neighbors in an incremental manner using TLAESA.
4. Show that when all of the objects in  $S$  are sorted in the preprocessing step of AESA/LAESA on the basis of their distance from  $o_1$ , the first object that is entered into  $S_c$ , then all alive objects lie in consecutive locations in the sorted array. In other words, for all  $o_i$  that are alive, we have  $x_{i_0} \leq d(o_1, o_i) \leq x_{hi}$ , for some values  $x_{i_0}$  and  $x_{hi}$ .

### 4.5.8 SASH: Indexing without Using the Triangle Inequality

Neighborhood search strategies for the Delaunay graph and approximations such as the sa-tree [1347] (see Section 4.5.5) all make use of the triangle inequality to identify and prune search paths that are guaranteed not to lead to objects that belong to the query result set. However, as we demonstrated in Figure 4.1, when the dimensionality of the data increases, the curse of dimensionality causes the majority of interobject distances to be concentrated around their mean value, thereby drastically reducing the effectiveness of the triangle inequality in pruning search paths. The recently proposed *Spatial Approximation Sample Hierarchy* (SASH)<sup>47</sup> approximate search strategy [883, 884] attempts to circumvent this problem by appealing to the triangle inequality, regardless of whether or not it is satisfied for all objects, to establish links to objects that are likely to be neighbors of the query object, instead of using it, in the conventional manner, to eliminate objects that are guaranteed not to be neighbors.

This likelihood-based linking strategy can be understood best by considering the set  $S$  of objects, letting  $S'$  be a fixed random sample consisting of roughly half the objects of  $S$ , and assuming that we have some as-yet-unspecified search index that allows efficient approximate neighborhood queries to be performed over the points of  $S'$ . Consider the two points  $x' \in S'$  and  $x \in S \setminus S'$  in the vicinity of object  $q$  taken with respect to  $S$  (e.g., when seeking the nearest neighbors in  $S$  of  $q$ ). The triangle inequality is but one of many possible embodiments of a "closeness" relationship that stipulates that if  $a$  is close to  $b$ , and if  $b$  is close to  $c$ , then  $a$  is close to  $c$ . In particular, the triangle inequality

---

<sup>46</sup> Vilar [1932] employs a performance-improvement technique in which all of the objects in  $S$  are sorted in the preprocessing step of AESA/LAESA on the basis of their distance from  $o_1$ . It can be shown (see Exercise 4) that this means that all alive objects lie in consecutive locations in the sorted array so that the next object to become alive will be one of the objects just beyond the region of alive objects.

<sup>47</sup> This notion of SASH is different from the SASH (Self Adaptive Set of Histograms) of Lim, Wand, and Vitter [1170].

$d(x', q) \leq d(x, q) + d(x', x)$ , whether or not it is always satisfied, can be interpreted as indicating that when the distances from  $q$  to  $x$  and from  $x'$  to  $x$  are both very small, the distance from  $q$  to  $x'$  must also be small. In practice, this means that we can reasonably expect that if  $x$  is a highly ranked neighbor of both  $q$  and  $x'$  among the objects of  $S \setminus S'$ , then  $x'$  is also likely to be a highly ranked neighbor of  $q$  with respect to the set  $S'$  (e.g., when seeking the nearest neighbors in  $S'$  of  $q$ ).

The key idea in the SASH method is to treat the approximate nearest neighbor relation as an equivalence relation, even though this is not generally true (see also [450, 2064] in the fuzzy logic area). In particular, the symmetry property does not hold in general—that is,  $x$  being an approximate nearest neighbor of  $x'$  does not mean that  $x'$  must be an approximate nearest neighbor of  $x$ . In addition, the transitivity property also does not hold in general—that is,  $x$  being an approximate nearest neighbor of  $q$  and  $x'$  being an approximate nearest neighbor of  $x$  do not mean that  $x'$  must be an approximate nearest neighbor of  $q$ . The process of constructing a SASH is analogous to a UNION operation, while the process of finding the approximate nearest neighbor is analogous to a FIND operation. Transitivity plays the same role as the triangle inequality, as discussed above, with the approximate nearest neighbor relation corresponding to the “ $\leq$ ” relation on the distance values. Now, with the aid of this interpretation, we see better that instead of the conventional use of the triangle inequality to eliminate objects from consideration that are guaranteed not to be neighbors, the SASH method appeals to the triangle inequality,  $d(x', q) \leq d(q, x) + d(x', x)$ , regardless of whether or not it holds, to establish links to objects likely to be neighbors of query object  $q$ . Again, as mentioned above, this is based on the fact that when  $d(q, x)$  and  $d(x', x)$  are both very small, then  $d(q, x')$  is also very small, a property that is analogous to “nearest.” This leads us again to the implication that if  $x \in S \setminus S'$  is a highly ranked neighbor of both  $q$  and  $x' \in S'$  among objects in  $S \setminus S'$ , then  $x'$  is also likely to be a highly ranked neighbor of  $q$  among objects in  $S'$ . Now, given the assumption that the approximate nearest neighbor relation is an equivalence relation, by symmetry we have that  $x'$  is a highly ranked neighbor of  $x$ , combined with the premise that  $x$  is a highly ranked neighbor of  $q$ , leads us to conclude by transitivity that  $x'$  is a highly ranked neighbor of  $q$ .

The basic SASH approximate nearest neighbor search strategy exploits this closeness relationship, which generally, but not always, holds by using the neighbors of  $q$  in  $S'$  to generate candidate neighbors of  $q$  from among the objects of  $S \setminus S'$ . This action corresponds to the final step in a search strategy that is applied in a top-down manner to a hierarchy of successively larger subsets of the objects until encountering  $S \setminus S'$ . The hierarchy is built in two phases in a recursive manner starting with  $S$ . In the first phase, we initially partition  $S$  at random into two sets  $S'$  and another set  $S \setminus S'$ , each of which is approximately one-half the size of  $S$ . We then recursively apply the same partitioning process to  $S'$ , thereby yielding  $S''$  and  $S' \setminus S''$ , each of which is approximately one-half the size of  $S'$ . This halving process is applied to  $S''$ , and so on, to obtain successively smaller sets until obtaining a pair of sets, at least one of which contains just one object. Assuming that  $S$  contains  $N$  objects, we have  $h = \lceil \log_2(N + 1) \rceil$  sets in the hierarchy. The complete hierarchy of  $h$  sets is called a *SASH*, and it is distinguished from subsets of the hierarchy by being identified as  $\text{SASH}_h$ . In general,  $\text{SASH}_i$  ( $1 \leq i \leq h$ ) corresponds to the first  $i$  subsets of the hierarchy starting at the root of the hierarchy. Using our example of subsets of  $S$ , we find that  $\text{SASH}_{h-1}$  contains the objects in  $S'$  and, at times, we refer to it as the *subSASH*. Similarly,  $\text{SASH}_{h-2}$  contains the objects in  $S''$  and, again, at times, we refer to it as the *subsubSASH*. As an example, consider a set of 31 objects drawn from a one-dimensional space so that the distance between them is reflected by their horizontal separation. Figure 4.74 shows one example of how these 31 objects are distributed among the five sets that form a SASH hierarchy for this data.

Once the hierarchy of sets has been obtained in the first phase, we are ready to begin the second phase in the construction of a SASH. In this phase, a directed graph is constructed. The graph is defined so that for each object  $x$  in  $\text{SASH}_i \setminus \text{SASH}_{i-1}$ , there are at most  $p$  edges to  $x$ , one from each of  $p$  approximate nearest neighbors of  $x$ , which

Figure 4.74  
Example of how 31 objects drawn from a one-dimensional space so that the distance between them is reflected by their horizontal separation are distributed among the five sets that form a SASH hierarchy for this dataset. Labels are assigned to objects that are used in subsequent figures and are positioned (i.e., above or below the objects) in a manner that facilitates subsequent rendering of the SASH hierarchy.

are labeled  $x'_j$  ( $1 \leq j \leq p$ ) in  $SASH_{i-1} \setminus SASH_{i-2}$ , where  $p$  is a small, fixed, positive value. The graph corresponding to  $SASH_h$  is constructed recursively, making use of the graph corresponding to  $SASH_{h-1}$  and starting at the root said to be at level 1, which corresponds to  $SASH_1$  and contains the root object. Again, we repeat that before starting the construction of the directed graph, the objects that form the various SASHes have been already determined by a random selection process as described above so that each level of a SASH contains approximately the same number of objects as the sum of the objects in the shallower levels.

The second phase starts at the root, which is said to be at level 1 corresponding to  $SASH_1$ , and constructs  $SASH_2$ . In general, assuming that we have constructed  $SASH_i$  for the objects at levels 1 through  $i$ , we construct  $SASH_{i+1}$  by using the edges in the directed graph that was already built for  $SASH_i$  to find the  $p$  approximate nearest neighbors in  $SASH_i \setminus SASH_{i-1}$  of each object  $o$  in the set of objects at level  $i + 1$  (i.e.,  $SASH_{i+1} \setminus SASH_i$ ). The  $p$  approximate nearest neighbors are obtained by a process described later. Once these  $p$  approximate nearest neighbors  $a_{oj}$  ( $1 \leq j \leq p$ ) are determined for each  $o$ , an edge is added from each of the  $a_{oj}$  to  $o$ . The rationale for this step is the assumption (recalling that it need not necessarily be true) that the approximate nearest neighbor relation is an equivalence relation and thus corresponds to making use of the symmetry property of the relation. If there are more than  $c$  edges emanating for a particular object  $b$  in  $SASH_i \setminus SASH_{i-1}$ , then only the edges to the closest  $c$  objects at level  $i + 1$  are retained, while the remaining objects that had  $b$  as one of their  $p$  approximate nearest neighbors are said to be *rejected* by  $b$ . This process could result in objects that cannot be reached by a path starting from the root of a SASH (such objects are termed *orphan objects*). In order to avoid this situation, it is stipulated that there must be at least one edge to each object  $o$  at level  $i + 1$  from an object  $t$  at level  $i$ , regardless of the distance from  $o$  to  $t$ , and hence an additional search is invoked to find some neighboring object that has excess capacity for a connection to it (see Exercise 10). This guarantees that  $o$  can be reached by subsequent searches that start at the root of the SASH hierarchy when executing an approximate  $k$ -nearest neighbor query. Once there is at least one edge to each object at level  $i + 1$  from an object at level  $i$ , the construction of the directed graph corresponding to  $SASH_{i+1}$  is completed. The construction process is repeated at each successively deeper level of the SASH until the edges that complete the directed graph corresponding to  $SASH_h$  have been added.

At this point, it is important to reemphasize that all neighbors that were found during the process of constructing the directed graphs corresponding to the different SASHes are approximate, as for  $x$  at level  $i$  of the SASH (i.e., in  $SASH_i \setminus SASH_{i-1}$ ), the set of candidate nearest neighbors is constrained to contain only objects at level  $i - 1$  (i.e., in  $SASH_{i-1} \setminus SASH_{i-2}$ ), rather than all of the objects in  $S$ , which is the usual case in

nearest neighbor finding. Moreover, all of the neighboring objects at level  $i$  (i.e., that have incoming edges from objects at level  $i - 1$ ) during the construction of  $SASH_i$  were found by traversing the directed graph corresponding to the existing  $SASH_{i-1}$ .

One potential problem with this construction process is that an object may have many edges emanating from it to objects in the immediately deeper level. This is not surprising as it can easily arise, for example, when we have a cluster of objects  $C$  at level  $i$  around an object  $o$  at level  $i - 1$  so that for each object  $b$  in  $C$ ,  $b$  is closer to  $o$  than to any other object in  $S \setminus C$  (e.g., as is the case for sites in a Voronoi diagram). This is why a firm limit  $c$  is placed on the number of connections each object of any  $SASH_i \setminus SASH_{i-1}$  ( $1 \leq i < h$ ) can have to an object external to it (i.e., in  $SASH_{i+1} \setminus SASH_i$ ). This limit on the out degree of SASH nodes permits better management of the execution time of the approximate  $k$ -nearest neighbor query. In practice, the limit is set at  $c = 4p$ .

The rationale for setting the limit  $c$  to  $4p$  can be seen by examining the construction of the connections from the nonsubSASH objects to the nonsubsubSASH objects. In particular, we observe that if each of the  $N/2$  nonsubSASH objects (i.e., in  $SASH_h \setminus SASH_{h-1}$ ) is connected to at most its  $p$  nearest neighbors, then there is a total of approximately  $p \cdot N/2$  connections (i.e., edges) distributed among the roughly  $N/4$  objects of subSASH \setminus subsubSASH (i.e.,  $SASH_{h-1} \setminus SASH_{h-2}$ ), for an average out degree of  $2p$ . As we pointed out above, the limit may cause some objects to be rejected. In order to minimize the number of rejections,  $c$  is chosen to be twice the average out degree. This is in the spirit of constructing a hash table in uniform hashing [1484] where the number of available locations is twice the minimum number of locations required to store all of the elements [884].

We now examine a simple example SASH as given by Figure 4.75. It is the SASH built by letting  $p = 2$ , and, in order to simplify the presentation,  $c = 5$  for the set of 18 objects a–r whose distance matrix of interobject distances is given in Figure 4.63. Figure 4.64(a) is the result of embedding these objects in the two-dimensional plane, assuming that the distance metric is the Euclidean distance, and assigning the objects a consistent set of coordinate values so that these distance values hold. In this case, the full SASH has five levels, the subSASH contains the top four levels of the full SASH, the subsubSASH contains the top three levels of the full SASH, the subsubsubSASH contains the top two levels of the full SASH, and the subsubsubsubSASH contains just

Figure 4.75  
 The SASH built by letting  $p = 2$  and  $c = 5$  for the set of 18 objects a–r whose distance matrix of interobject distances is given in Figure 4.63, while the result of embedding these objects in the two-dimensional plane, assuming that the similarity measure is the Euclidean distance, is given in Figure 4.64(a). The positions of the objects in the SASH figure depicted here do not reflect their true locations.

Figure 4.76  
SASH<sub>1</sub>, SASH<sub>2</sub>, and SASH<sub>3</sub> corresponding to the SASH hierarchy given in Figure 4.74 with  $p = 2$  and  $c = 4$ .

the top level of the full SASH (i.e., the root). Note that, although object  $k$  is one of the  $p = 2$  nearest neighbors of objects  $\{f, i, l, n, p, o\}$ , since this set has more than  $c = 5$  members, we must reject one of the objects, say  $o$ , as it is the farthest from object  $k$ . Observe, however, that all objects have at least one edge going into them.

In order to gain a better understanding of the SASH construction process, we turn to Figures 4.76–4.80, which illustrate how the directed graph corresponding to the full SASH is constructed level by level for the set of 31 objects drawn from a one-dimensional space whose distribution into five levels of a SASH hierarchy is given by Figure 4.74. In this example, we assume that  $p = 2$  and  $c = 4$ . Figure 4.76 shows the result of the steps leading to SASH<sub>1</sub>, SASH<sub>2</sub>, and SASH<sub>3</sub>. The construction of SASH<sub>1</sub>, of course, is trivial as it consists of a single object serving as the root. For the next two levels, the small number of objects at the level means that at each stage of the SASH construction, every object at levels 2 and 3 has an edge directed towards each of the objects at levels 1 and 2, respectively, and, similarly, every object at levels 1 and 2 has an edge directed towards all objects at levels 2 and 3, respectively. Of course, once the edges of the directed graph from level  $i$  to level  $i + 1$  have been determined, the edges from level  $i + 1$  to level  $i$  are discarded, as is the case here, and thus the edges from level  $i$  to  $i + 1$  are drawn without showing the direction explicitly.

Figure 4.77 shows the result of the step that leads to SASH<sub>4</sub>. In this case, a bidirectional edge (illustrated by a solid line) between objects  $b$  and  $a$  at levels  $i + 1$  and  $i$  ( $i = 3$  here), respectively, denotes that  $b$  has determined  $a$  to be one of its  $p$  nearest neighbors in  $SASH_i \setminus SASH_{i-1}$  and that  $a$  has determined  $b$  to be one of its  $c$  nearest neighbors from the objects at level  $i + 1$  (i.e.,  $SASH_{i+1} \setminus SASH_i$ ) that have determined  $a$  to be one of their  $p$  nearest neighbors in  $SASH_i \setminus SASH_{i-1}$ . On the other hand, a one-directional edge (illustrated by a broken line) from object  $b$  at level  $i + 1$  to object  $a$  at level  $i$  denotes that  $b$  has determined  $a$  to be one of its  $p$  nearest neighbors in  $SASH_i \setminus SASH_{i-1}$  but that  $a$  has determined that  $b$  is not one of its  $c$  closest neighbors from the objects at level  $i + 1$  (i.e.,  $SASH_{i+1} \setminus SASH_i$ ) that have determined  $a$  to be one of their  $p$  nearest neighbors in  $SASH_i \setminus SASH_{i-1}$ . In other words, a one-directional edge (illustrated by a broken line) from  $x$  to  $y$  reflects the fact that, in reality, the  $k$ -nearest neighbor relation is asymmetric. In this figure, we see one-dimensional edges (i.e., broken lines) from  $j$  and  $k$  to  $f$ , from  $l$  to  $e$ , from  $m$  to  $g$ , and from  $p$  and  $q$  to  $f$ . Of course, they are not present in the actual directed graph corresponding to SASH<sub>4</sub>, which consists of just the solid edges.

Figure 4.78 shows the result of the step leading to SASH<sub>5</sub>. The description of this step is analogous to that for the step that led to SASH<sub>4</sub>. Once again, we use solid and broken lines to distinguish between bidirectional and one-directional edges. In this figure, we see one-dimensional edges (broken lines) from  $r$ ,  $s$ , and  $t$  to  $h$ ; and from  $s$ ,  $t$ ,  $u$ , and  $v$  to  $i$ . Of course, they are not present in the actual directed graph corresponding to SASH<sub>5</sub>, which consists of just the solid edges.

Figure 4.77  
SASH<sub>4</sub> corresponding to the SASH hierarchy given in Figure 4.74 with  $p=2$  and  $c=4$ . The solid lines correspond to the edges in the directed graph. The broken lines correspond to objects in SASH<sub>4</sub>\SASH<sub>3</sub> whose nearest neighbors in SASH<sub>3</sub>\SASH<sub>2</sub> do not find them to be among their  $c=4$  nearest neighbors in SASH<sub>4</sub>\SASH<sub>3</sub>.

Figure 4.78  
SASH<sub>5</sub> before the resolution of the presence of orphan objects corresponding to the SASH hierarchy given in Figure 4.74 with  $p=2$  and  $c=4$ . The solid lines correspond to the edges in the directed graph. The broken lines correspond to objects in SASH<sub>5</sub>\SASH<sub>4</sub> whose nearest neighbors in SASH<sub>4</sub>\SASH<sub>3</sub> do not find them to be among their  $c=4$  nearest neighbors in SASH<sub>5</sub>\SASH<sub>4</sub>.

From Figure 4.78, we see that there are no edges from objects in SASH<sub>4</sub>\SASH<sub>3</sub> to objects  $r$ ,  $s$ , and  $t$ . In other words,  $r$ ,  $s$ , and  $t$  are orphans. As each object must be reachable from the root, we double  $p$ , the number of nearest neighbors examined when attempting to establish links from  $r$ ,  $s$ , and  $t$  to objects in SASH<sub>4</sub>\SASH<sub>3</sub>, and reapply the graph formation process. This enables  $r$ ,  $s$ , and  $t$  to link to objects  $j$  and  $k$ , all of which, in turn, find  $s$  and  $t$  to be one of their  $c=4$  nearest neighbors (ranging from  $p$  to  $2p$  in this case) in SASH<sub>4</sub>\SASH<sub>3</sub>. This is shown in Figure 4.79, where we now see two additional one-dimensional edges (i.e., broken lines) from  $r$  to  $j$  and to  $k$ , as well as four additional solid edges (i.e., between  $j$  and  $s$ ,  $j$  and  $t$ ,  $k$  and  $s$ , and  $k$  and  $t$ ).

From Figure 4.79, we see that object  $r$  remains an orphan as there are still no edges from objects in SASH<sub>4</sub>\SASH<sub>3</sub> to it. Therefore, we now quadruple  $p$ , the number of nearest neighbors examined when attempting to establish links from  $r$  to objects in SASH<sub>4</sub>\SASH<sub>3</sub> and reapply the graph formation process. This enables  $r$  to link to additional objects  $l$ ,  $m$ ,  $n$ , and  $o$ , all of which, in turn, find  $r$  to be one of their  $c=4$  nearest neighbors from the objects in SASH<sub>5</sub>\SASH<sub>4</sub> that find them as their nearest neighbors (ranging from  $p$  to  $4p$  in this case) in SASH<sub>4</sub>\SASH<sub>3</sub>. At this point, there are no orphans, and the resulting complete SASH is shown in Figure 4.80, where there are only solid lines as we no longer show the edges used to construct the SASH.

Now, let us turn to the problem of finding the approximate  $k$  nearest neighbors of  $q$  using the completed SASH. They are determined by the following procedure,

Figure 4.79  
SASH<sub>5</sub> after doubling  $p$ , the number of nearest neighbors examined when attempting to establish links from orphan objects  $r$ ,  $s$ , and  $t$  to objects in  $SASH_4 \setminus SASH_3$ , for the SASH hierarchy given in Figure 4.74 with  $p=2$  and  $c=4$ . The solid lines correspond to the edges in the directed graph. The broken lines correspond to edges from objects in  $SASH_5 \setminus SASH_4$  whose nearest neighbors in  $SASH_4 \setminus SASH_3$  do not find them to be among their nearest neighbors (ranging from  $p$  to  $2p$  in this case) in  $SASH_5 \setminus SASH_4$ .

Figure 4.80  
SASH<sub>5</sub> after quadrupling  $p$ , the number of nearest neighbors examined when attempting to establish links from orphan object  $r$  to objects in  $SASH_4 \setminus SASH_3$ , for the SASH hierarchy given in Figure 4.74 with  $p=2$  and  $c=4$ .

which descends the SASH forming  $h$  sets  $U_i$  ( $1 \leq i \leq h$ ), one at each level  $i$ , each of which consists of a set of as many as  $f(k, i) = k_i$  approximate nearest neighbors of  $q$ . Once the  $h$  sets  $U_i$  have been formed, the  $k$  nearest neighbors of  $q$  taken from the union  $U_1 \cup U_2 \cup \dots \cup U_h$  are reported as the approximate  $k$  nearest neighbors of  $q$ . The actual sets  $U_i$  are formed as follows.  $U_1$  is initialized to the root object  $r$  of the SASH (i.e.,  $SASH_1$ ). Next, those objects external to  $SASH_1$  (i.e.,  $SASH_2 \setminus SASH_1$ ) that are connected by SASH edges to members of  $U_1$  are tentatively placed in  $U_2$ . The set  $U_2$  is then pruned by eliminating all but the  $k_2$  closest objects to  $q$ . If  $U_2$  contains fewer than  $k_2$  objects, then no objects are pruned from it. This process is repeated for each level  $i$  in the SASH, forming  $U_{i+1}$  and retaining the  $k_{i+1}$  closest objects to  $q$  from the objects in  $SASH_{i+1} \setminus SASH_i$  that are connected by SASH edges to members of  $U_i \subseteq SASH_i \setminus SASH_{i-1}$ . The process terminates with the construction of  $U_h$  from  $U_{h-1}$ . It is important to note that the rationale for following the links from objects in  $U_i$  to  $U_{i+1}$  in determining the sets of candidate approximate nearest neighbors for the  $k$ -nearest neighbor query is the assumption (recalling that it need not necessarily be true) that the approximate nearest neighbor relation is an equivalence relation and thus corresponds to making use of the transitivity property of the relation.

There are many ways of choosing  $f(k, i)$ . One possibility is to let  $f(k, i) = k$  regardless of  $i$ . The drawback of this choice is that it leads to an  $O(k \log_2 N)$  execution time for the query [884] (see Exercise 4). Instead, Houle and Sakuma [884] suggest that the quantity  $k_i$  depend on that of  $k_{i+1}$  ( $1 \leq i < h$ ), with  $k_h$  being initialized to  $k$  and the dependency being such that  $k_1 = 1$ . The rationale behind this choice follows from

the definitions of  $S$  and  $S'$  and the fact that the objects of  $S'$  were chosen uniformly at random. In particular, roughly half the  $k$  nearest neighbors of  $q$  in  $S$  would be expected to belong to  $S'$  as well, regardless of the actual distribution of  $S$  and the choice of query object  $q$ . In order to be able to discover these neighbors from  $S'$ , the ratio  $k_i/k_{i+1}$  should be at least  $1/2$ . The motivation for this choice is that by doing so, the number of candidate  $k$ -nearest neighbor objects generated at level  $i + 1$  (i.e., in  $SASH_{i+1} \setminus SASH_i$ ) will exceed the number of expected  $k$ -nearest neighbor objects at level  $i$  (i.e., in  $SASH_i \setminus SASH_{i-1}$ ). Ratios greater than  $1/2$  would enable us to consider an even larger number of objects of  $S \setminus S'$  as candidate neighbors of  $q$ , at the expense of execution time. Houle and Sakuma [884] use the quantity  $k_i = k^{1-(h-i)/\log_2 N}$  in their implementation. For this quantity, the ratio  $k_i/k_{i+1}$  is guaranteed to lie between  $1/2$  and  $1$  (see Exercise 9) and leads to an execution time of

$$O\left(\frac{k^{1+\frac{1}{\log_2 N}}}{k^{\frac{1}{\log_2 N}} - 1} + \log_2 N\right)$$

for the query (see Exercise 5). The execution time simplifies to  $O(k)$  for practical choices of  $k$  and  $N$  (see Exercise 6). Note that for this definition of  $k_i$ , the number of candidate neighbors at each level is smoothly geometrically interpolated between 1 at the top (i.e., root) level of the SASH and  $k$  at the bottom level.

As an example of the process of determining the approximate  $k$  nearest neighbors, consider again the SASH in Figure 4.75, which has been constructed with the same values of  $p = 2$  and  $c = 5$ . We want to find the three ( $k = 3$ ) neighbors of object  $c$ . Using  $f(k, i) = k_i = k^{1-(h-i)/\log_2 N}$  to generate the sequence  $k_i$  and rounding the values of  $k_i$  to the nearest integer yields the sequence  $k_i = (1, 1, 2, 2, 3)$ . The sequence of sets  $U_i$  is formed as follows.  $U_1$  is initialized to the root  $g$  of the SASH.  $U_2$  is set to the objects reachable from  $U_1$  is just object  $e$ , and, since  $k_2 = 1$ , we retain  $e$  in  $U_2$ .  $U_3$  is set to the objects reachable from  $U_2$ , which are objects  $b$  and  $j$ , and, since  $k_3 = 2$ , we retain  $b$  and  $j$  in  $U_3$ .  $U_4$  is set to the objects reachable from  $U_3$ , which are objects  $a, h, k, m$ , and  $r$ , and, since  $k_4 = 2$ , we retain  $a$  and  $h$  in  $U_4$ .  $U_5$  is set to the objects reachable from  $U_4$ , which are objects  $c, d, i$ , and  $q$ , and, since  $k_5 = 3$ , we retain  $c, d$ , and  $q$  in  $U_5$ . The union of  $U_1, U_2, U_3, U_4$ , and  $U_5$  is the set  $\{a, b, c, d, e, g, h, i, j, k, m, q, r\}$ , and the closest three neighbors to  $q$  are  $a, b$ , and  $c$ . If we exclude the query point  $c$ , then the closest three neighbors are  $a, b$ , and  $d$ .

One problem with using the sequence  $f(k) = k_i = k^{1-(h-i)/\log_2 N}$  to determine how many neighbors to consider at level  $i$  in forming the sets  $U_i$  of approximate  $k$  nearest neighbors is that for small  $k$ , and large  $N$ ,  $k_i$  is 1 for small values of  $i$ . This means that  $U_i$  consists of only one neighbor at shallower levels of the SASH, which will lead to a degradation in the performance of the search algorithm. In particular, at shallow levels  $i$ , as both  $k_i$  and the number of objects in  $SASH_i \setminus SASH_{i-1}$  are relatively small, it could be the case that a greater proportion of the number of objects at level  $i$  (i.e., in  $SASH_i \setminus SASH_{i-1}$ ) that are connected by an edge to elements of  $U_{i-1}$  are exact nearest neighbors than warranted by the small value of  $k_i$ , thereby possibly leading the subsequent search process to miss some neighbors as the low value of  $k_i$  means that they are not inserted in  $U_i$ . Houle and Sakuma [884] propose to overcome this problem by modifying the definition of  $k_i$  to ensure that a minimum number of objects is retained in  $U_i$  at each level of the search for the approximate  $k$  nearest neighbors of  $q$ .

$pc$  is a good choice for this minimum and is justified as follows. As the SASH is constructed, for each object  $o$  at level  $i + 1$ , we find its  $p$  approximate nearest neighbors at level  $i$ . Each of these  $p$  approximate nearest neighboring objects at level  $i$ , say  $b$ , can have as many as  $c$  edges to  $c$  different objects at level  $i + 1$  that deem  $b$  to be one of their  $p$  approximate nearest neighbors. Therefore, the  $p$  approximate nearest neighbors at level  $i$  of object  $o$  can be among the  $p$  approximate nearest neighbors of as many as  $pc$  objects at level  $i + 1$ . So, by retaining at least  $pc$  objects in  $U_{i+1}$ , we are increasing the likelihood of  $o$ 's presence in  $U_{i+1}$  should one of the  $p$  approximate nearest neighbors of

$o$  have been in  $U_i$  (see also Exercise 8). Houle and Sakuma [884] found that, in practice, there was little difference in the accuracy of the results when a minimum value of  $0.5pc$  was used instead of  $pc$ , and the execution time was lower with the smaller minimum value, thereby leading them to the redefinition of  $k_i$  as  $k_i = \max\{k^{1-(h-i)/\log_2 N}, 0.5pc\}$ .

At this point, it is interesting to observe the relationship between the kNN graph and SASH. In particular, in the kNN graph, there is an edge from every object to all of its exact  $k$  nearest neighbors drawn from the entire set  $S$  of objects. On the other hand, in SASH, there is an edge from every object  $o$  to as many as  $p$  of its approximate nearest neighbors drawn from samples of  $S$  of varying sizes depending on the level of the SASH at which  $o$  is found. We also note that both the kNN graph and SASH never actually evaluate the triangle inequality, either at construction time or at query time. Instead (at construction time), SASH trusts its subSASH to provide good approximate neighbors when needed, while the kNN graph makes use of the edges of the graph to find the required number of neighbors.

In addition, it is easy to see that the directed graph that makes up SASH is conceptually similar to the kNN graph. In both cases, the graphs have edges from their nodes, corresponding to objects, to other nodes corresponding to neighboring objects. There are several differences. The first is that SASH is more like a tree in the sense that there are no cycles, whereas the presence of cycles is always the case in the kNN graph when the  $k$ -nearest neighbor relation is symmetric. Of course, SASH is not a tree as there is usually more than one path from the root of the SASH to any object in the SASHes formed by the remaining levels. Actually, a more relevant characterization of SASH is that it is similar to a lattice.

A key difference is that each object  $a$  in the kNN graph has  $k$  edges to each of the  $k$  exact nearest neighbors of  $a$ . In contrast, each object  $a$  at level  $i$  of SASH has up to  $c$  edges to objects at level  $i + 1$  for which  $a$  is one of the  $p$  nearest neighbors. In other words, instead of edges to the exact nearest neighboring objects, as in the kNN graph, in SASH, the edges are to objects that are likely to be nearest neighbors. In fact, SASH is similar to a reverse kNN graph where  $k = p$ , as the edges in SASH do indeed reflect the reverse of the links from objects at level  $i + 1$  to their  $p$  nearest neighbors at level  $i$  (see Exercise 15). This analogy can be used to connect it to research results on the reverse nearest neighbor (RNN) problem (e.g., [162, 1060, 1674, 1800, 1801, 1854, 2041, 2042], as well as the distance semijoin (e.g., [847, 1756, 2030]), which addresses the problem in an implicit manner for  $k = 1$ , both of which are beyond the scope of this discussion.<sup>48</sup> In this context, the objects at level  $i + 1$  connected to object  $o$  at level  $i$  are said to make up the *influence set* [1060] of  $o$  as they are the objects that have  $o$  as one of their  $p$  nearest neighbors at level  $i$ .

Both the kNN graph and SASH play the role of indexes. The difference lies in the way in which these indexes are constructed. In the case of the kNN graph, the index is built by finding the  $k$  nearest neighbors for each object. Without an existing index, which is the usual case, building the kNN graph is an  $O(N^2)$  process (see also Exercise 14). In contrast, building a SASH is considerably more efficient as the fact that a SASH is built by adding levels one by one enables the construction process to make use of the index that it has already built for the existing levels. Thus, the process is incremental. Assuming  $N_i$  objects at level  $i$  of the SASH hierarchy and ignoring orphan objects, the fact that the  $p$  approximate nearest neighbors of each object at level  $i + 1$  of the SASH can be obtained in  $O(\log_2 N_i)$  time means that the directed graph for all of the levels can be constructed in  $O(N \log_2 N)$  time as there is a total of  $N$  objects in SASH.

<sup>48</sup> Given a set of objects  $O$  and a set of locations  $S$  (termed *sites*) from the same spatial domain as  $O$ , the reverse nearest neighbors of site  $s$  are the objects  $o \in O$  such that  $\forall s_i \in S \ni s_i \neq s, d(o, s) \leq d(o, s_i)$ , where  $d$  is a distance metric. The result is analogous to an implicit Voronoi diagram, where the Voronoi regions for a site  $s$  is defined by the space spanned by the objects that have  $s$  as their nearest neighbor.

Figure 4.81  
(a) Example illustrating an embedding of objects in two-dimensional space where (b) the directed graph of the resulting partial SASH shows that two of the objects  $P_3$  and  $P_4$  at level  $i$  are linked to the sets of three objects  $\{C_4, C_5, C_6\}$  and  $\{C_7, C_8, C_9\}$ , respectively, at level  $i + 1$ , instead of to their nearest neighbors  $C_1, C_2$ , and  $C_3$  at level  $i + 1$ .

The main drawback of SASH is that the links between an object  $a$  at level  $i$  and objects at level  $i + 1$  are usually established on the basis of which objects  $o_j$  ( $1 \leq j \leq p$ ) at level  $i + 1$  find  $a$  to be among the  $p$  approximate nearest objects to them<sup>49</sup> instead of on the basis of which of all of the objects at level  $i + 1$  are found by  $a$  to be among the  $p$  approximate nearest objects. Thus, the key idea is to take advantage of a symmetry argument where an assumption is made that if  $a$  at level  $i$  is an approximate nearest neighbor of  $o$  at level  $i + 1$ , then  $o$  is also likely to be an approximate nearest neighbor of  $a$ , which we know is not generally true as the approximate nearest neighbor relation is not necessarily symmetric. The lack of symmetry is compensated for, in part, by the parameter  $c$ , which is used to determine the maximum number of objects at level  $i + 1$  that can claim object  $a$  at level  $i$  as one of their  $p$  approximate nearest neighbors. By increasing  $c$  considerably above  $p$  and only retaining edges from  $a$  to the  $c$  closest objects at level  $i + 1$  that find  $a$  as one of their  $p$  approximate nearest neighbors, SASH can avoid forming edges to objects that are not as near to  $a$  as other objects at level  $i + 1$ . However, regardless of the value of  $c$ , if an object at level  $i + 1$  does not find object  $a$  as one of its  $p$  approximate nearest neighbors, then no edge can exist from  $a$  to  $o$ , even if  $o$  is in fact the nearest neighbor of  $a$  or one of the nearest neighbors of  $a$  at level  $i + 1$ .

In other words, the main drawback of SASH is that objects at level  $i$  will not necessarily be linked to their approximate nearest neighbors at level  $i + 1$ . Figure 4.81(a) is an example embedding of objects in a two-dimensional space whose partial SASH at levels  $i$  and  $i + 1$  is given in Figure 4.81(b) with  $p = 2$  and  $c = 3$ . In this case, each of objects  $C_1, C_2$ , and  $C_3$  have  $P_1$  and  $P_2$  as their two approximate nearest neighbors, while each of  $C_4, C_5, C_6, C_7, C_8$ , and  $C_9$  will have  $P_3$  and  $P_4$  as their two approximate nearest neighbors. Thus, the resulting SASH will have links directed from  $P_1$  to  $C_1, C_2$ , and  $C_3$ ; from  $P_2$  to  $C_1, C_2$ , and  $C_3$ ; from  $P_3$  to  $C_4, C_5$ , and  $C_6$ ; and from  $P_4$  to  $C_7, C_8$ , and  $C_9$ . Notice that both  $P_3$  and  $P_4$  are not linked to their nearest neighboring objects at level  $i + 1$ . This means that if  $U_i$  at level  $i$  in the search for the  $k$  approximate nearest neighbors

<sup>49</sup> In fact, even this statement is not always true as can be seen in the presence of orphan objects. In particular, object  $o$  at level  $i + 1$  of the SASH is an orphan object when none of the  $p$  objects at level  $i$  of the SASH, which  $o$  deems as its  $p$  approximate nearest objects, find  $o$  as one of their  $c$  nearest objects at the time of the formation of the SASH. In this case, Houle and Sakuma [884] suggest that the orphan  $o$  repeatedly increase the number of parent objects it attempts to link to (see Exercise 10) until it finds at least one parent  $a$  with open child slots that will accept the orphan  $o$  as a child (i.e., linked to fewer than  $c$  child approximate nearest neighbors). Thus, we see that it may be the case that an object  $a$  at level  $i$  of the SASH is linked to an object  $o$  at level  $i + 1$  of the SASH that does not find  $a$  as one of its  $p$  approximate nearest objects at level  $i$ .

at level  $i + 1$  contains  $P_3$  or  $P_4$ , or both, but does not contain  $P_1$  or  $P_2$ , then the three nearest neighbors of  $P_3$  and  $P_4$  (i.e.,  $C_1, C_2$ , and  $C_3$ ) will not be in  $U_{i+1}$ , and there cannot be another  $P_j$  ( $j > 4$ ) in  $U_i$  with  $C_1, C_2$ , or  $C_3$  as children since  $c = 3$ , and each of  $C_1, C_2$ , and  $C_3$  at level  $i + 1$  can be a child of at most  $p = 2$  parent objects at level  $i$ . Thus, the example illustrates the point that just because an object  $a$  at level  $i$  is one of the  $p$  approximate nearest neighboring objects of object  $b$  at level  $i + 1$  does not necessarily mean that  $b$  at level  $i + 1$  is one of the  $p$  approximate nearest neighbors of  $a$  at level  $i$ . Nevertheless, despite this example, it is important to bear in mind that the assignment of the objects to the various levels of the SASH hierarchy (i.e., which objects play the role of parents and children) is done at random. Therefore, even if we try to come up with a bad scenario of object placement, in fact, the sampling process tends to neutralize it.

The previous drawback of SASH was caused by the failure of the symmetry property to hold always. The failure of the transitivity property always to hold can also lead to some quirky pathological cases, occurring rarely at a very low probability, which will cause a query possibly to miss some of the nearest neighbors. In particular, the problem arises because, when we say that a relationship is transitive, then the relationship must be capable of being applied as many times as necessary. However, if we say that objects are within  $\varepsilon$  of each other, we cannot necessarily apply the within  $\varepsilon$  relation to a chain of objects  $o_1, o_2, \dots, o_i, \dots, o_n$  and expect  $o_n$  to be within  $\varepsilon$  of  $o_1$ . Such an example is shown in the partial SASH given in Figure 4.82, where the objects are drawn from a one-dimensional space so that the distance between them is reflected by their horizontal separation. We say that Figure 4.82 is a partial SASH because not all of the elements in each level of the SASH are shown here. The basic idea illustrated by this example is that the data in the different levels of the SASH is distributed so that it is clustered in such a manner that we have two chains of nodes emanating from the root  $r$ : one leads very much to the left of  $r$  for a few levels and then veers to the right towards the query point  $q$ , while the second leads to the right, getting ever farther away from root  $r$ . Observe that Figure 4.82 does not show all of the objects; instead, we note that they are clustered around the two chains.

Now, without loss of generality, let us consider the task of finding the approximate  $k = 2$  nearest neighbors of  $q$ . Applying the approximate  $k$ -nearest neighbor algorithm for the SASH will take us down the right chain from the root in the formation of the sets  $U_i$  of the  $k$  approximate nearest neighbors of  $q$  as we assume that there are enough nodes in the clusters for our purpose. Recall that  $U_{i+1}$  is formed by retaining the  $k_i$  nearest neighbors of  $q$  from the set of objects at level  $i$  that have edges leading into them from objects in  $U_i$ . Initially, we set  $U_1 = \{r\}$  and form  $U_2 = \{s, t\}$ . At this point, it is clear from the figure that  $d(s, q) \gg d(t, q)$  and thus  $U_3$  and subsequently generated sets  $U_i$  will be

Figure 4.82 Example illustrating the partial SASH for an embedding of objects in a one-dimensional space where the assumption of transitivity will lead to  $r$  and  $t$  being reported as the approximate two nearest neighbors of  $q$  instead of  $a$  and  $b$ .

formed from the descendants of  $t$ . Thus, it is not hard to see that some of the nearest neighbors of  $q$  will be missed. In particular, we see that the path down the right chain from  $r$  through  $t$  will eventually lead us away from  $q$ . On the other hand, the path down the left chain from  $r$  through  $s$  is initially worse but eventually leads closer to  $q$ . However, our algorithm does not follow it and hence will miss reporting  $a$  and  $b$  as the two nearest neighbors of  $q$  and, instead, will report  $r$  and  $s$  as the two nearest neighbors of  $q$ .

Again, it is important to bear in mind our earlier observation made with respect to the drawback of the symmetry assumption that the assignment of the objects to the various levels of the SASH hierarchy at the time of its construction (i.e., choosing which objects play the role of parents and children) is done at random. Therefore, even if we try to come up with a bad scenario of object placement, as in this example, in fact, the sampling process used in the SASH construction tends to neutralize it. Moreover, we have additional redundancy in the SASH construction process when  $p > 1$ , and when performing a query, a wider search is conducted near the root of the SASH in order to preclude the descent from only following the bad branches. Another way of rationalizing the minimization of the likelihood of this bad case scenario is to observe that SASH transitivity fails in this way from a probabilistic standpoint in the same way that both quicksort [857] with random pivot (i.e., partition value) selection can lead to an  $O(N^2)$  execution time for the sorting process, as well as by observing that a skip list [1520] with a randomly generated skip increment can lead to an  $O(N)$  item retrieval time (i.e., search cost). Of course, both quicksort and the skip list generally perform quite well.

Although the design of SASH makes it inherently unsuitable for performing exact neighborhood queries, careful management of the parameters  $k_i$  and  $p$ , as well as additional restrictions on the maximum out degree  $c$  of the SASH structure, allow for very efficient approximate neighborhood queries at practical rates of accuracy, even for extremely high-dimensional datasets (in the hundreds of thousands or even millions of dimensions). Discussions of these and other implementation details, as well as experimental results for a variety of data types, can be found in [884]. The ability of SASH to cope with large, high-dimensional datasets makes it particularly well suited for applications such as  $k$ -nearest neighbor-based clustering [882], in which meaningful results can be obtained even when approximate neighborhood information is used.

### Exercises

1. Give an algorithm to construct a SASH for a set of  $N$  objects and given values of  $p$  and  $c$ .
2. Show that a SASH takes  $O(pN)$  storage for  $N$  objects.
3. Show that building a SASH takes  $O(pcN \log_2 N)$  time for  $N$  objects, when we do not take into account the cost of dealing with orphan objects (see Exercise 10).
4. Show that the execution time of the algorithm for determining the approximate  $k$  nearest neighbors of  $q$  when  $f(k, i) = k_i = k$  is  $O(k \log_2 N)$  for  $N$  objects.
5. Show that the execution time of the algorithm for determining the approximate  $k$  nearest neighbors of  $q$  when  $f(k, i) = k_i = \max\{k^{1-(h-i)/\log_2 N}, 0.5pc\}$  is

$$O\left(\frac{k^{1+\frac{1}{\log_2 N}}}{k^{\frac{1}{\log_2 N}} - 1} + \log_2 N\right)$$

6. Show that the execution time of the algorithm for determining the approximate  $k$  nearest neighbors of  $q$ , for  $N$  objects, when  $f(k, i) = k_i = \max\{k^{1-(h-i)/\log_2 N}, 0.5pc\}$  in Exercise 5 simplifies to  $O(k)$  when  $k$  is in  $\Omega(N^\varepsilon)$  for any constant  $\varepsilon > 0$ .
7. Suppose that there are  $b$  candidate objects in the set of possible approximate  $k$  nearest neighbors at level  $i + 1$ . For given values of  $p$  and  $c$ , what is the range of the number of possible distinct candidate objects at level  $i$  through which these  $b$  candidates at level  $i + 1$  could have been reached?

8. Suppose that there are  $a$  reachable candidate objects in the set of possible approximate  $k$  nearest neighbors at level  $i$ . For given values of  $p$  and  $c$ , what is the range of the number of possible distinct reachable candidate objects at level  $i + 1$ ?
9. Show that the ratio  $k_i/k_{i+1}$  is guaranteed to lie between  $1/2$  and  $1$  when  $k_i = k^{1-(h-i)/\log_2 N}$ .
10. While describing the construction of SASH, we point out that the existence of the limit  $c$  on the out degree of SASH nodes means that it may not be possible to connect some of the objects at level  $i + 1$  to their  $p$  approximate nearest neighbors at level  $i$ . Such objects are said to be rejected (i.e., orphan objects), and attempts are made to connect them to some other nodes. Give a strategy to achieve this.
11. Consider the following alternative method of determining the  $k$  approximate nearest neighbors of query object  $q$  in the SASH that makes use of two sets  $U$  and  $V$  to accumulate the  $k$  approximate nearest neighbors. Initially,  $U$  is empty, and  $V$  is initialized to the root object  $r$  of the SASH hierarchy (i.e.,  $\text{SASH}_1$ ). Next, the objects in  $V$  are moved to  $U$ ; also, all of the objects formerly in  $V$  are replaced by the objects in  $\text{SASH}_2 \setminus \text{SASH}_1$  to which they are connected by edges in SASH. At this point, the  $k_2$  closest objects to  $q$  from the objects in  $U$  and  $V$  are retained, which means that objects may be removed from both  $U$  and  $V$ . This process is repeated for each level  $i$  in SASH where at each level  $i$ , the objects in  $V$  that are moved to  $U$  are replaced by the objects in  $\text{SASH}_{i+1} \setminus \text{SASH}_i$  to which they are connected by edges in SASH. Once  $V$  has been reformed, the  $k_{i+1}$  closest objects to  $q$  from the objects in  $U$  and  $V$  are retained and the process is applied at level  $i + 1$ . The process terminates at level  $h - 1$ , at which time we extract the  $k_h = k$  approximate nearest neighbors from  $U$  and  $V$ . Compare this method with the one of Houle and Sakuma [884] described in the text.
12. Give an algorithm to perform a range query for a query object  $q$  and query radius  $\varepsilon$  in a SASH.
13. Discuss the issues in devising an incremental approximate nearest neighbor algorithm for a SASH.
14. Consider EXSASH, a variant of SASH that is built on the basis of the kNN graph between subsets in the same way as SASH was built. It has the same recursive structure as SASH with  $h = \lceil \log_2(N + 1) \rceil$  sets in the hierarchy. We start with a set of objects  $S$ . We first form a set  $S'$  about one-half the size of  $S$ . The set  $S \setminus S'$  forms the deepest level of  $\text{EXSASH}_h$ . It is the same as the set  $\text{EXSASH}_h \setminus \text{EXSASH}_{h-1}$ . The deepest level of  $\text{EXSASH}_{h-1}$  is  $\text{EXSASH}_{h-1} \setminus \text{EXSASH}_{h-2}$ . We connect each element in  $\text{EXSASH}_{h-1} \setminus \text{EXSASH}_{h-2}$  to its exact  $k_i$  nearest neighbors in  $\text{EXSASH}_h \setminus \text{EXSASH}_{h-1}$ . Unlike SASH, no limit is placed on the number of incoming edges from objects at level  $i$  to a particular object at level  $i + 1$ . Thus, there is no need for parameters  $p$  and  $c$  in EXSASH, although orphan objects may exist at level  $i$  in EXSASH when there are no incoming edges into them from level  $i - 1$ . Notice the difference from a true kNN graph, where each object is linked to its exact  $k$  nearest neighbors. On the other hand, in EXSASH, an object at level  $i$  is linked to its exact  $k_i$  nearest neighbors at level  $i + 1$ . Compare EXSASH and SASH. What is the advantage and disadvantage of using EXSASH?
15. Suppose that you view SASH as a reverse kNN graph, as described in the text, so that the directions of the edges are reversed once the construction of the SASH has been completed. This means that the edges are directed from objects formerly at level  $i + 1$  to as many as  $p$  of their approximate nearest neighbors at level  $i$ , and thus it behaves somewhat like EXSASH in Exercise 14. How would you use the reverse kNN graph to find nearest neighbors, and what are the pitfalls of such an approach, if any?

## 4.6 Dimension Reduction Methods

Database designers are often interested in reducing the dimension of their data. In particular, the motivation is to be able to perform search more efficiently using some indexing structure. For example, if the dimension of the data can be reduced to one, then the data can be ordered and an index built on it using conventional methods such as B-trees, thereby enabling it to be searched easily. However, for high-dimensional data, it is usually desirable to reduce to a dimension larger than one so as not to lose too much of

the information inherent in the data, in which case a multidimensional indexing method can be employed.

Unfortunately, as we point out in Section 4.4.6, there are a number of difficulties associated with the use of multidimensional indexing methods for searching in high-dimensional spaces. In particular, most of the volume is rather close to the boundaries of the dataspace (which means that data objects tend to be close to the boundaries), and, in general, there is a relatively small amount of partitioning as most of the dimensions are split at most once. In addition, the distance between data objects tends to grow rather quickly (even in the unit hypercube) as the dimension increases. This means that even the search regions (i.e., the radii) for queries that only yield a few answers will have to be rather large. These effects cause multidimensional indexing methods to become inefficient as the dimensionality increases, typically at around 8–12 dimensions, and, in particular, they become less efficient than a simple sequential scan of the entire data (since the index uses relatively expensive random disk accesses) [212]. Briefly, the reason is that the search region tends to intersect most of the regions (corresponding to leaf and nonleaf nodes) of the index hierarchy [187].

Collectively, these and other effects arising as the dimensionality increases can be explained by appealing to the *curse of dimensionality* (e.g., [159] and described in the opening of this chapter). This problem is often overcome by reducing the dimensionality of the data, thereby making it feasible to use a multidimensional index in the search. Of course, this comes at the price of a reduction in the quality of the result of the query (as elaborated upon below) unless the original data is used to refine the query result.

Besides the effects of high-dimensional space that make it inherently difficult to perform searching, effects also arise that cause specific indexing methods to degenerate. For example, members of the R-tree [791] family (i.e., disk-based spatial indexes that make use of an object hierarchy) prune the search with the aid of bounding boxes (termed *filtering*) and make more exact comparisons using the original data (termed *refinement*). Recall that algorithms that follow such a query processing strategy are characterized as being filter-and-refine algorithms [1416].

One of the drawbacks of these spatial indexes (i.e., members of the R-tree family) is that the amount of information needed to keep track of the bounding boxes becomes quite large as the dimension of the underlying data increases. This means that the nodes, which usually correspond to disk pages, in the structures that represent the index have a small fanout. The small fanout causes the structures, which are variants of B-trees, to be deep, thereby increasing the I/O cost for search queries that must descend to the leaf nodes to perform the actual comparisons needed to satisfy the queries. Several techniques have been proposed for addressing this drawback, for example, reducing the storage cost of the bounding boxes (e.g., using k-d-tree-like techniques [317]), increasing the size of the nodes [190], or using bounding spheres [1991], as discussed in Section 4.4. Nevertheless, these techniques cannot escape the inherent effects that we have discussed above.

In this section, we focus on methods that reduce the dimension of a dataset, thereby enabling the use of efficient multidimensional indexing methods. The essential intuition behind dimension reduction is that, typically, the “inherent dimensionality” of a dataset is much lower than the dimensionality of the underlying space. In other words, the data objects often (roughly) lie on some lower-dimensional surface or manifold (e.g., a line or a sphere), and the implicit goal of dimension reduction methods is to reveal this structure. Of course, such methods differ in the extent to which they succeed in satisfying this goal. In addition, it is quite possible that the “inherent dimensionality” of the data is higher than the dimension to which the data is reduced. Thus, as we mentioned above, dimension reduction carries a price: the quality of query results when performing search operations in the dimension-reduced search space may suffer. In particular, queries may return objects that should not have been in the result (i.e., *false hits*), or objects that should have been in the query result may be missing (i.e., *false dismissals*).

Note that a number of the embedding methods discussed in Section 4.7 can also be described as dimension reduction methods (e.g., locality sensitive hashing (LSH) [924] in Section 4.7.4). However, they are discussed there because of the emphasis on properties of the embedding that enable them to be used for searching, whereas satisfaction of these properties for the methods discussed in this section is a straightforward matter.

## 4.6.1 Searching in the Dimension Reduced Space

A dimension reduction method can be thought of as providing a mapping  $f$  that transforms a vector  $v$  in the original space to a vector  $f(v)$  in the transformed lower-dimension space. Letting  $d$  be the distance metric in the original space of dimensionality  $n$ , and letting  $d'$  be the distance metric in the *transformed* space of lower dimensionality  $k$ , we observe that most dimension reduction techniques attempt (implicitly or explicitly) to yield a mapping such that distances in the transformed space approximate the distances in the original space—that is,  $d(v, u) \approx d'(f(v), f(u))$ . In the rest of this section, we discuss properties of the mapping  $f$  that relate to search in the transformed space, first for range searching and then for nearest neighbor searching.

### 4.6.1.1 Range Queries

For a range query (often also termed an *epsilon query* [2026]), the query radius to be used in the transformed space is related to the query radius in the original space in a manner that depends on the dimension reduction method, as well as the distance metrics  $d$  and  $d'$ . Under the assumptions listed above, the most appropriate choice is usually to use the same query radius in the transformed space.

An interesting issue is the effect of increasing or decreasing the query radius for range search in the transformed space on the quality of the query results in the transformed space. If we reduce the query radius, then we obtain fewer incorrect candidates in the query result (i.e., fewer false hits), thereby increasing precision [1611]. On the other hand, this will most likely mean that we get fewer correct responses (i.e., more false dismissals), thereby decreasing recall [1611]. The opposite effect arises if the query radius is enlarged (i.e., precision is decreased but recall is increased). Formally, letting  $R_n$  and  $R_k$  denote the set of responses retrieved in the original and dimension reduced spaces, respectively, *precision* is  $|R_n \cap R_k|/|R_k|$  and *recall* is  $|R_n \cap R_k|/|R_n|$ . Precision and recall are not the same for range queries (see Exercise 1). However, there are queries like finding the  $i$ th-nearest neighbor for which precision and recall are the same (see Exercise 1 in Section 4.6.1.2).

Ideally, we would like the query in the transformed space to include all the correct responses (i.e., 100% recall). This property can be achieved (while using the same query radius in the transformed space) if the dimension reduction method (i.e., transformation or mapping) has the property that the distance between the transformed objects in the dimension-reduced space is always less than the distance between the objects in the original space (i.e., the mapping is *contractive*). This property is known as the *pruning property*.

**Pruning Property** Given a distance metric  $d$  in the original space, a distance metric  $d'$  in the transformed space, and a transformation  $f$ , then  $d'(f(a), f(b)) \leq d(a, b)$  for any pair of objects  $a$  and  $b$ .

Of course, satisfaction of the pruning property does not prevent the precision from being arbitrarily bad since, in the worst case, the query result in the transformed space includes all the transformed objects (i.e., the precision is  $F/N$ , where  $F$  is the size of the correct query result, and  $N$  is the size of the dataset). The practical significance of the pruning property is that the distance in the transformed space between the transformed

objects serves as a lower bound on the actual distance in the original space between the objects. In particular, the pruning property implies that if an object  $o$  in the original space is within a distance of  $r$  from a query object  $q$ , then  $f(o)$  is also within a distance of  $r$  from  $f(q)$ . Thus, a range query in the transformed space with radius  $r$  for the query object  $f(q)$  is guaranteed to yield no false dismissals.

### Exercise

1. Show that precision and recall are not the same for a range query when using dimension reduction techniques.

#### 4.6.1.2 Nearest Neighbor Queries

Unfortunately, in the case of nearest neighbor queries, the pruning property alone does not guarantee 100% recall. For such queries, a desirable property is for the relative ordering between objects to be preserved in the transformed space. This ensures that the result of performing a nearest neighbor query in the transformed space is identical to that obtained with a nearest neighbor query in the original space. This condition is stated as follows (termed the *proximity-preserving property*):

**Proximity-Preserving Property** Given a distance metric  $d$  in the original space, a distance metric  $d'$  in the transformed space, and a transformation  $f$ , then  $d(a, b) \leq d(a, c)$  implies  $d'(f(a), f(b)) \leq d'(f(a), f(c))$ , for any objects  $a, b$ , and  $c$ .

The advantage of a transformation that is proximity preserving is that nearest neighbor queries can be performed directly in the transformed space. In contrast, when only the pruning property holds (which is usually the case in our examples), then 100% recall can be achieved for nearest neighbor queries by combining nearest neighbor search in the transformed space, thereby obtaining a set of candidates, with a refine step that uses the distance values in the original space to discard incorrect candidates. Note that if we rewrite the proximity-preserving property such that  $d'(f(a), f(b)) > d'(f(a), f(c))$  implies  $d(a, b) > d(a, c)$ , then we can immediately see why there is no need to refine the candidate set when the proximity-preserving property holds.

An example of a proximity-preserving transformation is a scaling, a translation, or a combination thereof, in a vector space and when using any Minkowski distance metric  $L_p$  (where given the points  $(x_1, y_1)$  and  $(x_2, y_2)$ , the distance is defined as  $d_{L_p}((x_1, y_1), (x_2, y_2)) = ((x_1 - x_2)^p + (y_1 - y_2)^p)^{1/p}$ ). Rotation is proximity preserving when using the Euclidean distance metric in both the original and the transformed space and when there is no dimension reduction (but see Exercises 4 and 5 for other distance metrics that are not proximity preserving under rotation). However, there are many cases where the proximity-preserving property does not hold. For example, consider data in a two-dimensional space  $(x, y)$ , a dimension reduction transformation that projects the data onto the  $x$  coordinate axis, and use the Euclidean distance in both the original and the transformed space. Observe that the point  $p = (0, 0)$  is closer to point  $t = (2, 2)$  than to point  $u = (1, 10)$ , but after the projection onto the  $x$  axis,  $p$  is closer to  $u$  than to  $t$ . In general, it is difficult to find combinations of transformations and distance metrics that satisfy the proximity-preserving property while also leading to a reduction in dimension, and thus we do not deal further with this property here.

Nevertheless, even without proximity preservation, we can still implement efficient nearest neighbor query algorithms that guarantee no false dismissals, given that  $f$  satisfies the pruning property.<sup>50</sup> Such algorithms use the filter-and-refine query processing

---

<sup>50</sup> Variants of the algorithms that allow a small error in the result (thereby yielding an approximate nearest neighbor) are also possible if we wish to trade off accuracy for a possible increase in efficiency.

strategy (e.g., [851, 1063, 1716]). In particular, in the filter step, the embedding space is used as a filter to produce a set of candidates. The satisfaction of the pruning property makes it possible to guarantee that the correct result is among the candidates. For example, if  $o$  is the actual nearest neighbor of the query object  $q$ , then the filter step must at the very least produce as candidates all objects  $o'$  such that  $d'(f(q), f(o')) \leq d(q, o)$ . In the refine step, the actual distance must be computed for all the candidates to determine the actual nearest neighbor.

To elaborate on how such a query is implemented, suppose that we want to find the nearest object to a query object  $q$ . We first determine the point  $f(q)$  corresponding to  $q$ . Next, we examine the objects in the order of their distances from  $f(q)$  in the embedding space. When using a multidimensional index, this can be achieved by using an incremental nearest neighbor algorithm [846, 848]. Suppose that point  $f(a)$  corresponding to object  $a$  is the closest point to  $f(q)$  at a distance of  $d'(f(a), f(q))$ . We compute the distance  $d(a, q)$  between the corresponding objects. At this point, we know that any point farther from  $f(q)$  than  $d(a, q)$  cannot be the nearest neighbor of  $q$  since the pruning property guarantees that  $d'(f(x), f(q)) > d(a, q)$ , means that  $d(x, q) > d(a, q)$  for any object  $x$ . Therefore,  $d(a, q)$  now serves as an upper bound on the nearest neighbor search in the embedding space. We now find the next closest point  $f(b)$  corresponding to object  $b$  subject to our distance constraint  $d(a, q)$ . If  $d(b, q) < d(a, q)$ , then  $b$  and  $d(b, q)$  replace object  $a$  and  $d(a, q)$  as the current closest object and upper-bound distance, respectively; otherwise,  $a$  and  $d(a, q)$  are retained. This search continues until encountering a point  $f(x)$  with distance  $d'(f(x), f(q))$  greater than the distance to the current closest object, which is now guaranteed to be the actual closest object to  $q$ .

In fact, we may use the general version of the incremental nearest neighbor algorithm [851] described in Section 4.1.3 to find the nearest neighbor directly without needing to keep track explicitly of the upper-bound distance values above. This is achieved by extending the search hierarchy for  $T$ , the multidimensional index for  $f(S)$ , where  $S$  is the actual dataset whose dimension has been reduced by application of the transformation  $f$ , to include elements of  $S$  as well (i.e., in addition to those of  $f(S)$ ). In the search hierarchy for  $T$ , the elements of type 0 are points in  $f(S)$ , while the other elements represent nodes in  $T$  (and/or possibly some other aspects of the data structure). When extending the search hierarchy for  $T$  to form the new search hierarchy, we increment the type numbers for all the element types of the search hierarchy of  $T$  and add the objects in  $S$  as the new elements of type 0. Thus, an element  $e_1$  of type 1, representing a point  $f(o)$ , has as a child the element  $e_0$  of type 0 that represents the corresponding object  $o \in S$ .

When  $T$  is an R-tree, the extension can be simplified further. In this case (recalling Section 4.1.3), the elements of type 1 were minimum bounding rectangles of the objects. However, each object  $f(o)$  in  $f(S)$  is actually a point, so its minimum bounding box is degenerate, and thus equivalent to  $f(o)$ . Therefore, the elements of type 1 in the (original) search hierarchy for the R-tree, representing minimum bounding rectangles, always have identical distances as do the corresponding elements of type 0 (i.e., in the original search hierarchy), which represent the points in  $f(S)$  (recall from Section 4.1.2 that elements of type 2 represent R-tree nodes). Thus, the elements of type 1 can be thought of as representing the points in  $f(S)$ ,<sup>51</sup> leaving us free to let the elements of type 0 represent the objects in  $S$  (replacing the original type 0) when extending the search hierarchy for R-trees.

The distance functions of the elements in the hierarchy are based on  $d$  and  $d'$ , the distance functions for  $S$  and  $f(S)$ , respectively. In particular, for an element  $e_0$  of type 0,  $d_0(q, e_0) = d(q, o)$ , where  $o \in S$  is the object that corresponds to  $e_0$ . The distance function

<sup>51</sup> Since points occupy half as much space as rectangles, we could even replace the minimum bounding rectangles in the leaf nodes of the R-tree with the points themselves, thus doubling the capacity of the leaf nodes.

for elements of type 1, corresponding to points in  $f(S)$ , is defined as

$$d_1(q, e_1) = d'(f(q), f(o)) \quad (4.8)$$

where  $f(o)$  is the point represented by  $e_1$ . An element of type  $t \geq 2$  essentially represents a region in  $\mathbb{R}^k$  (i.e., the dimension-reduced space) that contains all the points in the corresponding subtree. If  $T$  is an R-tree, for example, elements of type 2 represent nodes, which cover regions that are rectilinear hyperrectangles. Thus, for  $t \geq 2$ , we define the distance function

$$d_t(q, e_t) = \min_{p \in R} \{d'(f(q), p)\} \quad (4.9)$$

where  $R$  is the region covered by element  $e_t$ . Usually, Equation 4.9 can be evaluated with fairly simple geometric calculations (e.g., if  $d'$  is some Minkowski distance metric and  $T$  is an R-tree, the distance is equal to the distance between  $f(q)$  and one of the faces of the hyperrectangle  $R$ , or zero if  $f(q)$  is inside  $R$ ).

Assuming that  $T$  is an R-tree, incremental nearest neighbor search using the above search hierarchy would proceed as follows (see procedure INCNEAREST). Initially, the root of the R-tree would be inserted on the priority queue as an element of type 2. If the element  $e_t$  taken off the queue is of type 2, representing a node  $u$ , we insert elements of type 1 (if  $u$  is a leaf node) or 2 (if  $u$  is a nonleaf node) into the priority queue based on the entries in  $u$ . If the element  $e_t$  that comes off the priority queue is of type 1, we insert the corresponding object as an element of type 0. Finally, if the element  $e_t$  is of type 0, we report the corresponding object as the next nearest neighbor. Figure 4.83 depicts how the algorithm would proceed on a small example consisting of three objects  $a$ ,  $b$ , and  $c$ , and their transformed versions  $F(a)$ ,  $F(b)$ ,  $F(c)$ , respectively, using transformation  $F$ . Both are shown here as two-dimensional points; we can also think of the figure as merely showing the relative distances of the objects from  $q$  and the mapped objects from  $F(q)$ . Observe that the distance  $d(q, c)$  need not be computed by the algorithm since  $\delta(F(q), F(c)) > d(q, b)$ .

### Exercises

1. Show that precision and recall [1611] are identical for finding the  $i$ th nearest neighbor when using dimension reduction techniques.
2. Consider data in a two-dimensional space  $(x, y)$  and a dimension reduction transformation  $f$  that projects the data onto the  $y$  coordinate axis. Use the Chessboard distance  $d_M$  in both the original and the transformed space, which, given the points  $(x_1, y_1)$  and  $(x_2, y_2)$ , is defined as  $d_M((x_1, y_1), (x_2, y_2)) = \max(|x_1 - x_2|, |y_1 - y_2|)$ . Give an example to show that the proximity-preserving property does not hold in this case.
3. Repeat Exercise 2 for the City Block distance metric, which, given the points  $(x_1, y_1)$  and  $(x_2, y_2)$ , is defined as  $d_A((x_1, y_1), (x_2, y_2)) = |x_1 - x_2| + |y_1 - y_2|$ .
4. Consider data in a two-dimensional space  $(x, y)$  and a rotation transformation. Use the Chessboard distance (see Exercise 2) in both the original and the transformed space. Show that the proximity-preserving property does not hold in this case.
5. Repeat Exercise 4 for the City Block distance metric.
6. Show that the proximity-preserving property can also be used to perform farthest neighbor queries directly in the transformed space.
7. Give an example where the proximity-preserving property holds while the pruning property does not hold.
8. Given a distance metric  $d$  in the original space, a distance metric  $d'$  in the transformed space, and a transformation  $f$ , Korn, Sidiropoulos, Faloutsos, Siegel and Protopapas [1063, 1064] use the following algorithm to find the  $k$  nearest neighbors to query object  $q$ . They first perform a standard  $k$ -nearest neighbor query on the multidimensional index that represents  $f(S)$ , using  $f(q)$  as a query object and distance function  $d'$ , resulting in a set  $R''$  of  $k$  candidate nearest neighbors of  $q$ . Next, the algorithm computes the actual distances (based on  $d$ ) of all the

Figure 4.83 Progress of the incremental nearest neighbor algorithm on a small example involving three objects. Both the objects and their mapped versions are depicted as two-dimensional points. (a) The search region first reaches  $F(a)$ , and  $d(q, a)$  is computed, (b)  $F(b)$  is reached next, causing  $d(q, b)$  to be computed, and (c) the object  $b$  is determined to be the nearest neighbor of  $q$ .

objects in  $R''$  and determines the distance of the object farthest from  $q$ ,  $\varepsilon = \max_{o \in R''} \{d(q, o)\}$ . A range query is then performed on  $f(S)$  with a query radius of  $\varepsilon$ , resulting in a candidate set  $R'$ . Finally, the set  $R$  of the  $k$  nearest neighbors of  $q$  is determined by computing the distances of all objects in  $R'$  and retaining the  $k$  objects that are closest to  $q$ . Given that  $f$  is contractive, prove that this algorithm is correct by showing that  $R'$  contains the  $k$  nearest neighbors of  $q$ .

9. What are the drawbacks of the algorithm of Korn et al. [1063] described in Exercise 8 in terms of the quality of the estimate  $\varepsilon$  and the number of probes to the multidimensional index representing  $f(S)$ ?
10. Seidl and Kriegel [1716] propose an improvement to the algorithm of Korn et al. [1063] described in Exercise 8 that is partially based on the incremental nearest neighbor search algorithm given in Section 4.1.3. In particular, the algorithm performs an incremental nearest neighbor query on the multidimensional index storing  $f(S)$ , using  $f(q)$  as the query object and a distance measure  $d'$ . As the algorithm obtains the neighboring mapped objects one by one, it computes the actual distance of each object using  $d$  and inserts the objects into a list  $L$  of the candidate nearest neighbors of  $q$  (termed the *candidate list*). If this insertion causes  $L$  to contain more than  $k$  objects, then the object farthest from  $q$  (based on  $d$ ) is discarded. Clearly, if all the objects in  $S$  were inserted into the candidate list  $L$  in this way, then  $L$  would eventually contain the actual  $k$  nearest neighbors. However, since the mapped objects are obtained from the incremental nearest neighbor query in order of the values of  $d'(f(q), f(o))$ , the algorithm can usually be terminated long before inserting all the objects into  $L$ . In particular, once  $d'(f(q), f(o)) \geq D_k$  for the mapped object  $o$  just obtained from the incremental nearest neighbor query, where  $D_k$  is the distance of the current  $k$ th candidate nearest neighbor, the contractiveness of  $f$  guarantees that  $d(q, o') \geq d'(f(q), f(o')) \geq D_k$  for all objects  $o'$  that have not yet been retrieved. Thus, when this condition arises, the candidate list  $L$  contains the actual  $k$  nearest neighbors of  $q$ , and the search can be halted. Note that in order to simplify our presentation of the algorithm, we assume that given any distance  $x$ , there is at most one object at this distance from  $q$ , although the algorithm as originally described by Seidl and Kriegel [1716] does report more than  $k$  neighbors when there is more than one object at the same distance from  $q$  as the  $k$ th-nearest neighbor.<sup>52</sup> Compare the algorithm of Seidl and Kriegel with an algorithm that uses the general version of the incremental nearest neighbor algorithm given in Section 4.1.3 that integrates  $L$  into the priority queue (i.e., stores both the objects and nodes of the multidimensional index on  $f(S)$  in the priority queue) and terminates once  $k$  objects have been output (i.e., upon outputting the  $k$ th-nearest neighbor). In essence, whenever the algorithm encounters an object  $o$  (i.e., when  $f(o)$  reaches the front of the priority queue), instead of inserting  $o$  into the candidate list  $L$ , it inserts  $o$  into the priority queue using  $d(q, o)$  as the key. In particular, does one of the algorithms access more nodes of the multidimensional index than the other? Similarly, does one of the algorithms compute the distance between more pairs of objects than the other?

## 4.6.2 Using Only One Dimension

There are many techniques for reducing the dimension of the data when its dimension is known, as is the case when the data is represented as feature vectors in a high-dimensional space. The simplest technique is to ignore some of the features. It should be clear that in this case it is best to retain the most discriminating of the features (although this may take some work to determine).

The pruning property will always hold if the distance metric that is used for the single feature is suitably derived from the distance metric on all of the objects. For example, for any Minkowski distance metric  $L_p$ , the appropriate single-feature distance metric is always the same—that is, the absolute difference  $|x_a - x_b|$ , where  $x_a$  and  $x_b$  are the values of the retained feature for objects  $a$  and  $b$ , respectively. However, for this technique, the proximity-preserving property will hold typically only in the rare case that all the other features have the same value for all the objects.

---

<sup>52</sup> In this case, the algorithm is terminated once  $d'(f(q), f(o)) > D_k$  instead of once  $d'(f(q), f(o)) \geq D_k$  for the mapped object  $o$  just obtained from the incremental nearest neighbor query.

The most drastic, and easiest to implement, dimension reduction technique is to use just one of the given features (without applying any transformation). A drawback of this method, which we ignore below, is that many of the objects may be represented by the same point. This method forms the basis of the  $k$ -nearest neighbor algorithm of Friedman, Baskett, and Shustek [649]. Once the feature  $f$  has been chosen, all objects are sorted with respect to this feature (termed  $f$ -distance). The  $k$  nearest neighbors are found by processing the objects in increasing order of their  $f$ -distance from the query object  $q$  until encountering an object  $o$  such that its  $f$ -distance from  $q$  is greater than the actual distance from  $q$  to the  $k$ th-nearest neighbor found so far. Thus, they are making direct use of the pruning property as the  $f$ -distance between two objects is always less than the actual distance, and the search is halted once the  $f$ -distance is greater than the actual distance to the  $k$ th-nearest object.

The efficiency of the  $k$ -nearest neighbor algorithm of Friedman et al. [649] depends, in part, on which feature  $f$  is used. At its simplest,  $f$  is selected at random. However, it is clear that the feature with the smallest projected density will result in examining a smaller set of objects. This feature can be obtained globally or locally.

From a global perspective,  $f$  is the feature with the largest range (termed *spread*) of values. This requires that we examine all of the objects before starting the search. Once  $f$  has been identified, we sort the objects with respect to their  $f$ -distance.

From a local perspective,  $f$  is the feature with the largest expected range of values about the value of feature  $f$  for query object  $q$  (denoted by  $q_f$ ). This is not so easy to determine. It requires that the objects be sorted with respect to all of the features. The local density around  $q$  depends on the expected number  $N'$  of objects that will be examined during the search. Friedman et al. [649] obtain  $N'$  from the radius of the expected search region, which is computed using a uniform distribution. The actual local density for each of the features  $i$  is determined by calculating the size of the range containing the  $N'/2$  values less than or equal to  $q_i$  and the  $N'/2$  values greater than or equal to  $q_i$  and choosing  $f$  as the one with the largest range.

Friedman et al. conducted a number of experiments comparing their algorithm with the brute-force method of examining all objects by varying  $k$ , the sample data sizes, and the dimension of the underlying space. They found that their method was considerably more efficient for different  $k$  and sample sizes and when the dimension of the underlying data was relatively small. However, once the dimension of the underlying space reached the value of 9, the effects of the curse of dimensionality become dominant, and the algorithm lost its advantage over the brute-force method. Of course, both the global and the local (to a lesser extent) methods are attractive only when the queries are performed many times as the preprocessing costs involved sorting the data.

Another technique of using just one dimension is one that is motivated by a desire to combine all of the different features into one representative feature by using some information from each of the features. For example, suppose that each object is represented by  $n$  different features, each of which has a 64-bit value. In this case, we can represent the object by a single number formed by concatenating the values of the most significant bit (or a small subset thereof) from each of the  $n$  different features.<sup>53</sup> This technique is similar to hashing and has the same drawback as the technique that retains only one of the features in that it is very likely that many of the objects will be represented by the same point. Satisfying the pruning property when using this technique is not simple, as is shown below for the space-ordering methods.

An alternative and related approach that is very well-known and frequently used in spatial databases transforms (i.e., maps) the feature vectors in high dimensions into one dimension by ordering the data using one of the various space-ordering methods such as

---

<sup>53</sup> We could also use the least-significant bit, although this is not particularly meaningful from the point of view of providing a summary (i.e., an approximation) of the values of the individual features.

the Morton and Peano-Hilbert orders (see Section 2.1.1.2 of Chapter 2). The resulting values are usually stored in a one-dimensional data structure, such as a B-tree.

Although it appears to be attractive as a dimension reduction technique, the space-ordering approach has a severe limitation for similarity queries since it cannot be guaranteed that points that are close to each other in the high-dimensional feature space from which they are drawn will be close to each other in the very low, one-dimensional space into which they will be transformed. In other words, the pruning property does not hold. For example, consider two adjacent points in a two-dimensional space that has been discretized prior to the ordering. In this case, the distance is measured using the Euclidean distance metric (although others can be used as well, with the same result). These two points need not be adjacent in the ordering, as can be seen by examining Figure 1.63 in Section 1.6 of Chapter 1, where we see that, although points (4,3) and (4,4) are adjacent in space, they are not adjacent when using the Morton order, where they appear in positions 26 and 48, respectively. Note that the pruning property does not hold regardless of which of the Minkowski distance metrics  $L_p$  is used for  $d$  (see Exercise 2).

### Exercises

1. Perform an empirical comparison of the local and global methods of choosing the feature for dimension reduction in the  $k$ -nearest neighbor algorithm of Friedman et al. [649]. Use the brute-force method of calculating the distances to all of the objects in the dataset as a benchmark. Note that no such comparison is reported in [649]. The objective of this comparison is to determine when the added overhead of sorting along the different feature dimensions incurred by the global method is worthwhile.
2. Prove that the pruning property fails to hold when using the Morton order, regardless of which of the Minkowski distance metrics  $L_p$  is used for  $d$ . Note that  $d'$  is the Morton ordering distance and is measured in terms of the difference in position.

### 4.6.3 Representative Point Methods

It is interesting to observe that the concept of representing objects with feature vectors can be interpreted as being a form of dimension reduction. For a simple example of an application where this technique is frequently applied, we need not turn far in that we can examine the representation of spatial objects of arbitrary shape. Recall from Chapter 2 that there are two basic ways to represent the objects: by their boundaries or by their interiors. The interior-based representation keeps track of the space occupied by the objects (e.g., the region quadtree). One use of this technique is to distinguish between the space occupied by the object and the space that is not occupied by the object. In this case, we could record a value for each pixel denoting whether it is occupied by the object. Each pixel can be considered as one feature, and thus the more pixels that make up the object, the larger is our feature vector. Clearly, such a feature vector is too large, and thus we usually try to use more general, and fewer, features to describe the objects.

An approach that is frequently used is to try to find some representative features of the objects that will serve as the basis of the feature vector. For example, it is common to represent a  $t$ -dimensional object by its centroid (requires  $t$  features), axis-aligned minimum bounding rectangle (requires  $2 \cdot t$  features corresponding to the coordinate values of two diagonally opposite corners and termed a *corner transformation* [1709]), minimum bounding sphere (requires  $t + 1$  features corresponding to the coordinate values of the centroid plus the magnitude of the radius), and so on. Note that these descriptors are really nothing more than a feature vector that is a point (termed a *representative point*) in a space of the same or higher dimension. They can be indexed using the methods for point data described in Chapter 1. Thus, we have transformed the spatial objects into points in a space of equal or higher dimension (with respect to the space from which they are drawn) via the use of the feature vectors, which also include coordinate values of points in the space from which the objects are drawn. We

loosely classify this method as dimension reduction because the number of features used to represent the object has been reduced in comparison with the feature per pixel method that was used to indicate that the space is occupied by the object. We have also seen the use of this technique to represent intervals and rectangles in Section 3.3.1 of Chapter 3.

Not surprisingly, the representative point method is plagued by the same problem as the transformation method that is based on space ordering. In particular, the transformation function  $f$  that we have used to obtain the feature vectors (i.e., the representative points) for the spatial objects usually does not satisfy the pruning property. In other words, the distance  $d'(f(a), f(b))$  in the transformed space between two transformed objects  $f(a)$  and  $f(b)$  does not serve as a lower bound on the actual distance  $d(a, b)$  in the original  $m$ -dimensional space between the two objects  $a$  and  $b$ , assuming  $d$  and  $d'$  are the same distance metric (but possibly for spaces of different dimensionality). This means that just because a search region of radius  $r$  around the transformed object  $f(o)$  in the transformed space is empty, we are not guaranteed that there is no other object within distance  $r$  of  $o$  in the original space, regardless of how we measure the closeness of objects in the original space. This significantly reduces the utility of the representative point dimension reduction technique. Of course, it could equally be argued that the representative point method is not really a dimension reduction technique as the dimension of the underlying space has in fact been increased. We do not dwell further on this aspect of the issue.

#### 4.6.4 Transformation into a Different and Smaller Feature Set

A direct method of achieving dimension reduction is to determine a subset of features that discriminate best between the data and only base the spatial index on them (e.g., [838]). These methods depend on the data domain and are not discussed further here. An alternative, and potentially more meaningful, approach is to transform the features into another set of more relevant (e.g., discriminating) features and then to find a subset of the transformed features that are the most important.

The basic idea is to try to transform the data so that most of the information is concentrated in a small number of features. For example, Figure 4.84 shows a set of points in two dimensions with respect to the  $x$  and  $y$  coordinate axes (i.e., these are our two features) and the result of rotating the axes to obtain the  $x'$  and  $y'$  axes, respectively. It should be clear that the  $x'$  axis is the dominant axis, and if we were to have just one dimension (i.e., feature), then this is the one that should be retained. Once the reduced set of features has been found, the new feature vectors are once again treated as points in a space of the appropriate dimension, and a spatial index is built for them. A number of techniques that make use of this idea have been proposed. They differ in the nature of the feature vectors that are used, the number of feature vectors that are taken into account in the process of determining the transformation, and in the transformation process itself. In the following, we examine some of these techniques using these ways of differentiating among them.

##### 4.6.4.1 SVD

The Singular Value Decomposition (SVD) [721], Karhunen-Loève Transform (KLT) [665], and Principal Component Analysis (PCA) [665] are equivalent techniques that are used to address the same goal of finding a linear transformation of  $n$ -dimensional feature vectors to  $k$ -dimensional feature vectors ( $k \leq n$ ) that minimizes the sum of the squares of the Euclidean distances between the set of  $n$ -dimensional feature vectors and their corresponding  $k$ -dimensional feature vectors. An alternative characterization is that we are minimizing the mean square error. This problem is also known as the *linear least squares* problem (e.g., [701]). It arises frequently when trying to fit a model to the results of experiments. Many of these techniques originated in the field of pattern recognition (e.g., [665]). In our applications, the goal of these techniques is to find the most important

Figure 4.84 Example illustrating the change of coordinate axes from  $(x, y)$  to  $(x', y')$  where now the  $x'$  axis corresponds to the most discriminating feature.

features (more precisely, a linear combination of features) for a given set of feature vectors. Their use leads to a transformation of the original set of feature vectors  $S$  to obtain a new set of feature vectors  $S'$  where the individual features that make up  $S'$  are ranked by their importance, so that if we ignore the less important features by projecting onto the most important features, then we preserve much of the variation between the elements of the original set of feature vectors  $S$ .

The problem that we are addressing can be stated as follows. We are given a set of  $m$   $n$ -dimensional feature vectors  $\vec{f}_1, \vec{f}_2, \dots, \vec{f}_m$  that are to be transformed into a set of  $m$   $k$ -dimensional feature vectors  $\vec{t}_1, \vec{t}_2, \dots, \vec{t}_m$ . The sets  $\{\vec{f}_i | 1 \leq i \leq m\}$  and  $\{\vec{t}_i | 1 \leq i \leq m\}$  of feature vectors can be written as an  $m \times n$  matrix  $F$  and an  $m \times k$  matrix  $T$  as follows:

$$F = \begin{pmatrix} f_{11} & f_{12} & \dots & f_{1n} \\ f_{21} & f_{22} & \dots & f_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ f_{m1} & f_{m2} & \dots & f_{mn} \end{pmatrix} \quad \text{and} \quad T = \begin{pmatrix} t_{11} & t_{12} & \dots & t_{1k} \\ t_{21} & t_{22} & \dots & t_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ t_{m1} & t_{m2} & \dots & t_{mk} \end{pmatrix}$$

From linear algebra, we know that any  $m \times n$  matrix  $F$ , where the number of rows  $m$  is greater than the number of columns  $n$ , can be written as the product of three matrices  $U$ ,  $\Sigma$ , and  $V$  as follows:

$$F = U \Sigma V^T \tag{4.10}$$

Equation 4.10 is known as the *singular value decomposition* of  $F$  (e.g., [721]).  $U$  is an  $m \times n$  matrix consisting of a set of  $n$  orthonormal column vectors  $\vec{u}_i$  (i.e.,  $\vec{u}_i \cdot \vec{u}_j = \delta_{ij}$  or, equivalently,  $\sum_{h=1}^m U_{hi} U_{hj} = \delta_{ij}$ ,  $1 \leq i \leq n$  and  $1 \leq j \leq n$ ). This is the same as stating that  $U^T U = I_n$ . Similarly,  $U U^T = I_m$ .  $\Sigma$  is an  $n \times n$  singular value matrix with nonnegative elements along its diagonal known as *singular values*:

$$\Sigma = \begin{pmatrix} \sigma_{11} & 0 & \dots & 0 \\ 0 & \sigma_{22} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \sigma_{nn} \end{pmatrix}$$

$V$  is an  $n \times n$  orthonormal matrix where  $V V^T = I_n$  and  $V^T V = I_n$ . The result of taking the singular value decomposition of a matrix  $F$  is the determination of a set of orthonormal column basis vectors  $\vec{v}_1, \vec{v}_2, \dots, \vec{v}_n$ . These basis vectors have the property that the original  $m$  feature vectors are spread out most widely along the  $\vec{v}_1$  direction, then along the  $\vec{v}_2$  direction, and so on. This is a direct result of the fact that the nonzero entries  $\sigma_{ii}$  in  $\Sigma$  correspond to the minimum variance of the data in  $F$  along the basis vectors in the  $\vec{v}_i$  ( $1 \leq i \leq n$ ) directions, assuming that the mean is at the origin. In order to take advantage of this property, we apply the transformation  $V$  to  $F$ , which in effect rotates the vectors that make up  $F$  in the direction that yields the best least squares fit (this is especially true once we start removing some of the dimensions, as discussed below). Therefore, the transformed feature vectors  $\vec{t}_1, \vec{t}_2, \dots, \vec{t}_m$  are obtained by multiplying each vector  $\vec{f}_i$  in the original matrix  $F$  with the basis matrix  $V$ . In other words,  $FV = T = U\Sigma$ , which can be verified by multiplying both sides of Equation 4.10 by  $V$  and taking note of the fact that  $V^T V = I_n$ .

$V$  is known as the *SVD transform matrix*. It is the same matrix that transforms the coordinates in PCA. It is also the matrix corresponding to the KLT.<sup>54</sup> For details on how to compute the SVD transform matrix of a matrix (i.e., the matrix formed by the composition of the  $m$   $n$ -dimensional feature vectors in our case), see [721, 1515]. The result of applying the rotation (i.e., via the SVD transform matrix) to the original data  $\vec{f}_1, \vec{f}_2, \dots, \vec{f}_m$  (i.e., by computing  $FV$ ) is a set of vectors  $\vec{t}_1, \vec{t}_2, \dots, \vec{t}_m$  so that their

<sup>54</sup> The principal components correspond to the eigenvectors with the biggest eigenvalues. These are the leading elements in the matrix  $\Sigma$ .  $V$  is a rotation matrix, and it is equal to the  $T$  matrix (i.e., the result of the transformation) only if the elements of the  $F$  matrix are of the form  $(1, 0, 0, \dots, 0)$ ,  $(0, 1, 0, \dots, 0)$ ,  $\dots$ ,  $(0, 0, 0, \dots, 1)$ , and so forth.

lengths are preserved when measured using the Euclidean norm—that is,  $\|\vec{f}_i\| = \|\vec{t}_i\|$  for  $i = 1, \dots, n$ . This is a direct result of the fact that  $V$  is an orthogonal matrix (i.e., for any column or row vector  $\vec{v}_i$  in  $V$ , we have that  $\vec{v}_i \cdot \vec{v}_j = 0$  for  $i \neq j$ ). It is also orthonormal (i.e.,  $\vec{v}_i \cdot \vec{v}_j = \delta_{ij}$ ), which means that  $V$  is an orthonormal transformation.<sup>55</sup> In particular, orthonormal transformations preserve the Euclidean norm of a vector. The practical significance of this property is that such transformations can rotate a point to a new location but cannot change its Euclidean distance from the origin.

We take advantage of this length-preserving property to reduce the dimension of the feature vectors in the transformed space to  $k$  by retaining only the  $k$  most significant values in  $\Sigma$  (i.e., the largest ones), thereby zeroing out the  $n - k$  least significant values (i.e., the smallest ones). We also discard the corresponding entries in the  $T$ ,  $U$ , and  $V$  matrices, yielding a new set of feature vectors  $\vec{w}_1, \vec{w}_2, \dots, \vec{w}_m$ , where  $\vec{w}_i$  ( $1 \leq i \leq m$ ) corresponds to the first  $k$  features of  $\vec{t}_i$ . It is easy to see that for the Euclidean distance metric  $d_E$ , the distance between any two feature vectors  $\vec{f}_i$  and  $\vec{f}_j$  is greater than or equal to the distance between the corresponding transformed feature vectors  $\vec{w}_i$  and  $\vec{w}_j$ , respectively, in the lower dimensional space. In other words, the pruning property holds as  $d_E(\vec{w}_i, \vec{w}_j) \leq d_E(\vec{f}_i, \vec{f}_j)$ . Note that the pruning property does not hold for the result of the SVD transformation in the case of distance metrics other than  $d_E$  for both  $d$  and  $d'$  (e.g., the City Block and the Chessboard distance metrics) since their values are not preserved under rotation (see Exercises 1 and 2, respectively).

To summarize, the SVD method (as well as the KLT and PCA methods) is based on concepts from linear algebra and results in a linear transformation of the feature vectors into vectors whose coordinates are ordered based on “importance” (which is defined in terms of variance). This enables us to keep only the first few features of the transformed feature vectors while retaining as much information as possible. From a mathematical point of view, we computed the eigenvectors of the covariance matrix, sorted them in order of decreasing eigenvalue, chosen a value  $k$  ( $k \leq n$ ), and then approximated each of the original  $n$ -dimensional feature vectors by its projection onto the first  $k$  eigenvectors.

The SVD method is data dependent, and thus is most appropriate in situations where the database is static (e.g., stored on CD-ROM) or changes little (at least in terms of data distribution). In particular, given  $m$  feature vectors in an  $n$ -dimensional feature space, computing the SVD transform matrix takes  $O(m \cdot n^2)$  time and is thus quite expensive. Note that although the complexity is linear in terms of the number of feature vectors  $m$ , the value of the constants involved in the computation are quite high.

The time necessary to calculate the SVD transform matrix is the principal drawback of the SVD method. In particular, regardless of the amount of dimension reduction, we must always calculate the SVD transform matrix  $V$  using the entire data. Next,  $V$  is applied to each of the feature vectors in the input data to obtain the  $n$ -dimensional transformed feature vectors. During this step, we can reduce the dimension of the newly transformed feature vectors to  $k$  dimensions just by retaining the coordinates in the first  $k$  dimensions. Thus, only in this step is the execution time reduced by a factor proportional to the amount of dimension reduction. This data is then indexed using one of the multidimensional spatial indexes.

The SVD method, despite its slowness, is reasonable when the underlying datasets are static. However, the situation changes when the underlying datasets are dynamic. As data is inserted and deleted, we have two choices. We can simply reuse the existing SVD transform matrix to compute the dimension reduced transformed feature vector or recompute the SVD transform matrix. We can reuse the existing SVD transform matrix as long as the precision of the query responses does not degrade by too much (e.g., a 5% to 10% degradation is deemed tolerable [988]). Alternatively, the recomputation of the SVD transform matrix could also be triggered by a drop in the variance of the chosen

---

<sup>55</sup> Orthogonal transformations preserve relative angles while they do not necessarily preserve lengths, whereas orthonormal transformations preserve both relative angles and lengths.

dimensions (as a fraction of the total variance). The motivation for the recomputation is the fact that the features that make up the dimension-reduced transformed feature vector are supposed to be the ones with the greatest variance.

Recalculating the SVD transform matrix and rebuilding the index is quite an expensive proposition. Some incremental techniques have been proposed [321, 468] for recalculating the SVD transform matrix that reduce the complexity of the process from  $O(m \cdot n^2)$  to  $O(m \cdot r)$ , where  $r$  is the rank of  $F$ , the matrix of the original  $m$   $n$ -dimensional feature vectors. These techniques are of interest because  $r$  is usually much smaller than  $n$ , and thus the proportionality factor in the execution time complexity decreases from  $n^2$  to  $r$ . Nevertheless, the process is still linear in the number of feature vectors  $m$ .

Kanth, Agrawal, El Abbadi, and Singh [988] propose to recompute the SVD transform matrix using a relatively small subset of the  $m$  feature vectors by making use of the aggregation information provided by the spatial index, thereby significantly reducing the complexity of the recomputation process. They also propose to reuse parts of the spatial index rather than always recomputing it. Their methods depend on the nature of the spatial index. They assume that the underlying spatial index is an object hierarchy such as an R-tree [791]. In particular, they make use of an SS-tree [1991] (see Section 4.4), which is an adaptation of an R\*-tree [152] that makes use of bounding spheres instead of bounding rectangles. All of their experiments tested the behavior of finding the  $i$ th nearest neighbor with the Euclidean distance metric.

The subset of the  $m$  feature vectors used to recompute the SVD transform matrix is obtained by choosing a level in the R-tree for which Kanth et al. [988] feel that the distribution of the underlying data is well captured. Next, they calculate the centroid of the values in the subtrees at this level. The new SVD transform matrix (termed the *Approximate SVD transform matrix*) is computed with these centroid values. The larger the reduction in dimension (i.e., the lower the dimensionality of the reduced feature vectors), the smaller is the set of aggregated centroid values obtained at any given level as the fanout of the index nodes is higher (i.e., the number of nodes at the level below is smaller). Similarly, the size of the set of the aggregated values gets smaller as we get closer to the root. This is expected to make the Approximate SVD transform matrix less accurate, thereby leading to more approximation errors (i.e., a decrease in precision for queries to find the  $i$ th nearest neighbor).

Experiments [988] were conducted comparing the effects of using the Approximate SVD transform matrix and the regular SVD transform matrix. The SVD transform matrix was initially computed for approximately 12% of the data, dimension reduction was applied, the index was built, and the remaining data was inserted into the existing spatial index with the existing SVD transform matrix. At this point, the Approximate SVD transform matrix and the regular SVD transform matrix were computed for the entire dataset. The spatial index was not rebuilt. The effects of the use of these two matrices on precision were tabulated when the number of nearest neighbors was varied and also when the amount of dimension reduction was varied for a particular number (i.e., 21) of neighbors. Note that the spatial index was not used to calculate the nearest neighbors in this comparison because the goal was solely one of evaluating the quality of the approximation provided by the Approximate SVD transform matrix. If the spatial index were used, then the precision might also be affected by the different amounts of overlap and coverage for the R-trees corresponding to the two matrices.

Most of the experiments [988] used a level of aggregation immediately above that of the leaf nodes of the R-tree. Using this level of aggregation, while varying the amount of dimension reduction, led to two orders of magnitude of reduction in the execution time for the computation of the Approximate SVD transform matrix vis-à-vis the regular SVD transform matrix that took all of the data points into account. Use of the Approximate SVD transform matrix resulted in a very minor decrease in precision (ranging between 2% and 3%) in comparison to the regular SVD transform matrix for the different amounts of dimension reduction. Note that, although the use of dimension reduction resulted in

different index node fanout values, its effect on the computation time of the Approximate SVD transform matrix was relatively minor aside from requiring fewer feature vectors for lower dimensions (as more feature vectors made up each aggregated value). This resulted in slightly lower overall precision than when the extent of the dimension reduction was higher, thus requiring a bit more time to calculate the query responses (i.e., to find the nearest neighbors). Nevertheless, since in all experiments' use of the Approximate SVD transform matrix had a relatively minor effect on precision, its use also had a relatively minor effect on query response time. Increasing the level of aggregation by one to a total of two levels above that of the leaf nodes of the R-tree led to a similar, further relative drop of precision. Observe also that all of these results with respect to the effect of using the Approximate SVD transform matrix on precision were not affected by varying the number of nearest neighbors.

Once the new SVD transform matrix has been constructed, its results must be incorporated into the spatial index. The first step is to transform all of the data points and store the results in the leaf nodes. Kanth et al. [988] propose three methods of incorporating the newly transformed points into the spatial index.

1. Build a new index from scratch.
2. Reuse the existing index while adjusting the extents of the bounding spheres of the SS-tree, which is the basis of the R\*-tree used in the experiments. The extents of the bounding spheres are likely to increase as the SVD axes have been reoriented. This will degrade the query performance because the degree of filtering that can be achieved by the index is reduced.
3. Pick some level in the index and rebuild the index for each of the subtrees at the lower levels. The index is retained for all index nodes above this level, although the sizes of the bounding spheres for these nodes will have to be adjusted and most likely will have to be increased as the SVD axes have been reoriented. It should be clear that if we choose a level close to the root, then more memory is needed for the rebuilding process of the subtrees as a larger subtree needs to be manipulated. Each subtree is reconstructed using the VAMSplit method [1989] (see Section 1.7.1.7 of Chapter 1) where the partitioning process recursively splits the data items in the subtree until each partition fits in a single node (i.e., disk page). The partitioning axis is chosen corresponding to the dimension with the maximum variance, while the partitioning position is chosen so that the leaf nodes are as full as possible.

Kanth et al. [988] conducted experiments to evaluate the three methods when the new SVD transform matrix is the Approximate SVD transform matrix. Their experiments showed that method 3 worked almost as well as method 1 for query response time (within 10%), with a much lower cost of incorporating the new data into the index (almost 30 times faster), while being only twice as slow as method 2 for incorporating the new data into the index. The query response time for method 2 was almost twice that of methods 1 and 3 due to the much larger bounding spheres (sometimes their radius value tripled). These results held even as the extent of the reduction in dimension was varied. Method 3 was improved by selectively deleting some data items and reinserting them when it was determined that deleting them caused a considerable decrease in volume (e.g., a 50% decrease in the radius). Such a situation is a direct result of an item's not fitting into the subtree after application of the SVD transform matrix.

The SVD method and the accompanying dimension reduction may not always work for large databases when different subclusters are oriented along different axes as too much information can be lost, thereby leading to poor query performance. In this case, it is better first to identify the clusters, compute their individual SVD transform matrices, and then apply dimension reduction to the SVD transform matrices of the individual clusters [1873]. The methods of [988] are also applicable to the SVD transform matrices of the individual clusters.

1. It is easy to see that the Euclidean distance metric is preserved under rotation. Show that, unlike the Euclidean distance metric, the City Block distance metric value  $d_A$  is not preserved under rotation.
2. Show that, unlike the Euclidean distance metric, the Chessboard distance metric value  $d_M((0,0), (a,b))$  is not preserved under rotation.

#### 4.6.4.2 Discrete Fourier Transform (DFT)

As we saw in Section 4.6.4.1, the main drawback of the SVD method is the need to recompute the SVD transform matrix whenever one of the feature vectors is modified. This process takes  $O(m \cdot n^2)$  time for  $m$  feature vectors in  $n$  dimensions. Moreover, all of the transformed feature vectors must be recomputed with the new SVD transform matrix, which requires additional  $O(m \cdot n^2)$  time. This relatively high complexity has led to interest in more local methods, such as the Discrete Fourier Transform (DFT), the Discrete Cosine Transform (DCT), wavelets, and the Haar Transform (e.g., [701]), which apply the same transformation to each feature vector  $f$  regardless of the value of  $f$  or of any of the other feature vectors. In particular, when using methods such as the DFT, we will see that a modification of a single feature vector usually requires only that we recompute the corresponding transformed feature vector, which takes  $O(n^2)$  time. Thus, we can characterize these methods as local,<sup>56</sup> in contrast with the SVD method, which would be characterized as global.

The DFT is a transformation that is usually interpreted as enabling one to go from the time domain to the frequency domain (or vice versa), although it has applications in many other domains (e.g., space to space). The DFT of a feature vector has the same number of components (termed *coefficients*) as the original feature vector. It is used in signal processing, as well as many other domains, to gain insight into data that is time varying by permitting a closer examination of the dependence of the variation on time as well as its repeatability, rather than just looking at the strength of the signal (i.e., the amplitude), as can be seen from the conventional representation of the signal in the time domain. The DFT results in the replacement of a sequence of values at different instances of time by a sequence of an equal number of coefficients in the frequency domain. Thus, the idea of using the DFT is similar to a mapping from a high-dimensional space to another space of equal dimension.

As in other transformations, such as the SVD, the DFT can be made more manageable (i.e., amenable to use with a spatial indexing method such as the R-tree) by applying dimension reduction. In this case, the result is the elimination of some of the coefficients in the frequency domain. This is not the same as eliminating some of the components (i.e., individual features) of the original feature vector (i.e., the less discriminating ones), which is the usual effect when applying dimension reduction to transformations such as the SVD. The justification for applying dimension reduction to the DFT lies in the DFT's nature as a summary of the combined behavior of the various components (i.e., the individual features, which of course must be scaled<sup>57</sup>) of each of the original feature vectors. Therefore, taking fewer coefficients into account is analogous to having a less precise summary of each of the original feature vectors. We now give the definition of

---

<sup>56</sup> We will see below that, at times, when using dimension reduction where the identities of the elements of the set of retained coefficients of the DFT depend on the actual values of the feature vectors (e.g., their mean or variance) and if one of the elements changes, then we have to recompute the DFT for all of the feature vectors.

<sup>57</sup> For example, suppose that we are looking at a feature vector with features age, height, weight, gender, and salary. If we compute the components of the DFT, we want the contribution of each of the features to be approximately the same. However, the magnitude (and, to a lesser extent, the variability) of all but the gender fields are much greater than that of the gender field. Thus, in order to make the contributions of the features approximately the same, we scale them.

the DFT, as well as present some of its key properties and show how dimension reduction is obtained and used.

Our definition uses the same notation as in [26, 588, 2026], where its usage in database applications has been proposed. We represent each  $n$ -dimensional feature vector as a finite-length sequence of length  $n$ . The  $n$ -point DFT of a finite-length sequence of  $n$  real or complex-valued numbers  $\vec{x} = \{x_t | 0 \leq t \leq n - 1\}$ , corresponding to a feature vector, is a sequence  $\vec{X}$  of complex numbers  $\{X_f | 0 \leq f \leq n - 1\}$ , given by<sup>58</sup>

$$\begin{aligned} X_f &= 1/\sqrt{n} \sum_{t=0}^{n-1} x_t \exp(-j2\pi ft/n) \\ &= 1/\sqrt{n} \sum_{t=0}^{n-1} x_t [\cos(2\pi ft/n) - j \sin(2\pi ft/n)] \\ &= 1/\sqrt{n} \sum_{t=0}^{n-1} x_t \cos(2\pi ft/n) - j/\sqrt{n} \sum_{t=0}^{n-1} x_t \sin(2\pi ft/n), \end{aligned}$$

where  $j$  is the imaginary number equal to  $\sqrt{-1}$ . It is important to note that when the feature vector is real valued, then the Fourier coefficients  $X_f$  occur in conjugate pairs, which means that the only difference between them is the sign of the complex part (i.e.,  $a - bj$  is the complex conjugate of  $a + bj$ ). For more details on the nature of the coefficients, see the subsequent discussion of the choice of coefficients that serve as members of the dimension-reduced DFT.

Note that  $\vec{x}$  can be recovered from the DFT  $\vec{X}$  by use of the inverse transform:

$$\begin{aligned} x_t &= 1/\sqrt{n} \sum_{f=0}^{n-1} X_f \exp(-j2\pi ft/n) \\ &= 1/\sqrt{n} \sum_{f=0}^{n-1} X_f [\cos(2\pi ft/n) - j \sin(2\pi ft/n)] \\ &= 1/\sqrt{n} \sum_{f=0}^{n-1} X_f \cos(2\pi ft/n) - j/\sqrt{n} \sum_{f=0}^{n-1} X_f \sin(2\pi ft/n). \end{aligned}$$

In a practical sense, the DFT is an orthogonal transformation (see Exercise 1) that enables us to represent a set of  $n$  complex values as a linear combination of  $n$  sine and cosine functions of  $n$  different frequencies (denoted by the quantity  $f/n$  in the definition of  $x_t$ )  $0, 1/n, 2/n, \dots, (n - 1)/n$ . The  $X_f$  values serve as the coefficients in the representation, with  $X_{n-1}$  being the coefficient of the highest frequency, which is  $f = n - 1$ . The DFT yields exact values for  $x_t$  ( $0 \leq t \leq n - 1$ ), while it is an interpolation in terms of the sine and cosine functions for all other values. Of course, when we are dealing with  $n$ -dimensional feature vectors, it is meaningless to interpolate between the components of the feature vectors (i.e., there is no such entity as feature 2.5). Thus, we see that the sine and cosine functions serve as the basis functions. Notice that, unlike the SVD method, these basis functions are independent of the actual data, whereas they do depend on the data in the SVD method.

As an example of how  $\vec{x}$  can be recovered from the DFT, consider Figure 4.85, which shows the decomposition of the real-valued, five-dimensional feature vector

<sup>58</sup> Note that we have used a normalizing factor of  $1/\sqrt{n}$  in our definition instead of  $n$ . The reason for doing so is to ensure that the inverse of the DFT, which yields the original data (as shown below), has the same normalizing factor  $1/\sqrt{n}$  instead of 1, which would have been the case if we had used the normalizing factor  $n$  in our definition.

(a)

Figure 4.85

Example illustrating the decomposition of the real-valued, five-dimensional feature vector  $\vec{x} = (1.2, 1.4, 0.65, -0.25, -0.75)$  into its constituent Fourier coefficients and their corresponding cosine (solid lines) and sine (broken lines) basis functions. The solid circles denote the actual values of the components of the feature vectors and are obtained by summing up the individual values of the component cosine and sine functions whose values are denoted by hollow circles.

$\vec{x} = (1.2, 1.4, 0.65, -0.25, -0.75)$  into its constituent Fourier coefficients and their corresponding cosine and sine basis functions. In particular, we denote the cosine functions with solid lines and the sine functions with broken lines. Notice that there are four non-constant cosine (sine) functions corresponding to the four frequencies  $1/5, 2/5, 3/5,$  and  $4/5,$  while the cosine (sine) function corresponding to the frequency 0 is a constant equal to 0.45 (0) since the product of 0 with anything is 0, and the cosine (sine) of 0 is 1 (0) and hence is denoted with a straight (broken) line passing through 0.45 (0) in this example. The actual value of the components  $x_t$  ( $0 \leq t \leq 4$ ) of the feature vector  $\vec{x}$ , denoted by a solid circle in the figure, are obtained by summing the value of the cosine and sine functions at that component, denoted by a hollow circle in the figure. Note that if two curves pass through the same point, then the point has to be counted twice in the sum. Both the cosine and sine function must be summed for each component  $x_t$  ( $0 \leq t \leq 4$ ) because each coefficient  $X_f$  of the DFT is a complex number of the form  $a + bj$  and is being multiplied by  $\exp(-j2\pi ft/n)$ , which is equal to  $1/\sqrt{n}[\cos(2\pi ft/n) - j \sin(2\pi ft/n)]$ . The fact that  $\vec{x}$  is real valued means that the complex-valued components of these sums are zero. Observe that all of the sine functions pass through 0 at the zeroth component of the feature vector since the sine of 0 is 0, whereas the cosine functions attain their extremal values (which are usually different) at the zeroth component of the original feature vector. Note also that the value of the zeroth coefficient  $X_0$  (i.e., the amplitude of the constant cosine function) is equal to the average of the five components, which is 0.45 in this example.

If the feature vector  $\vec{x}$  were of even dimensionality (i.e., the number of components  $n$  is even), then there are two Fourier coefficients that are real valued (i.e.,  $X_0$  and  $X_{n/2}$ ) in contrast to just one when  $n$  is an odd number. This is a direct result of the fact that

(b)

Figure 4.86

Example illustrating the decomposition of the real-valued, four-dimensional feature vector  $\vec{x} = (1.2, 1.4, 0.65, -0.25)$  into its constituent Fourier coefficients and their corresponding cosine (solid lines) and sine (broken lines) basis functions. The solid circles denote the actual values of the components of the feature vectors and are obtained by summing up the individual values of the component cosine and sine functions whose values are denoted by hollow circles. Notice the difference from Figure 4.85: there is one more cosine function than sine functions as the broken line through zero actually corresponds to two sine functions.

the coefficients of the DFT occur in conjugate pairs (as explained in greater detail in the subsequent discussion of the choice of coefficients that serve as members of the dimension-reduced DFT) and that  $\vec{x}$  is real valued. This means that the analog of Figure 4.85 would have  $n - 1$  nonconstant cosine functions and only  $n - 2$  nonconstant sine functions as the imaginary part of the coefficient of  $X_{n/2}$  is 0, and thus the corresponding sine function plays no role in determining the values of the components of  $\vec{x}$ . Therefore, the analog of Figure 4.85 would actually have two broken lines passing through 0. This situation is illustrated in Figure 4.86 for the real-valued, four-dimensional feature vector  $\vec{x} = (1.2, 1.4, 0.65, -0.25)$ . Notice that we have three nonconstant cosine functions and two nonconstant sine functions. The cosine function corresponding to the frequency 0 is a constant equal to 0.75 (equal to the average of the four components). The amplitude of this constant cosine function corresponds to the value of the zeroth coefficient  $X_0$  and is equal to the average of the four components.

The Euclidean distance norm of a complex-valued sequence  $\vec{x} = \{x_t | 0 \leq t \leq n - 1\}$  is defined as

$$\|\vec{x}\| = \sqrt{\sum_{t=0}^{n-1} |x_t|^2}$$

We now show that the Euclidean distance norms of a sequence  $\vec{x}$  and its DFT  $\vec{X}$  are equal—that is,

$$\|\vec{x}\| = \|\vec{X}\| \quad (4.11)$$

Equation 4.11 is often referenced as Parseval's theorem [741, p. 1101]. Its validity can be seen by noting that the DFT is an example of a unitary transformation matrix  $M$  [701] (see Exercise 1). A matrix  $M$  is said to be *unitary* if the complex conjugate of the transpose of  $M$  (termed the *adjoint of  $M$*  and denoted by  $M^\dagger$ ) is equal to the inverse of  $M$ . In other words  $M^\dagger \cdot M = I$ , where  $I$  is the identity matrix with 1s on the diagonal and 0s elsewhere. The adjoint (like the transpose for real-valued matrices) has the property that it interchanges the order of a product of two matrices  $A$  and  $B$ —that is,

$$(A \cdot B)^\dagger = B^\dagger \cdot A^\dagger$$

Using this property, while also recalling that matrix multiplication is distributive (i.e.,  $A \cdot (B + C) = A \cdot B + A \cdot C$ ) and associative (i.e.,  $A \cdot (B \cdot C) = (A \cdot B) \cdot C$ ), and rewriting the DFT as  $\vec{X} = M \cdot \vec{x}$  enables us to verify equation 4.11:

$$\begin{aligned} \|\vec{X}\|^2 &= |(M \cdot \vec{x})^\dagger \cdot (M \cdot \vec{x})| \\ &= |(\vec{x}^\dagger \cdot M^\dagger) \cdot (M \cdot \vec{x})| \\ &= |\vec{x}^\dagger \cdot (M^\dagger \cdot M) \cdot \vec{x}| \\ &= |\vec{x}^\dagger \cdot \vec{x}| \\ &= \|\vec{x}\|^2 \end{aligned}$$

Equivalently, taking the squares of the two sides of Equation 4.11, we have

$$\|\vec{x}\|^2 = \sum_{t=0}^{n-1} |x_t|^2 = \sum_{f=0}^{n-1} |X_f|^2 = \|\vec{X}\|^2 \quad (4.12)$$

It can be shown that the DFT is a linear transformation (see Exercise 4), and thus from Equation 4.11, we know that the DFT also preserves the Euclidean distance  $d_E$  between two sequences  $\vec{x} = \{x_t | 0 \leq t \leq n-1\}$  and  $\vec{y} = \{y_t | 0 \leq t \leq n-1\}$ . In other words, the Euclidean distance between  $\vec{x}$  and  $\vec{y}$  is the same as the Euclidean distance between their corresponding DFTs  $\vec{X}$  and  $\vec{Y}$ , respectively—that is,

$$d_E(\vec{x}, \vec{y}) = d_E(\vec{X}, \vec{Y})$$

Next, we apply dimension reduction by truncating the sequence forming the DFT  $\vec{X}$  to  $k$  terms to form the new sequence  $\vec{X}_k$ , which is termed the *Compressed Discrete Fourier Transform (CDFT)* (or simply the *Compressed DFT*). Therefore, for  $k \leq n$ , we have that

$$\|\vec{X}_k\|^2 = \sum_{f=0}^{k-1} |X_f|^2 \leq \sum_{f=0}^{n-1} |X_f|^2 = \|\vec{X}\|^2 = \|\vec{x}\|^2 \quad (4.13)$$

This can be rewritten as

$$\|\vec{X}_k\| \leq \|\vec{X}\| = \|\vec{x}\| \quad (4.14)$$

If we now keep the first  $k$  components (i.e., coefficients) of the DFTs  $\vec{X}$  and  $\vec{Y}$  of two sequences (i.e., feature vectors)  $\vec{x}$  and  $\vec{y}$  to yield  $\vec{X}_k$  and  $\vec{Y}_k$ , respectively, then from Equations 4.13 and 4.14, we have that the Euclidean distance between  $\vec{X}_k$  and  $\vec{Y}_k$  is less than or equal to the Euclidean distance between  $\vec{x}$  and  $\vec{y}$ . This can be formally stated as

$$\|\vec{X}_k - \vec{Y}_k\| \leq \|\vec{x} - \vec{y}\| \quad (4.15)$$

Equation 4.15 is the same as the pruning property with the Euclidean distance:

$$d_E(\vec{X}_k, \vec{Y}_k) = d_E(\vec{x}, \vec{y})$$

Thus, we see that the pruning property holds for the CDFT when using the Euclidean distance. Note that the pruning property does not necessary hold for the CDFT when using other distance metrics (e.g., the City Block, Chessboard, or other distance metrics regardless of whether they are Minkowski distance metrics).

Although we have defined Equation 4.15 in terms of the first  $k$  coefficients of the DFT, it holds for any subset of  $k$  coefficients of the DFT. Thus, we broaden the definition of the CDFT to permit the subset to contain any of the coefficients of the DFT. Unfortunately, one of the main difficulties in using the DFT in a wide range of applications is deciding which of the coefficients should be retained as a result of dimension reduction when forming the CDFT.

This is in contrast to the SVD method, where the transformed coordinates are ordered by their discriminating power and thus we choose the  $k$  most discriminating transformed coordinates. Recall that, in the DFT, the coefficients of one feature vector are computed independently of the coefficients of the other feature vectors. The only intuition that we have about the coefficients is that the first one,  $X_0$ , corresponds to a mean value over all of the features that make up the feature vector, but we do not have such a simple intuitive interpretation for the remaining coefficients. Similarly,  $x_0$  (the first feature in the feature vector) is equal to the mean value over all of the coefficients.

A number of researchers (e.g., [26, 588]) have argued for retention of the first  $k$  coefficients of the DFT. They use the DFT to represent one-dimensional sequences in time-series databases for applications such as stock market price movements, as well as exchange rate fluctuations over time. In order to reduce the volume of data, they retain only a few of the Fourier coefficients in the DFT (the  $k$  leading ones), which are stored as points in an  $R^*$ -tree with dimension equal to the number of terms that make up the first few coefficients (usually the first two), thereby yielding four terms corresponding to the values of the real and imaginary components. The  $R^*$ -tree is used to index the points. This method was applied to similarity queries [26] and finding subsequences [588] in time-series databases.<sup>59</sup>

Although not explicitly stated in [26], in the case of similarity queries, it is most likely that the second ( $f = 1$ ) and third ( $f = 2$ ) Fourier coefficients are used rather than the first two. The reason is that the time series is real valued, which means that the first ( $f = 0$ ) Fourier coefficient has no imaginary part, and its real part is the mean of the time series. This has a number of ramifications. First, the true dimensionality of the feature vectors is three as one of the features is always zero. Second, if the corresponding elements of two sequences differ by a constant, then all of their coefficients will be the same except for the first one. In this case, if all of the coefficients are retained, then it is clear that the two series are very similar. However, if only two coefficients are retained, one of which is the first coefficient, then there will be a false impression that the two series are different when they are actually quite similar. Of course, if normalization is performed, as is often the case, then we have a time series with a zero mean and now the first coefficient is the same (i.e. both the real and imaginary parts are zero), for all of the time series, and once again it does not aid in discriminating between the different time series regardless of whether or not they differ by a constant. Thus, it is not advisable to use the first coefficient.

For finding subsequences, the situation is more complex, but the approach is similar. Faloutsos, Ranganathan, and Manolopoulos [588] assume that the smallest subsequence is of length  $w$ . Each time-series sequence of length  $l$  is decomposed into  $l - w + 1$  subsequences starting at the first instance of time, and the DFT of each subsequence is computed. Next, the  $k$  leading coefficients of the DFT of each subsequence are represented as  $2k$ -dimensional points using the values of their real and imaginary components. The difference from the way similarity queries were handled is that the  $R^*$ -tree does not index the points directly. Instead, the points (corresponding to subsequences) belonging to each different time-series sequence are connected to form a continuous curve, termed a *trail*, where there is one trail per sequence. Each trail is then decomposed into *subtrails* of appropriate length using heuristics (see Exercise 3), and minimum bounding boxes

---

<sup>59</sup> For a very different treatment of the two-dimensional problem for trajectories of moving objects, see [348].

are built for each subtrail (observe that the subtrails are not connected as they are formed by breaking up a sequence of points into subsequences). The  $R^*$ -tree indexes the minimum bounding boxes of the subtrails that are aggregated. Note that the minimum boxes of the subtrails of a given trail may overlap. Furthermore, the subtrails that make up the minimum bounding boxes in the levels other than the leaf nodes do not have to belong to the same trail. Thus, the result is that the  $R^*$ -tree is an index on all subsequences of length  $w$ .

Unlike the situation for similarity queries, as discussed above, it is not immediately obvious that the first ( $f = 0$ ) Fourier coefficient should be omitted for finding subsequences. We point out that even if the time series of length  $l$  is normalized so that it has a zero mean, each subsequence of length  $w$  does not necessarily have a zero mean. In fact, how the mean is changing over successive subsequences can be important for finding a complete similar time series. In particular, a time series is mapped to a trail, and the shape of this trail is different depending on which Fourier coefficients are used for the feature vector. Thus, we may have better accuracy for the matches when the mean is included. To see this, suppose that we consider single-element feature vectors that just consist of the mean. In this case, the trail can be visualized as a time series of length  $l - w + 1$  (i.e., we have  $l - w + 1$  subsequences with one feature vector per subsequence). Considered as a time series, the trail would be equal to the low-pass-filtered original time series. The filter is a moving average of width  $w$ , and thus the trail would represent the essential shape of the time series. Therefore, it might be useful to include the mean. Whether its inclusion as one of the coefficients will improve the accuracy of the match is unknown as this is done using different choices of coefficients. On the other hand, if we search for a subsequence, then we will probably miss many matching subsequences if we include the mean. This can be seen by observing that, if the first coefficient is not omitted and if all the corresponding elements of two sequences differ by a constant, then the corresponding elements of their subsequences also differ by a constant, and all of their coefficients will be the same except for the first one. This will result in their having two different trails instead of having the same trail (since they will coincide). Given all of these considerations, it is probably better to ignore the first coefficient.

Matching subsequences subject to a given error tolerance  $\varepsilon$  are found by applying the same transformation to the query sequence  $q$  (i.e., compute the DFT of  $q$ , retain the same  $k$  coefficients as the data sequences, and represent the result as a  $2k$ -dimensional points using the amplitude values of their real and imaginary components). The search is conducted in the  $2k$ -dimensional space indexed by the  $R^*$ -tree with a tolerance  $\varepsilon$  by finding overlapping bounding boxes. Once the bounding boxes are found, the corresponding subtrails are examined to determine which ones are within the desired tolerance, and the original subsequences are checked. Thus, we see that the bounding boxes serve to prune the search. Searches for larger subsequences are obtained by merging the results of the searches on the smaller subsequences.

The argument for retaining just the first few coefficients is made via an analogy to the problem of random walks. In particular, the first few coefficients represent the low-frequency components of the signal corresponding to the sequence, which are believed to be the dominant ones in this stock market price movements application [26, 588]. In fact, this was probably the case as the stock price movement data was relatively smooth and slow growing, thereby resulting in very few high-frequency components.

Experiments were conducted [26] using the  $R^*$ -tree with a varying number of leading coefficients. The results showed that the search time increased as the number of leading coefficients increased, although the filtering was a bit better with more coefficients. Nevertheless, the overall search time still increased when taking into account the filtering time. The reason the search time increased with more leading coefficients was due to the increased complexity of the  $R^*$ -tree search as the fanout of the nodes became smaller, and thus the tree was of greater height. However, no tests were conducted as to the effect of keeping the number of coefficients constant and varying which subset of the coefficients led to better performance. Of course, given the problem domain of

one-dimensional sequences in time-series databases, as mentioned above, the lower coefficients correspond to lower-frequency components that reflect less abrupt changes, thereby enabling matching over a longer time period with a lesser emphasis on sudden local variations.

In contrast with the results reported above, Wu, Agrawal, El Abbadi, Singh, and Smith [2026] describe the results of experiments using texture images modeled with a DFT where the identities of the retained Fourier coefficients make a difference in the efficiency of the search time. In such application domains, the question of which coefficients of the DFT ought to be retained is open. We now examine more closely the nature of the Fourier coefficients following the presentation of Wu et al. [2026]. This is dependent on the assumption that the components of the original feature vectors are constrained to be real valued. There are  $n$  coefficients  $X_i$  ( $0 \leq i \leq n-1$ ). Given that the components of the original feature vector are real valued, we have that coefficient  $X_0$  is a real number, and  $X_{n/2}$  is also a real number if  $n$  is an even number, while the remaining coefficients are complex numbers. Again, noting that the components of the original feature vector are real valued, the remaining coefficients occur in complex conjugate pairs such that  $X_{n-i} = X_i^*$ , where we say that, if  $A = a + bj$ , then the complex conjugate  $A^*$  of  $A$  is  $A^* = a - bj$ . Thus, the sequence of coefficients  $X_0, X_1, \dots, X_{n-1}$  can be rewritten as

$$X_0, X_1, \dots, X_{n/2-1}, X_{n/2}, X_{n/2-1}^*, \dots, X_2^*, X_1^*$$

where  $X_{n/2}$  is nonexistent if  $n$  is odd. In this sequence,  $X_i$  is said to be the  $i$ th *harmonic* using signal-processing terminology.

As mentioned above, in contrast to the SVD,<sup>60</sup> the order in which the coefficients appear in the DFT, save for the first one, is not particularly meaningful for most applications, and thus the coefficients are often reordered when dimension reduction is performed. In particular, the close relationship between a coefficient  $X_i$  and its conjugate pair  $X_{n-i}$  (i.e., being the  $i$ th harmonic) leads to an ordering that retains conjugate pairs in the CDFT. This is done by reformulating what constitute the components of each DFT sequence using Equation 4.12 and the fact that  $|X_i|^2 = |X_i^*|^2$  to obtain

$$\begin{aligned} \|\vec{X}\|^2 &= |X_0|^2 + |X_1|^2 + |X_1^*|^2 + \dots + |X_{n/2-1}|^2 + |X_{n/2-1}^*|^2 + |X_{n/2}|^2 \\ &= |X_0|^2 + 2|X_1|^2 + \dots + 2|X_{n/2-1}|^2 + |X_{n/2}|^2 \\ &= |X_0|^2 + |\sqrt{2}X_1|^2 + \dots + |\sqrt{2}X_{n/2-1}|^2 + |X_{n/2}|^2 \end{aligned}$$

Rewriting  $\|\vec{X}\|^2$  in this manner enables us to obtain a new set of  $n$  coefficients for the purpose of approximating the Euclidean distance norm of the DFT  $\vec{X}$  as follows:

$$X_0, \sqrt{2}\text{Re}(X_1), \sqrt{2}\text{Im}(X_1), \dots, \sqrt{2}\text{Re}(X_{n/2-1}), \sqrt{2}\text{Im}(X_{n/2-1}), X_{n/2} \quad (4.16)$$

We use the term *values* to describe the elements in Sequence 4.16 as they cannot be used as coefficients to recover the original feature vector from the DFT. Here, we have merged each pair of conjugates into a pair of single values corresponding to the real and imaginary parts of the corresponding coefficients by scaling them by a  $\sqrt{2}$  factor. It should be clear that the pruning property holds regardless of the size or the identities of the elements in the subset of the values or coefficients that are used in the CDFT. Assuming that we are using the values in Sequence 4.16, using terminology from signal processing, the first value is what is usually referred to as the *DC* component of the signal and is equal to  $X_0$ , the second term corresponds to the average contribution of the real parts of  $X_1$  and  $X_{n-1}$ , and the third term corresponds to the average contribution of the imaginary parts of  $X_1$  and  $X_{n-1}$ . In other words, the second and third terms correspond to the real and imaginary components of the first harmonic, the fourth and fifth terms correspond to

<sup>60</sup> Recall that the algorithm that calculates the SVD transform matrix  $V$  produces the component basis vectors in the order of decreasing variability.

the real and imaginary parts of the second harmonic, and so on. If we restrict ourselves to dimension reduction using an odd number of dimensions (i.e.,  $k$  components in the DFT), then we ensure that the harmonic contribution from each component is intact.

Despite the above reformulation of the components of the DFT, we still do not know for sure if the subset of the leading components (i.e., in increasing order of harmonics) is the right one. It could be that the leading components (if we truncate) are all zero, in which case we lose all information when we perform dimension reduction. Although this situation appears contrived, examples can be constructed that exhibit this behavior. In other words, regardless of how we reformulate the DFT, when we truncate the values or coefficients, we do not know if we have retained the most important ones. Again, we can be sure only that the first coefficient or value corresponds to an average over all the feature values (which could also be zero! and thus of not much help).

One way of overcoming this lack of knowledge is to look at all of the possible coefficients for all of the feature vectors and just pick the  $k$  dominant ones (i.e., the ones with the largest values). However, this cannot be done in a consistent manner because, for one feature vector, the last two coefficients could be dominant, while for another feature vector, the first two coefficients could be dominant. Thus, we must use some statistical measure, such as the largest mean (i.e., average) [2026] or the largest variance [988]. The result is termed a *Sorted DFT* (SDFT) [2026] when the Compressed DFT is formed with the  $k$  coefficients having the largest mean, and it is termed a *Variance DFT* (VDFT) [988] when the Compressed DFT is formed with the  $k$  coefficients having the largest variance. Keeping track of the coefficients with the largest mean or variance is quite simple and is achieved with a pair of constants  $M$  and  $V$  corresponding to the current value of the mean and variance, respectively, for each of the coefficients. Each time a new feature vector is added, we compute the coefficients of its DFT and update  $M$  and  $V$ . If there is a change in the set of  $k$  dominant coefficients, then we must recalculate the appropriate coefficients of the CDFT; otherwise, no additional work needs to be done.

Wu et al. [2026] compare the use of the CDFT and the SDFT with the SVD method. In order to make the comparison meaningful, comparisons are made using only an odd number of terms. In this way, whenever a CDFT or SDFT component is used, both its real and imaginary parts are taken into account. Thus, the harmonic contribution from each component is intact. Building the DFT for  $m$  feature vectors in  $n$ -dimensional space requires  $O(m \cdot n^2)$  operations, which is the same number needed to calculate the SVD. However, the constant of proportionality involved in building the DFT is considerably lower. The number of operations involved in building the DFT can be further reduced to  $O(mn \cdot \log n)$  when  $n$  is a power of 2 by calculating it using the Fast Fourier Transform (FFT) [421] (see Exercise 2). Computing the SDFT and the VDFT is a bit more complex as it requires keeping track of the mean and variance of the various coefficients.

Experiments have shown that the SVD method significantly outperforms the CDFT [2026]. Comparisons of the SVD method with the SDFT instead of the CDFT showed much better performance for the SDFT, which often rivaled the SVD method. In particular, this was the case for range queries with relatively small radius values and nearest neighbor queries with a small number of neighbors. These comparisons were more meaningful as they reflect a better trade-off between the local nature of the SDFT (for a small radius and a small number of neighbors) and the global nature of the SVD method. Recall that the DFT method applies a fixed transformation (not dependent on the values of the feature vectors) to each feature vector (albeit some global information is used to determine the dominant coefficients in the case of the SDFT). In contrast, the SVD method applies a transformation (based on the values of all of the feature vectors) to each feature vector and finds optimal dimensions (i.e., in terms of the greatest amount of variation) by using a least squares fit to the feature vectors. Kanth et al. [988] compare the SVD method with the VDFT and show that the precision of nearest neighbor queries is higher for the SVD method. However, no data is given on the relative execution time for the two methods, which in certain cases could make the VDFT a viable alternative to the SVD method.

1. Prove that the DFT is a unitary transformation.
2. Show how the DFT can be computed in  $O(n \log n)$  time for an  $n$ -dimensional feature vector.
3. In [588], curves (termed *trails*) formed by a sequence of points are decomposed into subcurves (termed *subtrails*) formed by subsequences of points. Note that the subcurves are not connected. How would you decompose the curve into subcurves? What is a good criterion for the decomposition process? Recall that the subcurves are indexed by an  $R^*$ -tree. Thus, are the conditions that make for a good  $R$ -tree decomposition (i.e., minimum overlap and minimum total area) also valid here? Alternatively, you may want to look at monotonicity of the subcurves.
4. Show that the DFT is a linear transformation.
5. Show that a shift in the time domain is equivalent to a rotation of the coefficients of the DFT.

### 4.6.5 Summary

Dimension reduction techniques have a number of drawbacks with respect to the ability to use them in conjunction with indexing methods so as to facilitate similarity searching:

1. As we have seen, search accuracy can suffer if the pruning property is not satisfied.
2. Most dimension reduction methods are tied to a specific distance metric (typically  $L_2$ , as in SVD/KLT/PCA discussed in Section 4.6.4.1 and DFT discussed in Section 4.6.4.2) and do not guarantee that the pruning property is satisfied for other distance metrics.
3. In order to be effective, they require that the data be strongly correlated, which means that, in the high-dimensional space, there are only a few independent dimensions, while the rest of the dimensions depend on them. This results in a loss of precision as many distinct points will be potentially mapped to the same representative point in the lower-dimension transformed space, which will result in degraded search performance.
4. Even if we reduce the number of dimensions, the resulting number may still be quite high with respect to the number of dimensions for which conventional indexing methods work well.
5. There are challenges in making them work in a dynamic environment, as the quality of the transformation may degrade (i.e., newly added data may not follow the same distribution as existing data), and thus it may be preferable to compute a new transformation based on the entire database. However, some work has been done to address this challenge (e.g., [988] for SVD).

## 4.7 Embedding Methods

Embedding methods are designed to facilitate similarity queries in an environment where we are given a finite set of  $N$  objects and a distance metric  $d$  indicating the distance values between them (collectively termed a *finite metric space*). As we discuss in Section 4.5, there are many applications where the cost of evaluating the distance between two objects is very high. Thus, the number of distance evaluations should be kept to a minimum, while (ideally) maintaining the quality of the result. At times, this distance function is represented by an  $N \times N$  similarity matrix containing the distance  $d$  between every pair of objects. One way to approach this goal is to *embed* the data objects in a vector space so that the distances of the embedded objects as measured by a distance metric  $d'$  approximate the actual distances. Thus, queries can be performed (for the most part) on

the embedded objects. In this section, we are especially interested in examining the issue of whether the embedding method returns the same query result as would be returned if the actual distances of the objects were used, thus ensuring that no relevant objects are left out (i.e., there are no false dismissals). In this context, particular attention is paid to SparseMap [886], a variant of Lipschitz embeddings [1181], and FastMap [587], which is inspired by the linear transformations discussed in Section 4.6.4.1 (e.g., KLT and the equivalent PCA and SVD). We also discuss locality sensitive hashing (LSH) [924] (Section 4.7.4), which is a method that combines an embedding into a Hamming space with a set of random projections into a subspace of the Hamming space. The key to its utility for similarity searching is its deployment in randomized approximate nearest neighbor algorithms. All three of these methods can be applied to arbitrary metric spaces.

This section is organized as follows. Section 4.7.1 contains an introduction to embedding methods, including a brief overview of multidimensional scaling. Section 4.7.2 describes Lipschitz embeddings, where the coordinate axes correspond to reference sets consisting of subsets of the objects. This includes a discussion of SparseMap. Section 4.7.3 presents the FastMap method. Section 4.7.4 discusses locality sensitive hashing in the context of randomized algorithms. As we point out earlier, embedding methods such as, locality sensitive hashing could have also been discussed in the context of dimension reduction techniques. We have placed them here as our emphasis is on how the distances in the embedding space approximate the actual distances.

Although it is not explicitly mentioned in the original presentations of some of the embedding methods (e.g., FastMap [587] and SparseMap [886]), we shall see below that it is desirable that the mapping  $F$  be such that distance functions  $d$  and  $d'$  obey the pruning property. Recall from Section 4.6.1 that the pruning property is satisfied if and only if  $d'(F(a), F(b)) \leq d(a, b)$  for all pairs of objects  $a$  and  $b$ . Satisfaction of the pruning property is useful for responding to similarity queries (such as nearest neighbors) when using a spatial index that has been built on the result of the mapping. This is because the pruning property ensures 100% recall, which guarantees that no correct responses are missed. The bulk of the presentation in this section is drawn from the analysis of Hjaltason and Samet [850, 855] of the extent to which various embedding methods satisfy the pruning property.

Nevertheless, despite our focus on the extent to which  $F$  satisfies the pruning property (i.e.,  $F$  is contractive), we also briefly discuss the alternative or additional notion of constructing an embedding that is proximity preserving. This turns out to be harder than merely requiring that the embedding be contractive. As we saw in Section 4.6.1.2, the proximity-preserving property is not commonly satisfied. Therefore, there has been some interest in devising embeddings that are approximately proximity preserving. One example of such a mapping is known as *BoostMap* and was developed by Athitsos, Alon, Sclaroff, and Kollios [106] (see also extensions [105, 107, 108]). BoostMap uses machine learning techniques to construct the mapping from a collection of one-dimensional embeddings that are classified as weakly proximity preserving. A mapping is said to be *weakly proximity preserving* if we know that, given triples of elements  $s$ ,  $t$ , and  $u$  in the underlying data domain  $S$ , the following properties are both either true or false for more than half of all of the triples of elements:

1.  $d(s, u) \leq d(t, u)$
2.  $|f(s) - f(u)| \leq |f(t) - f(u)|$

In other words, whenever  $u$  is closer to  $s$  than to  $t$ , we want  $f(u)$  to be closer to  $f(s)$  than to  $f(t)$  and vice versa (i.e., when  $f(u)$  is closer to  $f(s)$  than to  $f(t)$ , we want  $u$  to be closer to  $s$  than to  $t$ ). The notion of being weakly proximity preserving is used to capture the fact that this property is necessarily satisfied for all triples in  $S$ .

Some possible weakly proximity preserving one-dimensional mappings include  $f_r(s) = d(r, s)$ , where  $r$  and  $s$  are both in  $S$ , and  $r$  serves as a parameter reference object, termed a *pivot*, which means that in effect we are computing the distance of the objects

with respect to  $r$ . Another possibility, among many others, is to take the analog of a projection of an object  $s$  onto the line joining two parameter reference objects (i.e., two pivots)  $p$  and  $q$ —that is,

$$f_{p,q}(s) = \frac{d(p,s)^2 + d(p,q)^2 - d(q,s)^2}{2 \cdot d(p,q)}$$

The interpretation of this mapping as a projection only makes sense if the underlying domain  $S$  is a vector space; of course, the mapping is still valid regardless of the nature of  $S$ .

The AdaBoost machine learning technique (e.g., [648, 1682]) is used by BoostMap to construct an optimal linear combination of  $k$  of these weakly proximity preserving one-dimensional mappings, where “optimal” is with respect to the proximity-preserving property. In particular, the  $k$  one-dimensional mappings that make up the linear combination are used as the coordinates of an embedding into  $\mathbb{R}^k$ , and the coefficients  $a_j$  ( $1 \leq j \leq k$ ) of the linear combination are used as the coefficients for a generalized  $L_1$  distance,  $D(X, Y) = \sum_{j=1}^k a_j \cdot |Y_j - X_j|$ , where  $X$  and  $Y$  are in  $\mathbb{R}^k$  (an image of  $S$ ).

With this embedding and easily computable distance function, we can use an appropriate indexing technique, coupled with a filter-and-refine strategy, to perform nearest neighbor queries, although we may not achieve 100% recall as there is no guarantee that the embedding is completely proximity preserving. Note that the construction process of the embedding that we have described does not make any provisions for contractiveness or for a limited amount of distortion (i.e., the ratio of the distance in the embedding space to that in the original space). Of course, it is desirable for an embedding to be both contractive and proximity preserving, although neither is necessary for the other—that is, an embedding can be contractive while not being proximity preserving. Similarly, an embedding can be proximity preserving while not being contractive.

### 4.7.1 Introduction

The motivation behind the development of embedding methods is that, given a sufficiently high value of  $k$ , we can find a function  $F$  that maps the  $N$  objects into a vector space of dimensionality  $k$ , such that the distances between the points are approximately preserved when using a distance function  $d'$  in the  $k$ -dimensional space. In other words, for any pair of objects  $a$  and  $b$ , we have  $d(a, b) \approx d'(F(a), F(b))$ . Formally, the mapping  $F$  embeds a finite metric space  $(S, d)$  into a vector space  $\mathbb{R}^k$  possessing a distance metric  $d'$ , where  $S \subset U$  is a dataset of  $N$  objects drawn from a universe  $U$ , and  $d : U \rightarrow \mathbb{R}^+$  is the original distance function on  $U$ . The mapping  $F : S \rightarrow \mathbb{R}^k$  is often said to be an *embedding*, and, if  $d'$  is the Euclidean distance metric, then  $F$  is a *Euclidean embedding*. Note that this problem setting also includes the situation where the  $N$  objects are described by an  $n$ -dimensional feature vector (this is an example of the case that the original distance function  $d$  is computed from the objects rather than existing in a distance matrix). In this case, the mapping  $F$  reduces the dimensionality of the problem setting from  $n$  to  $k$ .

In practice, our goal is to use a relatively low value for  $k$  in the mapping (i.e.,  $k \ll N$ ), while still achieving reasonable distance preservation. Observe that distance computation can be expensive (e.g., the Euclidean distance in very high-dimensional spaces), so the mapping  $F$  should ideally be fast to compute (i.e., take  $O(N)$  time or  $O(N \log N)$  time for the  $N$  objects rather than requiring the computation of the distances between all  $O(N^2)$  pairs of objects), should preserve distance to a reasonable extent, and should provide a fast way of obtaining the  $k$ -dimensional point corresponding to the object.

At times, the distances between the objects are preserved exactly by the mapping  $F$ —that is,  $d(a, b) = d'(F(a), F(b))$  for all objects  $a, b \in S$ . Of course, in this case,  $F$  is also proximity preserving. When this occurs, we say that  $(S, d)$  and  $(\mathbb{R}^k, d')$  are *isometric* (strictly speaking,  $(S, d)$  is isometric to  $(F(S), d')$ , where  $F(S) \subset \mathbb{R}^k$  is the image of  $S$

under  $F$ ). For example, this is possible when the data objects are originally drawn from a vector space, and  $d$  and  $d'$  are both Euclidean distance metrics. In this particular case, distance preservation among the  $N$  objects is ensured when  $k = N - 1$  (but a much lower value suffices in most cases). However, usually, the distances cannot be preserved exactly for an arbitrary combination of  $d$  and  $d'$ , regardless of the value of  $k$  (i.e., there is no guarantee that a distance-preserving mapping  $F$  exists).

As an example of a situation where distances cannot be preserved exactly, suppose that we are given four objects  $a$ ,  $b$ ,  $c$ , and  $e$  with a distance function  $d$  such that the distance between each pair in  $\{a, b, c\}$  is 2, and the distance from  $e$  to each of  $a$ ,  $b$ , and  $c$  is 1.1. This distance function  $d$  satisfies the triangle inequality. However, these four objects cannot be embedded into a three-dimensional Euclidean space (i.e., where  $d'$  is the Euclidean distance metric). In other words, we cannot position the objects in a three-dimensional space so that the Euclidean distance  $d'$  between the positions corresponds to the distance between the objects given by  $d$ . On the other hand, if the distance between  $e$  and the three remaining objects is at least  $2/\sqrt{3}$ , then such a positioning is possible by placing  $a$ ,  $b$ , and  $c$  in a plane  $p$  and placing  $e$  on the line perpendicular to  $p$  that passes through the centroid of the triangle in  $p$  formed by  $a$ ,  $b$ , and  $c$ .

Interestingly, the above embedding can be achieved if we use the City Block distance metric. In particular, we position objects  $a$ ,  $b$ , and  $c$  at locations  $(0,0,0)$ ,  $(2,0,0)$ , and  $(1,1,0)$ , respectively, and  $e$  at  $(1,0,0.1)$ . Thus, we see that we can often obtain better distance correspondence by being flexible in choosing the distance function  $d'$ . In fact, it is always possible to achieve exact distance preservation when  $d'$  is the Chessboard metric ( $L_\infty$ ). In one such embedding, there is one dimension for each object  $o_i$ , where  $o_1, o_2, \dots, o_N$  is an enumeration of the objects. Each object  $o$  is mapped by  $F$  into the vector  $\{d(o, o_1), d(o, o_2), \dots, d(o, o_N)\}$ . For any pair of objects  $o_i$  and  $o_j$ , their distance in the embedding is  $d'(F(o_i), F(o_j)) = d_M(F(o_i), F(o_j)) = \max\{|F(o_i) - F(o_j)|\} = \max_l\{|d(o_i, o_l) - d(o_j, o_l)|\}$ . Observe that for any  $l$ ,  $|d(o_i, o_l) - d(o_j, o_l)| \leq d(o_i, o_j)$  by the triangle inequality, while equality is achieved for  $l = i$  and  $l = j$ , and thus distances are indeed preserved by  $F$  when using the Chessboard metric.

Notice that the number of dimensions in this distance-preserving embedding is rather high (i.e.,  $k = N$ ). Thus, we may want to define  $F$  in terms of a subset of the objects as done by Faragó, Linder, and Lugosi [595], although they do not indicate how to choose the  $k$  objects that form the subset. However, for lower values of  $k$ , it is possible that a better approximation of the original distances is obtained by a choice of  $d'$  other than  $L_\infty$ . The same type of embedding is also used by Vleugels and Veltkamp [1934], who employ an application-dependent method to choose the  $k$  reference objects (e.g., in an application involving hue, the dominant colors of each of the objects differ), which are called *vantage objects*.

In most applications, it is not possible to achieve distance preservation given a particular choice for  $d'$  and  $k$ . In fact, we are often satisfied when the distance  $d'$  in the  $k$ -dimensional embedding space between the points that correspond to any pair of individual objects  $a$  and  $b$  is less than the true distance  $d$  between the objects in the original space—that is,  $d'(F(a), F(b)) \leq d(a, b)$ . This property is known as the *pruning property* and is discussed in Section 4.6.1. As pointed out earlier, satisfaction of the pruning property is useful for responding to similarity queries (such as nearest neighbors) when using a spatial index that has been built on the result of the mapping. This is because the pruning property ensures 100% recall, which guarantees that no correct responses are missed.

The concept of *distortion* (e.g., [1181]) is frequently used for measuring the quality of an embedding procedure (i.e., a method that constructs a mapping  $F$ ) or of a particular embedding  $F$  produced by such a procedure. Distortion measures how much larger or smaller the distances in the embedding space  $d'(F(o_1), F(o_2))$  are than the corresponding distances  $d(o_1, o_2)$  in the original space. In particular, the distortion is defined as  $c_1 c_2$  when we are guaranteed that

$$\frac{1}{c_1} \cdot d(o_1, o_2) \leq d'(F(o_1), F(o_2)) \leq c_2 \cdot d(o_1, o_2) \quad (4.17)$$

for all pairs of objects  $o_1, o_2 \in S$ , where  $c_1, c_2 \geq 1$ . In other words, the distance values  $d'(F(o_1), F(o_2))$  in the embedding space may be as much as a factor of  $c_1$  smaller and a factor of  $c_2$  larger than the actual distances  $d(o_1, o_2)$ . Note that for a given embedding procedure, there may be no upper or lower bound on the distance ratio for the embeddings that it constructs, so  $c_1, c_2$ , or both may be infinite in this case. Of course, the distortion is always bounded for any given embedding  $F$  and finite metric space  $(S, d)$ . A number of general results are known about embeddings—for example, that any finite metric space can be embedded in Euclidean space with  $O(\log N)$  distortion [1181].

Another common measure of a particular embedding  $F$  with respect to a dataset  $S$  is *stress* [1090]. Stress measures the overall deviation in the distances (i.e., the extent to which they differ) and is typically defined in terms of variance:

$$\frac{\sum_{o_1, o_2} (d'(F(o_1), F(o_2)) - d(o_1, o_2))^2}{\sum_{o_1, o_2} d(o_1, o_2)^2}$$

Alternative definitions of stress may be more appropriate for certain applications. For example, the sum in the denominator may be on  $d'(F(o_1), F(o_2))^2$ , or the division by  $d(o_1, o_2)^2$  may occur inside the sum (instead of in a separate sum). Multidimensional scaling (MDS) [1090, 1879, 2056] is a method of constructing  $F$  that is based on minimizing stress. It has been widely used for many decades, in both the social and physical sciences, for purposes such as visualizing and clustering the data resulting from experiments. MDS is defined in many ways, some of which even allow nonmetric distances (i.e., the triangle inequality is not required).

Minimizing stress is essentially a nonlinear optimization problem, where the variables are the  $N \cdot k$  coordinate values corresponding to the embedding (i.e.,  $k$  coordinate values for each of the  $N$  objects). Typically, solving such a problem involves starting with an arbitrary assignment of the variables and then trying to improve on it in an iterative manner using the method of steepest descent (e.g., [1090]). The result of the optimization is not always the embedding that achieves the absolute minimum stress, but instead it is one that achieves a local minimum (i.e., the minimization can be pictured as finding the deepest valley in a landscape by always walking in a direction that leads downhill; the process can thus get stuck in a deep valley that is not necessarily the deepest).

In principle, it is possible to make the result of MDS satisfy the pruning property by constraining the minimization of the stress with  $O(N^2)$  pruning property conditions, one for each pair of objects—that is, to minimize

$$\sum_{a, b \in S} (d'(F(a), F(b)) - d(a, b))^2 / \sum_{a, b \in S} d(a, b)^2$$

subject to the  $O(N^2)$  conditions  $d'(F(a), F(b)) - d(a, b) \leq 0$  (for all pairs  $a, b \in S$ ). Note that simply minimizing the stress does not necessarily mean that the pruning property is satisfied. In particular, the stress could be minimized when the distance difference in the  $k$ -dimensional space (relative to the distance in the original space) increases by a large amount for one of the object pairs, whereas it decreases by just a small amount for all remaining pairs.

Unfortunately, MDS has limited applicability in similarity search, regardless of whether the resulting embedding satisfies the pruning property. This is partly due to the high cost of constructing the embedding, both in terms of the number of distance computations (i.e.,  $O(N^2)$ , one for each pair of objects) and partly due to the inherent complexity of the optimization process. More seriously, when performing similarity queries, we must compute the embedding of the query object  $q$ , again, by minimizing stress subject only to varying the coordinate values of  $F(q)$ . Although the minimization process is itself expensive, the most serious drawback is that the distances of all objects in  $S$  from  $q$  must be computed in order to evaluate the stress—that is,  $O(N)$  distance

computations are required. This completely defeats the goal of performing similarity queries in terms of the embedding space, namely, to avoid as many distance computations as possible. In fact, after computing the distances of all objects in  $S$  from  $q$ , we can immediately tell what the result of the query should be, thereby making the embedding of  $q$  unnecessary.

The Karhunen-Loève Transform (KLT), as well as the equivalent Principal Component Analysis (PCA) and the Singular Value Decomposition (SVD) methods discussed in Section 4.6.4.1, are the optimal methods of linearly transforming  $n$ -dimensional points to  $k$ -dimensional points ( $k \leq n$ ). In particular, they minimize the *mean square error*—that is, the sum of the squares of the Euclidean distances between each  $n$ -dimensional point and its corresponding  $k$ -dimensional point (notice the similarity to minimizing the stress function in MDS described above). The goal of these methods is to find the most important features (more precisely, a linear combination of features) for a given set of feature vectors. The rationale behind them is that they can be interpreted as providing a new set of features ranked by their importance (i.e., their variation) so that if we ignore the less important (i.e., varying) ones by projecting onto the most important (i.e., varying) ones, then we preserve as much as possible of the variation between the original set of feature vectors as measured by the Euclidean distance between them.

These methods have several drawbacks. First, they cannot be applied when we are given only the distances between the objects (i.e., the distance function) and do not have the  $m$ -dimensional feature vectors. Second, they are very slow to compute, taking  $O(N \cdot m^2)$  time, especially when there are many feature vectors ( $N$ ), and the dimension  $m$  of the original space is very high.

Moreover, these methods are really meaningful only if  $d$  is the Euclidean distance metric and not one of the other Minkowski metrics. The reason is twofold. First, the other Minkowski metrics are not invariant under rotation. In other words, the distance between some pairs of points may increase or decrease, depending on the direction of the rotation. Second, variance is defined in terms of second powers, just like the Euclidean distance metric. Thus, the variance criteria that determine the rotation and, in turn, what axes to drop when reducing the dimensionality are inherently related to the Euclidean distance metric. In particular, the sum of the variances over all coordinate axes corresponds to the sum of the squared Euclidean distances from the origin to each point (recall that we are assuming that the mean along each dimension is at the origin). Therefore, dropping the axes having the least variance corresponds to reducing as little as possible the sum of the squared Euclidean distances from the origin to each point.

In contrast, as we will see, the embedding methods that we describe can be used with other distance metrics than the Euclidean distance metric. Moreover, they can be used with data from an arbitrary metric space (i.e., the only information about the data objects consists of the interobject distances). However, for some of the methods, such as FastMap, such usage is usually of limited interest as it does not necessarily satisfy the pruning property, and it may work only for very small values of  $k$  (even as small as just 1), instead of an arbitrary value of  $k$  when  $d$  is the Euclidean distance metric. However, the general class of Lipschitz embeddings does satisfy the pruning property, and, as we shall see, even the SparseMap method can be made to satisfy the pruning property.

### Exercise

1. Devise an implementation of MDS where the variance in the difference of the distance values is minimized and the distance in the  $k$ -dimensional space satisfies the pruning property. If this is not possible, then give a counterexample.

## 4.7.2 Lipschitz Embeddings

A powerful class of embedding methods is known as *Lipschitz embeddings* [237, 962]. They are based on defining a coordinate space where each axis corresponds to a reference set that is a subset of the objects. This is the subject of this section, which is organized as follows. Section 4.7.2.1 defines a Lipschitz embedding. Section 4.7.2.2 describes how to select the reference sets. Section 4.7.2.3 presents an example of a Lipschitz embedding. Section 4.7.2.4 explains SparseMap, which is an instance of a Lipschitz embedding that attempts to reduce the computational cost of the embedding.

### 4.7.2.1 Definition

A Lipschitz embedding is defined in terms of a set  $R$  of subsets of  $S$ ,  $R = \{A_1, A_2, \dots, A_k\}$ .<sup>61</sup> The subsets  $A_i$  are termed the *reference sets* of the embedding. Let  $d(o, A)$  be an extension of the distance function  $d$  to a subset  $A \subset S$  such that  $d(o, A) = \min_{x \in A} \{d(o, x)\}$ . An embedding with respect to  $R$  is defined as a mapping  $F$  such that  $F(o) = (d(o, A_1), d(o, A_2), \dots, d(o, A_k))$ . In other words, we are defining a coordinate space where each axis corresponds to a subset  $A_i \subset S$  of the objects, and the coordinate values of object  $o$  are the distances from  $o$  to the closest element in each of  $A_i$ .

Notice that the distance-preserving  $L_\infty$  embedding that we describe in Section 4.7.1 is a special case of a Lipschitz embedding, where  $R$  consists of all singleton subsets of  $S$  (i.e.,  $R = \{\{o_1\}, \{o_2\}, \dots, \{o_N\}\}$ ). Recall also the embedding of Faragó et al. [595], which made use of a subset of singleton subsets of  $S$  for a nearest neighbor search application (although they do not specify how to choose the objects that make up  $R$ ). Another variation on a Lipschitz embedding is presented by Cowen and Priebe [426], where the number and sizes of the reference sets  $A_i$  are chosen based on an objective function that is meant to capture the quality of clustering that results. The distance-based indexing methods that make use of distance matrices described in Section 4.5.7 (e.g., see [130, 1292, 1743, 1930, 1951]) are also somewhat related to Lipschitz embeddings. These methods typically (e.g., see [1292]) make use of a matrix  $D = (D_{ij})$  of distances, where  $D_{ij} = d(o_i, p_j)$  and  $T = \{p_1, p_2, \dots, p_k\}$  is a set of  $k$  reference objects; for some methods (e.g., AESA [1930]),  $T = S$  and  $k = N$ . The row vectors of  $D$  are equivalent to the result of a Lipschitz embedding using the singleton reference sets of objects in  $T$ . However, the search algorithms proposed for distance matrix methods do not explicitly treat the row vectors as if they represent points in geometric space (i.e., by using the Euclidean metric or some other Minkowski metric).

The intuition behind the Lipschitz embedding is that if  $x$  is an arbitrary object in the dataset  $S$ , some information about the distance between two arbitrary objects  $o_1$  and  $o_2$  is obtained by comparing  $d(o_1, x)$  and  $d(o_2, x)$  (i.e., the value  $|d(o_1, x) - d(o_2, x)|$ ). This is especially true if one of the distances  $d(o_1, x)$  or  $d(o_2, x)$  is small. Observe that, due to the triangle inequality, we have  $|d(o_1, x) - d(o_2, x)| \leq d(o_1, o_2)$ , as illustrated in Figure 4.87. This argument can be extended to a subset  $A$ . In other words, the value  $|d(o_1, A) - d(o_2, A)|$  is a lower bound on  $d(o_1, o_2)$ . This can be seen as follows. Let  $x_1, x_2 \in A$  be such that  $d(o_1, A) = d(o_1, x_1)$  and  $d(o_2, A) = d(o_2, x_2)$ . Since  $d(o_1, x_1) \leq d(o_1, x_2)$  and  $d(o_2, x_2) \leq d(o_2, x_1)$ , we have  $|d(o_1, A) - d(o_2, A)| = |d(o_1, x_1) - d(o_2, x_2)|$ . Accounting for the fact that  $d(o_1, x_1) - d(o_2, x_2)$  can be positive or negative, we have  $|d(o_1, x_1) - d(o_2, x_2)| \leq \max\{|d(o_1, x_1) - d(o_2, x_1)|, |d(o_1, x_2) - d(o_2, x_2)|\}$ . Finally, from the triangle inequality, we have  $\max\{|d(o_1, x_2) - d(o_2, x_2)|, |d(o_1, x_1) - d(o_2, x_1)|\} \leq d(o_1, o_2)$ . Thus,  $|d(o_1, A) - d(o_2, A)|$  is a lower bound on  $d(o_1, o_2)$ . By using a set  $R$  of subsets, we increase the likelihood that the distance  $d(o_1, o_2)$  between two objects  $o_1$  and  $o_2$  (as measured relative to other distances) is captured adequately by the distance in the embedding space between  $F(o_1)$  and  $F(o_2)$  (i.e.,  $d'(F(o_1), F(o_2))$ ).

Figure 4.87  
Demonstration of the distance bound  $|d(o_1, x) - d(o_2, x)| \leq d(o_1, o_2)$ . The objects  $o_1$ ,  $o_2$ , and  $x$  are represented as points, and the distances between them by the lengths of the line segments between them.

<sup>61</sup> Note that the union of the set of elements comprising the subsets that make up  $R$  is not necessarily equivalent to  $S$ .

### 4.7.2.2 Selecting Reference Sets

With a suitable definition of  $R$ , the set of reference sets, we can establish bounds on the distance  $d'(F(o_1), F(o_2))$  for all pairs of objects  $o_1, o_2 \in S$ , where  $d'$  is one of the  $L_p$  metrics. Such a definition was provided by Linial, London, and Rabinovich [1181], based in part on previous work by Bourgain [237]. In particular, in their definition [1181],  $R$  consists of  $O(\log^2 N)$  randomly selected subsets of  $S$ , where each group of  $O(\log N)$  subsets is of size  $2^i$ , where  $i = 1, \dots, O(\log N)$ . More concretely, the value  $O(\log N)$  is typically approximately  $\lfloor \log_2 N \rfloor$  (or perhaps  $\lfloor \log_2(N-1) \rfloor$ ). Thus,  $R = \{A_1, A_2, \dots, A_k\}$ , where  $k = \lfloor \log_2 N \rfloor^2$ , and  $A_i$  is of size  $2^j$  with  $j = \lfloor (i-1)/(\log_2 N) + 1 \rfloor$ . The embedding proposed by Linial et al. [1181] is a variant of the basic Lipschitz embedding, where each coordinate value is divided by a factor that depends on  $k$ . In particular, if  $d'$  is the  $L_p$  metric,  $F$  is defined such that  $F(o) = (d(o, A_1)/q, d(o, A_2)/q, \dots, d(o, A_k)/q)$ , where  $q = k^{1/p}$ . Given this definition, Linial et al. [1181] prove that  $F$  satisfies

$$\frac{c}{\lfloor \log_2 N \rfloor} \cdot d(o_1, o_2) \leq d'(F(o_1), F(o_2)) \leq d(o_1, o_2) \quad (4.18)$$

for any pair of objects  $o_1, o_2 \in S$ , where  $c > 0$  is a constant.<sup>62</sup> Thus, the distortion in distance values (i.e., the relative amount of deviation of the distance values in the embedding space with respect to the original distance values) is guaranteed to be  $O(\log N)$  (with high probability). The proof for the bound  $c/\lfloor \log_2 N \rfloor d(o_1, o_2) \leq d'(F(o_1), F(o_2))$  is rather sophisticated [237, 1181] and is beyond the scope of this discussion. However, the bound  $d'(F(o_1), F(o_2)) \leq d(o_1, o_2)$  is easy to show. In particular, for each  $A_i \in R$ , we have  $|d(o_1, A_i) - d(o_2, A_i)| \leq d(o_1, o_2)$ , as shown in Section 4.7.2.1. Thus, when  $d'$  is an arbitrary  $L_p$  distance metric,

$$d'(F(o_1), F(o_2)) = \left( \sum_{i=1}^k \left( \frac{d(o_1, A_i) - d(o_2, A_i)}{k^{1/p}} \right)^p \right)^{1/p} \quad (4.19)$$

$$\leq \left( k \cdot \frac{d(o_1, o_2)^p}{k} \right)^{1/p} = d(o_1, o_2) \quad (4.20)$$

A distortion of  $O(\log N)$  may seem rather large and may render the embedding ineffective at preserving relative distances. For example, if the range of distance values is less than the distortion, then the relative order of the neighbors of a given object may be completely scrambled. However, note that  $O(\log N)$  is a worst-case (probabilistic) bound. In many cases, the actual behavior is much better. For example, in a computational biology application [886, 1180], the embedding defined above was found to lead to good preservation of clusters, as defined by biological functions of proteins.

Notice that the mapping  $F$  as defined by Linial et al. [1181] satisfies the pruning property (i.e., it is contractive), which is advantageous in similarity search. In many other situations, only relative differences in distance are important in the embedding space, while the satisfaction of the pruning property is immaterial. In other words, the crucial information that we wish to retain is which objects are close to each other and which are far (i.e., a weak form of proximity preservation). An example of an application of this sort is cluster analysis [886, 1180]. In such situations, it may be more convenient to use the regular Lipschitz embedding definition of  $F$  with respect to the set of reference sets  $R$  defined in [1181] (i.e., without dividing by  $k^{1/p}$ ). Recall that  $k = \lfloor \log_2 N \rfloor^2$ , thereby implying that  $\sqrt{k} = \lfloor \log_2 N \rfloor$ . Therefore, when the Euclidean distance metric is being used, this embedding guarantees distance bounds of

$$c \cdot d(o_1, o_2) \leq d_E(F(o_1), F(o_2)) \leq \lfloor \log_2 N \rfloor \cdot d(o_1, o_2)$$

for any pair of objects  $o_1, o_2 \in S$ , where  $c > 0$  is a constant (with high probability).

<sup>62</sup> More accurately, since the sets  $A_i$  are chosen at random, the proof is probabilistic, and  $c$  is a constant with high probability.

Object	$o_1$	$o_2$	$o_3$	$o_4$	$o_5$	$o_6$	$o_7$	$o_8$	$o_9$	$o_{10}$
$o_1$	0	2	13	7	3	8	11	4	9	10
$o_2$	2	0	11	9	3	10	9	2	11	8
$o_3$	13	11	0	6	10	9	4	9	6	3

$A_2$	0	2	10	6	0	7	8	3	8	7
$A_3$	4	2	3	2	3	0	3	0	0	0
$A_4$	0	2	4	0	3	3	0	0	2	3

Figure 4.89  
Four-dimensional coordinate values for the 10 objects based on the distances in Figure 4.88, as determined by a Lipschitz embedding with the four reference sets  $A_1 = \{o_2, o_8\}$ ,  $A_2 = \{o_1, o_5\}$ ,  $A_3 = \{o_6, o_8, o_9, o_{10}\}$ , and  $A_4 = \{o_1, o_4, o_7, o_8\}$ .

Unfortunately, the embedding of [1181] described above is rather impractical for similarity searching for two reasons. First, due to the number and sizes of the subsets in  $R$ , there is a high probability that all  $N$  objects appear in some set in  $R$ . Thus, when computing the embedding  $F(q)$  for a query object  $q$  (which generally is not in  $S$ ), we will need to compute the distances between  $q$  and practically all objects in  $S$ , which is exactly what we wish to avoid. Second, the number of subsets in  $R$ , and thus the number of coordinate values (i.e., dimensions) in the embedding, is relatively large—that is,  $\lceil \log_2 N \rceil^2$ . Even with as few as 100 objects, the number of dimensions is 36, which is much too high to index on efficiently with multidimensional indexing methods. These drawbacks are acknowledged in [1181], but addressing them is left for future work (the only suggestion made is to drop the sets  $A_i$  of largest sizes).

### 4.7.2.3 Example of a Lipschitz Embedding

We now give an example of Lipschitz embedding. Figure 4.88 shows the interobject distances between 10 objects (these distance values were constructed by positioning 10 two-dimensional points and measuring the  $L_1$  distance between them). In this case,  $\lceil \log_2 N \rceil = 3$ , so we can have three reference sets of three different sizes (2, 4, and 8) for a total of nine dimensions. Since a set of size 8 contains nearly all of the objects, we instead choose to use only reference sets of sizes 2 and 4, and two sets of each size. Choosing objects at random, we arrive at the sets  $A_1 = \{o_2, o_8\}$ ,  $A_2 = \{o_1, o_5\}$ ,  $A_3 = \{o_6, o_8, o_9, o_{10}\}$ , and  $A_4 = \{o_1, o_4, o_7, o_8\}$ . The resulting four-dimensional coordinates are given in Figure 4.89. Here, we use the regular Lipschitz embedding, where coordinate value  $j$  for object  $o_i$  is  $d(o_i, A_j)$ , rather than  $d(o_i, A_j)/k^{1/p}$  as specified by Linial et al. [1181]. For example,  $d(o_4, A_2) = \min\{d(o_4, o_1), d(o_4, o_5)\} = \min\{7, 6\} = 6$ .

We now give an example of how to compute the distance between two objects in the embedding space, when  $d'$  is the Euclidean distance metric. In particular, for objects  $\mathbf{o}_3$  and  $\mathbf{o}_8$ , we have from Figure 4.89 that  $F(\mathbf{o}_3) = (9, 10, 3, 4)$  and  $F(\mathbf{o}_8) = (0, 0, 3, 0)$ . Therefore,

$$\begin{aligned} d'(F(\mathbf{o}_3), F(\mathbf{o}_8)) &= \sqrt{(9-0)^2 + (10-3)^2 + (3-0)^2 + (4-0)^2} \\ &= \sqrt{81 + 49 + 9 + 16} = \sqrt{155} \approx 12.4 \end{aligned}$$

In comparison, their actual distance is  $d(\mathbf{o}_3, \mathbf{o}_8) = 9$ . Notice that in this case the distance in the embedding space is greater than the actual distance. In contrast, when we use the embedding of Linial et al. [1181], the distance in the embedding space will be about  $12.4/\sqrt{4} = 6.2$ . Also, if  $d'$  is the Chessboard distance metric ( $L_\infty$ ), the distance in the embedding space will be  $\max\{9, 7, 3, 4\} = 9$ , which happens to equal  $d(\mathbf{o}_3, \mathbf{o}_8)$ .

#### 4.7.2.4 SparseMap

SparseMap [886] is an embedding method originally proposed for mapping a database of proteins into Euclidean space. It is built on the work of Linial et al. [1181] in that the same set of reference sets  $R$  is used. The SparseMap method [886] comprises two heuristics, each aimed at alleviating one of the drawbacks discussed in Section 4.7.2.2—that is, the potentially high cost of computing the embedding in terms of the number of distance computations that are needed and the large number of coordinate values. The first heuristic reduces the number of distance computations by calculating an upper bound  $\hat{d}(o, A_i)$  instead of the exact value  $d(o, A_i)$ . The second heuristic reduces the number of dimensions by using a “high-quality” subset of  $R$  instead of the entire set, as defined in Section 4.7.2.2. Both heuristics have the potential to reduce the quality of the embedding in terms of the correspondence of distances in the original metric space and in the embedding space, but their goal [886] is to maintain the quality to the greatest extent possible. Note that the embedding used in SparseMap employs the regular Lipschitz embedding with respect to  $R$ , rather than the embedding proposed in [1181] (which divides the distances  $d(o, A_i)$  by  $k^{1/p}$ ), and uses the Euclidean distance metric.

In SparseMap, the coordinate values of the vectors are computed one by one. In other words, if  $R = \{A_1, A_2, \dots, A_k\}$  is the sequence of reference sets in order of size, we first compute  $d(o, A_1)$  for all objects  $o \in S$ , next  $d(o, A_2)$  for all objects  $o$ , and so on. Since evaluating  $d(o, A_i)$  for any given object  $o$  can be very expensive in terms of distance computations, SparseMap adopts a heuristic that instead computes  $\hat{d}(o, A_i)$ , which is an upper bound on  $d(o, A_i)$ . This heuristic exploits the partial vector that has already been computed for each object, and only calculates a fixed number of distance values for each object (as opposed to  $|A_i|$  distance values). In particular, for each object  $x \in A_i$ , it computes  $d_E(F_{i-1}(o), F_{i-1}(x))$ , where  $F_{i-1}$  is the embedding based on  $A_1, \dots, A_{i-1}$ . On the basis of this approximate distance value, a fixed number  $l$  of objects in  $A_i$  having the smallest approximate distance value from  $o$  is picked, and the actual distance value  $d(o, x)$  for each such object  $x$  is computed. The smallest distance value among those serves as the upper-bound distance value  $\hat{d}(o, A_i)$ , which becomes the  $i$ th coordinate value of the vector corresponding to  $o$  in the embedding.

The second heuristic involved in SparseMap reduces the dimensionality of the result and is termed *greedy resampling* in [886]. Greedy resampling is applied after the  $k$  coordinate axes have all been determined, and its goal is to reduce the number of coordinate axes to  $k' < k$ . Essentially, this means eliminating some of the reference sets  $A_i$ . A natural question is whether we cannot eliminate a poor reference set  $A_i$  before computing all the approximate distances  $\hat{d}(o, A_i)$ . However, the problem is that we cannot know whether a set  $A_i$  is good before evaluating  $\hat{d}(o, A_i)$  (or  $d(o, A_i)$ ) for each object  $o$ . The basic idea of greedy resampling is to start with a single “good” coordinate axis and then incrementally to add coordinate axes that maintain “goodness.” In particular, initially, the coordinate axis whose sole use leads to the least stress [1090]

is determined (this is somewhat analogous in spirit to basing the first coordinate axis on a pair of objects that are far apart in the FastMap method as described in Section 4.7.3). Unfortunately, calculating the stress requires computing distances for all pairs of objects, which is prohibitively expensive. Instead, the heuristic computes the stress based on some fixed number of object pairs (e.g., 4,000 in experiments in [886], which constituted 10% of the total number of pairs). Next, the coordinate axis that leads to the least stress when used in conjunction with the first axis is determined. This procedure is continued until the desired number of coordinate axes has been obtained.

A drawback of the embedding that forms the basis of SparseMap (i.e., the regular Lipschitz embedding on the reference sets, without taking the heuristics into account) is that it does not satisfy the pruning property (i.e., it is not contractive). In particular, the distance value in the embedding may be as much as a factor of  $\log_2 N$  larger than the actual distance value. Two methods can be applied to obtain an embedding that satisfies the pruning property. First, the embedding proposed in [1181] (where the coordinate values are divided by  $k^{1/p}$ ) can be employed, which does satisfy the pruning property. Second, the distance function  $d'$  can be modified to yield the same effect. In particular, if  $d_p(F(o_1), F(o_2))$  is one of the Minkowski metrics, we can define  $d'(F(o_1), F(o_2)) = d_p(F(o_1), F(o_2)) / (k^{1/p})$ . The advantage of modifying the distance function  $d'$  rather than the embedding itself is that it allows modifying the number of coordinate axes (for example, during the construction of the embedding and in the second SparseMap heuristic) without changing existing coordinate values. With either method, the embedding will satisfy Equation 4.18 for any distance metric  $L_p$  (i.e., subject to modification when using the second method).

Unfortunately, the heuristics applied in SparseMap do not allow deriving any practical bounds (in particular, bounds that rely on  $N$ , or  $k$ , or both) on the distortion resulting from the embedding. In particular, the first heuristic can lead to larger distances in the embedding space, thus possibly causing the pruning property to be violated (in contrast, the second heuristic can reduce only distances in the embedding space). This is because the value of  $|\hat{d}(o_1, A_i) - \hat{d}(o_2, A_i)|$  may not necessarily be a lower bound on  $d(o_1, o_2)$ . To see why, note that the upper bound distances  $\hat{d}(o_1, A_i)$  and  $\hat{d}(o_2, A_i)$  can be larger than the actual distances  $d(o_1, A_i)$  and  $d(o_2, A_i)$  (which are the minimum distances from  $o_1$  and  $o_2$  to an object in  $A_i$ ) by an arbitrary amount. In particular, we cannot rule out a situation where  $\hat{d}(o_1, A_i) > \hat{d}(o_2, A_i) + d(o_1, o_2)$ , in which case  $|\hat{d}(o_1, A_i) - \hat{d}(o_2, A_i)| > d(o_1, o_2)$ .

Thus, we see that in order to satisfy the pruning property, we must use the actual values  $d(o, A_i)$  in the embedding, rather than an upper bound on these distances, as is done in SparseMap. Fortunately, there is a way to modify the first heuristic of SparseMap so that it computes the actual value  $d(o, A_i)$  while still (at least potentially) reducing the number of distance computations [850, 855]. We illustrate this for the case when the Chessboard distance metric,  $d_M$ , is used as  $d'$  in the embedding space. Note that  $d_M(F(o_1), F(o_2)) \leq d(o_1, o_2)$ , as shown in Section 4.7.2.2 (the key observation is that  $|d(o_1, A_i) - d(o_2, A_i)| \leq d(o_1, o_2)$  for all  $A_i$ ). Furthermore, if  $F_i$  is the partial embedding for the first  $i$  coordinate values, we also have  $d_M(F_i(o_1), F_i(o_2)) \leq d(o_1, o_2)$ . In this modified heuristic for computing  $d(o, A_i)$ , instead of computing the actual distance value  $d(o, x)$  for only a fixed number of objects  $x \in A_i$ , we must do so for a variable number of objects in  $A_i$ . In particular, we first compute the approximate distances  $d_M(F_{i-1}(o), F_{i-1}(x))$  for all objects  $x \in A_i$ , which are lower bounds on the actual distance value  $d(o, x)$ . Observe that in SparseMap the approximate distances  $d_E(F_{i-1}(o), F_{i-1}(x))$  are computed for each  $x \in A_i$ , which has the same cost complexity as evaluating  $d_M(F_{i-1}(o), F_{i-1}(x))$ , although the constants of proportionality are lower for  $d_M$  than for  $d_E$ . Next, we compute the actual distances of the objects  $x \in A_i$  in increasing order of their lower-bound distances,  $d_M(F_{i-1}(o), F_{i-1}(x))$ . Let  $y \in A_i$  be the object whose actual distance value  $d(o, y)$  is the smallest distance value so far computed following this procedure. Once all lower-bound distances  $d_M(F_{i-1}(o), F_{i-1}(x))$  of the remaining elements  $x \in A_i$  are greater than  $d(o, y)$ , we are assured that  $d(o, A_i) = d(o, y)$ .

Even though we described our modified heuristic in terms of the Chessboard distance metric, by using a suitable definition of the distance function  $d'$ , the heuristic can be applied to any Minkowski metric  $L_p$ . In particular, if  $k'$  is the current number of coordinate axes (at the completion of the process,  $k' = k$ ), the distance function  $d'$  based on  $L_p$  is defined as

$$d'(F_{k'}(o_1), F_{k'}(o_2)) = \frac{(\sum_i |d(o_1, A_i) - d(o_2, A_i)|^p)^{1/p}}{(k')^{1/p}} \quad (4.21)$$

For any choice of  $p$ , this distance metric makes  $F$  satisfy the pruning property; note the similarity with Equation 4.20.

Moreover, observe that for fixed values of  $o_1$ ,  $o_2$ , and  $F_{k'}$ , the function  $d'$  defined by Equation 4.21 increases with increasing values of  $p$ . For example, for  $p = 1$ ,  $d'(F_{k'}(o_1), F_{k'}(o_2))$  is the average among the coordinate value differences. On the other hand, for  $p = \infty$ , it is the maximum difference. Thus, the use of the Chessboard metric  $L_\infty$  would lead to the largest values of  $d'(F_{k'}(o_1), F_{k'}(o_2))$  for any given choice of the sets  $A_i$ . For similarity queries, as well as for the modified heuristic described above, given a fixed set of reference sets  $A_i$ , this would therefore lead to the best possible pruning during search. To see why this is the case, suppose that we are performing a range query with query object  $q$  and query radius  $r$ , and we wish to report all objects  $o$  such that  $d(q, o) \leq r$ . Let  $o'$  be an object that is too far from  $q$  (i.e.,  $d(q, o') > r$ ). However, if  $d'(F(q), F(o')) \leq r$ ,  $o'$  will be a part of the result set when performing a query in the embedding space. Thus, the situation can easily arise that  $d'(F(q), F(o')) \leq r$  when basing  $d'$  on the City Block or Euclidean distance metrics (i.e.,  $L_1$  or  $L_2$ ), but  $d'(F(q), F(o')) > r$  when  $d'$  is based on the Chessboard distance metric  $L_\infty$ . Such a hypothetical example is illustrated in Figure 4.90 with distance values  $r_1$ ,  $r_2$ , and  $r_\infty$  corresponding to the use of  $L_1$ ,  $L_2$ , and  $L_\infty$  distance metrics, respectively.

Figure 4.90  
A hypothetical range query example where an object  $o'$  is outside the distance range  $r$  from the query object  $q$ . The distance  $d'(F(q), F(o'))$  from  $q$  to  $o'$  in the embedding space will lie somewhere on the line between  $q$  and  $o'$ . Thus, this distance may lie inside the query range if  $d'$  is based on  $L_1$  or  $L_2$  but outside it if  $d'$  is based on  $L_\infty$ .

Although the modified heuristic presented above will likely lead to a higher number of distance computations than the SparseMap heuristic, the higher cost of the embedding (which mainly affects preprocessing) may be justified, as the resulting embedding satisfies the pruning property. This allows effective pruning in similarity queries, while obtaining accurate results, as we get 100% recall and thus do not miss any relevant answers.

One way to measure the quality of embeddings such as those produced by SparseMap is to use the concept of a cluster preservation ratio (CPR) [886]. It can be applied to a dataset when a known clustering exists for the objects. In particular, for each object  $o$  whose cluster is of size  $s$ , we find the  $s$  nearest neighbors in the embedding space and compute the fraction of cluster objects that are among these  $s$  neighbors. The CPR indicates the average ratio of cluster preservation over all objects in the dataset.

In order to study the validity of the SparseMap method, the results of various experiments are described in [886] in which the datasets consist of proteins (or more accurately, the amino acid sequences that make up each protein). This data is useful because these proteins have been studied extensively in terms of their biochemical functions, so proteins having similar functions can be grouped together. Therefore, we can test whether amino acid sequences representing these known proteins follow this grouping when an embedding is performed. The focus of the experiments is mainly on comparing the performance of SparseMap with that of FastMap [587], another embedding method proposed for similarity searching and described in greater detail in Section 4.7.3. Both methods are based on heuristics where some parameter controls the number of distance computations that are performed. In SparseMap, this is the number of actual distance computations performed in evaluating  $\hat{d}(o, A_i)$ , while in FastMap, it is the number of iterations performed in the pivot-finding process (see Section 4.7.3.2). Thus, the two methods can be made to perform approximately the same number of distance computations when obtaining a given number of coordinate axes. Using this technique, the embedding produced by SparseMap was of a higher quality than that produced by

FastMap in terms of stress and how well clusters are retained by the embedding using CPR [886], especially for a small number of coordinate axes. In addition, SparseMap was found to scale up better than FastMap, in terms of the time to perform the mapping, as the pattern in which the database is accessed leads to fewer disk I/Os.

### 4.7.3 FastMap

In this section, we explain how the FastMap method works in some detail. Recall from the introduction to Section 4.7, that FastMap was inspired by dimension reduction methods for Euclidean space that are based on linear transformations such as KLT (and the equivalent PCA and SVD) while also being applicable to arbitrary metric spaces. As we will see, FastMap is most useful for query processing when both  $d$  and  $d'$  are the Euclidean distance metric (i.e., the original objects are points in a multidimensional space) since these are the only cases in which satisfaction of the pruning property is guaranteed. This is primarily a result of the fact that many of the derivations used in the development of FastMap make an implicit assumption that  $d$  is the Euclidean distance metric in a vector space of varying dimensionality. Nevertheless, FastMap can be applied, with varying success, with other distance metrics as well as with data from an arbitrary metric space (i.e., the only information about the data objects consists of the interobject distances). However, in such cases, often some key aspects such as the pruning property will not necessarily hold; nor will we always be able to obtain as many as  $k$  coordinate axes. Similarly, due to the nature of the FastMap method, the best result is obtained when  $d'$ , the distance function in the embedding space, is the Euclidean distance metric. Thus, unless otherwise stated, we assume  $d'$  to be the Euclidean distance metric.

This section is organized as follows. Section 4.7.3.1 gives an overview of the basic mechanics of the FastMap method. Section 4.7.3.2 describes how to obtain the pivot objects. Section 4.7.3.3 shows how to derive the first coordinate value. Section 4.7.3.4 indicates how to calculate the projected distance. Section 4.7.3.5 shows how to derive the remaining coordinate values. Section 4.7.3.6 discusses in great detail when the pruning property is satisfied. Section 4.7.3.7 points out the extent of the deviation of the distance in the embedding space from that in the original space (termed *expansion*). Section 4.7.3.8 discusses a heuristic that has been proposed to deal with the case that the projected distance is complex valued. Section 4.7.3.9 summarizes the properties of FastMap and the Lipschitz embeddings described in Section 4.7.2, while also briefly comparing FastMap with some other embeddings such as MetricMap [1950].

#### 4.7.3.1 Mechanics of FastMap

The FastMap method works by imagining that the objects are points in a hypothetical high-dimensional Euclidean space of unknown dimension—that is, a vector space with the Euclidean distance metric. However, the various implications of this Euclidean space assumption are not explored by Faloutsos and Lin [587]. In the sequel, the terminology reflects the assumption that the objects are points (e.g., a line can be defined by two objects). The coordinate values corresponding to these points are obtained by projecting them onto  $k$  mutually orthogonal directions, thereby forming the coordinate axes of the space in which the points are embedded. The projections are computed using the given distance function  $d$ . The coordinate axes are constructed one by one, where at each iteration two objects (termed *pivot objects*) are chosen, a line is drawn between them that serves as the coordinate axis, and the coordinate value along this axis for each object  $o$  is determined by mapping (i.e., projecting)  $o$  onto this line.

Assume, without loss of generality, that the objects are actually points (this makes it easier to draw the examples that we use in our explanation) and that they lie in an  $m$ -dimensional space. We prepare for the next iteration by determining the  $(m - 1)$ -dimensional hyperplane  $H$  perpendicular to the line that forms the previous coordinate axis and projecting all of the objects onto  $H$ . The projection is performed by defining

Figure 4.91 Examples of projections of objects with the FastMap method on (a) the first coordinate axis and (b) the second coordinate axis.

a new distance function  $d_H$  that measures the distance between the projections of the objects on  $H$ . In particular, we will see that  $d_H$  is derived from the original distance function  $d$  and the coordinate axes determined so far. At this point, the problem has been replaced by a recursive variant of the original problem with  $m$  and  $k$  reduced by one, and a new distance function  $d_H$ . This process is continued until the necessary number of coordinate axes has been determined.

Figure 4.91 illustrates how the first coordinate axis is determined, how the objects are mapped onto the hyperplane  $H$ , and how the projected objects are used to determine the second coordinate axis. Again, we assume, without loss of generality, that the objects are actually points. Figure 4.91(a) shows the result of the projection that yields the first coordinate axis where the pivot objects are  $r$  and  $s$ . In particular, the first coordinate value  $x_a$  for object  $a$  (i.e., the first coordinate value in the vector  $F(a)$ ) is the distance from  $r$  to the projection of  $a$  onto the line through  $r$  and  $s$ . We postpone for now the discussion of Figure 4.91(b), which illustrates how  $d_H$  and the next set of coordinate values are determined.

### 4.7.3.2 Choosing Pivot Objects

As we saw, the pivot objects that are chosen at each step serve to anchor the line that forms the newly formed coordinate axis. Ideally, there should be a large spread of the projected values on the line between the pivot objects, where *spread* is defined as  $\max_{a,b \in S} |x_a - x_b|$ , and  $a$  and  $b$  are arbitrary objects. The reason is that a greater spread generally means that more distance information can be extracted from the projected values—that is, for any pair of objects  $a$  and  $b$ , it is more likely that  $|x_a - x_b|$  is large, thereby providing more information. This principle is similar to that used in the KLT (as well as the equivalent SVD and PCA) method, described in Section 4.6.4.1. The difference here is that spread along an axis is a weaker notion than variance, which is used by KLT (as well as the equivalent SVD and PCA). The reason why spread is a weaker notion is that a large spread may be caused by a few outliers, while most of the other values may be clustered within a small range. On the other hand, a large variance means that the values are genuinely scattered over a large range. Nevertheless, spread usually provides a reasonably good estimate of the variance. In order to maximize the likelihood of obtaining a large spread, the pivot objects should be as far as possible from each other. Unfortunately, determining the farthest pair of objects in a given set of  $N$

objects is computationally expensive. In particular, it takes  $O(N^2)$  distance computations as we need to examine the distance between each pair of objects, although we need not sort them (which is actually not very costly in comparison to the cost of the distance computation) as we want only the maximum value.

Faloutsos and Lin [587] propose a heuristic for computing an approximation of the farthest pair of objects. This heuristic first arbitrarily chooses one of the objects  $a$ . Next, it finds the object  $r$  that is farthest from  $a$ . Finally, it finds the object  $s$  that is farthest from  $r$ . The last step can be iterated a number of times (e.g., 5 [587]) in order to obtain a better estimate of the pair that is farthest apart. In fact, it can be shown that for a given set of  $N$  objects, the procedure for finding the farthest pair of objects can be iterated a maximum of  $N - 1$  steps (see Exercise 1) for a total of  $O(N^2)$  distance computations. The process of finding the farthest pair of points in Euclidean space is also known as the *diameter* of the point set (see [1535] for some background on the problem and [799] for a recent practical approximate algorithm). The above heuristic process of finding the pivot objects requires  $O(N)$  distance computations as long as the number of iterations is fixed. Unfortunately, the  $O(N)$  cost bound for the heuristic may not always hold (see Exercise 2 in Section 4.7.3.7). Note that the original distance function  $d$  is used only when determining the first coordinate axis. However, the modified distance functions (resulting from successive projections on hyperplanes) used for subsequent coordinate axes are based on  $d$ , and thus an evaluation of  $d$  is also required for any distance computations in later steps.

Choosing pivot objects  $r$  and  $s$  in this way guarantees that for any objects  $a$  and  $b$ , we have  $d(a, b) \leq 2d(r, s)$ , or  $d(r, s) \geq \frac{1}{2}d(a, b)$  (see Exercise 3). In other words,  $d(r, s)$  is at least half of the distance between the most distant pair of objects. This follows directly from the triangle inequality and the assumption that  $s$  is the object farthest from  $r$ . However, this bound is guaranteed to hold only for the first pair of pivot objects, as shown in Section 4.7.3.6, since it is possible that the distance functions used to determine the second and subsequent coordinate values do not satisfy the triangle inequality. Notice that a tighter lower bound for  $d(r, s)$  (i.e., larger than one-half of the distance between the objects that are the farthest apart) cannot be guaranteed for any fixed number of iterations in the pivot-choosing heuristic since  $N - 1$  iterations may be needed to find pivots whose distance is any greater than this lower bound. As an example of such a situation, suppose that one pair of objects has distance 2 while all other pairs have distance 1. Determining the pair having distance 2, which is the only one greater than 1, requires  $O(N^2)$  distance computations, on the average, instead of the  $O(N)$  used by the heuristic, since the number of distinct pairs is  $O(N^2)$ .

### Exercises

1. Prove that the procedure for finding the farthest pair of objects to serve as pivots in the FastMap algorithm can be iterated a maximum of  $N - 1$  steps.
2. Can you prove that the maximum number of iterations in the algorithm for finding the pivot objects in Exercise 1 can indeed be attained? If so, construct an example where this happens.
3. Show that choosing the pivot objects  $r$  and  $s$  by using the heuristic described in the text guarantees that  $d(r, s)$  is at least half the distance between the most distant pair of objects.

#### 4.7.3.3 Deriving the First Coordinate Value

In order to understand better how and why the FastMap mapping process works, let us examine its mechanics in greater detail as we compute the first coordinate value. Initially, we project the objects onto a line between the pivot objects, say  $r$  and  $s$ , as shown in Figure 4.92 for an object  $a$ . Note that the projection of object  $a$  may actually lie beyond the line segment between  $r$  and  $s$ , as shown in Figure 4.92(b). This does not pose problems but may cause  $x_a$  to be negative. The actual value of  $x_a$  is obtained by

solving the following equation for  $x_a$ :

$$d(r,a)^2 - x_a^2 = d(s,a)^2 - (d(r,s) - x_a)^2 \quad (4.22)$$

Expanding terms in Equation 4.22 and rearranging yields

$$x_a = \frac{d(r,a)^2 + d(r,s)^2 - d(s,a)^2}{2d(r,s)} \quad (4.23)$$

Observe that Equation 4.22 is obtained by applying the Pythagorean theorem to each half of the triangle in Figure 4.92(a) (a similar interpretation applies to the case in Figure 4.92(b)). Since the Pythagorean theorem is specific to Euclidean space, here we have an instance where Faloutsos and Lin [587], in their development of the method, make the implicit assumption that  $d$  is the Euclidean distance metric. Thus, the equation is only a heuristic when used for general metric spaces. The implications of the use of this heuristic are explored in Section 4.7.3.6. In particular, we find that in this case the embedding produced by FastMap might not satisfy the pruning property, and this may cause the mapping process to terminate prematurely.

A number of observations can be made about  $x_a$ , based on Equation 4.23 and the selection of pivot objects. First,  $x_r = 0$  and  $x_s = d(r,s)$ , as would be expected. Second, note that  $|x_a| \leq d(r,s)$  (see Exercise 1). This implies that the maximum difference between two values  $x_a$  and  $x_b$  (i.e., the spread for the first coordinate axis as defined earlier) is  $2d(r,s)$ , which is equal to the maximum possible distance between any pair of objects, as shown in Section 4.7.3.2. In fact, it can be shown that the spread is never larger than the distance between the farthest pair of objects (see Exercise 2). Since the spread is at least  $d(r,s)$  when  $r$  and  $s$  serve as the pivot objects (as  $x_r = 0$  and  $x_s = d(r,s)$ ), this implies that the spread obtained from pivots  $r$  and  $s$  is at least half of the maximum obtainable spread, which is  $2d(r,s)$ . Unfortunately, as we show in Section 4.7.3.6, it is possible that the distance functions used in subsequent iterations of FastMap do not satisfy the triangle inequality if  $d$  is not the Euclidean distance metric. Thus, the above bounds may not hold when determining the subsequent coordinate values. Note that Equation 4.23 is also used in BoostMap as one of two possible weakly proximity preserving mappings (see the preamble to Section 4.7).

Figure 4.92  
Examples of two possible positions for the projection of an object on the line joining the points corresponding to the pivot objects.

### Exercises

1. Prove that  $|x_a| \leq d(r,s)$  for any distance metric  $d$ , where  $x_a$  is the first coordinate value of  $a$  as defined in Equation 4.23 for pivot objects  $r$  and  $s$  (see Figure 4.92).
2. Let  $t$  and  $u$  be the two objects that are farthest apart of all the objects in  $S$ . Prove that for any distance metric  $d$  the spread (i.e.,  $\max_{a,b} |x_a - x_b|$  for any objects  $a$  and  $b$ ) is never more than  $d(t,u)$  for any choice of pivot objects.

### 4.7.3.4 Projected Distance

Before we can determine the second coordinate value for each object, we must derive  $d_H$ , the distance function for the distances between objects when projected onto the hyperplane  $H$ , as mentioned in Section 4.7.3.1. Figure 4.91(b) illustrates how the objects are projected onto the hyperplane  $H$ , and how the projected objects are used to determine the second coordinate axis. For expository purposes, assume that the underlying space is three-dimensional. In this case, points  $A$  and  $B$  are the projections of objects  $t$  and  $u$ , respectively, on the first coordinate axis (formed by the line joining the pivot objects  $r$  and  $s$ ) with a separation of  $|x_t - x_u|$ . Points  $t'$  and  $u'$  are the projections of objects  $t$  and  $u$ , respectively, on the plane  $H$  that is perpendicular to the line between  $r$  and  $s$  that forms the first coordinate axis. Point  $C$  is the projection of  $u$  onto the line through  $t$  and  $t'$  parallel to the line through  $r$  and  $s$ . Thus, the distance between  $t'$  and  $u'$  equals the distance between  $C$  and  $u$ . The latter can be determined by applying the Pythagorean theorem since the

angle at  $C$  in the triangle  $tuC$  is  $90^\circ$ . Therefore, we have

$$d(t, u)^2 = d(t, C)^2 + d(C, u)^2 = (x_t - x_u)^2 + d(t', u')^2 \quad (4.24)$$

Thus, defining  $d_H(t, u) = d(t', u')$  and changing the order of the terms, we obtain

$$d_H(t, u)^2 = d(t, u)^2 - (x_t - x_u)^2 \quad (4.25)$$

Note that Equation 4.25 applies to any pair of objects  $t$  and  $u$  and not just to the ones that serve as pivots in the next iteration, as is the case in Figure 4.91(b). Also, note that Faloutsos and Lin [587] use the notation  $d_H(t', u')$  rather than  $d_H(t, u)$ .

Observe that this is another occasion where Faloutsos and Lin [587], in their development of the method, make the implicit assumption that  $d$  is the Euclidean distance metric (or that  $(S, d)$  is isometric to a subset of some Euclidean space). This assumption has some undesirable side effects. For example, as we show in Section 4.7.3.6, if  $d$  is not a Euclidean distance metric, then it is possible for  $d_H$  to fail to satisfy the triangle inequality, which in turn may cause Equation 4.23 to produce coordinate values that violate the pruning property. Furthermore, violation of the pruning property in earlier iterations of FastMap may cause negative values of  $d_H(a, b)^2$ . This complicates the search for pivot objects as the square root of a negative value is a complex number, which in this case means that  $a$  and  $b$  (or, more precisely, their projections) cannot serve as pivot objects.

### 4.7.3.5 Subsequent Iterations

Each time we recursively invoke the FastMap coordinate determination method, we must determine the distance function  $d_H$  for the current set of projections in terms of the current distance function (i.e., the one that was created in the previous recursive invocation). Thus, the original distance function  $d$  is used only when obtaining the first coordinate axis. In subsequent iterations,  $d$  is the distance function  $d_H$  from the previous iteration. At this point, it is instructive to generalize Equations 4.23 and 4.25 to yield a recursive definition of the distance functions and the resulting coordinate values for each object. Before we do so, we must define a number of symbols, each representing the  $i$ th iteration of FastMap. In particular,  $x_o^i$  is the  $i$ th coordinate value obtained for object  $o$ ,  $F_i(o) = \{x_o^1, x_o^2, \dots, x_o^i\}$  denotes the first  $i$  coordinate values of  $F(o)$ ,  $d_i$  is the distance function used in the  $i$ th iteration, and  $p_1^i$  and  $p_2^i$  denote the two pivot objects chosen in iteration  $i$  (with the understanding that  $p_2^i$  is the farthest object from  $p_1^i$ ). Now, the general form of Equation 4.23 for iteration  $i$  is

$$x_o^i = \frac{d_i(p_1^i, o)^2 + d_i(p_1^i, p_2^i)^2 - d_i(p_2^i, o)^2}{2d_i(p_1^i, p_2^i)} \quad (4.26)$$

given the recursive distance function definition

$$\begin{aligned} d_1(a, b) &= d(a, b) \\ d_i(a, b)^2 &= d_{i-1}(a, b)^2 - (x_a^{i-1} - x_b^{i-1})^2 \\ &= d(a, b)^2 - d_E(F_{i-1}(a), F_{i-1}(b))^2 \end{aligned} \quad (4.27)$$

As an example consider again Figure 4.88, which shows the interobject distances between 10 objects that were constructed by positioning 10 two-dimensional points and measuring the  $L_1$  distance between them. We now show how FastMap obtains two-dimensional coordinate values for the objects. Seeing that the largest distance in the table is that between  $o_1$  and  $o_3$ , we choose these objects as pivots. The result is shown as the first dimension in Figure 4.93 (i.e., in the first row), where the values are given to a precision of one fractional digit. In order to see how these values are determined, we derive the first coordinate value of  $o_5$ :

Coordinate	$o_1$	$o_2$	$o_3$	$o_4$	$o_5$	$o_6$	$o_7$	$o_8$	$o_9$	$o_{10}$
First	0.0	2.0	13.0	7.0	3.0	5.8	10.5	4.0	8.2	10.0
Second	4.4	1.0	4.4	8.5	3.7	9.7	0.7	0.0	10.2	2.8

Figure 4.93

Two-dimensional coordinate values for the 10 objects based on the distances in Figure 4.88, as determined by FastMap using  $o_1$  and  $o_3$  as pivot objects for the first coordinate axis and  $o_8$  and  $o_9$  for the second coordinate axis.

Object	$o_1$	$o_2$	$o_3$	$o_4$	$o_5$	$o_6$	$o_7$	$o_8$	$o_9$	$o_{10}$
$o_1$	0.0	0.0	0.0	0.0	0.0	29.8	9.9	0.0	13.3	0.0
$o_2$	0.0	0.0	0.0	56.0	8.0	85.2	8.1	0.0	82.2	0.0
$o_3$	0.0	0.0	0.0	0.0	0.0	29.8	9.9	0.0	13.3	0.0
$o_4$	0.0	56.0	0.0	0.0	20.0	7.7	51.5	72.0	2.5	16.0
$o_5$	0.0	8.0	0.0	20.0	0.0	40.9	7.2	8.0	36.6	0.0
$o_6$	29.8	85.2	29.8	7.7	40.9	0.0	59.0	96.6	3.3	18.7
$o_7$	9.9	8.1	9.9	51.5	7.2	59.0	0.0	6.2	94.7	8.7
$o_8$	0.0	0.0	0.0	72.0	8.0	96.6	6.2	0.0	103.1	0.0
$o_9$	13.3	82.2	13.3	2.5	36.6	3.3	94.7	103.1	0.0	45.9
$o_{10}$	0.0	0.0	0.0	16.0	0.0	18.7	8.7	0.0	45.9	0.0

Figure 4.94

Distances of the 10 sample objects as determined by the first projected distance function,  $d_H$ . The values in the table are actually the squared distances,  $d_H(o_i, o_j)^2$ .

$$\frac{d(o_1, o_5)^2 + d(o_1, o_3)^2 - d(o_3, o_5)^2}{2d(o_1, o_3)} = \frac{3^2 + 13^2 - 10^2}{2 \cdot 13} = 78/26 = 3$$

Figure 4.94 shows the (squared) projected distances  $d_H(o_i, o_j)^2$  for the 10 objects obtained by projecting them on the hyperplane  $H$  perpendicular to the line through the pivot objects  $o_1$  and  $o_3$ . Again, the distance values are given to a precision of only one fractional digit. As an example of how these distance values are computed, we derive  $d_H(o_5, o_6)^2$  with the help of Figure 4.93:

$$d_H(o_5, o_6)^2 = d(o_5, o_6)^2 - |x_5 - x_6|^2 \approx 7^2 - |3 - 5.8|^2 = 49 - 2.8^2 \approx 41.2$$

This value does not exactly match the value  $d_H(o_5, o_6)^2 \approx 40.9$  found in Figure 4.94 due to roundoff error.

The largest distance value is  $d_H(o_8, o_9)^2 \approx 103.1$ , so the objects  $o_8$  and  $o_9$  (or, more precisely, their projected versions) get chosen as the second pair of pivot objects used to determine the values along the second dimension, as given in Figure 4.93. Again, let us show how the coordinate value for  $o_5$  is determined, this time along the second coordinate axis:

$$\frac{d_H(o_8, o_5)^2 + d_H(o_8, o_9)^2 - d_H(o_9, o_5)^2}{2d_H(o_8, o_9)} \approx \frac{8 + 103.1 - 36.6}{2\sqrt{103.1}} \approx 74.5/20.3 \approx 3.7$$

The process of mapping the  $N$  objects to points in a  $k$ -dimensional space makes  $O(k \cdot N)$  distance computations as there are  $O(N)$  distance calculations at each of  $k$  iterations. It requires  $O(k \cdot N)$  space to record the  $k$  coordinate values of each of the points corresponding to the  $N$  objects. It also requires a  $2 \times k$  array to record the identities of the  $k$  pairs of pivot objects as this information is needed to process queries. Note that query objects are transformed to  $k$ -dimensional points by applying the same algorithm that was used to construct the points corresponding to the original objects, except that we use the

existing pivot objects. In other words, given query object  $q$ , we obtain its  $k$ -dimensional coordinate values by projecting  $q$  onto the lines formed by the corresponding pivot objects using the appropriate distance function. This process is facilitated by recording the distance between the points corresponding to the pivot objects so that it need not be recomputed for each query, although this can be done if we do not want to store these distance values. The entire process of obtaining the  $k$ -dimensional point corresponding to the query object takes  $O(k)$  distance computations (which is actually  $O(1)$  if we assume that  $k$  is a constant), in contrast to the size of the database, which is  $O(N)$ .

### Exercises

1. Show that the total number of distance computations performed by FastMap is  $kP(N - 1)$ , assuming  $P$  iterations in the pivot-finding heuristic.
2. Prove that at least  $k + 1$  of the pivot objects in the process of constructing a point in  $k$ -dimensional space in the FastMap method are different, assuming that it is indeed possible to apply  $k$  iterations of FastMap.
3. Given  $N$  objects and a distance function that indicates the interobject distances, implement the FastMap algorithm to find the corresponding set of  $N$  points in a  $k$ -dimensional space.
4. Given  $N$  objects, a distance function that indicates the interobject distances query object  $q$ , and a set of  $N$  points in a  $k$ -dimensional space that have been obtained via the use of the FastMap algorithm, give an algorithm to find the point in the  $k$ -dimensional space corresponding to  $q$ .

#### 4.7.3.6 Pruning Property

The embedding  $F$  produced by FastMap satisfies the pruning property when  $(S, d)$  is a subset of a Euclidean space (or isometric to such a subset). This is not surprising since key aspects of FastMap are based on a property unique to Euclidean spaces, namely, the Pythagorean theorem. In particular, both Equation 4.23, which computes a single coordinate value, and Equation 4.25, which computes the projected distance  $d_H$  used in the next iteration, are based on the Pythagorean theorem. Equivalently, FastMap can be seen to be based on the Euclidean distance metric's property of being invariant to rotation and translation. Below, we present an intuitive argument for the satisfaction of the pruning property by FastMap and show that total distance preservation can be achieved.

For  $(S, d_E)$ , where  $S \subset \mathbb{R}^m$  and  $d_E$  is the Euclidean distance metric, an iteration of FastMap essentially amounts to performing a rotation and a translation, followed by extracting the value of a coordinate axis. This is depicted in Figure 4.95 for pivot objects  $r$  and  $s$ . Notice that  $x_a$  for object  $a \in S$  is simply the coordinate value along the new axis  $x'$  since the Euclidean distance metric is invariant to rotation and translation. Furthermore,  $d_H(a, b)$  as defined by Equation 4.25 can be shown to be equivalent to the Euclidean distance between the projections of  $a$  and  $b$  onto the hyperplane  $H$ . In general, we can show that  $d_i(a, b) = d_E(a_i, b_i)$  for  $a, b \in S$ , where  $d_i$  is defined by Equation 4.27, and  $a_i$  and  $b_i$  are the projections of objects  $a$  and  $b$ , respectively, onto the intersection of the  $i - 1$  hyperplanes obtained in iterations 1 through  $i - 1$ . Thus, we can obtain coordinate axis  $i$  by rotating and translating along the  $(m - i + 1)$ -dimensional hyperplane formed by the intersection of these  $i - 1$  hyperplanes. After  $k$  iterations, Equation 4.27 yields  $d_{k+1}(a, b)^2 = d_E(a_{k+1}, b_{k+1})^2 = d_E(a, b)^2 - d'_E(F(a), F(b))^2$ , where  $d'_E$  is the Euclidean distance metric for  $\mathbb{R}^k$ . Thus, since  $d_E(a_{k+1}, b_{k+1})^2 \geq 0$ , we have  $d_E(a, b)^2 - d'_E(F(a), F(b))^2 \geq 0$ , which directly implies  $d_E(a, b) \geq d'_E(F(a), F(b))$ . In other words,  $F$  satisfies the pruning property.

We can also show that with enough iterations,  $F$  will preserve the distances between all objects. In particular, observe that projecting on an  $(m - 1)$ -dimensional hyperplane in each iteration reduces the number of points by at least one since the two pivot points get projected to the same point. In other words, if  $S_i$  is the set of points obtained by projecting on the hyperplanes in iterations 1 through  $i - 1$ , then  $|S_i| \leq |S| - (i - 1)$

Figure 4.95  
An example of how to rotate and translate a coordinate system such that the first axis is coincident to the line passing through  $r$  and  $s$  when the data reside in a Euclidean space. In the new coordinate system, the coordinate values of the projected images of data objects  $a$  and  $b$  become  $(x_a, 0)$  and  $(x_b, 0)$ , respectively.

(as each iteration reduces the number of points by one). Thus, since  $|S_{k+1}| \geq 1$ , this implies that  $1 \leq N - k$  or  $k \leq N - 1$ , where  $N = |S|$ . Furthermore, when  $k = m$ ,  $S_{k+1}$  is the result of projecting  $S$  onto a 0-dimensional hyperplane (i.e., a point), so  $k \leq m$ . In summary, after at most  $\min\{m, N - 1\}$  iterations, all the points get projected to the same point. Therefore,  $d_E(a_{k+1}, b_{k+1})$  is then zero for all objects  $a, b \in S$ , so  $d_E(a, b) = d'_E(F(a), F(b))$ , implying that total distance preservation is obtained.

Above, we saw that applying FastMap is essentially equivalent to applying a linear transformation involving translation and rotation and then retaining only some of the coordinate axes. Thus, FastMap works in a manner analogous to applying KLT (and the equivalent PCA and SVD) for dimension reduction as described in Section 4.6.4.1. However, we can expect that applying KLT (and the equivalent PCA and SVD) will yield a better approximation to the original distances as the coordinate axes with the greatest variance are the ones that are retained.

We also saw that the distances between all objects are preserved if  $|S_{k+1}| = 1$  since all objects in  $S$  are then projected onto a single point in  $S_{k+1}$ . An interesting perspective is that even if  $F$  does not preserve all distances,  $F$  will still preserve the distances between some of the objects. In particular, the distances between any objects  $a$  and  $b$  that are projected onto the same point in  $S_{k+1}$  are preserved by the embedding since  $d_{k+1}(a, b)$  is then zero. In fact, we can form equivalence classes for the objects based on the points in  $S_i$  such that objects mapped to the same point in  $S_i$  belong to the same equivalence class. Thus, the set of objects is partitioned into  $|S_{k+1}| \leq N - k$  equivalence classes after  $k$  iterations of FastMap.

Figure 4.96  
Example projection of two objects on the line joining the points corresponding to the pivot objects.

Figure 4.96 illustrates how FastMap maps objects  $a$  and  $b$  after having determined just one coordinate value, assuming that  $r$  and  $s$  are the pivot objects. Notice how it seems intuitively obvious that the distance between  $F(a)$  and  $F(b)$  is smaller than that between  $a$  and  $b$ . Unfortunately, intuition is misleading here as it is colored by the fact that we perceive the three-dimensional world around us as obeying Euclidean geometry. In particular, the relative lengths of the line segments between the points in Figure 4.96 can arise only if  $d$  is the Euclidean distance metric (or if  $(S, d)$  is isometric to a subset of a Euclidean vector space). Thus, we see that in the figure,  $d(a, b)^2 = (x_a - x_b)^2 + D^2$  (according to the Pythagorean theorem), so we clearly have  $d(a, b) \geq |x_a - x_b|$  (and thus the pruning property is satisfied). In general, we cannot assume that this relationship holds (i.e.,  $D^2$  may be negative!).

The pruning property is guaranteed to hold only when  $(S, d)$  is a subset of a Euclidean space, and  $d'$  is the Euclidean distance metric. There are two general scenarios where the pruning property is not guaranteed to hold. The first is when  $d$  is the Euclidean distance metric, and  $d'$  is a non-Euclidean distance metric. The second is when  $d$  is not the Euclidean distance metric (and  $(S, d)$  is not isometric to a subset of a Euclidean vector space), regardless of the nature of  $d'$ , and is due to the implicit assumption in Equations 4.23 and 4.25 that  $d$  is the Euclidean distance metric.

An example of the first scenario occurs when the City Block ( $L_1$ ) distance metric  $d_A$  is used for  $d'$ . To illustrate this, note that the City Block distance  $d_A(F(1), F(2))$  between two points  $F(1)$  and  $F(2)$  may be greater than the Euclidean ( $L_2$ ) distance  $d_E(F(1), F(2))$  between the same points. For example,  $d_A((0, 0), (3, 4)) = 7$  while  $d_E((0, 0), (3, 4)) = 5$ . Thus, we may have  $d_A(F(a), F(b)) > d(a, b)$ , even though  $d_E(F(a), F(b)) \leq d(a, b)$ , where  $F(a)$  and  $F(b)$  are the result of mapping  $a$  and  $b$  with FastMap. In fact, the pruning property is guaranteed to hold only if  $d'$  is the Euclidean distance metric (i.e.,  $L_2$ ) or some other Minkowski distance metric  $L_p$ , where  $p \geq 2$  (see Exercise 1).

The second, and more serious, scenario where the pruning property does not hold occurs when  $d$  is not a Euclidean metric, regardless of the choice of  $d'$ . This is serious because the pruning property may be violated after determining any number of coordinate axes. In particular, this means that the value of  $d_i(a, b)^2$  in Equation 4.27 can be negative (or zero) for any  $i \geq 2$ , which precludes using  $a$  and  $b$  as the pivot pair in iteration  $i$  of

Object	a	b	c	e
a	0	10	4	5
b	10	0	8	7
c	4	8	0	1
e	5	7	1	0

Figure 4.97  
Distance matrix for an example where Equation 4.23 causes the pruning property to be violated.

FastMap. Thus, the situation can arise that  $d_i(a, b)^2 \leq 0$  for all pairs of objects  $a$  and  $b$ , in which case no more coordinate values can be determined (but see Section 4.7.3.8).

There are two possible causes for the violation of the pruning property: Equation 4.23 and Equation 4.25. Both are due to the implicit assumption made in deriving these equations that the Pythagorean theorem applies to the distance metric  $d$ . However, the Pythagorean theorem is unique to Euclidean spaces. As an example where Equation 4.23 causes the pruning property to be violated, consider objects  $a$ ,  $b$ ,  $c$ , and  $e$ , with the distance matrix given in Figure 4.97, for which satisfaction of the triangle inequality can be easily verified.

Since  $a$  and  $b$  are the objects that are the farthest apart, they are selected as the pivot objects in FastMap when determining the first coordinate axis. Following Equation 4.23, the values of the first coordinate of the points derived from objects  $c$  and  $e$  are as follows:

$$x_c = (4^2 + 10^2 - 8^2)/(2 \cdot 10) = 52/20 = 13/5$$

$$x_e = (5^2 + 10^2 - 7^2)/(2 \cdot 10) = 76/20 = 19/5$$

Thus, the distance between these one-dimensional points corresponding to objects  $c$  and  $e$  used in the first iteration of FastMap is  $x_e - x_c = 6/5 = 1.2$ , which is higher than the original distance between them, obtained from the distance matrix, which is 1. Thus the pruning property does not hold for  $c$  and  $e$ .

The pruning property is not directly, but indirectly, violated by Equation 4.25. In particular, if  $d$  is not a Euclidean distance metric, then Equation 4.25 may lead to a definition of  $d_H$  such that  $d_H$  does not satisfy the triangle inequality (thereby also failing to be a distance metric), and this, in turn, causes the pruning property to be violated in the next iteration of FastMap. We first show how the violation of the triangle inequality causes the pruning property to be violated.

Assuming that  $r$  and  $s$  are the pivot objects, the pruning property is violated if  $d(r, a) < |x_r - x_a| = x_a$  (since  $x_r = 0$ ). Now, let us explore what conditions are equivalent to  $d(r, a) < x_a$ , and thus give rise to a pruning property violation.

$$d(r, a) < x_a \Leftrightarrow d(r, a) < \frac{d(r, a)^2 + d(r, s)^2 - d(s, a)^2}{2d(r, s)}$$

$$\Leftrightarrow 2d(r, a)d(r, s) < d(r, a)^2 + d(r, s)^2 - d(s, a)^2$$

$$\Leftrightarrow d(s, a)^2 < d(r, a)^2 - 2d(r, a)d(r, s) + d(r, s)^2 = (d(r, a) - d(r, s))^2$$

$$\Leftrightarrow d(s, a) < |(d(r, a) - d(r, s))|$$

$$\Leftrightarrow d(s, a) + d(r, a) < d(r, s) \vee d(s, a) + d(r, s) < d(r, a)$$

Similarly, it can be shown that  $d(s, a) < |x_s - x_a|$  if and only if  $d(r, a) + d(s, a) < d(r, s) \vee d(r, s) + d(r, a) < d(s, a)$ . Thus, we see that the pruning property is violated (for  $d(r, a)$ ,  $d(s, a)$ , or both) if and only if the triangle inequality is violated for any of the distances between the two pivot objects  $r$  and  $s$  and an arbitrary object  $a$ .

Object	a	b	c	e
a	0	6	5	4
b	6	0	3	4
c	5	3	0	6
e	4	4	6	0

Figure 4.98  
Distance matrix for an example where Equation 4.25 indirectly causes the pruning property to be violated.

Next, we give an example that actually results in  $d_H$  failing to satisfy the triangle inequality (thereby, also failing to be a distance metric). Consider objects a, b, c, and e, with the distance matrix given in Figure 4.98, for which satisfaction of the triangle inequality can be easily verified.

Following Equation 4.23, the values of the first coordinate of the points derived from c and e using a and b as the pivot objects are obtained as follows:

$$x_c = (5^2 + 6^2 - 3^2) / (2 \cdot 6) = 13/3$$

$$x_e = (4^2 + 6^2 - 4^2) / (2 \cdot 6) = 3$$

The distances between the projections of a, c, and e onto the hyperplane  $H$  that is orthogonal to the first coordinate axis follow from Equation 4.25:

$$d_H(a, c) = \sqrt{5^2 - (0 - 13/3)^2} \approx 2.494$$

$$d_H(a, e) = \sqrt{4^2 - (0 - 3)^2} \approx 2.647$$

$$d_H(c, e) = \sqrt{6^2 - (13/3 - 3)^2} \approx 5.850$$

Thus, we see that  $d_H(a, c) + d_H(a, e) \approx 5.141$ , which is less than  $d_H(c, e)$ , thereby violating the triangle inequality.

Thus far, we have examined the source of violation of the pruning property in FastMap and given examples where FastMap results in an embedding that does not satisfy the pruning property. This enables us to conclude that the embedding produced by FastMap may fail to satisfy the pruning property when  $d$  is not a Euclidean distance metric. It is possible to make an even stronger statement: if  $d$  is not a Euclidean distance metric, then FastMap will eventually result in an embedding that does not satisfy the pruning property if enough iterations are performed. Toward proving this, we first show that only a finite number of iterations can be applied in FastMap. At the start of this section, we used geometric arguments to show that when  $d$  is the Euclidean distance metric, the pivot objects used in an iteration of FastMap are effectively merged and are thereby indistinguishable in subsequent iterations. This is also true for arbitrary metric spaces. In particular, if  $r$  and  $s$  are pivot objects in iteration  $i - 1$  of FastMap, it can be shown that  $d_i(r, s) = 0$  and  $d_i(r, t) = d_i(s, t)$  for an arbitrary object  $t$ , regardless of whether  $d_{i-1}$  satisfies the triangle inequality (see Exercise 2). Thus,  $r$  and  $s$  will have identical coordinate values for coordinate axes  $i$  through  $k$ . Furthermore, we can show that when the distances of any two objects  $r$  and  $s$  satisfy the distance property above (i.e.,  $d_i(r, s) = 0$  and  $d_i(r, t) = d_i(s, t)$ ), then the distance between  $r$  and  $s$  is preserved by FastMap (see Exercise 3).

Based on this, we argue below that if  $(S, d)$  is a finite metric space that is not isometric to a subset of any Euclidean space, then repeated iterations of FastMap (i.e.,  $k$ ) will eventually result in a mapping  $F$  that violates the pruning property. We will show that  $k < N - 1$ . In particular, since  $(S, d)$  is not isometric to a subset of any Euclidean space, we know that no distance-preserving Euclidean embedding exists for  $(S, d)$ . Thus, such

an embedding cannot be produced by FastMap either. Also, note that  $d_E(F_i(a), F_i(b))$  is nondecreasing in  $i$  for any objects  $a, b \in S$ . Therefore, the only way in which FastMap can be applied repeatedly without ever resulting in  $d_E(F_i(a), F_i(b)) > d(a, b)$ , for some objects  $a$  and  $b$ , is if an infinite series of iterations can be performed. Below, we show that at most  $N - 2$  iterations can be performed by FastMap and that the final iteration necessarily will result in an embedding that does not satisfy the pruning property. In the process, we characterize the level of distance preservation among the objects obtained by the embedding.

The above observations can be used to define equivalence classes for data objects whose distances are preserved (in a similar way as we mentioned for Euclidean vector spaces). In particular, we say that two objects  $r$  and  $s$  (not necessarily pivot objects) belong to the same equivalence class in iteration  $i$  if  $d_i(r, s) = 0$  and  $d_i(r, t) = d_i(s, t)$  for all objects  $t \in S$ . Initially, each object belongs to a distinct equivalence class (except for objects having a distance of zero from each other). Furthermore, the fact that pivot objects become indistinguishable in the remaining iterations ensures that each iteration of FastMap causes the merger of at least two equivalence classes, namely, the ones containing the two pivot objects. Thus, the number of equivalence classes after  $i$  iterations is clearly at most  $N - i$ , as we initially have at most  $N$  equivalence classes and each iteration reduces the number of equivalence classes by at least one.

Since a distance-preserving embedding does not exist for  $(S, d)$ , at least two equivalence classes must remain after the performance of the last iteration of FastMap (as the existence of just one equivalence class means that the embedding is distance preserving). Hence, the number of iterations  $k$  must satisfy  $N - k \geq 2$ , or  $k \leq N - 2$ . Furthermore, if no more iterations can be performed, then we must have  $d_{k+1}(a, b)^2 < 0$  for any objects  $a$  and  $b$  from distinct equivalence classes since  $a$  and  $b$  could otherwise be chosen as the next pair of pivot objects, thereby allowing yet another iteration. However, Equation 4.27 then implies that  $d(a, b)^2 - d_E(F_k(a), F_k(b))^2 < 0$ , or, in other words,  $d(a, b) < d_E(F(a), F(b))$ , since  $F = F_k$ . Therefore, we have shown that  $F$  does not satisfy the pruning property (as  $d' = d_E$ ). Moreover, since  $F$  was chosen in an arbitrary way (i.e., we made no assumption on the choices of pivot objects), we have shown that such a noncontractive embedding is always produced by FastMap, given enough iterations.

### Exercises

1. Letting  $(S, d)$  be a subset of a Euclidean vector space and  $d'$  be some Minkowski distance metric  $L_p$ , prove that the embedding  $F$  produced by FastMap is guaranteed to satisfy the pruning property only if  $p \geq 2$ .
2. Letting  $r$  and  $s$  be the pivot objects in iteration  $i - 1$  of FastMap, show that  $d_i(r, s) = 0$  and  $d_i(r, t) = d_i(s, t)$  for an arbitrary object  $t$ , regardless of whether  $d_{i-1}$  satisfies the triangle inequality.
3. Let  $r$  and  $s$  be data objects, not necessarily pivot objects. Show that if  $d_i(r, s) = 0$  and  $d_i(r, t) = d_i(s, t)$  for all objects  $t$  after  $i - 1$  iterations of FastMap, then  $d'(F(r), F(s)) = d(r, s)$  where  $F$  is the final embedding produced after  $k$  iterations of FastMap. In other words, show that the distance between  $r$  and  $s$  is preserved by  $F$ .

### 4.7.3.7 Expansion

Satisfaction of the pruning property means that  $d'(F(o_1), F(o_2)) \leq d(o_1, o_2)$ . We are also interested in how much larger the distances in the embedding space can be in comparison to the original distances. This is termed the *expansion* of  $F$  and is defined as

$$\max_{o_1, o_2} \left\{ \frac{d'(F(o_1), F(o_2))}{d(o_1, o_2)} \right\}$$

Note that if the expansion is not greater than 1, then  $F$  satisfies the pruning property. Furthermore, if we can derive an upper bound  $c$  on the expansion, then any embedding  $F$

produced by FastMap can be made to satisfy the pruning property by defining  $d'(o_1, o_2) = d_E(F(o_1), F(o_2))/c$  such that the expansion with respect to this  $d'$  is no more than 1. Unfortunately, the expansion of embeddings produced by FastMap when determining even just one coordinate is already relatively large (i.e., 3; see Exercise 1) [850], and for additional coordinates the expansion can be very large (see Exercise 2) [850].

### Exercises

1. Prove that the expansion after determining one coordinate with FastMap is at most 3 and that this bound is tight.
2. As we saw in Section 4.7.3.6, the triangle inequality does not necessarily hold for the distance functions used in the second and subsequent iterations of FastMap. This means that the upper bound on the expansion derived in Exercise 1 holds only for the first coordinate value obtained by FastMap. The basic problem is that for iteration  $i > 1$ , the value of  $d_i(r, s)^2$ , as defined in Equation 4.27, may be less than or equal to zero for all objects  $s$ , even after several iterations of the pivot-finding heuristic (see Section 4.7.3.2). Moreover, even when  $d_i(r, s)^2$  is found to be strictly positive, it can be arbitrarily close to zero, thereby yielding an arbitrarily large expansion. One solution is to set a strict lower bound on the distance between the pivot objects, based on the distance between the first pair of pivot objects. In other words, if  $r$  and  $s$  are the first two pivot objects, then any pivot objects  $t$  and  $u$  chosen in any subsequent iteration  $i$  must obey  $d_i(t, u) \geq d(r, s)/\beta$ , where  $\beta > 1$  is some constant. Unfortunately, this requirement means that the pivot-finding heuristic may no longer succeed in finding a legal pair of pivots in a constant number of iterations, and the number of distance computations may become  $O(N^2)$ . An alternative solution is to terminate FastMap if a legal pivot pair is not found in  $O(1)$  iterations of the pivot-finding process (see Section 4.7.3.2). This means that we may obtain fewer coordinate axes than desired. However, this is usually not a problem as a low number of coordinate axes is preferable in most applications. Nevertheless, it is still not clear that the original distances are adequately approximated in the embedding space in cases when legal pivots cannot be found in  $O(N)$  distance computations. In any case, letting  $d(r, s)/\beta$  ( $\beta > 1$  is some constant) be the minimum distance value  $d_2(t, u)$  for the pivot objects  $t$  and  $u$  used in the second iteration of FastMap (i.e., when finding the second coordinate value for each object), as well as for the distances between any two pairs of objects (using the original distance function), show that the expansion after determining two coordinates with FastMap is no more than  $36\beta^2$ .

### 4.7.3.8 Heuristic for Non-Euclidean Metrics

As we pointed out in Section 4.7.3.4, it is possible for the value  $d_H(t, u)^2$  in Equation 4.25 to be negative when  $d$  is not a Euclidean distance metric. More generally, this implies that  $d_i(a, b)^2$  may be negative for  $i \geq 2$  in Equation 4.27. Such a situation is undesirable since it means that  $d_i(a, b)$  becomes complex valued, which precludes the choice of  $a$  and  $b$  as the pair of pivot objects in iteration  $i$  of FastMap. Furthermore, since  $d_i(a, b)^2$  can have a large negative value, such values can cause a large expansion in the distances between coordinate values determined by Equation 4.26, as discussed in Section 4.7.3.7.

Wang, Wang, Lin, Shasha, Shapiro, and Zhang [1950] introduce a heuristic to alleviate the situation that  $d_i(a, b)^2$  may be negative for  $i \geq 2$  in Equation 4.27. The heuristic defines  $d_i(a, b)$  ( $i \geq 2$ ) in such a way that it is always real valued but possibly negative:

$$d_i(a, b) = \begin{cases} \sqrt{d_{i-1}(a, b)^2 - (x_a^{i-1} - x_b^{i-1})^2} & \text{if } d_{i-1}(a, b)^2 \geq (x_a^{i-1} - x_b^{i-1})^2 \\ -\sqrt{(x_a^{i-1} - x_b^{i-1})^2 - d_{i-1}(a, b)^2} & \text{otherwise} \end{cases} \quad (4.28)$$

Equivalently, we can use the definition  $d_i(a, b) = \text{sign}(d_i(a, b)^2) \cdot \sqrt{|d_i(a, b)^2|}$ , where  $d_i(a, b)^2$  is defined as in Equation 4.27. Although this heuristic apparently resolves the drawbacks of negative  $d_i(a, b)^2$  values, it does not correct the fundamental problem with Equation 4.27, namely, that  $d_i$  may violate the triangle inequality if  $d$  is not the Euclidean distance metric (see the discussion in Section 4.7.3.6). Furthermore, notice

that this formulation also means that if  $d_i(a, b)$  is negative for some  $i$ , then  $d_j(a, b)^2$  is not equal to  $d(a, b)^2 - d_E(F_{j-1}(a), F_{j-1}(b))^2$  for all  $j \geq i$ .

Notice that when  $d_i(a, b)$  is defined according to Equation 4.28, the value of  $d_i(a, b)^2$  is always nonnegative, regardless of whether  $d_i(a, b)$  is negative. Thus, in situations where Equation 4.27 leads to negative values, the coordinate value  $x_o^i$  for an object  $o$  as determined by Equation 4.26 can be different, depending on which definitions of  $d_i$  is used—that is, Equation 4.27 or 4.28. If we focus on the result of just one iteration of FastMap, neither definition of  $d_i$  is always better than the other in terms of how well distances are preserved. In particular, sometimes it is better to use Equation 4.27, and sometimes it is better to use Equation 4.28. However, the advantage of the definition in Equation 4.28 is that the value of  $d_i(a, b)^2$  tends to decrease as  $i$  increases (i.e., as more iterations are performed). In particular, Equation 4.28 implies that  $d_i(a, b)^2 = |d_{i-1}(a, b)^2 - (x_a^{i-1} - x_b^{i-1})^2|$ , so  $d_i(a, b)^2$  is only larger than  $d_{i-1}(a, b)^2$  if  $(x_a^{i-1} - x_b^{i-1})^2 > 2d_{i-1}(a, b)^2$ . In contrast, according to Equation 4.27, the value of  $d_i(a, b)^2$  is monotonically nonincreasing in  $i$ , so it can become a large negative value, which makes the mapping not very attractive in similarity searching applications as it results in a large expansion with concomitant adverse effects on search performance (see Section 4.7.3.7). Recall that any amount of expansion means that the distance in the embedding space becomes larger than the distance in the original space, thereby violating the pruning property (see Section 4.7.3.6).

The heuristic of Equation 4.28 enables the use of two objects  $a$  and  $b$  as a pivot pair even when  $d_i(a, b)$  is negative. In contrast, such pairs cannot be utilized with Equation 4.27. However, it is not clear how appropriate such a choice of pivot objects is in terms of attempting to reduce the distance in the embedding space. In particular, the fact that  $d_i(a, b)$  is negative implies that the distance between  $F_{i-1}(a)$  and  $F_{i-1}(b)$  is greater than  $d(a, b)$ , so using  $a$  and  $b$  as pivot objects further increases the amount by which the distance in the embedding space exceeds the distance in the original space (i.e., expansion).

In Section 4.7.3.6, we show that FastMap eventually results in an embedding that does not satisfy the pruning property if enough iterations are performed. This result still holds when the heuristic of Equation 4.28 is used. In particular, Equation 4.28, which defines the computation of the intermediate distance functions, is equivalent to Equation 4.27 unless the intermediate mapping  $F_{i-1}$  obtained in iteration  $i - 1$  already violates the pruning property. To see why they are otherwise equivalent, note that if  $i$  is the lowest value for which  $d_{i-1}(a, b)^2 < (x_a^{i-1} - x_b^{i-1})^2$  for some objects  $a$  and  $b$  (thereby causing the invocation of the second case in Equation 4.28), then we can apply Equation 4.27 to show that  $d(a, b)^2 < d_E(F_{i-1}(a), F_{i-1}(b))^2$  (i.e.,  $F_{i-1}$  violates the pruning property). Furthermore, when  $F_{i-1}$  violates the pruning property, the final mapping  $F$  also violates the pruning property as  $d_E(F_i(a), F_i(b))$  is monotonically nondecreasing in  $i$  (since, as we add coordinate axes, the distance can only get larger).

It is interesting to observe that the largest possible expansion when determining just one coordinate value is just as large with the heuristic as without (i.e., 3, as mentioned in Section 4.7.3.7). Nevertheless, for a larger number of coordinates, use of the heuristic may reduce the worst-case expansion somewhat, but it can still be large (e.g., 7 when determining two coordinate values) [850].

### 4.7.3.9 Summary and Comparison with Other Embeddings

In this section and in Section 4.7.2, we examine the embeddings of finite metric spaces and evaluate them in the context of their usage for similarity searching in multimedia databases with 100% recall. In similarity search, achieving 100% recall is important as it ensures that no relevant object is dropped from the query response. Particular attention has been paid to Lipschitz embeddings (as exemplified by SparseMap) and FastMap, which was inspired by dimension reduction methods for Euclidean space that are based

on linear transformations such as KLT (and the equivalent PCA and SVD), while also being applicable to arbitrary metric spaces. When the resulting embedding satisfies the pruning property, 100% recall is achieved. Although Linial et al. [1181] have shown how to make the Lipschitz embeddings satisfy the pruning property, we prove that the speedup heuristics that make up the SparseMap adaptation result in an embedding that does not satisfy the pruning property. Moreover, we demonstrate how to modify the SparseMap heuristics so that the resulting embedding does indeed satisfy the pruning property.

In the case of FastMap, we first prove that it satisfies the pruning property when the data is drawn from a Euclidean vector space, and the distance metric in the embedding space is a Minkowski metric  $L_p$  ( $p \geq 2$ , which also includes the Euclidean distance metric). In their development of FastMap, Faloutsos and Lin [587] claim two advantages for FastMap over SVD:

1. SVD takes  $O(N \cdot n^2)$  time while FastMap requires  $O(N \cdot k)$  distance computations, each of which is  $O(n)$ , assuming that the data is drawn from an  $n$ -dimensional Euclidean vector space. Thus, a more accurate assessment of the execution time complexity of FastMap is  $O(Nnk)$  in this setting.
2. FastMap can work for data drawn from an arbitrary metric space (i.e., the only information about the data objects consists of the interobject distances, which are required to satisfy the triangle inequality). SVD, on the other hand, only works for data drawn from a Euclidean vector space (i.e., a vector space with the Euclidean distance metric). Of course,  $d'$  for both SVD and FastMap can be any Minkowski distance metric  $L_p$  provided  $p \geq 2$ , although  $p = 2$  is usually the most appropriate.

However, we show that the second advantage is somewhat mixed since, in the arbitrary metric space case, it is possible for FastMap not to satisfy the pruning property, which reduces the accuracy of similarity search queries (i.e., we can no longer guarantee 100% recall). We show that this is a direct result of the implicit assumption by Faloutsos and Lin [587] of the applicability of the Pythagorean theorem, which, in the case of a general metric space, can be used only as a heuristic in computing the projected distance values. In fact, this leads to definitions of distance functions at intermediate iterations that do not satisfy the triangle inequality and, thereby, fail to be distance metrics. Failure to satisfy the pruning property enables us to prove the following properties of FastMap for this situation:

1. Given a value  $k$ , application of FastMap may not always be possible in the sense that we are not guaranteed to be able to determine  $k$  coordinate axes.
2. The distance expansion (as well as the more general concept of distortion) of the embedding can be very large, as evidenced by the bounds that we gave, some of which were attainable, on how much larger the distances in the embedding space can be.
3. The fact that we may not be able to determine  $k$  coordinate axes limits the extent of achievable distance preservation. However, more importantly, failure to determine more coordinate axes does not necessarily imply that relative distances among the objects are effectively preserved.
4. The presence of many nonpositive, or very small positive, distance values (which can cause large expansion) in the intermediate distance functions (i.e., those used to determine the second and subsequent coordinate axes) may cause FastMap no longer to satisfy the claimed  $O(N)$  bound on the number of distance computations in each iteration. In particular, finding a legal pivot pair may, in the worst case, require examining the distances between a significant fraction of all possible pairs of objects, or  $\Omega(N^2)$  distance computations.

In Section 4.7.3.8, we describe a heuristic for non-Euclidean distance metrics in FastMap proposed by Wang et al. [1950]. This heuristic alleviates some of the drawbacks listed above. In particular, it should reduce the amount of distance expansion (as well

as distortion) in the embedding, and the number of object pairs that do not qualify as pivots should be lower, thus reducing the likelihood of not satisfying the  $O(N)$  bound on the number of distance computations in each iteration of FastMap. However, a detailed empirical study of the effect of the heuristic on actual datasets remains to be performed.

Wang et al. [1950, 1955, 2045] propose an interesting embedding, termed *MetricMap*, that has some similarity to SVD, FastMap, and a special class of Lipschitz embeddings. In essence, given a finite metric space  $(S, d)$ ,  $2k$  of the objects (termed *reference objects*) are selected at random and used to form a coordinate space in  $\mathbb{R}^{2k-1}$ . In particular, one of the reference objects  $o_0$  is mapped to the origin, while the remaining objects  $O_i$  ( $1 \leq i \leq 2k - 1$ ) are mapped to unit vectors  $e_i$  in  $\mathbb{R}^{2k-1}$ . The interobject distances of the reference objects are used to form a matrix  $M$  that serves as the basis of a distance measure that preserves the distances between the reference objects. Through a process that resembles SVD, the  $k$  “most important” coordinate axes determined by  $M$  are established, from which a suitable linear transformation is computed. The  $k$  coordinate values for each object in  $S$  are then obtained by using the pairs  $(o_0, o_i)$  as pivots in a manner similar to FastMap and then applying the linear transformation. The result of MetricMap, like that of FastMap, may violate the pruning property if  $d$  is not the Euclidean distance metric. Furthermore, the way in which the original  $2k$  reference objects are reduced down to  $k + 1$  means that, even if  $d$  is Euclidean, the result may still violate the pruning property.

The distance function  $d'$  used on the coordinate values produced by MetricMap is *pseudo-Euclidean* in that it is defined in terms of the squares of the differences of the individual coordinate values just like the Euclidean distance metric. However, some of the coordinate axes may make a negative contribution to the overall distance between two points. Thus, in extreme cases, the squared distance between points can be negative. In order to produce the square root of such a negative value, MetricMap takes the square root of the absolute value and makes it negative (i.e.,  $-\sqrt{-D}$ ). This is similar to what was done in the FastMap heuristic to deal with non-Euclidean distance metrics. Thus, due to the possibility of negative distance values, the values produced by  $d'$  should really be termed “pseudo-distances” or “quasi-distances.” In contrast, in a Euclidean space, all coordinate axes have a positive contribution to the overall distance so that the more coordinates that we have, the greater is the distance.

At a first glance, MetricMap appears to resemble the Lipschitz embedding of Faragó et al. [595] (mentioned in Sections 4.7.1 and 4.7.2.1) in that each of the reference objects except  $o_0$  are, in some sense, used to construct a dimension in  $\mathbb{R}^{2k-1}$ . However, this resemblance is superficial as the values of each of the  $k$  coordinate axes in the final embedding are potentially influenced by all of the reference objects.

#### 4.7.4 Locality Sensitive Hashing

Locality sensitive hashing (LSH) is a randomized algorithm for similarity searching developed by Indyk and Motwani [924]. A *randomized algorithm* is any algorithm that makes some random (or pseudorandom) choices (e.g., [398, 1318, 1325]). Randomized algorithms are usually characterized as being either Monte Carlo or Las Vegas. A *Monte Carlo randomized algorithm* [1318] is a randomized algorithm that may produce incorrect results, but with bounded error probability. In particular, a Monte Carlo algorithm gives more accurate results the more often it is invoked. On the other hand, a *Las Vegas randomized algorithm* (e.g., [397, 398, 1318]) is a randomized algorithm that always produces correct results, with the only variation from one run to another being its execution time.

One way to understand the difference between these two classes of randomized algorithms is to observe that a Monte Carlo algorithm yields a probabilistic result, while the Las Vegas algorithm yields a deterministic result. For example, the algorithm for finding the nearest neighbor in a kNN graph [1704] (see Section 4.5.6) is a Monte Carlo

algorithm due to the use of pseudorandom seeds to identify the object at which the search starts. Thus, the more times we invoke the algorithm, using different seeds, the greater the likelihood of a correct answer. A bound on the error probability of this method should be derivable, hence justifying its characterization as a Monte Carlo algorithm (see Exercise 2). Therefore, the result of the search process is probabilistic, with some likelihood of an error. On the other hand, the nearest neighbor finding algorithm for a Delaunay graph [1424] (see Section 4.5.5) is a Las Vegas algorithm as the result is always correct, but the execution time varies depending on the starting object.

The approximate  $k$ -nearest neighbor algorithm for the SASH (Spatial Approximation Sample Hierarchy) method [883, 884] (see Section 4.5.8) is an example of an algorithm that is neither a Monte Carlo nor a Las Vegas algorithm. Recall that SASH uses a probabilistic algorithm to distribute the objects at the various levels. However, once the SASH has been constructed, all instantiations of an algorithm such as the one for finding the  $k$  nearest neighbors of a query object will have the same execution time and will return the same result, which may not be accurate; moreover, there is no known bound on the extent to which the answer deviates from the correct one. Thus, the SASH approximate  $k$ -nearest neighbor algorithm fails to be a Las Vegas algorithm on two counts. First, it does not necessarily yield the correct result, and, second, there is no variation in its execution time from one instantiation to another. The algorithm also fails to be a Monte Carlo algorithm in that repeated invocations with the same query object yield the same result—that is, neither does the accuracy of the answer change, nor is there a known bound on it.

The goal in LSH is to find a hashing function that is approximately distance preserving. LSH differs from other approaches by using a two-stage process that employs the embed-project-hash paradigm [510]. The key idea is for the hashing functions used in the two stages to be distance preserving, or at least to be approximate distance preserving within some tolerance.

Indyk and Motwani implement the first stage by embedding objects (usually point objects) drawn from  $\mathbb{R}^d$  under a Minkowski  $L_p$  norm (i.e., distance metric) into the Hamming space  $\{0, 1\}^i$  for some  $i$ , which is a vector space whose elements are strings of zeros and ones (i.e., bitstrings), and then use the  $L_1$  distance metric (i.e., City Block). In essence, the value  $c_i$  of each feature  $f_i$  that makes up the multidimensional object at hand is mapped into a vector  $v_i$  in a Hamming space. In particular, letting feature value  $c_i$  be in range  $[0, t]$  so that  $t$  is the integer greater than or equal to ( $\geq$ ) the maximum among all feature values [709],  $v_i$  is represented by a string of  $c_i$  ones followed by  $t - c_i$  zeros (e.g., the feature value 5 in the domain  $[0, 7]$  is mapped into the bitstring 111100, corresponding to five ones followed by two zeros). The vectors  $v_i$  are concatenated to form a single bitstring  $V$  (see also Exercise 3), which is an element of the Hamming space  $\{0, 1\}^{td}$ . It should be clear that this embedding, coupled with the  $L_1$  distance metric, is distance preserving.

Indyk and Motwani implement the second stage by projecting the result  $V$  of the first stage onto an  $m$ -dimensional subspace of the Hamming space, which we term the *projection space*. This projection is achieved by drawing  $m$  bit positions at random with replacement. As we point out below, Indyk and Motwani show that coupling this embedding with the  $L_1$  distance metric is approximately distance preserving within some tolerance.

Notice that this two-stage process involves two “hashing” functions. The first hashing function,  $h_1$ , corresponds to mapping the original data to the Hamming space. The second hashing function,  $h_2$ , corresponds to projecting from the Hamming space to the projection space. Queries are performed in the projection space. In order to make the approach practical, we need to be able to map a query object  $o$  in the original metric space to an object in the projection space, and this is achieved by making use of a third hashing function  $h_3$  corresponding to the composition of  $h_2$  and  $h_1$  (i.e.,  $h_3 \equiv h_2 \circ h_1$ ). Note that the unary hashing function  $h_1$  based on a Hamming space proposed by Indyk

and Motwani [924] is just one of several possible hashing functions that could be used for the LSH function. In particular, Indyk [923] points out that similar hashing functions were used by Karp, Waarts, and Zweig [995] for the bit vector intersection problem and by Broder, Glassman, Manasse, and Zweig [265] in information-retrieval and pattern recognition applications.

As a more concrete example of LSH using the Hamming space, let us consider the set of records consisting of eight cities and their locations specified by their  $x$  and  $y$  coordinate values, as shown in Figure 1.1 in Chapter 1 and given in Figure 4.99. In order to make our example manageable, we have quantized the  $x$  and  $y$  coordinate values so that they lie in the range  $[0, 7]$  by applying the mapping  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$ , respectively. The result of mapping the quantized coordinate values (i.e.,  $f(x)$  and  $f(y)$ ) to the Hamming space is given by the function unary, and the result of the concatenation of the mappings is given by the function HS.

Figure 4.99 contains four examples of possible instances of projections involving three bit positions (i.e.,  $\{2,9,13\}$ ,  $\{7,10,14\}$ ,  $\{1,5,11\}$ , and  $\{8,12,14\}$ ). The physical interpretations of the mapping of the original data from the Hamming space to the projection space for these examples are given in Figure 4.100. In particular, the fact that  $m = 3$  means that we are effectively mapping the objects into vertices of the unit cube. From this figure, we can quickly see that collisions exist whenever more than one object is mapped into the same vertex. Thus, by examining the locations in the original metric space of the objects associated with the same vertex of a cube (i.e., at a projected Hamming distance of 0), we find that some collisions, such as Chicago and Omaha for the  $\{2,9,13\}$  projection instance (Figure 4.100(a)), can be characterized as “good” collisions as they are close to each other in both the original metric space and in the projected Hamming space. On the other hand, collisions such as Atlanta and Denver for the  $\{8,12,14\}$  projection (Figure 4.100(d)) can be characterized as “bad” collisions as they are far from each other in the original metric space, while they are close to each other in the projected Hamming space.

It should be clear that the motivation for the formulation of  $h_3$  is to reduce the probability of bad collisions to less than the probability of good collisions. Any hashing function that has this effect can be characterized as *locality preserving*, and such functions are termed *locality sensitive hashing functions* by Indyk and Motwani [924]. Indyk and Motwani [924] reduce the probability of bad collisions by increasing the number of different projections (i.e., increasing the number of hashing functions  $h_2$ ) that are taken into account when computing the approximate nearest or  $k$  nearest neighbors to  $j$ . Notice that using this approach makes LSH a Monte Carlo randomized algorithm as the effect is to increase the accuracy of the query results by additional invocations. In this respect, the effect is reminiscent of (and analogous to) that which results from increasing the

Example of LSH using the data in Figure 1.1 in Chapter 1.

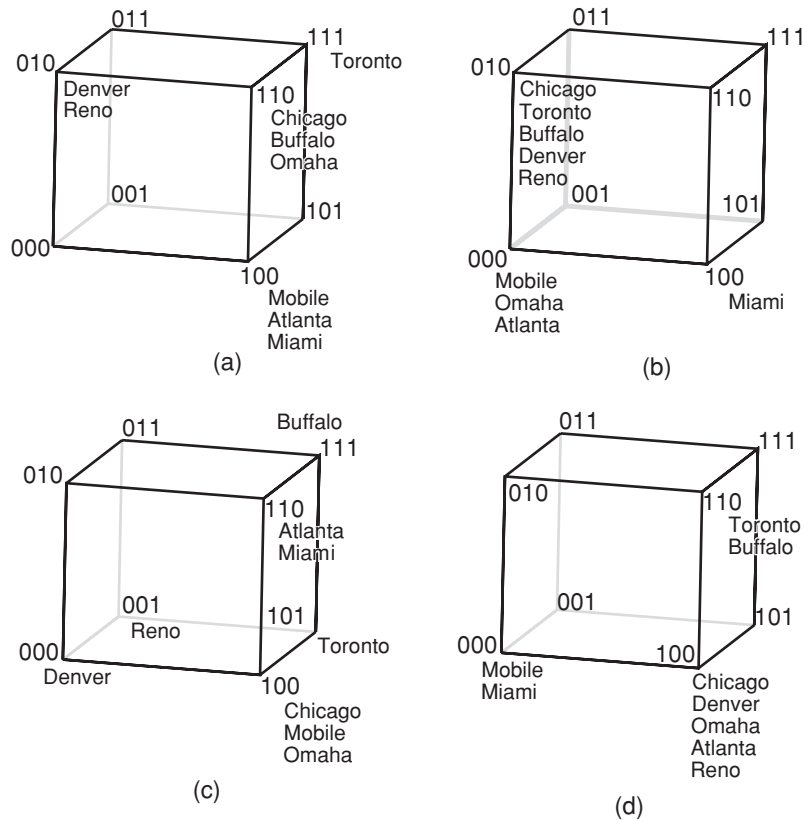

Figure 4.100  
The physical interpretation of the mapping of the quantized representation of the original data in Figure 1.1 in Chapter 1 from the Hamming space to the projection space given by considering the three-bit position sequences (a) {2,9,13}, (b) {7,10,14}, (c) {1,5,11}, and (d) {8,12,14}.

number of seeds when finding the  $k$  nearest neighbors using the kNN graph. In addition, we can also attempt to increase the dimension  $m$  of the projected space to  $s$  as a means of reducing the number of additional projections  $a$  needed while maintaining the same number of bit positions drawn from the Hamming space (i.e., a total of  $j \cdot m = a \cdot s$ ).

Executing a  $k$ -nearest neighbor query for  $q$  in LSH is accomplished by applying the hashing function  $h_3$  to  $q$ , thereby obtaining  $q_p$ , and collecting all of the objects associated with  $q_p$  (i.e., these objects collide with  $q$  as they are associated with the same elements of the projection space and make up the *collision set* of  $q_p$ ). This process is repeated  $j$  times, once for the  $j$  different projections, obtaining  $q_{pi}$  for each projection  $i$  ( $1 \leq i \leq j$ ). At this point, we must decide what to report as the response to the query. One possible response to the  $k$ -nearest neighbor query is to report the  $k$  most frequently occurring objects in the  $j$  collision sets of  $q_{pi}$  for each projection  $i$  ( $1 \leq i \leq j$ ). Of course, for some query objects, the situation could arise that the corresponding collision sets are empty. In this case, a reasonable solution is to examine the objects associated with elements of the projection space that are at an increasing distance from the elements  $q_{pi}$  for each projection  $i$  ( $1 \leq i \leq j$ ).

As an example of the use of LSH, let us examine how it is used to determine the approximate nearest neighbor of  $q = \text{Reno}$  at (5,55), whose corresponding embedding is shown in the last row and column of the table in Figure 4.99. We make use of the same four instances of projections involving three bit positions shown in Figure 4.99, whose physical interpretation of the mapping of the original data from the Hamming space to the projection space is given in Figure 4.100. Applying these four projections to  $q = \text{Reno}$ , we find that  $q$  collides with Denver at object 010 for projection {2,9,13};

Object	Chicago	Mobile	Toronto	Buffalo	Denver	Omaha	Atlanta	Miami	$q = \text{Reno}$
Chicago		1	1	11	11	111	1		1

Figure 4.101

The upper triangular half of the matrix, above the empty diagonal, indicates the unary representation of the number of times objects (a,b) are members of the collision list of the same element of the projection space for the projections given in Figure 4.99. The lower triangular half of the matrix, below the empty diagonal, indicates the interobject distances in the quantized original metric space.

with Chicago, Toronto, Buffalo, and Denver at object 010 for projection  $\{7,10,14\}$ ; with an empty set at object 001 for projection  $\{1,5,11\}$ ; and with Chicago, Omaha, Atlanta, and Denver at object 100 for projection  $\{8,12,14\}$ . Clearly, Reno collides most often with Denver, and hence Denver is returned as the approximate nearest neighbor of Reno. The upper triangular half of the matrix, above the empty diagonal, given in Figure 4.101 summarizes the various collision lists by indicating, using a unary representation, how many times each pair of objects, including Reno, collides, where, for example, the entry (Mobile, Miami) has a value of 111, denoting that Mobile and Miami occur three times as members of the collision lists of the same element of the projection space for the four instances of projections involving the three bit positions. The lower triangular half of the matrix, below the empty diagonal, gives the interobject distances in the quantized original metric space.

Assuming a  $d$ -dimensional metric space,  $N$  objects, and  $j$  projection instances, the approximate nearest neighbor query using LSH has an execution time of  $O(d \cdot j)$  and requires  $O(N \cdot (d + j))$  space. The fact that we repeat the process serves to reduce the likelihood that there are no collisions. If, in fact, we have no collisions for a particular query, then we could examine the objects associated with elements of the projection space that are at increasing distance from the elements  $q_{pi}$  for each projection  $i$  ( $1 \leq i \leq j$ ), as mentioned earlier. Alternatively, we can increase the number of projections, but this is not very attractive as it is equivalent to rebuilding a hash table upon overflow, which is not always practical. Thus, such an occurrence serves as a reminder that LSH is an approximate nearest neighbor algorithm and has a probability of not returning the proper response.

Indyk and Motwani [924] prove that  $h_2$  is approximately distance preserving within a tolerance, thereby justifying its use and thereby rendering  $h_3$  also to be approximate distance preserving as  $h_3$  is the result of composing  $h_2$  with a distance-preserving hashing function  $h_1$ . This is done by appealing to the result of Frankl and Maehara [631] that improves upon the Johnson-Lindenstrauss Lemma [962], which states that given an  $\epsilon$  and  $N$  points in a metric space, a mapping that projects onto some subspace defined by approximately  $9\epsilon^{-2} \ln N$  random lines is a distance-preserving mapping within an error of  $\epsilon$ . Indyk [923] notes that this appeal to the improvement of the Johnson-Lindenstrauss Lemma by Frankl and Maehara is similar to that deployed by Kleinberg [1032] and Kushilevitz, Ostrovsky, and Rabani [1097] in their use of normal projections onto randomly chosen lines that pass through the origin in approximate nearest neighbor searching.

Note that, although we earlier characterized LSH as a Monte Carlo algorithm, Indyk [922] has also subsequently shown how the LSH method can be converted into a Las Vegas algorithm using a greedy set cover algorithm (e.g., [385]). The LSH method has been found to perform well in large databases where the data resides on disk [709]. It has found use in a number of applications in similarity searching of images in a number of computer vision applications (e.g., [700, 1523, 1737]).

Loosely speaking, LSH can be said to be similar in spirit to Lipschitz embeddings (see Section 4.7.2). Recall that in Lipschitz embeddings objects are embedded in a vector space where the coordinates consist of reference sets, each of which makes up a subset of the objects in the underlying domain  $S$ . The embedding is constructed by computing the distance of the embedded objects from the different reference sets, which is a form of a projection onto the reference sets. By using a sufficiently large number of randomly formed reference sets, the distortion of the values of distances in the embedding space is guaranteed to be bounded with a high probability. This is a form of approximate distance preservation. LSH replaces the “large” number of randomly formed reference sets by repeated application of the projection step using different elements of the embedding space that are somewhat analogous to reference sets in the Lipschitz embedding. The analogy can be made more concrete by appealing to the connection that we mentioned earlier between LSH and the solutions of Kleinberg [1032] and Kushilevitz, Ostrovsky, and Rabani [1097] in their use of random projections onto lines in approximate nearest neighbor searching. In particular, in this case, the random lines are analogous to the reference sets (see Exercise 4).

### Exercises

1. Compare LSH and SASH for finding the approximate  $k$  nearest neighbors.
2. Derive a bound on the error probability of the algorithm for finding the nearest neighbor in a  $k$ NN graph, thereby demonstrating that it can be characterized as a Monte Carlo randomized algorithm.
3. At an initial glance, the mapping into a Hamming space that we described appears to resemble bit concatenation as described in Section 1.6 of Chapter 1 in the sense that the unary representations of the quantized values of the individual features that describe the multidimensional object are concatenated. Would using the analog of bit interleaving applied to the unary representation lead to improved performance?
4. (Sydney D’Silva) In the text, we argue that LSH is similar in spirit to Lipschitz embeddings (see Section 4.7.2). One way to rationalize this connection is to consider the related predecessor methods of Kleinberg [1032] and Kushilevitz, Ostrovsky, and Rabani [1097] that make use of random projections onto lines. In particular, we claim that the random choice of a subset of objects  $A_i$  and the mapping of each object  $o$  to  $(d_1, d_2, \dots, d_k)$ , where  $d_i$  is the distance from  $o$  to the nearest object in  $A_i$ , is akin to the random projections used in LSH. D’Silva [510] has observed that one of the difficulties with such an analogy is the absence of a common reference object with respect to which all of the distances that form the “coordinate” values are measured (e.g., an “origin” object) in the case of the Lipschitz embedding. In order to overcome this difficulty, D’Silva proposes to modify the Lipschitz embedding by imposing a point of origin  $O$  so that for each object  $o$  its mapping to tuple  $(d_1, d_2, \dots, d_k)$  is such that  $d_i$  is the distance from the origin  $O$  to the closest object to  $o$  in  $A_i$ , instead of the distance from  $o$  to the closest object in  $A_i$ . The result is that this modified Lipschitz embedding is analogous to the method of Kleinberg [1032]. In order to complete the comparison, can you prove that the modified Lipschitz embedding is approximately distance preserving within a tolerance, thereby validating the relationship between Lipschitz embeddings and LSH?

## Overview of B-Trees

Tree-based searching methods involve making branches based on the results of comparison operations. When the volume of data is very large, we find that often the tree is too large to fit in memory at once. Therefore, the tree is stored on many disk pages, and some of the pages might not be in memory at the time the comparison is made. In such an environment, the branches in the tree contain disk addresses, and it is not uncommon for a comparison operation to result in a page fault. This calls for search techniques known as *external searching*. The B-tree and its variants are the most commonly used external searching techniques and are the subject of this appendix.

When the tree is a binary tree, the number of page faults can be quite high. For example, for a binary tree of  $N$  records, the number of comparison operations is minimized if the binary tree is complete (a concept similar to global balance). In this case, we need to make approximately  $\log_2 N$  comparisons before reaching a leaf node. If  $N$  is 2 million, then we will make 21 comparison operations, which potentially could cause 21 page faults. Thus, binary trees are not good for external searching.

Our goal is to minimize the number of page faults. There are several ways of achieving this goal. One way is to aggregate the results of the comparisons by delaying the branch operation to the missing page. For example, when  $N$  is 2 million, we can transform the complete binary tree of depth 21 to a complete tree of depth 7, where groups of seven key values are formed at every three levels of the tree. The result is that each node of the new tree has eight branches instead of two, and the effect is more like an 8-ary tree (see Figure A.1). Thus, we will have at most 7 page faults (instead of 21) when retrieving the data. It is important to note that we have separated the comparison operations from the branching process. This is clear in the figure, where we see the locality of the comparisons—that is, a branch is only attempted once the appropriate sequence of three comparisons has been executed.

The small page sizes (i.e., seven nodes), as in the example above, are widely used to improve cache locality of main memory data structures in modern processors where cache lines are typically 256 bytes at the present [746]. Nevertheless, when the above scheme is used, we usually aggregate more than seven key values. The aggregation is such that the result is stored on a page. It is not inconceivable to store as many as 500 key values on one of the pages. For example, if we store 511 key values on a page, then we have 512 branches and with at most three page faults, we can access over 128 million records. In fact, this is the basis of the *indexed-sequential file organization* (ISAM) [705] for storing data on disk. In this case, the first branch indicates a cylinder address, the second branch indicates a track along the cylinder, and the third address indicates the address of the record.

Another way to minimize the page faults is to use a multiway tree instead of a binary tree. A *multiway tree* is a generalization of a binary search tree where at each

Figure A.1  
8-ary tree.

Figure A.2  
Example of a B-tree of order 5.

nonleaf node, instead of testing just one key value and making a 2-way branch, we test  $m$  ( $m \geq 1$ ) key values and make an  $(m + 1)$ -way branch. By being somewhat flexible about the capacity of each nonleaf node, we can guarantee that the resulting tree structure is balanced in the sense that all leaf nodes are at the same level. This is at the expense of leaving some of the space in each node unutilized. The result is known as a B-tree [143]. It has its roots in the 2-3 tree [874], which is a variant of a balanced binary search tree where all leaf nodes appear at the same level and every nonleaf node has two or three children. The B-tree is also related to the AVL tree [15, 27], which is a variant of a balanced binary search tree. The key difference between them is that the B-tree is globally balanced while the AVL tree is locally balanced (recall that the AVL tree only guarantees that the maximum depths of the two subtrees of any node differ by at most 1).

A B-tree of order  $m$  satisfies the following properties:

1. All leaf nodes appear at the same level and contain no key values (i.e., they are empty).
2. Unless the root is a leaf node, it has at least two children.
3. All nodes other than the root and the leaf nodes have at least  $\lceil m/2 \rceil$  children.
4. A node has a maximum of  $m$  children.
5. A nonleaf node with  $j$  key values has  $j + 1$  children.

For example, Figure A.2 is an example of a B-tree of order 5. Notice that each node has two, three, or four key values. The only exception is the root, which is permitted to have just one key value. In this example, we show the pointers to the empty leaf nodes (i.e., empty square boxes), although they are usually left out, as we will also do in the other examples. The leaf nodes are analogous to the external nodes in what is known as an *extended binary tree*.<sup>1</sup>

A nonleaf node containing  $j$  key values and  $j + 1$  children has the following format:

$$p_0 k_1 p_1 k_2 p_2 k_3 \dots k_{j-2} p_{j-2} k_{j-1} p_{j-1} k_j p_j$$

where  $k_1 < k_2 < k_3 \dots < k_j$ , and  $p_i$  ( $0 < i < j$ ) points to a node (i.e., subtree) containing key values ranging between  $k_i$  and  $k_{i+1}$ .  $p_0$  points to a node containing key values less than or equal to  $k_1$ , while  $p_j$  points to a node containing key values greater than  $k_j$ . Our definition assumes that the key values are distinct (i.e., no duplicates). If this is not the case, then the definition of a node must be modified (see Exercise 1). There is a close relationship between nodes and pages in a B-tree. Often, we use the terms *node* and *page*

<sup>1</sup> In many applications, we find it useful for each node to be either a leaf node or to have  $k$  ( $k > 1$ ) children. When  $k = 2$ , such a tree is called an *extended binary tree* because it can be constructed by taking a binary tree and replacing each null subtree by a special node.

interchangeably. It is easy to see that properties 1–5 guarantee that each page will be at least 50% full.

Searching for a record with key value  $k$  in a B-tree is very easy. Assume a nonleaf node format as given above. We start at the root node. The process is analogous to search in a binary search tree, with the exception that we must also perform a search within each nonleaf node. In particular, we must search for  $k$  among the  $k_i$  stored in the node. Either we find  $k$  and exit, or we find the largest  $i$  such that  $k_i < k$  and retrieve the node pointed at by  $p_i$ . If we are at a leaf node, then the search is unsuccessful. When the nodes are large, it is preferable to use binary search within the node rather than sequential search.

Insertion in a B-tree is a bit more complex. We search for the record with key value  $k$ . An unsuccessful search leads us to the position where  $k$  should be inserted. This will be at the bottom of the tree in a leaf node  $t$ . We attempt to insert the record in the nonleaf node  $p$  containing the pointer to  $t$ . If node  $p$  is not already full (i.e., it contains less than  $m - 1$  key values), then we make the insertion and exit. Otherwise, node  $p$  is full (i.e., it contains  $m$  key values after the insertion), a situation that is termed *overflow*. In this case, we split node  $p$  into two nodes, dividing the  $m$  key values as evenly as possible into two sets, and move the median key value to the ancestor node, say  $a$ . The same process is applied recursively to node  $a$ . The process terminates upon encountering a node that need not be split or if we are at the root node. If we are at the root node, and if it must be split, then we simply create a new node containing a single key value, and the process terminates.

As an example, consider the insertion of 16 into the B-tree in Figure A.2. We find that 16 belongs in node C and make the insertion. Node C is already full, and we have an overflow. Therefore, we split node C into two nodes, C1 and C2, and promote key value 15 to node A, which is not too full. The result is given in Figure A.3(a).

Alternatively, we can often perform the insertion without having to split any nodes by applying *rotation* (also known as *deferred splitting*). The basic idea is that whenever overflow occurs in node  $a$ , we examine the adjacent brother nodes to see if they are full. If one of the adjacent brother nodes, say  $b$ , is not full, then we perform a rotation from  $a$  to  $c$ , the father of  $a$  and  $b$ . For example, when inserting 16 into the B-tree in Figure A.2, we find that node C is full. However, adjacent brother node D is not full. So, we promote node 18 from C to A and demote 20 from A to D. The resulting B-tree, given in Figure A.3(b), satisfies properties 1–5 of the B-tree definition.

Formally, rotation is specified as follows. Assume that node  $a$  is full, and adjacent brother node  $b$  to the right of  $a$  is not full. Let  $c$  be the father node of  $a$  and  $b$ . Promote the maximum key value,  $d$ , in  $a$  to  $c$ , and demote to  $b$  the smallest key value,  $e$ , in  $c$  that is greater than  $d$ . A similar process is applied if the adjacent brother node that is not full is to the left of  $a$  instead of to the right (see Exercise 3). In general, although rotation avoids splitting a node (an operation analogous to allocating a new page), it is not a good idea to use it as its implementation becomes very complicated if the adjacent brother nodes are full.

Figure A.3  
The result of inserting 16 into the B-tree of Figure A.2 with (a) node splitting and (b) rotation. Only the subtree rooted at node A is shown.

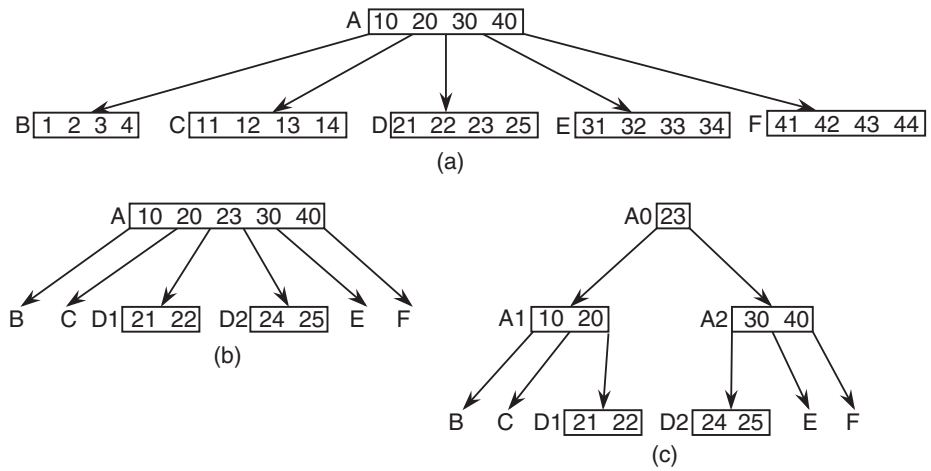

Figure A.4  
(a) A B-tree awaiting insertion of 24, (b) an intermediate split of node D, and (c) the final result.

Notice that B-trees do not grow downwards. Instead, they grow from the top (i.e., at the root) since their depth can only increase when the root node splits (this happens relatively infrequently). For example, suppose we want to insert 24 into the B-tree in Figure A.4(a). We find that 24 belongs in node D and make the insertion. Unfortunately, node D is already full, and we have an overflow. Therefore, we split node D into two nodes, D1 and D2, and promote key value 23 to node A (see Figure A.4(b)). Again, we find that node A is already full, and we have an overflow. Thus, we split node A into two nodes, A1 and A2, and promote key value 23, thereby creating a new node, and the tree has grown by one level (see Figure A.4(c)).

Deletion in a B-tree is closely related to B-tree insertion. To delete a record with key value  $k$ , we start at the root and search for it. Once we find it, we continue searching for the maximum key value  $j$  that is less than  $k$  or for the minimum key value  $j$  greater than  $k$ . Key value  $j$  is found in node  $p$ , which is at the next to bottom level of the tree (i.e., the one containing the leaf nodes).  $j$  is moved to replace  $k$ . If node  $p$  contains at least  $\lceil m/2 \rceil - 1$  key values after the move, then we are done. Otherwise, the node has too few key values, a situation that is termed *underflow*. In this case, we have two choices: rotation or merging.

Figure A.5  
The result of deleting 22 from the B-tree of Figure A.2 with node C containing (a) {13, 14, 15, 18} and (b) {15, 18}.

Rotation is explained above in conjunction with B-tree insertion. Rotation can be applied if there is underflow in node  $a$ , while an adjacent brother node, say  $b$ , contains at least  $\lceil m/2 \rceil$  key values. In this case, we rotate from  $b$  to  $c$ , the father of  $b$ , and from  $c$  to  $a$ . For example, when deleting 22 from the B-tree in Figure A.2, we find that there is underflow in node D. However, adjacent brother node C contains more than the minimum number of key values. So, we promote key value 18 from C to A and demote 20 from A to D. The resulting B-tree, given in Figure A.5(a), satisfies properties 1–5 of the B-tree definition.

Rotation is not always possible. For example, if node C in Figure A.2 contained just two key values (e.g., 15 and 18) instead of four key values, then we would have underflow in adjacent brother nodes. In this case, rotation from C to A and from A to D would not solve our problem as now there would be underflow in node C instead of node D (see Figure A.5(b)). This calls for a more complex rotation algorithm. In particular, we would have to rotate key values over brothers that were not necessarily adjacent (e.g., promote 8 from B to A, demote 10 from A to C, promote 18 from C to A, and demote 20 from A to D), as well as over several levels. The implementation of such an algorithm is quite complicated. For this reason, in such cases, it is preferable to make use of merging.

When simple rotation among adjacent brothers is not possible, then we merge node  $p$  with one of its adjacent brother nodes (both of which contain  $\lceil m/2 \rceil - 1$  key values)

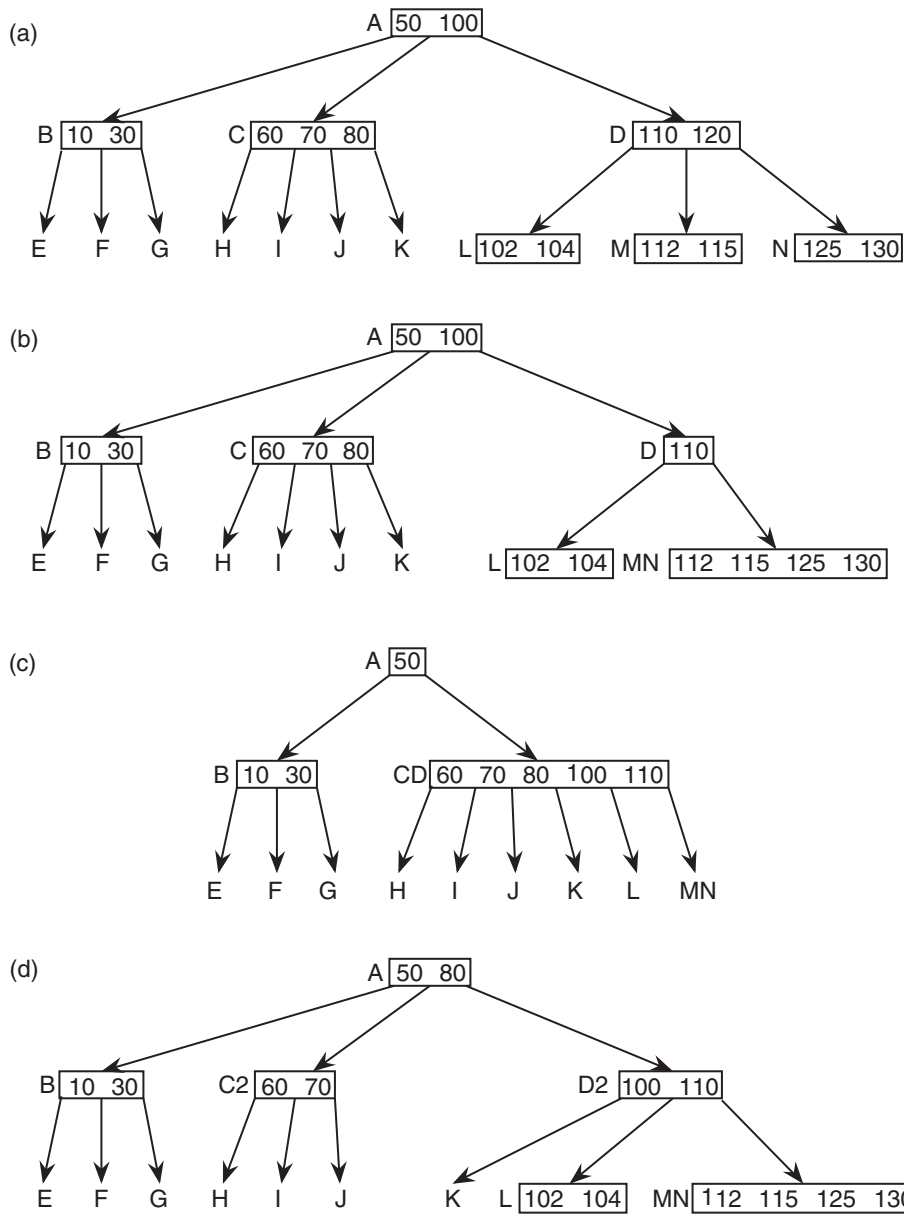

Figure A.6  
(a) A B-tree awaiting deletion of 120, (b) the underflow created by its removal from node D, (c) the overflow created by the merge of nodes C and D, and (d) the final result.

and demote the intermediate key value from the ancestor node, say  $a$ . This, in turn, can cause further underflow. In such a case, we continue applying the process recursively to node  $a$  and its ancestors. The process terminates upon encountering a node that need not be merged or if we are at the root node. If we are at the root node, and it used to contain a single key value but is now empty as a result of the demotion, then the root node is removed, and the process terminates. The result is that B-trees shrink from the top. Thus, the effect on tree growth of the deletion process is the reverse of the insertion process.

As an example of the deletion process using merging, suppose we want to delete 120 from the B-tree in Figure A.6(a). We first search for 120, and having found it in node D, we replace it by the maximum key value less than 120—that is, 115 in node M. This causes node M to underflow. Therefore, we merge nodes M and N and demote 115 from node D, thereby creating node MN (see Figure A.6(b)). Unfortunately, this causes node D to underflow. Thus, we merge node D with node C and demote 100 from node A, thereby creating node CD (see Figure A.6(c)). At this point, node CD is too full (i.e., overflow).

We split it into nodes C2 and D2 and promote 80 to node A2 (see Figure A.6(d)). At this point, we are done.

Note that deletion in Figure A.6 could have also been achieved by using rotation. In particular, we apply rotation to Figure A.6(b) by moving 100 from node A to node D, moving 80 from node C to node A, and linking node K to node D instead of to node C. However, if we modify Figure A.6(a) so that node C and key 100 are not present and stipulate that each of nodes E, F, and G contain just two keys, then rotation cannot be used. In this case, once again M and N will be merged to yield MN. This will cause an underflow in D, and it will be merged with B to yield BD, with 50 being demoted from A. We see that the depth of the B-tree has been reduced by one level.

B-trees are attractive because they are balanced, and storage utilization is at least 50% and is usually much better. Searching, insertion, and deletion can be performed in  $O(d)$  time, where  $d$  is the depth of the B-tree. The number of disk retrievals and writes is at most  $3d + 4$  for each operation (see Exercise 9).

Earlier, we mentioned that the B-tree is rooted in the 2-3 tree. In fact, it is a generalization of a 2-3 tree. In particular, each node in the corresponding B-tree has one or two key values, and the result is an order 3 B-tree. We can also define a 2-3-4 tree, which is the same as a B-tree of order 4, which means that each node contains between one and three key values. Both 2-3 and 2-3-4 trees require several different node types depending on the number of key values. Red-black balanced binary trees [766] enable the implementation of 2-3 and 2-3-4 trees as binary trees in a manner similar to the natural correspondence between a forest and a binary tree.<sup>2</sup> Thus, all nodes are now uniform.

In essence, in a red-black balanced binary tree, the nodes of the 2-3 and 2-3-4 trees are represented as one-level binary trees consisting of zero or more red edges, while black edges are used to link up the nodes of the 2-3 and 2-3-4 trees.<sup>3</sup> The implementation makes use of an additional one-bit field with each node that indicates if the incoming edge from its father is red or black. For example, Figure A.7(b) is the red-black balanced binary tree corresponding to the 2-3-4 tree in Figure A.7(a). Red edges are drawn with heavier lines and marked with  $r$ , while black edges are drawn with normal lines and marked with  $b$ .

We make the following observations. In the case of a 2-3 tree, the one-level binary tree has at most one edge, while it has at most two edges in the case of a 2-3-4 tree. The choice of whether a red edge is the left child or the right child of the root of the one-level binary tree corresponding to the 2-3 tree depends on which of the values in the node of the 2-3 tree is used as the root of the one-level binary tree. Also, it is easy to see that it is impossible to have two successive red edges in red-black balanced binary trees that correspond to 2-3 or 2-3-4 trees.

At this point, let us discuss the insertion of a record  $r$  with key value  $k$  in a red-black balanced binary tree corresponding to a 2-3 tree (see Exercise 15 for a discussion

<sup>2</sup> This correspondence arises from a concern that since a tree has a variable number of children, its implementation is somewhat cumbersome due to the need for extra storage to allow for a maximum number of children. An alternative solution is to represent the tree as a binary tree. In this case, the pointer structure of the tree rooted at  $t$  is modified so that each node in the corresponding binary tree rooted at  $u$  has two children, pointed at by LCHILD and RCHILD, say  $v$  and  $w$ , respectively. The LCHILD field of  $u$  is used to point to  $t$ 's first child and results in the node  $v$ . The brothers of each node (i.e., the remaining children of  $t$ ) are linked together in a list using the RCHILD field of  $v$ . Thus, the root  $u$  of the new binary tree has an empty RCHILD field  $w$ . This representation is also very useful for a forest, which is a set of zero or more disjoint trees. In this case, if the forest has at least two elements, then the RCHILD field  $v$  of the new binary tree rooted at  $u$  is no longer empty—that is, it points to the second member of the forest. The representation of a forest as a binary tree is known as the *natural correspondence* [1044] between a forest and a binary tree.

<sup>3</sup> Some descriptions of red-black balanced binary trees (e.g., [422]) assign colors to the nodes instead of the edges. In this case, a node is red if its parent is from the same node in the 2-3 or 2-3-4 tree; otherwise, it is black. In addition, if a node is red, then both of its children (if present) are black. Also, every path to a leaf node contains the same number of black nodes (see Exercise 13).

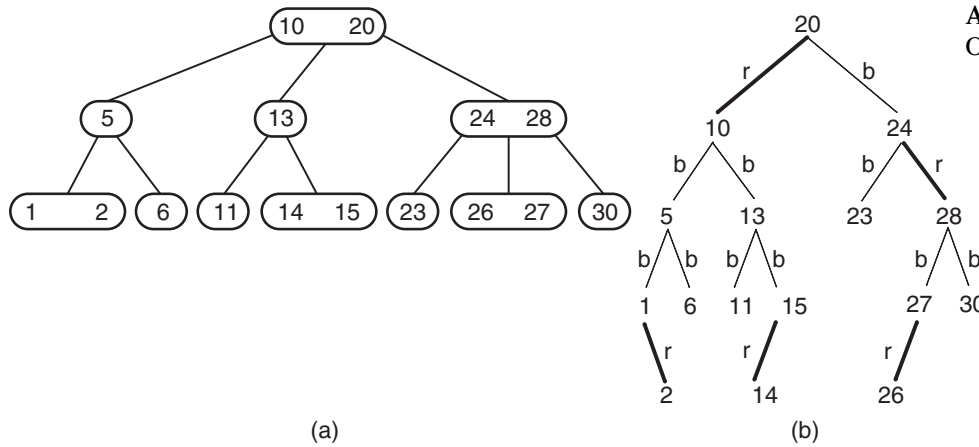

Figure A.7  
(a) A 2-3-4 tree and (b) a corresponding red-black balanced binary tree. Red edges are drawn with heavier lines and marked with 'r' while black edges are drawn with normal lines and marked with 'b.'

of insertion into a red-black balanced binary tree corresponding to a 2-3-4 tree, which is a bit more complex as there are a few more cases to handle).<sup>4</sup> The algorithm is analogous to insertion in a B-tree in the sense that we first search for a record with key value  $k$  and find the leaf node  $y$  in which it belongs, make the insertion, determine if any splits are necessary, and propagate them up the tree. We make the insertion as a red edge  $d$  from some node  $x$  to  $y$ . Now, determine if a split is necessary. This is done by checking the color of the father edge  $f$ , which corresponds to an edge from a node  $w$  to  $x$ .

1. If  $f$  is black or empty (i.e., it does not exist), then test the brother edge  $b$  (if it exists) of  $d$  as  $x$  may have a child  $z$ .
  - (a) If  $b$  is black or empty, then we are done.
  - (b) If  $b$  is red, then we have a situation analogous to an overflow in a B-tree since nodes  $x$ ,  $y$ , and  $z$  are like brothers. Thus, we change the colors of edges  $b$  and  $d$  to be black. Next, if  $f$  exists, then we change the color of  $f$  to be red and reapply steps 1 and 2 to  $f$ . Otherwise, if  $f$  does not exist, then we exit.
2. If  $f$  is red, then the configuration is an illegal 2-3 tree as we have two successive red edges. Therefore, we apply a single (Figure A.8(a)) or double (Figure A.8(b)) rotation as in the case of an AVL tree, which will make the two red edges brothers. This situation is not allowed in a 2-3 tree. Thus, we change the colors of these edges (i.e.,  $d$  and  $f$ ) to be black, make their father edge  $g$  red, and reapply steps 1 and 2 to edge  $g$ . Notice that, in this case, if edge  $g$  does not exist, then we are at the root, and we are done.

There are a number of ways of improving the performance of B-tree methods. Since they are primarily of interest for external (i.e., disk-based) searching, the focus is on reducing the number of disk accesses and on increasing the storage utilization. The number of disk accesses can be reduced by using a buffer pool of pages. In this case, a fixed number of pages are always kept in memory. We make use of a least recently used (LRU) page replacement policy to make room for a new page if all the pages in the buffer pool are full (i.e., we write to disk the page that was least accessed and replace it with the new page). Such a strategy is very efficient since the root page and some pages corresponding to the nodes at depth 1 will usually be in memory and will most likely

<sup>4</sup> This algorithm is complicated and may be skipped.

(a)

(b)

Figure A.8

Examples of right rotation operations in AVL trees. Each subtree is labeled with its depth. The labels L, R, and E associated with each node  $n$  are balance factors corresponding to the left subtree of  $n$  being one level deeper than, equal to, and one level shallower than, respectively, the right subtree of  $n$ . A right rotation is necessary when the depth of the left subtree of a node is more than one greater than the depth of the right subtree. L' denotes this situation. (a) Example of an AVL tree (left) and the result of applying a single right rotation to it (right) when the balance factor of the left subtree is L. (b) Example of an AVL tree (left) and the result of applying a double right rotation to it (right) when the balance factor of the left subtree is R. The rotation is termed a double rotation because we first rotate the pair (b,c) to the left and then the pair (a,c) to the right.

have been accessed, thereby insuring that they will not be the ones chosen to be written out to make room for the new pages.<sup>5</sup>

When pages are modified (e.g., when an insertion and a split occur), we do not necessarily write the modified page to disk. Instead, we only write to disk when the modified page is the one chosen to be replaced by the buffer pool manager. We can try to delay writing the modified pages to disk by using a page replacement policy that replaces the least recently unmodified page instead of just the least recently accessed. However, if such a policy is followed, then we should be careful that the page that is written out is not the root page or one of the pages at depth 1.

There are a number of ways of increasing the storage utilization. One obvious improvement suggested by Knuth [1046] is to require that whenever a node split occurs, the  $n$  adjacent brother nodes be split to yield  $n + 1$  adjacent nodes, each of which

<sup>5</sup> For a discussion of alternative strategies, including a most recently used (MRU) page replacement policy, see [380].

contains at least  $\lfloor n \cdot (m - 1) / (n + 1) \rfloor$  key values so that storage utilization increases to  $n / (n + 1) \cdot 100\%$  instead of 50%, as in the conventional definition of a B-tree. When  $n = 2$ , the result is termed a *B\*-tree* [1046].

Other improvements suggested by Knuth [1046] include the use of different values of  $m$  at different levels of the tree. Assume that the nonleaf nodes are at levels 0 through  $d$ . This can be used to eliminate wasted space in the leaf nodes by making  $m$  be 1 at level  $d + 1$ . In fact, we observe that only nodes at level  $d$  contain pointers to  $\Lambda$ . Thus, we can dispense with level  $d + 1$  and, instead, use a value of  $m$  at level  $d$  that is twice as large as that at all other levels than the root. In this way, we can store more key values in the nodes at the bottom level (i.e.,  $d$ ) of the B-tree.

A major improvement is made by limiting the amount of information stored in the nonleaf nodes. This has the effect of increasing the number of records that can be stored in each node, thereby reducing the maximum depth of the B-tree. There are several options. One option is just to store the key value plus a pointer to a page that contains the rest of the record's data.

In fact, using this option, we can also dispense with the empty leaf nodes. Knuth [1046] suggests that once the empty leaf nodes have been eliminated, only the nodes at the deepest level contain key values (henceforth referred to as *leaf nodes*, although they contain between  $\lceil m/2 \rceil - 1$  and  $m - 1$  key values). In this case, the nonleaf nodes only provide an index so that the appropriate leaf node that contains the desired record can be located. The nonleaf nodes can contain some of the same key values that are stored in the leaf nodes, but this need not be so. The only requirement is that if a key value  $k$  is stored in a nonleaf node between pointers to subtrees pointed at by  $p$  and  $q$ , then all key values in  $p$  are less than or equal to  $k$ , and all key values in  $q$  are greater than  $k$ .

These modifications to the B-tree definition result in what is called a *B<sup>+</sup>-tree* [414]. B<sup>+</sup>-trees still grow and shrink as do B-trees; however, key values are never passed up or down between levels of the tree. This also means that the leaf nodes in a B<sup>+</sup>-tree are always at least half full instead of being empty as in the B-tree. Notice that since we no longer need the pointers to the empty leaf nodes (i.e.,  $\Lambda$ ), the space that they required can be used for the pointers to the pages that contains the rest of the data of the records associated with the key values stored in the node.

As an example of a B<sup>+</sup>-tree, consider Figure A.9, which corresponds to the key values of the B-tree in Figure A.2. Notice that all the nodes at the deepest level contain key values, although their number is different from that shown in Figure A.2. We also observe that some of the key values have been duplicated in the nonleaf nodes (e.g., 25 and 40 in nonleaf nodes A and B, and C and D, respectively).

In fact, the nonleaf nodes in the B<sup>+</sup>-tree need not contain the key values. In particular, if the key values are long strings of characters, we need only store enough characters to enable us to differentiate the key values in the subtrees. For example, to differentiate between jefferson and jones, we could use jefferson but actually jf is sufficient. Using

Figure A.9  
The B<sup>+</sup>-tree corresponding to the key values of the B-tree of Figure A.2.

the shortest possible key value enables us to store more key values in the nonleaf nodes, thereby resulting in shallower trees. This is known as a *prefix B<sup>+</sup>-tree* [144].

A further improvement is to link all the leaf nodes in the B<sup>+</sup>-tree by adding a pointer to each leaf node that points to the next leaf node in the sequence. This enables us to traverse the records in sequence without ever referencing the nonleaf nodes. The result is a representation that efficiently supports both random and sequential access.

### Exercises

1. Modify the definition of a B-tree node to permit duplicate key values.
2. Prove that the number of leaf nodes in a B-tree is one greater than the number of key values.
3. Suppose that you are implementing insertion in a B-tree with rotation. How would you treat the case that the adjacent brother node  $b$  that is not full is to the left of the full node  $a$ ?
4. Consider a B-tree of order  $m$ , and suppose that deletion has taken place and nodes  $a$  and  $b$  have been merged. Assume further that underflow has occurred in node  $a$  and that deletion of one more key value will cause node  $b$  to underflow as well. What is the total number of key values in the two adjacent brother nodes before the merge?
5. Given a B-tree of order  $m$  with  $N$  records, what is the maximum search length (i.e., in terms of levels)?
6. What is the maximum search length in a B-tree of order 512 with 128,000 records?
7. Given a B-tree of order  $m$  with  $p$  nodes at  $i$  levels (i.e., at depth 0 through  $i - 1$ ), prove that the total number of node splits that occur when building it is  $p - i$ .
8. Derive an upper bound on the average number of node splits per insertion in a B-tree of order  $m$  with  $N$  records.
9. What is the maximum number of disk accesses made when searching, inserting, and deleting in a B-tree with a root at depth 0 and leaf nodes at depth  $d + 1$ ?
10. Write an algorithm to insert a record into a B-tree.
11. Write an algorithm to delete a record from a B-tree.
12. What is the minimum number of key values that can be stored in a B-tree of order  $m = 2a - 1$  ( $a > 1$ ) with a root at depth 0 and leaf nodes at depth  $j$ ?
13. A red-black balanced binary tree can also be defined in terms of node colors rather than edge colors. In particular, a node is red if its parent is from the same node in the 2-3 or 2-3-4 tree; otherwise, it is black. Moreover, if a node is red, then both of its children (if present) are black. Prove that every path to a leaf node in a red-black balanced binary tree contains the same number of black nodes.
14. Prove that the maximum depth of a red-black balanced binary tree is at most twice the maximum depth of the corresponding 2-3 or 2-3-4 trees.
15. What changes need to be made to the insertion algorithm given in the text for red-black trees corresponding to 2-3 trees so that it also works for 2-3-4 trees?
16. Write an algorithm for deletion in red-black balanced binary trees that correspond to 2-3 trees.
17. Write an algorithm for deletion in red-black balanced binary trees that correspond to 2-3-4 trees.
18. The insertion routine given in the text for B-trees is bottom up in the sense that we insert the key value at the deepest level followed by a node split if there is overflow, in which case the median key value is propagated up the tree where the same process is repeated. An analogous bottom-up algorithm for insertion into a red-black balanced binary tree that corresponds to a 2-3 tree is presented in the text. Devise a top-down insertion algorithm for a red-black balanced binary tree that corresponds to a 2-3-4 tree. In this case, you will split if necessary as you descend the tree when making the insertion. Assume that the key value is not yet in the tree.
19. Can you apply the same algorithm devised in Exercise 18 to insert into a 2-3 tree? If not, explain why.

20. Under what conditions can you apply the algorithm devised in Exercise 18 to insert into a B-tree of order  $m$ ?
21. Suppose that you are implementing B-trees in a multiuser environment. In this case, once an insertion is taking place, all other users must be prevented from accessing all the nodes on the path from the root  $r$  to the leaf node  $i$  where the insertion is taking place. The rationale is that since the insertion process is bottom up, there is a possibility that a node split will be propagated all the way up to the root. How would the application of the top-down insertion process described in Exercise 18 to a B-tree (see Exercise 20) reduce the need to prevent the access of nodes on the path from  $r$  to  $i$ ?
22. Implement a B-tree of order  $m$  as a binary tree. The idea is to use the analog of a red-black balanced binary tree where the red edges are used to link the contents of the order  $m$  nodes of the B-tree, and the black edges are used to link up the nodes of the B-tree.
23. What is the difference between searching for a record with a particular key value in a B<sup>+</sup>-tree and for one in a B-tree?
24. What is the difference between deleting a record with a particular key value from a B<sup>+</sup>-tree and one from a B-tree?

## Linear Hashing

Linear hashing addresses the situation that arises when the hash table (usually consisting of buckets) is full or when the hash chains in a chaining method (attributed to Luhn by Knuth [1046, p. 547]) get too long. One solution is to expand the size of the hash table. Since the number of buckets (or chains in a chaining method) is usually fixed by the hash function, we must modify our hash function to generate more buckets. This modification should ideally require a minimal amount of rehashing—that is, only a few records should have to be moved to new buckets. Generally, most hashing methods do not allow the number of buckets to grow gracefully.

Knott [1040] suggests storing the buckets using a trie (see the definition in the opening section of Chapter 1) in the form of a binary tree (e.g., Figure B.1(a)). In this scheme, dealing with bucket overflow is rather trivial since the bucket is split into two parts (e.g., bucket B in Figure B.1(a) is split into buckets E and F in Figure B.1(b)). The problem with such a scheme is that accessing a bucket at depth  $l$  requires  $l$  operations. However, the tree is usually kept in memory, and thus these  $l$  operations are considerably faster than a disk access, and, in fact, only one disk access is required.

A more general formulation of Knott's approach is described by Larson [1104], who makes use of  $m$  binary trees, each of which contains just one leaf node initially. These leaf nodes correspond to buckets with a finite capacity  $c$ . Given a key  $k$ , applying a hash function  $h$  to  $k$  (i.e.,  $h(k)$ ) yields the binary tree that contains  $k$ . The collection of  $m$  one-node binary trees is analogous to a hash table with  $m$  buckets. As items are added to the hash table, the buckets corresponding to the leaf nodes become full, and thus they are expanded by splitting them, thereby creating two new buckets for each split. Subsequent insertions may cause these buckets also to fill up, thereby resulting in further splits. The splitting process is represented by a binary tree.

This method is analogous to the separate chaining method,<sup>1</sup> where, instead of placing the overflow buckets in a chain (i.e., linked list), we organize each bucket and its set of overflow buckets as a binary tree whose leaf nodes consist of these buckets. Thus, we have  $m$  binary trees. Note also that, unlike separate chaining, all buckets have the same capacity.

At this point, it is hard to see the advantage of using the binary tree organization of the overflow buckets over the separate chaining approach unless we can impose some access structure on the binary tree that enables us to avoid examining all of the buckets in the worst case of a search (whether or not it is successful). Larson [1104] proposes to

<sup>1</sup> Briefly, in this case, we have a table of  $m$  hash values and pointers to  $m$  hash lists—that is, one for each hash value. The hash value is commonly referred to as a *bucket address* since, frequently, more than one key value is associated with it. The hash lists are used to store all of the records whose key values have the same hash value.

(a)

(b)

Figure B.1  
Example illustrating the representation of a hash table as a binary tree and (b) the result of splitting bucket B into buckets E and F upon overflow.

Figure B.2  
Example illustrating the representation of the hash table of Figure B.1 using extendible hashing and (b) the result of splitting bucket B into buckets E and F upon overflow.

remedy this drawback by constructing an additional hashing function  $g$  that is a mapping from the set of keys into a set of infinite binary sequences where the binary sequences are used to determine a unique path in a binary tree. In particular, given key  $k$ , we have  $g(k) = (b_0, b_1, b_2, \dots, b_i, \dots)$  where  $b_i \in \{0, 1\}$  with the interpretation that the left branch of the tree is taken when  $b_i = 0$  and that the right branch is taken when  $b_i = 1$ . Larson [1104] proposes that the binary sequence  $g(k)$  be constructed by a random process so as to avoid generating lopsided binary trees (i.e., if the key values are clustered). One way of doing so is to use a binary pseudorandom function (i.e., that returns 0 and 1 with equal probability) and to use  $f(k)$  as a seed, where  $f$  is a hash function that forms the basis of the construction of  $g$ . Notice that, in this case, it is imperative that the function  $f$  be different from  $h$  as, otherwise, the same seed would be used for all keys belonging to the same binary tree. Thus, we have reduced the work necessary to access the relevant bucket to just one disk operation for both unsuccessful and successful searches.

The technique that we have just described is termed *dynamic hashing* [1104]. It should be clear that if we want to increase or decrease the original number (i.e.,  $m$ ) of buckets, thereby increasing the number of binary trees, then we still may have to rehash the entire hash table. Nevertheless, the fact that the binary trees allow for a gradual increase in the number of buckets makes it highly unlikely that we will need to increase the number of binary trees. In fact, the only reason for increasing  $m$  is if the height of some of the binary trees (or the average height) becomes excessively large, thereby making it expensive to traverse the trees to locate a bucket. However, the cost of the tree traversal (being CPU bound) is usually much less than that of accessing the buckets from disk, assuming the binary trees fit in main memory.

It is interesting to observe that Knott's method is a special case of dynamic hashing where the binary sequence  $g(k)$  is obtained from the binary representation of the actual key value  $k$ . Furthermore, Knott's method dispenses with the first hashing function  $h$ , which accesses one of the  $m$  buckets. Therefore, Knott's method always starts out with just one bucket (i.e.,  $m = 1$ ), and thus there is no need to worry about increasing the original number of buckets.

Extendible hashing of Fagin, Nievergelt, Pippenger, and Strong [579] is analogous to a trie except that all buckets are at the same level. It is usually implemented as a directory of pointers to buckets. For example, Figure B.2(a) corresponds to the binary tree in Figure B.1(a). This means that accessing a bucket can be done in one operation; however, when a bucket overflows, the size of the directory may have to be doubled to accommodate the split. For example, when bucket B in Figure B.2(a) is split into buckets, E and F, we find that the directory has now been doubled, as shown in Figure B.2(b).

A number of methods have been proposed to address the growth in the number of buckets as overflow takes place. The simplest is *bounded-index extendible hashing* by Lomet [1202], which avoids doubling the number of hash buckets once a predetermined maximum number has been attained by, instead, simply doubling the size of the buckets. Linear hashing is a less drastic alternative. Linear hashing has been proposed by Litwin [1106, 1187] as a technique providing for linear growth of the file (i.e., one bucket at a time). Its principal innovation is the decoupling of the bucket-splitting deci-

sion from the identity of the bucket that overflowed. Although there are many variations of linear hashing, the one we explain is due to Litwin and is fairly typical. Given a file containing  $m$  ( $2^n \leq m \leq 2^{n+1} - 1$ ) buckets starting at address 0 and a key value  $k$ , use the hashing function  $h_n(k) = k \bmod 2^n$  to access buckets  $m - 2^n$  through  $2^n - 1$ , and use  $h_{n+1}(k) = k \bmod 2^{n+1}$  to access buckets 0 through  $m - 2^n - 1$  and buckets  $2^n$  through  $m - 1$ . Such a file is said to be of level  $n, n + 1$  so that the buckets accessed by  $h_n$  are at level  $n$  while those accessed by  $h_{n+1}$  are at level  $n + 1$ . Note that when  $m = 2^n$ , no buckets are accessed by  $h_{n+1}$ .

A file implemented using linear hashing has both primary and overflow buckets. When a record hashes to a full primary bucket, it is inserted into an overflow bucket associated with the primary bucket. Generally, the overflow buckets are chained to the primary bucket. When the buckets are addressed from 0 to  $m - 1$ , there is no need for a directory. The storage utilization factor,  $\tau$ , is defined to be the ratio of the number of records in the file to the number of positions available in the existing primary and overflow buckets.

When the storage utilization factor exceeds a predetermined value, say  $\alpha$ , then one of the buckets is split. When bucket  $b$  is split, its records are rehashed using  $h_{n+1}$  and distributed into buckets  $b$  and  $b + 2^n$ . The identity of the next bucket to be split is maintained by the pointer  $s$  that cycles through the values 0 to  $2^n - 1$ . When  $s$  reaches  $2^n$ , all of the buckets have been split and thus  $n$  is incremented, and  $s$  is reset to 0. It is important to observe that a bucket split does not necessarily occur when a record hashes to a full primary bucket, nor does the split bucket have to be full.

The principle behind linear hashing is that, eventually, every bucket will be split and, ideally, all of the overflow buckets will be emptied and reclaimed. This is similar to the rationale for analyzing algorithms using the amortization method [163]. From a consistency standpoint, when the storage utilization factor falls below a predetermined value, say  $\beta$ , buckets should be merged (i.e., the bucket-splitting process should be reversed). However, this has not been the subject of much research, and we ignore  $\beta$  here (see Exercise 2). Note also the similarity to the “buddy system” of dynamic storage allocation [1042, 1044], although the buddies (i.e., the buckets that are merged) are formed differently.

As an example of linear hashing, consider the point set in Figure 1.1 of Chapter 1. First, apply the mapping  $f$  defined by  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$  to the values of the  $x$  and  $y$  keys, respectively. The result of this mapping is given in columns 4 and 5 of Figure B.3. Next, apply bit interleaving to its keys to yield the mappings given in columns 6 and 7 of Figure B.3, depending on whether we take the  $x$  coordinate as the most significant (column 6 of Figure B.3, labeled CODEX) or the  $y$  coordinate (column

NAME	X	Y	$f(X)$	$f(Y)$	CODEX	CODEY

7 of Figure B.3, labeled CODEY). In our example, we treat the  $y$  coordinate as the most significant and thus make use of the values in column 7 of Figure B.3.<sup>2</sup> Assume that the primary and overflow buckets are both of size 2 and that a bucket will be split whenever  $\tau$ , the storage utilization factor, is greater than or equal to 0.66 (i.e.,  $\alpha = 0.66$ ).

Figure B.4 shows the resulting bucket organization. In the figure, solid lines designate primary buckets, broken lines designate overflow buckets, and a rightward pointing arrow indicates the next bucket to be split. There are six primary buckets, labeled 0–5, and one overflow bucket. To understand the splitting process, let us examine more closely how linear hashing copes with a sequence of insertion operations. In particular, we observe how Figure B.4 is constructed for the records of Figure B.3 in the order in which they appear there: Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami.

Initially, only bucket 0 exists, it is empty, and the file is of level 0,1. The pointer to the next bucket to be split,  $s$ , is initialized to 0. The insertion of Chicago and Mobile yields  $\tau = 1.00$ , causing bucket 0 to be split and bucket 1 to be allocated.  $s$  retains its value of 0, and both Chicago and Mobile remain in bucket 0 (see Figure B.5(a)). Toronto is inserted in bucket 0, but  $\tau = 0.75$ , which causes bucket 0 to be split,  $s$  to be set to 1, bucket 2 to be allocated, and Chicago to be placed in it (see Figure B.5(b)). Our file is now of level 1, 2. Next, we try to insert Buffalo. It belongs in bucket 2. However, now  $\tau = 0.67$ , causing bucket 1 to be split,  $s$  to be reset to 0, and bucket 3 to be allocated (see Figure B.5(c)).

<sup>2</sup> Note that, in an actual implementation, it is better to reverse the result of the interleaving as, in this case, points in the same bucket are in spatial proximity to each other. In fact, this is what is done in Section 1.7.2.3.1 of Chapter 1.

Attempting to insert Denver causes bucket 2 to overflow and leads to the allocation of an overflow bucket attached to bucket 2 once Denver has been placed in it. Similarly, inserting Omaha results in an overflow of bucket 0 and the allocation of an overflow bucket attached to 0 once Omaha has been placed in it. Atlanta belongs in bucket 2 and, since bucket 2 is full, it is placed into its overflow bucket (see Figure B.5(d)). Miami is inserted into bucket 1, resulting in  $\tau = 0.67$ . This causes bucket 0 to be split,  $s$  to be set to 1, bucket 4 to be allocated, and Omaha to be moved to bucket 4. Our file is now of level 2,3. Since bucket 0's overflow bucket is now empty, it is deallocated, yielding  $\tau = 0.67$ . Thus, bucket 1 is split,  $s$  is set to 2, bucket 5 is allocated, and Miami is moved to it (see Figure B.4).

Linear hashing as described above may require complex searches when many of the records hash to a subset of the buckets. Let  $S$  denote this subset. This means that several overflow buckets will be associated with each element of  $S$ . On the other hand, there will be few overflow buckets associated with the remaining primary buckets (i.e., not elements of  $S$ ). Ramamohanarao and Sacks-Davis [1530] suggest that the linear hashing function used to distinguish between the primary buckets also be applied to distinguish between the contents of the overflow buckets for each of the primary buckets. This technique is called *recursive linear hashing*, and the result can be viewed as a separate file, termed an *overflow file*. This process is applied as many times as necessary (hence, the term *recursive*), each time creating an additional overflow file. However, in practice, it is rare for the hashing function to be applied more than three times [1530]. The only difference from the original application of the hashing function is that, for the second and subsequent applications of the hashing function, the overflow file is at a lower (i.e., smaller) level than that of the original file.

One problem with recursive linear hashing is that when primary bucket  $P$  is split, records in the overflow files that originally hashed to  $P$  may have to be moved either to a primary bucket or to another overflow file. A similar problem arises when two primary buckets are merged. Of course, these problems also arise with conventional linear hashing. Nevertheless, recursive linear hashing has the property that all records that originally hashed to  $P$  will be stored in a single bucket in each of the overflow files (see Exercise 18). Hence, the insertion costs for recursive linear hashing and for conventional linear hashing with optimal overflow bucket size [1105, 1529] are similar [1530]. (For more details on recursive linear hashing, see [1531].)

### Exercises

1. Give an algorithm to look up a record with key value  $k$  in a file implemented with linear hashing of  $m$  buckets. The file is at level  $n, n + 1$ . In particular, do you use  $h_n$  first or  $h_{n+1}$ ? If it makes a difference, explain why.
2. Discuss the issue of merging buckets for linear hashing—that is, when the storage utilization factor falls below a particular threshold, say  $\beta$ .
3. The insertion algorithm for linear hashing described in the text splits bucket  $s$  whenever insertion of a record causes the storage utilization factor,  $\tau$ , to exceed a predetermined value. This is done even if bucket  $s$  does not overflow or if no records will move as a result of the bucket-splitting operation. Of course, allocating an overflow bucket is also a method of reducing the storage utilization factor. Modify the insertion algorithm so that when the storage utilization factor is too high and there is overflow, a split of bucket  $s$  only occurs if it will resolve the overflow; otherwise, allocate an overflow bucket. If there is no overflow, then split bucket  $s$  as before. Define a measure to compare these two methods, and do so analytically and empirically.
4. Show the result of applying linear hashing to the point set of Figure B.3 when the  $x$  coordinate is the most significant. Again, assume that the cities are inserted in the order Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami. Draw the analogs of Figures B.4 and B.5.

5. Repeat the example shown in the text illustrating the mechanics of linear hashing by inserting the cities Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami in this order when the  $x$  coordinate is the most significant. Draw the analogs of Figures B.4 and B.5.

Exercises 6–13 are based on an asymptotic analysis of linear hashing described by Larson [1106]. Assume that there are no deletions. The implementation is slightly different than the one described in the text. The capacity of the buckets is not restricted, and thus there is no need for overflow buckets. Each bucket is implemented as a linked list (i.e., a chain). In this case, the storage utilization factor  $\tau$  is the total number of records in the table divided by the number of buckets.

6. Suppose that no bucket splits are ever allowed. Compute  $s(\tau)$  and  $u(\tau)$ , the expected number of key value comparisons for a successful and unsuccessful search, respectively. In your answer, for the unsuccessful search case, assume that no key value comparison is necessary when the key value is hashed to an empty bucket.
7. For Exercises 7–13, assume that a bucket is split each time the storage utilization factor exceeds  $\alpha$ . At any instant, let  $x$  ( $0 \leq x \leq 1$ ) denote the fraction of the buckets that have been split and  $z$  the expected number of records in an unsplit bucket. The expected number of records in a split or new bucket is  $z/2$ . Show that  $z = \alpha \cdot (1 + x)$ .
8. Let  $S(\alpha, x)$  denote the expected number of key value comparisons for a successful search when a fraction  $x$  of the buckets have been split. Calculate  $S(\alpha, x)$ .
9. Calculate  $U(\alpha, x)$ , the expected length of an unsuccessful search.
10. When do the minimum expected search lengths occur?
11. When do the maximum expected search lengths occur?
12. Calculate the average search cost over a cycle (i.e., as  $x$  ranges from 0 to 1).
13. The cost of each insertion of a record can be decomposed into two parts. The first part is just the cost of placing the record at the end of the chain. The second part reflects the situation that a bucket is split, and the table is expanded. The cost of the first part is the same as that of an unsuccessful search and the cost of linking the record to the end of the chain. The second part arises with a probability of  $1/\alpha$ . Here, we must rehash each record on the chain and update some pointers. Calculate  $A(\alpha, x)$ , the expected number of rehashing operations per record that is inserted, and its average over a cycle.
14. Repeat the analyses of Exercises 6–13 when the primary buckets have a finite capacity, say  $c$ . This means that overflow buckets will be necessary. Assume an overflow bucket capacity of  $v$ .
15. Give an algorithm to insert a record with key value  $k$  into a file implemented with recursive linear hashing of  $m$  primary buckets that is at level  $n, n + 1$ .
16. Give an algorithm to look up a record with key value  $k$  in a file implemented with recursive linear hashing of  $m$  primary buckets that is at level  $n, n + 1$ .
17. Give an algorithm to delete a record with key value  $k$  from a file implemented with recursive linear hashing of  $m$  primary buckets that is at level  $n, n + 1$ .
18. Prove that recursive linear hashing has the property that all records that originally hashed to primary bucket  $P$  will be stored in a single bucket in each of the overflow files.

---

## Spiral Hashing

---

One of the drawbacks of linear hashing (see Appendix B) is that the order in which the buckets are split is unrelated to the probability of the occurrence of an overflow. In particular, all the buckets that are candidates for a split have the same probability of overflowing. Moreover, the expected cost of retrieving a record and updating the table of active buckets varies cyclically in the sense that it depends on the proportion of the buckets that have been split during a bucket expansion cycle (see Exercises 6–13 in Appendix B).

Proposed by Martin [1247], spiral hashing [324, 384, 1106, 1247, 1324] is a technique whose performance (i.e., the expected search length in a bucket) has been observed to be independent of the number (or fraction) of the buckets that have been split. Thus, it is said to have uniform performance (see Exercise 23). This is achieved by distributing the records in an uneven manner over the active buckets. Moreover, it always splits the bucket that has the highest probability of overflowing.

Spiral hashing is similar in spirit to linear hashing. To simplify our explanation, we identify the buckets by their addresses. The central idea behind spiral hashing is that there is an ever-changing (and growing) address space of active bucket addresses that is moving forward (e.g., Figure C.1). This is in contrast to linear hashing in which the active bucket addresses always range from 0 to  $m - 1$ . Recall that in linear hashing, when the bucket at address  $s$  is split, then a new bucket is created at location  $m$ , and the previous contents of bucket  $s$  are rehashed and inserted into buckets  $s$  and  $m$ , as is appropriate.

In the following discussion, we assume that a bucket can be split into  $r$  buckets rather than just two as was the case in our explanation of linear hashing.  $r$  is called the growth factor. We assume further that  $r$  is an integer; however, this restriction can be lifted. Let  $s$  and  $t$  denote the addresses of the first and last active buckets, respectively, so that each bucket with address  $i$  ( $s \leq i \leq t$ ) is active. Define the storage utilization factor,  $\tau$ , in the same way as for linear hashing—that is, the ratio of the number of records in the file to the number of positions available in the existing primary and overflow buckets. A bucket is split whenever  $\tau$  exceeds a predetermined value, say  $\alpha$ . When  $\tau$  falls below a predetermined value, say  $\beta$ , buckets should be merged (i.e., the bucket-splitting process should be reversed). However, this has not been the subject of much research, and we ignore  $\beta$  here (see Exercise 5).

When the bucket at address  $s$  is split, say into  $r$  buckets, then  $r$  new buckets are allocated starting at bucket address  $t + 1$ , and the contents of bucket  $s$  are rehashed into these new buckets. Bucket address  $s$  is no longer used (but see Exercise 7), and the active bucket addresses now range from  $s + 1$  to  $t + r$ . As we will see, the manner in which the hashing function is chosen guarantees that the expected load (i.e., the expected number of records per bucket) is always at a maximum at bucket  $s$  and is at a minimum at bucket

Figure C.1  
Example of a changing (and growing) address space of active bucket addresses with a growth factor  $r = 3$ . This means that when a bucket is split, three new buckets are created, and the bucket that has been split is no longer active.

$t$ . Moreover, the expected load of bucket  $i + 1$  is less than the expected load of bucket  $i$  ( $s \leq i < t$ ).

The presentation is simplified considerably if we assume that initially there are  $r - 1$  active buckets starting at address 1. For example, when  $r = 2$ , initially there is one active bucket starting at address 1; after the first split, there are two active buckets starting at address 2; after the second split, there are three active buckets starting at address 3; and so on. When  $r = 3$ , initially there are two active buckets starting at address 1; after the first split, there are four active buckets starting at address 2; after the second split, there are six active buckets starting at address 3; and so on. This splitting sequence (i.e., for  $r = 3$ ) is illustrated in Figure C.1. In general, it can be shown that for arbitrary values of  $r$ , after the occurrence of  $s$  bucket-splitting operations, there are always  $(s + 1) \cdot (r - 1)$  active bucket addresses (see Exercise 1).

The growth pattern described above can be modeled by observing the behavior of the function  $y = r^x$ . We know that  $r^{x+1} - r^x = r^x \cdot (r - 1)$ . Assume that bucket  $s$  has just been split. Letting  $r^x = s + 1$ , we find that  $r^{x+1} - r^x = (s + 1) \cdot (r - 1)$ , which is the number of active bucket addresses. Moreover,  $r^x = s + 1$  is the address of the first active bucket, which means that the last active bucket is at  $r^{x+1} - 1$ . This relation serves as the basis of a combination of two hashing functions.

The first function, say  $h(k)$ , is used to map key value  $k$  uniformly into a value in  $[0, 1)$ . Next, we map  $h(k)$  into its bucket address, denoted by  $y(h(k))$ , such that  $y(h(k))$  is in the range  $[s + 1, s + 1 + (s + 1) \cdot (r - 1))$ . This is achieved by the second function  $y(h(k)) = \lfloor r^{x(h(k))} \rfloor$ , where  $x(h(k))$  is in the range  $[\log_r(s + 1), \log_r(s + 1) + 1)$ . The difficulty lies in defining  $x(h(k))$ . A simple solution is to let  $x(h(k)) = \log_r(s + 1) + h(k)$ . Unfortunately, in this solution,  $x(h(k))$  changes whenever  $s$  changes. This is unacceptable as it means that whenever a bucket split occurs, all key values have to be rehashed.

What we want is a definition of  $x(h(k))$  such that once bucket  $s$  has been split, all key values  $k$  whose previous  $x(h(k))$  value was in the range  $[\log_r(s), \log_r(s + 1))$  (i.e. key values in bucket  $s$ ) are rehashed to one of the newly generated buckets by a new  $x(h(k))$  in the range  $[\log_r(s) + 1, \log_r(s + 1) + 1)$ . In contrast, the new  $x(h(k))$  value of all other key values whose previous  $x(h(k))$  value was in the range  $[\log_r(s + 1), \log_r(s + 1) + 1)$  are unchanged. This is achieved by letting  $x(h(k)) = \lceil \log_r(s + 1) - h(k) \rceil + h(k)$  (see Figure C.2 for  $r = 2$ ). Therefore,  $x(h(k))$  is a number in the range  $[\log_r(s + 1), \log_r(s + 1) + 1)$  whose fractional part is  $h(k)$ . Thus, once key value  $k$  is hashed into a bucket with a particular bucket address, say  $b$ , key value  $k$  is guaranteed to continue to be hashed into  $b$  until  $b$  has been split.

Figure C.3 illustrates the use of the second hashing function  $y(h(k))$  for  $r = 2$ . Given a bucket address, it shows the corresponding interval from  $[0, 1)$  that maps to the address and the proportion of the data that the bucket contains (labeled “relative load”). Notice that the relative load decreases as the bucket addresses increase (see also Figure C.4).

Figure C.2  
The function  $y = 2^x$ .

Bucket Address	Hash Interval	Relative Load
1	[0.0000,1.0000)	1.0000
2	[0.0000,0.5849)	0.5849

Figure C.3  
Bucket address mapping for  $r = 2$ .

This verifies our claim that the bucket to be split is the one with the highest probability of overflowing.

Now, let us illustrate the use of spiral hashing by examining how the representation is built for the point set of Figure 1.1 of Chapter 1 when processing it one by one. First, apply the mapping  $f$  such that  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$  to the values of the  $x$  and  $y$  coordinates, respectively. The result of this mapping is given in columns 4 and 5 of Figure C.5. Next, apply bit interleaving to its keys to yield the mappings given in columns 6 and 8 of Figure C.5. Two mappings are possible since we can either take the  $x$  coordinate value as the most significant (column 6 of Figure C.5, labeled CODEX) or the  $y$  coordinate value (column 8 of Figure C.5, labeled CODEY). Finally, reduce each interleaved value to a point in  $[0,1)$  by using  $h(k) = k/64$  to yield columns 7 and 9 of Figure C.5. In our example, we treat the  $y$  coordinate as the most significant and thus make use of the values in columns 8 and 9 of Figure C.5. Assume that the primary and overflow buckets are both of size 2,  $r = 2$ , and that a bucket will be split whenever  $\tau$ , the storage utilization factor, is greater than or equal to 0.66.

Figure C.4  
Relative load of buckets 1–15 when  $r = 2$ .

Figure C.6  
Result of applying spiral hashing to the data of Figure C.5. A rightward-pointing arrow indicates the next bucket to be split.

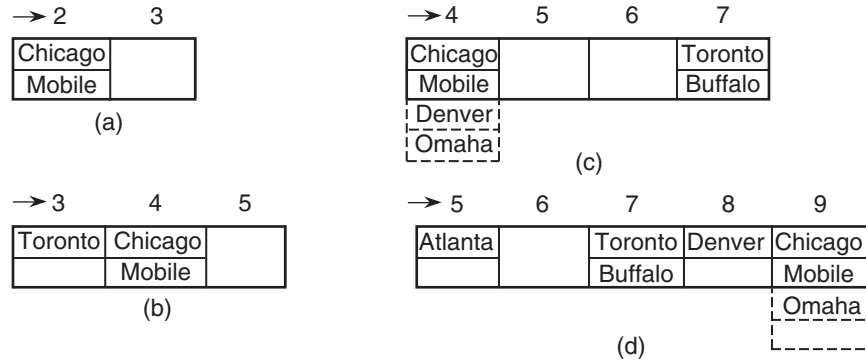

Figure C.7  
Sequence of spiral hashing bucket contents demonstrating the insertion of (a) Chicago and Mobile, (b) Toronto, (c) Buffalo, Denver, and Omaha, and (d) Atlanta. A rightward-pointing arrow indicates the next bucket to be split.

Figure C.6 shows the resulting bucket organization. In the figure, solid lines designate primary buckets, broken lines designate overflow buckets, and a rightward-pointing arrow indicates the next bucket to be split. At the end of the construction process, there are six primary buckets, at addresses 6–11, and one overflow bucket. To understand the splitting process, let us examine more closely how spiral hashing copes with a sequence of insertion operations. In particular, we observe how Figure C.6 is constructed for the records of Figure C.5 in the order in which they appear there: Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami.

Initially, only bucket 1 exists, and it is empty. The pointer to the last bucket to have been split,  $s$ , is initialized to 0. Applying the hashing function to Chicago and Mobile yields the values 0.21875 and 0.25, respectively. Since these values are in the range  $[0,1)$ , they both belong to bucket 1, into which they are inserted. However, this results in  $\tau = 1.00$ , causing bucket 1 to be split,  $s$  to be set to 1, buckets 2 and 3 to be allocated, and both Chicago and Mobile to be moved to bucket 2 (see Figure C.7(a)) since their hash values are both in the range  $[0,0.5849)$ . Bucket 1 is no longer active. Buckets 2 and 3 are now the active buckets.

Toronto hashes to 0.875. This value is in the range  $[0.5849,1)$ , and Toronto is inserted into bucket 3. As a result of this action,  $\tau = 0.75$ , causing bucket 2 to be split,  $s$  to be set to 2, buckets 4 and 5 to be allocated, and both Chicago and Mobile to be moved into bucket 4 (see Figure C.7(b)) since their hash values fall in the range  $[0,0.3219)$ . Bucket 2 is no longer active. The active buckets now range from 3 to 5.

Buffalo hashes to 0.84375. This value is in the range  $[0.5849,1)$ , and Buffalo is inserted into bucket 3. However, now  $\tau = 0.67$ , causing bucket 3 to be split,  $s$  to be set to 3, buckets 6 and 7 to be allocated, and both Toronto and Buffalo to be moved into bucket 7 since their hash values fall in the range  $[0.8073,1)$ . Bucket 3 is no longer active. The active buckets now range from 4 to 7.

Denver hashes to 0.15625. This value is in the range  $[0, 0.3219)$ , which belongs to bucket 4. However, attempting to insert Denver causes bucket 4 to overflow and leads to the allocation of an overflow bucket attached to bucket 4 once Denver has been placed into it. Omaha hashes to 0.1875. This value is in the range  $[0, 0.3219)$ , which belongs to bucket 4. Bucket 4 already has an overflow bucket associated with it, and thus Omaha is placed into it (see Figure C.7(c)).

Atlanta hashes to 0.34375. This value is in the range  $[0.3219, 0.5849)$ , which belongs to bucket 5. However, now  $\tau = 0.70$ , causing bucket 4 to be split,  $s$  to be set to 4, and buckets 8 and 9 to be allocated. In addition, Denver moves to bucket 8 since its value falls in the range  $[0, 0.1699)$ , while Chicago, Mobile, and Omaha belong in bucket 9 since they fall in the range  $[0.1699, 0.3219)$ . This means that an overflow bucket must be allocated and attached to bucket 9, and Omaha is placed into it (see Figure C.7(d)). Bucket 4 is no longer active. The active buckets now range from 5 to 9.

Miami hashes to 0.328125. This value is in the range  $[0.3219, 0.5849)$ , which belongs to bucket 5. But  $\tau = 0.67$ , causing bucket 5 to be split,  $s$  to be set to 5, buckets 10 and 11 to be allocated, and both Atlanta and Miami to be moved into bucket 10 (see Figure C.6) since they fall in the range  $[0.3219, 0.4594)$ . Bucket 5 is no longer active. The active buckets now range from 6 to 11.

The main advantage of spiral hashing over linear hashing is that the bucket that is split is the one that is most likely to overflow. There are two disadvantages to spiral hashing. The first is that the buckets that have been split are not reused (although they could be used also as overflow buckets). However, this problem can be overcome by using one of a number of alternative mappings between logical and physical addresses [1106, 1324] (see Exercises 7 and 10). The second is that it is computationally expensive to calculate a function such as  $y = r^x$ —that is, the bucket address. Of course, most programming languages have a runtime library where such functions are available. However, their computation is time-consuming since it usually requires a polynomial approximation.

Martin [1247] suggests replacing  $r^x$  by another function,  $f(x)$ , which is easier to compute. In particular,  $f(x)$  is used to approximate  $r^x$  in  $[0, 1]$  so that  $r^x$  is approximated in  $[n, n + 1]$  ( $n$  is an integer) by  $r^n \cdot f(x - n)$ . One such function, according to Martin, is

$$f(x) = \frac{a + b}{c - x} \quad (0 \leq x \leq 1).$$

The values of  $a$ ,  $b$ , and  $c$  are obtained by calculating the value of  $f$  at three points. The most appropriate points are the endpoints— $x = 0$  and  $x = 1$ —and another point in  $[0, 1]$ , such as  $x = 0.5$ . We also need the inverse of  $f(x)$ , which is

$$x = \frac{c + b}{a - y}.$$

Larson [1106] reports on some experiments that compare spiral hashing with linear hashing, as well as unbalanced binary search trees, and an open addressing scheme that uses double chaining. In each case, the tables and trees are all stored in main memory. Using large files, averaging over many insertions, and different storage utilization factors, he found that linear hashing consistently outperformed spiral hashing in terms of average CPU time per key value in both loading the tables and searching them. The differences ranged from 1% to 20%. Larson attributes these differences primarily to the cost of address computation.

Further experiments with binary search trees showed that spiral hashing was faster at loading small key value sets than linear hashing; however, in all cases, searching was faster when hashing methods were used. A comparison of linear hashing with a traditional hash table implemented using double hashing, so that the costs of a periodic reorganization of the hash table are taken into account, resulted in a definite trend showing that the cost of linear hashing was usually lower (although at times slightly higher).

Figure C.8  
Spiral corresponding to  $\rho = e^{(\ln 2) \cdot \theta / 2\pi} = 2^{\theta / 2\pi}$ .

When the tables and trees are not constrained to be stored in main memory, the results of the comparison may be different. Recall that the number of overflow records and their distribution over the buckets of the file (table) are different for linear and spiral hashing. In particular, at certain stages of a cycle, linear hashing has more overflow records clustered on a few pages. The expected search lengths per bucket depend on how these overflow records are handled. For example, some overflow-handling methods, such as linear probing [1046], are more sensitive to clustering of overflow records. In such a case, spiral hashing should have better performance than linear hashing. Moreover, since we are dealing with external files, the fact that spiral hashing has a higher address computation cost is not important.

At this point, it is interesting to explain the motivation for the qualifier “spiral” used to describe this variant of linear hashing. In the earlier discussion, we mapped each key value into a real number  $x$ , which was, in turn, mapped into an address  $y$  by the function  $y = \lfloor r^x \rfloor$ . This mapping can be rewritten in terms of polar coordinates,  $\rho$  and  $\theta$ , as  $\rho = \lfloor (e^j)^\theta \rfloor = \lfloor e^{j\theta} \rfloor$ , with  $\rho$ ,  $e^j$ , and  $\theta$  taking on the roles of  $y$ ,  $r$ , and  $x$ , respectively. This is the equation of a spiral. For example, Figure C.8 is the spiral corresponding to  $\rho = e^{(\ln 2) \cdot \theta / 2\pi}$  and is equivalent to  $\rho = 2^{\theta / 2\pi}$ . Of course, any spiral (i.e.,  $c^\theta$ ) can be used, not just the natural spiral.

Using polar coordinates in this way means that the active buckets are always within one complete arc of the spiral. For example, if the first active bucket is at  $a = \lfloor e^{jb} \rfloor$  (i.e., at  $\theta = b$ ), then the last active bucket is at  $c = \lceil e^{j \cdot (b+2\pi)} \rceil - 1$ . This is illustrated in Figure C.8 by the infinite line that emanates from the origin and passes through  $\rho = 3, 6, 12, \dots$ . A bucket split has the effect that the active bucket at  $\rho = a$  (i.e., at  $\theta = b$ ) is split and its contents are distributed into buckets  $c + 1$  through  $g$ , where  $g = \lfloor e^{j \cdot (b+2\pi+\phi)} \rfloor$  and  $\phi = (\ln(a + 1)) / j - b$ . The value of  $\phi$  is the solution of  $a + 1 = e^{j \cdot (b+\phi)}$ . Buckets  $a + 1$  through  $g$  are now the active buckets.

Two items are worthy of further note. First, instead of using the hash function  $h(k)$  to initially map key value  $k$  uniformly into  $[0,1)$ , we use a different hash function, say  $h_\theta(k)$ , to initially map key value  $k$  uniformly into a value in  $[0, 2\pi)$ . Second, the length of the arc of the spiral is also meaningful as it has a constant value between successive integer values of  $\rho$  (see Exercise 24); however, it has no relation to the capacity of the bucket.

### Exercises

1. Prove that for arbitrary values of  $r$ , after the occurrence of  $s$  bucket-splitting operations, there are always  $(s + 1) \cdot (r - 1)$  active bucket addresses.
2. Suppose that, regardless of the value of the growth factor  $r$ , there is initially just one active bucket. How does this affect the function that maps  $h(k)$  to a bucket address?
3. Show the result of applying spiral hashing to the point set of Figure 1.1 of Chapter 1 subject to bit interleaving with the  $x$  coordinate being the most significant, as shown in columns 6 and 7 of Figure C.5. Again, assume that the cities are inserted in the order Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami. Also, assume that the primary and overflow buckets are both of size 2,  $r = 2$ , and that a bucket will be split when  $\tau$ , the storage utilization factor, is greater than or equal to 0.66. Draw the analogs of Figures C.6 and C.7.
4. Show the result of applying spiral hashing to the point set of Figure 1.1 in Chapter 1 subject to bit interleaving with the  $y$  coordinate being the most significant, as shown in columns 8 and 9 of Figure C.5 when the capacity of the buckets is not constrained to be finite. Instead, each bucket is implemented as a linked list (i.e., a chain). Thus, there is no need for overflow buckets. The storage utilization factor  $\tau$  is the total number of points (i.e., cities) in the point set divided by the number of buckets. Again, assume that the cities are inserted in the order Chicago, Mobile, Toronto, Buffalo, Denver, Omaha, Atlanta, and Miami. Also, assume that  $r = 2$  and that a bucket will be split when  $\tau$  is greater than or equal to 0.66. Draw the analogs of Figures C.6 and C.7.

5. Discuss the issue of merging buckets—that is, when the storage utilization factor falls below a particular threshold, say  $\beta$ .
6. In the discussion of the use of polar coordinates, we calculated a value of  $\phi$  to determine the buckets into which the contents of the split bucket were to be redistributed. It is given as the solution of  $a + 1 = e^{j \cdot (b + \phi)}$ . Why did we not use  $a + 1 = \lfloor e^{j \cdot (b + \phi)} \rfloor$ ?
7. One of the deficiencies of the implementation of spiral hashing described in the text is that each time a bucket is split, its address is no longer used. This can be wasteful of storage. It would be nice if these locations could be reused. This is facilitated by making a distinction between a bucket's logical and physical addresses and finding a way to map a bucket's logical address to its physical address. This mapping is necessary for the implementation of all operations (e.g., insert, split, merge, access).

Mullin [1324] suggests the following approach. Assume again that initially there are  $r - 1$  buckets with logical addresses 1 through  $r - 1$  occupying physical addresses 1 through  $r - 1$ . The first bucket that is split is at logical address 1. This split results in the creation of  $r$  new buckets at logical addresses  $r$  through  $2 \cdot r - 1$ . The buckets at logical addresses  $r$  through  $2 \cdot r - 2$  are stored at physical addresses  $r$  through  $2 \cdot r - 2$ , while physical address 1 is reused to store the bucket at logical address  $2 \cdot r - 1$ . The second bucket that is split again results in the creation of  $r$  new buckets at logical addresses  $2 \cdot r$  through  $3 \cdot r - 1$ . This time the buckets at logical addresses  $2 \cdot r$  through  $3 \cdot r - 2$  are stored at physical addresses  $2 \cdot r - 1$  through  $3 \cdot r - 3$ , while physical address 2 is reused to store the bucket at logical address  $3 \cdot r - 1$ . It should be clear how the rest of the splits are handled. Give an algorithm that takes as its input the logical address of a bucket and returns its physical address.

8. The solution to Exercise 7 is specified using recursion. However, it is tail recursive and, thus, can be rewritten using iteration. Given a growth factor of  $r$  and a maximum logical bucket address  $t$ , what is the maximum number of iterations?
9. Assume that a bucket at physical address  $s$  is split. Let  $t$  be the maximum logical address that corresponds to physical address  $p$ . In such a case, the technique described in Exercise 7 creates  $r$  new buckets starting at logical addresses  $t + 1$  through  $t + r$ . The buckets at logical addresses  $t + 1$  through  $t + r - 1$  are stored at physical addresses  $p + 1$  through  $p + r - 1$ . The bucket at logical address  $t + r$  is stored in physical address  $s$ . Suppose that, instead, we store the buckets at logical addresses  $t + 2$  through  $t + r$  in physical addresses  $p + 1$  through  $p + r - 1$  and store the bucket at logical address  $t + 1$  at physical address  $s$ . Give an algorithm that takes as its input the logical address of a bucket and returns its physical address.
10. Mullin's [1324] technique of reusing the space occupied by the buckets that have been split requires the computation of an algorithm that maps a logical address to a physical address. As we saw in Exercise 8, its execution time may grow with the size of the logical address space. Can you avoid this growth by using a limited amount of extra space? In other words, devise a data structure that tries to reuse most of the buckets but is not guaranteed to reuse every bucket at each instance.
11. Suppose that the addresses corresponding to the buckets that have been split are reused as in Exercise 7. Repeat Exercise 5 in such an environment—that is, discuss the issue of merging buckets.
12. Suppose that the addresses corresponding to the buckets that have been split are reused as in Exercise 10. Repeat Exercise 5 in such an environment—that is, discuss the issue of merging buckets.
13. Suppose that the function  $y = r^x$  is approximated by  $r^n \cdot f(x - n)$ , where  $f(x - n) = a + b/(c - x + n)$  such that  $x$  is in  $[n, n + 1]$ . Calculate the values of  $a$ ,  $b$ , and  $c$  for  $r = 2$  by using  $x = 0$ ,  $x = 0.5$ , and  $x = 1$ .
14. Suppose that the function  $y = r^x$  is approximated by  $r^n \cdot f(x - n)$ , where  $f(x - n) = a + b/(c - x + n)$  such that  $x$  is in  $[n, n + 1]$ . Does use of the approximation affect the bucket-splitting algorithm?
15. Suppose that  $f(x)$  is approximated by a second-degree polynomial instead of by  $a + b/(c - x)$ . What is the disadvantage of such an approximation?

Exercises 16–21 are based on an asymptotic analysis of spiral hashing described by Larson [1106].

16. Assume that  $r = 2$  and that there are no deletions. The implementation is slightly different from the one described in the text. The capacity of the buckets is not restricted, and thus there is no need for overflow buckets. Each bucket is implemented as a linked list (i.e., a chain). In this case, the storage utilization factor  $\tau$  is the total number of records in the table divided by the number of buckets. Assume that the overall value of  $\tau$  is kept constant at  $\alpha$  ( $\alpha > 0$ ). However, the expected value of  $\tau$  for the different buckets can and does vary over the bucket address space. Assume a normalized address range  $[1, 2)$  as any address in the range  $[2^x, 2^{x+1})$  can be normalized by multiplying it by  $2^{-x}$ . Let  $p(y)$  be the probability that a key value hashes to a normalized address in  $[y, y + dy) \subseteq [1, 2)$ . Show that  $p(y)$  is  $dy/(y \cdot \ln 2)$ , and hence the probability density function is  $1/(y \cdot \ln 2)$ .
17. Assume that the expected value of the storage utilization factor of a bucket at address  $y$ , say  $\tau(y)$ , is proportional to the insertion probability at  $y$ . Use the result of Exercise 16 to show that  $\tau(y) = \alpha/(y \cdot \ln 2)$ .
18. Assume that each record is equally likely to be retrieved. Therefore, the probability that a successful search lands on a bucket at address  $y$ , say  $q(y)$ , is proportional to the storage utilization factor of the bucket. Show that  $q(y) = 1/(y \cdot \ln 2)$ .
19. Noting that each bucket is implemented as a linked list, calculate the expected cost of a successful search.
20. Noting that each bucket is implemented as a linked list, calculate the expected cost of an unsuccessful search.
21. When a record is inserted, its cost can be decomposed into two parts. The first part is just the cost of placing the record at the end of the chain. Its cost is the same as that of an unsuccessful search plus the cost of linking the record to the end of the chain. The second part reflects the situation that a bucket is split and the need to rehash its contents so that they can be properly distributed in the new buckets. This situation only arises for the first bucket. What is the expected number of extra hashing operations per record that is inserted?
22. What is the effect of using an arbitrary value of  $r$  in Exercises 16–21?
23. Prove that spiral hashing has uniform performance. In other words, prove that the expected search lengths in the buckets are independent of the table size, which in turn is a function of how many bucket-splitting operations have taken place.
24. Prove that the length of the arc of a spiral has a constant value between successive integer values of  $\rho$  (i.e., it is directly proportional to  $\rho$ ).

---

## Description of Pseudocode Language

---

The algorithms are given using pseudocode. This pseudocode is a variant of the ALGOL [1346] programming language, which has a data structuring facility that incorporates pointers and record structures. We do not make use of object orientation, although our use of record structures is similar in spirit to rudimentary classes in SIMULA [437] and FLEX [1008], which are the precursors of modern object-oriented methods. We make heavy use of recursion. This language has similarities to C [1017], C++ [1805], Java (e.g., [93]), PASCAL [952], SAIL [1553], and ALGOL W [137]. Its basic features are described below. All reserved words are designated in bold face. This also includes the names (i.e., types) of predefined record structures.

A program is defined as a collection of functions and procedures. Functions are distinguished from procedures by the fact that they return values via the use of the **return** construct. Also, the function header declaration specifies the type of the data that it returns as its value. In the following the term *procedure* is used to refer to both procedures and functions.

All formal parameters to procedures must be declared, along with the manner in which they have been transmitted (**value** or **reference**). All local variables are declared. Global variables are declared and are specified by use of the reserved word **global** before the declaration. Variables and arrays may be initialized to prespecified values by prefacing the declaration with the reserved word **preload** and appending the reserved word **with** and the initialization values to the declaration.

“Short-circuit” evaluation techniques are used for Boolean operators that combine relational expressions. In other words, as soon as any parts of a Boolean **or** (**and**) are true (false), the remaining parts are not tested. This is similar to what is used in LISP [1263] but is different from PASCAL, where the order of the evaluation is deemed to be immaterial.

Record structures are available. An instance of a record structure of type **rec** is created by use of the command **create(rec)**. The result of this operation is a pointer to a record structure of the appropriate type. Pointers to record structures are declared by use of the reserved word **pointer**, which is followed by the name of the type of the record structure. Instances of record structures are referred to by using functional notation where the field name is in the position of the function and the pointer is its argument. For example, if variable *L* points to an instance of a record structure of type **list**, then we use ‘NEXT(*L*)’ to refer to the NEXT field of this instance. Of course, *L* must be declared to be a pointer to a record structure of type **list** by using a declaration of the form ‘**pointer list L**’. Note the use of bold face for the specification of the type of the record structure since we assume that it has been predefined.

The fields of a record structure may be of any type including an array. For example, suppose that a record of type **rec** has a field called ARR, which is a one-dimensional

array. Moreover, assume that  $L$  has been declared as a pointer to a record of type **rec**. We use  $\text{ARR}(L)[I]$  to refer to the  $I$ th element of the **ARR** field of the **rec** record pointed at by  $L$ .

The procedures are usually recursive and make heavy use of the **if-then-elseif-else-endif** mechanism to establish flow of control. The value of an **if-then-elseif** can be a statement or an expression. They are frequently used like a select statement in BLISS [2027] and are similar to a **COND** in LISP. They are often nested. Observance of the placement of **endif** insures a proper understanding of their semantics. In other words, they must nest properly. A procedure is a block of statements. Statements are either assignments, **if-then-elseif-endif** that are sets of statements, or sets of statements that are repeated (i.e., loops) within the **for-do-endo**, **while-do-endo**, and **do-until-endo** constructs. The difference between **while-do-endo** and **do-until-endo** is the timing of the execution of the condition that must be satisfied for the loop to be repeated—that is, at the start and end, respectively.

There is a rich set of types. These types are defined as they are used. In particular, enumerated types in the sense of PASCAL are used heavily. For example, the type **quadrant** is an enumerated type whose values are NW, NE, SW, SE.

The array data type is treated as a special type of a record. However, there are some differences. Although an identifier that has been declared to be a record type is usually only used as a parameter to a function that allocates storage for an instance of the record type or to qualify the declaration of a pointer variable, when an identifier that has been declared to be an array appears by itself (i.e., without a suffix to indicate a particular array element, such as **ARR** instead of  $\text{ARR}[I]$ ), then the identifier is treated as a pointer to an instance of the data type associated with the array declaration. This is useful when it is desired to pass an array as a parameter to a procedure or to return an entire array as the value of a procedure. Thus, in such cases, the array identifier is analogous to a pointer to a record having a type equal to that of the array declaration.

Storage for an array is allocated from a heap rather than from a stack. This means that there is a need for some form of garbage collection for array elements that are not pointed to by any of the currently accessible pointers (i.e., pointer variables). If an array is local to a procedure, then its storage is allocated upon entering the block in which the array is declared. If the array is transmitted as a formal ‘value’ parameter to a procedure, then its storage is allocated upon entry to the procedure, and its elements are set to the value they had in the corresponding array in the calling procedure. If the array is transmitted as a formal ‘reference’ parameter to a procedure, then the array occupies the same storage in both the calling and called procedures. It is the user’s responsibility to make sure that the type declarations in the calling and called procedure match.

Two subtle points about memory management for arrays are worth noting. The first is that while storage for an array is usually deallocated when exiting from a procedure in which it has been declared or transmitted as a ‘value’ parameter, deallocation should not take place for an array that is returned as the value of a procedure. The second is that if an array name, say  $A$ , appears on the left-hand side of an assignment statement, and the right-hand side is an expression whose value is an array of the same type, then  $A$  is overwritten, and the original instance of the array that was bound to  $A$  is inaccessible once the assignment has taken place.

As an example of the first point above, let us examine the situation in which a procedure returns as its value an array that has been transmitted to it as a ‘value’ parameter. In such a case, once the called procedure has exited, there are two instances of the array, one of which is the value returned by the procedure, which is a (possibly modified) copy of the array that was transmitted as a parameter.

One shortcoming with the array data type is the absence of a true analogy with record structures. The problem is that the process of allocating storage for an array should be decoupled from its declaration (which is more like setting up a template). This is

a shortcoming of many implementations, including the one described here. It could be overcome easily by replacing the reserved word **array** with the reserved word **array\_pointer** whenever it is only desired to set up the template for the array, rather than also allocating the storage. For example, the declaration '**integer array\_pointer** ARR[0:N]' would set up the template for array ARR without actually allocating the space for it, while '**integer array** ARR[0:N]' retains its original meaning of template declaration and storage allocation.

Note that the C language allows for either array declaration with allocation or without allocation (i.e., template declaration). However, in C, for the case of the array template, the actual size of the array cannot be specified. In other words, the template is really a pointer to an element of the type of the members of the array but cannot indicate how many elements are in the array.

# Solutions to Exercises

---

## Solutions to Exercises in Section 1.1

1. See [649].
2. There are  $d!$  permutations of  $d$  attributes. It can be shown using symmetry arguments, as well as additional properties, that only  $\binom{d}{\lfloor (d+1)/2 \rfloor}$  of the permutations are needed. For more details, see [1214], as well as [1046, pp. 577, 743–744].
3. The worst case is  $N + d - 1$ , where the first attribute value is different for all records, and now the remaining chains are one element long at each level.
4. In the case of a doubly chained tree, in the worst case, we only test one attribute value at a time for a total of  $O(N)$  tests. On the other hand, in the case of a sequential list, in the worst case, we may have to test all attribute values of each record for a total of  $O(N \cdot d)$  tests.
5. (Hans-Peter Kriegel) This worst case arises when the resulting tree has the depth  $O(d \log_2 N)$ . To see how this case arises, assume a configuration of  $N$  records in the following sequence. The first  $N/d$  records have  $N/d$  different values for the first attribute, and the remaining  $d - 1$  attributes have arbitrary values. The first attribute value of the remaining  $N \cdot (d - 1)/d$  records is a constant, say  $c_1$ . The second set of  $N/d$  records in the sequence have  $N/d$  different values for the second attribute, and the remaining  $d - 2$  attributes have arbitrary values. The second attribute value of the remaining  $N \cdot (d - 2)/d$  records is a constant, say  $c_2$ . This same process is applied for the remaining  $d - 2$  sets of  $N/d$  records—that is, the  $i$ th set of  $N/d$  records in the sequence have  $N/d$  different values for the  $i$ th attribute and the remaining  $d - i$  attributes have arbitrary values. The second attribute value of the remaining  $N \cdot (d - i)/d$  records is a constant, say  $c_i$ . This results in a sequence of  $d$  height-balanced binary trees of height  $\log_2 N/d$  apiece. Thus, the total height of the structure is  $O(d \cdot \log_2 N/d) = O(d \cdot (\log_2 N - \log_2 d))$ , which can be approximated by  $O(d \log_2 N)$  since  $d \ll N$ .
6. Assume that all of the attribute values are distinct. This means that the subfile  $H$  of the records that lie on the partitioning hyperplane is empty as this maximizes the size of the left and right subtrees of each node. Let  $S(N, d)$  denote the time needed to build the tree and solve the following recurrence relation [1133]:

$$S(N, d) = 2 \cdot S(N/2, d) + 2 \cdot S(N/2, d - 1)$$

where  $S(1, d) = O(d)$  and  $S(N, 1) = O(N \cdot \log_2 N)$ . The recurrence relation indicates the space needed for the trees corresponding to the subfiles  $L$  and  $R$ , which contain  $N/2$  records, and the subfiles  $LH$  and  $RH$ , which also contain  $N/2$  records and are projections on the  $(d - 1)$ -dimensional hyperplane.  $S(N, 1)$  is the space needed for the one-dimensional structure where at each level  $LH$  and  $RH$  are just sets of pointers to the records corresponding to the elements of  $L$  and  $H$ , respectively, and there are  $N$  records at each of the  $\log_2 N$  levels.  $S(1, d)$  is the space needed for a  $d$ -dimensional record that lies on the hyperplane corresponding to the record, and there are  $d$  levels in this structure with an empty right subtree and a nonempty left subtree as there are  $d$  attributes. The solution to this recurrence relation is  $S(N, d) = O(N \cdot (\log_2 N)^d)$ . For more details, see [1133].

7. The derivation is similar to that used for the cost of building a quinary tree in the solution of Exercise 6. Assume that all of the attribute values are distinct. This means that the subfile  $H$  of the records that lie on the partitioning hyperplane is empty as this maximizes the size of the left and right subtrees of each node. Let  $P(N, d)$  denote the time needed to build the tree and solve the following recurrence relation [1133]:

$$P(N, d) = 2 \cdot P(N/2, d) + 2 \cdot P(N/2, d - 1) + O(N),$$

where  $P(1, d) = O(1)$  and  $P(N, 1) = O(N \cdot \log_2 N)$ . The recurrence relation corresponds to the cost of constructing the trees for the subfiles  $L$  and  $R$ , which contain  $N/2$  records, and the subfiles  $LH$  and  $RH$ , which also contain  $N/2$  records and are projections on the  $(d - 1)$ -dimensional hyperplane. The  $O(N)$  factor corresponds to the cost of the actual partition process, including obtaining the median and the subfile  $H$  (which is empty by virtue of our distinctness assumption).  $P(N, 1)$  is the process of obtaining the binary search tree for the one-dimensional hyperplane.  $P(1, d)$  is the cost of processing one  $d$ -dimensional record, which requires that a node with an empty left subtree (since there are no records with smaller attribute values) and a nonempty right subtree be created for each of the  $d$  attribute values. The solution to this recurrence relation is  $P(N, d) = O(N \cdot (\log_2 N)^d)$ . For more details, see [1133].

8. In the worst case, all of the attribute values are distinct, and thus the search may require that  $\log_2 N$  levels be descended while testing the first attribute. In this case, we may need to test the values of all of the remaining attributes. For more details, see [1133].
9. The algorithm is similar to that used for the partial range query with the exception that we must search through all three trees at the next lower level whenever an attribute value is left unspecified. This work is maximized when the  $s$  specified attributes are at the  $s$  deepest levels of the tree. For more details, see [1133].
10. Each interval  $[l_i, r_i]$  ( $1 \leq i \leq d$ ) can be subdivided into at most  $N$  subintervals at each level  $i$ . Therefore, the maximum number of nodes that are visited is bounded by  $O(\log_2 N)^d$  plus the number of records  $F$  that are found to satisfy the query—that is,  $O((\log_2 N)^d + F)$ .
11. The algorithm is the same as the range query algorithm except that we need to search through the attached three trees at the level whenever an attribute value is unspecified. This worst case occurs when the  $s$  specified attributes are at the  $s$  deepest levels of the tree. For more details, see [1133].
12. Using an ECDF tree, the ranking (i.e., ECDF) of  $q$  is determined as follows. If  $q$  falls in  $A$ , then no point in  $B$  can be dominated by  $q$ , and thus we only need to search  $A$ . Otherwise,  $q$  can dominate points in both  $A$  and  $B$ . However, in this case, since the value of the first attribute of any point in  $A$  is always smaller than the value of the first attribute of  $q$ , we only need to compare  $q$  with the projections of points in  $A$ —that is, the points in  $C$ . Letting  $T(N, d)$  denote the time to compute the rank of  $q$  in a set of  $N$  records in  $d$ -dimensional space, we have the following recurrence relation:  $T(N, d) = T(N/2, d) + T(N/2, d - 1)$ , where  $T(N, 1) = O(\log_2 N)$  and  $T(1, d) = O(d)$ , corresponding to a one-dimensional balanced binary search tree and a linear list, respectively. The solution to this recurrence relation is  $T(N, d) = O((\log_2 N)^d)$ .
13. Use the same solution process as in Exercise 12. Letting  $S(N, d)$  denote the number of nodes in an ECDF tree for a set of  $N$  records in  $d$ -dimensional space, we have the following recurrence relation:  $S(N, d) = 2 \cdot S(N/2, d) + S(N/2, d - 1)$ , where  $S(N, 1) = O(N)$  and  $S(1, d) = O(d)$ , corresponding to a one-dimensional balanced binary search tree and a linear list, respectively. The solution to this recurrence relation is  $S(N, d) = O(N \cdot (\log_2 N)^{d-1})$ .
14. Take the difference of the ranking of  $p$  and  $q$ .
15. Search the linked lists at the first level for values within the range of the first attribute and then recursively descend the links corresponding to the linked lists at the remaining levels that are within the range.
16. Start the search at the first level for which an attribute value or range is given. The rest of the process is analogous to that of a range query given in Exercise 15. The efficiency of the process is enhanced by the fact that all filial sets at the same level are linked.
17. (Hans-Peter Kriegel) The configuration is the same as the one used in Exercise 5 to show that the worst-case execution time for an exact match query when the linked list at each level of the doubly chained tree has been replaced by a height-balanced binary search tree is  $O(d \log_2 N)$ .

The only difference is that at each level we have a B-tree of depth  $O(\log_M N)$  instead of a height-balanced binary search tree of depth  $O(\log_2 N)$ .

18. Assuming a uniform distribution of points in the cells, say  $c$  points per cell, then the search must examine a maximum of  $2^d$  cells for a total amount of work equal to  $c \cdot 2^d$ . Since the query region is a region having the width of a cell (i.e., the query region has width of twice the query radius), we would expect that  $F = c$ . Therefore, the amount of work is  $F \cdot 2^d$ .
19. Assuming a uniform distribution of points in the cells, say  $c$  points per cell, then the search must examine a maximum of  $3^d$  cells for a total amount of work equal to  $c \cdot 3^d$ . Since the query region is  $2^d$  times the width of a cell, we would expect that  $F = c \cdot 2^d$  or  $c = F/2^d$ . Therefore, the amount of work is  $F \cdot 3^d/2^d$ . Yuval [2063] describes an alternative approach that examines a smaller number of larger cells. In particular, given a fixed-grid with cells of edge length  $e$ , Yuval examines  $d + 1$  cells of edge length  $(d + 1) \cdot e$  so that using the same density of points per cell  $c$ ,  $c \cdot (d + 1)^{d+1}$  points would be examined although some points would be examined more than once, thereby reducing the total number of different points that are examined. Note that this number is always greater than  $c \cdot 3^d$ , the number of points examined in the solution to this exercise.

## Solutions to Exercises in Section 1.2

1. Yes. In the one-dimensional range tree, the leaf nodes are linked in sorted order using a doubly linked list to facilitate retrieval of all elements within a given range in time proportional to the number of elements in the range.
2. The revised definition would cause problems for points with identical values. For example, suppose that there are eight points with identical values. In this case, it would be impossible to have a balanced tree with all values in left subtrees less than the MIDRANGE values.
3. The reason is that when  $B_x$  is less than MIDRANGE( $P$ ), then the  $x$  coordinate values of all points in the one-dimensional range trees that are searched in RIGHT( $P$ ) are greater than or equal to  $B_x$  and less than  $E_x$ . Similarly, the  $x$  coordinate values of all points in the one-dimensional range trees that are searched in LEFT( $P$ ) are less in value than  $E_x$  and greater than  $B_x$ .
4. The points that are found are unique; no point is reported twice since all one-dimensional range trees at a given level are disjoint. The one-dimensional range trees that are examined at the different levels are also disjoint.
5. When procedure 1DSEARCH is invoked, it must distinguish between a leaf node and a nonleaf node as the RANGETREE field points to a record of type *point* in the former and *node* in the latter. Moreover, care must be exercised in the search in the sense that only the specified node is tested and no transitions can be made via the NEXT field as it corresponds to another data structure—that is, the one-dimensional range tree for the  $x$  coordinate. Thus, the search should use procedure INRANGE in this case.
6. Procedure 2DSEARCH never makes use of the one-dimensional range trees of the nearest common ancestor and its two children. In the worst case, the nearest common ancestor is the root, and thus the one-dimensional range trees at the root and its two children are never used.
7. The balanced binary search tree, say  $T$ , for the main attribute uses  $O(N)$  space. For each level of  $T$ , each data point occurs in exactly one of the one-dimensional range trees for the secondary attribute that are associated with the nonleaf nodes at that level. There are  $O(\log_2 N)$  levels, and thus a total of  $O(N \cdot \log_2 N)$  space suffices.
8. Building the range tree in  $x$  at the lowest level takes  $O(N \cdot \log_2 N)$  for  $N$  points. The one-dimensional range trees for the  $y$  coordinate values are built based on the range trees for the  $x$  coordinate values. This is done by use of a merging process. In particular, the one-dimensional range tree in  $y$  at level  $i$  associated with node  $a$  is built by merging the two one-dimensional range trees in  $y$  associated with the two children of  $a$  at level  $i + 1$ . Since the  $y$  coordinate values of these two children are both sorted, we obtain the one-dimensional range tree at level  $i$  in time proportional to the number of points in the two merged one-dimensional range trees. The one-dimensional range trees at each level of the tree contain  $N$  points, and

since there are  $\log_2 N$  levels, building the one-dimensional range trees for the  $y$  coordinate values takes  $O(N \cdot \log_2 N)$  time. Thus, the total time to build the two-dimensional range tree is  $O(N \cdot \log_2 N)$  (see also [169]).

9. To perform a range query, it takes  $\log_2 N$  steps to locate the endpoints of the main attribute, plus  $O(\log_2 N)$  time to locate the endpoints of the secondary attributes in each of the  $O(\log_2 N)$  one-dimensional range trees of the secondary attribute, plus the time to sequence through the answers that are located.
10. Overmars [1442] (see also Bentley [169]) suggests using the solution of the following recurrence relation: Let  $M(k, N)$  denote the space necessary for a  $k$ -dimensional range tree for  $N$  points. At each level of the  $k$ -dimensional range tree, at most  $M(k-1, N)$  space is used. Therefore,  $M(k, N) \leq \log_2 N \cdot M(k-1, N)$ , and the fact that  $M(2, N) = O(N \cdot \log_2 N)$  leads to the desired result. The query time is analyzed in the same manner.
11. Use the same technique as in the solution to Exercise 10.

### Solutions to Exercises in Section 1.3

1. The balanced binary search tree is equivalent to an extended binary tree. Such a tree with  $N$  leaf nodes has  $N - 1$  nonleaf nodes.
2. Finding the nearest common ancestor requires at most  $2 \cdot \log_2 N$  steps. Once the nearest common ancestor has been found, say  $Q$ , the search process may visit each point on the path from  $Q$  to  $B_x$  and  $E_x$ , even if it does not satisfy the query. All other nodes that are visited either cut off or satisfy the search. Of the nodes that cut off the search, at most  $2 \cdot F$  are not on the path from  $Q$  to  $B_x$  and  $E_x$ . Empty nodes also cut off the search since their children have already been reported.
3. Procedure PRIORITYSEARCH2 performs more comparison operations than procedure PRIORITYSEARCH; however, they have the same execution time complexity. We prove this by showing that the number of comparison operations that they make differs by a constant factor. This can be seen once we are processing the left (right) subtree of the nearest common ancestor and have determined that the node and its left (right) child are on the path from the nearest common ancestor to  $B_x$  ( $E_x$ ). In this case, there is no longer any need to test whether the remaining nodes in the right (left) child are in the  $x$  range. Procedure PRIORITYSEARCH does not perform these additional comparison operations while they are made by procedure PRIORITYSEARCH2. However, the number of additional comparison operations made in this manner is no more than  $2 \cdot F$ , which is the number of points found to satisfy the query. In all remaining cases, once the nearest common ancestor  $Q$  has been found, for nodes in the left (right) subtree of  $Q$ , procedure PRIORITYSEARCH compares only the MIDRANGE field of each node with respect to  $B_x$  ( $E_x$ ), while procedure PRIORITYSEARCH2 compares both  $B_x$  and  $E_x$ . However, this doubles only the number of comparison operations and thus makes no difference in the order of complexity of the two procedures.
4. When procedure PRIORITYSEARCH is invoked, it must distinguish between an empty (i.e., NIL) value and a point for the HEAPMAX field, which it does already. Thus, we simply replace the use of POINT(HEAPMAX( $i$ )) for any priority search tree node  $i$  with HEAPMAX( $i$ ). This causes no problems as its use is always prefaced by a test for being NIL by virtue of the prior invocation of OUTOFRANGEY.
5. Assuming  $N$  data points, after making  $\log_2 N$  comparisons, exactly one point is found in the tree.
6. Use a derived pair  $(f(x, y), y)$ , where  $f(x, y) = k \cdot x + y$ .  $f$  is a mapping such that differences in  $x$  are more significant than differences in  $y$ . Of course, points must still be unique in the sense that every combination  $(x, y)$  must occur just once.
7. Build the one-dimensional range tree first on the  $x$  coordinate values of the points. This takes  $O(N \cdot \log_2 N)$  time for  $N$  points. The next step is to build a heap on the basis of the  $y$  coordinate values of the points, which can be done in  $O(N)$  time (e.g., [422]). This is easy to do. For the sake of this discussion, assume that the HEAPMAX field of each leaf node contains the actual value of the  $y$  coordinate of the point. Initialize the HEAPMAX field of all the nonleaf

- nodes to  $-\infty$  and apply an  $O(N)$  heap creation algorithm (e.g., [422]). At the end of the heap creation process, nodes whose HEAPMAX field is  $-\infty$  are the same as empty. Since the order of complexity of the heap creation process is less than that of the one-dimensional range tree construction process, the overall priority search tree construction process is still  $O(N \cdot \log_2 N)$  time for  $N$  points.
12. The problem is that the priority search trees attached to the successive right children of  $L$  are all inverse priority search trees that do not support the semi-infinite range query  $([B_x : E_x], [B_y : \infty])$ . Similarly, the problem with the modification to the third step of the algorithm is that the inverse priority search trees attached to the successive left children of  $R$  are all priority search trees that do not support the semi-infinite range query  $([B_x : E_x], [-\infty : E_y])$ .
  13. The balanced binary search tree is equivalent to an extended binary tree. Such a tree with  $N$  leaf nodes has  $N - 1$  nonleaf nodes. Each node appears in one priority search tree or inverse priority search tree at each level. There are  $\log_2 N$  levels.
  14. The analysis is similar to that used in Exercise 8 in Section 1.2. Building the one-dimensional range tree in  $y$  takes  $O(N \cdot \log_2 N)$  time. The total number of points in the priority and inverse priority search trees at each level is  $N$ . Each of these priority search trees consists of a one-dimensional range tree in  $x$  at the lowest level. Each of these one-dimensional range trees is built in time proportional to the number of points in it. To see this, we observe that the one-dimensional range trees in  $x$  at each level of the range priority tree are built using a merging process. In particular, the one-dimensional range tree in  $x$  at level  $i$  associated with node  $a$  is built by merging the two one-dimensional range trees in  $x$  associated with the two children of  $a$  at level  $i + 1$ . Since the  $x$  coordinate values of these two children are both sorted, we obtain the one-dimensional range tree at level  $i$  in time proportional to the number of points in the two merged one-dimensional range trees. The one-dimensional range trees in  $x$  at each level of the tree contain  $N$  points, and since there are  $\log_2 N$  levels, building the one-dimensional range trees for the  $x$  coordinate values takes  $O(N \cdot \log_2 N)$  time. The rest of each of the priority search trees is a heap in  $y$ , which can be built in time proportional to the number of points in it. Since there are  $N$  points at every level, and there are  $\log_2 N$  levels, the heap creation part also takes  $O(N \cdot \log_2 N)$  time.
  15. At each level  $i$  ( $1 \leq i \leq \log_2 N - 1$ ) of the range priority tree, we need to compute  $2^i$  priority and inverse priority search trees ( $2^{i-1}$  of each) containing  $N/2^i$  points apiece. Therefore, each level of the range priority tree takes  $O(2^i \cdot N/2^i \cdot \log_2 N/2^i) = O(N \cdot \log_2 N/2^i)$  time to construct. Summing this quantity over  $i$  ( $1 \leq i \leq \log_2 N/2$ ) yields approximately  $N \cdot \log_2^2 N$ , and the desired time bound is  $O(N \cdot \log_2^2 N)$ .
  16. See [535].
  17. Finding the nearest common ancestor requires at most  $\log_2 N$  steps, and the remaining work is proportional to the number of points found.
  21. See Figure S.1.
  22. The Cartesian tree is unique as long as each  $x$  coordinate value and  $y$  coordinate value occurs at most once. This can be seen by observing that the root is the node with a maximum  $y$  coordinate value. Once the root has been chosen, the corresponding  $x$  coordinate value partitions the remaining points between the left and right subtrees. The recursive application of this process guarantees the uniqueness of the Cartesian tree. Thus, we cannot balance it by the use of rotation operations (unless some of the coordinate values occur more than once).

### Solutions to Exercises in Section 1.4.1.1

1.
  - 1 **quadrant procedure** PTCOMPARE( $P, R$ )
  - 2 /\* Return the quadrant of the point quadtree rooted at node  $R$  in which node  $P$  belongs. \*/
  - 3 **value pointer node**  $P, R$
  - 4 **return**(if XCOORD( $P$ ) < XCOORD( $R$ ) **then**
  - 5       **if** YCOORD( $P$ ) < YCOORD( $R$ ) **then** 'SW')

- ```

6         else 'NW'
7         endif
8         elseif YCOORD(P) < YCOORD(R) then 'SE'
9         else 'NE'
10        endif)

```
- ```

1  procedure PTINSERT(P, R)
2  /* Attempt to insert node P in the point quadtree rooted at node R. */
3  value pointer node P
4  reference pointer node R
5  pointer node F, T
6  quadrant Q
7  if ISNULL(R) then R ← P /* The tree at R is initially empty */
8  else
9    T ← R
10   while not ISNULL(T) and not EQUALCOORD(P, T) do
11     F ← T /* Remember the father */
12     Q ← PTCOMPARE(P, T)
13     T ← CHILD(T, Q)
14   enddo
15   if ISNULL(T) then CHILD(F, Q) ← P /* P is not already in the tree */
16   endif
17   endif

```
  - $\lfloor \log_2 N \rfloor$  when all points are collinear (i.e., they lie on a straight line).
  - The maximum path length in an optimized point quadtree of  $N$  nodes is  $\lfloor \log_2 N \rfloor$ . Therefore, the maximum TPL is  $\sum_{i=1}^{\lfloor \log_2 N \rfloor} i \cdot 2^i$ .
  - The ordering step on  $N$  elements is  $O(N \cdot \log_2 N)$ . Selecting the median at each level of recursion is  $O(N)$ . Regrouping the records is also  $O(N)$ . The depth of the recursion is the maximum path length bounded by  $\lfloor \log_2 N \rfloor$ . Therefore, the running time of the algorithm is  $O(N \cdot \log_2 N)$ .
  - Overmars and van Leeuwen [1444] use an algorithm similar to that used by Finkel and Bentley [614] to construct their version of an optimized point quadtree. Insert the nodes using the property that for every set of  $N$  points, a point quadtree can be built in  $O(N \cdot \log_2 N)$  time such that for every nonleaf node with  $M$  nodes in its subtrees, every subtree contains at

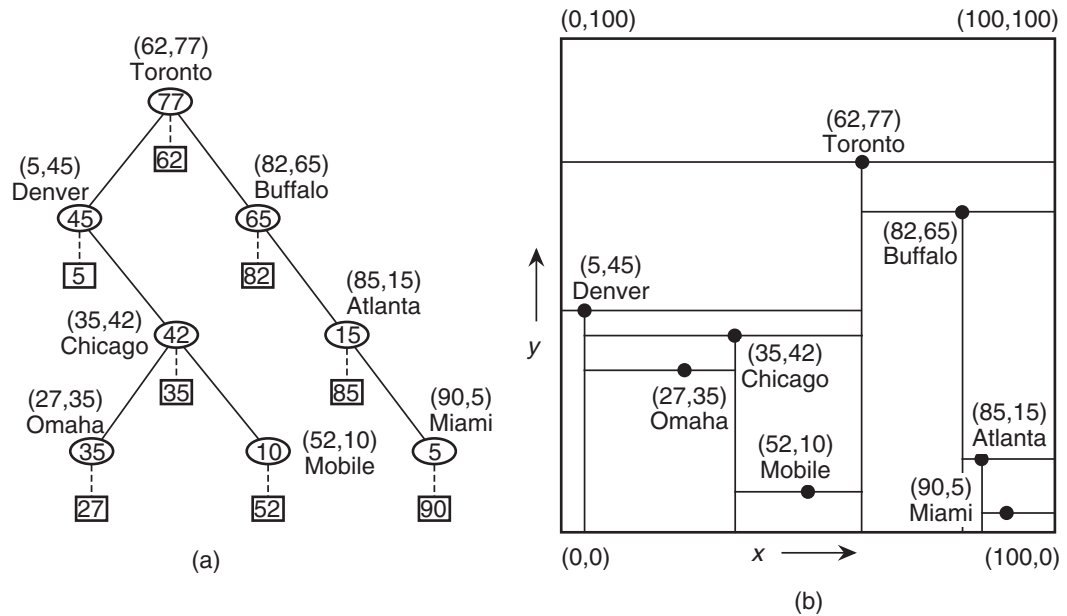

Figure S.1  
A Cartesian tree.

most  $\lceil M/2 \rceil$  nodes. Each subquadrant is repeatedly subdivided with respect to a point whose coordinate value is the median along a chosen axis. If the balance of the tree is destroyed upon the insertion of a point node, then rebuild the subtree rooted at the shallowest nonleaf node at which the tree is still balanced.

7. See [1444].
8. Finkel and Bentley [614, p. 4] suggest leaf balancing operations that they term *single balance* and *double balance*. Kersten and van Emde Boas [1018] report on an empirical study of different balancing operations.
9.  $N \cdot (N - 1)/2$ , which arises when the tree is linear so that the insertion of the  $i$ th point requires  $i - 1$  comparison operations.

3. (a) Let us first examine the case that B at (3,−5) is in the SE child of A. Let F at (5,−5) be the SE child of A. Before we replaced A with B, F was in the SE quadrant of A. Once we replace A with B, F is now in the NE quadrant of B due to the open and closed conventions,

- and thus we have to reinsert the entire subtree rather than take advantage of the pruning that is afforded by use of NEWROOT.
- (b) Let us now examine the case that B is in the SW child of A. There are two subcases depending on the exact position of B. In both cases, let F at  $(-5, -5)$  be the SW child of A.
- i. Let B be at  $(-5, -3)$ . Before we replaced A with B, F was in the SW quadrant of A. Once we replace A with B, F is now in the SE quadrant of B due to the open and closed conventions, and thus we have to reinsert the entire subtree rather than take advantage of the pruning that is afforded by use of NEWROOT.
  - ii. Let B be at  $(-3, -5)$ . Before we replaced A with B, F was in the SW quadrant of A. Once we replace A with B, F is now in the NE quadrant of B due to the open and closed conventions, and thus we have to reinsert the entire subtree rather than take advantage of the pruning that is afforded by use of NEWROOT.
5. Use induction. Assume that the root is at depth 0. The result is clearly true for  $N = 1$ . Assume that it is true for  $N = i$  and show that it is true for  $N = i + 1$ . Add the  $(i + 1)$ -th node at the bottom of the tree—say to a node at depth  $m$ —and let  $T'$  denote the new tree.  $TPL(T')$  increases by  $m$ . Also, each of the subtrees rooted at nodes at depths 0 through  $m - 1$  in which the new node is a member have increased in size by 1 for a total increase of  $m$ . Furthermore, there is one additional subtree of size 1 corresponding to the  $(i + 1)$ -th node. The result follows, and holds for trees, as well as binary search trees and point quadtrees, since empty trees and orientation make no difference.
  6. See [1618].
  7. See [1618].
  10. See [1617].
  12. In the two-dimensional case, first divide the data points into two sets containing  $\lceil N/3 \rceil$  and  $\lfloor 2 \cdot N/3 \rfloor$  points. Next, divide the larger set into two parts containing  $\lceil N/3 \rceil$  points each. This process is applied recursively. Overmars and van Leeuwen [1444] give more details.
  13. See [1444].
  14. Consider a collinear set of data points (i.e., a straight line). Alternatively, the set of points need have only monotonically increasing or monotonically decreasing coordinate values. If the line coincides with one of the axes lines, then the axes are rotated slightly.
  15. See [1444].
  16. See [1444] for a proof similar to that for Exercise 7 in Section 1.4.1.1.

### Solutions to Exercises in Section 1.4.1.3

2. The subtrees at level  $m - i$  form a regular checkerboard of  $4^i$  squares. The expected number of squares intersected along the  $x$  and  $y$  directions is bounded by  $x \cdot 2^i + 1$  and  $y \cdot 2^i + 1$ , respectively. Therefore, the number of squares at level  $i$  overlapped by the search rectangle is bounded by  $(x \cdot 2^i + 1) \cdot (y \cdot 2^i + 1)$ . Summing this quantity over all levels  $0 \leq i \leq m - 1$ , together with the fact that  $N$ , the number of nodes, is  $(4^m - 1)/3$ , yields  $x \cdot y \cdot N + (x + y) \cdot \sqrt{3 \cdot N} + \log_4(3 \cdot N)$ .
3. The expected number of records in a square search region is  $N \cdot x^2$ . The expected number of records visited in such a search in an inverted list is  $N \cdot x$ , and the expected overwork is  $(1 - x) \cdot x \cdot N$ . From Exercise 2 we have that for a square search region in a perfect point quadtree, the amount of overwork is approximately  $2 \cdot x \cdot \sqrt{3 \cdot N}$ . Thus, we see that the overwork for square search regions in perfect point quadtrees is asymptotically less than that for inverted lists.
4. See [1132].
6. See [2000].

48 endif

```

5. The worst case arises when the boundaries of the rectangular query region intersect  $2^n$  nodes (i.e., regions).
7.  $\sum_{i=0}^{n-1} 4^i = (4^n - 1)/3$ .
8. For a complete MX quadtree (i.e., where no sparseness occurs), the array representation requires one-third less space since the MX quadtree representation needs pointers. However, using the array, one-third more interchange operations must be performed while computing the transpose.
9. Wise [2006] observes that a quadtree-like decomposition admits a hybrid algorithm that uses *both* Strassen's recurrence [1804] and the conventional one (e.g., [578, Section 1.4]). The conventional recurrence requires eight quadrant multiplications, which is reduced when some of the quadrants correspond to nonleaf nodes that correspond to blocks of zeros. For example, only six quadrant multiplications are necessary when only one of the eight quadrants corresponds to a nonleaf node. The amount of reduction depends on how many such zero quadrants are present, but the improvement is profound with sparse matrices [1]. On larger

matrices, use of Strassen's recurrence reduces the count of eight in the conventional recurrence to seven, but with a loss of sparseness and a well-known loss of floating-point stability.

10. Using a runlength representation speeds up the matrix multiplication. However, once the matrices have been multiplied, the dual representation must be built for the resulting matrix. Ironically, in some sense, the quadtree, by being a variant of a two-dimensional runlength representation, addresses this problem in part!

```

4. The  $\sqrt{2}$  term arises from the fact that the points may be at opposite corners of the smallest square of side width  $s/d$ .
5. Overmars [1442] suggests that the  $N$  points be chosen in such a way that they form  $N/2$  clusters of two points each. These  $N/2$  clusters are the leaf nodes of a complete PR quadtree of depth  $\log_4(N/2)$  such that each leaf contains one cluster. At this point, each of the  $N/2$  clusters must be further decomposed by use of the PR quadtree. The  $N/2$  clusters of points are chosen in such a way that the elements of each cluster appear at the maximum depth in the PR quadtree (i.e.,  $n$ ). The result is that we need  $O(N)$  space for the nodes at depth 0 through  $\log_4(N/2)$  and  $O((n - \log_4(N/2)) \cdot N)$  for the nodes at the remaining depths up to  $n$ . When  $2^n$  is large in comparison to  $N$ , this is  $O(N \cdot n)$ .

6. This occurs when  $2^n$  is  $O(N)$  or smaller than  $N$ .
8. The worst case arises when the boundaries of the rectangular query region intersect  $2^n$  nodes (i.e., regions).
9.  $1/4^k$ .
10.  $\left(1 - \frac{1}{4^k}\right)^v$ .
11.  $\binom{v}{1} \cdot \frac{1}{4^k} \cdot \left(1 - \frac{1}{4^k}\right)^{v-1}$ .
12.  $1 - \left(1 - \frac{1}{4^k}\right)^v - \binom{v}{1} \cdot \frac{1}{4^k} \cdot \left(1 - \frac{1}{4^k}\right)^{v-1}$ .
13.  $4^{k+1} \cdot \left(1 - \left(1 - \frac{1}{4^k}\right)^v - \binom{v}{1} \cdot \frac{1}{4^k} \cdot \left(1 - \frac{1}{4^k}\right)^{v-1}\right)$ .
14.  $E = 1 + \sum_{k=0}^{\infty} 4^{k+1} \cdot \left(1 - \left(1 - \frac{1}{4^k}\right)^v - \binom{v}{1} \cdot \frac{1}{4^k} \cdot \left(1 - \frac{1}{4^k}\right)^{v-1}\right)$ .
16. All instances of  $2^2$  or 4 are replaced by  $2^m$ .

4. Bentley [164] shows that the probability of constructing a given k-d tree of  $N$  nodes by inserting  $N$  nodes in a random order into an initially empty k-d tree is the same as the probability of constructing the same tree by random insertion into a one-dimensional binary search tree. Once this is done, results that have been proved for one-dimensional binary search trees will be applicable to k-d trees. The proof relies on viewing the records as  $d$ -tuples of permutations of the integers  $1, \dots, N$ . The nodes are considered random if all of the  $(N!)^k$   $d$ -tuples of permutations are permitted to occur. It is assumed that the key values in a given record are independent.
5. See [1912] for some hints.

```

6. Assume the worst case: a complete k-d tree with the  $D$  discriminator found at depth  $d - 1$ . Therefore, all nodes at depth 0 through  $d - 1$  will have to be visited (i.e.,  $2^d - 1$  nodes), while the right subtrees of nodes at depth  $d - 1$  are pruned. This pruning occurs repeatedly at depths  $h \cdot d - 1$ , where  $h > 0$ . At all other depths, all nodes in nonpruned subtrees must be visited (e.g., all nodes at depth  $h \cdot d$  through  $h \cdot d - 1$  in the nonpruned subtrees). Summing up yields the desired result.

### Solutions to Exercises in Section 1.5.1.3

1. If the search region would have been chosen in the middle of the space, then in the worst case, we would want the root of the k-d tree to partition the region somewhere in the middle. In this case, the subtrees contain identically shaped subregions of the original search region, and the analysis is applied recursively.
5. The search region is a  $(d - s)$ -dimensional hyperplane.
6. Assume the most pessimistic case: the first  $d - s$  discriminators in the tree correspond to the  $d - s$  unspecified keys of the partial range query. Therefore, all nodes at depth 0 through  $d - s$  must be visited (i.e.,  $2^{d-s} - 1$  nodes), while pruning occurs at depth  $d - s$  through  $d - 1$ , resulting in  $t \cdot 2^{d-s-1}$  nodes being visited. This pruning occurs repeatedly at depth  $h \cdot d - s$  through  $h \cdot d - 1$ . At all other depths, all nodes in nonpruned subtrees must be visited (e.g., all nodes at depth  $h \cdot d$  through  $h \cdot d - s$  in the nonpruned subtrees). Summing up yields the desired result.

### Solutions to Exercises in Section 1.5.1.4

2. See [1444].
4.  $N \cdot \log_2 N$  for  $N$  points.
5. See [650].
7. See [1226, 1228].
8. Compute the approximate nearest neighbors for each of the training points. For training point  $i$ , let  $d_{ei}$  be the distance to the exact nearest neighbor and  $d_{ai}$  be the distance to the approximate nearest neighbor. Therefore,  $d_{ei} \leq d_{ai} \leq (1 + \varepsilon) \cdot d_{ei}$ . When determining the discriminator key and value for partitioning the cell, use a distance  $d_{si}$  obtained by shrinking the distance  $d_{ai}$  to the approximate nearest neighbor of training point  $i$  by the factor  $(1 + \varepsilon)$ —that is,  $d_{si} = d_{ai} / (1 + \varepsilon)$ . The effect of the shrinking serves to decrease the likelihood that

the computation of the nearest neighbor of a training point needs to examine points in both halves of the cell that is being split as it enables a nearest point in the half of the cell that does not contain  $i$  to be ignored subject to the approximation error tolerance  $\varepsilon$ . Although it appears that the  $\varepsilon$  factor is accounted for twice—that is, once in the original determination of the approximate nearest neighbors and once in the determination of the discriminator key and value for the cell. This is not true, as can be seen by noting that  $d_{ei}/(1 + \varepsilon) \leq d_{si} \leq d_{ei}$ . In other words, use of the distance to the actual approximate nearest neighbor means that we have not shrunken the nearest neighbor distance by the maximum amount for the given approximation error tolerance  $\varepsilon$ .

10. This is a result of the requirement that both  $R_1$  and  $R_2$  be  $\alpha$ -balanced.
11. Start with an initial  $\alpha$ -balanced canonical region. As this region is  $k$ -cuttable, use a sequence of  $k$  canonical cuts to subdivide the region into  $k + 1$   $\alpha$ -balanced canonical subregions so that each one contains fewer than  $\beta N$  of the points. Apply this process recursively to each of the resulting subregions until each subregion has fewer than some constant number of points (i.e., the bucket capacity). This process cannot be repeated more than  $O(\log_{1/\beta} N)$  times down any path of subregions. Each time the process is applied, we obtain a binary tree of maximum depth  $k$ , and thus the maximum depth of the BAR tree is  $O(k \log_{1/\beta} N)$  as desired [517].
12.  $k = O(d)$  and  $\beta = O(d/(d + 1))$  implies  $\log_{1/\beta} N = O(d \log N)$ , and thus  $O(k \log_{1/\beta} N) = O(d^2 \log N)$  as desired.
14. No.

### Solutions to Exercises in Section 1.5.2.1

2. It has a greater potential for saving space.
3. See [483], who obtain a result of  $N \cdot (n - \log_2 N + 2.402)$ .
5. See [1046, Section 6.3] for a proof for  $d = 1$ , which is generalized to hold for arbitrary values of  $d$ .
6. Flajolet and Puech [621] perform such an analysis for a k-d tree and a PR k-d tree and show that the PR k-d tree is asymptotically better than the k-d tree.

Figure S.2  
Example of a set of four points in two dimensions illustrating how the worst case can arise that an open-sliding midpoint k-d tree can require  $O(N \cdot d)$  leaf nodes.

### Solutions to Exercises in Section 1.5.2.2

1. See [297] for the basis of a solution.
2. (David M. Mount) In the worst case,  $O(N \cdot d)$  leaf nodes are needed. To see how this situation can arise, consider the following point set consisting of  $N$   $d$ -dimensional points  $\{p_i | i = 1 \dots N\}$  contained within the unit cube where the coordinate values for each point are identical. In particular, let  $p_i = (1/2^i - \varepsilon, 1/2^i - \varepsilon, \dots, 1/2^i - \varepsilon)$ , where  $\varepsilon$  denotes an arbitrarily small quantity greater than 0, and the origin is the lower-left corner (minimum) corner. In (virtually) all instances (except where a point is separated and no slide occurs), the points will lie below the partitioning plane, and hence the slide will move the splitting plane to the left (lower coordinate value). For example, Figure S.2 illustrates this case for four points in two dimensions. The broken lines indicate the original position of the partition plane before it has been slid to its final position, which is indicated by a solid line.

The initial cell has corner points  $(0, 0, \dots, 0)$  and  $(1, 1, \dots, 1)$ . Let  $x_1$  be the first splitting axis. Since  $p_1$ 's coordinate values are all  $1/2 - \varepsilon$ , the first partitioning plane is  $x_1 = 1/2$ , which is then slid to the left and is placed at  $x_1 = 1/2 - \varepsilon$ . The upper-right (maximum) corner of the resulting cell is  $(1/2 - \varepsilon, 1, 1, \dots, 1)$ . The second splitting axis is  $x_2$  as it is one of the axes along which the corresponding coordinate value has the maximum range (i.e., one of the longest sides of the cell). The partitioning plane is now  $x_2 = 1/2$ , which is then slid to the left and is

placed at  $x_2 = 1/2 - \varepsilon$ . It yields a cell with an upper-right corner at  $(1/2 - \varepsilon, 1/2 - \varepsilon, 1, 1, \dots, 1)$ . This partition-and-slide process is repeated  $d$  times, resulting in a cell whose upper-right corner is the point  $p_1$ .

Now, let us turn our attention to point  $p_2$ , all of whose coordinate values are  $1/4 - \varepsilon$ . The first split is at  $x_1 = 1/2(1/2 - \varepsilon) = 1/4 - \varepsilon/2$ . This split separates  $p_1$  from  $p_2$ , and so is not slid. The lower-left corner of the cell containing  $p_2$  is at the origin, while the upper-right corner is at  $(1/4 - \varepsilon/2, 1/2 - \varepsilon, 1/2 - \varepsilon, \dots, 1/2 - \varepsilon)$ . The next splitting axis is  $x_2$ , which is bisected at  $x_2 = 1/2(1/2 - \varepsilon) = 1/4 - \varepsilon/2$ , which is then slid to the left and is placed at  $x_2 = 1/4 - \varepsilon$ . This partition-and-slide process is repeated once for each of the remaining coordinate values for a total of  $d - 1$  times, and hence the final upper-right corner of this cell is located at  $(1/4 - \varepsilon/2, 1/4 - \varepsilon, 1/4 - \varepsilon, \dots, 1/4 - \varepsilon)$ . Note that the value of the first coordinate is different from the rest because it was used to separate  $p_1$  from  $p_2$ , and thus was not subject to sliding.

Next, we process  $p_3$ . Again, the first split will be on  $x_1$ . It is used to separate  $p_2$  from  $p_3$ , and so is not slid. The process that we have just described is repeated for the remaining points, once per point, except for the last point. Therefore, we have made  $d$  partition-and-slide operations to separate  $p_1$  from the rest of the points, while for each of the remaining points  $p_i$  ( $1 < i < N$ ), we have made  $d - 1$  partition-and-slide operations to separate  $p_i$  from  $p_{i-1}$ . Thus, for  $n$  points, we have a total of  $d + (N - 2) \cdot d + 1 = (N - 1) \cdot d + 1$  partition operations of which  $d + (N - 2) \cdot (d - 1) = (N - 1) \cdot (d - 1) + 1$  are partition-and-slide operations. Since each partition-and-slide operation results in the creation of one empty leaf node, we have  $(N - 1) \cdot (d - 1) + 1 = O(N \cdot d)$  empty leaf nodes. Alternatively, since the total number of leaf nodes is one more than the number of partitions, and since there are  $N$  nonempty leaf nodes, the number of empty leaf nodes is  $N$  less than the number of partitions—that is,  $1 + (N - 1) \cdot d + 1 - N = (N - 1) \cdot (d - 1) + 1$ .

To see that the number of empty leaf cells is at most  $N \cdot d$ , we observe that each empty leaf node results from a partition-and-slide operation and hence is supported by a point. Each point can support at most  $d$  different empty leaf nodes, one for each coordinate or dimension. A point cannot support more than  $d$  different empty leaf nodes because this would imply that for some dimension it has been slid into from two different sides, which is impossible.

To see why this is impossible, consider an example in two dimensions, and suppose that point  $p$  has been slid into from a vertical split to the right of  $p$ . We now show how a slide could hit  $p$  from the other side. Assume that we make a subsequent vertical split to left of  $p$ . In order for such a split to be attempted, there must be some other point  $p'$  in the same cell as  $p$  (otherwise this would be a leaf). For a slide to take place,  $p'$  must be to the right of the midpoint split, as is  $p$ , since otherwise it is not a trivial split. Thus, the empty cell on the right side of  $p$  would be supported by  $p$ , and the empty cell on the left side of  $p$  would be supported by a different point  $p'$ . Therefore, we cannot slide into  $p$  from two different sides. Observe that if points are not in general position, and  $p$  and  $p'$  have the same  $x$  coordinate value, then  $p$  could be slid into from both sides. However, as this example shows, there must be at least two points  $p$  and  $p'$  sandwiched between the two lines, so the above argument still applies.

## Solutions to Exercises in Section 1.5.2.4

(a)

(b)

(c)

(d)

### Solutions to Exercises in Section 1.5.2.3

1. The probability that  $i$  bit positions of  $c$  records are not sufficient to resolve the overflow (i.e., they have identical values) is  $p_i = 2^{-ic}$ , and the expected number of bits that must be compared is  $E = \lim_{h \rightarrow \infty} \sum_{i=1}^h i \cdot p_{i-1} \cdot (1 - p_i)$ . Orenstein [1413] shows that  $E$  is bounded by  $28/9$ , and as  $c$  increases, it approaches 1.

### Solutions to Exercises in Section 1.5.2.4

2. Make sure that at least one split results in more than one point in each node. For example, compare Figure S.3(a,b) and Figure S.3(c,d), which correspond to the block and tree representations of a path-compressed PR k-d tree and a sliding-midpoint k-d tree, respectively, for the same four-point dataset where the path-compressed PR k-d tree is shallower than the sliding-midpoint k-d tree.

Figure S.3

The (a) block and (b) tree representations of a path-compressed PR k-d tree, for the same four-point dataset, that is shallower than its sliding-midpoint k-d tree with corresponding (c) block and (d) tree representations.

**Solutions to Exercises  
in Section 1.5.2.4**

(a)

(b)

(c)

(d)

Figure S.4  
The (a) block and (b) tree representations of a path-compressed PR k-d tree, for the same six-point dataset, that is deeper than its sliding-midpoint k-d tree with corresponding (c) block and (d) tree representations.

3. No, as can be seen by comparing Figure S.4(a,b) and Figure S.4(c,d), which correspond to the block and tree representations of a path-compressed PR k-d tree and a sliding-midpoint k-d tree, respectively, for the same six-point dataset where the path-compressed PR k-d tree is deeper than the sliding-midpoint k-d tree.
4. Both structures have the same number of leaf and nonleaf nodes. However, the nonleaf nodes of the path-compressed PR k-d tree are less complex than those of the sliding-midpoint k-d tree as they only need to store a bit pattern corresponding to the splits or coordinate values whose testing has been avoided, in contrast to the sliding-midpoint k-d tree where the full value of the split partition must also be recorded.
5. The path-compressed PR k-d tree avoids the worst case of the open-sliding midpoint k-d tree by not having any empty nodes, thereby enabling the retention of the property of having  $N$  leaf nodes for  $N$  points. Thus, the number of nodes in the path-compressed PR k-d tree is always less than or equal to the number of nodes in the open-sliding midpoint k-d tree. In particular, we see that the empty nodes that result in the worst case of the open-sliding midpoint k-d tree are avoided by the bitstring corresponding to the splits that have been avoided whose constituent bits indicate which coordinate values need not be tested as testing them will result in trivial splits. However, no such conclusion can be drawn about the relationship between the maximum depths of the path-compressed PR and open-sliding midpoint k-d trees. In particular, the maximum depth of the open-sliding midpoint k-d tree corresponding to the four-point dataset in Figure S.3 is deeper than that of the corresponding path-compressed PR k-d tree due to the presence of the two empty nodes at the left son of the root and the left son of the right son of the root. On the other hand, compare Figure S.5(a,b) and Figure S.5(c,d), which correspond to the block and tree representations of a path-compressed PR k-d tree and an open-sliding midpoint k-d tree, respectively, for the same eight-point dataset where the path-compressed PR k-d tree is deeper than the open-sliding midpoint k-d tree.

1. See [441].
2. See [441].
3. See [441].
5. See [441].

## Solutions to Exercises in Section 1.5.2.7

1. When a centroid shrink operation is applied to a region with an inner box, we cannot create two inner boxes, and thus we must use a decomposition process that may require as many as one shrink, one split, and one shrink operation, each of which requires one additional level in the tree for a maximum of three additional levels. There is also one more level corresponding to the split of the alternating split and shrink sequence of operations. Of course, the split does not necessarily result in a reduction of the number of points in each of the child regions.
2. No. This is true only if  $2/3 \leq x < 1$ . If  $x \geq 2/3$ , then the BBD-tree shrink described earlier will trivially satisfy this requirement. However, if  $x < 2/3$ , consider an instance of a square cell  $c$ , where  $b/3$  of the points are clustered near three of the four distinct corners of  $c$ . The first midpoint split will create two cells containing  $b/3$  and  $2b/3$  points each. The subsequent split applied to the cell containing  $2b/3$  points will create two cells each containing  $b/3$  points. An inner box based on midpoint splits either contains at least two clusters (and hence at least  $2b/3$  points) or no more than one cluster (and hence the outer box has at least  $2b/3$  points). Thus, the  $2/3$  factor is tight. Notice that if we remove the restriction that splits occur along midpoint lines, then a more balanced decomposition may be possible, but the issue of maintaining cells of bounded aspect ratios must also be considered. See the BAR tree of Duncan et al. [516, 517], discussed in Section 1.5.1.4, for an alternative approach.

## Solutions to Exercises in Section 1.5.3

1. Given a conjugation tree storing  $N$  points, the time required to perform a halfplanar search is given by the recurrence relation

$$Q(N) = Q(N/2) + Q(N/4) + O(\log_2 N)$$

This can be seen by observing that given an arbitrary node  $v$  of a conjugation tree  $T$ , the range of at least one of the grandchildren of  $v$  is either in  $h$  or has an empty intersection with  $h$ . This is because, given a pair of intersecting lines  $A$  and  $B$  in the plane, a third line  $C$  can only intersect three of the regions formed by the intersection of  $A$  and  $B$ . The  $O(\log N)$  factor arises from the need to determine  $\text{int}(v)$  (i.e., the intersection of  $g$ , the line which bounds  $h$ , with  $\text{range}(v)$ ). This process can take as much as  $O(\log_2 N)$  time as, at the maximum depth of the tree,  $\text{range}(v)$  consists of  $O(\log_2 N)$  line segments. In fact, this intersection test need not take as much as  $O(\log_2 N)$  time even though the region corresponding to  $\text{range}(v)$  gets more complicated in terms of the number of edges since, as the tree is descended, only one additional edge (i.e., line) needs to be tested at each new level. This recurrence relation is similar to the definition of a sequence of Fibonacci numbers and is solved in a similar manner to yield  $Q(N) = O(N^{\log_2(1+\sqrt{5}-1)}) = O(N^{0.695})$ . Note that when solving the line search problem, the  $O(\log_2 N)$  factor is needed as it corresponds to the complexity of searching the array of points that lie on the line stored at the node.

**Solutions to Exercises  
in Section 1.6**

2. For three dimensions, we need to be able to find three planes that subdivide a set of  $N$  points into eight subsets, each of which is approximately of size  $N/8$ . This is possible [2048] but not via a sequence of Ham-Sandwich cuts as a Ham-Sandwich cut for four sets in three dimensions cannot be found [2048]. In general, it is known that in  $d \geq 5$  dimensions, there are sets of  $N$  points such that no  $d$  hyperplanes can simultaneously equipartition them so that each  $d$ -dimensional “quadrant” can contain at most  $N/2^d$  points [114]. The problem is open for  $d = 4$  [540].

**Solutions to Exercises in Section 1.6**

3. See [1992].
4. See [1992].
6. The query  $x < 2$ .
7. See [582].
10. See the Peano-Hilbert order discussed in Section 2.1.1.2 of Chapter 2 and shown in Figure 2.5(d). It has the property that every element is a 4-adjacent neighbor of the previous element in the sequence. Goldschlager [718], Goodchild and Grandfield [725], and Witten and Wyvill [2012] give algorithms to extract the  $x$  and  $y$  coordinate values of a point given its Peano-Hilbert code. Fisher [616], Faloutsos and Roseman [591], Jagadish [937], and Liu and Schrack [1190, 1191] give algorithms to construct a Peano-Hilbert code for a point given its  $x$  and  $y$  coordinate values.

**Solutions to Exercises in Section 1.7.1.1**

1. Consider a region page  $f$  that spans the region with a lower-left corner at  $(0, 0)$  and upper-left corner at  $(100, 10 \cdot (c + 1))$ . Let the region have  $c + 1$  horizontal regions of equal length that are parallel (i.e., partitions at  $y_i = 10i$ ,  $1 \leq i \leq c$ ). Now, introduce a partition at  $x = 50$ . The result is that  $f_1$  and  $f_2$  each contain  $c + 1$  regions, and thus both  $f_1$  and  $f_2$  overflow. Of course, this can be avoided by splitting along  $y$  such as at  $y_c$  (i.e.,  $y = y_c = 10c$ ).
2. We can choose the partition at the root of the  $k$ -d tree corresponding to the space partition induced by the overflowing region page.

**Solutions to Exercises in Section 1.7.1.3**

1. See [829].
2. See [829].

**Solutions to Exercises in Section 1.7.1.4**

1. Pick a point  $p$  inside a rectangle  $R$ , draw a horizontal and vertical line through  $p$ , and distribute the  $4k$  points so that  $k$  points lie on each of the lines intersecting at  $p$ . It is impossible to partition  $R$  with a vertical or horizontal line so that each of the resulting partitions has  $2k$  points [1201].
2. We use a constructive proof. Examine the root node of the generalized  $k^+$ -d tree. If one of the subtrees, say  $i$ , contains more than two-thirds of the nodes of the tree, then descend to  $i$ . This process is repeated until neither subtree of  $i$  contains more than two-thirds of the nodes in the

entire tree. In this case, at least one of the subtrees  $S$  contains at least one-third of the total number of nodes. Note that if neither subtree contained at least one-third of the total number of nodes, then the total number of nodes in both subtrees would be less than two-thirds, thereby contradicting the assumption that the subtree rooted at  $i$  has more than two-thirds of the total number of nodes in the tree. Thus, we can extract  $S$  from the whole tree and replace it with an external marker, resulting in two generalized  $k^+$ -d trees that both have at least one-third of the nodes in the original tree.

3. We only sketch a proof of the two-dimensional case here. For more details, including a proof for arbitrary dimensions, see [1201]. Let  $m_x$  and  $m_y$  be the median values along the  $x$  and  $y$  dimensions. If either of  $m_x$  or  $m_y$  splits the underlying space so that at least one-third of the points have  $x$  ( $y$ ) coordinate values less than  $m_x$  ( $m_y$ ) and at least one-third of the points have  $x$  ( $y$ ) coordinate values greater than  $m_x$  ( $m_y$ ), then we can use  $m_x$  ( $m_y$ ) for splitting, and we are done. Otherwise, the problem is that at least one-third of the points have an  $x$  ( $y$ ) coordinate value equal to  $m_x$  ( $m_y$ ). In this case, we can show that at least one of the closed quadrants formed by the partition lines  $x = m_x$  and  $y = m_y$  contains between one-third and two-thirds of the points. To see this, we observe that less than one-third of the points are to the left of  $m_x$  (i.e., with a smaller  $x$  value) and less than one-third of the points are below  $m_y$  (i.e., with a smaller  $y$  value). Thus, at most two-thirds of the points are either on the left side or lower side. This means that at least one-third of the points have  $x$  and  $y$  values that are greater than or equal to  $m_x$  and  $m_y$  (i.e., lie in the closed top-right quadrant). We can make a similar argument to show that at least one-third of the points lie in the closed bottom-left quadrant. At this point, we see that at least one of these closed quadrants contains at most two-thirds of the points since, if both of the closed quadrants contain more than two-thirds of the points, then the sum of the number of points in the two quadrants (possibly subtracting one if they share a point) is larger than the total number of points. Therefore, we have established that at least one of the quadrants contains between one-third and two-thirds of the points. Similar techniques are used to establish this bound for higher dimensions.
4. See [1201].

### Solutions to Exercises in Section 1.7.1.5

2. No, because the page being split is a leaf node in a  $k$ -d trie that is a B-partition before the split, and it remains so after the split.
3. Use the solution of Ouksel and Mayer [1438], which is essentially a two-stage binary search process. Assume for the moment that all blocks are in main memory, and thus each of the sets of blocks at a nesting level is represented by a balanced binary tree. Using binary search through the  $h$  nesting levels means that  $\delta = \log_2(h + 1)$  nesting levels will be accessed. The maximum number of blocks contained in these nesting levels is  $N - (h - \delta)$  as each of the nesting levels that has been bypassed by the search contains at least one block. Assuming that the  $\delta$  examined nesting levels are numbered  $s_1, s_2, \dots, s_\delta$ , with  $1 \leq s_j \leq h$  for  $1 \leq j \leq \delta$ , and letting  $N_{s_1}, N_{s_2}, \dots, N_{s_\delta}$  denote their cardinality, then in the worst-case the binary search through the  $\delta$  nesting levels will require accessing  $\max\{\sum_{j=1}^{\delta} \log_2(N_{s_j} + 1) \mid \sum_{j=1}^{\delta} N_{s_j} \leq N - (h - \delta)\}$  blocks. We know that  $\sum_{j=1}^{\delta} \log_2(N_{s_j} + 1) = \log_2 \prod_{j=1}^{\delta} (N_{s_j} + 1)$ , and since the logarithm is a monotonic function, the worst-case access quantity attains its maximum if and only if  $\prod_{j=1}^{\delta} (N_{s_j} + 1)$  is maximal under the condition  $\sum_{j=1}^{\delta} N_{s_j} \leq N - (h - \delta)$ . However, this maximum is attained if  $N_{s_j} = (N - (h - \delta)) / \delta$  for each  $j, 1 \leq j \leq \delta$ . Substituting this value in the worst-case access quantity yields

$$\begin{aligned} & \delta \cdot \lceil \log_2 \left( \frac{N - (h - \delta)}{\delta} + 1 \right) \rceil \\ &= \log_2(h + 1) \cdot \lceil \log_2(N - h + 2 \cdot \log_2(h + 1)) - \log_2(\log_2(h + 1)) \rceil. \end{aligned}$$

This quantity is  $O(\log_2 h \cdot \log_2 N)$ . Now, suppose that each set of blocks at a nesting level is represented by a B-tree. In this case, we use a similar analysis to that used when the blocks are in a balanced binary search tree in main memory so that, in the worst case, the search through

the  $h$  nesting levels will require accessing the following number of B-tree nodes:

$$\begin{aligned} & \sum_{j=1}^{\delta} \log_{\lceil m/2 \rceil} (N_{s_j} + 1) \\ &= \log_2(h+1) \cdot [\log_{\lceil m/2 \rceil} (N - h + 2 \cdot \log_2(h+1)) - \log_{\lceil m/2 \rceil} (\log_2(h+1))] \end{aligned}$$

This quantity is  $O(\log_2 h \cdot \log_{\lceil m/2 \rceil} N)$ .

4. See [1710].
6. See [1710].
7. See [1710].
8. See Theorem 1 in [1710], whose proof can be found in [1706], which assumes that the smallest partition size on the domain of each key is the same.

### Solutions to Exercises in Section 1.7.1.6.1

1. (Houman Alborzi)

*Proof* Let  $n = |V|$ . Mark all vertices  $v$  of  $F(V)$  that have  $n_V(v) \geq \lfloor \frac{1}{2}n \rfloor$ . Observe that if any such vertex could be marked, then the marked vertices form a single path starting at a root of  $F(V)$ . Consider the two cases:

- (a) At least one vertex was marked. Now, consider  $u$ , the marked vertex with the minimum height. Observe that no children of  $u$  were marked as, otherwise,  $u$  does not have the minimum height. We either have
  - i.  $\lfloor \frac{1}{2}n \rfloor \leq n_V(u) \leq \lfloor \frac{2}{3}n \rfloor$ . We let  $U$  be the set of regions in  $V$  contained by  $u$ .
  - ii.  $n_V(u) = \lfloor \frac{2}{3}n \rfloor + 1$ . We let  $U$  be the set of regions in  $V$  properly contained by  $u$ .
  - iii.  $n_V(u) > \lfloor \frac{2}{3}n \rfloor + 1$ . Notice that for all children  $w$  of  $u$ , we have  $n_V(w) < \lfloor \frac{1}{2}n \rfloor$ , and hence  $u$  has more than one child. Build  $X$ , a subset of children of  $u$  as follows. First, let  $X$  be the set of children of  $u$ . Next, arbitrarily remove elements of  $X$  until  $\sum_{w \in X} n_V(w) \leq \lfloor \frac{2}{3}n \rfloor$ . Now, in case  $\sum_{w \in X} n_V(w) \geq \lceil \frac{1}{3}n \rceil$ , let  $U = X$ . Otherwise, letting  $x$  denote the last element taken out from  $X$ , we have  $\lfloor \frac{2}{3}n \rfloor < \sum_{w \in X} n_V(w) + n_V(x)$  and  $\sum_{w \in X} n_V(w) < \lceil \frac{1}{3}n \rceil$ . These two inequalities can be rewritten as  $\lfloor \frac{2}{3}n \rfloor \leq \sum_{w \in X} n_V(w) + n_V(x) - 1$  and  $\sum_{w \in X} n_V(w) \leq \lceil \frac{1}{3}n \rceil - 1$  as we know that for any integers  $i$  and  $j$ ,  $i < j$  implies that  $i \leq j - 1$ . Combining these relations and eliminating  $\sum_{w \in X} n_V(w)$ , we have that  $\lfloor \frac{2}{3}n \rfloor - n_V(x) + 1 \leq \lceil \frac{1}{3}n \rceil - 1$ , which can be rewritten as  $\lfloor \frac{2}{3}n \rfloor - \lceil \frac{1}{3}n \rceil + 2 \leq n_V(x)$ . This is simplified by noting that  $\lfloor \frac{2}{3}n \rfloor + 1 \geq \lceil \frac{2}{3}n \rceil$  and  $\lceil \frac{2}{3}n \rceil + 1 \geq \lceil \frac{1}{3}n \rceil + \lceil \frac{1}{3}n \rceil$  to yield the desired result  $n_V(x) \geq \lceil \frac{1}{3}n \rceil$ , and we let  $U$  be the set of regions in  $V$  contained by  $x$ .
- (b) No vertex was marked. Follow case (iii) above with  $X$  initially being the set of roots of  $V$ .

In all cases above, we choose  $U$  to be a subset of  $V$  such that  $\lceil \frac{1}{3}n \rceil \leq |U| \leq \lfloor \frac{2}{3}n \rfloor$ . We let  $S = V \setminus U$ . Observe that in case (a),  $S$  encloses  $U$ , and in case (b),  $S$  and  $U$  are disjoint. ■

### Solutions to Exercises in Section 1.7.1.6.2

1. Splitting the overflowing region  $r$  into two regions  $a$  and  $b$  that are disjoint may result in a situation where neither  $a$  nor  $b$  corresponds to guards (for this to happen,  $a$  or  $b$  must

have been shrunk so that their union is no longer the same as  $r$ ), which means that  $a$  and  $b$  must be reinserted, thereby possibly causing other reinsertions while descending the directory hierarchy. For more details about the complexity of this process, see the brief discussion in Section 1.7.1.6.4 as well [644]. In contrast, if the resulting split is into contained regions, say  $a$  contains  $b$ , then there are two possibilities:

- (a) The node corresponding to region  $a$  continues to guard the same regions as  $g$  while  $b$  does not. This means that  $a$  is retained as a guard at level  $v$ .  $b$  must be demoted to its proper position in the directory hierarchy using the search algorithm. In some cases, it could be that  $b$  also encloses other regions at a shallower level, and thus it must be properly inserted as their guard. This involves modifying the exact match search procedure to check if there exist other regions  $c$  that are contained in  $b$  and do not have a guard at level  $v$  that is contained in  $b$ , in which case  $b$  becomes their guard and any existing guard  $d$  of  $c$  at the same level is now the candidate for demotion. If  $c$  does have a guard at level  $v$  that is contained in  $b$ , then  $b$  is not a guard of  $c$ , and  $b$  is demoted to the next deeper dlevel (unless there is another region for which it can serve as a guard).
- (b)  $b$  replaces  $g$  as a guard. This means that  $a$  is demoted using the same procedure as in (a).

Note that the eventual insertion of a demoted region may cause overflow of a directory node, in which case it is dealt with in the same way as discussed in the text. For more details, see [643].

2. The main issue with deletion in a BV-tree is how to redistribute the contents of the result of merging an underflowing directory node with another directory node (as well as how to choose it) while adhering to the minimum node occupancy conditions. The redistribution question is one of finding an appropriate splitting strategy for the merged directory nodes. See [642] for more details.

### Solutions to Exercises in Section 1.7.1.6.3

1. Assume that the root of the directory hierarchy is at level  $v$  and that the deepest directory node is at level 1. The search starts at dlevel  $v$ . At each step, the search always descends to a node at the next deeper dlevel. This is done either through an unpromoted entry in the current node or an entry in the guard set representing a region at the next deeper level. The search terminates upon reaching a point page (corresponding to a region at level 0). Thus, all searches are of length  $v$ .
2. The unpromoted entries in the root of a BV-tree cover the entire dataspace spanned by the tree. Also, any region formed by the partitioning process is carved from this space. Thus, if no unpromoted entry  $e_s$  exists in the root that covers  $p$ , then this implies that no region in the whole tree covers  $p$ . In particular, there cannot be a guard  $e_r$  in the root that covers  $p$ .
3. Suppose that there is another matching guard  $e_t$  whose region  $t$  is contained by  $s$ . In this case, assume that  $t$  does not enclose  $r$ . Below we prove that this is impossible. Since both  $r$  and  $t$  are matching guards,  $r$  and  $t$  contain  $p$ , and thus they must intersect. However, according to the nonintersection boundary property, this can occur only if  $t$  contains  $r$  or vice versa. Since we assumed that  $t$  does not contain  $r$ , it must be that  $r$  contains  $t$ . However, this contradicts our original assumption that  $r$  was the best match guard as we have now found a better best match, namely  $e_t$ . Thus, any guards enclosed by region  $s$  also enclose  $r$ .
4. (Gísli R. Hjaltason) Since guards in  $a$  correspond to regions at a deeper level than  $v - 1$  in the containment hierarchy, the fact that the best match  $e_r$  is a guard in  $a$  means that  $p$  is contained in a region at a deeper level than  $v - 1$ . A basic assumption of the BV-tree is that all regions that are not at the topmost level in the containment hierarchy must be covered by regions at a shallower level. Therefore, a region at level  $v - 1$  in the containment hierarchy that contains  $p$  must exist. Let  $s$  be the smallest such region. Since the search led to  $a$ , the region  $b$  corresponding to  $a$  must contain  $p$ . Thus,  $s$  must either be contained in  $b$ , or  $b$  must be contained in  $s$  (this is a consequence of the nonintersection property of region boundaries). However, if  $s$  is contained in  $b$ , then  $e_s$  must be in  $a$ . Otherwise, if  $b$  is contained in  $s$ , then  $e_s$

would be a guard for  $a$ , and therefore,  $e_s$  must be in the guard set. In either case, a desired  $e_s$  is found.

5. This modification is not valid. For example, suppose that we search for point  $z$  in Figure 1.85. The modified search procedure would find the guard corresponding to region  $a_0$  as the best match and would continue the search in the directory node corresponding to  $a_0$ . This will lead to an answer of  $a_0$ , which is wrong. In contrast, the unmodified algorithm will descend to the directory node whose corresponding region is  $b_2$  with a guard set consisting of  $a_1$  and  $a_0$ . Next, it would descend to  $b_1$  with guard  $e_0$  replacing  $a_0$ . At this point, it determines that  $z$  is in  $e_0$ .

### Solutions to Exercises in Section 1.7.1.6.4

1. The maximum number of directory nodes arises when there are no guards. In this case, we have a structure similar to a B-tree. A B-tree of height  $v$  where each directory node has  $F$  children contains  $F^{v-i}$  directory nodes at dlevel  $i$ ,  $1 \leq i \leq v$ , when the leaves are at dlevel 1. Thus, the total number of directory nodes is  $\sum_{i=1}^v F^{v-i} = \sum_{i=0}^{v-1} F^i$ , which is  $(F^v - 1)/(F - 1) \approx F^{v-1}$  for  $F \gg 1$ .
2. This case arises when we have the maximum number of guards in each directory node. This means that every directory node at level  $i$  contains  $F$  children among which are included  $i - 1$  guards for each unpromoted entry. There are  $F/i$  unpromoted entries at dlevel  $i$  whose corresponding directory nodes are subtrees of height  $i - 1$ . For each of the  $F/i$  unpromoted entries at dlevel  $i$ , we have one guard corresponding to a promoted region whose corresponding directory node is a subtree of height  $i - 2$ , another corresponding to a promoted region whose corresponding directory node is a subtree of height  $i - 3$ , and so on. Finally, for each unpromoted entry we have a guard whose corresponding region is a point page (i.e., a region at level 0 in the containment hierarchy). This leads to the following recurrence relation for  $td(v)$ , the number of point pages in a subtree of height  $v$ :  $td(v) = F/v \cdot (1 + \sum_{i=1}^{v-1} td(i))$ , where  $td(1) = F$ . This resolves to the closed form  $td(v) = (F + v - 1)! / ((F - 1)!v!) \approx F^v/v!$  for  $F \gg v$ . For more details on the summation, see [643].
3. The solution is obtained in the same manner as that for Exercise 2. In particular, for a subtree of height  $i$  in a BV-tree, we have one directory node at the root of the subtree. The root node contains  $F/i$  unpromoted entries, each of whose corresponding directory node is a subtree of height  $i - 1$ . Each unpromoted entry in the root has  $i - 1$  guards, for regions whose corresponding directory nodes are subtrees of heights  $i - 2$  through 0. The regions corresponding to subtrees of height 0 are point pages, so they do not get counted. Once again, we use a recurrence relation for  $ti(v)$ , the number of directory nodes for a subtree of height  $v$ :  $ti(v) = 1 + F/v \cdot \sum_{i=1}^{v-1} ti(i)$ . This is simplified by ignoring the root index in the initial sum, thereby obtaining  $ti(v) \approx F/v \cdot \sum_{i=1}^{v-1} ti(i)$ , where  $ti(0) = 1$ . This resolves to the closed form  $ti(v) \approx (F/v!) \cdot ((F + v - 1)! / (F + 1)!) \approx F^{v-1}/v!$  for  $F \gg v$ . For more details on the summation, see [643].
4. Combine the results of Exercises 1, 2, and 3.
5. Modify the recurrence relation used in the solution to Exercise 2 to be  $td(v) = F \cdot (1 + \sum_{i=1}^{v-1} td(i))$ , which is equivalent to  $td(v) = td(v - 1) \cdot (F + 1)$ , where  $td(1) = F$ . This gives the closed formula  $td(v) = F \cdot (F + 1)^{v-1} \approx F^v$  for  $F \gg 1$ . For more details on the summation, see [643].
6. Modify the recurrence relation used in the solution to Exercise 3 to be  $ti(v) = 1 + F \cdot \sum_{i=1}^{v-1} ti(i)$ , which is equivalent to  $ti(v) = ti(v - 1) \cdot (F + 1)$ , where  $ti(1) = 1$ . In general, we have  $ti(v) = (F + 1)^{v-1} \approx F^{v-1}$  for  $F \gg 1$ . For more details on the summation, see [643].
7. Divide the result of Exercise 6 by the result of Exercise 5.
8. Using the same reasoning as in the solution to Exercise 6, the total size of the directory nodes is given by the recurrence relation  $si(v) = B \cdot v + F \cdot \sum_{i=1}^{v-1} si(i)$ , which is equivalent to  $si(v) = si(v - 1) \cdot (F + 1) + B$ , where  $si(1) = B$ . If  $F \gg 1$ , then  $si(v) \cdot (F + 1) \gg B$  so that  $si(v) \approx si(v - 1) \cdot F$ . Solving this recurrence, we have  $si(v) \approx BF^{v-1}$  for  $F \gg 1$ . For more details on the summation, see [643].

## Solutions to Exercises in Section 1.7.1.6.5

1. See Figure S.6, which shows a dataset that cannot be subdivided into two sets where the minimum bounding hyperrectangles of the sets are either disjoint or one is contained in the other.
2. One possible solution is always to split the rectangles using methods similar to those used in the construction of an  $R^+$ -tree [593, 1718, 1803] (see Section 2.1.5.3 of Chapter 2). This is only possible if the actual data objects do not have extent and are not allowed to overlap. Otherwise, for example, if all the objects are lines passing through a point  $p$ , then unless the objects are decomposed into line segments, it is impossible to form a containment hierarchy. In fact, any region that contains point  $p$  must contain all the line segments as well, and hence all the line segments need to be placed in the same region.

## Solutions to Exercises in Section 1.7.1.7

1. Assume a set of 15 points. In this case, partitioning at the median yields a tree with four leaf nodes all at the same depth such that from left to right we have 3, 4, 4, and 4 points. In contrast, using the approximate median split, we have a leaf node containing 5 points in the left subtree of the root, while the right subtree of the root is a binary tree with two leaf nodes each containing 5 points. Thus the total number of leaf nodes is three, which is less than four.
3. There are two cases, depending on whether the number of elements  $N$  to be inserted is a multiple of  $b$ . If  $N$  is a multiple of  $b$ , then the number of elements in each subtree is also a multiple of  $b$ , and thus all leaf nodes are full as they correspond to subtrees of size one node. If  $N$  is not a multiple of  $b$ , then check if  $N$  is less than  $2b$ . If it is, then we have at most two nonfull nodes. Otherwise, if it is not (i.e.,  $N$  is greater than  $2b$ ), then the number of elements in the left subtree will always be a multiple of  $b$ , while the number of elements in the right subtree will not be a multiple of  $b$ . Thus, the left subtree will get constructed such that all the leaf nodes are full. Applying this argument inductively (by recurring on the depth of the tree), we obtain a VAMSplit  $k$ -d tree in which all the leaf nodes are full except for the two child nodes of the rightmost internal node.
4. See [1989].

## Solutions to Exercises in Section 1.7.2.1

1. Insertion and deletion of partitions would be easier as no data movement would be required. Notice that the array could also be searched using binary searching (i.e., the binary trees are not necessary for logarithmic search).
3. In the twin grid file, instead of partitioning a grid upon the insertion of a point, which would otherwise cause overflow, we have an opportunity to avoid the partition by inserting the point into the other grid file. Thus, the likelihood of overflow is reduced, especially if some of the points are clustered in a region that would have to be split otherwise.
4. By adding more grid files.
5. See [1550].

## Solutions to Exercises in Section 1.7.2.3.1

1. No. None of the properties hold. For example, the value of  $l(c)$  ( $u(c)$ ), the location of the point in the underlying space at the corner of grid cell  $c$  that is closest to (farthest from) the origin, is not necessarily smaller (greater) than or equal to that of every other point in  $c$ . Similarly, some of the values of the points in  $c$  are larger than  $l(c)$  and smaller than  $u(c)$ .

---

## Solutions to Exercises in Section 1.7.2.3.1

Figure S.6  
A generalized pattern for a collection of an arbitrary number of hyperrectangle minimum bounding objects for which it is impossible to guarantee satisfaction of the containment hierarchy requirements.

### Solutions to Exercises in Section 1.7.2.3.2

1. Each time we had a partition, we would have to rearrange the contents of the arrays.
2. See [1428].

### Solutions to Exercises in Section 1.7.2.3.3

1. See [906].
2. See [906].
3. The property does not hold in general, although it appears to hold one-half of the time. Can you prove that it holds exactly one-half of the time?

### Solutions to Exercises in Section 1.7.2.3.4

1. See [1084].

### Solutions to Exercises in Section 1.7.2.4.2

1. If they were implemented as arrays, then we could not capture the order in which the partitioning hyperplanes were applied. Varying this order is what distinguishes PLOP hashing from quantile hashing and conventional linear hashing with MDEH as the hashing function.

### Solutions to Exercises in Section 1.7.2.4.3

3. See the Peano-Hilbert order discussed in Section 2.1 of Chapter 2 and shown in Figure 2.5(d) of Chapter 2. It has the property that every element is a 4-adjacent neighbor of the previous element in the sequence.
4. Reversed bit interleaving applied to the result of  $f(x) = x \div 12.5$  and  $f(y) = y \div 12.5$ :

5. No. Since the hash function is of the form  $h(k) = k/2^n$ , reversed bit interleaving will have an effect analogous to that in which all records in a given bucket agree in the least significant digits. This is not quite true due to the nonuniformity of the relative load of the buckets.

## Solutions to Exercises in Section 1.7.2.4

1. See [1288, 1428] for a discussion of how this might be achieved.
3. Although theoretically feasible, this would require a different hashing function than MDEH, whose specification and computation would be quite complex.
4. It is true for  $d = 2$  when there are just 16 grid cells. For example, consider the splits that take place in the two methods once grid cells 0–7 have been created in Figures 1.100(d) and 1.101(d). Figures 1.100(e) and 1.101(e) show the resulting space decomposition after creating the same number of grid cells (i.e., 8–11) using the two methods. In particular, we find that using MDEH resulted in splitting 4 grid cells that are contiguous (i.e., 0, 4, 1, and 6), while this was not the case for the 4 grid cells that were split when using linear hashing with reversed bit interleaving (LHRBI) (i.e., 0–3). However, once more partitions are performed (e.g., 64 grid cells), this property no longer holds within a slice for grid cells that are split in succession.

## Solutions to Exercises in Section 1.7.2.5

1. The reason is that buckets are not necessarily full when they are split by linear hashing. Also, linear hashing requires overflow buckets and makes use of a storage utilization factor in deciding when to split a bucket.
2. As long as the grid directory does not grow too large (i.e., there are not too many clusters of size larger than the bucket capacity), EXCELL seems to be the choice due to its simplicity and performance guarantees.
3. MLOPLH looks up a value as follows. Let  $i = n + 1$ . Start with  $h_i(v)$ , and assume that the result is bucket  $b$ . If  $b \geq m$ , then rehash using  $h_i(v)$ , where  $i = n$ , and again let the result be bucket  $b$ . In either case, if  $b$  is empty, then decrement  $i$  by 1 and rehash using  $h_i$ . This rehashing and decrementing process is repeated until either  $i < 0$ , or a nonempty bucket  $b$  is obtained, at which time we check to see if  $v$  is indeed in  $b$ .

## Solutions to Exercises in Section 1.8.5.3

2. No. Doing this would violate the  $k$ -instantiation property because of the partition tree block corresponding to  $r$  is no longer the minimum enclosing quadtree block of its  $k$  elements. In particular, since the block corresponding to  $s$  is  $k$ -instantiated (based on the fact that  $s$  was a node in the PK-tree before the deletion), it should correspond to a node in the PK-tree after the deletion as its partition tree block is still  $k$ -instantiated.

## Solutions to Exercises in Section 1.8.6

1. As long as the partitioning process stores the objects (i.e., points) in the leaf nodes, the PK-tree can be applied. The conventional point quadtree and the k-d tree store the objects (i.e., points) in both the leaf and nonleaf nodes. Thus, we cannot use them with the PK-tree. However, partitioning processes such as the pseudo quadtree and the pseudo k-d tree [1444] can be used.

## Solutions to Exercises in Section 1.9

1. It is difficult to place the pseudo quadtree in the tree as, on the one hand, it is a refinement of the point quadtree of type D in a manner analogous to the way in which the adaptive k-d tree

---

## Solutions to Exercises in Section 2.1.1.1

is a refinement of the k-d tree. However, according to our taxonomy, this type of refinement belongs at depth 6, and we have nothing in the tree at depth 5 to lead into it. On the other hand, the pseudo quadtree can also be viewed as a refinement of the grid file of type D at the same level as the point quadtree. This is the choice that we make. Making such an adjustment means that depth 6 is no longer meaningful, and we move the adaptive k-d tree to depth 5 as a descendant of the pseudo quadtree.

2. We are confronted with the same choices as in Exercise 1, and we resolve the problem in the same manner. Thus the optimized point quadtree is added as a refinement of type D of the grid file at the same level as the point quadtree and the pseudo quadtree.
3. The BD-tree should be placed alongside the PR k-d tree because it is a PR k-d tree with a truncated path to each node. This path bypasses the tests when one child is empty.
4. The range tree should be placed as a descendant of the sequential list at the same level as the inverted list. It should be of type H as the key governing the partition exhibits behavior of type D, while the data values of the remaining keys have no influence on the way the space is organized and hence exhibit behavior of type N. The priority search tree, inverse priority search tree, and multidimensional range tree should all be placed as descendants of the range tree at the same level as the fixed-grid method and of type D. They are of type D as they organize the data to be stored.
5. At depth 3, EXCELL is now type  $E_1$ , the grid file is type  $D_1$ , and the pyramid is type  $E_d$ . At depth 4, the PR k-d tree is a type  $E_1$  child of EXCELL, the PR quadtree is a type  $E_d$  child of the pyramid, the point quadtree is a type  $E_d$  child of the grid file, and the k-d tree is a type  $E_1$  child of the grid file. At depth 5, the adaptive k-d tree is a type  $E_1$  child of the k-d tree. How does the MX quadtree fit into the revised taxonomy?
6. Look at decompositions that make use of the Platonic solids in three dimensions.
10. A solution that proceeds by finding the closest pair of points in sequence need not be optimal as can be seen by considering the four points (0,2), (1,0), (3,0), and (4,2). The closest pair is (1,0) and (3,0). This means that the remaining pair is (0,2) and (4,2), which has a cost of 6. On the other hand, taking the pairs (0,2) and (1,0) followed by the pair (3,0) and (4,2) leads to a cost of  $2 \cdot \sqrt{5}$ , which, of course, is smaller. This is termed the greedy-method heuristic. The best known solution to the Euclidean matching problem using it is  $O(N^{3/2} \cdot \log_2 N)$  [179]. Although the greedy-method heuristic is not optimal, Reingold and Tarjan [1552] have shown that the result of its use is never worse than  $4/3 \cdot N^{\log_2 1.5}$ . For other literature on this topic, see the survey of Avis [113] and Tarjan [1859]. For approximate solutions based on space-filling curves, see Section 2.1.1.2 of Chapter 2 as well as [133, 926].  
Vaidya [1906] has developed an algorithm for finding the smallest Euclidean matching (i.e., for finding an exact solution) that runs in  $O(N^{2.5} \cdot \log_2^4 N)$  time. Previously, the best upper bound for solving this problem was  $O(N^3)$  [1119, 1859].
12. Lee [1126] suggests a transformation of the problem into an instance of the maximum clique problem (see Section 3.2 of Chapter 3 and the solution to Exercise 13 therein).

## Solutions to Exercises in Section 2.1.1.1

1.  $1/\sqrt{3}$ , 1,  $2/\sqrt{3}$ .
2.  $\sqrt{3}$  for  $[3^6]$ ; 1 and  $\sqrt{2}$  for  $[4^4]$ .
3. Treat every even-numbered row as if it has been shifted to the right (or left) by one-half of the interpixel distance.

## Solutions to Exercises in Section 2.1.1.2

1. If the image grows by the addition of rows or shrinks by the removal of rows from the end.
2. If the image grows from the center outwards by the addition of shells on the outside or shrinks inwards by the removal of shells on the outside.

3. Recall the definition of the Peano-Hilbert order, which stipulates that orientation is a key part of the construction process. In fact, after doubling the resolution, the Peano-Hilbert order of the  $4 \times 4$  square in the upper-left corner of Figure 2.5(d) should look like Figure 2.6(b). Note also that when we double the resolution to yield the  $4 \times 4$  square in the upper-left corner, the spatial orientation of the final cell in the order with respect to that of the first cell in the order is not the same. In other words, the curve exits the  $4 \times 4$  square in a different position—that is, assuming that the first cell is at the upper-left corner of a two-dimensional space, after an odd number of doublings, the Peano-Hilbert order exits at the upper-right corner of the space. On the other hand, after an even number of doublings, it exits at the lower-left corner. In contrast, all of the curves in Figure 2.6 exit the embedded space at the same position—that is, the lower-left corner of the space.
4. See Section 3.4.1 in [1636].
5. Assuming a  $2^n \times 2^n$  image, an  $O(n^2)$  algorithm is given in [725]. Algorithms are also given in [718, 2012]. An  $O(n)$  algorithm can be achieved by inverting the algorithm given in [937].
6. See [591] for an  $O(n^2)$  algorithm and [616, 937, 1190] for an  $O(n)$  algorithm, assuming a  $2^n \times 2^n$  image. The algorithm in [591] is the inverse of the algorithm given in [725] to obtain the  $x$  and  $y$  coordinate values of a number in the Peano-Hilbert order. For algorithms to construct and decode a Peano-Hilbert key in three dimensions, see [1191].
7. See [1192, 1698]. In two dimensions, let  $x_{r-1} \dots x_1 x_0$  and  $y_{r-1} \dots y_1 y_0$  represent the binary representation of the  $x$  and  $y$  coordinate values of a point  $(X, Y)$  in a  $2^r \times 2^r$  space, and let  $u_{2r-1} \dots u_1 u_0$  denote the corresponding location code when using a U order. In this case, assuming that the  $y$  coordinate value is the most significant, we have  $u_{2i+1} = y_i$  and  $u_{2i} = x_i \oplus y_i$  ( $0 \leq i \leq r-1$ ). Thus, to form the bit-interleaved value, we simply interleave the  $y$  coordinate values with the “exclusive or” of the  $x$  and  $y$  coordinate values. Of course, the order differs depending on which of the coordinate values is taken as the most significant. In three dimensions, the addition of the  $z$  coordinate, with  $Z = z_{r-1} \dots z_1 z_0$ , and letting  $z$  be the most significant coordinate yields  $u_{3i+2} = z_i$ ,  $u_{3i+1} = z_i \oplus y_i$ , and  $u_{3i} = z_i \oplus y_i \oplus x_i$  ( $0 \leq i \leq r-1$ ). The extension to  $d$  dimensions is straightforward.
8. For the row-prime, Peano-Hilbert, and spiral orders, it is 1. For the row order it is

$$\frac{(2^n - 1) \cdot (2^n + \sqrt{1 + (2^n - 1)^2})}{2^{2 \cdot n} - 1}$$

For the Cantor-diagonal order, it is

$$\frac{2^n \cdot (2^n + 3) - 4}{2^{2 \cdot n} - 1}$$

For the Morton order, it is

$$\frac{2^{2 \cdot n - 2}}{2^{2 \cdot n} - 1} \cdot \sum_{i=0}^{n-1} \frac{2 \cdot \sqrt{1 + (2^i - 1)^2} + \sqrt{1 + (2^{i+1} - 1)^2}}{2^{2 \cdot i}}$$

For the U order, it is

$$\frac{2^{2 \cdot n - 2}}{2^{2 \cdot n} - 1} \cdot \sum_{i=0}^{n-1} \frac{2 \cdot \sqrt{2^{2 \cdot i} + (2^i - 1)^2} + 1}{2^{2 \cdot i}}$$

For the Gray order, it is

$$\frac{2^{2 \cdot n - 2}}{2^{2 \cdot n} - 1} \cdot \sum_{i=0}^{n-1} \frac{3 \cdot 2^i}{2^{2 \cdot i}} = \frac{3}{2} \cdot \frac{2^{2 \cdot n} - 2^n}{2^{2 \cdot n} - 1}$$

For the double Gray order, it is

$$\frac{2^{2 \cdot n - 2}}{2^{2 \cdot n} - 1} \cdot \sum_{i=0}^{n-1} \frac{3 \cdot (2^{i+1} - 1)}{2^{2 \cdot i}} = \frac{2^{2 \cdot n + 1} - 3 \cdot 2^n + 1}{2^{2 \cdot n} - 1}$$

As  $n$  gets large (i.e.,  $n = 16$ ), these values converge to 2.0000, 1.6724, 1.5000, and 1.4387 for the double Gray, Morton, Gray, and U orders, respectively. Thus, the U order is the best of the approximations of the Peano-Hilbert order in terms of the average distance between successive positions, and the double Gray order is the worst. The latter confirms our observation in Section 1.6 of Chapter 1 that there is no need to Gray code the individual

keys. Gotsman and Lindenbaum [734] discuss the inverse problem of correlating the distance between different locations along the space-filling curve to the Euclidean distance between their actual locations in space. This is done for a subset of space-filling curves where the distance in the original space between successive locations along the curve is 1 (e.g., the row-prime, Peano-Hilbert, and spiral orders) using a variant of a measure proposed by Pérez, Kamata, and Kawaguchi [1481].

9. For the Morton, Peano-Hilbert, U, Gray, and double Gray orders, it is  $1 + 2^{2-m}$  as each page represents a  $2^m \times 2^m$  block. The four corner pixels require that three pages be accessed; the remaining  $4 \cdot (2^m - 2)$  pixels along the edges require that two pages be accessed; and as the neighbors of all other pixels are on the same page, only one page needs to be accessed. For the row order, it is  $3 + 2^{1-2-m}$  as each page represents a portion of a row of size  $2^{2-m}$ . The first and last pixels require that four pages be accessed; the remaining pixels require that three pages be accessed.
10. The upper-left corner of the rectangle.
11. This is not as simple as for the Morton ordering. The orientation of the Peano-Hilbert ordering depends on whether the image width is an odd or even power of 2 (i.e., the value  $n$  in the image width  $2^n$ ). Once this is done, we recursively determine which of the quadrants of the image contain the rectangle, and then for each level of decomposition, we compute which part of the rectangle contains the point with the minimum Peano-Hilbert order value.

The interesting point is that this point need not necessarily be a corner of the rectangle. In fact, it is easy to see using contradiction that the only requirement is that this point lies on the boundary of the rectangle. In particular, suppose that the point  $p$  in rectangle  $r$  with the minimum Peano-Hilbert order value  $m$  does not lie on the boundary. Therefore, there must be some point  $q$  with a Peano-Hilbert order value  $m - 1$  that is adjacent to  $p$  in the horizontal or vertical direction. If  $q$  does not lie on the boundary, then  $q$  must also be in the rectangle, which contradicts the fact that  $p$  was the point with the minimum Peano-Hilbert order value. Otherwise,  $q$  lies on the boundary, but this also contradicts the premise that  $p$  was the point with the minimum Peano-Hilbert order value and was not on the boundary. An alternative way of proving this is to recall that the Peano-Hilbert order value of a pixel corresponds to the number of the pixel's position along the Peano-Hilbert space-filling curve. The Peano-Hilbert space-filling curve, as drawn in Figure 2.5(d), starts at the top left of the space (the origin in this figure) and ends at the bottom left or top right depending on whether the image width is an odd or even power of 2. Thus, for any rectangle, the Peano-Hilbert space-filling curve enters it at a pixel on the boundary (i.e., that pixel has the lowest Hilbert code for any in the rectangle). Otherwise, the Peano-Hilbert space-filling curve starts in the interior of the rectangle, which is clearly not the case since it starts at the origin (assuming the rectangle is fully inside the data space).

The actual process of determining the point in rectangle  $r$  with the minimum Peano-Hilbert order value is as follows. Initialize  $b$  with the root block. Test the child blocks of  $b$  in order of the Peano-Hilbert order value of their corner with the lowest Morton order value (that order depends on whether we are at an odd or even level of decomposition, which should not be too hard to calculate, although it is not trivial) to see if they intersect  $r$ . Set  $b$  to the first child block found to intersect and recursively reapply if  $b$  was not already a pixel. This process requires many intersection tests, and thus is fairly expensive (but not as expensive as computing the Peano-Hilbert codes of all locations along the boundary).

12. Unlike the Morton ordering, and as in the Peano-Hilbert ordering, the location in the rectangle with the smallest U order value is not the upper-left corner of the rectangle. Assuming that the upper-left corner of the image is the first one in the ordering, the problem arises when the upper-left corner of the rectangle is in the NW child of the root (and its NW child, etc.). This is resolved by applying the same recursive procedure as in the solution to Exercise 11. Similar issues arise for the Gray and double Gray orderings.

## Solutions to Exercises in Section 2.1.2.1

1. Let  $p$  be the position of  $l$  in the Morton ordering. Check if  $p$  is in the block associated with the root of the binary search tree  $T$ . If it is, then exit. Else if  $p$  is less than the value associated with the root of  $T$ , then the block containing  $l$  must be in the left subtree, and we descend

the tree. Otherwise,  $p$  is greater than the value associated with the root of  $T$ , and we must examine both the left and right subtrees of  $T$  as there may be a block in the left subtree that contains  $l$ . As we can see, it is not possible to prune the search in all cases. The problem is that in the case of an arbitrary decomposition, the Morton ordering (as well as all other orderings in Figure 2.5) does not guarantee that all of the cells in each block will appear in consecutive order.

### Solutions to Exercises in Section 2.1.2.2

3. It resembles a sawtooth approximation to a circle.
4. The Chessboard metric is represented by the pair (1,1) since  $d_M(p, q) = e + f$ . The City Block metric is represented by the pair (1,2) since  $d_A(p, q) = e + 2 \cdot f$ .

### Solutions to Exercises in Section 2.1.2.4

1. The array, not surprisingly, has no such bias. The list is ordered by adjacency in one dimension. The region quadtree is ordered by adjacency in a hierarchical sense (i.e., by use of a parent relation).
2. There are several possible ways to proceed. The first mimics the top-down definition of the region quadtree and hence makes use of a top-down process. In practice, the construction process is bottom-up, and one usually uses one of two approaches. The first approach [1619] is applicable when the image array is not too large. In such a case, the elements of the array are often inspected in Morton order (Figure 2.5(c) and, more specifically, the order given by the labels in the array in Figure 2.8). By using such a method, a leaf node is never created until it is known to be maximal (this property is also shared by the Peano-Hilbert, Gray, double Gray, and U orders, given in Figures 2.5(d), 2.5(g), 2.5(h), and 2.5(i), respectively). An equivalent statement is that the situation does not arise in which four leaf nodes of the same color  $c$  necessitate the changing of the color of their parent from gray to  $c$ . For more details, see Section 4.1 of [1636].

The second approach [1621] is applicable to large images. In this case, the elements of the image are processed one row at a time—for example, using row order (Figure 2.5(a)), which is also known as a *raster-scan order*. The corresponding region quadtree is built by adding pixel size nodes one by one in the order in which they appear in the file. For more details, see Section 4.2.1 of [1636]. This process can be time-consuming due to the many merging and node-insertion operations that need to take place.

The above method has been improved by using a predictive method [1722, 1729], which only makes a single insertion for each node in the final quadtree and performs no merge operations. It is based on processing the image in row order (top to bottom, left to right), always inserting the largest node (i.e., block) for which the current pixel is the first (upper-leftmost) pixel. Such a policy avoids the necessity of merging since the upper-leftmost pixel of any block is inserted before any other pixel of that block. Therefore, it is impossible for four sibling nodes to be of the same color. This method makes use of an auxiliary array of size  $O(2^n)$  for a  $2^n \times 2^n$  image. For more details, see Section 4.2.3 of [1636].

3. No two spheres can occupy the same leaf node. In other words, each leaf node contains a part of just one sphere.
4. Since the staircases are usually infinite, a tree is inadequate, and a graph is necessary. Use an octgraph!
5. Compression is a result of the property of the exclusive or operation that  $0 \oplus 0 = 0$  and  $1 \oplus 1 = 0$ .
6.  $Q_i \oplus Q_{i-1} = (P_i \oplus Q_{i-1}) \oplus Q_{i-1} = P_i \oplus (Q_{i-1} \oplus Q_{i-1}) = P_i \oplus 0 = P_i$ .
7.  $16 \times 32$ .
8. No. The four resulting blocks must be congruent. Thus, the only valid size is  $8 \times 12$ .

9.  $(B + W - 1)/3$ .
10.  $(B + W - 1)/7$ .
11. See [525].
12.  $O(2^q)$ . The worst case is a rectangle of width  $2^q \times 2$  that straddles the  $x$  axis (i.e., one pixel on each side). It needs  $5 + 16 \cdot 2^{q-2}$  nodes.
13. The probability that the entire image is black is  $P_b(q) = (\frac{1}{2})^q$ . Similarly, the probability that the entire image is white is  $P_w(q) = (\frac{1}{2})^q$ . To find  $E(q)$ , solve the recurrence relation  $E(q) = 4 \cdot E(q-1) + 1 - 4 \cdot (P_b(q) + P_w(q))$  with the initial condition  $E(0) = 1$ . The result is approximately  $(29/24) \cdot 2^{2q}$ . The expected number of black nodes,  $B(q)$ , is obtained by solving the recurrence relation  $B(q) = 4 \cdot B(q-1) - 3 \cdot P_b(q)$  with the initial condition  $B(0) = \frac{1}{2}$ . The result is approximately  $(29/64) \cdot 2^{2q}$ . The expected number of white nodes is the same as  $B(q)$ , and the expected number of gray nodes is approximately  $(29/96) \cdot 2^{2q} - 1/3$ . For more details, see [383].
14. See [383].
15. See Olken and Rotem [1397], who discuss a number of sampling strategies for spatial databases involving both region quadtrees and R-trees [791].
16. See [757]. Intuitively, shifting the region may require fewer nodes as long as the region's maximum extent is such that the region occupies at least one block of size  $1 \times 1$  in three horizontally (or vertically) adjacent blocks of size  $2^m \times 2^m$ . For the given value of  $w$ , the value of  $m$  is  $q - 1$ , and hence the  $q + 1$  result follows.
17. Li, Grosky, and Jain [1161] developed the following algorithm. First, enlarge the image to be  $2^{q+1} \times 2^{q+1}$ , and place the region within it so that the region's northernmost and westernmost pixels are adjacent to the northern and western borders, respectively, of the image. Next, apply successive translations to the image of magnitude power of two in the vertical, horizontal, and corner directions, and keep count of the number of leaf nodes required. Initially,  $2^{2q+2}$  leaf nodes are necessary. The following is a more precise statement of the algorithm:
  - (a) Attempt to translate the image by  $(x, y)$ , where  $x$  and  $y$  correspond to unit translations in the horizontal and vertical directions, respectively. Each of  $x$  and  $y$  takes on the values 0 or 1.
  - (b) For the result of each translation in step (a), construct a new array at one-half the resolution. Each entry in the new array corresponds to a  $2 \times 2$  block in the translated array. For each entry in the new array that corresponds to a single-color (not gray)  $2 \times 2$  block in the translated array, decrement the leaf node count by 3.
  - (c) Recursively apply steps (a) and (b) to each result of steps (a) and (b). This process stops when no single-color  $2 \times 2$  block is found in step (b) (i.e., they are all gray), or if the new array is a  $1 \times 1$  block. Record the total translation and the minimum leaf node count.

Step (b) makes use of the property that for a translation of  $2^k$ , there is a need to check only if single color blocks of size  $2^k \times 2^k$  or more are formed. In fact, because of the recursion, at each step we check only for the formation of blocks of size  $2^{k+1} \times 2^{k+1}$ . Note that the algorithm tries every possible translation since any integer can be decomposed into a summation of powers of 2 (i.e., use its binary representation). In fact, this is why a translation of (0,0) is part of step (a). Although the algorithm computes the positioning of the quadtree with the minimum number of leaf nodes, it also yields the positioning of the quadtree with the minimum total number of nodes since the number of nonleaf nodes in a quadtree of  $T$  leaf nodes is  $(T - 1)/3$ .

18. See [43], where given a depth  $k$ , checking whether or not a block  $b$  at depth  $k$  exists that contains  $q$  is done by forming the locational code of  $q$  and then applying a mask with the trailing  $d \cdot k$  bits set to 0, where  $d$  is the dimension of the underlying space (i.e.,  $d = 2$  and  $d = 3$  for a region quadtree and octree, respectively). The actual check is a simple lookup in a hash table. The overall search process is a binary search on the depth  $k$  in the range  $l \dots r$  where initially  $l = 1$  and  $r = s$ . If  $b$  exists and if  $b$  corresponds to a leaf node, then the search halts with  $v = b$  and  $h = k$ . If  $b$  exists and if  $b$  corresponds to a nonleaf node, then the search continues with another value  $k'$  in the range  $k + 1 \dots r$ , because if there is a block containing  $q$ , then its corresponding leaf node must be deeper in the tree structure (i.e., smaller). If  $b$  does not exist, then  $k$  is larger than  $h$  (i.e.,  $b$  is at a deeper level than  $v$ ), and the search must

be resumed at a shallower level with another value  $k'$  in the range  $l \dots k - 1$ . Using a binary search ensures that the process terminates in  $\log s$  steps as the query point must be contained in one of the blocks as they span the entire environment.

19. See [43], where an unbounded binary search on the range of depths in the order 1, 2, 4, 8, ... is used. The idea, an adaptation of the method of van Emde Boas [558], is that we repeatedly check for the presence of a block  $b$  at depth  $k$  that contains  $q$  while doubling the value of the depth  $k$  at each successive instantiation until we encounter a depth  $k = k'$  for which the check fails. At this point, we apply a binary search in the range  $k'/2 \dots k'$  as in the solution to Exercise 18, but now we only need to perform at most  $\log h$  checks for the presence of a block  $b$  at depth  $k$  that contains  $q$ . The total number of such checks is at most  $2 \cdot \log h$ .
20. Define a locational code where the right part contains the size of the block and the left part contains the result of applying bit interleaving to the coordinate values of the lower-right corner of the block.
21. When the maximum number of bits is 32, then the locational code can represent a three-dimensional image of side length  $2^{10}$ , and EPICT can represent an image of side length  $2^{11}$ . In contrast, when the maximum number of bits is 64, then the locational code can represent a three-dimensional image of side length  $2^{19}$ , and EPICT can represent an image of side length  $2^{21}$ . Thus, with a 64-bit locational code, EPICT enables the representation of a three-dimensional image with four times the resolution of that possible with a locational code.
22. See [1625, 1636, 1652]. Assume that we are trying to find the equal-sized neighbor of node  $P$  in direction  $I$ . Our initial aim is to locate the nearest common ancestor of  $P$  and its neighbor. We need to ascend the tree to do so. We must also account for the situation in which the ancestors of  $P$  and its neighbor are adjacent along an edge. Let  $N$  denote the node that is currently being examined in the ascent. There are three cases described below. They are implemented by procedure `DIAGONALNEIGHBOR`, which makes use of tables `ADJ` and `REFLECT` given in Figure 2.20, as well as `COMMONEDGE` given below. This procedure ignores the situation in which the neighbor may not exist (e.g., when the node is on the border of the image).

COMMONEDGE(I,O)				
I(VERTEX)	Q(QUADRANT)			
	NW	NE	SW	SE
NW	$\Omega$	N	W	$\Omega$
NE	N	$\Omega$	$\Omega$	E
SW	W	$\Omega$	$\Omega$	S
SE	$\Omega$	E	S	$\Omega$

- (a) As long as  $N$  is a child of type  $O$  such that `ADJ(I, O)` is true, we continue to ascend the tree. In other words,  $I$ 's label is a subset of  $O$ 's label.
- (b) If the parent of  $N$  and the ancestor of the desired neighbor, say  $A$ , are adjacent along an edge, then calculate  $A$  using procedure `LATERALNEIGHBOR` given in Figure 2.20. This situation and the exact direction of  $A$  are determined by the table `COMMONEDGE` applied to  $I$  and the child type of  $N$ . Once  $A$  has been obtained, the desired neighbor is located by applying the retracing step outlined in step (c).
- (c) Otherwise,  $N$  is a child of a type, say  $O$ , such that neither of the labels of the edges incident at vertex  $I$  is a subset of  $O$ 's label. Its parent, say  $T$ , is the nearest common ancestor. The desired neighbor is obtained by simply retracing the path used to locate  $T$ , except that we now make diagonally opposite moves about the vertex shared by the neighboring nodes. This process is facilitated by use of the function `REFLECT`.

```

1 recursive pointer node procedure DIAGONALNEIGHBOR( $P, I$ )
2 /* Locate an equal-sized vertex-neighbor of node  $P$  in direction  $I$ . */
3 value pointer node  $P$ 
4 value vertex  $I$ 
5 return(CHILD(if ADJ( $I, \text{CHILDTYPE}(P)$ ) then
6     DIAGONALNEIGHBOR(FATHER( $P$ ),  $I$ )
7     elseif COMMONEDGE( $I, \text{CHILDTYPE}(P)$ )  $\neq \Omega$  then
```

```

8           LATERALNEIGHBOR(FATHER( $P$ ),
9           COMMONEDGE( $I$ , CHILDTYPE( $P$ )))
10          else FATHER( $P$ )
11          endif,
12          REFLECT( $I$ , CHILDTYPE( $P$ )))

```

23. The proof follows [1626, 1636]. Assume that the quadtree skeleton is not unique. Let  $T_1$  and  $T_2$  both be quadtree skeletons of the same image—that is,  $B = \cup_{t \in T_1} s_t$  and  $B = \cup_{t \in T_2} s_t$ . Assume, without loss of generality, that there exists  $t_1 \in T_1$  such that  $t_1 \notin T_2$ . Therefore, by property 3, treating  $t_1$  as an element of  $B$ , there exists  $t_2 \in T_2$  ( $t_2 \neq t_1$ ) such that  $s_{t_1} \subseteq s_{t_2}$ . However, this contradicts property 2, which stipulates that, for any  $t \in T_1$ , there does not exist  $b \in B$  ( $b \neq t$ ) such that  $s_t \subseteq s_b$ . Hence, the quadtree skeleton of a collection of objects represented by a region quadtree is unique.
24. No. For example, for the region quadtree in Figure 2.17(a), both  $\{1, 11, 15\}$  and  $\{1, 12, 15\}$  would be legal quadtree skeletons.
25. Consider the region quadtree in Figure 2.17(a) where both  $\{1, 11, 15\}$  and  $\{1, 12, 15\}$  are legal quadtree skeletons. It is clear that the QMAT corresponding to  $\{1, 12, 15\}$  results in more blocks than the QMAT corresponding to  $\{1, 11, 15\}$  as block 12 is smaller than block 11 and thus the nonobject sibling blocks of block 12 must also be included in the QMAT.
26. The QMAT corresponding to the quadtree skeleton of Figure 2.21(a) using property 3 is given in Figure 2.21(b), and Figure 2.21(c) shows the QMAT corresponding to the quadtree skeleton using property 3'. We see that the total number of blocks is the same. The only difference is that the additional blocks are represented by object blocks rather than empty blocks—for example, the node corresponding to block 14 in Figures 2.21(b) and 2.21(c). To see that this is always true, observe that for a block to be extraneous by virtue of property 3', it must be subsumed by its neighbors, which must themselves correspond to objects. Thus, the extraneous block, when represented by an empty block, cannot be merged with its neighbors to yield a larger block and must remain a part of the QMAT. In addition, the QMAT creation algorithm is considerably simpler when property 3 is used [1626, 1636].

## Solutions to Exercises in Section 2.1.2.6

1. The ATree requires that all blocks at a particular level of subdivision  $e$  be partitioned in the same way (i.e., into the same number of congruent blocks along the same axes). This is not the case for the generalized bintree, as can be seen in Figure 2.24, where we see that some of the partitions at depth 3 are based on the value of the  $x$  coordinate, and others are based on the value of the  $y$  coordinate.
2. The same as for a binary tree: one more leaf node than nonleaf nodes. It is independent of  $d$ !
3. The lower bound is  $1/2^{d-1}$ , and the upper bound is 1.
4. No, since the number of nonleaf nodes in a bintree can be considerably larger than that in the corresponding region quadtree.
5. For a  $2^n \times 2^n$  image, there are  $(n+1) \cdot (n+1)$  different sizes of rectangles. For a given rectangle of size  $2^i \times 2^j$ , there are  $(2^n/2^i) \cdot (2^n/2^j)$  positions where it can be placed when using the AHC method.

## Solutions to Exercises in Section 2.1.2.7

1. No, as not all the shapes can be squares since we cannot aggregate these squares into larger squares that obey this rule.
2. In two dimensions, we have  $g_{m,n} = g_{m-1,n-1} + g_{m-1,n-2} + g_{m-2,n-1} + g_{m-2,n-2}$ , where  $g_{m,n}$  corresponds to the area of the rectangle with sides of length  $f_m$  and  $f_n$ .

3. Consider a  $3 \times 3$  square. It can only be split into two  $1 \times 2$  rectangles, a  $1 \times 1$  square, and a  $2 \times 2$  square. The  $1 \times 2$  rectangles cannot be further decomposed into  $1 \times 1$  pixels using a quadtree splitting rule.
4. Dillencourt and Mount [492] propose the following solution. An optimal hierarchical decomposition of a binary image can be obtained by using a method based on dynamic programming [836]. Dynamic programming is a general technique in which a problem is solved by storing the solution to all subproblems and combining them appropriately. Assume an  $M \times N$  image. The subproblems consist of the possible positions of the rectangles that correspond to the quadrants. There are at most  $O(M^2 \cdot N^2)$  subproblems as there are  $M \cdot N$  possible positions for the upper-leftmost corner of the rectangles, and for each of these rectangles, there are at most  $M \cdot N$  positions for the lower-rightmost corner. Thus, the total storage is  $O(M^2 \cdot N^2)$ .

The algorithm stores with each subproblem (i.e., rectangle) the best decomposition into quadrants, along with the number of rectangles in the decomposition. If the image is a single pixel (i.e., if  $M = N = 1$ ), then there is only one way to subdivide the image—namely, not to subdivide it at all. Otherwise, the image may be subdivided into quadrants in  $M \cdot N$  ways, as any grid point splits the image into four quadrants. For an  $M \times N$  rectangle, this information is computed by examining all  $(M - 1) \cdot (N - 1)$  possibilities, provided the information is known for all smaller rectangles.

The heart of the algorithm is the computation of the solutions of the subproblems. The execution time of the algorithm is  $O(M^3 \cdot N^3)$ . This is obtained by noting that for each rectangle of size  $i \times j$ , there are  $i \cdot j$  possible partitions, and they must all be examined. There are  $(M - i + 1) \cdot (N - j + 1)$  rectangles of size  $i \times j$ . Since  $i$  and  $j$  vary from 1 to  $M$  and 1 to  $N$ , respectively, the result follows. Therefore, for an  $N \times N$  image, the optimal quadtree can be computed in  $O(N^6)$  time using  $O(N^4)$  space.

### Solutions to Exercises in Section 2.1.2.8

1. Consider a  $3 \times 3$  square. It can only be split into  $1 \times 3$  and  $2 \times 3$  rectangles. The  $1 \times 3$  square does not obey the 2-d Fibonacci condition; its sides are not of equal length, nor are they successive Fibonacci numbers.
2. When the lengths of the sides of a rectangle are equal, the rectangle is split into four rectangles such that the lengths of the sides satisfy the 2-d Fibonacci condition. When the lengths of the sides of a rectangle are not equal, the rectangle is split into two rectangles with the split along a line (an axis) that is parallel to the shorter (longer) of the two sides. Interestingly, the dimensions of the A-series of European paper are based on a Fibonacci sequence—that is, the elements of the series are of dimension  $f_i \times f_{i-1}$  multiplied by an appropriate scale factor.

### Solutions to Exercises in Section 2.1.2.9

1. The puzzletree in Figure 2.28 satisfies the linear homogeneity heuristic. Actually, use of the heuristic leads to two choices on the first level of partitioning. Assuming the rows and columns are numbered from 1 to 8, both row 5 and column 6 have the maximum linear homogeneity values of 1. In Figure 2.28 the initial partition was made on the two sides of column 6, resulting in partition lines  $x = 4$  and  $x = 5$ .
3. The transformation will result in the same number of leaf nodes if at most one of the children of  $c$  corresponds to an empty region, and if the objects associated with the blocks of the remaining children are the same as the object associated with the block of child  $d$  of  $b$ , which is a leaf node. This is the best case as the transformation enables us to move a test only one level up in the tree. In this application of the transformation (e.g., see Figure 2.33), the number of tests stays the same, and so does the number of leaf nodes as it is always equal to one more than the number of tests (a direct result of properties of binary and multiway trees). In other cases (e.g., more than one child of  $c$  corresponds to an empty region), the interchange of the tests will cause the introduction of new tests and will create new leaf nodes. Another example of this increase would occur if blocks B1 and B2 in Figure 2.28 were associated with different

objects as this would force us to split the node corresponding to block B4 in Figure 2.33 at  $x = 6$ , thereby resulting in more leaf nodes.

4. In the following, we use  $w[i]$  to refer to the  $i$ th element of list  $w$ .

```

1  node procedure COMPRESS( $n1, n2, u, p0$ )
2  /* Merge the two nodes  $n1$  and  $n2$  that are partitioned along the  $u$  coordinate axis
   at value  $p0$ . */
3  value pointer node  $n1, n2$ 
4  value axis  $u$ 
5  value integer  $p0$ 
6  list  $p1, p2, p3, c1, c2, c3$ 
7  integer  $i, j, k, m, n, pi, pj$ 
8   $p1 \leftarrow P(n1)$ 
9   $p2 \leftarrow P(n2)$ 
10  $n \leftarrow \text{LENGTH}(p1)$ 
11  $m \leftarrow \text{LENGTH}(p2)$ 
12  $c1 \leftarrow S(n1)$ 
13  $c2 \leftarrow S(n2)$ 
14  $i \leftarrow j \leftarrow k \leftarrow pi \leftarrow pj \leftarrow 1$ 
15 while not ( $i > n + 1$  and  $j > m + 1$ ) do
16   if ( $i > n$  and  $j > m$ ) or  $p1[i] = p2[j]$  then
17     if  $pi = i$  and  $pj = j$  then
18       if  $c1[i] = c2[j]$  then  $c3[k] \leftarrow c1[i]$ 
19       else  $c3[k] \leftarrow \text{MAKELIST}(u, p0, (c1[i], c2[j]))$ 
20       endif
21     else
22        $c3[k] \leftarrow \text{MAKELIST}(u, p0$ 
23         ( $A(n1)$  ( $p1[pi] \dots p1[i-1]$ )
24           ( $c1[pi] \dots c1[i]$ ))
25         ( $A(n2)$  ( $p2[pj] \dots p2[j-1]$ )
26           ( $c2[pj] \dots c2[j]$ )))
27     endif
28     if  $p1[i] = p2[j]$  then  $p3[k] \leftarrow p1[i]$ 
29     endif
30      $i \leftarrow i + 1$ 
31      $j \leftarrow j + 1$ 
32      $k \leftarrow k + 1$ 
33      $pi \leftarrow i$ 
34      $pj \leftarrow j$ 
35   elseif  $j > m$  and  $i \leq n$  then  $i \leftarrow n + 1$ 
36   elseif  $i > n$  and  $j \leq m$  then  $j \leftarrow m + 1$ 
37   elseif  $p1[i] < p2[j]$  then  $i \leftarrow i + 1$ 
38   else  $j \leftarrow j + 1$  /*  $p1[i] > p2[j]$  */
39   endif
40 enddo
41 return  $\text{MAKELIST}(A(n1), p3, c3)$ 

```

5. The solution is a merge of two nodes.

```

1  pointer node procedure COMPRESSTREE( $u, p0, a, b$ )
2  /* Merge the two two-dimensional puzzletree nodes pointed at by  $a$  and  $b$  that
   represent a partition on axis  $u$  at coordinate value  $p0$  and return the result in
    $c$ . The algorithm assumes that there is at least one common partition. */
3  value axis  $u$ 
4  value integer  $p0$ 
5  value pointer node  $a, b$ 
6  integer  $i, j, k, m, n, pi, pj$ 
7  pointer node  $c, d, e, f$ 
8   $c \leftarrow \text{CREATE}(\text{node})$ 
9   $\text{TEST}(c) \leftarrow \text{TEST}(a)$ 
10  $k \leftarrow 0$ 
11  $i \leftarrow j \leftarrow 1$ 

```

```

12  $pi \leftarrow pj \leftarrow 0$ 
13 while  $i \leq \text{NUMCHILDS}(a)$  and  $j \leq \text{NUMCHILDS}(b)$  do
14   if  $V(a)[i] < V(b)[j]$  then  $i \leftarrow i + 1$ 
15   elseif  $V(b)[j] < V(a)[i]$  then  $j \leftarrow j + 1$ 
16   else /* A common partition has been found */
17      $k \leftarrow k + 1$ 
18     if  $pi = i - 1$  and  $pj = j - 1$ 
19       and ISLEAF( $\text{CHILDS}(a)[i]$ ) and ISLEAF( $\text{CHILDS}(b)[j]$ )
20       and  $\text{OBJECT}(\text{CHILDS}(a)[i]) = \text{OBJECT}(\text{CHILDS}(b)[j])$  then
21         /* A merge is possible */
22          $V(c)[k] \leftarrow V(a)[i]$ 
23          $\text{CHILDS}(c)[k] \leftarrow \text{CHILDS}(a)[i]$ 
24          $pi \leftarrow i$ 
25          $i \leftarrow i + 1$ 
26          $pj \leftarrow j$ 
27          $j \leftarrow j + 1$ 
28       else /* Create a new node one level deeper */
29          $d \leftarrow \text{CREATE}(\text{node})$ 
30          $\text{CHILDS}(c)[k] \leftarrow d$ 
31          $V(c)[k] \leftarrow V(a)[i]$ 
32          $\text{TEST}(d) \leftarrow u$ 
33          $\text{NUMCHILDS}(d) \leftarrow 2$ 
34          $V(d)[2] \leftarrow \infty$ 
35          $V(d)[1] \leftarrow p0$ 
36         if  $pi = i - 1$  then  $\text{CHILDS}(d)[1] \leftarrow \text{CHILDS}(a)[i]$ 
37         else
38           /* Left child */

   31        j ← j + 1
   32      else
   33        p3 [k] ← p1 [i]
   34        i ← i + 1
   35        j ← j + 1
   36      endif
   37    else exit_while_loop ;
   38    endif
   39    k ← k + 1
   40  enddo
   41  return MAKELIST(A(n1) p3 c3)

```

7. Consider the puzzletree given in Figure 2.31, which has 13 leaf nodes. The partitions at the root that yield the regions  $0 \leq x < 1$  and  $1 \leq x < 3$  are both subdivided further at  $y = 6$ , and they form the common partitions  $0 \leq y < 6$  and  $6 \leq y < 8$ . The regions corresponding to the partition  $6 \leq y < 8$  can be merged as neither is associated with any object. For the method in Exercise 4, the resulting block decomposition is given in Figure S.7(a) and has 12 leaf nodes (i.e., blocks). For the method in Exercise 6, the result is given in Figure S.7(b) and has 14 leaf nodes (i.e., blocks).

8. Each of the methods eliminates the same number of tests for each merge that takes place, which means one fewer leaf node for each eliminated test. The method described in Exercise 4 never creates new leaf nodes as it does not introduce new tests. When merging is not possible, it just rearranges the order in which tests are made on account of the factoring that has taken place as a result of the elimination of common tests. On the other hand, the method described in Exercise 6 creates new partitions accompanied by the introduction of additional tests wherever a merge is impossible, which increases the number of leaf nodes by one for each additional test.

2. 80 and 60 faces, respectively.

### Solutions to Exercises in Section 2.1.3.1

3. No. See the two-dimensional example in Figure 2.37, where line segment B does not intersect the halfspace of line segment D, whereas line segment D does intersect the halfspace of line segment B.
4. In two dimensions,  $P_1$  and  $P_2$  must intersect. In three dimensions, either  $P_1$  and  $P_2$  are coplanar, or else both  $P_1$  and  $P_2$  intersect the line along which their planes intersect (it does not imply that  $P_1$  and  $P_2$  intersect).
6.  $n + 1$ .
7. When all line segments (polygonal faces) span the entire two- (three-) dimensional space from which they are drawn. Alternatively, referring to Exercise 3,  $\text{CONFLICT}(P_1, P_2) = \text{CONFLICT}(P_2, P_1)$  for every pair of line segments (polygonal faces).

8.  $\sum_{i=0}^d \binom{n}{i}$  in a  $d$ -dimensional space.

9. There are two basic techniques [657]. The first technique assigns a visibility number to each polygon in the order in which it has been visited. This order depends on whether we are using a back-to-front or a front-to-back display algorithm. We shall assume a back-to-front algorithm. In such a case, the higher numbers correspond to a higher priority. They are assigned by traversing the BSP tree in such a way that for given node  $N$ , all the polygons in  $\text{INCHILD}(N, V)$  are given a lower number than  $N$ 's polygon, and all the polygons in  $\text{OUTCHILD}(N, V)$  are given a higher number than  $N$ 's polygon. It should be clear that this is nothing more than an inorder traversal with respect to the viewpoint. These priorities can be used by conventional hidden-surface elimination algorithms whenever a visibility determination must be made. In fact, we do not even have to assign the visibility numbers.

The second technique does not use the visibility numbers. Instead, the traversal is used to control a back-to-front (i.e., painter's) algorithm that paints each polygon on the screen as it is encountered. If one polygon overlaps another polygon, then the most recently painted polygon determines the color of the overlapped region. Given viewpoint  $V$ , BSP tree node  $N$ , and the previous definition of  $\text{INCHILD}$  and  $\text{OUTCHILD}$ , the polygons in  $\text{OUTCHILD}(N, V)$  are visited before the polygon in the root, which, in turn, is visited before the polygons in  $\text{INCHILD}(N, V)$ . Correctness is assured since polygons that occlude other polygons are closer to the viewpoint and are visited later in the traversal.

### Solutions to Exercises in Section 2.1.3.2

1. Use induction on the number of vertices, and start with one triangle.
2. Use induction on the number of vertices, and start with one triangle.
3. Each vertex is visible from every other vertex. To obtain a triangulation, simply pick a vertex at random, and draw lines from it to the remaining vertices. This is an  $O(v)$  process.
4. Sort the vertices seen so far by their  $y$  coordinate values. See [834], as well as [1282], for more details.
5. The greedy method cannot be performed in time faster than  $O(v^2 \log(v^2)) = O(v^2 \log v)$  as we must first sort the edges in order of increasing length, and there are  $O(v^2)$  possible edges. Checking if an edge intersects an existing edge in a partial triangulation takes at most  $O(v)$  time as there are only  $O(v)$  edges in a triangulation (see Exercise 2). The  $O(v)$  time factor for checking the intersection of an edge with an existing edge can be reduced to  $O(\log v)$  by use of a cleverer data structure [717] so that the entire greedy method can obtain a triangulation in  $O(v^2 \log v)$  time and  $O(v)$  space. Interestingly, Levkopoulos and Krznaric [1155] describe

---

**Solutions to Exercises  
in Section 2.1.3.3.1**

- a nongreedy algorithm to obtain the same triangulation in  $O(v \log v)$  time. This algorithm can also be used to convert a Delaunay triangulation (see Exercise 8 and Section 2.2.1.4) into the same triangulation (i.e., the one obtained by the greedy method) in  $O(v)$  time.
6. We look for  $p_k$  in step 2 by minimizing a quantity that takes  $O(v)$  time and the process is performed for each of the  $O(v^2)$  possible entries in  $w$  that correspond to the edges. Thus, the total time is  $O(v^3)$ .
  9. Use an array of edge-adjacency lists such that there is one edge-adjacency list per vertex.
    - (a) Identify all K-vertices.
    - (b) Initially, the set of mutually independent K-vertices, say  $M$ , is empty.
    - (c) Pick a K-vertex, say  $V$ , that has not been marked as not mutually independent with elements of  $M$ , and insert it into  $M$ . Now, mark all elements of  $V$ 's edge-adjacency list as not mutually independent with  $M$ , and repeat until there are no vertices left. This process is  $O(v)$  since we mark all edges, and by Euler's formula, given  $v$  vertices, the number of edges is  $3 \cdot v - 6$ . The data structure requires  $O(v)$  array entries and  $O(v)$  edge-adjacency list elements.
  10. If the removed K-vertex had degree  $k$ , then its neighborhood (i.e., polygon) had  $k$  triangles and  $k$  sides. The triangulation of a  $k$ -sided polygon contains  $k - 2$  triangles.
  12. There is no obvious way to achieve map overlay using the K-structure. Nevertheless, since the triangulation forms a convex map, a plane-sweep algorithm can be used to do the overlay in  $O(v \log_2 v + s)$  time and  $O(v)$  space [1377], where  $s$  denotes the number of intersections of edges from the first map with edges from the second map, and  $v$  denotes the total number of vertices in the two maps. From this result, a new K-structure can be built in  $O(v)$  time.

### Solutions to Exercises in Section 2.1.3.3.1

1. Note that there are no regions to the left (right) of the extreme left (right) endpoints that are introduced by the regularization process.
2. Yes. Each vertex formed by the intersection of the new edge with an existing edge already has at least one edge to each of its right and left sides.
3. Yes. The intersection of any two  $y$ -monotone regions is always  $y$ -monotone.
4. A polygonal map of  $m$  edges has at most  $m + 1$  vertices. Two of these vertices are at the extreme left and right of the map, and thus no edges are added to them. At most one edge can be added to each of the remaining  $m - 1$  vertices since they must have at least either one edge to a vertex at their right or one edge to a vertex at their left.
5. Use a plane-sweep algorithm (see Section 3.1 of Chapter 3). First, sort the edges by their  $x$  coordinate values. Next, sweep a vertical line through the sorted list of edges. During the sweep, use a balanced binary search tree to represent the active intervals of the sweep line (i.e., crossed by edges), and order it by the  $y$  coordinate values.
6. For example, the vertex with the larger  $y$  coordinate value can be treated as the left vertex. The "immediately above" relation must be extended to mean "immediately right" in such a case. The general relation "above" becomes "right."
7. This is an open question.
8. Use contradiction.
9. No. Consider the case that regions  $R_i$  and  $R_j$  in the left and right subtrees, respectively, of  $S_k$  do not exist such that  $R_i = \text{BELOW}(e)$  and  $R_j = \text{ABOVE}(e)$ .
10. See Theorem 8 in [541].
11. Edge  $e$  is contained in separator  $S_k$  if and only if  $S_k$  lies above region  $R_i$  and below region  $R_j$  for  $i < k \leq j$ .

12. Use the edge-ordering property and contradiction. In other words, assume that the least common ancestor does not contain  $e$ .
13.  $lca(i, j) = j \wedge \neg(msb(i \oplus j) - 1)$  [541].
14.  $lca(i, j) = rev(x \oplus (x - 1)) \wedge j$ , where  $x = rev(i \oplus j)$  [541].
15. Adopt the convention that each edge contains its left endpoint but not its right endpoint.
16. Use an array of edge-adjacency lists such that there is one edge-adjacency list per vertex. The reregularization process simply scans the array and, for each vertex whose edge-adjacency list does not contain vertices to the left (right), it adds the edge to the succeeding (preceding) vertex in the sorted list. By Euler's formula, this is an  $O(v)$  space and time process.

### Solutions to Exercises in Section 2.1.3.3.2

1.  $L_2$  consists of vertices C, E, F, I, and K; the  $x$ -intervals making up edges CE and IK; and the gaps  $\alpha$ C, EF, FI, and K $\delta$ .  $L_6$  consists of vertices B, C, D, G, J, and L; the  $x$ -intervals making up edges  $\alpha$ B, BC, DG, and GJ; and the gaps CD, JL, and L  $\delta$ .  $L_4$  consists of vertices A, C, D, E, G, I, J, K, L, and M; the  $x$ -intervals making up edges  $\alpha$  A, AC, CD, DE, EG, GI, IJ, JK, KL, LM, and M  $\delta$ ; there are no gaps.
2. If it were common to more than one  $x$ -interval, then the  $x$ -intervals would have to overlap, which is impossible.
3. See [541]. The inductive hypothesis is  $B_v + b_v \leq 4 \cdot A_v$ , which holds trivially for the leaf nodes of the gap tree. Letting  $l(u)$  and  $r(u)$  denote the left and right children of node  $u$  of the gap tree,  $B_u = B_{l(u)} + B_{r(u)} + b_u$  and  $A_u = A_{l(u)} + A_{r(u)} + a_u$ . Moreover,  $b_u \leq 2 \cdot a_u + (b_{l(u)} + b_{r(u)})/2$  since each edge in  $S_u$  contributes at most two vertices to  $L_u$ . Applying the inductive hypothesis to the subtrees using this inequality and the previous two equalities leads to the desired result.
5. For example, there is no need for links between vertices and adjacent  $x$ -intervals. Instead, the elements of the layered dag can be stored in consecutive memory locations by use of an array.
8. There is no obvious way to achieve map overlay using the layered dag. In particular, performing map overlay for the layered dag is more complex than for the K-structure since the map created by a  $y$ -monotone subdivision process is not convex. However, the algorithm still has the same execution time behavior and the same space requirement as the algorithm for the K-structure.

### Solutions to Exercises in Section 2.1.4.1

1. A depth-first policy might reach the upper bound on the number of elements before some very large regions covering the object would have a chance to be split.
2. If the radius of the minimum bounding box for  $o$  is smaller than or equal to  $p \cdot w/4$ , then  $o$  will be associated with one of the subblocks of  $b$  of width  $w/2$  whose expanded block is of width  $(p + 1) \cdot w/2$ . This situation arises when  $o$  overlaps the center point  $c$  of  $b$ , as well as at least one pair of two diametrically opposite points at a distance of  $p \cdot w/4$  from  $c$  along at least one of the two axes that pass through  $c$ .
3. One issue here concerns how many subblocks will have to be checked for a tighter fit. Also, what is the guaranteed radius of  $o$ 's minimum bounding box when it is stored at a given depth?

### Solutions to Exercises in Section 2.1.4.2

1. If such an angle is present, then we cannot draw a line between the two edges that form this angle that will be part of a polygon that completely surrounds the vertex. Thus, we cannot eliminate the vertex.
2. After application of vertex enlargement to vertex  $v$ , the degree of  $v$  is either two or three. It is two if the angle between two of the adjacent edges originally incident at  $v$  was greater than  $180^\circ$ ; otherwise, it is three. Thus, we need to apply vertex enlargement to every vertex of degree greater than three, and we end up with a polygonal map where every vertex has a maximum degree of three.
3. Four, because polygonal maps often arise from road networks, in which case it is quite natural for four polygons to be incident at a vertex, and it does not make sense to replace it. In this case, a value of three for  $T$  does not make sense as often it will result in a T-like junction.
4. No. The problem arises when a block contains the edge of just one polygon. Unless the edge is along one of the sides of the block, the decomposition goes on forever.
5. No. Whenever a block  $b$  contains just one vertex  $v$ , there are two or three edges incident at  $v$ , thereby corresponding to two or three polygons. However,  $b$  can contain additional edges that are not incident at  $v$ . Each of these edges must pass through two sides of  $b$  as otherwise they would meet at a vertex in  $b$ , which would contradict our initial assumption that  $b$  contains only one vertex. If there are at least  $T - 1$  such edges, then  $b$  could be a part of as many as  $T - 1$  additional polygons, for a total of  $T + 1$ , thereby violating the decomposition rule.
6. Since each polygon has at least one CDT node, the number of CDT nodes is never smaller than the number of polygons. Therefore, it is impossible for the total number of CDT nodes in the four subblocks of a block that has been split according to the initial decomposition rule (i.e., based on the total number of polygons in a block) to be smaller than the bucket threshold. This means that we need not worry about merging.

### Solutions to Exercises in Section 2.1.5.1

1. If the object occupies every element in the space, then  $4^{n+1}/3 + 1$  elements of the pyramid will be examined.
2.  $E_p = (4n + 1)/4^n$  and  $O_p = 4n + 1$ .
3.  $E_p$  and  $O_p$  are both  $(4^{n+1} - 1)/(3 \cdot 4^n)$ .
4.  $E_p = (2^{n+2} - 3)/4^n$  and  $O_p = (2^{n+2} - 3)/2^n$ .
5.  $E_p = (2^{n+2} - 3)/4^n$  and  $O_p = (2^{n+2} - 3)/2^n$ .
6. In the worst case, the square is positioned in the center of the image.  $E_p = (5 + 16(n - 2))/4^n$  and  $O_p = (5 + 16(n - 2))/4$ .

### Solutions to Exercises in Section 2.1.5.2.1

1. Determine the extreme left, right, top, and bottom sides by scanning all of the rectangles as they are not assumed to be sorted. This process takes  $O(M)$  time.

### Solutions to Exercises in Section 2.1.5.2.2

1. Use the circle center or the circle center plus the radius.
2. Assume, without loss of generality, that  $N = M^n$ . At the initial stage ( $j = 1$ ), we must examine  $\sum_{i=0}^{N/M-1} \binom{M+iM}{M}$  combinations. At stage  $j$ , we have  $N/M^{j-1}$  bounding boxes, and we

must examine  $\sum_{i=0}^{N/M^j-1} \binom{M+iM}{M}$  combinations. Therefore, a total of  $\sum_{j=1}^{n-1} \sum_{i=0}^{N/M^j-1} \binom{M+iM}{M}$  combinations are examined.

3. See [698] for an example algorithm that tries to minimize an objective function consisting of the sum of the areas of the bounding boxes.

### Solutions to Exercises in Section 2.1.5.2.3

1. A node in a B-tree of order  $2c + 1$  has  $c$  records and  $c + 1$  children.
2. If the value  $k$  is such that there is no leaf node  $p$  containing two successive keys  $p_i$  and  $p_{i+1}$ , where  $p_i \leq k \leq p_{i+1}$ . In this case, there are two choices: either the leaf node containing the largest key  $q$  such that  $q \leq k$ , or the leaf node containing the smallest key  $s$  such that  $k \leq s$ .
3.  $\lceil \log_m(N) \rceil$ .
4.  $\lceil N/m \rceil + \lceil N/m^2 \rceil + \dots + 1$ .
5. This requires a search starting at the root. At each level, we examine the  $M$  children of the node and descend the one for whom the corresponding block is increased the least by the addition. This takes  $O(M \log_M(N))$  time.
7. Deletion of an object, say  $O$ , from an R-tree proceeds by locating the leaf node, say  $L$ , containing  $O$  and removing  $O$  from  $L$ . Next, adjust the bounding boxes on the path from  $L$  to the root of the tree while removing all nodes in which underflow occurs and adding them to the set  $U$ . Once the root node is reached, if it has just one child, then the child becomes the new root. The nodes in which underflow occurred (i.e., members of  $U$ ) are reinserted at the root. Elements of  $U$  that correspond to leaf nodes result in the placement of their constituent bounding boxes in the leaf nodes, while other nodes are placed at a level so that their leaf nodes are at the same level as those of the whole tree.
8. For a set of  $M + 1$  items, there are  $2^{M+1}$  subsets. Of these subsets, we exclude the empty set and the set of  $M + 1$  items, leaving  $2^{M+1} - 2$  subsets. Removing duplicate partitions yields  $2^M - 1$  partitions.
11. No. The new variant of the algorithm must compute the separation between every pair of bounding boxes (an  $O(M^2)$  process) instead of the minimum separation between every bounding box and the upper and lower boundaries of the bounding box associated with the node that is being split (an  $O(M)$  process).
12. In general, the farther apart the seeds are, the larger their combined bounding box is and the greater the amount of wasted space in their bounding box is. Also, the smaller their size is, the greater the area wasted when their area is subtracted from that of their combined bounding box. Thus, the combination of small seeds that are far part is ideal for maximizing the amount of wasted area [152].
13. Since  $s$  is so small and has almost the same coordinate values as  $r$ ,  $r$  must also be very small, and the area increase relative to  $s$  will be very small as well, while the area increase from the other seed  $t$  may be large, thereby resulting in a large value of  $|d_{rt} - d_{rs}|$  [152].
14. Since the bounding box of  $s$  was the first to be enlarged, it will be bigger than the bounding box of the other seed  $t$ . Thus, the enlarged bounding box of  $s$  needs less area enlargement to include bounding box  $b_2$ , which is the next one to be redistributed. Therefore,  $s$  will be enlarged again and again. Thus, the first  $M - m$  bounding boxes may all be redistributed to the bounding box of  $s$ , which means that the remaining  $m - 1$  bounding boxes are redistributed to the bounding box of  $t$  regardless of the minimum area enlargement computation [152]. This will result in a large overlap between the nodes  $s$  and  $t$ .
15. First, the algorithm must examine all possible pairs of bounding boxes to determine which combination wastes the most area. There are  $M^2$  pairs of bounding boxes. Next, the algorithm computes, for each of the remaining bounding boxes, the preferred of new nodes  $i$  and  $j$ . This is also an  $O(M^2)$  process as there are  $2c$  area differences ( $1 \leq c \leq M - 2$ ) computed at the remaining  $M - 2$  stages.
16. See [152] for a comparison of the R\*-tree (discussed in Section 2.1.5.2.4) and technique 1.

17. Seed-picking takes  $O(M^2)$  time. The process of redistributing the remaining bounding boxes takes  $O(M \log M)$  time as sorting is required. Thus, the algorithm takes  $O(M^2)$  time.
18. The problem is that the algorithm blindly redistributes  $M/2$  of the bounding boxes in one node and the remaining ones in the other node without taking any geometric factors into account, such as minimizing overlap or coverage. The result is that the split could be quite bad in the sense of having overlap, which could have been avoided by distributing more of the bounding boxes in one node than in another, as is done in the R\*-tree (see Section 2.1.5.2.4) node redistribution algorithm. This algorithm is closely related in the sense that it also makes use of a sort of the bounding boxes according to one of their sides.
23. The probability that R-tree node  $q$ 's bounding box  $b$  with volume  $v$  covers query point  $p$  is  $v/v$ .  $v$  is also the expected number of times that node  $q$  is visited in the search for  $p$ . Therefore, the expected number of nodes that are visited in the search for  $p$  is the sum of the volumes of the bounding boxes of all of the nodes in the R-tree [983]. This analysis assumes that the R-tree is implemented so that node  $p$  contains  $k$  ( $m \leq k \leq M$ ) pointers to  $p$ 's children and the  $k$  bounding boxes of  $p$ 's children instead of containing just one bounding box corresponding to the union of the bounding boxes of  $p$ 's children. Otherwise, we would have to make one more node access to determine whether the query point is covered by the bounding box of the root node.
25. Node  $q_j$  will be visited by the window query as long as the lower-right corner of the window has a nonempty intersection with the region of size  $\prod_{i=1}^d (b_{ji} + w_i)$  that has the same upper-left corner as  $b_j$ . Thus, the probability that  $q_j$  is visited is  $\prod_{i=1}^d (b_{ji} + w_i)$ . This is also the expected number of times that node  $q_j$  is visited in the search for  $w$ . Therefore, the expected number of nodes that are visited in the search for  $w$  is the sum of the volumes of the expanded bounding boxes of all of the nodes in the R-tree, which is  $\sum_j \prod_{i=1}^d (b_{ji} + w_i)$  [983].
26. See [1586] for an algorithm designed specifically for finding the nearest object in an R-tree. See also [846] for a general algorithm that works for arbitrary spatial data structures that ranks the objects according to their distance from the query point in an incremental manner.
28. Each rectangle may have to be tested against every other rectangle.

### Solutions to Exercises in Section 2.1.5.2.4

1. The problem is that most of the keys that are reinserted would end up in the same node or a neighboring node, thereby achieving the same result as if we had rotated the overflowing items. The problem is that we usually do not have a choice of which record will contain a given key (see also the solution to Exercise 2 in Section 2.1.5.2.3).
3. This requires a search starting at the root. At each level other than the one containing the leaf nodes, we examine the  $M$  children of the node and descend the one for whom the corresponding block is increased the least by the addition. This takes  $O(M \log_M(N))$  time. At the leaf level, given a parent node  $f$ , we need to check each of the children of  $f$  for overlap with all of its siblings, which takes  $O(M^2)$  time for an order  $(m, M)$  R\*-tree. Thus, the process takes  $O(M^2)$  time.
4. For each child  $p$  of  $s$ , compute the increase in area resulting from the insertion of  $b$  in  $p$ . Sort the children of  $s$  in increasing order of area increase and select the first  $a$  entries forming a set  $I$ . Now insert  $b$  in the element of  $I$  for whom the resulting bounding box has the minimum increase in the amount of overlap with all remaining children of  $s$ . The answer is approximate as we did not check the overlap of each of the children of  $s$  [152].
7. Perimeter is often a better indication of spatial extent than area as we could have very long and thin slivers of minimal total area that span a large part of the node, thereby increasing the possibility of overlapping with the bounding box of the other node if the splitting axis is not perpendicular to the longest side of the bounding box. Thus, in the case of many parallel slivers, the choice of the split axis serves to insure that the slivers are separated with little overlap. Notice that the areas of the slivers can be made as small as possible, even approaching zero in the limit, while the perimeter does not go to zero and can be as big as twice the larger of the two sides of the bounding box of the node being split.

8. Instead of computing the averages along the axes and comparing them, it is simpler just to compare the sum of the perimeters along each axis. For a given sort order, perform a sweep of the bounding boxes in increasing order, starting with the first one, incrementally computing the union of the bounding boxes seen so far. For each legal group of bounding boxes (i.e., containing at least  $m$  entries and at most  $M - m$  entries), compute the perimeter and add it to the perimeter sum for the corresponding axis. The same process is repeated in decreasing order starting with the last bounding box. Each of these processes computes the union of  $M - m$  bounding boxes and performs  $M - 2m$  perimeter computations, for a cost of  $O(M)$ . There are two sort orders for each axis, so the total cost of computing the perimeter sums is  $O(dM)$ . The final task of determining the minimum of the perimeter sums for the  $d$  axes can be done in  $O(d)$  time.
  
9. The drawback of this approach is that it leads to a higher likelihood that the split position chosen in the second phase will result in a partition with a large perimeter. The reason is that the split position with the minimum perimeter is not necessarily the split position with the minimum coverage along the axis. In contrast, the approach that chooses the axis for which the average perimeter is the smallest results in a greater number of possible split positions with a low perimeter value.
  
10. The fact that  $s'$  may not necessarily minimize overlap can best be seen by considering an example consisting of a  $10 \times 10$  grid with two bounding boxes  $b_1$  and  $b_2$  corresponding to sets of objects  $s_1$  and  $s_2$ , respectively.  $b_1$  is adjacent to the upper-left corner and has width 5 and height 4, and  $b_2$  is adjacent to the lower-left corner and has width 8 and height 8. The sum of the perimeters of  $b_1$  and  $b_2$  is 50 with an overlapping area of 6. Suppose that we move a  $1 \times 1$  object  $o$  in the lower-left corner of  $b_1$  from  $s_1$  to set  $s_2$ . This means that the new bounding box of the set  $s_1 - o$  is now of height 3 and width 5 with perimeter 16, and the new bounding box of the set  $s_2 + o$  is now of height 8 and width 10 with perimeter 36. The sum of the perimeters of the new bounding boxes is 52 with an overlapping area of 3. Thus, the split position that minimizes the sum of the perimeters of the constituent bounding boxes is not necessarily the one yielding a minimum overlap.
  
19. Yes. If we process them in increasing (decreasing) order from left to right (right to left), then the algorithm has a tendency to prefer the left (right) partition for the first insertion, and once the left (right) partition has been enlarged once, it is likely to be enlarged the least by the next element from left to right (right to left) in increasing (decreasing) order. Therefore, the left (right) partition will contain all of the remaining bounding boxes. This may result in a large overlap along the split axis. The same problem arose in the quadratic cost R-tree node-splitting algorithm proposed by Guttman [791] and is discussed in Exercise 14 in Section 2.1.5.2.3. A better solution is to continue to process the remaining line segments by choosing them in the same alternating fashion and increasing (decreasing) order from left to right (right to left) as before the determination that the storage utilization constraints have been satisfied.
  
20. An example can be constructed where the outlined approach does not find the partitioning for which the sum of the perimeters of the bounding boxes of the resulting nodes is a minimum. However, the evaluation of the quality of the partitioning obtained with the outlined approach in the use of R\*-trees is an important one. Note that the problem of finding the partition into two sets of nodes for which the sum of the perimeters of their bounding boxes is a minimum can be solved using the method of Becker et al. [146] in  $O(dM \log M + d^2 M^{2d-1})$  time for  $d$ -dimensional data subject to the minimum node occupancy constraints, whereas when these constraints are not required to hold, it can be solved in  $O(M^d)$  time using the method of García et al. [680].
  
21. See the solution to Exercise 20. In particular, the optimal cost algorithms of Becker et al. [146] and García et al. [680] are applicable.
  
23. See [983] for the predictions of the results of such tests using the expected number of nodes calculated in Exercises 23 and 25 in Section 2.1.5.2.3. These calculations showed that a sort on the basis of the Peano-Hilbert order of the centroids of the objects results in the lowest expected number of retrieved R-tree nodes with respect to the other space orderings as well as the dynamic R-tree construction algorithms. Are your empirical results in agreement?

### Solutions to Exercises in Section 2.1.5.2.6

1. Let  $2 \cdot p \cdot B$  be the capacity of a buffer for a nonleaf node, where  $p$  is an integer, and  $B$  is the block size. If we distributed only the first  $p \cdot B$  entries in a buffer each time the number of entries in the buffer exceeds  $p \cdot B$ , the size of the children's buffers will never be larger than  $2 \cdot p \cdot B$ .

### Solutions to Exercises in Section 2.1.5.2.7

1. Compare your results to those reported in [983].
6. Let  $s_1$  and  $s_2$  be at depth  $i$  in the R-tree and let the leaf nodes be at depth  $j$ . Thus, the objects are at depth  $j + 1$ . Assume that  $s_1$  has  $m$  children and  $s_2$  has  $M$  children. Assume further that each of the descendants of  $s_1$  has  $m$  children, and each of the descendants of  $s_2$  has  $M$  children. Therefore,  $N_{s_1} = m^{j-i+1}$  and  $N_{s_2} = M^{j-i+1}$ , and thus the ratio  $N_{s_1}/N_{s_2} = (m/M)^{j-i+1}$  can get arbitrary large.

### Solutions to Exercises in Section 2.1.5.3

1. Repartitioning may lead to overflow because the objects are being decomposed into subobjects. However, point objects cannot be further decomposed. Thus, repartitioning cannot create nodes that will overflow.
2. Each  $R^+$ -tree node must store the bounding box of its subtrees. This requires storing the coordinate values of the diagonally opposite corners of the bounding box (i.e.,  $2d$  values for  $d$ -dimensional data). On the other hand, each k-d-B-tree node  $p$  at depth  $h$  must just store the identity of the discriminating dimension and the coordinate value along this dimension (i.e., 2 items for each node and  $2h$  values for the path from the root to  $p$ ). The size of the block corresponding to  $p$  can be determined from the values of the discriminating dimensions and corresponding coordinate values of the ancestors of  $p$ .
3. This is complicated by the fact that, in general, it is not possible to guarantee that each node in an  $R^+$ -tree will contain a minimum of  $m$  items.
9. Each rectangle may have to be tested against every other rectangle.

### Solutions to Exercises in Section 2.2.1.1

1. (a) Use two sets of lists. The first list contains the eight vertices and their coordinate values. The second list contains the faces. Each face is represented by a list of the identifiers corresponding to its constituent vertices.  
(b) Use three sets of lists. The first list contains the eight vertices and their coordinate values. The second list contains the faces, where each face is represented by a list of the identifiers corresponding to its constituent edges. The third list contains the twelve edges and the identifiers corresponding to their constituent vertices.
2. Two in the case of a two-manifold because an edge can touch at most two faces, each of which has a loop surrounding it.
3. Yes. For example, consider a hexagonal face with two holes. The holes are internal loops and still make up the boundary of the hexagon.
4. One way is to store with each loop all the faces that are incident at its edges. Another way is just to store the faces that contain all of the edges that make up the loop. The second alternative is superior since the importance of the loop-face relation is that, given a loop, we know which face(s) we are currently processing.

5. Two, in case each of the loop's edges touches the same two faces since an edge cannot touch more than two faces, and we have restricted all of the loop's edges to touch the same faces. For example, consider a cube. The surface of the cube consists of six squares. Assume that one of these squares, say  $s_o$ , contains a smaller square, say  $s_i$ . Now, one side of the cube contains the faces  $s_i$  and  $s_o - s_i$ . Let loop  $l$  be the external loop of the inner face  $s_i$ .  $l$  is also the internal loop of the outer face  $s_o - s_i$ .

## Solutions to Exercises in Section 2.2.1.2

2. The ordering can be clockwise or counterclockwise. Let  $v$  denote the vertex and  $e$  the first edge incident at  $v$  obtained from the vertex-edge table VERTEXEDGETABLE. For a clockwise ordering, if  $v = \text{VEND}(e)$ , then the next edge is  $\text{CVVEND}(e)$ ; otherwise,  $v = \text{VSTART}(e)$ , and the next edge is  $\text{CVVSTART}(e)$ . For a counterclockwise ordering, if  $v = \text{VEND}(e)$ , then the next edge is  $\text{CCVVEND}(e)$ ; otherwise,  $v = \text{VSTART}(e)$ , and the next edge is  $\text{CCVVSTART}(e)$ .

```

1  procedure EXTRACTEDGESINCIDENTATVERTEX( $v, CWFlag$ )
2  /* Extract the edges that are incident at vertex  $v$  in clockwise (counterclockwise)
   order if flag  $CWFlag$  is true (false) in a winged-edge-face data structure. */
3  value vertex  $v$ 
4  value Boolean  $CWFlag$ 
5  pointer edge  $e, FirstEdge$ 
6   $e \leftarrow FirstEdge \leftarrow \text{EDGE}(\text{VERTEXEDGETABLE}[v])$ 
7  do
8    output  $e$ 
9    if  $CWFlag$  then
10      $e \leftarrow$  if  $\text{VEND}(e) = v$  then  $\text{CVVEND}(e)$ 
11     else  $\text{CVVSTART}(e)$ 
12     endif
13   else  $e \leftarrow$  if  $\text{VEND}(e) = v$  then  $\text{CCVVEND}(e)$ 
14     else  $\text{CCVVSTART}(e)$ 
15     endif
16   endif
17   until  $e = FirstEdge$ 
18 enddo

```

3. We can obtain all of the edges incident at a starting vertex  $v$  in clockwise (counterclockwise) order by following the  $\text{CVVSTART}$  ( $\text{CCVVSTART}$ ) fields, while we can obtain all of the edges incident at an ending vertex  $v$  in clockwise (counterclockwise) order by following the  $\text{CVVEND}$  ( $\text{CCVVEND}$ ) fields—that is, all edges  $e$  satisfy  $\text{VSTART}(e) = v$  in the former and  $\text{VEND}(e) = v$  in the latter.
4. Any combination that results in the faces being traversed in the opposite order to that of the vertices. This includes a combination of preceding/clockwise with next/clockwise and likewise for next/counterclockwise and preceding/counterclockwise. Other invalid combinations include preceding/clockwise and preceding/counterclockwise, next/clockwise and next/counterclockwise. Note that combinations such as next/clockwise and preceding/counterclockwise, and so on, are valid as they are the same.
5. In the case of edges in the same face, a positive orientation for the next edge  $e$  (i.e., a reference to it) means that  $e$  starts at the ending vertex of the current edge  $e'$  and is directed away from it. Similarly, in the case of edges incident at the same vertex, the next edge  $e$  must also terminate at the ending vertex of the current edge  $e'$  that corresponds to a positive orientation for  $e$ .
6. The algorithm is very similar to procedure EXTRACTORIENTEDEDGESOFFACE with the difference that the body in lines 11–16 is replaced by the analog of lines 9–14 in procedure EXTRACTEDGESINCIDENTATVERTEX, given in the solution to Exercise 2, and the use of ORIENTEDVERTEXEDGETABLE instead of ORIENTEDFACEEDGETABLE. One additional item of note is that the semantics of a positive (negative) orientation are reversed—that is, a negative orientation means that  $\text{VSTART}(e) = v$ , and a positive orientation means that  $\text{VEND}(e) = v$ .

**Solutions to Exercises  
in Section 2.2.1.3**

```

1  procedure EXTRACTORIENTEDEDGESINCIDENTATVERTEX( $v, CWFlag$ )
2  /* Extract the edges incident at vertex  $v$  in clockwise (counterclockwise) order
   if flag  $CWFlag$  is true (false) in an oriented winged-edge-face data structure.
   For each edge  $e$ , a negative orientation value indicates that  $e$ 's direction makes
    $e$  a part of a traversal of a starting vertex  $v$  of  $e$  (i.e.,  $VSTART(e) = v$ ), and
   thus  $e$  is directed away from  $v$ . On the other hand, a positive value indicates
   that  $e$ 's direction makes  $e$  a part of a traversal of an ending vertex  $v$  of  $e$  (i.e.,
    $VEND(e) = v$ ), and thus  $e$  is directed towards  $v$ . */
3  value vertex  $v$ 
4  value Boolean  $CWFlag$ 
5  pointer edge  $FirstEdge$ 
6  pointer edge_orientation_pair  $p$ 
7   $p \leftarrow$  ORIENTEDGE(ORIENTEDVERTEXEDGETABLE [ $v$ ])
8   $FirstEdge \leftarrow$  EDGE( $p$ )
9  do
10 output EDGE( $p$ )
11 if  $CWFlag$  then
12    $p \leftarrow$  if ORIENT( $p$ ) then CVVEND(EDGE( $p$ ))
13     else CVVSTART(EDGE( $p$ ))
14   endif
15 else  $p \leftarrow$  if ORIENT( $p$ ) then CCVVEND(EDGE( $p$ ))
16     else CCVVSTART(EDGE( $p$ ))
17   endif
18 endif
19 until EDGE( $p$ ) =  $FirstEdge$ 
20 enddo

```

7. No. The problem is that many edges are incident at vertex  $v$ , and thus the exclusion of edge  $e$  from the singly linked list around vertex  $v$  means that we cannot have a valid singly linked list of edges around vertex  $v$ . Therefore, in effect, there is no singly linked list of edges around vertex  $v$ , which means that this proposed data structure cannot be used to represent the necessary topological relationships. This can be seen by looking at the object consisting of a pair of adjacent triangular faces shown in Figure 2.95. In this case, forming a singly linked list around vertex E means that we cannot have any singly linked lists around vertices D, F, and G. Thus, we cannot represent the object. A similar argument can be made about singly linked lists of edges around adjacent faces by considering a tetrahedron object where each of the four triangular faces is adjacent to all of the remaining three faces. Thus, we cannot represent this object either. Note that the D-CEL-face-vertex data structure does not qualify as an answer unless the various links (i.e., pointers to next or preceding edges) are shared between the vertex  $v$  at which they are incident and the face  $f$  along which they lie.

**Figure S.8**  
The physical interpretation of the fields of a half-edge-vertex data structure (i.e., the vertex variant of the half-edge data structure that is based on a traversal of the edges that are incident at a vertex).

8. Obtain one vertex from each of the two companion half-edges.
11. The half-edge-vertex data structure is defined as follows. With each half-edge  $h$ , we record the following information (see Figure S.8):
- Starting vertex ( $VSTART(h)$ )
  - Companion half-edge ( $h'$ )
  - Face ( $FCW(h)$ ) along whose boundary  $h$  lies when moving in clockwise order
  - Preceding half-edge ( $CCV(VSTART(h))$ ) in clockwise order around vertex  $VSTART(h)$
  - Next half-edge ( $CV(VSTART(h))$ ) in clockwise order around vertex  $VSTART(h)$

**Solutions to Exercises in Section 2.2.1.3**

1. Each edge has two vertices, and thus the number of edge-vertex pairs is two times the number of edges. Each edge is adjacent to two faces, and therefore the number of edge-face pairs is two times the number of edges. Each face-vertex pair corresponds to the presence of a vertex

in the face, and there are as many vertices in a face as there are edges. Therefore, for each face-vertex pair, there is one edge-face pair, and thus the number of face-vertex pairs is the same as the number of edge-face pairs, which is the same as the number of edge-vertex pairs.

### Solutions to Exercises in Section 2.2.1.3.1

1. The problem is that, given lath  $L$ , knowing  $CF(L)$  and  $CCF(L)$  will only enable us to traverse the edges that make up the face  $f$  implicitly associated with  $L$ . The absence of a primitive transition involving laths associated with another face  $f'$  than  $f$  using either of  $CV$ ,  $CCV$ , or  $CE$  precludes being able to make any transitions to laths corresponding to  $f'$ . Thus, we can only answer queries involving  $f$ , which is rather limiting.
2. The problem is that, given lath  $L$ , knowing  $CV(L)$  and  $CCV(L)$  will only enable us to traverse the edges incident at the vertex  $v$  explicitly associated with  $L$ . The absence of a primitive transition involving laths associated with another vertex  $v'$  other than  $v$  using either of  $CF$ ,  $CCF$ , or  $CE$  precludes our being able to make any transitions to laths corresponding to  $v'$ . Thus, we can only answer queries involving  $v$ , which is rather limiting.
3. This is easy to see for the split-face and split-vertex representations as, by the nature of the objects' being two-manifolds, each edge is a member of two laths since it consists of two vertices and separates two faces. In the case of the corner representation, each lath corresponds to a face-vertex pair, which is an implicit representation of an edge's membership in a face. As we have a two-manifold object, the edge can be a member in just two faces, and thus we again have just two possible laths.
4. The main effect is that the order of applying the various transitions is reversed.  $CCV(L)$  is obtained by  $CE(CF(L))$ .  $CV(L)$  can be obtained either by first applying  $CE(L)$  to obtain the lath  $L'$  of the same edge  $e$  but opposite face  $f'$ , and then successively traversing the laths representing the face  $f'$  using  $CF$  until obtaining a lath  $L''$  such that  $CF(L'') = L'$ , which means that  $CV(L) = L''$ , or by successively traversing the laths surrounding the vertex associated with  $L$  using  $CCV$  until obtaining a lath  $L'$  such that  $CCV(L') = L$ , which means that  $CV(L) = L'$ .  $CCF(L)$  is obtained by  $CV(CE(L))$ . As we see, regardless of the orientation, the split-face lath data structure is not conducive to finding the lath corresponding to the next face in the counterclockwise direction ( $CCF$ ) or the next vertex in the clockwise direction ( $CV$ ) efficiently.
5. As can be seen from Figure 2.102, this alternative would result in no changes as all it means is that the right lath of the pair of split-vertex laths would be associated with the left vertex while the left lath of the pair of split-vertex laths would be associated with the right vertex. However, all transitions are the same.
6. The main effect is that the order of applying the various transitions is reversed.  $CE(L)$  is obtained by  $CF(CV(L))$ .  $CCF(L)$  is obtained by  $CV(CE(L))$ .  $CCV(L)$  is obtained by  $CE(CF(L))$ .

### Solutions to Exercises in Section 2.2.1.3.2

2. For a counterclockwise order, first find a lath  $L$  for which  $CE(L) = \text{NIL}$ , report  $L$ , and set  $L'$  to  $CF(L)$ . Now, as long as  $CE(L') \neq \text{NIL}$ , set  $L'$  to  $CCV(L')$ ; otherwise, report  $L'$  and set  $L'$  to  $CF(L')$ . Repeat this process until you encounter lath  $L$  again in an attempt to report it, at which time the traversal of the boundary face is complete. For a clockwise order, again, first find a lath  $L$  for which  $CE(L) = \text{NIL}$ , report  $L$ , and set  $L'$  to  $L$ . Now, as long as  $CE(CCF(L')) \neq \text{NIL}$ , set  $L'$  to  $CV(L')$ ; otherwise, set  $L'$  to  $CCF(L')$  and report  $L'$ . Repeat this process until you encounter lath  $L$  again in an attempt to report it, at which time the traversal of the boundary face is complete. Observe that the clockwise process is quite similar to the counterclockwise process in the sense that it can be obtained by simply replacing all clockwise transitions around a face (i.e.,  $CF$ ) by counterclockwise transitions (i.e.,  $CCF$ ) and all counterclockwise transitions around a vertex (i.e.,  $CCV$ ) by clockwise transitions (i.e.,  $CV$ ).

3. Replace all comparisons of  $CE(L)$  with  $NIL$  in the solution to Exercise 2 by comparisons of  $CV(CE(L))$  with  $NIL$ .
4. For a counterclockwise order, first find a lath  $L$  for which  $CV(L) = NIL$ , report  $L$ , and set  $L'$  to  $CCV(L)$ . Now, as long as  $CV(CE(L')) \neq NIL$ , set  $L'$  to  $CCV(L')$ ; otherwise, report  $CE(L')$  and set  $L'$  to  $CF(L')$ . Repeat this process until you encounter lath  $L$  again in an attempt to report it, at which time the traversal of the boundary face is complete. For a clockwise order, again, first find a lath  $L$  for which  $CV(L) = NIL$ , report  $L$ , and set  $L'$  to  $CE(L)$ . Now, as long as  $CV(CV(L')) \neq NIL$ , set  $L'$  to  $CV(L')$ ; otherwise, report  $CV(L')$  and set  $L'$  to  $CCF(L')$ . Repeat this process until you encounter lath  $L$  again in an attempt to report it, at which time the traversal of the boundary face is complete.
5. In the split-vertex lath data structure, each edge has two laths associated with it, regardless of whether it is a boundary edge. In the case of a boundary edge  $e$  whose associated lath is  $L$  and whose companion lath  $L' = CE(L)$ , we have  $CV(L') = NIL$  and its associated face  $f'$  is actually the boundary face. It is meaningless to traverse the edges of  $f'$ . Therefore, in the case of a boundary edge  $e$ , the operation  $CCF(L)$  is always applied to the lath  $L$  for which the associated face  $f$  is not the boundary face, and thus  $CV(L)$  is not  $NIL$ , which means that  $CCF(L) = CE(CV(L))$  can be used safely.
6. For a counterclockwise order, first find a lath  $L$  for which  $CE(L) = NIL$ , set  $L''$  to  $CF(L)$ , and report  $CV(L'')$ . Now, as long as  $CE(L'') \neq NIL$ , set  $L''$  to  $CCV(L'')$ ; otherwise, set  $L''$  to  $CF(L'')$ , and report  $CV(L'')$ . Repeat this process until you encounter lath  $L$  again in an attempt to obtain its companion, at which time the traversal of the boundary face is complete. For a clockwise order, again, first find a lath  $L$  for which  $CE(L) = NIL$ , and set  $L''$  to  $L$ . Now, as long as  $CE(CCF(L'')) \neq NIL$ , set  $L''$  to  $CV(L'')$ ; otherwise, report  $CV(L'')$ , and set  $L''$  to  $CCF(L'')$ . Repeat this process until you encounter lath  $L$  again after having reported its companion, at which time the traversal of the boundary face is complete.
7. Letting  $B$  denote the set of vertices that make up the boundary and  $NEV(v)$  denote the number of edges incident at vertex  $v \in B$ , the cost is proportional to  $\sum_{\{v \in B\}} (NEV(v) - 1)$ .
8. Letting  $B$  denote the set of vertices that make up the boundary,  $FV(v)$  denote the set of faces incident at vertex  $v \in B$  excluding the boundary face, and  $NEF(f)$  denote the number of edges that make up face  $f$ , the cost is proportional to  $\sum_{\{v \in V\}} \sum_{\{f \in FV(v)\}} NEF(f)$ .
9. Same as the solution to Exercise 7.
10. Same as the solution to Exercise 8.
11. Same as the solution to Exercise 8.
12. Same as the solution to Exercise 7.
13. Same as the solution to Exercise 8.
14. Same as the solution to Exercise 7.
15. Yes, there is a loss. In essence, it is now impossible to implement the  $CCF$  transition and thus to obtain the laths corresponding to the edges or vertices that make up a face that has at least two adjacent boundary edges (i.e., they have a vertex in common). No such problems arise when only  $CV(L')$  is set to  $NIL$  because, in this case, we will be missing edges that lie in the boundary face. However, by virtue of the way we have defined the mesh, no such edges exist anyway.
16. When  $CV(L') = NIL$ , there are no possible transitions from  $L'$  except to  $L$ , and thus the absence of a transition from  $L$  to  $L'$  does not result in any loss of querying power.
17. The main difference caused by the change in orientation is that whereas with the previous definition, it was possible for some laths corresponding to some boundary edges to be incapable of being returned as a valid value for a  $CV$  transition, now the same possibility exists for a  $CCV$  transition. This can be overcome in part by returning a lath corresponding to the desired boundary edge but whose associated vertex is not the same as the one associated with  $L$ . In addition, once again, both the  $CV$  and  $CCF$  transitions must be implemented in terms of the definitions that make use of the successive traversals of the laths representing the face  $f$  in which the laths  $CE(L)$  and  $L$ , respectively, are members.
18. The main difference caused by the change in orientation is that whereas with the previous definition, it was possible for some laths corresponding to some boundary edges to be

incapable of being returned as a valid value of a CV transition, now the same possibility exists for a CCV transition. This can be overcome in part by returning a lath corresponding to the desired boundary edge but whose associated vertex is not the same as the one associated with  $L$ . In addition, once again, the CCF transition must be implemented in terms of the definition that makes use of the traversal of the laths representing the face  $f$  in which lath  $L$  is a member. Moreover, as  $CE(L)$  is defined in terms of CV (i.e.,  $CF(CV(L))$ ), we must modify the definition of CF to not apply CF if CV( $L$ ) is NIL and simply to return NIL as the result in this case.

### Solutions to Exercises in Section 2.2.1.3.3

1. For each face-vertex lath  $L$ , the counterclockwise variant of the corner lath data structure records the transitions to both the next lath  $CCF(L)$  along the face  $F$  associated with  $L$ , to the next lath  $CCV(L)$  incident at the vertex  $V$  associated with  $L$  and both in the same direction (i.e., counterclockwise in this example). The key to the close relationship is the observation that the transition to the next lath  $CCF(L)$  along  $F$  is equivalent to the transition to the companion half-edge of the next half-edge  $CE(CV(L))$  incident at  $V$ . Recalling that, given half-edge  $L$ , the half-edge-vertex data structure is defined in terms of  $CE(L)$ ,  $CV(L)$ , and  $CCV(L)$  leads to the desired result as we have formulated  $CCF(L)$  in terms of two of the existing half-edge primitives (i.e.,  $CE(L)$  and  $CV(L)$ ). Alternatively, we can show that the transition to the companion half-edge  $CE(L)$  of half-edge  $L$  is equivalent to the transition to the next lath  $CCF(CCV(L))$  along the face associated with the next lath  $CCV(L)$  incident at  $V$ . Similarly, we know that we can obtain the transition to the half-edge  $CV(L)$  by simply following  $CE(CCF(L)) = CCF(CCV(CCF(L)))$ . Recalling that, given lath  $L$ , the counterclockwise variant of the corner lath data structure is defined in terms of  $CCF(L)$  and  $CCV(L)$  leads to the desired result as we have formulated both  $CE(L)$  and  $CV(L)$  in terms of the two existing primitives of the counterclockwise variant of the corner lath data structure (i.e.,  $CCF(L)$  and  $CCV(L)$ ).

### Solutions to Exercises in Section 2.2.1.4

1. Construct the perpendicular bisectors of the edges of the Delaunay triangulation. The bisectors meet in triplets at the circumcenters of the triangles, which are also the vertices of the Voronoi diagram.
2. Computing the convex hull takes  $O(v \log v)$  time (e.g., [743, 1511]). The Delaunay triangulation has  $O(v)$  edges. Step (b) takes  $O(v)$  time, which can be reduced to  $O(1)$  time if we use a grid [1260]. Steps (c) and (d) require  $O(v)$  time, but they could be implemented in  $O(\log v)$  time by assigning each edge a unique encoding and storing the edges in a balanced binary tree. Since steps (a) through (d) are iterated  $O(v)$  times, the total cost is  $O(v^2)$ , and the result follows.
3. Step (a) takes  $O(v)$  time as there are  $O(v)$  triangles in a triangulation regardless of whether it is a Delaunay triangulation (see Exercise 2 in Section 2.1.3.2). Steps (b) and (c) take  $O(v)$  time as there are at most  $O(v)$  triangles found in step (a). Steps (a) through (c) are applied  $v$  times as there are  $v$  vertices, and the result follows. When the points are chosen in arbitrary order, the expected execution time is  $O(v \log v)$  [765] due to the use of an amortized algorithm that enables the location of the points in an expected  $O(\log v)$  time.
4. The proof consists of two parts, where the second part is more general than the first part:
  - (a) When  $\alpha < \pi/2$ , showing that edge  $uv$  is in the Delaunay triangulation is straightforward. In particular, consider the minimum disc containing  $u$  and  $v$ , which is of diameter  $d(u, v)$ . Observe that for a point  $s$ ,  $\angle usv$  determines the location of  $s$  with respect to the disc. That is,  $\angle usv < \pi/2$  if and only if  $s$  is outside the disc;  $\angle usv > \pi/2$  if and only if  $s$  is inside the disc; and finally  $\angle usv = \pi/2$  if and only if  $s$  is on the disc. It is now easy to see that when  $\alpha < \pi/2$ , the minimum disc containing  $u$  and  $v$  is empty. On the other hand, if the minimum disc contained vertex  $t$ , then  $\angle utv \geq \pi/2$ , and hence as  $\alpha \geq \angle utv$ , we would

have  $\alpha \geq \pi/2$ , which is contrary to our initial assumption. Thus, from the disc property of the definition of the Delaunay triangulation, this means that edge  $uv$  is in the Delaunay triangulation.

- (b) The general case, independent of the value of  $\alpha$ , is a bit more complex. There are two cases due to the use of if and only if:

- i. The assumption  $\forall w \in O_p, \angle uwp \leq \pi - \alpha$  implies that edge  $uv$  is in the Delaunay triangulation.

*Proof* Let  $C$  denote the circle passing through  $u$ ,  $v$ , and  $p$ . Let  $q$  denote a point on  $C$  that is not on the same side of  $uv$  as  $p$ . Chord  $uv$  divides  $C$  into two parts,  $C_p$  and  $C_q$ , such that  $p \in C_p$  and  $q \in C_q$ . We know that  $\angle upv + \angle uqv = \pi$  since the sum of these two inscribed angles is one-half of the sum of the arcs that they subtend, which is  $2\pi$ . However,  $\angle upv = \alpha$ , and thus subtracting  $\alpha$  from both sides of the equality yields  $\angle uqv = \pi - \alpha$ . Observe that if there is a point  $t$  inside  $C_p$ , then  $\angle utv > \angle upv = \alpha$ , and as we know that  $\alpha$  is the largest such angle, we can conclude that there is no point inside  $C_p$ . We can also see that if there is a point  $t$  inside  $C_q$ , then  $\angle utv > \pi - \alpha$ . Now, since  $\forall w \in O_p, \angle uwp \leq \pi - \alpha$ , we can conclude that no point in  $O_p$  is inside  $C_q$ .

Note that by definition of  $S_p$  and  $C_q$ , no point of  $S_p$  could be inside  $C_q$ . Hence, we can see that no point of  $S$  is inside  $C$ . Therefore, by using the disc property, we have that edge  $uv$  is in the Delaunay triangulation. ■

- ii. The assumption that edge  $uv$  is in the Delaunay triangulation implies that  $\forall w \in O_p, \angle uwp \leq \pi - \alpha$ .

*Proof* Consider point  $w \in O_p$ . We show that  $\angle uwp \leq \pi - \alpha$ . As edge  $uv$  is in the Delaunay triangulation, from the disc property we know that there exists an empty disc  $D$  with center  $O$  passing through  $uv$ . Let  $C$  denote the boundary of  $D$ . As  $D$  is empty, neither  $p$  nor  $w$  is inside  $D$ . Consider points  $r$  and  $t$ , such that  $r$  is the intersection of  $C$  with line segment  $Op$ , and  $t$  is the intersection of  $C$  with line segment  $Ow$ . As  $r$  and  $t$  are points on  $C$  on opposite sides of chord  $uv$ , we have  $\angle urv + \angle utv = \pi$  since the sum of these two inscribed angles is one-half of the sum of the arcs that make them up, which is  $2\pi$ . As  $p$  is not inside  $C$ , we have  $\angle upv \leq \angle urv$ . Similarly, as  $w$  is not inside  $C$ , we have  $\angle uww \leq \angle utv$ . Hence,  $\angle upv + \angle uww \leq \angle urv + \angle utv = \pi$ , and thus  $\angle upv + \angle uww \leq \pi$ . Noting that  $\angle upv = \alpha$  and subtracting  $\alpha$  from both sides yields the desired result that  $\angle uww \leq \pi - \alpha$ . ■

5. The fact that each vertex of the Voronoi diagram has degree 3 leads to the following elegant solution developed independently by Michael B. Dillencourt and Franco P. Preparata.

- (a) Pick some face  $f$  of the Voronoi diagram, and let  $s_f$  be its site. Pick some vertex  $v_1$  of  $f$ , and compute a line  $L_1$  through  $v_1$  such that  $s_f$  lies on  $L_1$  (we discuss how to do this below).
- (b) Pick some other vertex  $v_2$  (not necessarily adjacent to  $v_1$ ) of  $f$ , and, as in step (a), compute a line  $L_2$  through  $v_2$  such that  $s_f$  lies on  $L_2$ .
- (c)  $s_f$  is the unique point of intersection of  $L_1$  and  $L_2$ . Once we have determined  $s_f$ , we can find all the other sites by repeatedly reflecting  $s_f$  about the edges of the Voronoi diagram as each edge of the Voronoi diagram is the perpendicular bisector of the line joining the sites of its two adjacent Voronoi faces. Therefore, knowing  $s_f$  of face  $f$ , the reflection process about an edge  $e$  of  $f$  into the other face  $g$  adjacent to  $e$  determines the location  $s_g$  of the site of  $g$ .

Given a face  $f$  of a Voronoi diagram and a vertex  $v$  of  $f$ , the key to this algorithm is to find a line  $L_1$  through  $v$  (actually a ray originating at  $v$  and passing through  $f$ ) such that  $L_1$  is guaranteed to contain the generating site  $s_f$  of  $f$ . This is achieved as follows. Based on our initial assumption, each vertex of the Voronoi diagram has degree 3. Let  $v$  be a vertex of face  $f$ , and let  $va$ ,  $vb$ , and  $vc$  be the edges, without loss of generality, in clockwise order that are incident at  $v$  with vertices  $a$ ,  $b$ , and  $c$ , respectively. Assume that  $f$  is the face between  $va$  and

$vb$ ,  $g$  is the face between  $vb$  and  $vc$ , and  $h$  is the face between  $vc$  and  $va$ . Let  $s_f$ ,  $s_g$ , and  $s_h$  be the generating sites of faces  $f$ ,  $g$ , and  $h$ , respectively. Now, let us name the angles formed by  $v$  and its neighboring vertices and sites—that is,  $r = \angle avb$ ,  $s = \angle bvc$ ,  $t = \angle cva$ ,  $x = \angle avs_f$ ,  $y = \angle bvs_g$ , and  $z = \angle cvs_h$ . Note that we also have that  $x = \angle s_hva$ ,  $y = \angle s_fvb$ , and  $z = \angle s_gvc$  as the triangle pairs  $s_hva$  and  $s_fva$ ,  $s_fvb$  and  $s_gvb$ , and  $s_gvc$  and  $s_hvc$  are congruent. From these relations, we have that  $r = x + y$ ,  $s = y + z$ , and  $t = x + z$ . Subtracting  $s = y + z$  from corresponding sides of  $r = x + y$  yields  $r - s = x - z$ . Adding  $r - s = x - z$  to corresponding sides of  $t = x + z$  yields  $r - s + t = 2x$ , and solving for  $x$  yields  $x = (r - s + t)/2$ . At this point, we are done as we now know that the generating site  $s_f$  for face  $f$  is on the ray originating at  $v$  that makes an angle of  $x = (r - s + t)/2$  with the ray  $va$ . This is  $L_1$  from step (a) of the above algorithm. We now execute step (b) in the same manner to obtain  $L_2$ , and intersect the two rays to obtain  $s_f$ . Given a Voronoi diagram with  $N$  vertices, the running time of the algorithm after repeated application of step (c) is  $O(N)$ , assuming that the Voronoi diagram is represented using some reasonable planar graph structure. For example, use one of the variants of the winged-edge data structure discussed in Sections 2.2.1.2 and 2.2.1.3, or even a data structure that imposes a spatial index on the edges, such as one of the variants of the PM quadtree discussed in Sections 2.2.2.6 and 2.2.2.8. For more details on the use of the spatial index data structures in this context, see the discussion of the use of the  $PM_2$  quadtree for the representation of a Voronoi diagram in Sections 2.2.2.6 of this chapter and 4.4.5 in Chapter 4. In particular, having chosen an appropriate data structure, determining the site for the first face takes  $O(1)$  time. After that, traverse the faces of the Voronoi diagram in some depth-first order (which takes  $O(N)$  time), and every time a new face is visited, its site is computed by reflecting the site of its parent across the edge that was just crossed to get from the parent face to the current face.

To elaborate further on the depth-first search process mentioned in the preceding paragraph, we note that, at times, we may be more interested in marking all of the edges of the faces of the polygonal map that is a Voronoi diagram with their associated sites instead of in just identifying all of the sites of the Voronoi diagram. In this case, once we have determined one site, say  $s_f$  of  $f$ , we trace all of the remaining edges in  $f$  and mark the relevant sides of the edges having  $s_f$  as its region's site. This is equivalent to a depth-first graph traversal where each edge is bidirectional. When the tracing process visits a side of an edge that has been visited already, we attempt to visit its other side and, if necessary, determine the site associated with its face. If both sides of an edge have been visited, then we backtrack. Thus, since a depth-first graph traversal can be performed in  $O(N)$  time, we can also identify the sites associated with all of the edges of the Voronoi diagram in  $O(N)$  time.

6. David M. Mount suggests turning to [807, 1616] for an alternative solution that addresses the more general variant of this problem by reducing it to a two-dimensional linear programming problem that can be solved in linear time, as well as the more general problem that, for a given integer  $k$  and an arbitrary polygonal map  $T$ , finds the set of  $k$  points, if one exists, whose Voronoi diagram contains every edge in  $T$ . Intuitively, this problem can be posed as a linear system as follows. Our solution assumes the two-dimensional plane but actually works in any dimension. Suppose that two Voronoi sites  $s_1$  and  $s_2$  are separated by an edge  $e$  of the Voronoi diagram. We do not know the coordinates of  $s_1$  and  $s_2$ , but if we know the location (i.e., coordinate values) of  $s_1$ , then knowing that  $e$  is the perpendicular bisector of the edge formed by  $s_1$  and  $s_2$  enables us to fix the location of  $s_2$ . Thus, even though  $s_1$  and  $s_2$  have four degrees of freedom (two for each of the  $x$  coordinate values and two for each of the  $y$  coordinate values), the knowledge of the perpendicular bisector of the edge between them reduces this to two independent degrees of freedom. Therefore, as long as the number of Voronoi edges  $m$  exceeds the number of Voronoi sites  $n$ , the system will be fully constrained, and so, any linear solver (involving  $2n$  variables and  $2m$  equations) will provide the answer. Once the system has been solved and  $N$  sites have been obtained, it is possible in  $O(N)$  time to verify that the topology of the planar subdivision is the same as the Voronoi diagram. This can be done by a simple traversal of the diagram. This verification step is necessary because the linear system of equations is typically overconstrained, and thus some of the constraints may have been omitted when solving the system. In particular, the problem with the linear programming solution is that it simply verifies that for each edge  $e$  in the Voronoi diagram there exists a pair of points whose bisector is collinear with  $e$ . However, the solution process does not verify the locations of the Voronoi vertices or that the edges are connected in the proper orientation to the Voronoi vertices. Note also that the solution may not be unique, as

is the case, for example, when we have the Voronoi diagram of just three sites. In particular, assume, without loss of generality, that all three sites lie on a unit circle centered at the origin. In this case, their Voronoi diagram consists of one Voronoi vertex at the origin and three semi-infinite edges. Now, observe that if we scale the coordinate values of the sites by any positive constant, they still lie on a scaled circle centered at the origin and their bisectors do not change, and we obtain exactly the same Voronoi diagram. The same result holds for a degenerate configuration where more than three sites lie on a circle (e.g., four sites that lie at the vertices of an origin-centered axis-aligned rectangle). Thus, again, we have a case where the Voronoi diagram does not determine its sites.

### Solutions to Exercises in Section 2.2.1.6

1. In  $d$  dimensions, the topological analog of the Delaunay triangulation arises whenever no  $d + 2$  vertices or points lie on the surface of a  $d$ -dimensional sphere.
2.  $d - 1$ , corresponding to the sharing of an edge, face, ..., and  $(d - 1)$ -dimensional face.

### Solutions to Exercises in Section 2.2.1.7

1. Restriction (1) is violated by an hourglass object that consists of two pyramids. Restriction (2) is violated by a pyramid whose vertex or edge is adjacent to a flat surface.
2. No. For example, consider the hourglass object that consists of two pyramids. This object can be formed by the union of two pyramids, each of which is a two-manifold object, yet the result is not a two-manifold object.
3. The triangle table contains six items of information for each triangle (i.e., three pointers to the three constituent vertices and three pointers to the three adjacent triangles) for a total of  $6T$ . The storage requirements of the connectivity table are obtained as follows. Each triangle consists of three vertices, which means that each triangle participates in the connectivity list of three vertices. The planar subdivision formed by the triangulation also contains an exterior face that has  $H$  vertices ( $H \leq V$ ). Thus, there is a total of  $3T + H \leq 3T + V$  entries in the connectivity table, and the result follows, assuming that  $H$  is usually much smaller than  $V$  and  $T$ . Actually, the connectivity table also contains one end of a list marker for the list of each vertex, and thus the true storage requirement of the connectivity table is bounded by  $3T + 2V$ .
4. (David M. Mount) Assume a connected graph corresponding to a triangulation with  $V$  vertices,  $E$  edges, and  $T$  triangles. Let  $H$  denote the number of vertices on the exterior face. The number of faces  $F$  in the graph is  $T + 1$  (counting the exterior face). All faces have degree 3 except the exterior face, which has degree  $H$ . Thus, the sum of face degrees is  $3T + H$ , which is equal to  $2E$ . Since  $H$  is not larger than  $V$ , we have  $2E \leq 3T + V$ . Combining this with Euler's formula we have

$$\begin{aligned} 2 &= V - E + F \\ 4 &= 2V - 2E + 2F \\ &\geq 2V - (3T + V) + 2 \cdot (T + 1) \\ &= 2V - 3T - V + 2T + 2 \\ &= V - T + 2 \end{aligned}$$

Rearranging this inequality, we have that  $V \leq T + 2$ . From Exercise 3, we have that the connectivity table method requires  $3T + 2V$  storage units. Replacing  $V$  with its upper bound  $T + 2$  leads to the desired bound of  $5T + 4$ . Thus, we see that so long as  $T \geq 4$ , the connectivity table method using  $3T + 2V$  storage units will be better from a space-efficiency standpoint than the triangle table method.

5. From Exercise 3, we have that the connectivity table of the connectivity table method requires  $3T$  storage units, and since the connectivity table of the star vertex data structure contains twice as much information (i.e., one additional pointer per entry), we have that the star vertex data structure requires  $6T + V$  storage units.

## Solutions to Exercises in Section 2.2.2.1

1. The line quadtree is nothing but a region quadtree with additional information stored at the nonleaf nodes.
2. The SE quadrant of the line quadtree requires one node, whereas in the revised line quadtree, this quadrant requires four leaf nodes since the northern boundaries of the NW and NE subquadrants differ.

## Solutions to Exercises in Section 2.2.2.2

1. Use  $B(i) = 2 \cdot \lceil p/2^i \rceil$  instead of  $B(i) = 6 \cdot \lceil p/2^i \rceil$  in the proof of Theorem 2.1.
2. Let the four squares defining each curve be called  $A$ ,  $B$ ,  $C$ , and  $D$ . If the curve is less than  $d$  in length, no two of  $A$ ,  $B$ ,  $C$ , and  $D$  can be  $d$  or more apart at their closest points and still permit the curve to enter a fifth different square. The rest of the proof is analogous to that of Theorem 2.1. In particular, use  $B(i) = 2 \cdot \lceil p/2^i \rceil$  instead of  $B(i) = 6 \cdot \lceil p/2^i \rceil$  in the proof of Theorem 2.1.
3. The MX quadtree contains 1 node at level  $q$  (i.e., the root node), 4 nodes at level  $q - 1$ , and 16 nodes at each of levels  $q - 2$  through 0. Summing up yields the desired result.
4. The MX quadtree contains 1 node at level  $q$  (i.e., the root node), 4 nodes at level  $q - 1$ , and  $4 \cdot 2^{q-i}$  nodes at level  $i$ , where  $i$  ranges between 0 and  $q - 2$ . Summing up yields  $5 + 8 \cdot (2^q - 2)$ , equal to  $8 \cdot p - 11$ .
6. When  $p \leq 4 \cdot q$ , use the polygon of Figure 2.119 for the given value of  $q$  by extending the perimeter arbitrarily to achieve the desired value of  $p$  so that the extended polygon intersects all of the pixels that it intersected prior to the extension. This polygon requires at least  $16 \cdot q - 11$  nodes, which is more than  $p + q$  but is still less than  $5 \cdot q$ . When  $p > 4 \cdot q$ , construct a polygon in the form of a concatenated sequence of “U” patterns of minimal width. The components of the “U” are reduced in size or perturbed as necessary to yield a polygon of perimeter  $p$ . Since each pixel is a leaf, summing up the nodes at all levels yields at least  $(4/3) \cdot p$  nodes or  $(2/3) \cdot (p + q)$  as  $p > q$ .
8. See [1273] for a proof that the size of the MX octree is bounded by four times the surface area.
10. See [1948].
11. See [1948].
12. See [111] for some examples.

## Solutions to Exercises in Section 2.2.2.5

3. When the boundaries of the object are straight lines (polygonal faces), then the resulting decompositions may be the same when using a zero error tolerance on the edge quadtree (face octree). Otherwise, the situation depends heavily on the shape of the object that is being represented.

6      L ← SETUNIONSAMEMULTIPLICITY(L, DICTIONARY(P))
7      /* SETUNIONSAMEMULTIPLICITY supports duplicate instances of an edge by
         making sure that edges that occur more than once in the sets maintain their
         multiplicity. If no duplicate instances are allowed, then can use a conven-
         tional set union operation. */
8      return TRUE
9  else return(TRYTOMERGEPM1(CHILD(P, 'NW'), R, L) and
10             TRYTOMERGEPM1(CHILD(P, 'NE'), R, L) and
11             TRYTOMERGEPM1(CHILD(P, 'SW'), R, L) and
12             TRYTOMERGEPM1(CHILD(P, 'SE'), R, L) and
13             PM1CHECK(L, SQUARE(R)))
14 endif

1  recursive procedure RETURNTREETOAVAIL(P)
2  /* Return the PM quadtree rooted at P to the free storage list. This process is
       recursive in the case of a PM1 quadtree. */
3  value pointer node P
4  quadrant I
5  if ISLEAF(P) then return
6  else
7      for I in {'NW', 'NE', 'SW', 'SE'} do
8          RETURNTREETOAVAIL(CHILD(P, I))
9          RETURNTOAVAIL(CHILD(P, I))
10         CHILD(P, I) ← NIL
11     enddo
12 endif

```

3. Replace calls to procedure PM1CHECK in Exercise 1 by procedure PM2CHECK.

```

1  Boolean procedure PM2CHECK(L, S)
2  /* Determine if the square pointed at by S and the list of edges pointed at by
       L form a legal PM2 quadtree node. SHAREPM12VERTEX is invoked with L
       instead of NEXT(L) because the edge might have one vertex in the square
       and share the other vertex with the list, which violates the PM2 quadtree
       definition conditions. Assume that an isolated vertex (i.e., an edge with zero
       length) does not serve as an endpoint of another edge. */

```

```

3 value pointer edgelist L
4 value pointer square S
5 return(if ISEMPY(L) then TRUE
6     elseif P1(DATA(L))=P2(DATA(L)) then
7         ONEELEMENT(L) /* Isolated vertex */
8     elseif PTINSQUARE(P1(DATA(L)),S) and
9         PTINSQUARE(P2(DATA(L)),S)
10        /* Ensure that when a vertex is shared, the other vertex is not in
11           same square */
12        then FALSE
13     elseif SHAREPM12VERTEX(P1(DATA(L)),L,S) or
14        SHAREPM12VERTEX(P2(DATA(L)),L,S) then TRUE
15     else FALSE
16     endif)

```

4. Replace calls to procedures POSSIBLEPM1MERGE and TRYTOMERGEPM1 in PMDELETE with calls to procedures POSSIBLEPM23MERGE and TRYTOMERGEPM23, respectively, to determine if an attempt should be made to merge the four children of a gray node after processing them—that is, the conditions of a  $PM_2$  quadtree definition are satisfied. A merge is feasible only if all four children of a gray node are leaf nodes. This situation is checked by POSSIBLEPM23MERGE. If the merge is feasible, then TRYTOMERGEPM23 is applied to determine if the conditions of the definition of the  $PM_2$  quadtree are satisfied by using PM2CHECK.

```

1 Boolean procedure POSSIBLEPM23MERGE(P)
2 /* Determine if an attempt should be made to merge the four children of the PM2
3    or PM3 quadtree. Such a merger is feasible only if all four children of a gray
4    node are leaf nodes. */
3 value pointer node P
4 return(ISLEAF(CHILD(P,'NW')) and ISLEAF(CHILD(P,'NE')) and
5        ISLEAF(CHILD(P,'SW')) and ISLEAF(CHILD(P,'SE')))

1 Boolean procedure TRYTOMERGEPM23(P,R,L)
2 /* Determine if the four children of the PM2 or PM3 quadtree rooted at node P
3    can be merged. Variable L is used to collect all of the edges that are present in
4    the subtrees. Note that there is no need for parameter R, and the procedure is
5    not recursive. The call to PM2CHECK is replaced by PM3CHECK when delet-
6    ing from a PM3 quadtree. */
3 value pointer node P,R
4 reference pointer edgelist L
5 quadrant I
6 for I in {'NW','NE','SW','SE'} do
7     L ← SETUNIONSAMEMULTIPLICITY(L,DICTIONARY(CHILD(P,I)))
8     /* SETUNIONSAMEMULTIPLICITY supports duplicate instances of an edge by
9        making sure that edges that occur more than once in the sets maintain their
10       multiplicity. If no duplicate instances are allowed, then use a conventional
11       set union operation. */
9 enddo
10 return PM2CHECK(L,SQUARE(P))

```

5. Replace calls to procedures PM1CHECK and SHAREPM12VERTEX in Exercise 1 with calls to procedures PM3CHECK and SHAREPM3VERTEX, respectively. The  $PM_3$  quadtree is somewhat different from the  $PM_1$  and  $PM_2$  quadtrees in that an isolated vertex is allowed to coexist in a leaf node along with the q-edges that do not intersect it. This is achieved by using INF to represent a fictitious point at  $(\infty, \infty)$  and to invoke SHAREPM3VERTEX with it as the shared vertex.

```

1 recursive Boolean procedure PM3CHECK(L,S)
2 /* Determine if the square pointed at by S and the list of edges pointed at by L
3    form a legal PM3 quadtree node. Assume that an isolated vertex (i.e., an edge
4    with zero length) does not serve as an endpoint of another edge. */
3 value pointer edgelist L
4 value pointer square S

```

```

5  return(if ISEMPY(L) then TRUE
6      elseif P1(DATA(L)) = P2(DATA(L)) then /* Isolated vertex */
7          SHAREPM3VERTEX(INF, NEXT(L), S)
8          /* INF ensures that the remaining edges have no vertices in S */
9      elseif PTINSQUARE(P1(DATA(L)), S) and
10         PTINSQUARE(P2(DATA(L)), S)
11         /* Ensure that when a vertex is shared, the other vertex is not in
12            same square */
13         then FALSE
14         elseif PTINSQUARE(P1(DATA(L)), S) then
15             SHAREPM3VERTEX(P1(DATA(L)), NEXT(L), S)
16         elseif PTINSQUARE(P2(DATA(L)), S) then
17             SHAREPM3VERTEX(P2(DATA(L)), NEXT(L), S)
18         else PM3CHECK(NEXT(L), S)
19     endif)

1  recursive Boolean procedure SHAREPM3VERTEX(P, L, S)
2  /* The vertex pointed at by P is the shared vertex in a PM3 quadtree. It is in-
3     side the square pointed at by S. Determine if all the edges in the list of edges
4     pointed at by L either share P and do not have their other vertex within S, or
5     do not have either of their vertices in S. When P is INF, then the rest of the
6     edges have no vertex in S. */
3  value pointer point P
4  value pointer edgelist L
5  value pointer square S
6  return(if ISEMPY(L) then TRUE
7      elseif P = P1(DATA(L)) then
8          not(PTINSQUARE(P2(DATA(L)), S)) and
9          SHAREPM3VERTEX(P, NEXT(L), S)
10     elseif P = P2(DATA(L)) then
11         not(PTINSQUARE(P1(DATA(L)), S)) and
12         SHAREPM3VERTEX(P, NEXT(L), S)
13     else not(PTINSQUARE(P1(DATA(L)), S)) and
14         not(PTINSQUARE(P2(DATA(L)), S)) and
15         SHAREPM3VERTEX(P, NEXT(L), S)
16     endif)

```

6. Replace the call to procedure PM2CHECK in TRYTOMERGEPM23 with a call to PM3CHECK to check if the conditions of a PM<sub>3</sub> quadtree definition are satisfied.
7. Since a vertex node in a PM<sub>3</sub> quadtree can contain edges that do not intersect the vertex, more vertex nodes appear at shallower levels. The result follows as the total number of vertex nodes is the same for all three variants of the PM quadtree, and thus fewer vertex nodes will appear in the deeper levels.
9. First, determine the quadtree block  $b$  of side length  $w$  containing  $q$ . The radius of the search region cannot be larger than  $2w\sqrt{2}$ , which is the case when  $b$  is empty as one of the siblings of  $b$  must contain a q-edge as otherwise the siblings would have been merged to yield a larger node. The actual search examines the blocks adjacent to  $b$  subject to the maximum search radius. Of course, the search radius is much smaller if  $b$  is not empty. For another approach, see the incremental nearest neighbor algorithm of Hjaltason and Samet [846, 848], as well as Section 4.1.3 of Chapter 4.
10. See [1665] for a solution for the PM<sub>3</sub> quadtree.
12. The difficulty is that unlike the two-dimensional plane, we cannot assume that two nonparallel lines will intersect.

## Solutions to Exercises in Section 2.2.2.7

1. As we saw in the discussion of the PM quadtree, there are a number of possible PM<sub>1</sub> octree variants, largely depending on whether a vertex- or edge-based approach is pursued. In three

dimensions, the most logical approach is to adapt the  $PM_1$  quadtree. In such a case, the resulting decomposition insures that each octree leaf node corresponds to a single vertex, a single edge, or a single face. The only exceptions are that a leaf node may contain more than one edge if all the edges are incident at the same vertex. Similarly, a leaf node may contain more than one face if all the faces are incident at the same vertex or edge. The result is termed a *PM octree*. The above subdivision criteria can be stated more formally as follows:

- (a) At most, one vertex can lie in a region represented by an octree leaf node.
  - (b) If an octree leaf node's region contains a vertex, then it can contain no edge or face that is not incident at that vertex.
  - (c) If an octree leaf node's region contains no vertices, then it can contain at most one edge.
  - (d) If an octree leaf node's region contains no vertices and contains one edge, then it can contain no face that is not incident at that edge.
  - (e) If an octree leaf node's region contains no edges, then it can contain at most one face.
  - (f) Each region's octree leaf node is maximal.
2. In the case of the *vertex'* node type, the node also contains the edges at which the faces meet, but this is not the so for the *vertex''* node type.
  3. For a polyhedron, the face octree requires more space than the  $PM_1$  octree when the error tolerance is zero. However, as the error tolerance is increased, the use of the planar approximation could result in the elimination of edges and vertices by merging the faces and edges that are incident at them, thereby not eliminating the need to decompose around them and thus not requiring as much space as the  $PM_1$  octree.
  4.  $h_1 \wedge h_2 \wedge h_3$ ,  $h_1 \vee h_2 \vee h_3$ ,  $(h_1 \wedge h_2) \vee h_3$ , and  $(h_1 \vee h_2) \wedge h_3$ . The first two yield a vertex of a convex object, and the third and fourth yield the vertex of a concave object.
  5. 12.
  7. See [1352].
  8. See [1352].
  11. This is not possible when the CSG primitives are approximated in the PM octree. However, it is possible when the CSG tree is specified using halfspaces.
  14. See the solution for the  $PM_1$  quadtree in Exercise 9 in Section 2.2.2.6.

## Solutions to Exercises in Section 2.2.2.8

1. They are not the same. The problem is that when block  $b$  in a vertex bucket polygon quadtree is a part of more than  $T$  polygons while containing just one vertex  $v$ , the edges of the polygons in  $b$  are not required to intersect at  $v$ . In this case, in the vertex bucket polygon quadtree  $b$  is not decomposed further, but  $b$  is decomposed further in the bucket  $PM_1$  quadtree for line segments if the  $T$  line segments do not intersect at  $v$ .
2. They are not the same. The problem is that the only time that a block  $b$  in the vertex bucket polygon quadtree is permitted to be a part of more than  $T$  polygons is when  $b$  contains  $v$ . However, this is not necessarily the case in the bucket  $PM_2$  quadtree for line segments as  $b$  can contain  $L > T$  nonintersecting line segments and hence be a part of  $L + 1$  polygons as long as all of the  $L$  line segments intersect at some vertex  $v$ , which could be outside  $b$ . This violates the decomposition rule for the vertex bucket polygon quadtree.
3. They are not the same. The problem is that a block  $b$  in the vertex bucket polygon quadtree can contain more than one vertex, but this is not possible for the  $PM_3$  quadtree. Moreover, in the vertex bucket polygon quadtree,  $b$  can contain no vertices, in which case  $b$  is split if  $b$  is a part of more than  $T$  polygons, but  $b$  is not split in the case of a  $PM_3$  quadtree.
4. The result is not equivalent to any of the PM quadtree decomposition rules for line segments.

- (a)  $PM_1$  quadtree for line segments: The problem is that in the vertex bucket polygon quadtree, the decomposition halts whenever a block contains just one vertex, but there is no stipulation that all the edges contained in the block must meet at the vertex as is required in the  $PM_1$  decomposition rule for line segments.
- (b)  $PM_2$  quadtree for line segments: The problem is the same as for the  $PM_1$  quadtree. In addition, the case where the line segments passing through the block intersect in the same vertex outside the block permits a block that does not contain a vertex to be a part of more than two polygons in the  $PM_2$  quadtree for line segments, but this is not allowed in the vertex bucket polygon quadtree.
- (c)  $PM_3$  quadtree for line segments: The problem is that whenever a block  $b$  does not contain any vertices, the  $PM_3$  quadtree for line segments does not restrict the number of line segments that can pass through  $b$ , while the vertex bucket polygon quadtree implicitly restricts it to just one line segment since the only way to have two polygons in a block is if the block contains just one line segment. Notice that, unlike the  $PM_1$  quadtree for line segments, the two structures are identical when the block contains just one vertex as in both cases the line segments that pass through the block need not intersect at the vertex.
5. We use contradiction. Let  $X$  be the property that the number of line segments in a node is bounded from above by the splitting threshold plus the depth of the node. Assume the existence of a node, say  $P$ , at depth  $k$  in a tree built with splitting threshold  $m$  that contains  $n$  line segments, where  $n > k + m$  (i.e., the existence of  $P$  contradicts property  $X$ ). Also, assume that of the nodes that violate property  $X$ , node  $P$  is the closest one to the root. We have two cases:  $k = 0$  (i.e.,  $P$  is a root node) or  $k > 0$ . If  $k = 0$ , then we have a tree of just the one node  $P$ , which contains more items than the splitting threshold. Since line segments are inserted one at a time,  $P$  must have been created by inserting one line segment into a node, say  $Q$ , that previously contained  $n - 1$  line segments. From  $k = 0$  and  $n > k + m$ , we have  $n - 1 \geq m$ . However, since  $Q$  contains  $n - 1$  line segments and must be at level 0 itself, it follows that upon inserting yet another line segment into a node  $Q$  that is already at or over threshold  $m$ , only leaf nodes at depth 1 will result. Therefore,  $k$  could not be zero, and hence  $P$  cannot be a root node.
- Since  $P$  is not a root node, it has a parent node. Using analogous reasoning to that above yields the observation that  $P$ 's parent, say  $PP$ , must be one level closer to the root and contains one fewer line segment prior to the creation of  $P$ . However, since  $n > k + m$ , it follows that  $n - 1 > k - 1 + m$ . Thus,  $PP$  will also violate property  $X$  and is one level closer to the root of the tree. This contradicts the assumption that  $P$  was the node closest to the root of the tree that could violate property  $X$ . Therefore, there can be no such node  $P$  that contradicts property  $X$ . Hence, property  $X$  is true—that is, for every node, the number of line segments in the node is bounded from above by the sum of the splitting threshold and the depth of the node.
6. This is not a problem for the  $PM_3$  quadtree, but the  $PM_1$  and  $PM_2$  quadtrees will not be able to deal with it. The problem is that for the  $PM_1$  and  $PM_2$  quadtrees, it may be impossible to achieve a situation where each node contains just one line segment.
7. Every line in  $L$  passes through one, two, or three quadrants of the quartered block. Let  $A$  be a line perpendicular to the set  $L$ , and for any point  $P$  on  $A$ , let  $q(P)$  be the number of quadrants intersected by the element of  $L$  that is perpendicular to  $A$  at  $P$ .  $A$  can be partitioned into sections depending on the value of  $q(P)$ . Because of the symmetry of the square block, the total length of the sections with  $q(P) = 1$  is equal to the total length of the sections with  $q(P) = 3$ , independent of the value of  $\theta$ . The value of  $q(P)$  over the remainder of the intersection of  $A$  with  $L$  is 2. Therefore, the average number of quadrants intersected by the block is 2 [1361].
8. The expected number of quadrants of occupancy  $i$  produced by splitting a node of occupancy  $c$  is  $\binom{c}{i} \cdot 2^{2-i}$ .
9. From Exercise 7, we know that each quadrant has a 0.5 probability of intersecting each line segment in the parent node. Therefore, the average occupancy of the nodes produced is 0.5 times the occupancy of the parent node.
10. A node of occupancy  $i > c$  must be produced by a split such that all  $i$  line segments intersect the same quadrant. Assuming a uniform distribution, the expected number of children for  $i = c + 1$  is  $4 \cdot 2^{c+1}$  per split; for  $i = c + 2$ , the expected number of children is  $4 \cdot 2^{c+1} \cdot 4 \cdot 2^{c+2}$ ; and so on. Thus, the expected number of nodes with occupancy greater than  $c$  decreases exponentially with  $i - c$ .

12. Use procedure PMDELETE given in Exercise 2 in Section 2.2.2.6 with POSSIBLEPMR-MERGE and TRYTOMERGEPMR instead of POSSIBLEPMIMERGE and TRYTOMERGEPM1, respectively.

### Solutions to Exercises in Section 2.2.2.9

1. Let  $r$  be the length of the perpendicular sides of the triangle. The true perimeter is  $2r + r\sqrt{2}$ , and the approximated perimeter is  $4r$ .
2.  $4/\pi$ .
3. Use linear interpolation in  $x$  and  $y$  instead of  $\rho$  and  $\theta$  for the arc of the sector. A combination of polygonal and nonpolygonal blocks could also be implemented by using an additional bit with each sector to indicate the block type.
4. The inner approximation means that the object is made larger since it is the part outside the object that is truncated. On the other hand, the outer approximation implies the addition of two newly created subregions to the collection represented by the sector.
5. No, because the boundary may repeatedly snake through a number of adjacent nodes.
6. Let  $P$  be the contact point in question, and let  $Q$  and  $R$  be the immediately preceding and following, respectively, contact points on the other side of the sector. Duplicate  $P$  in the sector's leaf node, and define a three-sided region bounded by the side of the sector between  $Q$  and  $R$  and the spiral arc approximations of  $PQ$  and  $PR$ .
7. The only difference is that when the origin of the polar plane is outside the object, each leaf node of a sector tree contains an even number of pairs of points instead of an odd number. Each successive two pairs of points define a region within the object.
8. Use different origins for the approximating arcs. In particular, the origins are on opposite sides of the arcs. For example, in Figure 2.132(b) the arc between points 5 and C would have an origin somewhere to the SW of the arc between points 4 and D.
9. No, for both approximations since this depends on the curvature of the boundary where the approximation takes place.
11. Rotation only requires rearranging pointers. All interpolations remain the same since each sector corresponds to an angular range of  $2\pi/2^n$ . Therefore, all the approximated arcs remain unchanged.
12. Traverse the tree in such a way that nodes corresponding to adjacent boundary segments are visited in sequence. Note that each leaf node may be visited more than once because the boundary may repeatedly snake through a number of adjacent nodes.

### Solutions to Exercises in Section 2.2.2.10

1.
 
$$\rho(s, t) = \rho_{11} + (\rho_{12} - \rho_{11}) \cdot s + (\rho_{21} - \rho_{11}) \cdot t + (\rho_{22} - \rho_{21} - \rho_{12} + \rho_{11}) \cdot st$$

$$\theta(s, t) = \theta_1 + (\theta_2 - \theta_1) \cdot s \phi(s, t) = \phi_1 + (\phi_2 - \phi_1) \cdot t.$$
2. Each cone would be a collection of spherical patches similar to that used in the sector tree.
3. The only difference is that when the origin of the polar sphere is outside the object, then each leaf node of a cone tree contains an even number of spherical patches instead of an odd number. Each successive pair of patches defines a region within the object.

### Solutions to Exercises in Section 2.2.3.1

1. At each level of the tree, we must examine  $n$  points to determine the points on the curve that are at a maximum distance from the line joining the curve's endpoints. The tree has  $\log_2 n$  levels.
3. At each level of the tree, we must process one-half of as many rectangles as were processed on the previous level. Initially, we process  $n + 1$  pairs of points to yield  $n$  rectangles. The result follows since we have a geometric series with a ratio of  $1/2$ .
5. In the top-down method, the enclosing rectangles are formed by using points on the curve, whereas in the bottom-up method, all rectangles at levels other than the deepest level are based on the strips. In other words, in the bottom-up method the width of the final rectangle is not necessarily the sum of the maximum distances to the curve from the line joining the endpoints of the curve.
7. Constructing the rectangular strip takes  $O(N)$  time for  $N$  points since the perpendicular distance of each point from the line joining the curve's endpoints must be calculated. In contrast, constructing the rectangle of minimum bounding area for  $N$  points takes  $O(N \cdot \log_2 N)$  time as the convex hull for the points must be obtained first.
8. See [639].
9. When all the strip segments in one tree intersect all the strip segments in the other tree, the algorithm will take  $O(2^{d_1+d_2})$  time.
11. Represent it as two closed curves. Alternatively, draw an imaginary line across the area, and order the points so that the region is always to the right of the curve.
12. See [121].
13. The key is that if the intersection of any strip of the curve, say  $S_c$  corresponding to a node  $T_c$ , with the strip tree of the area, say  $T_a$ , is null, then (1) if any point on  $S_c$  is inside  $T_a$ , then every point in  $T_c$  is inside or on the boundary of  $T_a$ , and (2) if any point on  $S_c$  is outside  $T_a$ , then every point in  $T_c$  is outside  $T_a$ . See [121].
14. The key is to decompose the problem into two subproblems of intersecting curves with areas. Let  $T_1$  and  $T_2$  represent the strip trees corresponding to the two areas. First, intersect the curve corresponding to  $T_1$  with the area corresponding to  $T_2$  and then reverse the roles of the two strip trees. The final result is represented by the union of the previous two steps. See [121].
15. Not when the curve is closed.
16.  $\int_a^b \sqrt{1 + f'^2(x)} \cdot dx$ .
17. Use contradiction. The length of the major axis of the ellipse is equal to the length of the corresponding arc that is being approximated. An ellipse, say  $E$ , has the property that the sum of the distances from any point on  $E$  to the two foci is equal to the length of the major axis. Thus, the arc must be internal to the ellipse. The only way in which the arc can lie outside the ellipse is if its length exceeds the length of the major axis, which is a contradiction because the endpoints of the arc are the two foci of the ellipse.
18. Check if the sum of its distances from the foci of the ellipse is less than or greater than the length of the major axis of the ellipse.
19. Check if the approximation can be used instead of the actual curve. This requires the point to be outside the ellipses represented by the approximation. This can be tested using the result of Exercise 18. Traverse the arc tree in a breadth-first manner. Whenever the point is internal (external) to a node's ellipse, then the children of the node must (not) be tested. A conventional point inclusion test can be used once it has been determined that the approximation is sufficient.
20. The two ellipses must intersect, and the two foci of each ellipse must be external to the other ellipse.
21. See [769].

22. Yes, in principle, since an area is a closed curve. However, if the curves do not intersect, then their areas can still overlap as one area can be totally contained in the other. This can be determined by a point inclusion test.
23. See [769]. The common edges contribute to the output only if their orientation is identical when the curves of the areas are traversed in the same order (e.g., clockwise).
24. Consider a sawtoothlike polyline. The approximating line between the start and endpoints is a straight line that acts like an average, while the approximating line between alternating points has a larger error for the intermediate point.

### Solutions to Exercises in Section 2.2.3.2

3. If only the split step is used, then even though the initial edges are very bad approximations of the surface, they are never removed.
4. The split and adjustment steps result in some faces being bases of new tetrahedra.
5. It is alleviated, in part, by the application of the adjustment step after each split step.
6. Use neighbor finding techniques similar to those discussed in Chapter 3 of [1636] (see [1501]).
9. No.
10. We prove that if the prism is not regular, then the surface is not convex. If the prism is not regular, then there is a line, lying outside the interior of the surface and in the bisecting plane, from a vertex on the surface to another point of intersection of the surface and the bisecting plane. This implies that the surface is not convex.
11. Yes.
14. Perform an initial step of subdivision into components of genus 0.

### Solutions to Exercises in Section 2.2.3.3

1. The minimum bounding disc can be found in  $O(n)$  time (see the solution to Exercise 4 in Section 4.4.2 of Chapter 4). Two vertices on the boundary of a disc that are the farthest apart can be found in  $O(n \log_2 n)$  time [1511]. The new vertex to be included in the approximation polygon can be found in  $O(n)$  time by testing the vertices sequentially. In the best case, the polygon is split into equally sized parts at each step, resulting in  $\lceil \log_2 n \rceil$  iterations. The  $i$ th iteration processes  $2^i$  polylines of size  $n/2^i$ , and thus in the best case, the HAL tree construction algorithm takes a total of  $O(n) + O(\sum_{i=0}^{\lceil \log_2 n \rceil} 2^i \cdot (n/2^i)) = O(n \log_2 n)$  time. In the worst case, a polyline of  $j$  segments is split into one polyline of size 1 and one polyline of size  $j - 1$  at each iteration. Thus, in the worst case, the algorithm takes a total of  $O(n) + O(\sum_{i=1}^n i) = O(n^2)$  time.
2. The root stores the smallest bounding disc and two of the vertices that lie on the disc. They define the initial two polylines. Each node in the remaining levels corresponds to a vertex that splits its corresponding polyline and the two discs that make up its minimum bounding box. There are as many nodes in the tree as there are vertices, and therefore the HAL tree takes  $O(n)$  space.

### Solutions to Exercises in Section 2.2.3.4

1. See [693, Ch. 8], [695], and [2004, Ch. 5].

## Solutions to Exercises in Section 2.2.4

1. Each introduction of a new vertex causes the addition of two triangles.
2. The alternative would be to split at the interior if the error on  $t$  is greater than  $e$  (Figure 2.151(a)). However, such a split would not resolve the errors on the three original edges, and thus they would eventually have to be split.
3. There are four alternatives, none of which is useful:
  - (a) Split at the interior (Figure 2.151(a)). However, as we saw in the solution to Exercise 2 such a split would not resolve the errors on the two original edges, and thus they would eventually have to be split.
  - (b) Split at one edge (Figure 2.151(b)). However, this does not resolve the error on the other edge.
  - (c) Split at one edge and at the interior (Figure 2.151(c)). However, this does not resolve the error on the other edge.
  - (d) Split at three edges (Figure 2.151(e)). However, this results in a possibly needless split of one of the adjacent triangles.
4. If both vertex neighbors of a node along one of its edges  $e$  are of equal size, then it is impossible for the neighboring node along  $e$  to be of greater size. If one of the vertex neighbors along  $e$  is of greater size, then the neighbor along edge  $e$  can only be twice the size as, otherwise, the other vertex neighbor would be of greater than twice the size. It is easy to construct an example where all edge neighbors are of equal size or have a ratio of 2:1, while the vertex neighbors are larger than twice the size.
5. See the work of Moore [1312, 1313]. These bounds are better than the bound of 9 reported elsewhere [1300, 1981]. In fact, the bound of 9 reported by Weiser [1981] was really for the variant of the restricted quadtree where all vertex neighbors are either of equal size or of ratio 2:1 (termed a *0-balanced quadtree* [1312]).
6. See [1312].
7. See [1312], which is a better result than the factor of 13 originally reported in [1981].
8. See [1312].
9. This can be seen by construction. The newly added point will cause  $t$  to be split into two triangles, and likewise for the adjacent triangle  $u$ , if one exists, along  $h$ . If  $u$  is equal in size to  $t$  (i.e.,  $h$  serves as a hypotenuse of  $u$ ), then  $u$  is split just once. Otherwise,  $u$  must be split twice—once into two triangles of size equal to  $t$  and then one more split of one of these triangles. This second split is why we say that we may have to split two triangles of a given size. This process is applied repeatedly to the triangle  $v$  that is adjacent along the hypotenuse of  $u$  as long as the hypotenuse that is split is a leg of the adjacent triangle  $v$ . This process will stop once we are at the largest possible triangle (i.e., at the root of the restricted bintree).

## Solutions to Exercises in Section 2.3.1

6. (A,2), (W,0), (W,0), (W,0), (B,0), (B,1), (W,1), (W,1), (A,0), (A,0), (W,0), (W,0), (A,0), (A,0), (W,0), (W,0), (W,1), (W,1), (W,1), (W,1), (W,1), (W,0), (C,0), (W,0), (C,0), (C,1).
8. This is not as simple as for the Morton size ordering because the order of the subblocks of each block differs depending on the depth of the block and the size of the image.
9. IAIIWWWBWWIIAAWWIAAWWWIWWIWCWCC.
10. Reconstruct the space spanned by the quadtree while traversing the elements of the DF-expression until finding a leaf block that contains  $c$ .
11. Use a similar process as in the DF-expression. In essence, traverse the linear tree and the color table in tandem. Transitions are made in the color table only when a leaf node (i.e., 1) is encountered in the linear tree.

12. See [970].
14. There are two possible reasons for characterizing the resulting structure as a prefix B<sup>+</sup>-tree. They both stem from the use of the term *linear prefix* to describe the keys.
- (a) The S<sup>+</sup>-tree makes use of a B-tree to store portions of the segments of the linear tree representation of the region quadtree. Each segment of the linear tree has a key that is its corresponding linear prefix. The B-tree is implemented as a B<sup>+</sup>-tree where all data is in the leaf nodes and the keys are used as indexes stored in the nonleaf nodes. The keys are also stored in the leaf nodes along with their corresponding linear trees. The confusion stems from treating the key of the B-tree as the result of appending the linear tree to the linear prefix. In this case, the linear prefix plays the role of the prefix of the entire key. Thus, the issue of whether the S<sup>+</sup>-tree is a B<sup>+</sup>-tree or a prefix B<sup>+</sup>-tree hinges solely on the nature of the key. However, since the original string corresponding to the linear tree has been decomposed into segments, each of which is stored in a separate page (leaf node) in the B-tree, it makes sense to treat each of these segments as the data that is stored in each node and the linear prefix as the key. Thus, the B<sup>+</sup>-tree characterization seems more appropriate than the prefix B<sup>+</sup>-tree characterization.
- (b) In the original formulation of the S<sup>+</sup>-tree, the segment stored on each page terminates with a leaf node. Now, instead of identifying each string segment *S* by *F*, which is the linear prefix of the node *N* in the original tree corresponding to the first element in *S*, use the linear prefix *P* of the last leaf node *L* in the immediately preceding segment of *S*. It is easy to show that *F* is the prefix of *P*. Thus, we see that if we identify each segment *S* by the last leaf node in the immediately preceding segment of *S*, then the S<sup>+</sup>-tree is a prefix B<sup>+</sup>-tree, while if we identify *S* by the first node in *S*, then the S<sup>+</sup>-tree is a conventional B<sup>+</sup>-tree.
15. None of the proposed solutions will work. The problem is the presence of “Z”-like transitions. In other words, given an  $M \times M$  image, the difference in the  $x$  coordinate values of two successive  $1 \times 1$  cells in the Morton order may be as large as  $M - 1$ , while the  $y$  coordinate values may differ by as much as  $(M - 2)/2$ .
16. Given that blocks  $a$  and  $b$  appear in consecutive positions in the ordering so that  $a$  precedes  $b$ , the size of  $a$  is equal to the logarithm to the base 4 of the maximum difference of the corresponding  $x$  and  $y$  coordinate values of their location entries. This works because successive elements in the Peano-Hilbert order are always edge neighbors (i.e., one of the coordinate values is the same for both of the successive elements).
17. Recall that given the Morton numbers of two successive blocks  $f_1$  and  $f_2$  in a Morton order, we can determine the size of block  $f_1$  only from the Morton numbers of  $f_1$  and  $f_2$ . Thus, in order to determine the size of  $f_1$ , we need to know the Morton number of the block that immediately follows  $f_1$  in the Morton sequence.

First, determine the Morton number, say  $d_1$ , of the largest block in the Morton sequence that can follow the block having pixel  $C_1$  at its upper-left corner. This is done by repeatedly incrementing  $C_1$  by  $4^L$  ( $L$  is initially 0) as long as the sum does not exceed  $C_2$ . Once  $d_1$  has been found, its block is output in the list,  $C_1$  is set to  $d_1$ , and the process is restarted. If  $C_2$  is exceeded prior to finding a sibling block of the desired size—that is,  $d_2 = C_1 + 4^{L-1}$  such that  $d_2 \leq C_2$  and  $C_2 < C_1 + 4^L$ , then output the block corresponding to  $d_2$ , reset  $C_1$  to  $d_2$ , and restart the process. The algorithm for decoding the two-dimensional runlength encoding is given by procedure DECODE2DRE below.

```

1  procedure DECODE2DRE( $C_1, C_2$ )
2  /* Given two successive nodes with Morton numbers  $C_1$  and  $C_2$  in a two-
   dimensional runlength encoding of a quadtree, determine the Morton num-
   bers and sizes of all blocks whose Morton numbers are between  $C_1$  and  $C_2$ ,
   including  $C_1$  but excluding  $C_2$ . */
3  value morton_number  $C_1, C_2$ 
4  integer  $L$ 
5  while  $C_1 < C_2$  do
6     $L \leftarrow 0$ 
7    while  $C_1 + 4 \uparrow L < C_2$  and  $(C_1 \bmod 4 \uparrow (L + 1)) = 0$  do
8       $L \leftarrow L + 1$ 
9  enddo

```

```

10  if  $C_1 + 4 \uparrow L > C_2$  then  $L \leftarrow L - 1$ 
11  endif
12  output( $C_1, L$ )
13   $C_1 \leftarrow C_1 + 4 \uparrow L$ 
14  enddo

```

If the block with Morton number  $C_1$  is not desired, then we need to make use of an additional variable  $T$  to store the initial value of  $C_1$  and perform the output step only if  $C_1$  is greater than its initial value  $T$ .

18. Given blocks  $a$  and  $b$  so that block  $a$  precedes block  $b$  in the ordering, then the size of  $b$  is determined by taking the logarithm to the base 4 of the difference between the Morton numbers of  $b$  and  $a$ . The Morton number of the block preceding the first block in the ordering is 0.
19. (W,(6,0)), (B,(6,2)), (W,(2,4)), (B,(3,5)), (W,(0,6)), (B,(4,7)), (W,(6,6)).
20. Such a definition leads to ambiguity in the sense that it is impossible to determine the sizes of the blocks. For example, consider the two-dimensional runlength encoding of the region quadtree in Figure 2.158(b) given by (W,(6,0)), (B,(6,2)), (W,(2,4)), (B,(3,5)), (W,(0,6)), (B,(4,7)), (W,(6,6)). In this case, we cannot tell if the block at (6,2) is of size  $1 \times 1$  or  $2 \times 2$ . This problem can be resolved by encoding each leaf node using the Morton number of the pixel that occupies its lower-right corner (i.e., the last pixel). The resulting reconstruction is achieved by procedure DECODE2DRE2. Note that DECODE2DRE2 yields the blocks with Morton numbers ranging from  $C_1$  to  $C_2$ , including  $C_2$  but not  $C_1$ .

```

1  procedure DECODE2DRE2( $C_1, C_2$ )
2  /* Given two successive nodes with Morton numbers  $C_1$  and  $C_2$  in a two-
   dimensional runlength encoding of a quadtree, determine the Morton num-
   bers and sizes of all blocks whose Morton numbers are between  $C_1$  and  $C_2$ ,
   including  $C_2$  but excluding  $C_1$ .  $C_1$  and  $C_2$  are the Morton numbers of the
   pixels in the lower-right corners of the last elements of each subsequence of
   the same color. */
3  value morton_number  $C_1, C_2$ 
4  integer  $L$ 
5  while  $C_1 < C_2$  do
6     $L \leftarrow 0$ 
7    while  $C_1 + 4 \uparrow L < C_2$  and  $((C_1 + 1) \bmod 4 \uparrow (L + 1)) = 0$  do
8       $L \leftarrow L + 1$ 
9    enddo
10   if  $C_1 + 4 \uparrow L > C_2$  then
11      $L \leftarrow L - 1$ 
12   endif
13    $C_1 \leftarrow C_1 + 4 \uparrow L$ 
14   output( $C_1, L$ )
15 enddo

```

If the block with Morton number  $C_2$  is not desired, then we perform the output step only if  $C_1$  is less than  $C_2$  in the algorithm.

21. (A,(0,0)), (W,(4,0)), (B,(5,1)), (W,(4,2)), (A,(0,4)), (W,(0,5)), (A,(2,4)), (W,(2,5)), (C,(5,6)), (W,(4,7)), (C,(5,7)).
23. The algorithm is the same as that for the two-dimensional runlength encoding based on the Morton location ordering.
24. See procedure WHITEBLOCKS in [1636, p. 38] for a similar algorithm.

## Solutions to Exercises in Section 2.3.2

1. Positive transitions correspond to clockwise turns, and negative transitions correspond to counterclockwise turns. The chain code that we have defined is a *clockwise* chain code as

the image is always to the right of the boundary elements. For any object without holes, a clockwise chain code requires a minimum of four clockwise turns. This means that we record three positive transitions as the final positive transition that closes the curve is omitted from our code. Any counterclockwise turn requires an additional clockwise turn in excess of the minimum so that we can eventually proceed in a direction that will return us to the starting point. Thus, we have proven our desired result.

2. Since the object is closed, the chain code must terminate at its starting point. Thus, the number of unit vectors in these opposite directions must be the same.

### Solutions to Exercises in Section 2.3.3

1. A vertex such as  $p$  is solely responsible for the mapping of the field in its immediate neighborhood. In particular, we want the mapping of  $(x_0, y_0)$  to be 1, and thus the vertex at that point must have a weight of +1 as there is no other point  $q$  on the boundary of the polygon that is dominated by the vertex at  $(x_0, y_0)$ . The weights of points such as  $q$  could have led to the field in the neighborhood of  $(x_0, y_0)$  having a value of +1, but this is impossible as there are no such points.
2. The topology of the polygon is irrelevant when we think of the problem domain as one involving scalar fields as the topology of the polygon can be anything. It can have any number of holes or connected components. However, if we look at the problem as one of finding the weights of the vertices of the holes, then we could simply create the polygon without the holes, say  $A$ , and create the polygons of the holes, say  $B_i$  for the  $i$ th hole. We now compute the vertex representations of  $A$  and the individual holes  $B_i$ . Next, we calculate the vertex representation of  $A - \sum_i B_i$  (i.e., by subtracting the vertex representations of the holes  $B_i$  from that of  $A$ ).
3. The reason for the different vertex representation is the fact that the two cases correspond to a different definition of what is inside and outside the object. In (a) all elements of the object are termed to be inside as the object is interpreted as a polygon with a self-intersecting boundary, whereas in (c) it is interpreted as a concave polygon. The latter is also the case when we say that for two elements with a nonzero area that are considered as interior (i.e., inside of an object) to be in the same object, the elements must be adjacent along an edge (termed *4-adjacent*). On the other hand, the exterior elements of the object are adjacent along an edge or a vertex of the element (termed *8-adjacent*), and the exterior of the object is considered as one connected region. To summarize, what is ambiguous here is the representation of an object as a circular list of vertices and not its vertex representation.
4. Suppose that this is not true. Therefore, there must be at least one horizontal or vertical edge whose endpoints are marked by vertices with weights of equal sign. Without loss of generality, suppose that it is a horizontal edge delimited by two vertices  $a$  and  $b$  with weight +1, where  $a$  is to the left of  $b$ . The other cases (i.e., vertical edges as well as vertices with weight -1) are treated in an analogous manner. Let us analyze the scalar field along the edge. The fact that the weight of  $a$  is +1 and  $b$  is to the right of  $a$  means that the value of the field at a point infinitely close to the right of and above  $a$  must be 1, and that the value of the field at a point infinitely close to the right of and above  $a$  must be 0. In other words, the horizontal edge must mark the boundary between a region that is mapped to 0 (below the edge) and a region that is mapped to 1 (above the edge). Notice that the only other possibility (i.e., that the field below the edge is 1 and the field above the edge is 0) is impossible as it would lead to a value of the field above the edge as being 2 by virtue of the fact that the value of the field above  $a$  is 1 higher than the value of the field below  $a$ , thereby leading to a contradiction. As we walk along the edge in the direction of the rightmost vertex ( $b$ ), the scalar field must also be mapped to 1. Suppose that this is not true at some point  $p$  along the way. In this case,  $p$  would have to be mapped to 0 since we allow only 0 and 1 as values of the scalar field. In order for  $p$  to be mapped to 0, there must exist some point  $q$  just below  $p$  that would have to be mapped to -1, which is not possible since we allow only 0 and 1 as values of the scalar field.

Now, let us turn our attention to  $b$ . Using the same reasoning (i.e., that 0 and 1 are the only possible values of the scalar field), when we reach  $b$  we know that the scalar field at  $b$  can take on only values of 0 or 1. For this to be true, the fact that the weight at  $b$  is +1 means that there must exist some point  $p$  just below  $b$  where the scalar field is mapped to either -2 or -1, respectively, which as we will see is impossible. To see this, we make use of the

relationship between the weight of a vertex at the upper-left corner of a  $2 \times 2$  block of pixels and the values of the pixels as shown in Figure 2.163. In particular, we note that the scalar field at  $b$  is equal to the sum of the weight of  $b$  (which is  $+1$ ), the scalar field just to the left of  $b$  (which is  $1$ ), the scalar field just below  $b$  at  $p$ , and the negation of the value of the scalar field below the edge (which is zero). If the scalar field at  $b$  is  $0$ , then the scalar field at  $p$  must be  $-2$ . On the other hand, if the scalar field at  $b$  is  $1$ , then the scalar field at  $p$  must be  $-1$ . Both of these cases are impossible as the only possible values for the scalar field are  $0$  and  $1$ . Thus, we see that if a horizontal edge is delimited on the left by a vertex with weight  $+1$ , then it must be delimited on the right by a vertex with weight  $-1$  and vice versa.

5. Use a procedure that works in the inverse manner to procedure RASTERTOVLIST. In two dimensions, instead of building successive one-dimensional lists and subtracting them pairwise, we extract consecutive one-dimensional prefixes of the two-dimensional list and add them together until the  $y$  coordinate value of the point is reached. The one-dimensional prefixes are lists consisting of all the vertices that have the same  $v$  coordinate value as the vertex at the head of the list. The inverse lexicographic ordering imposed on vertex lists guarantees that all such vertices are clustered at the beginning of the list, hence the term *prefix*. The weights of the vertices of the resulting one-dimensional list are then added together until reaching the  $x$  coordinate value of the point. The resulting sum of weights is the value of the desired location.
6. The algorithm is a generalization of the solution to Exercise 5. Assume that  $c$  has coordinate values  $c_1 \dots c_d$ . The scalar field on a hyperplane given by  $x_d = c_d$  can be represented by a  $(d - 1)$ -dimensional vertex list which can be obtained as follows:
  - (a) Take all vertices of the original vertex list such that their  $d$ th coordinate value is less than or equal to  $c_d$ .
  - (b) Project these vertices onto a  $d - 1$ -dimensional space by stripping their  $d$ th coordinate value. If two or more vertices assume the same position in the lower-dimensional space, then add their weights together and replace them with a single vertex with weight equal to their sum, provided that it is nonzero.

Now, we repeat steps (a) and (b) using the resulting vertex list as input. Thus, we obtain vertex lists of increasingly lower dimension. After  $d - 1$  iterations, we obtain a one-dimensional vertex list corresponding to the scalar field along the line given by  $x_d = c_d \wedge x_{d-1} = c_{d-1} \wedge \dots \wedge x_2 = c_2$ . At this point, all we need to do is evaluate the scalar field along this line at point  $x_1 = c_1$ , which is trivial. This process can be easily implemented by a recursive procedure. It should be clear that this procedure is equivalent to taking successive  $(d - 1)$ -dimensional prefixes of the original vertex list, stripping the last coordinate value of each vertex, and then adding them together until reaching the hyperplane corresponding to  $x_d = c_d$ .

7. See [567].
8. Using the conventional row order vertex list ordering, it is simple to decompose a  $d$ -dimensional problem into a series of  $(d - 1)$ -dimensional problems by examining prefixes, prefixes of prefixes, and so on. Recall from the solutions to Exercises 5 and 6 that a prefix of a  $d$ -dimensional vertex list is a sublist taken from the beginning of the list where all vertices have the same  $d$ th coordinate value. In fact, since all vertices of a prefix lie in the same hyperplane perpendicular to the  $d$ th coordinate axis, we do not need to keep the  $d$ th coordinate value of each vertex. Thus, we may make this list  $(d - 1)$ -dimensional by removing (or simply disregarding) the last coordinate from the representation.

This approach was used, for example, in the solution to Exercise 6. Partial results obtained in the processing of the  $k$ th dimension are easily carried over to the processing of the  $(k + 1)$ -th dimension by using a single  $k$ -dimensional vertex list.

On the other hand, suppose that we use a Morton order. In this case, a prefix of a list would correspond to the vertices that lie on a quadrant, octant, or the equivalent  $d$ -dimensional subregion. Therefore, depending on the dimensionality of the underlying space, the strategy for solving the problem would involve solving  $4$ ,  $8$ , or  $2^d$  subproblems (one for each subregion) and then combining their solutions to compute the solution for the whole region. Unfortunately, the vertices that lie in each subregion usually cannot be processed independently of those in the other subregions.

For instance, in two dimensions, if we use the standard  $x$ - $y$  axis orientation with the origin at the lower-left corner, then the vertices of the SW quadrant can be processed independently of the others, but the vertices in the NW and SE quadrants need to take into consideration the

vertices in the SW quadrant, and the vertices in the NE quadrant need to take into consideration the vertices in all of the quadrants.

Of course, we could employ the same techniques used in the processing of vertex lists ordered in row order lists to overcome this problem—that is, use vertex lists of lower dimension to transmit the result of the processing of earlier subregions to the processing of the remaining subregions. In the case of two dimensions, this would require that the processing of each quadrant produce (in addition to the transformed subregion) two one-dimensional lists that would hold the value of the regions along the northern and eastern borders, respectively.

As a concrete example, suppose that we want to evaluate the field inside the NE quadrant. In addition to the local changes that occur inside the quadrant itself, we must take into consideration the changes that are carried over from the processing of earlier quadrants. The changes that occurred in the SW quadrant can be summarized by a single vertex that dominates the entire NE quadrant. For convenience, let us position such a vertex at the lower-left corner of the NE quadrant. The weight of this vertex is the sum of the weights of all vertices in the SW quadrant. Now, let us consider the influence of all the vertices in the SE quadrant (with respect to the NE quadrant). Taken together, they define a series of semi-infinite regions whose southern boundary is the southern border of the NE quadrant and whose eastern and western boundaries are vertical lines. This series can be represented by a set of  $k$  vertices lying at the  $y$  coordinate value of the southern border of the NE quadrant having  $x$  coordinate values  $x_1 \dots x_k$ , where the weight of the vertex lying at  $x_i$  is the sum of the weights of all vertices that lie on the vertical line  $x = x_i$  inside the SE quadrant.

Similarly, the effect of the NW quadrant can be summarized by a set of  $n$  vertices placed over the western border of the NE quadrant and having  $y$  coordinate values equal to  $y_1 \dots y_n$ , where the weight of the vertex at  $y_i$  is the sum of the weights of all vertices that lie on the horizontal line  $y = y_i$  inside the NW quadrant.

In summary, the effect of one quadrant over the processing of another may be represented by vertex lists that describe how the field changes along their common boundary. In the cases that we have just described, we needed two one-dimensional lists (for quadrants that shared a common edge) plus a “zero”-dimensional list made up of a single vertex (for quadrants that are adjacent at a single point). In general, the processing of a  $d$ -dimensional subregion would require  $d(d-1)$ -dimensional lists,  $d-1(d-2)$ -dimensional lists,  $d-2(d-3)$ -dimensional lists, and so on.

Thus, the use of alternative orders does not reduce the complexity of the operations.

## Solutions to Exercises in Section 3.1.1

1. The line segments are not permitted to overlap.
2. No. For example, consider the segment tree of Figure 3.3 without line segment C (i.e., for segments A, B, D, E, F, and G). Line segments A and E overlap, yet no node in the segment tree contains both of them.
3. The alternative solution requires that the list be traversed when attempting to remove the line segment. This could lead to an extra factor of  $N$  in the cost of deletion.
4. Multiple intersections are reported for line segments that are totally contained within other line segments. Removing duplicates requires sorting a set that may have more than  $N$  elements, and the algorithm may take more than  $O(N \cdot \log_2 N)$  time.
5. Search for  $P$  starting at the root. Descend to the child whose interval contains  $P$ . Report all intervals associated with the nonleaf nodes on the path to the appropriate leaf node. This takes  $O(\log_2 N + F)$  time, where  $F$  is the number of intervals that contain  $P$ . The  $\log_2 N$  term results from the depth of the tree.
6.  $O(N)$  space is used since only the number of intervals need be stored at each nonleaf node of the segment tree (instead of the identities of the intervals). Descending the tree takes  $O(\log_2 N)$  time.
10. The segment tree is good for indicating all the one-dimensional intervals that contain a given point. It is not suitable for indicating which intervals lie within a given interval; a one-dimensional range tree is more appropriate. However, without additional structuring, many intervals that do not satisfy the query will be examined.

11. The segment tree is good for indicating all the one-dimensional intervals that contain a given point. One possible solution is to search for the endpoints of the given interval and take an intersection of the result. This takes more than  $O(\log_2 N + F)$  time. Can you find a better solution?

### Solutions to Exercises in Section 3.1.2

1. Each line segment can be marked in at most  $2 \cdot \lceil \log_2 N \rceil$  nodes of the segment tree. There are  $N$  line segments that are tested for intersection with these nodes.
2. Yes. However, now the intervals represented by the nonleaf nodes are not of uniform size, but once we know the maximum number of intervals, there is no problem. The segment tree of Figure 3.3 would have its external nodes marked as in Figure 3.4 with the following differences. Node 10 would be marked with {B} instead of {A, C}, and node 11 would be marked with {B} instead of being unmarked. The only changes in the marking of the nonleaf nodes are that the left child of the right child of the root is marked with {A,C} instead of being unmarked, and the left child of the left child of the right child of the root is now unmarked instead of being marked with {A,C}.
3. The search is analogous to that used in stage 2. The difference is a replacement of  $l$  with  $r$ ,  $L_i$  with  $R_i$ ,  $>$  with  $<$ , and all right children with left children and vice versa.
4. All leaf, and some nonleaf, nodes in the tertiary structure of the interval tree have nonempty secondary structures. The tertiary structure is a binary tree. A nonleaf node with an empty secondary structure must have two active children. The maximum number of such nonleaf nodes is one less than the total number of leaf nodes, all of which have a nonempty secondary structure. This result can also be obtained by viewing the tertiary structure as a variant of an extended binary tree.
5. The interval tree stabbing query is executed as follows. Search for  $P$  starting at the root. For each nonleaf node, say  $I$ , compare  $P$  with the value stored at  $I$ , say  $V_I$ . If  $P$  is less than  $V_I$ , then report all the intervals stored at  $I$  whose left endpoints are less than  $P$ . This takes time proportional to the number of intervals that contain  $P$ . Next, descend to the left child and repeat. If  $P$  is larger than  $V_I$ , then report all the intervals stored at  $I$  whose right endpoints are greater than  $P$ . Next, descend to the right child and repeat. This takes  $O(\log_2 N + F)$  time, where  $F$  is the number of intervals that contain  $P$ . The  $\log_2 N$  term results from the depth of the tree.
6. No. The problem is that the intervals that are stored with a nonleaf node of the interval tree do not span the entire interval associated with the node. Thus, we cannot execute the interval tree stabbing counting query.
7. Assume that the line segment  $[l:r]$  is being processed. The point query returns all line segments  $[a:b]$  such that  $a < l \leq b$ , and the range query returns all line segments  $[c:d]$  such that  $l \leq c < r$ . Clearly, these two sets are disjoint.
10. If the task is to be achieved in  $O(\log_2 N + F)$  time, then the interval tree needs modification, such as the addition of some auxiliary structures analogous to the secondary and tertiary structures. The problem is that presently the interval tree does not facilitate pruning. In particular, at each level of the tree a good part of the secondary structure may have to be searched without finding any intervals that satisfy the query.
11. Again, we start at the root and locate the first node  $v$  such that  $l < \text{VAL}(v) < r$ . At this point we update the secondary structure of  $v$ . We must also make  $v$  active if it was previously inactive. This means that we must keep track of its active predecessor in the tertiary structure while making the descent during the process of locating  $v$ . Once, this is done, the insertion is completed as no action is necessary in the subtrees of  $v$ .
12. See the solution to Exercise 10.
14. Construct two empty interval trees: one for  $S_1$  and one for  $S_2$ . Without loss of generality, assume that the sweep line is a vertical line. Sort all of the rectangles in  $S_1$  and  $S_2$  by their left endpoints, thereby forming a set  $S_C$ . Process the elements in  $S_C$  in order. For each rectangle

$r$  in  $S_1(S_2)$ , remove all inactive rectangles from the interval tree of  $S_2(S_1)$ ; search for all rectangles in the interval tree of  $S_2(S_1)$  that intersect  $r$ ; and insert  $r$  in the interval tree of  $S_1(S_2)$ . Note that an intersection is reported only when the second rectangle of the intersecting pair in the sorted order is inserted into the appropriate interval tree, thereby avoiding reporting duplicate intersections. Assuming that there is a total of  $N$  rectangles in the two sets  $S_1$  and  $S_2$  and that there are  $F$  intersecting pairs, then the algorithm takes  $O(N \cdot \log_2 N + F)$  time and  $O(N)$  space.

15. When there is insufficient memory to store a current rectangle  $r$  in the appropriate dynamic interval tree, Jacox and Samet [934] propose recording  $r$  and continue the algorithm. Once the sweep pass is done, if some unprocessed rectangles remain, then an additional sweep pass is performed where only the rectangles that have not yet been processed (i.e., whose intersections have not yet been tested) are inserted into the appropriate dynamic interval tree, although all rectangles in  $S_1(S_2)$  are checked for intersection with the rectangles in the dynamic interval tree of  $S_2(S_1)$ .

### Solutions to Exercises in Section 3.1.3

1. Draw the intervals, and the result will be apparent.
5. See [1858].
6. See [1266].
7. Perform the semi-infinite range query  $([-\infty:P), (P:\infty])$ . It takes  $O(\log_2 M + F)$  time, where  $F$  is the number of intersecting intervals found.
8. See [1266].
9. Perform the semi-infinite range query  $([-\infty:a), (b:\infty])$  in search of the points  $(x, y)$ .
10. Perform the semi-infinite range query  $((a:\infty], [-\infty:b))$  in search of the points  $(x, y)$ . This requires the use of an inverse priority search tree for the range of  $y$ . Since  $x < b$ , this can be simplified to  $((a:b], [-\infty:b))$ .
11. Perform the semi-infinite range query  $([-\infty:b), (a:\infty])$  in search of the points  $(y, x)$ . Since  $a < y$ , this can be simplified to  $((a:b], (a:\infty])$ .

### Solutions to Exercises in Section 3.1.4

1. Use a plane-sweep method [1740]. Sort the endpoints of the line segments and then sweep a vertical line through the set. If some of the lines are vertical, then rotate the set slightly. The key is that if there are no intersections, then the relative ordering of the line segments will be the same through the entire sweep. Use a balanced binary search tree to record the segments that intersect the sweep line. A line segment is inserted into (deleted from) the tree each time a left (right) endpoint is encountered. An intersection has occurred if, upon deletion, the relative ordering between the line segment and its top and bottom neighbors has changed.
2. Use a one-dimensional range tree at each nonleaf node of the segment tree. The one-dimensional range tree is sorted by the  $x$  coordinate values of the vertical line segments associated with it. The one-dimensional range tree for  $m$  items uses  $O(m)$  space.  $O(\log_2 N + F)$  nodes may be examined at each level of the segment tree. There are  $\log_2 N$  levels in the primary segment tree, and the result follows.
3. Overmars [1441] suggests decomposing this problem into two cases:
  - (a)  $R$  contains an element of  $L$ . Build a two-dimensional range tree that contains the left endpoint of each element of  $L$ , and perform a range query with  $R$ .
  - (b) An element of  $L$  intersects a boundary of  $R$ . Treat the horizontal and vertical boundaries of  $R$  separately. For the horizontal boundaries, project all the line segments on a vertical

line, and build a segment tree for the projections. Let  $V$  denote the projections of the line segments. Find all elements of  $V$  that intersect either of the two horizontal boundaries using the result of Exercise 2. The vertical boundaries are handled in the same way with the exception that we use the projections of the line segments on a horizontal line.

The storage and execution time requirements follow from previous analyses of these problems. Reporting some intersections more than once is avoided by checking for the possibility of case 2 while performing case 1. A positive answer means that the reporting of the intersection is delayed until it is detected by case 2. This will increase  $F$ , the number of intersections, by at most a constant multiplicative factor, and thus the order of execution time is not affected.

4. Assume that the balanced binary search tree contains nodes corresponding to the top and bottom boundaries of all active rectangles (i.e., one node per boundary) and that bottom boundaries are smaller in magnitude than top boundaries. A type bit indicates whether the node serves as a bottom or top boundary. There is at least one pair of intersecting rectangles if, upon inserting a rectangle, say  $R$ , with bottom and top boundaries  $B$  and  $T$ , respectively, in the tree, one of the following conditions holds:
  - (a) There exists a node  $L$  such that  $B$  and  $T$  are in different subtrees of  $L$ .
  - (b) There exists a node  $L$  such that  $L$  corresponds to a bottom boundary, and one of either  $B$  or  $T$  is inserted as a right child of  $L$ .
  - (c) There exists a node  $L$  such that  $L$  corresponds to a top boundary, and one of either  $B$  or  $T$  is inserted as a left child of  $L$ .
5. The algorithm proceeds as long as the boundaries in the tree are nonintersecting. Thus, it can be used to detect the occurrence of an intersection, but it can not be used to maintain a set of boundaries that are intersecting. For example, assuming that rectangles are specified by the pairs of coordinate values  $(x, y)$  of their lower-left and upper-right corners, consider the three rectangles  $(1,1)$  and  $(10,10)$ ;  $(3,7)$  and  $(9,9)$ ; and  $(5,3)$  and  $(7,5)$ . Assuming a horizontal scan from left to right, the intersection of the rectangle specified by  $(5,3)$  and  $(7,5)$  with either of rectangles  $(1,1)$  and  $(10,10)$  or  $(3,7)$  and  $(9,9)$  is not detected.
6. Use a plane-sweep method [178]. Sort the left and right boundaries of the rectangles. Sweep a vertical scan line through them. Let  $T$  be the balanced binary search tree that represents the bottom and top boundaries of the active rectangles, and link them in ascending order. Each time a rectangle, with bottom and top boundaries  $b$  and  $t$ , respectively, becomes active (inactive), enter (remove)  $b$  and  $t$  in (from)  $T$  and output the line segments whose entries in  $T$  lie between  $b$  and  $t$ . The output step visits only the nodes in the range since  $T$  is linked in ascending order. The time and space requirements follow.
7. Sort the rectangles by their left and right endpoints as well as by the  $x$  coordinate value of their centroid. Sweep a vertical line through them. Each time a left (right) endpoint is encountered, the corresponding boundary is inserted into (deleted from) the segment tree. Each time a centroid point is encountered, say corresponding to rectangle  $R$ , the segment tree is searched for all segments that overlap  $R$ 's  $y$  coordinate value. The rectangles corresponding to these segments either totally enclose  $R$  or intersect  $R$  [183].
8. See [1910].
9. The primary segment tree (containing the projections of the rectangles on the  $x$  axis) uses  $O(N \cdot \log_2 N)$  storage as there are  $O(N \cdot \log_2 N)$  possible segments. Each of these segments can appear in as many as  $O(\log_2 N)$  positions in the secondary segment trees [536, 542].
10. Use doubly linked lists. Each rectangle can appear in  $O(\log_2 N)$  nonleaf nodes in the primary segment tree. Each of these nonleaf nodes is the root of a secondary segment tree. Insertion in each of the relevant nodes in the secondary segment tree takes  $O(\log_2 N)$  time.
11. The insertion of each rectangle takes  $O(\log_2^2 N)$  time. There are  $N$  rectangles.
12. At each level of the primary segment tree, we perform a one-dimensional stabbing query on a segment tree. This takes  $O(\log_2 N + F)$  time. There are  $\log_2 N$  levels in the primary segment tree, and the result follows.
13.  $O(N \cdot \log_2^d N)$  storage and  $O(\log_2^d N + F)$  time for  $N$  points and  $F$  rectangles containing them.

14. Yes. Use the layered tree approach of Vaishnavi and Wood [1911] that makes use of additional pointers.
15. There are three possible cases:
- (a)  $R$  contains an element of  $V$ . Build a two-dimensional range tree that contains the lower-leftmost corner of each element of  $V$ , and perform a range query with  $R$ .
  - (b)  $R$  is contained in some element of  $V$ . Build a two-dimensional segment tree for  $V$ , and perform a two-dimensional stabbing query for the lower-leftmost corner of  $R$ .
  - (c) A side of  $R$  intersects a side of an element of  $V$ . Use the result of Exercise 2 to solve two problems. The first stores the line segments corresponding to the vertical sides of  $V$  in a segment tree and finds the elements of  $V$  that intersect either of the two horizontal sides of  $R$ . The second stores the line segments corresponding to the horizontal sides of  $V$  in a segment tree and finds the elements of  $V$  that intersect either of the two vertical sides of  $R$ .

The storage and execution time requirements follow from previous analyses of these problems.

16. When performing cases (a) and (b), check for the possibility of case (c). A positive answer means that the reporting of the intersection is delayed until it is detected by case (c). This will increase  $F$ , the number of intersections, by at most a constant multiplicative factor, and thus the order of execution time is not affected.
20. Project the rectangles on the  $x$  axis, and store these intervals in a segment tree, say  $T$ . Let  $I$  be a nonleaf node in  $T$ , and let  $R_I$  denote the rectangles whose horizontal sides are associated with  $I$ . For each  $I$ , build an interval tree for the projections of  $R_I$  on the  $y$  axis. The primary segment tree uses  $O(N \cdot \log_2 N)$  storage as there are  $O(N \cdot \log_2 N)$  possible segments. Each of these segments appears in one node in the secondary interval tree [536, 542].
21. Use doubly linked lists. Each rectangle can appear in  $O(\log_2 N)$  nonleaf nodes in the primary segment tree. Each of these nonleaf nodes is the root of a secondary interval tree. Insertion in each of the relevant nodes in the secondary interval tree takes  $O(\log_2 N)$  time since this many nodes may have to be examined.
22. The insertion of each rectangle takes  $O(\log_2^2 N)$  time. There are  $N$  rectangles.
23. At each level of the primary segment tree, we perform a one-dimensional stabbing query on an interval tree. This takes  $O(\log_2 N + F)$  time. There are  $\log_2 N$  levels in the primary segment tree, and the result follows.
24. See the solution to Exercise 15.

## Solutions to Exercises in Section 3.2

1. Use a segment tree with a plane sweep once the endpoints of the lines have been sorted [166]. Fredman and Weide [637] have shown that it is  $\Omega(N \cdot \log_2 N)$ .
2. 453.
3. These intervals are contained in rectangles A and C, but the corresponding horizontal intervals do not overlap. Thus, these nodes are not marked for A and C at the same time.
4. We only need to record whether a node is covered by an interval (and how many times). The identity of the covering interval need not be recorded.
5. At each insertion and deletion, you must update the length of the overlap with the vertical scan line. This is done by recomputing the LEN fields of all nodes encountered during the insertion process with a COUNT field value of 0. It must also be recomputed for all nodes encountered during the deletion process with a COUNT field value that became 0 or that are ancestors of nodes with a COUNT field value that became 0. This is an  $O(\log_2 N)$  process.
6. The procedure is very similar to that used for computing the area. The difference is that we must also take into account the contributions of the horizontal boundaries. In this case, we

must keep track of the number of disjoint segments in the segment tree. Each active disjoint segment  $[y_b:y_t)$  at  $X_i$  contributes  $2 \cdot (X_i - X_{i-1})$  to the perimeter unless there exists another segment  $[y_a:y_b)$  or  $[y_t:y_c)$ . Besides keeping track of the lengths of the vertical segments that are in the interval corresponding to a node, the node also keeps track of twice the number of disjoint segments in its interval. In addition, each node contains two flags that indicate whether each of the endpoints of its corresponding interval is a bottom or top extreme of a segment in the segment tree. The space and time requirements are the same as for the computation of area. For more details, see [166, 1145].

7. See [1126].
9. At each insertion and deletion, you must update the area of the overlap with the scan plane. This is done by recomputing it for all nodes encountered during the insertion process that are currently unmarked. It must also be done for those nodes encountered during the deletion process that are no longer marked or are ancestors of nodes that are no longer marked. This is an  $O(N)$  process.
11. See [1126].
13. Lee [1126] suggests that each point be treated as the center of a rectangle of size  $R$ . Now, compute the maximum clique (i.e., the identities of its members). Any point in the intersection of the maximum clique can be used as the center of  $R$ .
14. The solution is analogous to that of Exercise 13, except that, in the plane sweep, the total weights of the covering rectangles are recorded instead of their cardinality.
15. Use induction on the number of horizontal and vertical rectangles.
16. Property 1: Each top and bottom boundary goes through at most one cell in each slab. Each left and right boundary is totally contained in one slab.  
Property 2: Each cell can intersect at most  $2 \cdot \sqrt{N}$  left and right boundaries of rectangles because of the way the slabs are defined. Each cell can intersect at most two top and bottom boundaries of V-rectangles and at most  $\sqrt{N} + 1$  top and bottom boundaries of H-rectangles because of the way the cells are defined.  
Property 3: If the boundary of a rectangle intersects the cell, then the rectangle is either a V-rectangle or an H-rectangle with respect to the slab containing the cell. In the former case, the top and bottom boundaries of the rectangle are both cell boundaries, so the rectangle's intersection with the cell extends at least as far as the bottom and top boundaries of the cell (i.e., it is a vertical rectangle). In the latter case, the rectangle extends at least as far as the slab boundary in the left and right directions (i.e., it is a horizontal rectangle).
18. We only need to record whether a node is covered by an interval (and how many times). The identity of the covering interval need not be recorded.
21. Storing a  $(d - 1)$ -dimensional rectangle in a  $(d - 1)$ -dimensional quadtree of side length  $N$  uses  $O(N^{d-2})$  space, and thus each insertion and deletion is an  $O(N^{d-2})$  process.
24. An  $O(N^2)$  time solution to this problem can be based on computing an arrangement of the lines forming boundaries of the triangles. An *arrangement* formed by a set of lines is the set of all bounded or unbounded polygonal regions (i.e., cells) determined by the lines. The arrangement formed by  $N$  lines in the plane can be computed in  $O(N^2)$  time [543]. Once the arrangement has been obtained, we add up the area of all the cells in the arrangement that are contained in some triangle. It is not clear how to solve this problem in subquadratic time.

### Solutions to Exercises in Section 3.3.1

1.  $2^{i+1}$ .
2. A  $4 \times 4$  area of blocks (i.e., 16 blocks) is the maximum since the rectangle corresponding to the representative point can have a side length that is bounded by four times the length of the block containing the representative point.
3. Each point of the PR quadtree corresponds to the center of each black block.

4. When a black block has three white brothers, then the block can be merged with its brothers to yield a node that is one level higher in the tree.
5. The center  $(C_x, C_y, C_z)$  is a location parameter, and the radius  $r$  is an extension parameter.
6. Five parameters are necessary: two for the centroid, two for the perpendicular extents, and one for the rotation from the horizontal line.
7. Representation 2 is similar to representation 3. It does not suffer from a large unpopulated underlying space as does representation 1.
8. Use Figure 3.12 as an illustration. It is a rectangular region whose upper-left corner coincides with the figure and whose lower-right corner is at  $(p, p)$  [1265].
9. Representation 3 is a clockwise rotation by 45 degrees of representation 1 subject to a scale factor of  $\sqrt{2}$ . Recall that representation 3 has two empty triangular regions at its upper-left and -right corners corresponding to the stipulation that both starting and terminating endpoints of intervals lie in the underlying space.
10. For representation 1, the representative points are clustered within a band of width  $s/\sqrt{2}$  above the diagonal that runs through the underlying space. On the other hand, for representation 3, the representative points are clustered in a band of width  $s$  above the horizontal axis. In this case, we can shrink the underlying space when using representation 3 to be of size  $w \times w$ . On the other hand, when using representation 1, the underlying space does remain  $w \times w$ , unless some rotation is performed, in which case it is the same (i.e.,  $w\sqrt{2} \times s/\sqrt{2} = w \times s$ ), but the query processing will be more complex. Thus, the ratio of the useful space to the total underlying space is much larger when using representation 3 instead of representation 1.
11. The solution is identical to that for representation 3 subject to the clockwise rotation by 45 degrees of the search regions as described in the solution to Exercise 9.
13. A four-dimensional conelike region with the line at its tip and in the  $C_x$ - $C_y$  plane.
14. A four-dimensional conelike region with the circle at its tip and in the  $C_x$ - $C_y$  plane.
15. Three-dimensional conelike regions with the (a) point, (b) line, (c) circle, and (d) rectangle at its tip and in the  $C_x$ - $C_y$  plane.
16. (a) A cone-shaped region whose tip is at  $C$  and that opens in the direction of smaller radius values.  
(b) A cone-shaped region whose tip is at  $C$  and that opens in the direction of larger radius values.
17. Kurlander and Bier [1096] suggest using the center of mass and the point farthest from the center of mass. If there is more than one such farthest point, then the representative point is not unique.
18. Let  $P$  denote a pointer to a record, and let  $A$  take on the names of the coordinate axes (i.e., 'X' and 'Y' in two dimensions). Let the query point be represented by a record of type *point* with a field  $\text{VAL}(P, A)$  indicating its coordinate values. Let the rectangle be represented by a record of type *rectangle* with fields  $\text{MIN}(P, A)$ ,  $\text{MAX}(P, A)$ ,  $\text{EXT}(P, A)$ ,  $\text{CENT}(P, A)$ , and  $\text{HEXT}(P, A)$ , corresponding to the minimum value along coordinate axis  $A$ , maximum value along coordinate axis  $A$ , extent along coordinate axis  $A$ , centroid along coordinate axis  $A$ , and half-extent along coordinate axis  $A$ , respectively. Each of the rectangle representations makes use of a subset of these fields.

Using representation 1, we have the following code sequence, which requires at most two comparison operations for each coordinate axis.

```

1  value pointer point P
2  value pointer rectangle R
3  value axis I
4  if VAL(P, I) < MIN(R, I) or VAL(P, I) > MAX(R, I) then 'NOTINRECT'
5  endif

```

Using representation 2, we have the following code sequence, which requires one subtraction, one comparison, and one test for a negative result after a subtraction. In most machine architectures, a test for a negative result immediately after an arithmetic operation requires

---

### Solutions to Exercises in Section 3.3.2.1

only a single conditional branch operation (an optimizing compiler should be able to exploit this property when compiling the code below).

```
1 value pointer point P
2 value pointer rectangle R
3 value axis I
4 integer X
5 X ← VAL(P, I) − MIN(R, I)
6 if X < 0 then 'NOTINRECT'
7 endif
8 if X > EXT(R, I) then 'NOTINRECT'
9 endif
```

Using representation 3, we have the following code sequence, which requires one subtraction, one comparison, one negation operation (which is typically an inexpensive operation), and one test for negative result from an arithmetic operation.

```
1 value pointer point P
2 value pointer rectangle R
3 value axis I
4 integer X
5 X ← VAL(P, I) − CENT(R, I)
6 if X < 0 then X ← −X
7 endif
8 if X > HEXT(R, I) then 'NOTINRECT'
9 endif
```

### Solutions to Exercises in Section 3.3.2.1

3. Oustehout [1439] attributes the following proof to Carlo H. Séquin. Use induction. Insert the rectangles one at a time in order from right to left. When there is one rectangle, there are four space tiles. Each additional rectangle, say  $R$ , causes the creation of at most three new space tiles as follows. The top and bottom edges of  $R$  can each cause a space tile to be split, thereby creating one new space tile apiece. Only one new space tile will be created to the left of  $R$  since we are inserting them in right-to-left order and there can be no existing rectangle to the left of  $R$  at the time of its insertion. No additional space tile is created to the right of  $R$ . Note that the rectangles are inserted in a particular order to obtain the upper bound; however, the final configuration is independent of the order of insertion.
4. At least two of the rectangles have collinear edges.
5. Suppose that the search starts at one of the rightmost rectangles. First, move up or down until locating a tile whose vertical range covers the point. Next, move left or right until finding a horizontal range that contains the point. This may require several iterations due to vertical misalignment resulting from horizontal motion during the search [1439].
6. Locate a rectangle that intersects a corner of the window—say the lower-left corner. Now, use the links to traverse the set of rectangles with the window's boundaries serving to indicate the direction in which the traversal should proceed. Initially, up links are followed until a tile is encountered outside the window. Next, follow a right link and a down link.

### Solutions to Exercises in Section 3.3.2.2

1. No. For example, consider rectangles C and D in Figure 3.1.
2. Let  $(K_0, K_1, K_2, K_3)$  represent a rectangle whose lower-left corner is at  $(K_0, K_1)$  and whose upper-right corner is at  $(K_2, K_3)$ . Assume that node  $P$  is at level  $j$  of the four-dimensional  $k$ -d tree. Therefore, at  $P$ , we discriminate on key  $K_{j \bmod 4}(P)$ . With  $P$  are stored the lower and upper bounds of key  $K_{j \bmod 4}$ . The lower and upper bounds of the remaining keys are obtained

from the three ancestors of  $P$  in the four-dimensional k-d tree. Thus, only two bound values need to be stored at each node. However, these bound values may not be so useful. For example, when storing rectangles in a 4-d tree, the value of  $K_0$  at the root is an upper bound for the left edges of rectangles in LOCHILD, which is of little use in cutting off searches.

Rosenberg [1571] suggests storing three values at each node, LOMINBOUND, HIMAXBOUND, and OTHERBOUND. LOMINBOUND corresponds to the minimum value of a left or bottom edge in LOCHILD, and HIMAXBOUND is the maximum value of a right or top edge in HICHILD. For a node that discriminates on a left or bottom edge, OTHERBOUND is the maximum value of a right or top edge in LOCHILD, while for a node that discriminates on a right or top edge, it is the minimum value of a left or bottom edge in HICHILD. At the root we discriminate on the left edges of rectangles. LOMINBOUND is the minimum value of a left edge in LOCHILD. HIMAXBOUND is the maximum value of a right edge in HICHILD. OTHERBOUND is the maximum value of a right edge of a rectangle in LOCHILD. The minimum value of a left edge of a rectangle in HICHILD is the value of the discriminator key (i.e.,  $K_0$ ).

Searches in LOCHILD are cut off if the left edge of the search region exceeds OTHERBOUND or if the right edge of the search region is less than LOMINBOUND. Searches in HICHILD are cut off if the left edge of the search region exceeds HIMAXBOUND or the right edge of the search region is less than  $K_0$ . The cutoffs for searches at nodes in the remaining three levels are obtained in a similar manner. Of course, at odd depths of the tree (assuming that the root is at depth 0), the search cutoffs are in terms of the top and bottom edges of the search region.

6. Traversing the four-dimensional k-d tree is an  $O(N)$  process. Every node must be intersected with the remaining nodes in the tree. Pruning at every right subtree means that the number of comparison operations that are made is  $O(N \cdot \log_2 N)$  since this is the total path length, and for a node at depth  $L$ , at most  $L$  right subtrees will be examined.

### Solutions to Exercises in Section 3.3.2.4

1. The rationale is the same as that in a binary search tree, where the worst-case depth arises when the points are inserted in sorted (i.e., increasing order). In other words, the fact that the data is constantly increasing means that as full buckets are split, some of the newly created buckets will never be inserted into again.

### Solutions to Exercises in Section 3.3.2.5

1. If the maximum value in LOCHILD( $P$ ) is greater than the minimum value in HICHILD( $P$ ), and the point lies between the maximum and minimum values.

### Solutions to Exercises in Section 3.4.1.2

1. 

```

1  quadrant procedure CIFCOMPARE( $P, C_x, C_y$ )
2  /* Return the quadrant of the MX-CIF quadtree rooted at position ( $C_x, C_y$ ) that
   contains the centroid of rectangle  $P$ . */
3  value pointer rectangle  $P$ 
4  value real  $C_x, C_y$ 
5  return(if  $C(P, 'X') < C_x$  then
6      if  $C(P, 'Y') < C_y$  then 'SW'
7      else 'NW'
8      endif
9      else if  $C(P, 'Y') < C_y$  then 'SE'
10     else 'NE'
11     endif)

```

6. For example, suppose that two rectangles  $i$  and  $j$  share an edge that is coincident with the  $y$  axis that passes through block  $b$ . Assume, without loss of generality, that rectangle  $i$  is adjacent to the  $y$  axis in the SE quadrant of  $b$  whose block we call  $c$ , while  $j$  is adjacent to the  $y$  axis in the SW quadrant of  $b$  whose block we call  $d$ . Now, we see that procedure CIFINSERT in the solution to Exercise 4 will insert  $i$  in block  $b$  while inserting  $j$  in block  $d$ . Thus we do not have a real problem except that  $i$  should really have been inserted into block  $c$  instead of  $b$  since  $c$  is smaller than  $b$ . However, the remaining operations such as CIFDELETE in this exercise still work correctly if this change is made.
7. Procedure INSERTAXIS in the solution to Exercise 4 will insert the first rectangle properly. However, insertion of the second rectangle will overwrite the RECT field of the node containing the result of the first insertion, thereby resulting in a loss of the first rectangle.
9. If the tree is empty, then the rectangle is inserted. This can be resolved by introducing a check for this case in procedure CIFINSERT.
16. Letting  $o$  and  $b$  denote the two rectangles,  $l$  and  $h$  denote the lower and high boundary, respectively, and  $x$  and  $y$  denote the two sides, we have

$$test = o_{lx} < b_{hx} \text{ and } b_{lx} < o_{hx} \text{ and } o_{ly} < b_{hy} \text{ and } b_{ly} < o_{hy}.$$

17. Letting  $o$  and  $b$  denote the two rectangles,  $l$  and  $h$  denote the lower and high boundary, respectively, and  $x$  and  $y$  denote the two sides, we have

$$test = ((o_{lx} = b_{hx} \text{ or } b_{lx} = o_{hx}) \text{ and } o_{ly} \leq b_{hy} \text{ and } b_{ly} \leq o_{hy}) \text{ or } ((o_{ly} = b_{hy} \text{ or } b_{ly} = o_{hy}) \text{ and } o_{lx} \leq b_{hx} \text{ and } b_{lx} \leq o_{hx}).$$

34. Consider the four points  $A = (5, 6)$ ,  $B = (6, 5)$ ,  $C = (0, 4)$ , and  $D = (4, 0)$ . The closest point to  $A$  is  $B$ , the closest point to  $B$  is  $A$ , the closest point to  $C$  is  $A$ , and the closest point to  $D$  is  $B$ . The result is that the rectangles formed by  $A$  and  $C$  and by  $B$  and  $D$  intersect.

## Solutions to Exercises in Section 3.4.2

3. There are several cases. Assume without loss of generality that  $l$  is an  $x$  partition. If  $w$  intersects  $l$  but does not intersect  $p$ , then we just need to compare the  $y$  coordinate values of the elements of  $S$ . If  $w$  does not intersect  $l$ , then we just need to compare one of the two  $x$  coordinate values of the elements of  $S$  while we still need to compare both of the  $y$  coordinate values of these elements.

## Solutions to Exercises in Section 3.4.3

6. If subrectangle  $s$  of rectangle object  $r$  is an element of a list  $l$  of type 1, then the lower-left corner of  $r$  is also contained in  $l$ . However,  $r$  has just one lower-left corner, and there is just one subrectangle  $s$  that contains the lower-left corner. Thus, the subrectangle  $s$  containing the lower-left corner of  $r$  can be an element of only one list of type 1, and hence  $r$  can be pointed at by only one list of type 1.

7. When a block  $b$  is completely contained in window  $w$ , then for each subrectangle  $s$  of  $r$  that is an element of lists of type 2–4, there will be another subrectangle  $t$  of  $r$  that is in an adjacent block  $a$  to the left of, below, and to the southeast of  $b$  that is overlapped by  $w$  and can be reported when  $a$  is processed. When a block  $b$  is partially contained in  $w$  so that only the left (bottom) and not the bottom (left) side of  $b$  intersects  $w$ , then for each subrectangle  $s$  of  $r$  that is an element of lists of type 3 and 4 (2 and 4), there will be another subrectangle  $t$  of  $r$  that is in an adjacent block  $a$  below (to the left of)  $b$  that is overlapped by  $w$  and can be reported when  $a$  is processed. When a block  $b$  is partially contained in  $w$  so that both the left and bottom sides of  $b$  intersect  $w$ , then there are no adjacent blocks to the left of and below  $b$  that overlap  $w$ , and thus elements of all of the four lists associated with  $b$  must be examined for intersection with  $b$  and reported if they intersect  $w$ .
8. There are 16 cases corresponding to 4 instances of only one side of the block being intersected; 6 instances of two sides of the block being intersected, 4 of which correspond to the sides being adjacent and two of which correspond to the sides being opposite; 4 instances of three sides of the block being intersected; 1 instance of all sides being intersected; and 1 instance of none of the sides of the block being intersected. The type of intersection can be identified using a number ranging from 0 (all sides of the block being intersected) to 15 (none of the sides of the block being intersected). Letting  $o$  and  $b$  denote the object and block, respectively,  $l$  and  $h$  denote the lower and high boundary, respectively, and  $x$  and  $y$  denote the two sides, we have

$$test = (o_{lx} > b_{lx}) + 2 \cdot (o_{ly} > b_{ly}) + 4 \cdot (o_{hx} < b_{hx}) + 8 \cdot (o_{hy} < b_{hy})$$

## Solutions to Exercises in Section 4.1.2

1. The elements of the search hierarchy for the MX-CIF quadtree correspond to the objects (type 0), while the remaining elements correspond to rectangular regions resulting from a quaternary or binary regular decomposition of the underlying space (types 1, 2, and 3), which play the same role as the bounding rectangles in the R-tree search hierarchy. In particular, we have elements corresponding to nodes in the two-dimensional MX-CIF quadtree (type 3), nodes in the one-dimensional MX-CIF quadtree corresponding to objects that overlap the horizontal (i.e.,  $x$ ) axis passing through the center of a block corresponding to a two-dimensional MX-CIF quadtree node (type 2), and nodes in the one-dimensional MX-CIF quadtree corresponding to objects that overlap the vertical (i.e.,  $y$ ) axis passing through the center of a block corresponding to a two-dimensional MX-CIF quadtree node (type 1). Elements of type 3 can produce elements of types 0, 1, 2, and 3;<sup>1</sup> elements of type 2 can produce elements of types 0 and 2; and elements of type 1 can produce elements of types 0 and 1. The use of quadtree blocks as elements in the MX-CIF quadtree search hierarchy is similar to the use of bounding rectangles in the R-tree search hierarchy, with the difference being that for the R-tree, we have minimum bounding rectangles, while for the MX-CIF quadtree, we have minimum enclosing square (i.e., quadtree) blocks and minimum enclosing rectangle blocks that are the result of the application of a recursive halving process along a single dimension of the corresponding two-dimensional MX-CIF quadtree block. The distance functions are defined in the same way as for the R-tree and hold for all of the combinations of argument types. As in the R-tree, the distance functions also obey the condition that  $d_t(q, e_t) \leq d_{t'}(q, e_{t'})$  for any element  $e_{t'}$  that is a descendant of  $e_t$  in the search hierarchy.

## Solutions to Exercises in Section 4.1.3

1. See [821, 848]. Since we assume uniformly distributed points, the expected area of the search region is  $k/N$ , and the expected area of each of the leaf node regions is  $c/N$ . The area of

---

<sup>1</sup> Depending on the implementation, elements of type 3 could also produce elements of type 0 corresponding to objects that overlap the center of the corresponding quadtree block. For the sake of simplicity, we assume that the objects are associated only with nodes of the one-dimensional MX-CIF quadtree.

a circle of radius  $r$  is  $\pi r^2$ , so for the search region, we have  $\pi r^2 = k/N$ , which means that its radius is  $r = \sqrt{\frac{k}{\pi N}}$ . The leaf node regions are squares, so their side length is  $s = \sqrt{c/N}$ . It is easy to see [821] that the number of leaf node regions intersected by the boundary of the search region is the same as that intersected by the boundary of its circumscribed square. Each of the four sides of the circumscribed square intersects  $\lfloor 2r/s \rfloor \leq 2r/s$  leaf node regions. Since each two adjacent sides intersect the same leaf node region at a corner of the square, the expected number of leaf node regions intersected by the search region is bounded by

$$4(2r/s - 1) = 4 \left( \frac{2\sqrt{k/(\pi N)}}{\sqrt{c/N}} - 1 \right) = 4 \left( 2\sqrt{\frac{k}{\pi c}} - 1 \right).$$

It is reasonable to assume that, on the average, half of the  $c$  points in these leaf nodes are inside the search region, and the other half are outside. Thus, the expected number of points remaining in the priority queue (the points in the dark shaded region in Figure 4.3) is at most

$$\frac{c}{2} 4 \left( 2\sqrt{\frac{k}{\pi c}} - 1 \right) = 2c \left( 2\sqrt{\frac{k}{\pi c}} - 1 \right) = \frac{4}{\sqrt{\pi}} \sqrt{ck} - 2c \approx 2.26\sqrt{ck} - 2c,$$

which is  $O(\sqrt{kc})$ .

2. See [821, 848]. The number of points inside the search region (the light shaded region in Figure 4.3) is  $k$ . Thus, the expected number of points in leaf nodes intersected by the search region is at most  $k + 2.26\sqrt{ck} - 2c$ . Since each leaf node contains  $c$  points, the expected number of leaf nodes that were accessed to get these points is bounded by  $k/c + 2.26\sqrt{k}/c - 2$ , which is  $O(k + \sqrt{k})$ .
3. The number of objects inserted into the priority queue is  $O(k + \sqrt{k})$ , and the expected size of the queue is bounded by  $O(\sqrt{k})$ . Therefore, the total cost is  $O(k + \sqrt{k}) \cdot O(\log \sqrt{k}) = O(k \log k)$ . If we take the nonleaf nodes into account, then the cost becomes somewhat more complicated.
4. Follow the proof in [851]. Use contradiction. Assume that the condition holds for all elements of the search hierarchy and assume that  $e_0$  and  $e'_0$  represent two objects, with  $d_0(q, e_0) < d_0(q, e'_0)$ , that are reported out of order (i.e.,  $e'_0$  first). This implies that, at some point,  $e'_0$  is the element in the queue with the smallest distance from  $q$ , while an element  $e_t$  that represents some subset that contains  $e_0$  is also on the queue. In other words,  $d_t(q, e_t) \geq d(q, e'_0)$ . However, since  $d_t(q, e_t) \leq d_0(q, e_0) < d(q, e'_0)$ , we have  $d_t(q, e_t) < d(q, e'_0)$ , contradicting the assumption that  $e'_0$  is reported before  $e_0$ . Thus, the desired result holds.
5. Follow the proof in [851]. Use contradiction. Let  $o_k$  be the  $k$ th-nearest neighbor to  $q$ , and assume that  $e_t$  is an element that was visited before  $o_k$  was reported, with  $d_t(q, e_t) > d(q, o_k)$ . This assumption means that when  $e_t$  was visited, some ancestor  $e_{t'}$  of the element  $e_0$  representing  $o_k$  in the search hierarchy existed in the priority queue, with  $d_t(q, e_t) \leq d_{t'}(q, e_{t'})$ . By the correctness criterion, we have  $d_{t'}(q, e_{t'}) \leq d_0(q, e_0) = d(q, o_k)$ , which implies that  $d_t(q, e_t) > d_{t'}(q, e_{t'})$ . This contradicts the initial assumption that  $e_t$  was visited before  $o_k$  was reported, so the desired result holds.

## Solutions to Exercises in Section 4.1.4

1. The following is an informal proof. The modified correctness criterion guarantees that each object has at least one instance in the hierarchy for which the original correctness criteria holds. Thus, by the solution to Exercise 4 in Section 4.1.3, we are guaranteed that at least one instance of each object is reported at the proper time. Furthermore, the algorithm ensures (in the **if** statement in line 20) that object instances that do not satisfy  $d_t(q, e_t) \leq d_0(q, e_0)$  (as  $t' = 0$ ) for all ancestors  $e_t$  of  $e_0$  are never inserted into the priority queue, and that all duplicate instances of the same object that do satisfy it are removed together (in lines 14–16).
2. Follow the proof in [851]. Use contradiction. Let  $o_k$  be the  $k$ th-nearest neighbor to  $q$ . By the modified correctness criterion, we know that at least one instance  $e_0$  of  $o_k$  exists in the search hierarchy such that  $d_t(q, e_t) \leq d_0(q, e_0)$  for all ancestors  $e_t$  of  $e_0$ . Now, by way of contradiction, assume that  $e_{t'}$  is an element that was visited before  $o_k$  was reported, with  $d_t(q, e_{t'}) > d(q, o_k)$ .

This assumption means that when  $e_{t'}$  was visited, some ancestor  $e_t$  of  $e_0$  in the search hierarchy existed in the priority queue, with  $d_{t'}(q, e_{t'}) \leq d_t(q, e_t)$ . Since  $d_t(q, e_t) \leq d_0(q, e_0)$ , this implies that  $d_{t'}(q, e_{t'}) \leq d_0(q, e_0) = d(q, o_k)$ . However, this contradicts the assumption that  $d_t(q, e_{t'}) > d(q, o_k)$ , so the desired result holds.

### Solutions to Exercises in Section 4.1.5

4. Keep a counter  $c$  that indicates how many neighbors have been reported, and halt the algorithm once  $c = k$ .
5. See procedure BFTRAV in Section 4.2.6.
6. As pointed out in the text, all that is needed to obtain INCFARTHEST is to replace  $d_{t'}(q, e_{t'})$  in line 17 of INCNEAREST by  $-\hat{d}_{t'}(q, e_{t'})$ .
7. As pointed out in the text, there are two ways of modifying the incremental nearest neighbor algorithm to be an incremental farthest neighbor algorithm. The first is by replacing  $d_t(q, e_t)$  as a key for any element  $e_t$  on the priority queue with  $-\hat{d}_t(q, e_t)$  and thereby leaving the algorithm unchanged. The second orders the elements on the priority queue in decreasing order of key values, using  $\hat{d}_t(q, e_t)$  as a key value. Note that there is no need to modify the use of FRONTPRIORITYQUEUE in line 14 as now the element at the front of the priority queue is the one with the maximum distance from  $q$ , and if it is an object, then it would be the next object to be reported. The only modification required is to change the sense of the test in line 20 to be " $t' > 0$  or  $d_{t'}(q, e_{t'}) \leq d_t(q, e_t)$ ."
8. Since region  $a$  is empty, it can also be safely ignored. Ignoring  $b$  is preferable as it is nonempty, and thus we save the cost of checking if its points can be members of the skyline, which we already know to be impossible.

### Solutions to Exercises in Section 4.1.6

2. This is proved easily by noting that from the point of view of a graph, ignoring the spatial embedding of its vertices, all of the vertices that make up each of the regions  $r_{u_j}$  are connected. Therefore, the only way that the space spanned by one of these regions associated with vertex  $w_1$  incident at  $u_1$  can be disconnected, say consisting of two regions  $g_1$  and  $g_2$ , is if the shortest path from  $u_1$  to some vertex  $v_2$  in  $g_2$  would "jump" from vertex  $v_1$  in  $g_1$  over some region that is associated with a vertex  $w_2$  incident at  $u_1$ , which is impossible since the spatial network is planar.
3. Nonplanar spatial networks may lead to disconnected regions. Disconnected spatial networks can be handled by using a special color to indicate that the vertices are unreachable from the source vertex.
4. No. Although the two methods are equivalent, the original method is preferable as it only stores two values, while the alternative stores three values since a range consists of two values.
5. The space complexity would decrease as can be seen by results reported by Lindenbaum, Samet, and Hjaltason [1175]. However, the actual regions would have to be vectorized to create a polygonal map that could be complex in terms of the number of edges.
6. See [1749].

### Solutions to Exercises in Section 4.2.1

1. Because this may tighten the value of  $D_k$  so that there is no need to process the remaining elements of  $A$  of  $e$ .

2. Four changes are necessary in forming KFARTHEST and DFTRAVFARTHEST:
  - (a) Replace the condition “ $d(q, o) < D_k$ ” in line 14 of DFTRAV with the condition “ $d(q, o) > D_k$ .”
  - (b) Use an alternative definition of distance that incorporates the upper-bound information. This can be done if we know that for every nonobject element  $e$  of the search hierarchy,  $d(q, e) \geq d(q, e_0)$  for every object  $e_0$  in  $e$  and that the relation  $d(q, e) < D_k$  is satisfied.<sup>2</sup> Assuming that this property holds, define  $d(q, e)$  as the maximum (instead of the minimum) possible distance from  $q$  to any object  $e_0$  in nonobject  $e$ . This distance function  $d$  is termed  $\hat{d}$  by Hjaltason and Samet in [851], who use it in a best-first incremental farthest neighbor finding algorithm.
  - (c) Change the priority queue implementation of  $L$  so that it is ordered in such a way that accessing the nearest (instead of the farthest) of the  $k$  farthest neighbors, as well as updating (i.e., inserting and deleting the  $k$ th-farthest neighbor), can be performed without needless exchange operations. In other words, modify INSERTL to use MINPRIORITYQUEUE, the distance from  $q$  to the current nearest of the  $k$  farthest neighbors, instead of MAXPRIORITYQUEUE in line 12. Note that MINPRIORITYQUEUE is equivalent to FRONTPRIORITYQUEUE when priority is given to elements at a minimum distance.
  - (d) Initialize  $D_k$  to 0 before the first invocation of DFTRAV instead of to  $\infty$ .
3. There is no longer any need to replace the condition “ $d(q, o) < D_k$ ” in line 14 of DFTRAV with the condition “ $d(q, o) > D_k$ ” as it is equivalent to the condition “ $-d(q, o) < -D_k$ .” Moreover, there is no need to modify the priority queue implementation of  $L$  as the first element will still correspond to the element with the maximum distance (which is now the nearest of the farthest elements due to the use of negative distances). The only modification needed is to initialize  $D_k$  to  $-\infty$  before the initial invocation of DFTRAV instead of to  $\infty$ .
4. The property of the alternative distance measure that  $d(q, e) \geq d(q, e_0)$  for every object  $e_0$  in  $e$  for all nonobject elements  $e$  means that if we process the elements  $e_p$  of the active list  $A$  of  $e$  in order of decreasing values of  $d(q, e_p)$ , and once we have found one element  $e_i$  in  $A$  of  $e$  such that  $d(q, e_i) < D_k$ , then  $d(q, e_j) < D_k$  for all remaining elements  $e_j$  of  $A$  of  $e$ . In particular, this guarantees that none of these remaining elements need to be processed, and we simply exit the loop and backtrack to the parent of  $e$  or terminate if  $e$  is the root of the search hierarchy.

## Solutions to Exercises in Section 4.2.2

1. Let  $o$  be an object in  $e_p$ , which means that  $d(M_p, o) \leq r_{p, \max}$ . From the triangle inequality, we have  $d(q, o) + d(M_p, o) \geq d(q, M_p)$ . Subtracting  $d(M_p, o)$  from both sides and making use of the inequality  $d(M_p, o) \leq r_{p, \max}$  yields  $d(q, o) \geq d(q, M_p) - d(M_p, o) \geq d(q, M_p) - r_{p, \max}$ . Therefore, if  $d(q, M_p) - r_{p, \max} > D_k$ , which is the distance to the current  $k$ th-nearest neighbor of  $q$ , then  $o$  cannot be the  $k$ th-nearest neighbor of  $q$ , and, in fact, no object  $o$  of  $e_p$  can be the  $k$ th-nearest neighbor of  $q$  as they all satisfy  $d(M_p, o) \leq r_{p, \max}$ . Rewriting  $d(q, M_p) - r_{p, \max} > D_k$  as  $D_k + r_{p, \max} < d(q, M_p)$  leads to the desired result.
2. From the triangle inequality, we have  $d(q, M_p) \leq d(q, o) + d(M_p, o)$ . Subtracting  $d(M_p, o)$  from both sides yields  $d(q, M_p) - d(M_p, o) \leq d(q, o)$ . Therefore, if  $d(q, M_p) - d(M_p, o) > D_k$ , which is the distance to the current  $k$ th-nearest neighbor of  $q$ , then  $o$  cannot be the  $k$ th-nearest neighbor of  $q$ . Rewriting  $d(q, M_p) - d(M_p, o) > D_k$  as  $D_k + d(M_p, o) < d(q, M_p)$  leads to the desired result.
3. From the triangle inequality, we have  $d(q, p) \leq d(q, o) + d(o, p)$ . Subtracting  $d(o, p)$  from both sides leads to  $d(q, p) - d(o, p) \leq d(q, o)$ . Replacing  $d(q, p)$  with  $d_2$  and making use of the inequality  $d(o, p) < d_2 - d_1$  results in  $d_2 - (d_2 - d_1) < d(q, o)$ , which is simplified to yield

<sup>2</sup> This stopping condition ensures that all objects at the distance of the  $k$ th-farthest neighbor are examined. Note that if the size of  $L$  is limited to  $k$ , and if there are two or more objects at distance  $D_k$ , then some of them may not be reported in the set of  $q$ 's  $k$  farthest neighbors.

- $d_1 < d(q, o)$ . This inequality means that  $n$  at a distance of  $d_1$  is closer to  $q$  than  $o$ , and thus  $o$  cannot be  $q$ 's nearest neighbor.
4. Rule 2 stipulates that object  $o$  in element  $e_p$  at the deepest level of the search hierarchy with mean  $M_p$  and distance  $r_{p,max}$  from  $M_p$  to the farthest object within  $e_p$  cannot be the  $k$ th-nearest neighbor of query object  $q$  if  $D_k + d(o, M_p) < d(q, M_p)$ , where  $D_k$  is the distance from  $q$  to the farthest of the current candidate  $k$  nearest neighbors. This rule is applicable to arbitrary objects in the sense that  $M_p$  can also be one of the objects in  $e_p$ , and this is how we use it here. Letting  $M_p = p$ ,  $k = 1$ , and  $D_1 = d(q, n) = d_1$ , we have  $D_1 + d(o, p) < d(q, p)$ , which is the same as  $d_1 + d(o, p) < d_2$ . This can be rewritten as  $d(o, p) < d_2 - d_1$ , which is Lemma 2.2, and the desired equivalence holds.
  5. Set  $d_1$  to be the distance of the current  $k$ th-nearest neighbor of  $q$ .
  6. Let  $o$  be an object in  $e_p$ , which means that  $d(M_p, o) \geq r_{p,min}$ . From the triangle inequality we have  $d(q, o) + d(q, M_p) \geq d(M_p, o)$ . Subtracting  $d(q, M_p)$  from both sides and making use of the inequality  $d(M_p, o) \geq r_{p,min}$  yields  $d(q, o) \geq d(M_p, o) - d(q, M_p) \geq r_{p,min} - d(q, M_p)$ . Therefore, if  $r_{p,min} - d(q, M_p) > D_k$ , which is the distance to the current  $k$ th-nearest neighbor of  $q$ , then  $d(q, o) > D_k$  and  $o$  cannot be the  $k$ th-nearest-neighbor of  $q$ , and in fact, no object  $o$  of  $e_p$  can be the  $k$ th-nearest neighbor of  $q$  as they all satisfy  $d(M_p, o) \geq r_{p,min}$ . Rewriting  $r_{p,min} - d(q, M_p) > D_k$  as  $D_k + d(q, M_p) < r_{p,min}$  leads to the desired result.
  7. From the triangle inequality, we have  $d(M_p, o) \leq d(q, M_p) + d(q, o)$ . Subtracting  $d(q, M_p)$  from both sides yields  $d(M_p, o) - d(q, M_p) \leq d(q, o)$ . Therefore, if  $d(M_p, o) - d(q, M_p) > D_k$ , which is the distance to the current  $k$ th-nearest neighbor of  $q$ , then  $d(q, o) > D_k$  and  $o$  cannot be the  $k$ th-nearest neighbor of  $q$ . Rewriting  $d(M_p, o) - d(q, M_p) > D_k$  as  $D_k + d(q, M_p) < d(M_p, o)$  leads to the desired result.
  8. (Feustel and Shapiro [610]) From the triangle inequality, we have  $d(o, p) \leq d(q, o) + d(q, p)$ . Making use of  $d(o, p) > 2d(q, p)$ , we have  $2d(q, p) < d(o, p) \leq d(q, o) + d(q, p)$ . Subtracting  $d(q, p)$  from both sides of  $d(o, p)$  leads to  $d(q, p) < d(q, o)$ , which is the desired result as it means that  $o$  is not the nearest neighbor of  $q$  as at least  $p$  is closer.
  9.  $o$  cannot be the nearest neighbor of  $q$  if  $d(o, M_p) > 2d(q, M_p)$ .  $d(o, M_p) > 2d(q, M_p)$  implies that  $d(o, M_p) > d(q, M_p) + d(q, M_p)$ . But, clearly  $D_1 \leq d(q, M_p)$ , which means that  $d(o, M_p) > D_1 + d(q, M_p)$ . This is Pruning Rule 4, and thus  $o$  cannot be the nearest neighbor of  $q$ .
  10. Given the above constraints on  $k$ ,  $r_{p,min}$ ,  $M_p$ ,  $o$ , and  $q$ , Pruning Rule 4 states that if  $D_1 + d(q, M_p) < d(o, M_p)$ , then  $o$  is not  $q$ 's nearest neighbor. Similarly, Lemma 2.1 states that if  $2d(q, M_p) < d(o, M_p)$ , then  $o$  is not  $q$ 's nearest neighbor. Now, since  $M_p$  is an object of  $e_p$ , and  $D_1$  is the distance from  $q$  to its nearest known neighbor, we know that  $D_1 \leq d(q, M_p)$ . So, there are two cases:
    - (a) If  $D_1 = d(q, M_p)$ , then Lemma 2.1 and Pruning Rule 4 are equivalent.
    - (b) Otherwise, if  $D_1 < d(q, M_p)$ , which is the situation that we would normally expect to arise, then we see that  $D_1 + d(q, M_p) < d(q, M_p) + d(q, M_p) = 2d(q, M_p)$ . This last inequality implies that some object  $o$  may exist that cannot be pruned from the search by Lemma 2.1, while  $o$  can be pruned by Pruning Rule 4.

This result, combined with the result of Exercise 9, means that, under the specified constraints, Pruning Rule 4 is tighter than Lemma 2.1.

11. Replace  $d(q, p)$  with  $D_k$ , the distance to  $p$ , the current  $k$ th-nearest neighbor of  $q$ . In other words, restate Lemma 2.1 to stipulate that given a query object  $q$  and another object  $p$  that is the current  $k$ th-nearest neighbor of  $q$ , then any other object  $o$  such that  $d(o, p) > 2d(q, p)$  cannot be the  $k$ th-nearest neighbor of  $q$ .
12. From the triangle inequality,  $d(a, b) \leq d(a, q) + d(b, q)$  for any  $q$ . Choose  $q$  and let  $p$  be the object at a maximum distance from  $q$ , which means that  $d(a, q) \leq d(q, p)$  and  $d(b, q) \leq d(q, p)$ . Therefore,  $d(a, b) \leq d(a, q) + d(b, q) \leq d(q, p) + d(q, p) = 2d(q, p)$ , which is the desired result.
13. From the triangle inequality, we have  $d(q, M_p) + d(M_p, o) \geq d(q, o)$  for any object  $o$  in  $e_p$ .  $d(M_p, o) \leq r_{p,max}$ , and thus  $d(q, M_p) + r_{p,max} \geq d(q, o)$ . Therefore, if  $D_1 \geq d(q, M_p) + r_{p,max}$ , then  $D_1 \geq d(q, o)$ , and thus  $d(q, M_p) + r_{p,max}$  is a better bound on the distance from  $q$  to its nearest neighbor.

14. Let  $o'$  be an object in  $e_p$  such that  $d(M_p, o') = r_{p, \min}$ . There is at least one such object. From the triangle inequality, we have  $d(q, o') \leq d(q, M_p) + d(M_p, o')$ . By definition,  $d(M_p, o') = r_{p, \min}$ , and thus  $d(q, o') \leq d(q, M_p) + r_{p, \min}$ . Therefore, since there is an object  $o'$  within distance  $d(q, M_p) + r_{p, \min}$  of  $q$ , any object that is farther away may be removed from consideration. Therefore, the pruning distance  $D_1$  may be safely reset to  $\min(D_1, d(q, M_p) + r_{p, \min})$ .
15. Assume that  $k = 1$ . Consider element  $e_a = (M_a, r_{a, \max})$  with  $d(q, M_a) = 1$  and  $r_{a, \max} = r_{a, \min} = 20$ , and element  $e_b = (M_b, r_{b, \max})$  with  $d(q, M_b) = 2$  and  $r_{b, \max} = r_{b, \min} = 4$ . Since  $r_{a, \max} = r_{a, \min} = 20$ , we know that all of the objects in  $e_a$  are at a maximum distance  $r_{a, \max} = 20$  from  $M_a$ . Processing the active list in increasing MEANORPIVOTDIST order means that  $e_a$  is processed before  $e_b$  as  $d(q, M_a)$  is less than  $d(q, M_b)$ . Thus, once  $e_a$  has been processed, we have that  $19 \leq D_1 \leq 21$ . Next, we process  $e_b$ , for which we know that  $d(q, M_b) + r_{b, \min} \leq 6$ . When the active list  $A$  of  $e_b$  is generated, we can assume, without loss of generality, that its elements  $e_i = (M_i, r_{i, \max})$  can be formed in such a way that each of them satisfies  $d(q, M_i) + r_{i, \min} \leq 6 \leq 19$ , and thus we can reset  $D_1$  to 6.
16. If Pruning Rule 1 is satisfied, then  $d(q, M_p) - r_{p, \max} > D_1$ , which means that  $d(q, M_p) + r_{p, \min} > D_1$ , and thus Pruning Rule 5 cannot be applied. Similarly, if Pruning Rule 3 is satisfied, then  $r_{p, \min} - d(q, M_p) > D_1$ , which means that  $r_{p, \min} + d(q, M_p) > D_1$ , and thus Pruning Rule 5 cannot be applied. This should be obvious when we rewrite Pruning Rule 5 as  $\text{MAXNEARESTDIST}(q, e_p) > D_1$  and Pruning Rules 1 and 3 as  $\text{MINDIST}(q, e_p) > D_1$ , and observe that  $\text{MAXNEARESTDIST}(q, e_p) \geq \text{MINDIST}(q, e_p) > D_1$ .

Figure S.9  
Examples illustrating Pruning Rule 1 for computing the  $k$  farthest neighbors that eliminates element  $e_p$  and all its objects when  $D_k - r_{p, \max} > d(q, M_p)$ : (a) query object  $q$  outside  $e_p$ , and (b)  $q$  inside  $e_p$ .

17. The rationale for Pruning Rule 1 is that region  $E_k$ , containing all objects whose distance from  $q$  is greater than  $D_k$ , should be completely outside of element  $e_p$ , and thus it is possible to adapt it. The rationale for Pruning Rule 2 is that object  $o$  in  $e_p$  should be outside  $E_k$  while permitting the intersection of  $e_p$  and  $E_k$  to be nonempty, thereby making it possible to adapt it. However, Pruning Rules 3 and 4 are based on  $e_p$  having the shape of a multidimensional spherical shell and  $E_k$  being either completely inside the inner sphere of the spherical shell (i.e., Rule 3), or  $E_k$  being completely in the region formed by the union of the spherical shell  $e_p$  and the region spanned by the inner sphere of  $e_p$ , while  $o$  must be outside  $E_k$  and at the same time still be inside  $e_p$  (Rule 4). This means that Pruning Rules 3 and 4 rely on  $E_k$  being bounded, but  $E_k$  is unbounded, thereby making it impossible to adapt them. On the other hand, Pruning Rule 5 does not make use of the boundedness of  $E_k$ . The only important issue is whether  $e_p$  or its hole is totally contained within  $E_k$ , and thus Pruning Rule 5 is adaptable.
- Alternatively, we could say that for finding the  $k$  farthest neighbors, Pruning Rules 3 and 4 are the same as Pruning Rules 1 and 2, respectively, in the sense that when  $q$  is completely inside the inner sphere of the spherical shell  $e_p$  (Rule 3), or when  $q$  is inside the union of  $e_p$  and the region spanned by the inner sphere of  $e_p$ , the only pruning that is possible is when the upper bound on the distance from  $q$  to any object in  $e_p$  (Rule 3) or to a specific object  $o$  (Rule 4) is less than  $D_k$ .

Pruning Rule 1 now stipulates that element  $e_p$  in the active list with mean  $M_p$  and distance  $r_{p, \max}$  from  $M_p$  to the farthest object within  $e_p$  cannot contain the  $k$ th-farthest neighbor of query object  $q$  if  $D_k - r_{p, \max} > d(q, M_p)$ . In other words, Rule 1 amounts to computing the maximum distance from the query object  $q$  to an object in  $e_p$  (i.e.,  $\text{MAXDIST}$ ) and determining if it is less than  $D_k$ , the distance from  $q$  to the nearest of the current  $k$  candidate farthest neighbors of  $q$ . Rule 1 is illustrated by Figure S.9. Note that Rule 1 is applicable regardless of whether  $q$  is outside  $e_p$  (Figure S.9(a)) or in  $e_p$  (Figure S.9(b)). Moreover, it is also applicable even if  $e_p$  is a spherical shell.

Pruning Rule 2 now stipulates that object  $o$  in element  $e_p$  at the deepest level of the search hierarchy with mean  $M_p$  and distance  $r_{p, \max}$  from  $M_p$  to the farthest object within  $e_p$  cannot be the  $k$ th-farthest neighbor of query object  $q$  if  $D_k - d(o, M_p) > d(q, M_p)$ . Rule 2 is illustrated by Figure S.10. It is only meaningful when  $q$  is closer to  $M_p$  than  $D_k$ —that is,  $d(q, M_p) < D_k$ , and also only when  $d(o, M_p) < D_k$ . For this rule to be applicable,  $q$  can be both outside (Figure S.10(a)) and inside (Figure S.10(b))  $e_p$ —that is,  $d(q, M_p)$  has an arbitrary value (i.e., it is independent of  $r_{p, \max}$ ). In fact,  $D_k$  can also be such that all of the objects within  $D_k$  of  $q$  lie inside  $e_p$  (Figure S.10(c)).

Pruning Rules 1 and 2 make use of estimates of the maximum possible distance at which the farthest neighbor in nonobject element  $e$  can be found (i.e.,  $\text{MAXDIST}$ ) to prune the search process. The adaptation of Pruning Rule 5 makes use of estimates of the minimum possible distances at which the farthest neighbor can be found. The simplest way to do so is to use the minimum possible distance from  $q$  to an object in  $e$  (i.e.,  $\text{MINDIST}$ ) to tighten the estimate of

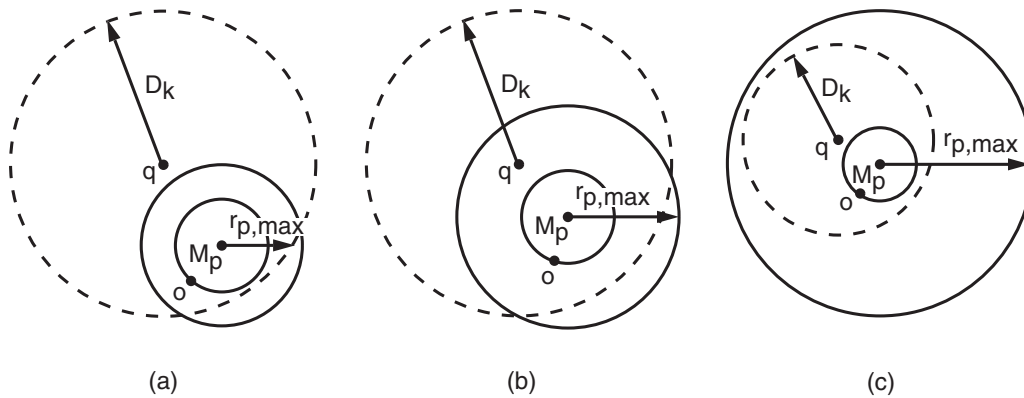

Figure S.10

Examples illustrating Pruning Rule 2 for computing the  $k$  farthest neighbors that eliminates any object  $o$  in element  $e_p$  when  $D_k - d(o, M_p) > d(q, M_p)$ : Query object  $q$  so that (a) query object  $q$  is outside  $e_p$ , (b)  $q$  is inside  $e_p$ , and (c) all of the objects within  $D_k$  of  $q$  lie inside  $e_p$ .

the distance to the farthest neighbor (i.e.,  $D_1$ ), which is an analog of the suggestion of Fukunaga and Narendra [666]. An even better estimate is to use the minimum possible distance from  $q$  to its farthest neighbor in  $e$  (referred to as MINFARTHESTDIST), which is an analog of the suggestion of Larsen and Kanal [1103].

The values of the MINDIST, MAXDIST, and MINFARTHESTDIST estimates are heavily dependent on the nature of the clustering process used to form the search hierarchy. For example, if all we know is that nonobject element  $e_p$  has mean  $M_p$  and distance  $r_{p,max}$  from  $M$  to the farthest object within  $e$ , then the distance from  $q$  to its farthest neighbor cannot be smaller than  $d(q, M_p) - r_{p,max}$  (i.e., MINDIST). In this case, Rule 5 results in setting  $D_1$  to the maximum of  $D_1$  and  $d(q, M_p) - r_{p,max}$  (Figure S.11(a)), and we see that MINDIST and MINFARTHESTDIST are the same. On the other hand, if nonobject element  $e_p$  is a multidimensional spherical shell, then given that  $r_{p,min}$  is the distance from  $M_p$  to the closest object within  $e_p$ , the distance from  $q$  to its farthest neighbor cannot be smaller than  $d(q, M_p) - r_{p,min}$  (i.e., MINFARTHESTDIST). In this case, Rule 5 results in setting  $D_1$  to the maximum of  $D_1$  and  $d(q, M_p) - r_{p,min}$  (Figure S.11(b)).

Note that, as in the case of the nearest neighbor, at the time we find that Rule 5 is applicable to element  $e_p$ , the actual object in  $e_p$  that could serve as the farthest neighbor has not yet been identified. Instead, all we are doing is setting a lower bound on the distance  $D_1$  from  $q$  to it. The extension of Pruning Rule 5 to find the  $k$  ( $k > 1$ ) farthest neighbors is not a simple matter, although it can be done, as discussed in Exercises 12 and 13 in Section 4.2.5.

Figure S.11

Examples illustrating the applicability of Pruning Rule 5 for computing the farthest neighbor: (a) the MINDIST estimate that resets the distance  $D_1$  from  $q$  to its farthest neighbor during the insertion into the active list of element  $e_p$  with  $M_p$  as the mean and distance  $r_{p,max}$  from  $M_p$  to the farthest objects within  $e_p$  if  $d(q, M_p) - r_{p,max} > D_1$ , and (b) the MINFARTHESTDIST estimate that resets the distance  $D_1$  from  $q$  to its farthest neighbor during the insertion into the active list of element  $e_p$  with mean  $M_p$  and  $r_{max}$  and  $r_{min}$  as the distances from  $M$  to the farthest and closest, respectively, objects within  $e_p$  if  $d(q, M_p) - r_{p,min} > D_1$ .

18. FNDFTRAVFARTHEST is formed by modifying the priority queue as in the solution to Exercise 2 in Section 4.2.1 so that the first element in the priority queue  $L$  corresponds to the nearest of the  $k$  farthest neighbors instead of the farthest of the  $k$  nearest neighbors. The condition “ $d(q, o) < D_k$ ” for the invocation of INSERTL in line 19 of FNDFTRAV is replaced with the condition “ $d(q, o) > D_k$ ” in FNDFTRAVFARTHEST.  $D_k$  is initialized to 0 in KFARTHEST. Procedure FNDFTRAVFARTHEST does not use Pruning Rules 3 and 4, while Pruning Rules 1 and 2 are incorporated by replacing the conditions in lines 36 and 13 of FNDFTRAV with the conditions “ $D_k > d(q, M_p) + r_{p,max}$ ” and “ $D_k > d(q, M_p) + d(o, M_p)$ ,” respectively. Pruning Rule 5 is incorporated by replacing the conditions in lines 29 and 30 of FNDFTRAV with “ $d(q, M_p) < D_1$ ” and “ $d(q, M_p) - r_{p,min} > D_1$ ,” while  $D_1$  in line 31 of FNDFTRAV is now reset to “ $d(q, M_p) - r_{p,min}$ .” Finally, the elements of the active list in FNDFTRAVFARTHEST are sorted in decreasing order using MEANORPIVOTDIST( $q, e_p$ ) =  $d(q, M_p)$  and are always processed in this order.
19. As in the solution to Exercise 3 in Section 4.2.1, replace all distances by their negation. Thus,  $d(q, o)$  in lines 19 and 20 must be replaced with  $-d(q, o)$ . This means that the priority queue need not be modified in the sense that the first element still corresponds to the element with the maximum distance (which is now the nearest of the  $k$  farthest elements due to the use of negative distances).  $D_k$  is initialized to  $-\infty$  in KFARTHEST. Pruning Rules 1 and 2 are incorporated by replacing the conditions in lines 36 and 13 of

FNDFTRAV with the conditions “ $D_k > d(q, M_p) + r_{p,max}$ ” and “ $D_k > d(q, M) + d(o, M)$ ,” respectively, which are rewritten as “ $-d(q, M_p) - r_{p,max} > D_k$ ” and “ $-d(q, M) - d(o, M) > D_k$ ,” respectively, when we use negative distances (i.e.,  $D_k$  is negative). Pruning Rule 5 is incorporated by replacing the conditions in lines 29 and 30 of FNDFTRAV with “ $D_1 > d(q, M_p)$ ” and “ $D_1 < d(q, M_p) - r_{p,min}$ ,” respectively, which is rewritten as “ $-d(q, M_p) > D_1$ ” and “ $-d(q, M_p) + r_{p,min} < D_1$ ,” respectively, when we use negative distances (i.e.,  $D_1$  is negative). In addition,  $D_1$  in line 31 of FNDFTRAV is now reset to “ $d(q, M_p) - r_{p,min}$ ,” which is rewritten as “ $-d(q, M_p) + r_{p,min}$ ” when we use negative distances. Finally, the elements of the active list in FNDFTRAVFARTHEST are sorted in increasing order using  $\text{MEANORPIVOTDIST}(q, e_p) = -d(q, M_p)$  and are always processed in this order.

### Solutions to Exercises in Section 4.2.3

1. Denote the query point by  $q = (q_0, q_1, \dots, q_{d-1})$  and the minimum bounding hyperrectangle by  $H = [l_0, u_0] \times [l_1, u_1] \times \dots \times [l_{d-1}, u_{d-1}]$ . Moreover, let  $a_i$  be  $l_i - q_i$  if  $q_i < l_i$ ,  $q_i - u_i$  if  $u_i < q_i$ , and 0 otherwise for  $0 \leq i \leq d - 1$ . Therefore, using the Euclidean distance metric, we have that  $\text{MINDIST}(q, H) = \sqrt{\sum_{i=0}^{d-1} a_i^2}$ .
2. Denote the query point by  $q = (q_0, q_1, \dots, q_{d-1})$  and the minimum bounding hyperrectangle by  $H = [l_0, u_0] \times [l_1, u_1] \times \dots \times [l_{d-1}, u_{d-1}]$ . Moreover, let  $a_i$  be  $|l_i - q_i|$  if  $|l_i - q_i| > |q_i - u_i|$ , and  $|q_i - u_i|$  otherwise for  $0 \leq i \leq d - 1$ . Therefore, using the Euclidean distance metric, we have that  $\text{MAXDIST}(q, H) = \sqrt{\sum_{i=0}^{d-1} a_i^2}$ .

Figure S.12  
Example showing the calculation of MINDIST and MAXDIST when the minimum bounding object is the intersection of the minimum bounding hyperrectangle and the minimum bounding hypersphere (e.g., an SR-tree).

3. Denote the query point by  $q = (q_0, q_1, \dots, q_{d-1})$  and the minimum bounding hyperrectangle by  $H = [l_0, u_0] \times [l_1, u_1] \times \dots \times [l_{d-1}, u_{d-1}]$ . Using the principle that every surface must contain a point, determine the farthest point on each surface and retain its minimum. For each dimension  $i$ , there are two surfaces. Clearly, the minimum of the maximums along dimension  $i$  will be attained at the surface that is closer to  $q$ . Therefore, let  $b_i$  be  $|q_i - l_i|$  if  $q_i \leq (l_i + u_i)/2$  and  $|q_i - u_i|$  otherwise for  $0 \leq i \leq d - 1$ . Now, let  $a_j$  denote the distance to the farthest of the remaining possible corner points of the closest surface along dimension  $i$ , where  $a_j$  is  $|q_j - l_j|$  if  $q_j \geq (l_j + u_j)/2$  and  $|q_j - u_j|$  otherwise for  $0 \leq j \leq d - 1$  and  $j \neq i$ . Therefore, using the Euclidean distance metric, we have that  $\text{MAXNEARESTDIST}(q, H) = \min_{0 \leq i \leq d-1} \sqrt{b_i^2 + \sum_{j=0, j \neq i}^{d-1} a_j^2}$ .
4. The value of MINDIST depends on the relative position of the query object and the minimum bounding object. Katayama and Satoh [999] suggest using the maximum of the values of MINDIST for the minimum bounding hyperrectangle and for the minimum bounding hypersphere, which we denote by MINDISTSR. It is easy to see that MINDISTSR is a lower bound on the value of MINDIST by examining query point  $q$  in Figure S.12. From this figure it would appear that we should use the minimum of the distance from the query point to the points of intersection of the minimum bounding hypersphere with all of the surfaces of the minimum bounding hyperrectangle, which we call MINDISTINTER (i.e.,  $i$  for query point  $q$  in Figure S.12). This solution is hinted at by Böhm, Berchtold, and Keim [224]. Unfortunately, MINDISTINTER may be too high as can be seen by examining query point  $p$  in Figure S.12. The real solution is to use a combination of these two methods. In particular, let  $p_r$  and  $p_s$  be the closest points to query point  $q$  on the minimum bounding hyperrectangle  $r$  and minimum bounding hypersphere  $s$ , respectively. If neither  $p_r$  nor  $p_s$  is on the minimum bounding object formed by the intersection of  $r$  and  $s$ , then the value of MINDISTSR is too low, and the correct value for MINDIST is MINDISTINTER. Otherwise, MINDISTSR is correct.
5. The value of MAXDIST also depends on the relative position of the query object and the minimum bounding object. We first form MAXDISTSR, which is the minimum of the values of MAXDIST for the minimum bounding hyperrectangle and for the minimum bounding hypersphere. It is easy to see that MAXDISTSR is an upper bound on the value of MAXDIST by examining query point  $p$  in Figure S.12. From this figure it would appear that we should use the maximum of the distance from  $p$  to the points of intersection of the minimum bounding hypersphere with all of the surfaces of the minimum bounding hyperrectangle, which we call MAXDISTINTER (i.e.,  $j$  in Figure S.12). Unfortunately, MAXDISTINTER may be too low as can be seen by examining query point  $r$  in Figure S.12. The real solution is to use a combination of these two methods. In particular, let  $p_r$  and  $p_s$  be the farthest points from query

point  $q$  on the minimum bounding hyperrectangle  $r$  and minimum bounding hypersphere  $s$ , respectively. If neither  $p_r$  nor  $p_s$  is on the minimum bounding object formed by the intersection of  $r$  and  $s$ , then the value of  $\text{MAXDISTSR}$  is too high, and the correct value for  $\text{MAXDIST}$  is  $\text{MAXDISTINTER}$ . Otherwise,  $\text{MAXDISTSR}$  is correct.

6. Notwithstanding claims to the contrary [224], the value of  $\text{MAXNEARESTDIST}$  is obtained in an analogous manner to that when the minimum bounding object is a hyperrectangle. In particular, we find the farthest point on every surface that is a planar face (i.e., contributed by the minimum bounding hyperrectangle) and retain their minimum. Note that these points are the points of intersection of the minimum bounding hypersphere with all of the surfaces of the minimum bounding hyperrectangle.
7. One of the problems with forming an object hierarchy for an arbitrary metric space is that in a metric space, unlike in a vector space, where we can use a search hierarchy such as an R-tree that uses summary information in the form of clusters that are minimum bounding hyperrectangles for all of the objects in the subtree, we cannot explicitly form the “regions” that enclose a set of objects. The M-tree [389] makes use of “balls” around pivot objects, which play the same role as the minimum bounding hyperrectangles in the R-tree.
8. Consider a two-dimensional set of points with two clusters  $a$  and  $b$  centered at  $M_a = (-5, 0)$  and  $M_b = (5, 0)$ , respectively, and a query point  $q$  at  $(-1, 0)$ . Suppose that the nearest point  $p_b$  to  $q$  in  $b$  is at  $(14, 0)$  and that  $r_{b,\min}$  is 9. If we process cluster  $a$  first and the current nearest point to  $q$  is  $p$  at  $(-3, 0)$ , then we can prune cluster  $b$  by applying Pruning Rule 3 as  $D_1 + d(q, M_b) < r_{b,\min}$ —that is,  $2 + 6 = 8 < 9$ .
10. (Houman Alborzi) Assume that the contrary is true—that is, the distance of the closest point  $p \in P$  to  $q$  is greater than  $\sqrt{d(q, c)^2 + r^2}$ . Thus,

$$\forall p \in P, d(p, q)^2 > d(q, c)^2 + r^2 \quad (\text{S.1})$$

Below, we show that this assumption results in  $B$  not being a minimum enclosing hypersphere of  $P$ . There are two cases:

- (a)  $c = q$ : In this case, Equation S.1 reduces to  $\forall p \in P, d(p, c)^2 > r^2$ , which means that the hypersphere  $B$  is not an enclosing hypersphere.
- (b)  $c \neq q$ : Consider the line  $l$  passing through  $q$  and  $c$ . Project all points in  $P$  on this line, and consider a point  $p_t$  whose projection  $c_t$  on line  $l$  is the closest to  $q$  among all of the projected points (e.g., Figure S.13 for the two-dimensional case with points  $p_1, p_2, p_t$  in point set  $P$ ,  $l$  passing through query point  $q$  and the center  $c$  of the minimum bounding hypersphere  $B$  of  $P$ ,  $c_t$  being the projection of  $p_t$  on  $l$ , and  $q$  outside of  $B$  without loss of generality). Let  $\vec{n}$  correspond to the unit vector oriented from  $q$  to  $c$ . Let  $\alpha \vec{n} = \vec{c} - \vec{q}$ ,  $\alpha > 0$ , where  $\vec{c} - \vec{q}$  denotes the vector pointing from  $q$  to  $c$ . Now, for point  $p_t$  we have

$$\forall p \in P, \overrightarrow{p - c} \cdot \vec{n} \geq \overrightarrow{p_t - c} \cdot \vec{n} \quad (\text{S.2})$$

Letting  $\varepsilon = \overrightarrow{p_t - c} \cdot \vec{n}$ , we have  $\forall p \in P, \overrightarrow{p - c} \cdot \vec{n} \geq \varepsilon$ . For  $c_t$ , the projection of  $p_t$  on  $l$ , we have  $c_t = c + \varepsilon \vec{n}$ . Now, we show that  $\varepsilon > 0$ , which means that  $c_t$  is distinct from  $c$  and does not lie on the line segment between  $c$  and  $q$ .

$$\begin{aligned} d(p_t, q)^2 &= \overrightarrow{p_t - q} \cdot \overrightarrow{p_t - q} \\ &= (\overrightarrow{p_t - c} + \overrightarrow{c - q}) \cdot (\overrightarrow{p_t - c} + \overrightarrow{c - q}) \\ &= \overrightarrow{p_t - c} \cdot \overrightarrow{p_t - c} + \overrightarrow{c - q} \cdot \overrightarrow{c - q} + 2\overrightarrow{p_t - c} \cdot \overrightarrow{c - q} \\ &= d(p_t, c)^2 + d(c, q)^2 + 2\alpha \overrightarrow{p_t - c} \cdot \vec{n} \\ &= d(p_t, c)^2 + d(c, q)^2 + 2\alpha \varepsilon \end{aligned}$$

Therefore, solving for  $\varepsilon$ , we have

$$\varepsilon = \frac{d(p_t, q)^2 - d(p_t, c)^2 - d(c, q)^2}{2\alpha}$$

At this point, we show that  $\varepsilon > 0$ . Knowing that  $B$  contains  $p_t$  means that  $d(p_t, c)^2 \leq r^2$  and thus replacing  $d(p_t, c)^2$  by  $r^2$  in the definition of  $\varepsilon$  yields  $\varepsilon \geq \frac{d(p_t, q)^2 - r^2 - d(c, q)^2}{2\alpha}$ .

Figure S.13  
Two-dimensional example illustrating the calculation of  $\text{MAXNEARESTDIST}$  when the minimum bounding object is a hypersphere.

However, from Equation S.1, we have that  $d(p_t, q)^2 > d(q, c)^2 + r^2$ , which means that the numerator of the definition of  $\varepsilon$  is positive. This coupled with the fact that  $\alpha$  is positive by definition means that  $\varepsilon > 0$ , and thus  $c_t$  is not between  $q$  and  $c$ .

Now, knowing that  $c_t$  is not between  $q$  and  $c$ , we show that the distance from  $c_t$  to all points of  $P$  is smaller than  $r$ , and thus  $B$  is not the minimum enclosing hypersphere of  $P$ . Formally, we show that,  $\forall p \in P, d(p, c_t) < r$ .

$$\begin{aligned}
 d(p, c_t)^2 &= \overrightarrow{p - c_t} \cdot \overrightarrow{p - c_t} \\
 &= (\overrightarrow{p - c} - \varepsilon \vec{n}) \cdot (\overrightarrow{p - c} - \varepsilon \vec{n}) \\
 &= \overrightarrow{p - c} \cdot \overrightarrow{p - c} + \varepsilon^2 \vec{n} \cdot \vec{n} - 2\varepsilon \overrightarrow{p - c} \cdot \vec{n} \\
 &= d(p, c)^2 + \varepsilon^2 - 2\varepsilon \overrightarrow{p - c} \cdot \vec{n} \\
 &\leq d(p, c)^2 + \varepsilon^2 - 2\varepsilon \overrightarrow{p_t - c} \cdot \vec{n} \quad \text{from Equation S.2} \\
 &\leq r^2 + \varepsilon^2 - 2\varepsilon^2 \\
 &\leq r^2 - \varepsilon^2 \\
 &< r^2 \quad \text{as } \varepsilon > 0
 \end{aligned}$$

Therefore,  $B$  cannot be the minimum enclosing hypersphere as the distance from all points  $p \in P$  to  $c_t$  is strictly less than  $r$ .

11. (Daniel DeMenthon) An intuitive explanation is that the centroid cannot lie outside the cloud of objects. Can you prove this more formally?
12. As in the computation of the MAXNEARESTDIST function, we take advantage of the fact that every face of the minimum bounding hyperrectangle  $b$  must contain at least one object. MINFARTHESTDIST is computed by determining the distances to the nearest points on each face of  $b$  from  $q$  and choosing their maximum. Denote the query point by  $q = (q_0, q_1, \dots, q_{d-1})$  and the minimum bounding hyperrectangle by  $H = [l_0, u_0] \times [l_1, u_1] \times \dots \times [l_{d-1}, u_{d-1}]$ . Using the principle that every surface must contain a point, determine the nearest point on each surface and retain its maximum. For each dimension  $i$ , there are two surfaces. Clearly, the maximum of the minimums along dimension  $i$  will be attained at the surface that is farther from  $q$ . Therefore, let  $b_i$  be  $u_i - q_i$  if  $q_i \leq (l_i + u_i)/2$  and  $q_i - l_i$  otherwise for  $0 \leq i \leq d - 1$ . Now, let  $a_j$  denote the distance to the nearest of the remaining possible corner points of the farthest surface along dimension  $i$ , where  $a_j$  is  $l_j - q_j$  if  $q_j < l_j$ ,  $q_j - u_j$  if  $u_j < q_j$ , and 0 otherwise for  $0 \leq j \leq d - 1$  and  $j \neq i$ . Therefore, using the Euclidean distance metric, we have that  $\text{MINFARTHESTDIST}(q, H) = \max_{0 \leq i \leq d-1} \sqrt{b_i^2 + \sum_{j=0, j \neq i}^{d-1} a_j^2}$ .
13. The MINFARTHESTDIST point is not always at a corner. For example, this is the case in Figure 4.19(a) where the MINFARTHESTDIST point is on the right edge of the minimum bounding rectangle with the same  $y$  coordinate value as the query object  $q$ . On the other hand, though, the MINFARTHESTDIST point for Figure 4.19(b) is at point  $b$ , which is a corner.
14. Same as MAXNEARESTDIST—that is,  $\sqrt{d(q, M_p)^2 + r_{p, \max}^2}$ , as derived in the text for the same situation.
15. The two cases are handled as follows:
  - (a) The minimum bounding hypersphere with radius  $r_{p, \max}$  and centered at  $M_p$  coincident with the exterior face of the spherical shell is formed first. From the solution to Exercise 14 when  $r_{p, \min}$  is unknown, we know that the minimum possible distance from  $q$  to an object  $o$  of  $e_p$  that is on the exterior face of  $e_p$  and that is to serve as the farthest neighbor of  $q$  is  $\sqrt{d(q, M_p)^2 + r_{p, \max}^2}$ . Next, given the above value of  $M_p$ , we determine the maximum bounding hypersphere with radius  $r_{p, \min}$  and centered at  $M_p$  coincident with the interior face of the spherical shell so that the interior is empty. From the discussion of Pruning Rule 5 in the solution to Exercise 17 in Section 4.2.2, we know that the minimum possible distance from  $q$  to an object  $o$  of  $e_p$  that is on the interior face of  $e_p$  and that is to serve as the farthest neighbor of  $q$  is  $d(q, M_p) - r_{p, \min}$ . The value of MINFARTHESTDIST is the maximum of these lower bounds, which is  $\sqrt{d(q, M_p)^2 + r_{p, \max}^2}$ . Thus, when forming the minimum bounding hypersphere corresponding to the exterior face of the spherical shell first, there is no need to take the maximum bounding hypersphere corresponding to

the inner face into account in determining the minimum possible distance to the farthest neighbor of  $q$ .

- (b) The maximum bounding hypersphere with radius  $r_{p,min}$  and centered at  $M_p$  coincident with the interior face of the spherical shell so that the interior is empty is formed first. Using similar reasoning as in the solution to Exercise 14, we know that the minimum possible distance from  $q$  to an object  $o$  of  $e_p$  that is on the interior face of  $e_p$  and is to serve as the farthest neighbor of  $q$  is  $\sqrt{d(q, M_p)^2 + r_{p,min}^2}$ . From the discussion of Pruning Rule 5 in the solution to Exercise 17 in Section 4.2.2, we know that the minimum possible distance from  $q$  to an object  $o$  of  $e_p$  that is on the exterior face of  $e_p$  and which is to serve as the farthest neighbor of  $q$  is  $d(q, M_p) - r_{p,max}$ . The value of MINFARTHESTDIST is the maximum of these lower bounds, which is  $\sqrt{d(q, M_p)^2 + r_{p,min}^2}$ . Thus, when forming the maximum bounding hypersphere corresponding to the interior face of the spherical shell first, there is no need to take the minimum bounding hypersphere corresponding to the outer face into account in determining the minimum possible distance to the farthest neighbor of  $q$ .
16. MINFARTHESTDIST is obtained in an analogous manner to that in which we obtained MAXNEARESTDIST for the same minimum bounding object. In particular, we find the nearest (instead of the farthest) point on every surface that is a planar face (i.e., contributed by the minimum bounding hyperrectangle) and retain its maximum (instead of its minimum). Note that these points are the points of intersection of the minimum bounding hypersphere with all of the surfaces of the minimum bounding hyperrectangle.

## Solutions to Exercises in Section 4.2.4

1. Assume that  $k = 1$ . Consider element  $e_a = (M_a, r_{a,max})$  with  $d(q, M_a) = 21$  and  $r_{a,max} = r_{a,min} = 20$  so that  $\text{MINDIST}(q, e_a) = 1$ , and element  $e_b = (M_b, r_{b,max})$  with  $d(q, M_b) = 6$  and  $r_{b,max} = r_{b,min} = 4$  so that  $\text{MINDIST}(q, e_b) = 2$ . Configure the objects in  $e_a$  so that they are all at a maximum distance from  $M_a$  so that the minimum distance  $D_1$  from  $q$  is 11. Processing the active list in increasing MINDIST order means that  $e_a$  is processed before  $e_b$  as  $d(q, M_a) - r_{a,max}$  is less than  $d(q, M_b) - r_{b,max}$ . Thus, once  $e_a$  has been processed, we have that  $D_1 = 11$ . Next, we process  $e_b$  for which we know that  $d(q, M_b) + r_{b,min} \leq 10$ . When the active list  $A$  of  $e_b$  is generated, we can assume, without loss of generality, that its elements  $e_i = (M_i, r_{i,max})$  can be formed in such a way that each of them satisfies  $d(q, M_i) + r_{i,min} \leq 10 \leq 11$ , and thus we can reset  $D_1$  to 10. The extension to arbitrary values of  $k$  is straightforward.
2. The proof follows the one given by Hjaltason and Samet [848] (see also Cheung and Fu [360] for a similar conclusion). Let  $r$  be the minimum bounding hyperrectangle of the element in the active list with the smallest MAXNEARESTDIST value. Using Strategy 1, we can prune any element in the active list with minimum bounding hyperrectangle  $r'$  such that  $\text{MINDIST}(q, r') > \text{MAXNEARESTDIST}(q, r)$ . However, Strategy 1 will not prune  $r$  or any element in the active list preceding it, regardless of the ordering used. If the active list is ordered based on MAXNEARESTDIST, this clearly holds since  $\text{MINDIST}(q, r) \leq \text{MAXNEARESTDIST}(q, r)$ . If the active list is ordered based on MINDIST, the elements preceding  $r$  have MINDIST values smaller than that of  $r$ , so their MINDIST values must also be smaller than MAXNEARESTDIST( $q, r$ ). Now, let us see what elements can be pruned from the active list by Strategy 3 after processing the element corresponding to  $r$ . In particular, at that point, from the definition of MAXNEARESTDIST, we have that the distance from  $q$  to  $o$  is less than or equal to MAXNEARESTDIST( $q, r$ ), where  $o$  is the candidate nearest object. Therefore, when Strategy 3 (based on MINDIST( $q, o$ )) is now applied to the active list, it will prune at least as many elements as Strategy 1 (based on MAXNEARESTDIST( $q, r$ )). Thus, we see that only Strategy 3 is needed for the implementation of Roussopoulos et al. [1586].
3. See Figure S.14, where the search for the nearest (i.e.,  $k = 1$ ) neighbor of  $q$  using the ordering MAXNEARESTDIST examines the contents of minimum bounding hyperrectangle B first, which is followed by examining the contents of minimum bounding hyperrectangle E. At this point, there is no need to examine the contents of E's sibling minimum bounding hyperrectangle F as it is farther from  $q$  than the farthest possible current candidate nearest neighbor

Solutions to Exercises  
in Section 4.2.4

Figure S.14  
Example where use of MAXNEARESTDIST(broken line) for ordering the processing of elements of the active list for finding the nearest neighbor of query point  $q$  results in examining the contents of fewer minimum bounding hyperrectangles than use of MINDIST(solid line).

Figure S.15  
Example where use of MINDIST(solid line) for ordering the processing of elements of the active list for finding the nearest neighbor of query point  $q$  results in examining the contents of fewer minimum bounding hyperrectangles than the use of MAXNEARESTDIST(broken line).

in E (represented by the point  $s$ ). Next, we examine the contents of minimum bounding hyperrectangle A as its distance from  $q$  is less than the distance to  $s$ , and, in fact, is less than the distance from the closest possible current candidate nearest neighbor in E (represented by  $t$ ). Regardless of the identity of the current candidate nearest neighbor (i.e.,  $s$  or  $t$ ), there is no need to examine the contents of minimum bounding hyperrectangles C and D as they are much farther from  $q$  than any possible current candidate nearest neighbor (i.e.,  $s$ ). On the other hand, ordering using MINDIST examines the contents of minimum bounding hyperrectangle A first, which is followed by examining the contents of minimum bounding hyperrectangle D. Note that we must examine the contents of minimum bounding hyperrectangle D even if we apply Pruning Rule 5, which sets  $D_1$  to MAXNEARESTDIST( $q, B$ ) (i.e., the distance from  $q$  to  $r$ ). In this case,  $D_1$  is greater than MINDIST( $q, D$ ) (i.e., the distance from  $q$  to  $v$ ), which is why D must be examined. At this point, there is no need to examine the contents of D's sibling minimum bounding hyperrectangle C as it is farther from  $q$  than the farthest possible current candidate nearest neighbor in D (represented by the point  $u$ ). Next, we examine the contents of minimum bounding hyperrectangle B as its distance from  $q$  is less than the distance to  $u$ , and, in fact, is less than the distance from the closest possible current candidate nearest neighbor in D (represented by  $v$ ). Regardless of the identity of the current candidate nearest neighbor (i.e.,  $u$  or  $v$ ), we examine the contents of minimum bounding hyperrectangle E as it is closer to  $q$  than any possible current candidate nearest neighbor (i.e.,  $v$ ). However, there is no need to visit E's sibling minimum bounding hyperrectangle F as it is farther from  $q$  than the farthest possible current candidate nearest neighbor in E (i.e.,  $s$ ), which is also closer than the closest possible current candidate neighbor resulting from visiting A and D (i.e.,  $v$ ). Thus, we find that in this example, using the MAXNEARESTDIST ordering, we examine the contents of fewer minimum bounding hyperrectangles (i.e., B, E, A) than when using the MINDIST ordering (i.e., A, D, B, and E).

4. See Figure S.15, where the search for the nearest (i.e.,  $k = 1$ ) neighbor of  $q$  using the ordering MAXNEARESTDIST examines the contents of minimum bounding hyperrectangle B first, which is followed by examining the contents of minimum bounding hyperrectangle E. At this point, there is no need to examine the contents of E's sibling minimum bounding hyperrectangle F as it is farther from  $q$  than the farthest possible current candidate nearest neighbor in E (represented by the point  $s$ ). Next, we examine the contents of minimum bounding hyperrectangle A as its distance from  $q$  is less than the distance to  $s$  and, in fact, is less than the distance from the closest possible current candidate nearest neighbor in E (represented by  $t$ ). Regardless of the identity of the current candidate nearest neighbor (i.e.,  $s$  or  $t$ ), there is no need to examine the contents of minimum bounding hyperrectangles C and D as they are much farther from  $q$  than any possible current candidate nearest neighbor (i.e.,  $s$ ). However, the contents of minimum bounding hyperrectangle G must be examined as it is closer to  $q$  than any possible current candidate nearest neighbor (i.e.,  $t$ ). On the other hand, ordering using MINDIST examines the contents of minimum bounding hyperrectangle A first, which is followed by examining the contents of minimum bounding hyperrectangle G. At this point, there is no need to examine the contents of either of G's sibling minimum bounding hyperrectangles C and D as they are farther from  $q$  than the farthest possible current candidate nearest neighbor in G (represented by the point  $w$ ). For this example, we also do not need to examine the contents of minimum bounding hyperrectangle B as it is farther from  $q$  than any possible candidate nearest neighbor (i.e.,  $w$ ). Thus, we find that in this example, using the MINDIST ordering, we examine the contents of fewer minimum bounding hyperrectangles (i.e., A and G) than when using the MAXNEARESTDIST ordering (i.e., B, E, A, and G).
5. See Friedman, Bentley, and Finkel [650], who use the relationship between the value of the discriminator key at each nonleaf node of the  $k$ -d tree and the corresponding attribute value of the query point to decide which subtree (i.e., one of the two elements of the active list) to explore first. Pruning is achieved whenever the distance to the current nearest neighbor is less than the minimum distance to an unexplored subtree (i.e., Pruning Rule 1). The same technique is applied by Eastman and Zemankova [530] to find the nearest neighbor when only some of the attribute values of the query point are specified (termed a *partial match nearest neighbor query*).
6. The MAXDIST ordering represents the optimistic choice. The MINFARTHESTDIST ordering represents the pessimistic choice.

1. One way is when  $L$  was initially set up when  $D_k$  was  $\infty$ . The second way is when we find ourselves at some point where a nonobject element has a MAXNEARESTDIST value  $x$  lower than  $D_k$  and there are other nonobject elements in  $L$  having  $x$  as their MAXNEARESTDIST value.
2. Ciaccia et al. [389] formulate Pruning Rules 2 and 4 for nonobjects for the M-tree by the condition  $|d(q, M) - d(M, M_p)| > D_k + r_{p,max}$ .
3. The proof is identical to the one for the correctness of Pruning Rule 1 in the solution to Exercise 1 in Section 4.2.2 with  $M$  instead of  $M_p$  and  $\text{MAXDIST}(M, e_p)$  instead of  $r_{p,max}$ .
4. The proof is identical to the one for the correctness of Pruning Rule 3 in the solution to Exercise 6 in Section 4.2.2 with  $M$  instead of  $M_p$  and  $\text{MINDIST}(M, e_p)$  instead of  $r_{p,min}$ .
5. Yes. Sorting the nonobjects in MINDIST order enables pruning all nonobjects  $e_p$  from consideration for which  $\text{MINDIST}(e_p)$  is greater than  $d(q, M) + D_k$  (Pruning Rule 4). The remaining nonobjects are only pruned if  $\text{MAXDIST}(M, e_p) < d(q, M) - D_k$  (i.e., Pruning Rule 2); otherwise, they are inserted into the active list. Note that in this case the nonobjects are sorted in decreasing, instead of increasing, order.
6. The reason is that in the case of an object  $o$ , regardless of whether  $M$  was closer to  $o$  than to  $q$  or  $M$  was closer to  $q$  than to  $o$ , in order for pruning to take place, we always tested the same quantity  $d(o, M)$  for being outside of the range lying between  $d(q, M) - D_k$  and  $d(q, M) + D_k$ . This was supported by storing the objects in  $e$  sorted by their distance from  $M$ . In contrast, in the case of a nonobject  $e_p$  with mean  $M_p$ , in order for pruning to take place, we test whether the quantity  $\text{MAXDIST}(M, e_p)$  is less than  $d(q, M) - D_k$  when  $M$  is closer to  $e_p$  than to  $q$  or test whether the quantity  $\text{MINDIST}(M, e_p)$  is greater than  $d(q, M) + D_k$  when  $M$  is closer to  $q$  than to  $e_p$ . Therefore, instead of testing just one quantity (i.e.,  $d(o, M)$ ) in the case of objects, we must test two different quantities in the case of nonobjects. Each sorting sequence (i.e., in increasing MAXDIST order as in OPTDFTRAV or in decreasing MINDIST order as in Exercise 5) supports one of the bounds. One possible approach to supporting both bounds is to maintain two sorted sequences with each nonleaf node  $e$  of the nonobjects in  $e$ : one in increasing MAXDIST order and one in decreasing MINDIST order (but see Exercise 7).
7. This algorithm is implemented with replacing lines 24–30 in OPTDFTRAV with the following code fragment:
 

```

1 /* Assume that all nonobjects  $e_p$  in  $e$  are sorted in both increasing and decreasing
   order with respect to  $M$  using MAXDIST and MINDIST, and stored in  $\text{MX}(e)$ 
   and  $\text{MN}(e)$ , respectively. Use INSERTACTIVELIST to generate the active list  $A$ 
   containing the nonpruned elements of  $e$  sorted in increasing order with respect
   to  $q$  using MINDIST and MEANORPIVOTDIST as primary and secondary keys,
   respectively, and process  $A$  in this order. */
2  $A \leftarrow \text{Empty}$ 
3 Find first nonobject  $e_p$  in  $\text{MX}(e)$  such that
4    $\text{MAXDIST}(M, e_p) \geq d(q, M) - D_k$ 
5   while  $\text{EXIST}(e_p)$  and  $d(M_p, M) \leq d(q, M)$  do /* Pruning Rule 2 for nonobjects
   */
6     INSERTACTIVELIST( $e_p, A$ )
7      $e_p \leftarrow \text{NEXT}(\text{MX}(e))$ 
8   enddo
9 Find first nonobject  $e_p$  in  $\text{MN}(e)$  such that
10    $\text{MINDIST}(M, e_p) \leq d(q, M) + D_k$ 
11   while  $\text{EXIST}(e_p)$  and  $d(M_p, M) > d(q, M)$  do /* Pruning Rule 4 for nonobjects
   */
12     INSERTACTIVELIST( $e_p, A$ )
13      $e_p \leftarrow \text{NEXT}(\text{MN}(e))$ 
14   enddo

```

This method will not work as it is not guaranteed to insert all relevant nonobjects into the active list. The problem is that the processing of the nonobjects in  $\text{MX}(e)$  in increasing order halts as soon as a nonobject  $e_a$  with mean  $M_a$  is found so that  $M$  is farther from  $M_a$

than from  $q$ . This means that another nonobject  $e_b$ , with mean  $M_b$  where  $\text{MAXDIST}(M, e_b) > \text{MAXDIST}(M, e_a)$  while  $M$  is closer to  $M_b$  than to  $q$ , will not be inserted into the active list as a result of this part of the algorithm. Unfortunately, as  $M$  is closer to  $M_b$  than to  $M$ ,  $e_b$  will also not be inserted into the active list by the second phase of the algorithm, which processes the nonobjects in  $\text{MN}(e)$  in decreasing order and halts as soon as a nonobject  $e_c$  with mean  $M_c$  is found so that  $M$  is closer to  $M_c$  than to  $q$ . The same problem arises for another nonobject  $e_n$ , with mean  $M_n$  where  $\text{MINDIST}(M, e_c) < \text{MINDIST}(M, e_n)$  while  $M$  is closer to  $q$  than to  $M_n$ , will not be inserted into the active list as a result of this part of the algorithm. Again, as  $M$  is closer to  $q$  than to  $M_n$ ,  $e_n$  will not have been inserted into the active list by the first phase of the algorithm, which processes the nonobjects in  $\text{MX}(e)$  and halts as soon as a nonobject  $e_a$  with mean  $M_a$  is found so that  $M_a$  is farther from  $M$  than from  $q$ . Thus, we cannot take advantage of sorting the nonobjects using  $\text{MAXDIST}$  and  $\text{MINDIST}$  as was done for objects.

11. As we pointed out in the solution to Exercise 17 in Section 4.2.2, it is not possible to adapt Pruning Rule 4 to the problem of finding the  $k$  farthest neighbors. On the other hand, Pruning Rule 2 can be easily adapted for nonobjects, in which case it stipulates that no object in nonobject  $e_p$  in nonobject element  $e$ , with mean  $M$  and  $\text{MAXDIST}(M, e_p)$  as the distance from  $M$  to the farthest object within  $e_p$ , can be the  $k$ th-farthest neighbor of query object  $q$  if  $D_k - \text{MAXDIST}(M, e_p) > d(q, M)$ . Again, as in the case of objects, the rule is only meaningful when  $q$  is closer to  $M$  than  $D_k$ —that is,  $d(q, M) < D_k$ , and  $q$  can be anywhere (inside and outside  $e$  and likewise inside and outside  $e_p$ ).
12. The code for  $\text{OPTDFTRAVFARTHEST}$  is almost the same, and the changes are similar to those described in the solution to Exercise 18 in Section 4.2.2. The main additional differences are the use of  $\text{MAXDIST}$ ,  $\text{MINFARTHESTDIST}$ , and  $\text{MINPRIORITYQUEUE}$  instead of  $\text{MINDIST}$ ,  $\text{MAXNEARESTDIST}$ , and  $\text{MAXPRIORITYQUEUE}$ , respectively. Moreover, all tests in terms of “ $< D_k$ ” are changed to be in terms of “ $> D_k$ ” (lines 19, 34, and 42 in  $\text{OPTDFTRAV}$  and line 20 in  $\text{OPTINSERTL}$ ) and tests in terms of “ $> D_k$ ” are changed to be in terms of “ $< D_k$ ” (line 39 in  $\text{OPTDFTRAV}$ ). Instead of being sorted and processed in increasing order, the elements of the active list in  $\text{OPTDFTRAVFARTHEST}$  are sorted in decreasing order with respect to  $q$ , using  $\text{MAXDIST}(q, e_p)$  and  $\text{MEANORPIVOTDIST}(q, e_p) = d(q, M_p)$  as the primary and secondary keys, respectively, and are processed in this order. Since there is no analog of Pruning Rule 4 when finding the  $k$  farthest neighbors, the code that handles Pruning Rule 2 is simplified considerably. In particular, Pruning Rule 2 for objects is implemented by storing the objects in leaf node  $e$  with mean  $M$  and maximum distance  $r_{max}$  sorted in decreasing order with respect to  $M$ , and they are processed in this order. The absence of the analog of Pruning Rule 4 means that there is no need in  $\text{OPTDFTRAVFARTHEST}$  for the analog of line 13 in  $\text{OPTDFTRAV}$ , and the condition “ $d(o, M) \leq d(q, M) + D_k$ ” (line 15 in  $\text{OPTDFTRAV}$ ) is replaced with the condition “ $d(o, M) \geq D_k - d(q, M)$ .” Similarly, Pruning Rule 2 for nonobjects  $e_p$  in nonleaf  $e$  with mean  $M$  is implemented by again storing them in  $C(e)$ , but this time sorted in decreasing order with respect to  $M$  using  $\text{MAXDIST}$  instead of in increasing order. The actual implementation is simplified considerably by the inapplicability of Pruning Rule 4, which means that line 24 is omitted, as is the condition in line 27 for the insertion of  $e_p$  in  $A$  (i.e., the call of  $\text{INSERTACTIVELIST}$ ). The actual condition for the pruning is incorporated by using “ $\text{EXIST}(e_p)$  and  $D_k - d(q, M) \leq \text{MAXDIST}(M, e_p)$ ” to condition the execution of the loop in lines 26–30.
13. Replace all distances by their negation. Thus,  $d(q, o)$  in lines 17 and 18 must be replaced with  $-d(q, o)$ , and, similarly,  $D_k$  must be initialized to  $-\infty$  in  $\text{KFARTHEST}$  instead of to  $\infty$  as in  $\text{KNEAREST}$ . This means that the priority queue need not be modified in the sense that the first element still corresponds to the element with the maximum distance (which is now the nearest of the  $k$  farthest elements due to the use of negative distances). We also replace all uses of the distance functions  $\text{MINDIST}$  and  $\text{MAXNEARESTDIST}$  with  $\text{MAXDIST}$  and  $\text{MINFARTHESTDIST}$ , respectively, which, of course, are now negative. Again, the elements of the active list in  $\text{OPTDFTRAVFARTHEST}$  are sorted in increasing order (using a negative  $\text{MAXDIST}$  and  $\text{MEANORPIVOTDIST}(q, e_p) = -d(q, M_p)$  as the primary and secondary keys, respectively) and are always processed in this order (which would really be a decreasing order if the distances were positive). Since there is no analog of Pruning Rule 4 when finding the  $k$  farthest neighbors, the code that handles Pruning Rule 2 is simplified considerably. In particular, in the case of objects, there is no need in  $\text{OPTDFTRAVFARTHEST}$  for the analog of line 13 in  $\text{OPTDFTRAV}$ , and the condition “ $d(o, M) \leq d(q, M) + D_k$ ” (line 15 in  $\text{OPTDFTRAV}$ ) is replaced with the condition “ $d(o, M) \geq D_k - d(q, M)$ ,” which is Pruning Rule 2 for finding the  $k$  farthest neighbors. Use of negative distances (i.e.,  $D_k$  is negative)

causes this condition to be rewritten as “ $-d(o, M) \leq D_k + d(q, M)$ ” and the objects in  $e$  to be processed in increasing order of their negative distance from  $M$ . Similarly, Pruning Rule 2 for nonobjects  $e_p$  in nonleaf  $e$  with mean  $M$  is implemented by again storing them in  $C(e)$ , but this time sorted in increasing order with respect to  $M$  using negative MAXDIST distance values and processed in this order. The implementation is simplified considerably by the inapplicability of Pruning Rule 4, which means that line 24 is omitted, as is the condition in line 27 for the insertion of  $e_p$  in  $A$  (i.e., the call of INSERTACTIVELIST). The actual condition for the pruning is incorporated by using “EXIST( $e_p$ ) and  $D_k - d(q, M) \leq \text{MAXDIST}(M, e_p)$ ” to condition the execution of the loop in lines 26–30. Use of negative distances (i.e.,  $D_k$  is negative) causes this condition to be rewritten as “ $-\text{MAXDIST}(M, e_p) \leq D_k + d(q, M)$ .” No changes are needed in procedure OPTINSERTL.

## Solutions to Exercises in Section 4.2.6

2. BFTRAVFARTHEST is almost the same as BFTRAV, and the changes are the same as those described in the solution to Exercise 2 of Section 4.2.1. Again, MINPRIORITYQUEUE and a definition of distance that incorporates upper bound information (i.e., MAXDIST) are used instead of MAXPRIORITYQUEUE and a definition of distance that incorporates lower-bound information (i.e., MINDIST), respectively. Similarly, all tests in terms of “ $< D_k$ ” and “ $> D_k$ ” are changed to be in terms of “ $> D_k$ ” (line 25) and “ $< D_k$ ” (line 20), respectively. No changes are needed in procedure INSERTL.
3. The result is similar to BFTRAV, and the modifications that are needed are virtually identical to those described in the solution of Exercise 3 of Section 4.2.1. Recall that in this case we replace all distances by their negation. Thus,  $d(q, o)$  in lines 24–26 must be replaced with  $-d(q, o)$ , and, similarly,  $D_k$  must be initialized to  $-\infty$  (line 16) instead of to  $\infty$ . This means that the priority queue need not be modified in the sense that the first element still corresponds to the element with the maximum distance (which is now the nearest of the farthest elements due to the use of negative distances). No changes are needed in procedure INSERTL.
4. OPTBFTRAVFARTHEST is almost the same as OPTBFTRAV, and the changes are similar to those described in the solution to Exercise 12 in Section 4.2.5. Again, MAXDIST, MINFARTHESTDIST, and MINPRIORITYQUEUE are used instead of MINDIST, MAXNEARESTDIST, and MAXPRIORITYQUEUE, respectively. Similarly, all tests in OPTBFTRAV in terms of “ $< D_k$ ,” “ $> D_k$ ,” and “ $\leq D_k$ ” are changed to be in terms of “ $> D_k$ ” (lines 23, 34, and 48), “ $< D_k$ ” (line 21), and “ $\geq D_k$ ” (line 46), respectively. Since there is no analog of Pruning Rule 4 when finding the  $k$  farthest neighbors, the code that handles Pruning Rule 2 is simplified considerably. In particular, Pruning Rule 2 for objects is implemented by storing the objects in leaf node  $e$  with mean  $M$  and maximum distance  $r_{max}$  sorted in decreasing order with respect to  $M$ , and they are processed in this order. The absence of the analog of Pruning Rule 4 means that there is no need in OPTBFTRAVFARTHEST for the analog of line 31 in OPTBFTRAV, and the condition “ $d(o, M) \leq d(q, M) + D_k$ ” (line 32 in OPTBFTRAV) is replaced by the condition “ $d(o, M) \geq D_k - d(q, M)$ .” Similarly, Pruning Rule 2 for nonobjects  $e_p$  in nonleaf  $e$  with mean  $M$  is implemented by again storing them in  $C(e)$ , but this time sorted in decreasing order with respect to  $M$  using MAXDIST instead of in increasing order. The actual implementation is simplified considerably by the inapplicability of Pruning Rule 4, which means that line 41 is omitted, as is the condition in lines 44 and 53 for determining whether actual processing of  $e_p$  should continue. The actual condition for the pruning is incorporated by using “EXIST( $e_p$ ) and  $D_k - d(q, M) \leq \text{MAXDIST}(M, e_p)$ ” to condition the execution of the remaining instructions in lines 46–52. No changes are needed in procedure OPTINSERTL.
5. The modifications needed are virtually identical to those made in the transformation of OPTDFTRAV to OPTDFTRAVFARTHEST in Exercise 13 of Section 4.2.5. Recall that in this case, we replace all distances by their negation. Thus,  $d(q, o)$  in lines 34 and 35 must be replaced with  $-d(q, o)$ , and, similarly,  $D_k$  must be initialized to  $-\infty$  (line 17) instead of to  $\infty$ . This means that the priority queue need not be modified in the sense that the first element still corresponds to the element with the maximum distance (which is now the nearest of the farthest elements due to the use of negative distances). We also replace all uses of the distance functions MINDIST and MAXNEARESTDIST by MAXDIST and MINFARTHESTDIST, respectively, which, of course, are now negative. Interestingly, this has no effect on the manner in which

Figure S.16  
Example of finding the nearest neighbor where using the general incremental algorithm performs fewer page accesses than using an implementation of the depth-first algorithm that makes use of a MINDIST ordering such as the one of Roussopoulos et al. [1586].

the priority queue is initialized in the sense that it is again initialized with the root of the search hierarchy but now with a MAXDIST value of 0 instead of with a MINDIST value of 0. As in OPTDFTRAVFARTHEST, the objects in leaf element  $e$  with mean  $M$  and maximum distance  $r_{max}$  are sorted in increasing order of their negative distance from  $M$  and are always processed in this order. Since there is no analog of Pruning Rule 4 when finding the  $k$  farthest neighbors, the code that handles Pruning Rule 2 is simplified considerably. In particular, in the case of objects, there is no need in OPTBFTRAVFARTHEST for the analog of line 31 in OPTBFTRAV. The failure to satisfy Pruning Rule 2 is incorporated by replacing the condition “ $d(o, M) \leq d(q, M) + D_k$ ” (line 32 in OPTBFTRAV) with the condition “ $D_k - d(q, M) \leq d(o, M)$ ,” which is rewritten as “ $-d(o, M) \leq D_k + d(q, M)$ ,” when we use negative distances (i.e.,  $D_k$  is negative). Similarly, Pruning Rule 2 for nonobjects  $e_p$  in nonleaf  $e$  with mean  $M$  is implemented by again storing them in  $C(e)$ , but this time sorted in increasing order with respect to  $M$  using negative MAXDIST distance values and processed in this order. The implementation is simplified considerably by the inapplicability of Pruning Rule 4, which means that line 41 is omitted, as is the condition in lines 44 and 53 for determining whether actual processing of  $e_p$  should continue. The actual condition for the pruning is incorporated by using “EXIST( $e_p$ ) and  $D_k - d(q, M) \leq \text{MAXDIST}(M, e_p)$ ” to condition the execution of the remaining instructions in lines 46–52. Use of negative distances (i.e.,  $D_k$  is negative) causes this condition to be rewritten as “ $-\text{MAXDIST}(M, e_p) \leq D_k + d(q, M)$ .” No changes are needed in procedure OPTINSERTL.

### Solutions to Exercises in Section 4.2.8

1. See Figure S.16, where A–F denote some of the pages that are to be accessed and we want to determine the nearest neighbor of query point  $q$ . The pages are specified in terms of their corresponding minimum bounding hyperrectangles and their relative spatial positions. We find that both algorithms process page A first. In particular, processing of the elements of the active list using the MINDIST ordering, an implementation of the depth-first algorithm, such as the one of Roussopoulos et al. [1586], places both A and B on the active list and processes A first. This means that at the next step, it processes the three children of A—that is, C, D, and E, with C being the first to be processed in the next stage. On the other hand, the general incremental algorithm inserts both A and B on the priority queue and removes A for processing first. This causes it to insert A’s three children C, D, and E on the priority queue after B, which is closer to  $q$ . Next, the general incremental algorithm processes B and inserts its three children F, G, and H on the priority queue, where F is now at the front of the queue and is thus the first to be processed in the next stage. It is clear that F contains the nearest neighbor as the value of  $\text{MINDIST}(q, C) > \text{MAXNEARESTDIST}(q, F)$ . Thus, we see that, at the very least, an implementation of the depth-first algorithm such as the one of Roussopoulos et al. [1586] will visit page C for naught.

### Solutions to Exercises in Section 4.3

1. A problem arises when  $\varepsilon \geq 1$ , in which case the denominator is zero or negative, both of which are problematic: the former means that the approximate error is unbounded, while it is difficult to interpret the latter. Thus, we retain the original definition.
2. The difference is that ANNBTRAV tries to avoid enqueueing nonobjects that are known to be too far away from  $q$  and thus will never be examined. Therefore, there is no need to enqueue them, possibly resulting in a smaller maximum size for the priority queue *Queue*.
3. The key idea behind approximate  $k$ -nearest neighbor finding is to ensure that for the object  $o'_k$  returned as the  $k$ th-nearest neighbor by the algorithm and the actual  $k$ th-nearest neighbor  $o_k$ , we have that  $d(q, o'_k) \leq (1 + \varepsilon) \cdot d(q, o_k)$ . This is usually achieved by shrinking the distance  $D_k$  from  $q$  to the  $k$ th-nearest neighbor by  $1 + \varepsilon$  or expanding the individual distances from  $q$  to the nonobjects by  $1 + \varepsilon$ . These shrunken or expanded distances are used in all comparisons that involve distances of nonobjects from  $q$ . However, since procedure DFTRAV does not make use of the distances of the nonobjects from  $q$  (i.e., it only makes use of distances

- of the actual objects from  $q$ ), we cannot report the approximate  $k$  nearest neighbors of  $q$  unless we modify the criteria for the applicability of the approximation to also involve the distances of the actual objects from  $q$ . In particular, we can only modify the test  $d(q, o) < D_k$  (line 14) to be  $d(q, o) < D_k/(1 + \varepsilon)$  or  $d(q, o) \cdot (1 + \varepsilon) < D_k$  depending on whether distances are shrunk or expanded, respectively. For the effect of this modification on procedure ANNBFTRAV, see Exercise 7. For its effect on procedures ANNFNDFTRAV, ANNOPTDFTRAV, and ANNOPTBFTRAV, see Exercise 8.
4. As in the modification of OPTBFTRAV to yield ANNOPTBFTRAV, the idea is to expand the distances of nonobject elements from  $q$  by  $1 + \varepsilon$ . In this case, we do not employ the estimates MINDIST and MAXNEARESTDIST directly. Instead, each nonobject element  $e_p$  is assumed to have a representative element  $M_p$  with  $r_{p,min}$  and  $r_{p,max}$  as the distances from  $M_p$  to the closest and farthest object in  $e_p$ , respectively. The distances of the nonobject elements from  $q$  are expressed in terms of  $M_p$ ,  $r_{p,min}$ , and  $r_{p,max}$ , and they are expanded in the comparisons with  $D_k$ . The tests for the applicability of Pruning Rules 1 and 3 become  $(d(q, M_p) - r_{p,max}) \cdot (1 + \varepsilon) > D_k$  (line 36) and  $(r_{p,min} - d(q, M_p)) \cdot (1 + \varepsilon) > D_k$  (line 37). The tests for the applicability of Pruning Rule 5 become  $d(q, M_p) \cdot (1 + \varepsilon) > D_1$  and  $(d(q, M_p) + r_{p,min}) \cdot (1 + \varepsilon) < D_1$  (lines 29 and 30, respectively). In the case that Pruning Rule 5 is found to be applicable, then we reset  $D_1$  to the expanded distance  $(d(q, M_p) + r_{p,min}) \cdot (1 + \varepsilon)$  (line 31).
  5. As in the modification of OPTBFTRAV to yield ANNOPTBFTRAV, the idea is to expand the distances (i.e., estimates and hence both MINDIST and MAXNEARESTDIST) of nonobject elements from  $q$  by  $1 + \varepsilon$ . These expanded distances are used in all comparisons with  $D_k$ , and the algorithm is simplified by also associating these expanded distances with the nonobjects in  $L$ . The test for the applicability of Pruning Rules 1 and 3 becomes  $\text{MINDIST}(q, e_p) \cdot (1 + \varepsilon) > D_k$  (line 39), the test for the applicability of Pruning Rules 2 and 4 for nonobjects become  $\text{MAXDIST}(M, e_p) \geq d(q, M) - D_k/(1 + \varepsilon)$  (line 24) and  $\text{MINDIST}(M, e_p) \leq d(q, M) + D_k/(1 + \varepsilon)$  (line 27), and the test for the insertion of nonobjects (i.e., pruning Rule 5) in  $L$  by OPTINSERTL becomes  $\text{MINDIST}(q, e_p) \cdot (1 + \varepsilon) > D_k$  (line 32) and  $\text{MAXNEARESTDIST}(q, e_p) \cdot (1 + \varepsilon) < D_k$  (line 34). The distances associated with the nonobjects  $e_p$  that are inserted in  $L$  by OPTINSERTL become  $\text{MAXNEARESTDIST}(q, e_p) \cdot (1 + \varepsilon)$  (line 35). The conditions involving MAXNEARESTDIST to determine whether it is necessary to remove a nonobject from  $L$  when processing its immediate descendants become  $\text{MAXNEARESTDIST}(q, e) \cdot (1 + \varepsilon) < D_k$  and  $\text{MAXNEARESTDIST}(q, e) \cdot (1 + \varepsilon) = D_k$  (lines 42–47).
  6. This means that each of the search hierarchy elements corresponding to each of these nonobjects, say  $b$ , is replaced with one of the objects in them. Note that there is no search involved here (in contrast to the situation when using the MAXNEARESTDIST estimate) as any object  $o_b$  in  $b$  satisfies the approximation criterion since  $\text{MAXDIST}(q, b) < D_k$ , even though  $\text{MINDIST}(q, b) \cdot (1 + \varepsilon) > D_k$ .
  7. If no use is made of the MAXNEARESTDIST estimate, as is the case in procedure ANNBFTRAV, then this modification can be made easily. In fact, this is how the basic depth-first  $k$ -nearest neighbor algorithm given by procedure DFTRAV in Section 4.2.1 is adapted to return the  $k$  approximate nearest neighbors (see the solution of Exercise 3). Use of this modification reduces the number of update manipulations on  $L$ , at the cost of not lowering  $D_k$ . Moreover, its use may cause the expansion of some nonobjects that would have otherwise been pruned by virtue of the tighter values of  $D_k$  that could be obtained since objects within  $\varepsilon$  of  $D_k$  would not have been ignored. For example, suppose that  $D_1 = 10$  with  $\varepsilon = 0.2$ . Using this modification, we ignore an object  $o$  with  $d(q, o) = 8.5$  in the sense that  $D_1$  is not reset to 8.5. Now, if we encounter a nonobject  $e$  with  $\text{MINDIST}(q, e) = 7.6$ , then we would have to process it as  $\text{MINDIST}(q, e) = 7.6 < D_1/(1 + \varepsilon) = 10/1.2 = 8.33$ ; whereas if we had not ignored  $o$ , then we could ignore  $e$  as  $\text{MINDIST}(q, e) = 7.6 > D_1/(1 + \varepsilon) = 8.5/1.2 = 7.08$ . Notice that when the approximation error tolerance is applied at the object level, it is pointless not to apply it explicitly at the nonobject level as well, as otherwise more objects would be examined (i.e., the objects in the nonobjects that would have been pruned otherwise), while yielding the same resulting set of  $k$  approximate nearest neighbors.
  8. It is impossible for the modified algorithms to terminate with nonobjects in  $L$ . We prove this by contradiction. Suppose that the algorithms terminate with a nonobject  $e_p$  in  $L$ . This means that  $\text{MAXNEARESTDIST}(q, e_p) \cdot (1 + \varepsilon) \leq D_k$ . There are two ways in which this situation could arise. The first is if  $\text{MINDIST}(q, e_p) \cdot (1 + \varepsilon) > D_k$ , which is always true for any unprocessed or pruned element  $e_p$ , but this is impossible in this case as  $\text{MINDIST}(q, e_p) \leq$

$\text{MAXNEARESTDIST}(q, e_p)$ . The second is if for all objects  $o$  in  $e_p$ ,  $d(q, o) \cdot (1 + \varepsilon) > D_k$ , which is also impossible as we know that for each nonobject  $e_p$  in  $L$  there exists at least one object  $o_p$  in  $e_p$  and its descendants with  $d(q, o_p) \leq \text{MAXNEARESTDIST}(q, e_p)$  and thus  $d(q, o_p) \cdot (1 + \varepsilon) \leq \text{MAXNEARESTDIST}(q, e_p) \cdot (1 + \varepsilon) \leq D_k$ . Therefore, when  $e_p$  and its descendants are processed by the algorithm, in the worst case,  $e_p$  will be replaced with  $o_p$  in  $L$ . Thus, it is impossible for the algorithms to terminate with nonobjects in  $L$ .

It is important to note that if the element  $e$  of  $L$  at distance  $D_k$  corresponds to a nonobject  $b$  such that  $D_k = \text{MAXNEARESTDIST}(q, b) \cdot (1 + \varepsilon)$ , then the actual effect of making this modification is to defeat, in part, the motivation for using the approximate  $k$  nearest neighbors, which is to avoid the processing of the nonobject elements and to let some of the farther objects be elements of  $L$  as now all objects  $o$  that are encountered subsequently such that  $\text{MAXNEARESTDIST}(q, b) < d(q, o) \leq D_k$  will be pruned from further consideration since the distance value of  $q$  from  $b$  that is associated with  $e$  has been expanded by a factor of  $1 + \varepsilon$ . Therefore, these objects  $o$  can no longer be reported “before their time.” On the other hand, if  $e$  corresponds to an object, then use of this modification will result in pruning even more objects from consideration—that is, all objects  $o$  such that  $d(q, o) < D_k \leq d(q, o) \cdot (1 + \varepsilon)$ . In fact, in this case, the effect is the same as that observed in the solution to Exercise 7 in that some nonobjects may have to be processed that would have been otherwise pruned had a lower value of  $D_k$  been obtained by virtue of not having pruned some of the objects  $o$  where  $d(q, o) \cdot (1 + \varepsilon) > D_k$  while  $d(q, o) < D_k$ .

9. Modify the conditions under which the rules are found to be applicable to be  $D_k/(1 + \varepsilon) < d(q, M_p) - d(o, M_p)$  for Pruning Rule 2 and  $D_k/(1 + \varepsilon) < d(o, M_p) - d(q, M_p)$  for Pruning Rule 4. For example, in the approximate  $k$ -nearest neighbor adaptation of OPTBFTRAV given by ANNOPTBFTRAV, the condition  $d(o, M) \geq d(q, M) - D_k$  in line 31 of OPTBFTRAV becomes  $d(o, M) \geq d(q, M) - D_k/(1 + \varepsilon)$ . Similarly, the looping condition  $d(o, M) \leq d(q, M) + D_k$  in line 32 becomes  $d(o, M) \leq d(q, M) + D_k/(1 + \varepsilon)$ . In addition, the tests  $d(q, o) < D_k$  and  $d(q, o) = D_k$  in line 34 become  $d(q, o) < D_k/(1 + \varepsilon)$  and  $d(q, o) = D_k/(1 + \varepsilon)$ , respectively. Procedures FNDFTTRAV and OPTDFTRAV are modified in the same way to yield ANNFNDFTTRAV and ANNOPTDFTRAV, respectively.
10. The resulting algorithm is identical to the incremental nearest neighbor algorithm given by INCNEAREST as the objects are now reported in increasing order of their distance from the query object. Notice the difference from the result of Exercise 7.
11. The resulting algorithm still reports the neighbors in increasing order of their distance from the query object. However, the algorithm is less efficient than INCNEAREST as the result is to delay the time at which the nearest objects are reported as some nonobjects are processed before the objects that could have already been reported. Thus, more nonobject elements are processed, and the priority queue may possibly get needlessly larger.
12. (Houman Alborzi) Let the query object be  $q$  and  $r \leq d(p, q)$ . The effect of shrinking the radius of  $b$  centered at  $p$  by  $\lambda$  is that an object at a distance of  $d(p, q) - r$  may be missed while an object at a distance of  $d(p, q) - \lambda \cdot r$  is reported as a nearest neighbor. Therefore, the maximum approximation error is  $(d(p, q) - \lambda \cdot r)/(d(p, q) - r) - 1 = (1 - \lambda) \cdot r/(d(p, q) - r)$ . This value approaches infinity as  $r$  approaches  $d(p, q)$ , so the maximum approximation error is unbounded. A similar argument shows that the error is also unbounded if  $r > d(p, q)$  as now the lower bound on the distance is 0 and dividing by 0 yields  $\infty$ .
14. When the query point coincides with the center of the hypercube,  $F_q(x) = (2 \cdot x)^d$ , and thus  $G_q(x) = 1 - (1 - (2 \cdot x)^d)^N = \delta$ . Solving for  $x$  in terms of  $\delta$ , we have  $x = (1 - (1 - \delta)^{1/N})^{1/d}/2$ . On the other hand, when the query point coincides with one of the  $2^d$  corners of the hypercube,  $F_q(x) = x^d$ , and thus  $G_q(x) = 1 - (1 - x^d)^N = \delta$ . Solving for  $x$  in terms of  $\delta$ , we have  $x = 1 - (1 - (1 - \delta)^{1/N})^{1/d}$ .
15. From the solution of Exercise 14, we have that  $x = (1 - (1 - (1 - \delta)^{1/N})^{1/d})/2$ . Substituting for  $\delta$ ,  $N$ , and  $d$ , we have  $x \approx 0.346$  [387], which means that the probability that the hypercube of width  $2 \cdot 0.346$  centered at the center of the unit hypercube is empty is at least 0.99.
17. ANNBFTTRAVFARTHEST is obtained as follows. Expand the distance  $D_k$  from  $q$  to the  $k$ th-farthest object  $o$  by a factor of  $1 + \varepsilon$ . Halt if the distance associated with the farthest nonobject  $e$  in *Queue* is greater than the expanded distance (line 20). Otherwise, if  $e$  is not a leaf, then only insert the nonobject child elements  $e_p$  of  $e$  into *Queue* for which the maximum distance from  $q$  to an object in  $e_p$  (i.e.,  $\text{MAXDIST}(q, e_p)$ ) is less than this expanded distance (line 31).

18. ANNINCFARTHEST is analogous to procedure INCFARTHEST in Exercise 6 in Section 4.1.5. Always shrink the distance value of a nonobject element  $e_{i'}$  (i.e., the maximum distance from  $q$  to an object in  $e_{i'}$  known as  $\text{MAXDIST}(q, e_{i'})$ ) by a factor of  $1 + \varepsilon$  before enqueueing it (line 19 of ANNINCNEAREST).
19. ANNOPTBFTRAVFARTHEST is analogous to procedure OPTBFTRAVFARTHEST in Exercise 5 in Section 4.2.6. Always shrink the distances (i.e., estimates and hence both  $\text{MAXDIST}$  and  $\text{MINFARTHESTDIST}$ , which are the analogs of  $\text{MINDIST}$  and  $\text{MAXNEARESTDIST}$ , respectively) of nonobject elements from  $q$  by  $1 + \varepsilon$ . These shrunken distances are used in all comparisons with  $D_k$ , and the algorithm is simplified by also associating these shrunken distances with the nonobjects in both  $L$  and  $Queue$ . In particular, the test for the applicability of Pruning Rule 1 becomes  $\text{MAXDIST}(q, e_p)/(1 + \varepsilon) < D_k$  (line 46), and the test for the insertion of nonobjects (i.e., pruning Rule 5) in  $L$  by  $\text{OPTINSERTL}$  becomes  $\text{MINFARTHESTDIST}(q, e_p)/(1 + \varepsilon) < D_k$  (line 48). The distances associated with the nonobjects  $e_p$  that are inserted in  $Queue$  and  $L$  become  $\text{MAXDIST}(q, e_p)/(1 + \varepsilon)$  (line 51) and  $\text{MINFARTHESTDIST}(q, e_p)/(1 + \varepsilon)$  (line 49), respectively. The conditions involving  $\text{MINFARTHESTDIST}$  to determine whether it is necessary to remove a nonobject from  $L$  when processing its immediate descendants become  $\text{MINFARTHESTDIST}(q, e)/(1 + \varepsilon) < D_k$  and  $\text{MINFARTHESTDIST}(q, e)/(1 + \varepsilon) = D_k$  (lines 23–28). Since there is no analog of Pruning Rule 4 when finding the  $k$  farthest neighbors, the code that handles Pruning Rule 2 is simplified considerably. As in  $\text{OPTBFTRAVFARTHEST}$ , we distinguish between the applicability of Rule 2 to objects and nonobjects. In the case of objects, the failure to satisfy Pruning Rule 2 for obtaining the  $k$  approximate farthest neighbors is incorporated by replacing the condition “ $d(o, M) \leq d(q, M) + D_k$ ” (line 32 in  $\text{OPTBFTRAV}$ ) by the condition “ $D_k \cdot (1 + \varepsilon) - d(q, M) \leq d(o, M)$ ,” which is rewritten as “ $-d(o, M) \leq D_k \cdot (1 + \varepsilon) + d(q, M)$ ,” when we use negative distances (i.e.,  $D_k$  is negative). In the case of nonobjects,  $e_p$  in nonleaf  $e$  with mean  $M$  is implemented by again storing them in  $C(e)$ , but this time sorted in increasing order with respect to  $M$  using negative  $\text{MAXDIST}$  distance values and processed in this order. The implementation is simplified considerably by the inapplicability of Pruning Rule 4, which means that line 41 is omitted, as is the condition in lines 44 and 53 for determining whether actual processing of  $e_p$  should continue. The actual condition for the pruning is incorporated by using “ $\text{EXIST}(e_p)$  and  $D_k \cdot (1 + \varepsilon) - d(q, M) \leq \text{MAXDIST}(M, e_p)$ ” to condition the execution of the remaining instructions in lines 46–52. Use of negative distances (i.e.,  $D_k$  is negative) causes this condition to be rewritten as “ $-\text{MAXDIST}(M, e_p) \leq D_k \cdot (1 + \varepsilon) + d(q, M)$ .” No changes are needed in procedure  $\text{OPTINSERTL}$ .
20. ANNFNDFTRAVFARTHEST is analogous to procedure FNDFTRAVFARTHEST in Exercise 19 in Section 4.2.2. Again, each nonobject element  $e_p$  is assumed to have a representative element  $M_p$  with  $r_{p,\min}$  and  $r_{p,\max}$  as the distances from  $M_p$  to the closest and farthest object in  $e_p$ , respectively. As in the solution to Exercise 19, always shrink the distances (i.e., estimates in terms of  $M_p$ ,  $r_{p,\min}$ , and  $r_{p,\max}$ ) of nonobject elements from  $q$  by  $1 + \varepsilon$ . These shrunken distances are used in all comparisons with  $D_k$  and  $D_1$ . In the case that Pruning Rule 5 is found to be applicable by virtue of comparisons that involve the shrunken distances, then we reset  $D_1$  to the shrunken distance  $(-d(q, M_p) + r_{p,\min})/(1 + \varepsilon)$ .
21. ANNOPTDFTRAVFARTHEST is analogous to procedure OPTDFTRAVFARTHEST in Exercise 13 in Section 4.2.5 and procedure ANNOPTDFTRAV in Exercise 5. As in the solution to Exercise 19, always shrink the distances (i.e., estimates and hence both  $\text{MAXDIST}$  and  $\text{MINFARTHESTDIST}$ , which are the analogs of  $\text{MINDIST}$  and  $\text{MAXNEARESTDIST}$ , respectively) of nonobject elements from  $q$  by  $1 + \varepsilon$ . These shrunken distances are used in all comparisons with  $D_k$  that correspond to Pruning Rules 1 and 5, and the algorithm is simplified by also associating these shrunken distances with the nonobjects in  $L$ . Pruning Rule 2 for objects and nonobjects is handled in the same way as in the solution to Exercise 19. In particular, in the case of objects, the inapplicability of pruning Rule 4 means that there is no need in ANNOPTDFTRAV for the analog of line 13 in  $\text{OPTDFTRAV}$ , and the failure to satisfy Pruning Rule 2 for obtaining the  $k$  approximate farthest neighbors is incorporated by replacing the condition “ $d(o, M) \leq d(q, M) + D_k$ ” (line 15 in  $\text{OPTDFTRAV}$ ) with the condition “ $D_k \cdot (1 + \varepsilon) - d(q, M) \leq d(o, M)$ ,” which is rewritten as “ $-d(o, M) \leq D_k \cdot (1 + \varepsilon) + d(q, M)$ ,” when we use negative distances (i.e.,  $D_k$  is negative). In the case of nonobjects,  $e_p$  in nonleaf  $e$  with mean  $M$  is implemented by again storing them in  $C(e)$ , but this time sorted in increasing order with respect to  $M$  using negative  $\text{MAXDIST}$  distance values and processed in this order. The implementation is simplified considerably by the inapplicability of Pruning Rule 4, which means that line 24 is omitted, as is the condition in line 27 for the

insertion of  $e_p$  in  $A$  (i.e., the call of INSERTACTIVELIST). The actual condition for the pruning is incorporated by using “EXIST( $e_p$ ) and  $D_k \cdot (1 + \varepsilon) - d(q, M) \leq \text{MAXDIST}(M, e_p)$ ” to condition the execution of the loop in lines 26–30. Use of negative distances (i.e.,  $D_k$  is negative) causes this condition to be rewritten as “ $-\text{MAXDIST}(M, e_p) \leq D_k \cdot (1 + \varepsilon) + d(q, M)$ .” No changes are needed in procedure OPTINSERTL.

23. We say that  $o'$  is an approximate nearest neighbor of  $q$  if  $d(q, o') \leq d(q, o) + \varepsilon D$ , where  $o$  is the actual nearest neighbor and  $D$  is the *diameter* of the point set (i.e., the distance between the two farthest points). Note that we do not want to define  $D$  in terms of the distance between the two nearest points as the rationale for using the relative error bound is for the data distribution to play a role in the quality of the approximation. Thus, a definition of  $D$  in terms of the two nearest points ignores the distance between the rest of the points.

## Solutions to Exercises in Section 4.4.2

2. The rationale of the SS-tree insertion strategy is that, as a result of its use, the maximum radius for the minimum hypersphere among the child nodes of  $n$  tends to be smaller than for alternative strategies. However, coverage and overlap may be greater. For example, take the alternative strategy mentioned in the question—that is, that of inserting  $o$  into a child node  $a$  if  $a$  covers the centroid of  $o$ , even though the centroid of  $b$  is closer. The disadvantage of this strategy is that if this situation occurs repeatedly,  $a$  may get ever larger and, in particular, much larger than  $b$ , increasing the likelihood of overlap with other child nodes. Another alternative strategy is to insert  $o$  into the child node whose coverage is increased the least by the expansion. This strategy has the same drawback as the alternative above. In particular, let  $a$  and  $b$  be two child nodes of  $n$  that do not overlap each other, and imagine that a series of points is inserted into the tree, all falling on the line segment between the centroids of  $a$  and  $b$ , starting closest to the centroid of  $a$  and proceeding toward  $b$ . With a suitable spacing between the inserted points,  $a$  will always be chosen as its coverage is increased the least, even as the points start to be closer to the centroid of  $b$ , until a point is inserted close to  $b$ . Thus, the minimum bounding sphere for  $a$  keeps growing, possibly far beyond the center point between the centroids of  $a$  and  $b$ , while  $b$  stays the same. In contrast, with the SS-tree strategy, the sum of the volumes of  $a$  and  $b$  would be much less, and the radii of the minimum bounding hyperspheres of  $a$  and  $b$  would both be at most one-half of the distance between their centroids. From this discussion, we see that perhaps the real rationale for inserting  $o$  into the child node of  $n$  with the nearest centroid is that it tends to minimize the largest radius among the minimum bounding hyperspheres of the child nodes of  $n$ .
4. Preparata and Shamos [1511] discuss the  $d = 2$  case. In particular, they point out that the minimum bounding circle is unique and is either the circumcircle of three of the points or is defined by two of them as a diameter. Algorithms can be devised that examine all pairs or triples of points and find the smallest circle that encloses the points. An obvious implementation of the algorithm takes  $O(N^4)$  time and has been reduced to  $O(N^2)$  by Elzinga and Hearn [556, 557]. This problem is known in operations research as the *minimax facilities location problem* [1511] and seeks the point  $p_0 = (x_0, y_0)$  (i.e., the center of a circle) whose greatest distance to any point in a given set  $S = \{x_i, y_i\}$  is a minimum—that is,

$$\min_{p_0} \max_i (x_i - x_0)^2 + (y_i - y_0)^2$$

Megiddo [1280, 1281] solves this by viewing it as an instance of a linear programming problem for which he obtains a deterministic  $O(C_d \cdot N)$  algorithm, where  $C_d = 2^{2^d}$ . Thus, the minimum bounding sphere is computed in  $O(N)$  time. Seidel [1711] devised a simpler randomized algorithm for linear programming with the same dependence on  $N$ . Welzl [1982] applied this randomized algorithm to the computation of the minimum bounding sphere in arbitrary dimensions and obtained an  $O(C_d \cdot N)$  algorithm, where  $C_d = d!$ . Even tighter bounds can be obtained by making use of more recent randomized algorithms for linear programming, such as one by Matoušek, Sharir, and Welzl [1257], who obtain an  $O(d^2 \cdot N + e^{\sqrt{d \cdot \ln d}})$  solution.

5. As we will see (Exercise 1 in Section 4.4.6), in high-dimensional spaces, most of the objects will tend to lie close to the boundary. Therefore, with a sufficient number of objects, we can expect that there is an object fairly close to each boundary hyperplane, so the minimum

bounding hypersphere can be expected to be almost as large as the circumscribing hypersphere for the unit hypercube.

6. Since the expected volume follows directly from the expected diameter, the result is obtained in the same manner as in Exercise 5.
8. The intuition for this result is that the maximum volume of the unit  $d$ -dimensional hypercube is 1, while the maximum volume of the minimum bounding hypersphere is quite large since the radius can be as large as  $(\sqrt{d})/2$ .

### Solutions to Exercises in Section 4.4.4

1. By definition,  $1 - f$  is the probability that when query point  $q$  is in the Voronoi region of a point  $p$ ,  $q$  is also in the approximate cover of the node containing  $p$ . This is the probability that the search finds the correct answer when  $q$  is in a particular Voronoi region of a leaf node. If  $q$  is actually in the approximating cover of some leaf node  $a$  that contains  $p$ , then  $a$  must be visited since  $q$  is also in the covers of all of the nodes on the path from the root to  $a$ . Since the Voronoi regions of all of the leaf nodes constitute a partition of the entire space, every query point lies in some Voronoi region. Therefore, the probability that the search returns the correct answer is at least  $1 - f$ , and thus the probability that it fails to provide the right answer is at most  $f$ .
2. When the training points are uniformly distributed, then the choice based on the number of points is much easier to compute as there is no need to calculate  $d$ -dimensional volume, which is computationally complex. On the other hand, even if the training points are not uniformly distributed, a choice based on volume may not be attractive as the situation could arise that the volume spanned by the training points on the right side of  $I_a$  whose nearest neighbors are elements of  $S_{al}$  is large while containing just a few points, whereas the volume spanned by the training points on the left side of  $I_a$  whose nearest neighbors are elements of  $S_{ar}$  is small while containing many points. In this case, we would like to give greater weight to avoiding the misclassification in the region with the smaller volume as it contains more training points. Thus, minimizing the number of misclassified training points seems the best choice regardless of the distribution of the training points.
3. If the hyperplane is closer to the two points, then their Voronoi regions (as defined by the training points) are more likely to cross over to the other side of the hyperplane.

### Solutions to Exercises in Section 4.4.5

1. See [98].

### Solutions to Exercises in Section 4.4.6

1. Consider a unit hypercube in a 20-dimensional space. In this case, consider an outer shell consisting of the portion of the hypercube that lies within 10% of the outer boundary. This means that we have extracted a hypercube of volume  $0.8^{20} = .01153$  of the volume of the hypercube. Assuming uniformly distributed data, this means that for 20-dimensional data, the outermost 10% of the hypercube contains 98.85% of the points. For even higher dimensions, such as 100, we find that the outermost 2% of the hypercube contains 98.31% of the data.
2. Böhm, Berchtold, and Keim [224] point out that it does not hold for all  $d$ . It is not hard to show that it holds for  $d = 2$ , and it is a bit more difficult for  $d = 3$ . However, it can be shown not to hold for  $d = 9$ . In particular, define a sphere around the point  $a = (0.2, 0.2, \dots, 0.2)$ . The Euclidean distance from  $a$  to  $c$  is  $\sqrt{9 \cdot 0.3^2} = 0.9$ . Defining a sphere around  $a$  with a radius of 0.8 results in touching or intersecting all eight-dimensional surfaces of the space while not containing the center point  $c$ .

## Solutions to Exercises in Section 4.4.7

1. See [188].
2. See [1408]. Letting  $[x_{i1}, x_{i2}]$  ( $1 \leq i \leq d$ ) denote the range of coordinate  $i$  for the window  $w$ , the result is the points that satisfy the query, which is the union of the subqueries  $w_i = [l_i, h_i]$  and is formed as follows:

$$w_i = \begin{cases} [i + \max_{1 \leq j \leq d} x_{j1}, i + x_{i2}] & \text{if } \min_{1 \leq j \leq d} x_{j1} + \theta \geq 1 - \max_{1 \leq j \leq d} x_{j1} \\ [i + x_{i1}, i + \min_{1 \leq j \leq d} x_{j2}] & \text{if } \min_{1 \leq j \leq d} x_{j2} + \theta < 1 - \max_{1 \leq j \leq d} x_{j2} \\ [i + x_{i1}, i + x_{i2}] & \text{otherwise} \end{cases}$$

The case  $\min_{1 \leq j \leq d} x_{j1} + \theta \geq 1 - \max_{1 \leq j \leq d} x_{j1}$  means that all of the points that satisfy the query window  $w$  have been mapped to the 1 (maximum) face, and thus a point  $v$  that satisfies  $w$  is mapped to  $v_{max}$  and would have been mapped to the  $d_{max}$ th coordinate, and has a key of  $d_{max} + v_{max}$ . The subquery range for the  $d_{max}$ th coordinate is  $[d_{max} + \max_{1 \leq j \leq d} x_{j1}, d_{max} + x_{d_{max}2}]$ . Since  $v$  satisfies  $w$ , we have  $v_i \in [x_{i1}, x_{i2}]$ ,  $\forall i, 1 \leq i \leq d$ . Moreover, we have  $v_{max} \geq x_{i1}$ ,  $\forall i, 1 \leq i \leq d$ . This implies that  $v_{max} \geq \max_{1 \leq i \leq d} x_{i1}$ ,  $\forall i, 1 \leq i \leq d$ . We also have  $v_{max} \leq x_{d_{max}2}$ . Therefore, we have  $v_{max} \in [\max_{1 \leq i \leq d} x_{i1}, x_{d_{max}2}]$ —that is,  $v$  can be retrieved using the  $d_{max}$ th subquery. Thus, the response to query  $w$  is a subset of the union of the responses to subqueries  $w_i, 1 \leq i \leq d$ .

Note that the range  $w_i$  is tight in the sense that if we let  $w'_i = [l'_i + \varepsilon_l, h'_i - \varepsilon_h]$  for some  $\varepsilon_l > 0$  and  $\varepsilon_h > 0$ . Consider a point  $z = (z_1, z_2, \dots, z_d)$  that satisfies  $w$ . Note that if  $l_i < z_{max} < l_i + \varepsilon_l$ , then we will miss  $z$  if  $w'_i$  has been used. Similarly, if  $h_i - \varepsilon_h < z_{max} < \max_{1 \leq j \leq d} x_{j2}$ , then we will miss  $z$  if  $w'_i$  has been used. Therefore, no  $w'_i$  provides the tightest bound that guarantees that no points will be missed.

Similarly, the case  $\min_{1 \leq j \leq d} x_{j2} + \theta < 1 - \max_{1 \leq j \leq d} x_{j2}$  means that all of the points that satisfy the query window have been mapped to the 0 (minimum) face, and thus a point  $v$  that satisfies  $w$  is mapped to  $v_{min}$  and would have been mapped to the  $d_{min}$ th coordinate, and has a key of  $d_{min} + v_{min}$ .

The third case means that responses to the subqueries may be found in both the 1 (maximum) and 0 (minimum) faces, and thus there are two cases to consider. In the first case,  $v$  is mapped to the minimum face, its index key is  $d_{min} + v_{min}$ , and it is indexed on the  $d_{min}$ th coordinate. To retrieve  $v$ , we need to examine the  $d_{min}$ th subquery  $[d_{min} + x_{d_{min}1}, d_{min} + x_{d_{min}2}]$ . Now, we have  $v_{min} \in [x_{d_{min}1}, x_{d_{min}2}]$  (since  $v$  is in the response) and thus the  $d_{min}$ th subquery will be able to retrieve  $v$ . The second case, which maps  $v$  onto the maximum face, is derived in a similar manner. It is easy to show that  $w_i$  is optimal and that narrowing its range may result in missing some points.

It is important to note that some of the subquery ranges may be empty as a result of the upper bound of the subquery range being smaller than the maximum of the lower bounds of the subquery ranges. In this case, there is no need to evaluate the subquery.

3. In two dimensions, the point common to all the regions is obtained by solving for  $x$  in  $y = 1 - x - \theta$  and  $y = x$ , thereby getting  $2 \cdot x = 1 - \theta$ , which implies that  $x = (1 - \theta)/2$ . The generalization to higher dimensions is straightforward.
4. The ranges of values of the different coordinates may be quite different, and this is not taken into account by the value of  $c$ . In contrast, the use of the unit cube as the underlying space reflects the application of an appropriate scaling factor to each of the individual coordinate values.
6. No, as in the M-tree, the objects that are associated with a particular reference object (termed *pivot*) are not necessarily closer to the reference object than the other ones.

## Solutions to Exercises in Section 4.4.8

1. As we want to quit as soon as possible (i.e., when encountering a candidate whose lower-bound distance is greater than the largest of the current  $k$  candidate nearest neighbors), sorting may be inefficient since, for  $N$  points, building a heap is an  $O(N)$  process while sorting is an  $O(N \cdot \log_2 N)$  process.

3. Refer to Figure 4.43(b), which depicts the relative distances for a query point  $q'$  that is above  $q$ . From  $\alpha^2 = a^2 + c^2$ , we obtain  $\alpha^2 - a^2 = (\alpha - a)(\alpha + a) = c^2$  or  $\alpha - a = \frac{c^2}{\alpha + a}$ . In the same manner, we can show that  $\beta - b = \frac{c^2}{\beta + b}$ . Since  $q$  is closer to  $p_2$ , we have  $a > b$  and  $\alpha > \beta$ , and therefore  $\alpha + a > \beta + b$ . Thus,  $\alpha - a = \frac{c^2}{\alpha + a} < \frac{c^2}{\beta + b} = \beta - b$ , implying that  $\alpha - \beta < a - b$ , and thus  $(d(q', p_1) - d(q', p_2))/2 < (d(q, p_1) - d(q, p_2))/2$ .

### Solutions to Exercises in Section 4.5.2.1.1

5. The definition of the boundary of an ellipse in two dimensions is the set of all points  $p$  such that  $d_E(p_1, p) + d_E(p_2, p) = r$ . This can be generalized to any dimension and metric  $d$  by replacing  $d_E$  by  $d$ . The two subsets  $S_1$  and  $S_2$  are defined as follows:

$$S_1 = \{o \in S \setminus \{p_1, p_2\} \mid d(p_1, o) + d(p_2, o) < r\}$$

$$S_2 = \{o \in S \setminus \{p_1, p_2\} \mid d(p_1, o) + d(p_2, o) \geq r\}$$

6. In this case, we have what Uhlmann terms the *generalized hyperplane method* (see Section 4.5.3) [1897]. In essence, we have a hyperplane, which partitions the objects into two sets  $S_1$  and  $S_2$  depending on which of the pivots is closer (if  $r = 0$ ) or which of the pivots is closer once the distance from  $p_1$  has been decreased by  $r$ —that is,  $d(p_1, o) - d(p_2, o) = r$ . The two subsets  $S_1$  and  $S_2$  are defined as follows:

$$S_1 = \{o \in S \setminus \{p_1, p_2\} \mid d(p_1, o) - d(p_2, o) < r\}$$

$$S_2 = \{o \in S \setminus \{p_1, p_2\} \mid d(p_1, o) - d(p_2, o) \geq r\}$$

### Solutions to Exercises in Section 4.5.2.1.2

5. (Gísli R. Hjaltason) Suppose that we have ball elements  $e_a$  and  $e_1$  centered at pivots  $p_a$  and  $p_1$  with ball radii  $r_a$  and  $r_1$ , respectively, so that  $e_1$  is a son of  $e_a$ . Note that in this example we have that  $d(p_1, p_a)$  is almost as large as  $r_a$ . In this case, it is possible for  $r_1$  to be larger than  $r_a - d(p_a, p_1)$ , which means that the ball  $e_1$  centered at pivot  $p_1$  extends beyond the ball  $e_a$  centered at pivot  $p_a$ . Now, if  $q$  is chosen appropriately as in the figure, we may find that  $q$  is closer to  $e_1$  than to  $e_a$ , as we wanted to show. Figure 4.59 in Section 4.5.3.3 illustrates this situation.
6. Each node  $A$  of the vp-tree partitions the domain  $S$  that it spans into two regions  $S_1$  and  $S_2$  based on a pivot  $p$  in  $S$  and a radius  $r$  so that  $S_1$  contains all objects in  $S$  that lie within radius  $r$  of  $p$  and  $S_2$  contains all objects in  $S$  whose distance from  $p$  is greater than  $r$ . We need to distinguish whether  $q$  lies in  $S_1$  or in  $S_2$  and the corresponding distance. If  $q$  lies in  $S_2$ , then the distance from  $q$  to  $S_1$  is  $d(q, p) - r$ , and the result of shrinking  $S_1$  is that its distance from  $q$  is  $d(q, p) - \lambda \cdot r$ . On the other hand, if  $q$  lies in  $S_1$ , then the situation is not so simple as now the distance from  $q$  to  $S_2$  is  $r - d(p, q)$  and shrinking  $S_2$  requires that  $r$  be increased by a factor of  $1 + 1 - \lambda$  instead of being reduced by a factor of  $\lambda$ . Therefore, the result of shrinking  $S_2$  is that its distance from  $q$  is  $(2 - \lambda) \cdot r - d(q, p)$ .

### Solutions to Exercises in Section 4.5.2.2

3. See [851].

### Solutions to Exercises in Section 4.5.2.3

3. See [851].

### Solutions to Exercises in Section 4.5.2.4

10. The only similarity is that they both use the same set of pivots at each node at a given level. They differ in several respects. The fixed-queries tree uses just one pivot at each level, while the mvp-tree uses a multiple number of pivots at a given level. The  $m$ -ary nature of the mvp-tree is derived from the multiple radius values used at each node at level  $i$ , which need not be the same for each node at level  $i$ . In contrast, the  $m$ -ary nature of the fixed-queries tree is derived from the partition values  $r_i$  ( $i = 0, \dots, m - 1$ ) of the underlying data domain, which are centered about the different pivots but are the same for every node at level  $i$ .
14. Let  $L$  consist of the objects in the ball  $B$  with pivot  $c$  and radius  $r$ , and let  $E$  be the set of objects outside  $B$ . Compute  $d(c, q)$ . If  $R$  is empty, then exit. If  $d(c, q) \leq \varepsilon$ , then add  $c$  to the results of the query. If  $d(c, q) \leq r + \varepsilon$ , then search  $B$  in its entirety. If  $d(c, q) \leq r - \varepsilon$ , then apply all of these steps recursively to  $E$ .

### Solutions to Exercises in Section 4.5.3.1

3. Faloutsos and Lin [587] suggest choosing an object  $a$  at random. Next, find the object  $r$  that is farthest from  $a$ . Finally, find the object  $s$  that is farthest from  $r$ . The last step can be iterated a number of times (e.g., 5 [587]) in order to obtain a better estimate of the pair that is farthest apart (see Section 4.7.3.2 for more details), although most implementations (e.g., [1270, 1272, 1286]) stop once they obtain the initial values for  $r$  and  $s$ .
4. For example, given that  $a$  and  $b$  are the objects that are the farthest apart, find two objects  $c$  and  $d$  separated by approximately  $d(a, b)/2$  and at a distance of  $d(a, b)/4$  from  $a$  and  $b$ , respectively.
7. This modification comes into play when  $q$  lies outside both  $e_1$  and its parent  $e_a$ . Its rationale is that although the nesting property of the partitioning process means that  $d_{min}$  of the parent  $e_a$  of  $e_1$  (based on the objects in the descendants of  $e_a$ ) cannot be greater than the minimum distance from  $q$  to any object in  $e_1$  and its descendants, the use of different pivots for the balls corresponding to partitions  $e_a$  and  $e_1$  can result in  $d_{min}$  of  $e_a$  being greater than  $d_{min}$  for  $e_1$ . In particular, this happens because the union of the balls corresponding to  $e_1$ , and its parent  $e_a$  can be greater than the ball corresponding to  $e_a$  although the additional hypervolume does not contain any objects. Such a situation is depicted in Figure 4.59 in Section 4.5.3.3 and the solution to Exercise 5 in Section 4.5.2.1.2, where, without loss of generality, the partitions and the corresponding balls are identical. The fact that the additional hypervolume is empty means that there is no real harm in setting  $d_{min}$  to  $d(q, p_1) - r_1$  in this case, which is less than  $d(q, e_a)$ , as no other node  $n$  with  $d(q, n) < d(q, e_a)$  is presently on the priority queue by virtue of the fact that we take elements off the queue in increasing order of their distance from  $q$ .

### Solutions to Exercises in Section 4.5.3.2

2. See [851].

### Solutions to Exercises in Section 4.5.3.3

1. In essence, we need to prove that the covering radii of the balls around the pivots  $p_1$  and  $p_2$  corresponding to the children of element  $e_a$  are smaller than the radius of the covering ball

of pivot  $p_a$  in  $e_a$ . Assume without loss of generality that  $p_1$  corresponds to the repeated pivot  $p_a$ . All objects that are closer to  $p_1$  than to  $p_2$  are in the ball around  $p_1$ , but the ball around  $p_a$  also includes the objects that are closer to  $p_2$  than to  $p_1$ , and thus these objects cause the covering radius of the ball around  $p_a$  to be larger than the covering radius of the ball around  $p_1$ . Similarly, all objects that are closer to  $p_2$  than to  $p_1$  are in the ball around  $p_2$ , but the ball around  $p_a$  also includes the objects that are closer to  $p_2$  than to  $p_1$ , and thus these objects cause the covering radius of the ball around  $p_a$  to be larger than the covering radius of the ball around  $p_2$ .

2. Use induction. When  $N = 2$ , only one node is needed. Each time we add an object, we add a node. The result follows.
6. The proof is analogous to the proof in Exercise 1 that none of the children in an mb-tree are eccentric. Again, we need to prove that the covering radii of the balls around the pivots  $p_1$ ,  $p_2$ , and  $p_3$  corresponding to the children of element  $e_a$  are smaller than radius of the covering ball of pivot  $p_a$  in  $e_a$ . Assume, without loss of generality, that  $p_1$  corresponds to the repeated pivot  $p_a$ . All objects that are closer to  $p_1$  than to  $p_2$  or  $p_3$  are in the ball around  $p_1$ , but the ball around  $p_a$  also includes the objects that are closer to  $p_2$  or closer to  $p_3$  than to  $p_1$ , and thus these objects cause the covering radius of the ball around  $p_a$  to be larger than the covering radius of the ball around  $p_1$ . Similarly, all objects that are closer to  $p_2$  ( $p_3$ ) than to  $p_1$  are in the ball around  $p_2$  ( $p_3$ ), but the ball around  $p_a$  also includes the objects that are closer to  $p_2$  ( $p_3$ ) than to  $p_1$  and thus these objects cause the covering radius of the ball around  $p_a$  to be larger than the covering radius of the ball around  $p_2$  ( $p_3$ ).
7. The process used to build the Voronoi tree ensures that at each stage we descend the path to the child corresponding to the closest of the pivots at the particular level. Note, however, that this process only ensures that the immediate ancestor is the closest of  $o$ 's ancestor pivots. In particular, it does not ensure that there is no other closer object/pivot to  $o$  in the Voronoi tree.
8. The search for the nearest neighbor of an object  $o$  stored in the root node proceeds as follows. Descend the child corresponding to  $o$ . If we are at node  $U$  such that no such child exists, then  $o$  is one of the pivot objects contained in  $U$ . Next, descend in parallel down the one or two paths corresponding to the remaining pivots  $p_1$  and  $p_2$  in  $U$  to nodes  $V_1$  and  $V_2$ , respectively. For each of the nodes  $V_1$  and  $V_2$  descend along the paths corresponding to the pivot in  $V_1$  that is closest to  $o$  and the pivot in  $V_2$  closest to  $o$ . When this process terminates, we have at most two candidate pivot objects, and the closest one to  $o$  is  $o$ 's nearest neighbor. The correctness of this process (i.e., that the candidate pivot object that is closest to  $o$  is indeed  $o$ 's nearest neighbor) is ensured by the fact that the Voronoi tree is transitive, as shown in Exercise 7.

## Solutions to Exercises in Section 4.5.3.4

1. See [723]. Observe that once the approximate  $k$ -center algorithm has been applied  $k$  times (i.e.,  $i = k - 1$ ), we have the  $k$  approximate  $k$ -centers  $\{v_0, v_1, \dots, v_{k-1}\}$ , which make up the set  $C_k$ . At this point, from property (b) we know that the object  $v_k$ , defined by  $d_k(v_k, C_k) = \max_{v \in S - C_k} \min_{c \in C_k} \|v - c\|$ , is the farthest object in  $S - C_k$  from its corresponding approximate  $k$ -center, where  $d_k(v_k, C_k)$  is the distance of  $v_k$  from its corresponding approximate  $k$ -center. Now, let us examine the partition  $P$  of  $S$  resulting from the use of the actual  $k$ -centers (rather than the approximate ones). By the pigeonhole principle, in partition  $P$ , two of the  $k + 1$  objects  $\{v_0, v_1, \dots, v_k\}$ , say  $v_i$  and  $v_j$ , must be in the same cluster. Without loss of generality, we assume that this cluster has  $c$  as its  $k$ -center. From the triangle inequality, we have  $\|v_i - c\| + \|v_j - c\| \geq \|v_i - v_j\|$ . Letting  $C_j = \{v_0, v_1, \dots, v_{j-1}\}$ , and assuming, without loss of generality, that  $j > i$ , we also know from property (b) that  $\|v_i - v_j\| \geq d_j(v_j, C_j)$  as  $v_j$  is the farthest object in  $S - C_j$  from  $C_j$  at a distance of  $d_j(v_j, C_j)$  and  $v_i$  is also in  $C_j$  resulting in its distance from  $v_j$  (i.e.,  $\|v_i - v_j\|$ ) being at least  $d_j(v_j, C_j)$ . In addition, we have that  $d_j(v_j, C_j) \geq d_j(v_k, C_j)$  as, by definition,  $v_j$  at distance  $d_j(v_j, C_j)$  is always the farthest object from an element of  $C_j$  after  $j$  iterations of the approximate  $k$ -center algorithm. Finally, given that  $j \leq k$ , from property (a) we have that  $d_j(v_k, C_j) \geq d_k(v_k, C_k)$  as the distance from each object  $v$  ( $v_k$  in this case) to  $C$  ( $C_a$  ( $j \leq a \leq k$ ) in this case) does not increase as the approximate  $k$ -center algorithm progresses. At this point, knowing that  $\|v_i - c\| \leq \delta$

and  $\|v_j - c\| \leq \delta$  means that  $2\delta \geq d_k(v_k, C_k)$ . Therefore, the maximum radius  $d_k(v_k, C_k)$  obtained by the approximate  $k$ -center algorithm is at most twice the optimum maximum radius  $\delta$  resulting from the use of the actual  $k$ -centers.

2. See [325]

### Solutions to Exercises in Section 4.5.5.1

1. For example, suppose that  $\mathbb{U} = \mathbb{U}' = \{a, b, c, x\}$ ,  $d(a, b) = d(a, c) = d(b, c) = 2$  and  $d'(a, b) = d'(a, c) = d'(b, c) = 2$ . Furthermore, assume that  $d(a, x) = 1$ ,  $d(b, x) = 2$ , and  $d(c, x) = 3$ , while  $d'(a, x) = 3$ ,  $d'(b, x) = 2$ , and  $d'(c, x) = 1$ . If  $S = S' = \{a, b, c\}$ , the distance matrices for the two sets are the same. The graph with edges  $(a, b)$  and  $(a, c)$  (i.e.,  $N(a) = \{b, c\}$  and  $N(b) = N(c) = \{a\}$ ) satisfies the Voronoi property for  $(S, d)$  since the nearest neighbor of any query object drawn from  $\mathbb{U}$  can be arrived at starting at any object in  $S$  by only transitioning to neighbors that are closer to or at the same distance from the query object. Thus, this graph is a Delaunay graph for  $(S, d)$ . However, it does not satisfy the Voronoi property for  $(S', d')$  since starting at  $b$  with  $q = x$ ,  $b$ 's only neighbor  $a$  is farther away from  $x$  than  $b$  is, so we cannot transition to the nearest neighbor  $c$  of  $x$ . Thus, it is not a Delaunay graph for  $(S', d')$ . It is interesting to note that the graph with edges  $(a, b)$  and  $(b, c)$  (i.e.,  $N(b) = \{a, c\}$  and  $N(a) = N(c) = \{b\}$ ) satisfies the Voronoi property for both  $(S, d)$  and  $(S', d')$ , and thus it is a Delaunay graph for both  $(S, d)$  and  $(S', d')$ . Of course, this example does not invalidate our observation that knowledge of  $(S, d)$  is insufficient to determine the Delaunay graph.
2. (Houman Alborzi) One possible effect is that if all  $N$  objects are equidistant, then a definition in terms of  $d(x, a) \leq d(x, y)$  would yield a tree with one of the objects, say  $a$ , as the root, and all remaining  $N - 1$  objects as  $a$ 's immediate children, in contrast to a tree in the form of a linear list so that each node has a fanout of one.
3. Navarro [1347] makes use of the following "greedy" heuristic to identify the set of neighbors  $N(a)$  of object  $a$ :
  - (a)  $N(a) \leftarrow \{\}$ .
  - (b) Process all objects  $x$  (besides  $a$ ) in increasing order of distance from  $a$ .
  - (c) If  $d(x, a) < d(x, y)$  for all  $y$  in  $N(a)$ , then add  $x$  to  $N(a)$ .

Although the algorithm does satisfy the criterion that any neighbor in  $N(a)$  be closer to  $a$  than to any other neighbor in  $N(a)$ , it is a heuristic because the set  $N(a)$  may not necessarily be the smallest possible set. An example of this is given in the text.

### Solutions to Exercises in Section 4.5.5.2

1. *Proof* Following [851, 853], we divide the proof into two parts. First, we show that  $b'$  is closer to  $b$  than to any of the ancestors of  $b$ , and then we do the same for any of the children of the ancestors.
 

Let  $c$  be an ancestor of  $b$  (or  $b$  itself), and let  $c'$  be the parent of  $c$ . We claim that  $b'$  is closer to  $c$  than to  $c'$ , or, more accurately,  $d(b', c) \leq d(b', c')$ . To show this, we will use contradiction. Assume that  $d(b', c) > d(b', c')$ . Since  $c \in N(c')$ , the definition of the neighbor set means  $b'$  should also be in  $N(c')$ , but this contradicts the original assumption that  $c$  is an ancestor of  $b$  (and, by extension, of  $b'$ ). Thus, our claim holds, implying that the ancestors of  $b$  are progressively farther away from  $b'$  (or, more accurately, "farther away or equidistant"). Clearly, this implication subsumes the statement that we wished to prove, that  $b'$  is closer to  $b$  than to ancestors of  $b$ .

Now, let  $a'$  be an ancestor of  $b$  (including, again,  $b$  itself), and let  $c$  be a member of  $N(a')$  that is not an ancestor of  $b$ ; the case of  $c$  being an ancestor was treated above. Suppose that  $b'$  is closer to  $c$  than to  $b$ —that is,  $d(b', c) < d(b', b)$ . Letting  $c' \in N(a')$  be the ancestor of  $b$  among

the siblings of  $c$ , we saw above that  $d(b', b) \leq d(b', c')$ . This, coupled with our assumption about  $c$ , further implies that  $d(b', c) < d(b', c')$ . However, in this case,  $b'$  should have been associated with the subtree rooted at  $c$  instead of the one rooted at  $c'$ , thereby contradicting the assumption that  $c$  is not an ancestor of  $b$ . Hence,  $b'$  cannot be closer to  $c$  than to  $b$ , and the proof is complete. ■

2. Hjalton and Samet [853] show that, unfortunately, the answer is no, as can be seen by examining the example in Figure S.17 from [853]. In the figure, the two-dimensional points  $b'$  and  $c'$  can be moved arbitrarily close to each other while maintaining the same sa-tree structure. Hence, an object  $b'$  can easily be closer to some other object  $c'$  than to its parent  $b$  if  $c'$  is not among the “ancestor neighbors” of  $b$ . Therefore, objects that are not among the ancestor neighbors of  $b$  can be arbitrarily close to  $b'$ , thereby precluding their consideration as candidates for improving the pruning power.
3. Each of  $A$ 's children  $e$  that is a leaf node is enqueued as an element of type ‘node’. However, when each leaf node child  $e$  is subsequently dequeued,  $e$ 's corresponding object  $a$  is enqueued as an element of type ‘object’ while no elements of type ‘node’ are enqueued as  $a$  has no children and thus  $N(a)$  is empty. Therefore, SATREEINCNEAREST terminates in this case.
4. Simply include  $d_a$  inside the  $\max\{\dots\}$  computation in line 22 of SATREEINCNEAREST.
5. *Proof* Following [853], we let  $o_k \in S$  be the  $k$ th neighbor of  $q$ . When the nonmonotonic version of SATREEINCNEAREST reports  $o_k$  as the next neighbor of  $q$ , the priority queue, by the definition of DEQUEUE, contains no element with a key smaller than  $D_k$ . Clearly, the nonmonotonic version of SATREEINCNEAREST cannot visit any node not visited by the monotonic version, as the  $d_{i_0}$  values computed in the former are never greater than those computed in the latter. Suppose  $b \in S$  corresponds to an sa-tree node  $n$  that is visited by the nonmonotonic version of SATREEINCNEAREST, thus having a  $d_{i_0}$  value smaller than  $d(q, o_k)$ . Since all the ancestors of  $n$  must be visited in order for  $n$  to be visited, the  $d_{i_0}$  value for the ancestors must also be smaller than  $d(q, o_k)$ . The  $d_{i_0}$  value computed for  $b$  by the monotonic version (i.e., by including  $d_a$  in the maximum computation of line 22) cannot be greater than that for the ancestors of  $n$ . Hence, these two facts imply that  $n$  is also visited by the monotonic version, so we have shown the two versions visit exactly the same set of nodes. ■
6. When at node  $a$  that is not a root, we first determine the object  $c \in \bigcup_{a' \in A(b)} (\{a'\} \cup N(a'))$ , where  $b$  is in  $N(a)$  such that  $d(q, c)$  is minimized. When at node  $a$  that is a root, then  $c$  is set to  $a$ . In either case, the search now continues as before by visiting each child  $b \in N(a)$ , except those for which  $(d(q, b) - d(q, c))/2 > \varepsilon$ .

## Solutions to Exercises in Section 4.5.6

Figure S.17  
A simple sa-tree for five two-dimensional points, with  $a$  as the root. The points  $b'$  and  $c'$  can move arbitrarily close to the broken line, as indicated by the gray arrows, without giving rise to a different tree structure.

## Solutions to Exercises in Section 4.5.6

1. Yes. Just because there is an edge from  $p$  to  $a$  (i.e.,  $a$  is one of the  $k$  nearest neighbors of  $p$ ) does not necessarily mean that there is an edge from  $a$  to  $p$  (i.e.,  $p$  is not necessarily one of the  $k$  nearest neighbors of  $a$ ).
2. (Houman Alborzi) Use contradiction. Suppose that for vertex (i.e., object)  $u$ , its nearest neighbor  $v$  is not in the MST. In this case, by adding edge  $uv$  to the minimal spanning tree, we are forming a cycle in the tree that passes through  $u$ . This means that there exists another edge  $uw$  in the cycle where  $uw$  is longer than edge  $uv$ . Therefore, by removing edge  $uw$ , we have decreased the cost of the minimal spanning tree. This contradicts the assumption that we started with a minimal spanning tree and that the nearest neighbor  $v$  of  $u$  was not in the minimal spanning tree. Thus, the claim holds.
8. Show that each edge  $uv$  of the MST is in the RNG. In particular, for edge  $uv$  in the MST, we want to show that for all other vertices,  $w$ ,  $d(u, v) \leq \max\{d(u, w), d(v, w)\}$ . The inequality holds iff  $d(u, v) \leq d(u, w)$  or  $(d(u, v) \leq d(v, w))$ . For any vertex  $w$  other than  $u$  or  $v$ , consider the possible edges  $uv$ ,  $vw$ , and  $uw$ .  $uv$  is in the MST, and among the other two edges, at most one of them is in the MST as otherwise the three edges form a cycle, which is impossible as the MST cannot have any cycles. If  $uw$  is not in the MST, then  $d(u, v) \leq d(u, w)$  as otherwise the MST would have included  $uw$  instead of  $uv$ . Similarly, we can show that if  $vw$  is not

in the MST, then  $d(u, v) \leq d(v, w)$ . In other words, we have shown that  $d(u, v) \leq d(u, w)$  or  $(d(u, v) \leq d(v, w))$ . Hence, by the definition of the RNG,  $uv$  is in the RNG. Therefore, every edge in the MST is in the RNG and thus the RNG is connected.

9. We can demonstrate an even stronger result than that the UNG is not connected. In particular, we show that it consists of isolated vertices or unconnected edges. Let us consider vertices  $u$  and  $v$  such that an edge  $uv$  exists in the UNG. If no such pair of vertices exists, then the graph is clearly unconnected. Now, consider any other vertex  $w$ . We show that neither edges  $uw$  nor  $vw$  are in the UNG, which means that the graph must be unconnected as there is no way to reach any vertex  $w$  from  $u$  or  $v$ . This can be seen by noting that since  $uv$  is in the UNG, we have from the definition of the UNG that  $\min\{d(w, u), d(w, v)\} > d(u, v)$ , which means that  $d(w, u) > d(u, v)$ , and  $d(w, v) > d(u, v)$ . From the definition of the UNG, this means that neither  $uw$  nor  $vw$  can be an edge in the UNG as  $v$  is closer to  $u$  than  $w$  is to  $u$  in the former, and  $u$  is closer to  $v$  than  $w$  is to  $v$  in the latter. Therefore, there are no edges incident at  $u$  and  $v$ , and thus we have an edge that is not connected to any other edges.
10. One possibility is to use it to detect two-element clusters and then use the pairs as cluster centers instead of single-element cluster centers.
11. It is easy to find nontrivial graphs where the DNG is connected. For example, this is the case when a third object is constrained to lie in the lune anchored at the two farthest objects.
12. (Houman Alborzi) Assume that the two vertices with the largest distances are  $u$  and  $v$ . Therefore, we know that  $\max\{d(w, u), d(w, v)\} \leq d(u, v)$  holds for all vertices  $w$ . This is equivalent to stipulating that there does not exist a vertex  $w$  for which  $\max\{d(w, u), d(w, v)\} > d(u, v)$ , and by using the definition of the DNG, we see that edge  $uv$  must be in the DNG.
13. As in the case of the UNG, as discussed in the solution to Exercise 10, the DNG could be used to detect larger clusters in the sense that the initial two-element clusters could be larger.
14. It is easy to see that  $\text{UNG} \subset \text{RNG}$ . For an edge to be included in the RNG, only the lune of the spheres must be empty, while for an edge to be included in the UNG, the union of the spheres must be empty, which also includes the lune.
15. In general,  $\text{RNG} \cap \text{DNG}$  is not equal to the UNG as can be seen when there are just three objects in the dataset, and they are all equidistant. In this case, both the DNG and the RNG consist of three edges, while the UNG is empty. However, if all distances between pairs of vertices are different, then this relationship would hold. This relationship would also hold if we had slightly altered the definitions of the UNG and the DNG as follows:
  - Edge  $uv$  is part of the UNG whenever the area defined by the objects  $p$  such that  $\min\{d(p, u), d(p, v)\} < d(u, v)$  is empty.
  - Edge  $uv$  is part of the DNG whenever the area defined by the objects  $p$  such that  $\min\{d(p, u), d(p, v)\} < d(u, v) < \max\{d(p, u), d(p, v)\}$  is empty.

Given such definitions,  $\text{RNG} \cap \text{DNG} = \text{UNG}$  as we observe that an edge can be included in the DNG regardless of whether the lune is empty, while the lune must be empty in the case of the RNG. However, these definitions were modified so that we could prove that the UNG is not connected.
16. In this case,  $d_1(p, (u, v)) = d(p, u) + d(p, v)$ , and the condition for the existence of an edge between  $u$  and  $v$  using bidistance metric  $d_1(p, (u, v))$  is one that stipulates that the locus of all objects  $p$  at a distance  $d_1(p, (u, v))$  from  $u$  and  $v$  that is less than  $d(u, v)$  must be empty. In other words, for all objects  $p$ , we must have that  $d(u, p) + d(v, p) \geq d(u, v)$ . However, the condition  $d(u, p) + d(v, p) \geq d(u, v)$  is the triangle inequality, which is always true for a distance metric  $d$ . The complete graph satisfies this condition, which means that in this graph, which we call the *Manhattan graph*, an edge exists between every pair of vertices.
17. From the definition of the RNG, we know that for an edge  $uv$  in RNG,  $d(u, v) \leq \max\{d(p, u), d(p, v)\}$  for all other vertices  $p$ . Squaring both sides of the inequality leads to  $d(u, v)^2 \leq \max\{d(p, u)^2, d(p, v)^2\}$ , which implies that the inequality also holds for their sum and thus  $d(u, v)^2 \leq d(p, u)^2 + d(p, v)^2$ . Therefore, edge  $uv$  is also in the GG.
18. It should be clear that whenever  $\alpha \leq \pi/2$  in the original definition of the augmented Gabriel graph (AGG), the angles formed by the remaining vertices are also less than or equal to  $\pi/2$ .

This means that they are less than or equal to  $\pi - \alpha$ , which, of course, is greater than or equal to  $\pi/2$ . When  $\alpha > \pi/2$ , the condition for the existence of edge  $uv$  is still that for all other vertices  $w$  in the graph,  $\angle u, w, v \leq \pi - \alpha$ .

19. When  $\alpha = \pi/2$ , vertices  $p, u$ , and  $v$  form a right triangle, and thus the vertex  $p$  responsible for  $\alpha$  has the property that  $d(u, p)^2 + d(v, p)^2 = d(u, v)^2$ . Using the fact that the vertices of the right triangle lie on a sphere of diameter  $d(u, v)$ , we have that for  $\alpha < \pi/2$ ,  $p$  lies outside the sphere and hence  $d(u, p)^2 + d(v, p)^2 \geq d(u, v)^2$ , which means that the edge  $uv$  is in the Gabriel graph. On the other hand, for  $\alpha > \pi/2$ ,  $p$  lies inside the sphere, and hence  $d(u, p)^2 + d(v, p)^2 < d(u, v)^2$ , and the edge  $uv$  is not in the Gabriel graph.
20. This definition is equivalent to stipulating that the disc whose boundary contains  $p, u$ , and  $v$  is empty, which is known as the disc property of the DT (see Section 2.2.1.4 of Chapter 2). It states that an edge  $uv$  exists in the DT if and only if there exists a disc with  $u$  and  $v$  on its boundary that does not contain any other vertex.
21. Consider the dataset with points  $u = (0, 2, 0)$ ,  $v = (0, -2, 0)$ ,  $a = (1, 0, 0)$ ,  $b = (-4, 0, 0)$ ,  $c = (0.9, 0, 0.5)$ , and  $d = (0.9, 0, -0.5)$ . Show that any sphere with  $u$  and  $v$  on its boundary contains at least one of  $a, b, c$ , or  $d$ . Hence, the DT does not contain edge  $uv$ . Also, show that the modification in Exercise 20 yields a graph with edge  $uv$  in it.
22. *Proof* From Exercise 19, we have that  $\text{GG}(E) \subset \text{AGG}(E)$  since every edge in the GG is in the AGG. However, the AGG may also contain other edges as well. Therefore,  $\text{MST}(E) \subset \text{RNG}(E) \subset \text{GG}(E) \subset \text{AGG}(E)$ . Showing that  $\text{AGG}(E) \subset \text{DT}(E)$  is a bit trickier. The proof is similar to that used in the solution to Exercise 4 in Section 2.2.1.4 of Chapter 2. There are two cases to consider depending on whether  $\alpha < \pi/2$  or  $\alpha \geq \pi/2$ .

(a)  $\alpha < \pi/2$ : We show that if edge  $uv$  is in the AGG, then it is also in the DT. From the definition of  $\alpha$ , we know that for all other vertices  $w$ ,  $\angle u, w, v \leq \alpha$ . In addition, as  $\alpha < \pi/2$ , we have  $\alpha < \pi/2 < \pi - \alpha$ , and therefore  $\angle u, w, v \leq \alpha < \pi/2 < \pi - \alpha$ . We have just shown that  $\angle u, w, v < \pi/2$ , which means that all vertices  $w$  are outside the minimum disc (sphere in higher dimensions) enclosing  $u$  and  $v$ . Therefore, by the disc property, we know that  $uv$  is in the DT.

(b)  $\alpha \geq \pi/2$ : We show that if edge  $uv$  is in the AGG, then it is also in the DT. As  $uv$  is in the AGG, from the definition of the AGG we know that, for all other vertices  $w$ ,  $\angle u, w, v \leq \pi - \alpha$ . Let  $D_{uvt}$  denote the disc passing through  $u, v$ , and an arbitrary point  $t$ . The line containing  $u$  and  $v$  divides the interior of disc  $D_{uvt}$  into two segments: segment  $S_t$  at the same side of  $t$  and segment  $O_t$  at the other side of point  $t$ . Now, consider the disc  $D_{uwp}$  passing through  $u, v$ , and  $p$ , remembering that  $\alpha = \angle upv$ . In this case, the line containing  $u$  and  $v$  divides the interior of  $D_{uwp}$  into two segments: segment  $S_p$  at the same side of  $p$  and segment  $O_p$  at the other side of point  $p$ .

We know that for all points  $t$  in  $S_p$ , the discs  $D_{uvt}$  formed by  $t, u$ , and  $v$  will have larger radii than the disc  $D_{uwp}$  formed by  $p, u$ , and  $v$  as the areas spanned by  $S_t$  are smaller than that spanned by  $S_p$ , which means that the angles  $\angle utv$  are larger than the angle  $\angle upv = \alpha$ . Therefore, by the definition of the AGG,  $S_p$  cannot contain any vertices as any of the angles that they form with  $u$  and  $v$  would be larger than  $\alpha$ , thereby contradicting the definition of the AGG.

Now, consider the case of points in  $O_p$ . Consider a point  $q$  on the disc  $D_{uwp}$  passing through  $u, v$ , and  $p$  such that  $q$  is not on the same side of  $uv$  as  $p$ . We know that  $\angle upv + \angle uqv = \pi$  since the sum of these two inscribed angles is one-half of the sum of the arcs that they subtend, which is  $2\pi$ . However,  $\angle upv = \alpha$ , and thus subtracting  $\alpha$  from both sides of the equality yields  $\angle uqv = \pi - \alpha$ .

We now use the same reasoning as in the case of points in  $S_p$ . In particular, we know that for all points  $t$  in  $O_p$ , the discs  $D_{uvt}$  formed by  $t, u$ , and  $v$  will have larger radii than the disc  $D_{uwp}$  formed by  $p, u$ , and  $v$  (equivalently,  $D_{uwp}$  where  $q$  has been replaced by  $p$ ) as the areas spanned by  $S_t$  are smaller than that spanned by  $O_p$ , which means that the angles  $\angle utv$  are larger than the angle  $\angle uqv = \pi - \alpha$ . Therefore, by the definition of the

AGG,  $O_p$  cannot contain any vertices as any of the angles that they form with  $u$  and  $v$  would be larger than  $\alpha$ , thereby contradicting the definition of the AGG. Thus, we have shown that the disc  $D_{uvp}$  does not contain any vertices, and hence by the disc property, we know that edge  $uv$  is in the DT.

Notice that the proof of case (b), as written, only applies to two dimensions. Nevertheless, it can be applied with a few more details in higher dimensions as well.

Therefore, since  $GG(E) \subset AGG(E)$  and  $AGG(E) \subset DT(E)$ , we have now shown that  $MST(E) \subset RNG(E) \subset GG(V) \subset AGG(E) \subset DT(E)$ . ■

From the proof we see that the AGG is more restricted than the DT as every edge in AGG is in the DT. We can also see this from the definition of the DT in terms of the statement of the definition of the AGG in Exercise 20. In particular, in the case of the AGG, the constraint on the angle formed by  $w$ ,  $u$ , and  $v$  must be satisfied regardless of the side of the line or hyperplane on which  $w$  lies. On the other hand, in the case of the DT, the constraint must be satisfied only on the side of the line or hyperplane opposite to that containing  $p$ . Thus, an edge may fail to be in the AGG while still being in the DT.

23. It is easy to generalize this property to other  $L_p$  metrics or dimensions. In particular, notice that the minimum disc containing edge  $uv$  is centered at  $w$  such that  $d(w, v) = d(w, u)$  and  $d(w, v)$  is the smallest distance among all points of the space that are equidistant from  $u$  and  $v$ . So, for any space for which such a  $w$  can be found, the GG can be defined as having an edge  $uv$  iff for all other vertices  $t$ ,  $d(w, t) \geq d(w, u)$ . Notice that this definition is equal to the one given in the text for any dimension when using the Euclidean distance.

25. (Houman Alborzi) Define  $\angle u, p, v$  as

$$\arccos((\text{dist}(u, p)^2 + \text{dist}(p, v)^2 - \text{dist}(u, v)^2) / (2 \cdot \text{dist}(u, p) \cdot \text{dist}(p, v))).$$

Basing the definition only on distance values, rather than in terms of an angle that breaks down in non-Euclidean metrics, ensures that the definition can be applied to any other metric. Observe that as distances are drawn from a metric space, we can show that the argument of  $\arccos()$  always lies between  $-1$  and  $1$ . Hence, the expression is always well defined. In particular, the expression results in the actual angle when the Euclidean metric is used. However, note that the definition does not guarantee that any of the properties of the AGG mentioned earlier will necessarily hold.

### Solutions to Exercises in Section 4.5.7.1

1. See [851].

### Solutions to Exercises in Section 4.5.7.2

1. See [851].

### Solutions to Exercises in Section 4.5.7.3

4. Let  $x = \min\{d_n, d_a\}$  denote the threshold value of  $d_{10}$ , which is used to decide which objects to move from  $S_q$  to  $S_a$ .  $d_n$  is monotonically nonincreasing as it starts at  $\infty$ .  $d_a$  is monotonically nondecreasing as it starts with the smallest value in  $S_a$  (except for being  $\infty$  when  $S_a$  is empty). Let  $o_i$  be an element of the alive set  $S_a$ . We want to show that  $|d(q, o_1) - x| \leq d(o_1, o_i) \leq x + d(q, o_1)$ .

$$\begin{aligned} |d(q, o_1) - d(o_1, o_i)| \leq x &\Rightarrow d(q, o_1) - d(o_1, o_i) \leq x \vee d(o_1, o_i) - d(q, o_1) \leq x \\ &\Rightarrow d(o_1, o_i) \geq d(q, o_1) - x \vee d(o_1, o_i) \leq d(q, o_1) + x \\ &\Rightarrow d(q, o_1) - x \leq d(o_1, o_i) \leq x + d(q, o_1). \end{aligned}$$

1. See [884].
2. At most  $p$  edges enter each object in the SASH, and there are  $N$  objects over the  $h = \log_2 N$  levels of the SASH.
3. See [884].
4. There are  $\log_2 N$  levels, and at each level  $i$ , we add  $k$  objects to set  $U_i$ , and the desired result follows. Note that the  $0.5pc$  term in the computation of  $k_i$  that is used to ensure that at least  $0.5pc$  objects are obtained at each level of the search is accounted for by the  $\log_2 N$  term in the execution time.
5. The execution time is proportional to the work expended in forming the sets  $U_i$  ( $1 \leq i \leq h$ ), which is proportional to the number of objects  $k_i$  found at level  $i$  as the SASH is descended:

$$\begin{aligned} & \sum_{i=1}^h k^{1-(h-i)/\log_2 N} \\ &= k^{1-h/\log_2 N} \sum_{i=1}^h (k^{1/\log_2 N})^i \leq k^{1-h/\log_2 N} \frac{k^{(h+1)/\log_2 N}}{k^{1/\log_2 N} - 1} \leq \frac{k^{1+1/\log_2 N}}{k^{1/\log_2 N} - 1} \end{aligned}$$

The closed form, if any of this sum, varies depending on the relative magnitudes of  $k$  and  $N$ . Note that the  $\log_2 N$  term arises from the  $0.5pc$  term in the computation of  $k_i$  that is used to ensure that at least  $0.5pc$  objects are obtained at each level of the search.

6. (Michael E. Houle) Substituting  $N^\epsilon$  for all but one factor of  $k$  in the expression

$$\frac{k^{1+\frac{1}{\log_2 N}}}{k^{\frac{1}{\log_2 N}} - 1}$$

yields

$$k \frac{N^{\epsilon \frac{1}{\log_2 N}}}{N^{\epsilon \frac{1}{\log_2 N}} - 1}$$

which is equal to  $ck$ , where  $c = \frac{2^\epsilon}{2^\epsilon - 1}$  is a constant, thereby leading to the desired result. We ignore that  $\log_2 N$  term as  $N^\epsilon$  dominates  $\log_2 N$ .

7. The minimum is  $b/c$ . It arises when as many as possible of the candidate objects at level  $i + 1$  can be reached from the same object at level  $i$ , which is  $c$  for each such object at level  $i$ . The result follows as there are  $b$  reachable objects at level  $i + 1$ . The maximum is  $bp$  and is easy to see as each of the  $b$  objects at level  $i + 1$  can have as many as  $p$  different approximate  $p$  nearest neighbors at level  $i$ .
8. The minimum is 0 as it could be that none of the reachable candidate objects at level  $i$  are among the  $p$  approximate nearest neighbors of the objects at level  $i + 1$ . The maximum is  $ac$  and arises when each of the  $a$  reachable candidate objects at level  $i$  is one of the  $p$  approximate nearest neighbors of as many different objects at level  $i + 1$  as possible, assuming a maximum of  $c$  objects at level  $i + 1$  for each of the  $a$  objects at level  $i$ . In other words, for each object in the reachable candidate objects at level  $i + 1$ , only one of its  $p$  approximate nearest neighbors at level  $i$  is in the set of reachable candidate objects at level  $i$ , and these approximate nearest neighbors are unique. Of course, there could be many more objects at level  $i + 1$  than the reachable candidate objects at level  $i + 1$ .
9.  $k_i/k_{i+1} = k^{1-(h-i)/\log_2 N} / k^{1-(h-(i+1))/\log_2 N} = k^{-1/\log_2 N} = 1/k^{1/\log_2 N}$ , which is equal to 1 for  $k = 1$ , monotonically decreasing as  $k$  increases, and equal to  $1/2$  when  $k = N$ .
10. Houle and Sakuma [884] suggest to apply a repeated doubling process in terms of the number of neighbors sought on subsequent iterations. Therefore, once the first  $p$  nearest objects are rejected, an attempt is made to connect to the  $2p, 4p, \dots, 2^i p$  nearest neighbors until a node with excess capacity is found.
11. The method proposed here immediately eliminates some candidates obtained early in the search process from further consideration when closer candidates have been found. In contrast,

once  $U_i$  has been computed for level  $i$  and we are processing level  $j$  ( $j > i$ ), the method of Houle and Sakuma [884] does not examine  $U_i$  again until it is ready to report the  $k$  approximate nearest neighbors.

12. (Michael E. Houle) The algorithm is similar to that used for determining the approximate  $k$  nearest neighbors except that there are no fixed upper bounds  $k_i$  on the number of objects retained at each SASH level during the descent. Let  $W_i$  denote the set of objects that are retained at level  $i$ .  $W_1$  is the root object.  $W_{i+1}$  is formed at level  $i$  by adding each object  $o$  at level  $i + 1$  that is adjacent to at least one object in  $W_i$ . Next, any objects in  $W_{i+1}$  that do not lie in the search range are removed from  $W_{i+1}$  unless doing so will reduce the number of remaining objects so that it is less than  $0.5pc$ , in which case we retain the closest  $0.5pc$  objects to  $q$  even if some of them lie outside the search range. The final range query result for  $q$  consists of the union of those objects retained over all SASH levels, minus those objects that lie outside the search range.
13. As the approximate  $k$  nearest neighbor algorithm for a SASH inherently finds a relatively large set of candidate neighbors before reducing it, one possible approach is to turn to this set for additional neighbors, although the fact that we only wanted  $k$  neighbors initially does influence the implementation of the approximate  $k$  nearest neighbor algorithm. Thus, there must be some way to reconsider some of the candidate nearest neighbors that were eliminated during the search for the approximate  $k$  nearest neighbors.
14. The advantage of SASH over EXSASH is that it takes  $O(N_i^2)$  time to build  $\text{EXSASH}_i$ , assuming  $N_i$  objects in  $\text{EXSASH}_i \setminus \text{EXSASH}_{i-1}$ , as, unlike in SASH, the existing edges in  $\text{EXSASH}_{i-1}$  are of no use to us in determining the edges from the objects in  $\text{EXSASH}_i \setminus \text{EXSASH}_{i-1}$  to the objects in  $\text{EXSASH}_{i+1} \setminus \text{EXSASH}_i$ . Of course, once the directed graph corresponding to  $\text{EXSASH}_h$  has been built,  $\text{EXSASH}_h$  is likely to yield more accurate results than  $\text{SASH}_h$  as the edges reflect exact nearest neighbors rather than likely nearest neighbors.
15. Given a query object  $q$ , an immediate problem is finding an object or objects at level  $h$  that are close to  $q$  to start the search. The index represented by the reverse kNN graph does not provide any information to help find these objects. Thus, this step will require search, which could take as much as  $O(N^2)$  time. Once these initial objects have been found, the search can proceed in the same way as in the kNN graph.

### Solutions to Exercises in Section 4.6.1.1

1. This is easy to see when we realize that the number of responses for the query in the original and dimension reduced spaces are not necessarily the same assuming that we use the same query radius value.

### Solutions to Exercises in Section 4.6.1.2

1. Letting  $R_n$  and  $R_k$  denote the set of responses retrieved in the original and dimension reduced spaces, respectively, remember that precision is equal to  $|R_n \cap R_k|/|R_k|$  and recall is equal to  $|R_n \cap R_k|/|R_n|$ . However,  $|R_k| = |R_n| = K$ , and the result holds. Therefore, using recall and precision to measure the quality of a query to find the  $i$ th nearest neighbor is somewhat meaningless as they do not reflect the fact that the sets  $R_k$  and  $R_n$  may differ, even though their cardinality is the same.
2. Given points  $a = (0, 0)$ ,  $b = (5, 2)$ , and  $c = (7, 1)$ , we have that  $d(a, b) = 5$  and  $d(a, c) = 7$ , while  $d'(f(a), f(b)) = 2$  and  $d'(f(a), f(c)) = 1$ .  $d(a, b) = 5 \leq d(a, c) = 7$ , but  $d'(f(a), f(b)) = 2 > d'(f(a), f(c)) = 1$  instead of the desired  $d'(f(a), f(b)) \leq d'(f(a), f(c))$ . Thus, the proximity-preserving property does not hold.
3. The proximity-preserving property does not hold as can be seen by using the same example as in the solution to Exercise 2.
4. The proximity-preserving property does not hold as can be seen by examining the points  $a = (0, 0)$ ,  $b = (1, 0)$ , and  $c = (.8, .8)$  and applying a rotation of 45 degrees counterclockwise.

- In this case, using the Chessboard distance, before the rotation we have that  $d(a, c) < d(a, b)$ , but after the rotation  $f$ , we have that  $d(f(a), f(c)) > d(f(a), f(b))$ .
5. The proximity-preserving property does not hold as can be seen by using the same example as in the solution to Exercise 4.
  6. Given a distance metric  $d$  in the original space, a distance metric  $d'$  in the transformed space, and a transformation  $f$ , then the proximity-preserving property stipulates that  $d(a, b) \leq d(a, c)$  implies  $d'(f(a), f(b)) \leq d'(f(a), f(c))$  for any objects  $a, b$ , and  $c$ . This property can be rewritten to be  $d(a, c) \geq d(a, b)$  implies  $d'(f(a), f(c)) \geq d'(f(a), f(b))$ . Interchanging  $b$  and  $c$  yields the desired relationship:  $d(a, b) \geq d(a, c)$  implies  $d'(f(a), f(b)) \geq d'(f(a), f(c))$ . Thus, when finding the farthest neighbors, whenever we have that  $d'(f(a), f(b)) < d'(f(a), f(c))$  implies  $d(a, b) < d(a, c)$ , we do not have to refine the candidate list.
  7. Consider a scaling transformation with the Euclidean distance metric. If the scaling factor is greater than 1, then the distance in the transformed space (which has been scaled upward) will be larger than the distance in the original space, and the pruning property is no longer meaningful as it is not satisfied. In particular, let  $c$  be the scaling factor, and let  $a = (x_a, y_a)$  and  $b = (x_b, y_b)$  be any two objects. Therefore,  $d'(f(a), f(b)) = \sqrt{(cx_a - cx_b)^2 + (cy_a - cy_b)^2} = \sqrt{c^2(x_a - x_b)^2 + c^2(y_a - y_b)^2} = c\sqrt{(x_a - x_b)^2 + (y_a - y_b)^2} = c \cdot d(a, b)$ . So, for any  $c$  larger than 1, we have  $d'(f(a), f(b)) > d(a, b)$ .
  8. By the contractiveness of  $f$  and the definition of  $\varepsilon$ , we know that  $d'(f(q), f(o)) \leq d(q, o) \leq \varepsilon$  for all  $o \in R''$ . Thus, since  $R'$  is the set of all  $o$  in  $S$  for which  $d'(f(q), f(o)) \leq \varepsilon$ , we have  $R'' \subset R'$ . Therefore, since  $R''$  contains  $k$  objects,  $R'$  contains at least  $k$  objects, and thus the  $k$  nearest neighbors of  $q$  must be in  $R'$ .
  9. The first is that  $\varepsilon$  may overestimate the distance of the  $k$ th nearest neighbor of  $q$  by a considerable margin [1716] so that  $R'$  may be significantly larger than necessary. Furthermore, the fact that two queries are issued to the multidimensional index that represents  $f(S)$  (i.e., the  $k$  nearest neighbor query yielding  $R''$  and the range query yielding  $R'$ ) means that some duplication of effort is inevitable.
  10. The algorithm of Seidl and Kriegel [1716] is a  $k$ -nearest neighbor algorithm, requiring the number of desired neighbors to be known in advance, while the general version of the incremental nearest neighbor algorithm is an overall incremental process. The two algorithms have almost identical performance characteristics. The algorithm of Seidl and Kriegel halts upon encountering mapped object  $f(o)$  such that  $d'(f(q), f(o)) \geq D_k$ , where  $D_k$  is the distance of the current candidate  $k$ th-nearest neighbor, as this implies that no other object exists with distance from  $q$  less than  $D_k$ . Thus, the algorithm performs the same number of object distance computations as the general version of the incremental nearest neighbor algorithm. However, the general version of the incremental nearest neighbor algorithm has a slight edge in that it sometimes accesses fewer multidimensional index nodes. To see this, suppose that Seidl and Kriegel's algorithm has just inserted an object into  $L$  that made it contain the actual  $k$  nearest neighbors—that is,  $D_k$  has reached its final value. If the next element obtained from the priority queue is a mapped object  $f(o)$ , then it will serve to establish the terminating condition, and Seidl and Kriegel's algorithm terminates without making any more node accesses than the general version of the incremental nearest neighbor algorithm. On the other hand, if the next element obtained from the priority queue is a multidimensional index node, then Seidl and Kriegel's algorithm will access that node, whereas the general version of the incremental nearest neighbor algorithm will not. However, since it's much more likely that the next element on the priority queue is a mapped object, Seidl and Kriegel's algorithm usually will not perform any more node accesses than the general version of the incremental nearest neighbor algorithm.

## Solutions to Exercises in Section 4.6.2

2. Consider the points  $(0,0)$  and  $(1,1)$ , whose Morton order difference is 3. The pruning property fails to hold for all of the Minkowski distance metrics  $L_p$  used for  $d$  since the Minkowski distance for these points is at most 2 (when  $p = 1$ ).

### Solutions to Exercises in Section 4.6.4.1

- (Isaac Weiss) Consider a point in two-dimensional space at location  $(a, b)$ . Let  $h = \sqrt{a^2 + b^2} = d_E((0, 0), (a, b))$  be the Euclidean distance of  $(a, b)$  from the origin  $(0, 0)$ . Letting  $\theta = \text{atan}(a/b)$ , the City Block distance  $d_A((0, 0), (a, b))$  of the point at location  $(a, b)$  from the origin can be written as a function of  $h$  and  $\theta$ —that is,  $d_A(h, \theta) = h(\sin(\theta) + \cos(\theta))$ . It is easy to see that this function attains a maximum at  $\theta = \pi/4$ , and thus the City Block distance can increase and decrease as the points are rotated. In particular, for a given point  $(a, b)$  and the corresponding values of  $h$  and  $\theta$ , the City Block distance value  $d_A(a, b)$  is maximized when the coordinate axes are rotated by  $\phi = \pi/4 - \theta$  degrees and minimized when the rotation is by  $-\theta$  degrees.
- Consider a point in two-dimensional space at location  $(a, b)$  and apply a rotation of  $\theta = \text{atan}(a/b)$  degrees to the coordinate axes. In this case, the original value of the Chessboard distance metric  $d_M$  is  $\max\{a, b\}$ , but once the rotation has been applied, the value of  $d_M$  for the rotated point is  $\sqrt{a^2 + b^2}$ , which is larger than  $\max\{a, b\}$ .

### Solutions to Exercises in Section 4.6.4.2

- The proof follows the one in [701]. Let  $M$  be the DFT matrix.  $M_{rs} = \exp(-j2\pi rs/n)/\sqrt{n}$ . Therefore, the elements of the product of  $M$  and its adjoint  $M^\dagger$  are given by

$$(M^\dagger \cdot M)_{rs} = \sum_{t=0}^{n-1} M_{rt}^\dagger M_{ts} = 1/n \sum_{t=0}^{n-1} \exp(-j2\pi t(r-s)/n)$$

The diagonal elements correspond to  $r = s$ .

$$(M^\dagger \cdot M)_{rr} = 1/n \sum_{t=0}^{n-1} \exp(0) = 1/n \sum_{t=0}^{n-1} 1 = 1$$

For the remaining terms, we note that we have a geometric sum with  $x = \exp(-j2\pi(r-s)/n)$  for which we know that

$$\frac{1-x^n}{1-x} = 1+x+x^2+\dots+x^{n-1}$$

Thus, we can rewrite  $(M^\dagger \cdot M)_{rs}$  as

$$\begin{aligned} & \frac{1}{n} \sum_{t=0}^{n-1} [\exp(-j2\pi(r-s)/n)]^t \\ &= \frac{1}{n} \frac{1 - \exp(-j2\pi(r-s))}{1 - \exp(-j2\pi(r-s)/n)} = \frac{1}{n} \frac{1 - \cos(2\pi(r-s)) - j \sin(2\pi(r-s))}{1 - \exp(-j2\pi(r-s)/n)} = 0 \end{aligned}$$

Therefore, we have shown that  $(M^\dagger \cdot M)_{rs} = \delta_{rs}$  as desired.

- Decompose  $X_f$  as follows:

$$\begin{aligned} X_f &= 1/\sqrt{n} \sum_{t=0}^{n-1} x_t \exp(-j2\pi ft/n) \\ &= 1/\sqrt{n} \sum_{t=0}^{n/2-1} x_{2t} \exp(-j2\pi f(2t)/n) + 1/\sqrt{n} \sum_{t=0}^{n/2-1} x_{2t+1} \exp(-j2\pi f(2t+1)/n) \\ &= 1/\sqrt{n} \sum_{t=0}^{n/2-1} x_{2t} \exp(-j2\pi f(2t)/n) + \exp(-j2\pi f/n)/\sqrt{n} \sum_{t=0}^{n/2-1} x_{2t+1} \exp(-j2\pi f(2t)/n) \\ &= 1/\sqrt{n} \sum_{t=0}^{n/2-1} x_{2t} \exp(-j2\pi ft/(n/2)) + \exp(-j2\pi f/n)/\sqrt{n} \sum_{t=0}^{n/2-1} x_{2t+1} \exp(-j2\pi ft/(n/2)) \\ &= X_f^{\text{even}} + \exp(-j2\pi f/n) X_f^{\text{odd}} \end{aligned}$$

Thus, instead of calculating one transform with  $n$  points, we now have two transforms, each having  $n/2$  points: one transform for the even-numbered points and one for the odd-numbered points. This requires  $O((n/2)^2) + O((n/2)^2) = O((n/2)^2)$  steps to calculate the transform, plus one final multiply and add operation to combine the results instead of the  $O(n^2)$  steps that would have been required had we not performed this decomposition. Next, we repeatedly apply the same splitting procedure to the even and odd transforms until we have obtained single-point transforms. At this stage, we reassemble them via  $\log_2 n$  multiplication and addition operations for a total of  $O(n \log_2 n)$  steps. This results in quite a savings in the execution time when  $n$  is relatively large. This method is known as the Fast Fourier Transform (FFT) [421].

3. See [588].
4. We need to show that the DFT is preserved under addition (equivalent to translation and rotation in Euclidean space) and multiplication by a scalar.<sup>3</sup> Preservation under addition and multiplication by a scalar are straightforward to show as  $\text{DFT}(x + y) = \text{DFT}(x) + \text{DFT}(y)$  and likewise for  $\text{DFT}(\alpha \cdot x) = \alpha \cdot \text{DFT}(x)$ .
5. Rotation results in changing the phase of the coefficients of the DFT and not the amplitude. In particular,  $\text{DFT}(x_{t+\Delta t}) = \text{DFT}(x_t) \cdot \exp(-j2\pi f \Delta t/n) = X_f \cdot \exp(-j2\pi f \Delta t/n)$ .

### Solutions to Exercises in Section 4.7.3.2

1. Assuming that we start with object  $o_1$  and that at iteration  $j$  we find that object  $o_{j+1}$  is the farthest from object  $o_j$  and at a distance  $d_j$ , then no object can be repeated in the sequence as this would result in a contradiction. Note that the sequence  $d_j$  is increasing. Assume that  $o$  is an object that occurs twice in the sequence (i.e.,  $o = o_i = o_k$ , where  $i < k$ ). Since the sequence  $d_j$  is increasing, we have that  $d_i < d_k$ . However, this contradicts the fact  $o_{i+1}$  was the farthest object from  $o$  as now we find that  $o_{k+1}$  is even farther from  $o$ , which is impossible. Thus, an object can occur only once in the sequence.
3. Given objects  $a$  and  $b$ , from the triangle inequality we have that  $d(a, b) \leq d(r, a) + d(r, b)$ . Since  $s$  is the farthest object from  $r$ ,  $d(r, a) \leq d(r, s)$  and  $d(r, b) \leq d(r, s)$ . Therefore,  $d(a, b) \leq d(r, a) + d(r, b) \leq d(r, s) + d(r, s) = 2d(r, s)$ . As pointed out in the text, this bound is guaranteed to hold only for the first pair of pivot objects since it is possible that the distance functions used to determine the second and subsequent coordinate values may not satisfy the triangle inequality (see Section 4.7.3.6).

### Solutions to Exercises in Section 4.7.3.3

1. First, we show that  $x_a \leq d(r, s)$ :

$$\begin{aligned} x_a &= \frac{d(r, a)^2 + d(r, s)^2 - d(s, a)^2}{2d(r, s)} \\ &\leq \frac{d(r, s)^2 + d(r, s)^2}{2d(r, s)} = d(r, s) \end{aligned}$$

since  $d(r, a) \leq d(r, s)$  and  $d(s, a) \geq 0$ . Second, we show that  $-x_a \leq d(r, s)$ :

---

<sup>3</sup> Note that the DFT is a general linear space, which is not necessarily a Euclidean space.

$$\begin{aligned}
 -x_a &= \frac{d(s,a)^2 - d(r,a)^2 - d(r,s)^2}{2d(r,s)} \\
 &\leq \frac{(d(r,a) + d(r,s))^2 - d(r,a)^2 - d(r,s)^2}{2d(r,s)} \\
 &\quad \text{by the triangle inequality (i.e., } d(s,a) \leq d(r,a) + d(r,s)\text{)} \\
 &= \frac{d(r,a)^2 + d(r,s)^2 + 2d(r,a)d(r,s) - d(r,a)^2 - d(r,s)^2}{2d(r,s)} \\
 &= \frac{2d(r,a)d(r,s)}{2d(r,s)} = d(r,a) \leq d(r,s)
 \end{aligned}$$

2. Let  $r$  and  $s$  be pivot objects chosen according to the heuristic in Section 4.7.3.2, and let  $d(t,u) = \alpha d(r,s)$ . We know that  $1 \leq \alpha \leq 2$  as  $d(r,s) \leq d(t,u) \leq 2d(r,s)$ . An upper bound on the value of  $x_a$  for any object  $a$  is easily derived given the upper bound of  $d(r,s)$  for  $d(r,a)$  and the lower bound of 0 on  $d(s,a)$ :

$$\begin{aligned}
 x_a &= \frac{d(r,a)^2 + d(r,s)^2 - d(s,a)^2}{2d(r,s)} \\
 &\leq \frac{2d(r,s)^2}{2d(r,s)} = d(r,s)
 \end{aligned}$$

To determine a lower bound on  $x_a$ , we appeal to the triangle inequality, which yields  $|d(r,s) - d(s,a)| \leq d(r,a)$ . Raising both sides to the second power yields

$$(d(r,s) - d(s,a))^2 = d(r,s)^2 + d(s,a)^2 - 2d(r,s)d(s,a) \leq d(r,a)^2$$

In other words, we have

$$d(r,a)^2 - d(s,a)^2 \geq d(r,s)^2 - 2d(r,s)d(s,a) \geq (1 - 2\alpha)d(r,s)^2$$

since  $d(s,a) \leq d(t,u) = \alpha d(r,s)$ . Substituting this lower bound into Equation 4.23 yields

$$\begin{aligned}
 x_a &= \frac{d(r,a)^2 + d(r,s)^2 - d(s,a)^2}{2d(r,s)} \\
 &\geq \frac{(2 - 2\alpha)d(r,s)^2}{2d(r,s)} = (1 - \alpha)d(r,s).
 \end{aligned}$$

Combining the upper and lower bounds on the value of  $x_a$  and the fact that  $\alpha \leq 2$  yields the desired bound,  $|x_a| \leq d(r,s)$ . Furthermore, for any  $\alpha \geq 1$  we can derive the maximum spread as

$$|x_a - x_b| \leq d(r,s) - (1 - \alpha)d(r,s) = \alpha d(r,s) = d(t,u)$$

Thus, the maximum spread is at most  $d(t,u)$  for any choice of pivots, as desired.

## Solutions to Exercises in Section 4.7.3.5

- Each pivot-finding iteration requires  $N - 1$  distance computations (as we do not need to compute the distance of the current object to itself). Thus, determining one pair of pivot objects requires  $P(N - 1)$  distance computations. Since we assume  $k$  iterations of FastMap, the total number of distance computations is  $kP(N - 1)$ . Note that this derivation assumes that all the distances computed in the pivot-finding phase can be stored and used later in the coordinate computation phase. If there are too many objects to store all the distances in memory, then more distances may have to be computed.
- The distance function used in the  $i$ th iteration is given in Equation 4.27. Once  $d_i(r,s)^2$  for two objects  $r$  and  $s$  becomes nonpositive (i.e., zero or negative), the projections of  $r$  and  $s$  cannot be used as a pivot pair in any subsequent iterations. In particular, if  $r$  and  $s$  are used as a pivot pair in iteration  $i - 1$ , then  $d_i(r,s) = 0$  and  $d_i(r,t) = d_i(s,t)$  for an arbitrary object  $t$ . This can be shown by plugging the appropriate values into Equations 4.26 and 4.27 (see Exercise 2 in Section 4.7.3.7). Thus,  $r$  and  $s$  become indistinguishable in subsequent iterations of FastMap

and are in effect merged for the purpose of pivot pair selection. This can be interpreted as removing one of the pivot objects, say  $r$ , thereby reducing the number of objects by one. With this interpretation, we have  $N - k$  objects left after  $k$  iterations. Since each of the  $k$  objects that were removed participated in a pivot pair and since at least one of the remaining objects has been used as a pivot, at least  $k + 1$  distinct objects have been used as pivot objects. An alternative way of seeing this is to observe that it takes a minimum of  $k + 1$  points to define a  $k$ -dimensional object. For example, two nonidentical points define a line, three noncollinear points define a plane, four noncoplanar points define a solid, and so on. The minimal object is termed a *simplicial complex* (e.g., [1326]). The simplicial complexes of dimension 1, 2, and 3 are lines, triangles, and tetrahedra, respectively.

4. See [587].

### Solutions to Exercises in Section 4.7.3.6

1. In the text, we show, that for a subset of a Euclidean vector space  $(S, d)$ , FastMap satisfies the pruning property if  $d'$  is the Euclidean distance metric (i.e.,  $L_2$ ). Let  $x = \{x_1, \dots, x_m\}$  and  $y = \{y_1, \dots, y_m\}$  be arbitrary points in  $S$ . The  $L_p$  distance between  $x$  and  $y$ ,  $d_p(x, y) = (\sum_{i=1}^m |x_i - y_i|^p)^{1/p}$ , can be shown to be nonincreasing as a function of  $p$ . Thus, if  $d_A$  is the  $L_1$  metric, then  $d_A(F(o_1), F(o_2)) \geq d_E(F(o_1), F(o_2))$ , so we may have  $d_A(F(o_1), F(o_2)) > d(o_1, o_2) \geq d_E(F(o_1), F(o_2))$ . Therefore,  $F$  is not guaranteed to satisfy the pruning property if  $d'$  is  $L_1$  (i.e.,  $p = 1$ ). This situation cannot arise if  $d'$  is some other Minkowski metric  $L_p$ , where  $p \geq 2$ , since  $d'(F(o_1), F(o_2)) \leq d_E(F(o_1), F(o_2)) \leq d(o_1, o_2)$  for such a  $d'$ .
2. The following proof is from [850]. We first show that  $d_i(r, s) = 0$ . From Equation 4.26, we have

$$x_r^{i-1} = \frac{d_{i-1}(r, r)^2 + d_{i-1}(r, s)^2 - d_{i-1}(r, s)^2}{2d_{i-1}(r, s)} = 0$$

and

$$x_s^{i-1} = \frac{d_{i-1}(r, s)^2 + d_{i-1}(r, s)^2 - d_{i-1}(s, s)^2}{2d_{i-1}(r, s)} = d_{i-1}(r, s)$$

Substituting into Equation 4.27 we have

$$d_i(r, s)^2 = d_{i-1}(r, s)^2 - (x_r^{i-1} - x_s^{i-1})^2 = d_{i-1}(r, s)^2 - d_{i-1}(r, s)^2 = 0$$

Now, let  $t$  be an arbitrary object. Using Equations 4.26 and 4.27, we can compute the values of  $d_i(r, t)^2$  and  $d_i(s, t)^2$ :

$$\begin{aligned} d_i(r, t)^2 &= d_{i-1}(r, t)^2 - |x_r^{i-1} - x_t^{i-1}|^2 = d_{i-1}(r, t)^2 - (x_t^{i-1})^2 \\ &= d_{i-1}(r, t)^2 - \left( \frac{d_{i-1}(r, t)^2 + d_{i-1}(r, s)^2 - d_{i-1}(s, t)^2}{2d_{i-1}(r, s)} \right)^2 \\ &= \frac{4d_{i-1}(r, s)^2 d_{i-1}(r, t)^2 - (d_{i-1}(r, t)^2 + d_{i-1}(r, s)^2 - d_{i-1}(s, t)^2)^2}{4d_{i-1}(r, s)^2} \\ &= \frac{1}{4d_{i-1}(r, s)^2} (4d_{i-1}(r, s)^2 d_{i-1}(r, t)^2 - d_{i-1}(r, s)^4 \\ &\quad - d_{i-1}(r, s)^2 (d_{i-1}(r, t)^2 - d_{i-1}(s, t)^2) - (d_{i-1}(r, t)^2 - d_{i-1}(s, t)^2)^2) \\ &= \frac{-d_{i-1}(r, s)^4 + 2d_{i-1}(r, s)^2 (d_{i-1}(r, t)^2 + d_{i-1}(s, t)^2) - (d_{i-1}(r, t)^2 - d_{i-1}(s, t)^2)^2}{4d_{i-1}(r, s)^2} \end{aligned}$$

and

$$\begin{aligned}
d_i(s,t)^2 &= d_{i-1}(s,t)^2 - |x_s^{i-1} - x_t^{i-1}|^2 = d_{i-1}(s,t)^2 - |d_{i-1}(r,s) - x_t^{i-1}|^2 \\
&= d_{i-1}(s,t)^2 - \left( \frac{d_{i-1}(s,t)^2 + d_{i-1}(r,s)^2 - d_{i-1}(r,t)^2}{2d_{i-1}(r,s)} \right)^2 \\
&= \frac{4d_{i-1}(r,s)^2 d_{i-1}(s,t)^2 - (d_{i-1}(s,t)^2 + d_{i-1}(r,s)^2 - d_{i-1}(r,t)^2)^2}{4d_{i-1}(r,s)^2} \\
&= \frac{1}{4d_{i-1}(r,s)^2} (4d_{i-1}(r,s)^2 d_{i-1}(s,t)^2 - d_{i-1}(r,s)^4 \\
&\quad - d_{i-1}(r,s)^2 (d_{i-1}(s,t)^2 - d_{i-1}(r,t)^2) - (d_{i-1}(s,t)^2 - d_{i-1}(r,t)^2)^2) \\
&= \frac{-d_{i-1}(r,s)^4 + 2d_{i-1}(r,s)^2 (d_{i-1}(s,t)^2 + d_{i-1}(r,t)^2) - (d_{i-1}(s,t)^2 - d_{i-1}(r,t)^2)^2}{4d_{i-1}(r,s)^2}
\end{aligned}$$

It should be clear that the final formulas for  $d_i(r,t)^2$  and  $d_i(s,t)^2$  are the same, even if the triangle inequality is not satisfied.

3. Since  $d_i(r,s) = 0$ , we have  $d(r,s) = d_E(F_{i-1}(r), F_{i-1}(s))$ , where the notation  $F_{i-1}(v)$  denotes the  $(i-1)$ -dimensional partial vector for  $v$  determined in the first  $i-1$  iterations. Furthermore, since  $d_i(r,t) = d_i(s,t)$  for all objects  $t$ , coordinate values  $i$  through  $k$  will be the same for  $r$  and  $s$ . Thus,  $d(r,s) = d_E(F(r), F(s))$ , and since  $d'$  is the Euclidean distance metric  $d_E$ , we have  $d(r,s) = d'(F(r), F(s))$  as desired.

### Solutions to Exercises in Section 4.7.3.7

1. The following proof is from [850]. Using Equation 4.23 with pivot objects  $r$  and  $s$ , we can derive an upper bound on the expansion, with the help of the triangle inequality and the upper bound  $d(r,s)$  on  $d(r,a)$  and  $d(r,b)$ :

$$\begin{aligned}
\frac{|x_a - x_b|}{d(a,b)} &= \left| \frac{d(r,a)^2 - d(s,a)^2 - d(r,b)^2 + d(s,b)^2}{2d(r,s)d(a,b)} \right| \\
&= \left| \frac{(d(r,a) - d(r,b))(d(r,a) + d(r,b)) + (d(s,b) - d(s,a))(d(s,b) + d(s,a))}{2d(r,s)d(a,b)} \right| \\
&\leq \frac{|d(r,a) - d(r,b)|(d(r,a) + d(r,b)) + |d(s,b) - d(s,a)|(d(s,b) + d(s,a))}{2d(r,s)d(a,b)} \\
&\leq \frac{d(a,b)(d(r,a) + d(r,b)) + d(a,b)(d(s,b) + d(s,a))}{2d(r,s)d(a,b)} \\
&= \frac{d(r,a) + d(r,b) + d(s,b) + d(s,a)}{2d(r,s)} \\
&\leq \frac{d(r,a) + d(r,b) + d(r,s) + d(r,b) + d(r,a) + d(r,s)}{2d(r,s)} \leq \frac{6d(r,s)}{2d(r,s)} = 3.
\end{aligned}$$

We now show that this bound is tight. Consider the following assignment of the distances among the objects  $a$ ,  $b$ ,  $r$ , and  $s$ , where  $d(r,s)$  is left as a variable:

$$\begin{aligned}
d(r,a) &= d(r,s) & d(s,a) &= (2 - 2\alpha)d(r,s) \\
d(r,b) &= (1 - \alpha)d(r,s) & d(s,b) &= (2 - \alpha)d(r,s) \\
d(a,b) &= \alpha d(r,s)
\end{aligned}$$

The resulting distances clearly satisfy the triangle inequality for  $0 < \alpha < 1$ . Using these distance values leads to the following value of  $|x_a - x_b|$ :

$$\begin{aligned}
 |x_a - x_b| &= \left| \frac{d(r,s)^2 - (2-2\alpha)^2 d(r,s)^2 - (1-\alpha)^2 d(r,s)^2 + (2-\alpha)d(r,s)^2}{2d(r,s)} \right| \\
 &= \left| \frac{1}{2} (1-4-4\alpha^2+8\alpha-1-\alpha^2+2\alpha+4+\alpha^2-4\alpha)d(r,s) \right| \\
 &= \left| \frac{1}{2} (-4\alpha^2+6\alpha)d(r,s) \right| = d(r,s)(3\alpha-2\alpha^2)
 \end{aligned}$$

Thus, dividing by  $d(a,b) = \alpha d(r,s)$  gives the expansion on  $d(a,b)$ , namely,  $3 - 2\alpha$ . Clearly, as  $\alpha$  approaches 0, the expansion approaches 3.

2. The following proof is from [850]. We derive an upper bound for

$$\frac{|x_a^2 - x_b^2|}{d(a,b)}$$

using the definitions from Section 4.7.3.5. Notice that the formula for  $|x_a^2 - x_b^2|$  is symmetric in  $a$  and  $b$ , so we can use it without the absolute value operator. In the derivation, we make use of the lower bound  $d(r,s)/\beta$  and the upper bound  $2d(r,s)$  on any distance values. Furthermore, we use the bound obtained in Exercise 1. In particular, for any objects  $u$  and  $v$ , we obtain

$$d_2(u,v)^2 = d(u,v)^2 - |x_u - x_v|^2 \geq d(u,v)^2 - (3d(u,v))^2 = -8d(u,v)^2$$

Thus, applying Equation 4.26 with  $i = 2$ , the lower bound  $-8d(u,v)^2$  on  $d_2(u,v)^2$  derived above, the upper bound  $d(u,v)^2$  on  $d_2(u,v)^2$  derived above, and the bounds on the original distances, we obtain

$$\begin{aligned}
 \frac{x_a^2 - x_b^2}{d(a,b)} &= \frac{d_2(p_1^2, a)^2 - d_2(p_2^2, a)^2 - d_2(p_1^2, b)^2 + d_2(p_2^2, b)^2}{2d_2(p_1^2, p_2^2)d(a,b)} \\
 &\leq \frac{d(p_1^2, a)^2 - (-8d(p_2^2, a)^2) - (-8d(p_1^2, b)^2) + d(p_2^2, b)^2}{2(d(r,s)/\beta)(d(r,s)/\beta)} \\
 &\leq \frac{4d(r,s)^2 + 8 \cdot 4d(r,s)^2 + 8 \cdot 4d(r,s)^2 + 4d(r,s)^2}{2d(r,s)^2/\beta^2} \\
 &= \frac{18 \cdot 4d(r,s)^2}{2d(r,s)^2/\beta^2} = \frac{72}{2/\beta^2} = 36\beta^2
 \end{aligned}$$

This upper bound is not tight as the triangle inequality on the original distances and the pivot criteria for  $p_1^2$  and  $p_2^2$  prevent all the upper bounds used in the derivation from being realized simultaneously. It is difficult to derive a tighter bound that takes into account all of these criteria. Nevertheless, an attempt was made in [850] to construct an example exhibiting large expansion, through the use of a nonlinear optimization tool. The objective function describing the expansion involved 14 variables and the number of constraints (incorporating all the relevant criteria) was about 80. Due to this relatively large number, the optimizer frequently got stuck at local maxima rather than finding the true maximum. However, it was clear that the maximum expansion is at least proportional to  $\beta$ . For example, for  $\beta = 5$  (which meant that the largest distance value was never more than 10 times larger than the smallest one), the optimizer was able to discover a legal assignment of distance values that yielded an expansion of about 30. For  $\beta = 50$ , it yielded an expansion of about 300, and for  $\beta = 100$ , it yielded an expansion of about 600.

## Solutions to Exercises in Section 4.7.4

3. No. Remember that once we have mapped the objects into the Hamming space with hashing function  $h_1$ , the hashing function  $h_2$  chooses  $m$  bitstring positions at random. Therefore, the ordering of the 1s and 0s that form the bitstring is irrelevant and thus using bit interleaving makes no difference, which is why the simpler method of bit concatenation is used in  $h_1$ .
4. You will probably need to appeal to the result of Frankl and Maehara [631] that improves upon the Johnson-Lindenstrauss Lemma [962] in much the same way as done by Indyk and Motwani [924], Kleinberg [1032], and Kushilevitz, Ostrovsky, and Rabani [1097].

Solutions to Exercises in Appendix A

2. Use the same proof technique used to show that there are  $N + 1$  external nodes in an extended binary tree with  $N$  internal nodes. In particular, there is one leaf node for each key value in a node at the next to the bottom level (i.e., the one containing the leaf nodes), plus one for each predecessor node. Applying this reasoning recursively as we ascend the B-tree, we find that the root node has one fewer key value than its successors, where each successor corresponds to a leaf node. Thus, the total number of leaf nodes is one greater than the number of key values. In other words, given  $N$  key values, there are  $N + 1$  leaf nodes.
3. Let  $c$  be the father node of  $a$  and  $b$ . Promote the minimum value,  $d$ , in  $a$  to  $c$ , and demote to  $b$  the key value,  $e$ , in  $c$  with the largest value that is less than  $d$ .
4.  $m - 2$  if  $m$  is odd, and  $m - 3$  if  $m$  is even.
5. From Exercise 2 we know that given  $N$  key values, there are  $N + 1$  leaf nodes at depth  $i$ . The search length is maximized when each B-tree node has  $\lceil m/2 \rceil$  key values. In this case, the number of nodes at depth 0, 1, 2, 3, ...,  $i$  is at least 1, 2,  $2\lceil m/2 \rceil$ ,  $2(\lceil m/2 \rceil)^2$ , ...,  $2(\lceil m/2 \rceil)^{i-1}$ . The number of leaf nodes at depth  $i$  is  $2(\lceil m/2 \rceil)^{i-1}$ . Solving for  $i$ , we have  $i \leq 1 + \log_{\lceil m/2 \rceil}((N + 1)/2)$ .
6. 3.
7. Let  $r$  be the number of node splits. Let  $q$  be the number of nodes in the B-tree whose splitting creates one new node. This is the situation whenever the node that splits is not a root node. When the  $i - 1$  root nodes split, we have  $2(i - 1)$  new nodes. Therefore, we have  $r = q + i - 1$  node splits, yielding  $p = 1 + q + 2(i - 1)$  nodes, and thus  $r = p - i$ .
8. If there are  $p$  nodes in the B-tree, then there are at least  $1 + (\lceil m/2 \rceil - 1) \cdot (p - 1)$  key values since the root has at least one key value, and all remaining nodes have at least  $\lceil m/2 \rceil - 1$  key values. Therefore,  $N \geq 1 + (\lceil m/2 \rceil - 1) \cdot (p - 1)$  or  $p \leq 1 + (N - 1)/(\lceil m/2 \rceil - 1)$ . From Exercise 7 we know that the number of node splits can be approximated by the number of nodes, and thus the average number of times that a node is split is less than  $1/(\lceil m/2 \rceil - 1)$  per insertion of a record, assuming at least one node split.
9. Assume that each node is on a page. Nonleaf nodes are at levels 0 through  $d$ . Searching retrieves at most  $d + 1$  pages (one per node) as we only know that the key value is not present when we reach a leaf node at depth  $d + 1$  that is empty and does not involve a disk access. Insertion retrieves  $d + 1$  disk pages (one per node) while searching for the key value and the node  $p$  in which it is to be inserted. Once  $p$  has been found, nodes may be split, and up to  $d + 2$  new nodes can be created as a result of splitting. In this case,  $2d + 3$  nodes will have to be written, which means  $2d + 3$  disk accesses. Deletion retrieves  $d + 1$  pages (one per node) while searching for the key value and the node  $p$  at depth  $d$  that contains its replacement key value. Once  $p$  has been found, nodes may be merged. Each merge involves the retrieval of an adjacent brother node, and the merged node must be written. A maximum of  $d$  merges can take place and  $d$  new nodes created, which means  $d$  disk accesses for the retrieval and  $d$  disk accesses for writing. If fewer than  $d$  merges occur, then a merge may be followed by a split.
12. The root node has at least two child nodes. There are at least two nodes at depth 1, and at the remaining depths 2 through  $j$ , there are at least  $2a^{i-1}$  nodes at depth  $i$ . Summing up yields  $1 + 2\sum_{i=1}^j a^{i-1}$ , which is  $1 + 2 \cdot (a^j - 1)/(a - 1)$  nodes. All but one of these nodes have  $a - 1$  key values, and thus the total is  $2a^j - 1$  key values.
13. This can be seen by observing that all leaf nodes in the red-black balanced binary tree correspond to nodes at the bottom level of the 2-3 or 2-3-4 tree. This means that the number of black edges from the root of the tree to the leaf nodes is the same for each leaf node. The red edges correspond to the case where the source node in the red-black tree is black, while the destination node is red. Thus, there is a one-to-one correspondence between the black edges and the black nodes on the path from the root to each leaf node, and our result follows.
14. The number of black edges on any path from the root of the tree to a leaf node is always the same. For every black edge there is at most one incoming red edge. Thus, the path from the root of the tree to any leaf node is at most twice the maximum depth of the original tree.
15. The case that the father edge  $f$  is black with two children that are red edges is now a valid node (i.e., it does not correspond to an overflow as in the 2-3 tree), and thus once we determine

- that  $f$  is black, we can exit. Another change is when edge  $d$  is red, the father edge  $f$  of  $d$  is red, and the brother edge  $e$  of  $f$  is red. In this case, change the colors of both edges  $e$  and  $f$  to be black, change the color of the father  $g$  of  $f$  to be red, and reapply steps 1 and 2 to  $g$ . Notice that before this step, edge  $g$  had to be black as two consecutive red edges are not permitted. Finally, if edge  $d$  is red, the father edge  $f$  of  $d$  is red, and the brother edge  $e$  of  $f$  is black, then apply a single or double rotation to edges  $d$  and  $f$ , keeping the results red, and exit.
18. Descend the tree while doing the search. Whenever you encounter a node  $s$  with four children, no father, and key values  $a$ ,  $b$ , and  $c$ , then split  $s$  as follows. Create a new node containing  $b$ , the median key value, and two children consisting of two new nodes  $s_1$  and  $s_2$  containing keys  $a$  and  $c$ , respectively, and attach the leftmost two children of  $s$  to  $s_1$  and the rightmost two children of  $s$  to  $s_2$ . Whenever you encounter a node  $s$  with four children whose father  $f$  has exactly one more child  $x$ , then split  $s$  into nodes  $s_1$  and  $s_2$  with two children each, and transform  $f$  into a node with three children consisting of  $x$ ,  $s_1$ , and  $s_2$ . Similarly, if the father node  $f$  has three children (i.e.,  $x$ ,  $y$ , and  $s$ ), then apply the same transformation except that now  $f$  is transformed into a node with four children consisting of  $x$ ,  $y$ ,  $s_1$ , and  $s_2$ .
  19. The algorithm cannot work because a node  $s$  with three children whose father  $f$  has two children cannot be split into a node containing one child and two children since a node with one child is not permitted in a 2-3 tree.
  20. The top-down algorithm will work as long as  $m$  is even. The rule is that we descend the tree and whenever we encounter a node  $s$  with  $m$  children whose father  $f$  has  $i$  children, then we split  $s$  into nodes  $s_1$  and  $s_2$  with  $m/2$  children each, transform  $f$  into a node with  $i + 1$  children, and promote the median key value in  $s$  to  $f$ . Also, whenever the algorithm encounters a node  $s$  with  $m$  children and no father, then a new node is created with the median key value in  $s$  and two children each containing  $m/2$  children. The algorithm will not work if  $m$  is odd as now  $\lceil m/2 \rceil$  is also odd and is equal to  $(m + 1)/2$ . The problem is that when we split a node containing  $m$  children and promote a key value, we create one node with  $\lceil m/2 \rceil$  children and one node with  $\lfloor m/2 \rfloor$  children. The second node is not a valid node in a B-tree of order  $m$  when  $m$  is odd. Thus, the algorithm will not work in this case.
  21. There is only a need to prevent access to the node being currently searched and its father. Once a split has taken place, subsequent searches and insertions can proceed as the resulting nodes can accommodate the additional child. Remember that if the parent  $f$  of the current node  $s$  could not have accommodated the extra child, then  $f$  would have been split before  $s$ .
  22. Note that satisfying the properties of a B-tree will require extensive examination of the red-black balanced binary tree to determine the appropriate sequence of red and black edges corresponding to a node split or merge in a B-tree (i.e., satisfying the constraints on the minimum and maximum number of children in a B-tree node).
  23. In a B<sup>+</sup>-tree, the search is successful only if we find the key value in a leaf node. The presence of the desired key value in a nonleaf node of the B<sup>+</sup>-tree does not mean that the corresponding record must be present, whereas this is true for a B-tree.
  24. In a B<sup>+</sup>-tree, the search for the key value to be deleted is only successful if it is found in a leaf node. If the search is successful, then the key value is deleted, and if the node meets the requirements of the B<sup>+</sup>-tree definition, then nothing more needs to be done. Note that the deleted key value is not removed from the nonleaf nodes. In the B-tree, once the key value is found, we must replace it by the closest key value that appears in the next to the bottom level of the tree and then check if the resulting node meets the requirements of the B-tree definition.

## Solutions to Exercises in Appendix B

1. Either one of  $h_n$  or  $h_{n+1}$  can be used first. The difference is in the mechanics of the lookup operation. Let  $2^n \leq m \leq 2^{n+1} - 1$ . Ignore the case where  $m = 2^n$  because, in this case, only  $h_n$  is applicable. We apply  $h_{n+1}$  first. Let  $h_{n+1}(k) = x$ . If  $x < m$ , then we have found the location; otherwise,  $x \geq m$ , and we apply  $h_n(k)$ . Suppose that we apply  $h_n$  first. Let  $h_n(k) = x$ . If  $x \geq m - 2^n$ , then we have found the location; otherwise,  $x < m - 2^n$ , and we apply  $h_{n+1}(k)$ . Suppose that  $x < m - 2^n$ , and that  $h_{n+1}(k) = 2^n + x$ . If we had not applied  $h_{n+1}$  in this case,

and, instead, stored  $k$  in bucket  $x$ , then we would have had a problem in the future. To see this, we observe that since we are now at level  $n, n + 1$ , the next time that bucket  $x$  is split, we will be at level  $n + 1, n + 2$ . This means that the records in bucket  $x$  will be rehashed using  $h_{n+2}$  and distributed into buckets  $x$  and  $2^{n+1} + x$ . However, at this time, if we want to look up the record with key value  $k$  with which we have been dealing, we will have to use hash function  $h_{n+1}$ , which will hash to bucket  $2^n + x$ , and  $k$  will not be there.

2. There are two possibilities depending on whether  $s$ , the next bucket to be split, is nonzero. If  $s$  is nonzero, then bucket  $2^n + s - 1$  is merged into bucket  $s - 1$ ,  $s$  is reset to  $s - 1$ , and bucket  $2^n + s - 1$  is no longer used. If  $s$  is zero, then bucket  $2^n - 1$  is merged into bucket  $2^{n-1} - 1$ ,  $s$  is reset to  $2^{n-1} - 1$ , bucket  $2^n - 1$  is no longer used, and  $n$  is reset to  $n - 1$ .
6.  $s(\tau) = 1 + \tau/2$ , and  $u(\tau) = \tau$  (see [1046, p. 525]).
7. Calculate the expected number of records as a function of  $x$  and  $z$  and also as a function of  $x$  and  $\alpha$ , and then solve for  $z$ . Therefore,  $2 \cdot x \cdot (z/2) + (1 - x) \cdot z = \alpha \cdot (2 \cdot x + 1 - x)$ .
8. The probability of encountering a split group is  $x$  with an expected search length of  $s(\alpha \cdot (1 + x)/2)$ . On the other hand, for an unsplit group, it is  $1 - x$  with an expected search length of  $s(\alpha \cdot (1 + x))$ . Therefore,  $S(\alpha, x) = x \cdot s(\alpha \cdot (1 + x)/2) + (1 - x) \cdot s(\alpha \cdot (1 + x))$ , which reduces to  $1 + \alpha \cdot (2 + x - x^2)/4$ .
9.  $U(\alpha, x) = x \cdot u(\alpha \cdot (1 + x)/2) + (1 - x) \cdot u(\alpha \cdot (1 + x))$ , which reduces to  $\alpha \cdot (2 + x - x^2)/2$ .
10. They arise when the expected number of records in all of the buckets is the same—that is, when  $x = 0$  or  $x = 1$ .  $S(\alpha, 0) = 1 + \alpha/2$  and  $U(\alpha, 0) = \alpha$ .
11. When  $x = \frac{1}{2}$ ,  $S(\alpha, \frac{1}{2}) = 1 + (\alpha/2) \cdot (\frac{9}{8})$ , and  $U(\alpha, \frac{1}{2}) = (\alpha/2) \cdot (\frac{9}{8})$ .
12.  $\bar{S}(\alpha) = \int_0^1 S(\alpha, x) dx = 1 + (\alpha/2) \cdot \frac{13}{12}$ , and  $\bar{U}(\alpha) = \int_0^1 U(\alpha, x) dx = (\alpha/2) \cdot \frac{13}{12}$ .
13.  $A(\alpha, x) = \alpha \cdot (1 + x)/\alpha = 1 + x$ , and  $\bar{A}(\alpha, x) = \int_0^1 A(\alpha, x) dx = \frac{3}{2}$ .
15. See [1530].
16. See [1530].
17. See [1530].
18. This should be apparent by noting that the overflow files are accessed with the same hashing function, albeit at a lower level. Thus, a bucket in the overflow file corresponds to “brother” primary buckets.

## Solutions to Exercises in Appendix C

1. Use induction on  $s$ .
5. The last  $r$  buckets should be merged and their contents stored in bucket  $s - 1$ .
6.  $a$  is already an integer, and thus they are equivalent.
7. Mullin [1324] gives the following procedure:
 

```

1  recursive integer procedure PHYSICAL( $L, R, Origin$ )
2  /* Given a spiral hashing implementation with a growth factor  $R$  and a
3   physical bucket addressing system starting at  $Origin$ , return the
4   physical bucket address corresponding to logical bucket address  $L$ . */
5  value integer  $L, R, Origin$ 
6  integer  $Low, High$ 
7  if  $L < R$  then return  $L$ 
8  endif
9   $High \leftarrow (L + 1) \div R$ 
10  $Low \leftarrow L \div R$ 
11 return(if  $Low < High$  then PHYSICAL( $Low, R, Origin$ )
12         /* This is a reused address */
13         else  $L - Low + Origin$ 
14         endif)

```

8.  $\log_r t$ .
10. Larson [1106] suggests the use of a table of segments. Each segment contains a fixed number of buckets. As segments become full, new ones are allocated. Once all of the buckets in a particular segment have been split, then the segment can be reused. Of course, this requires a directory whose size is fixed.
13.  $c = (2 - \sqrt{2}) / (3 - 2\sqrt{2}) \approx 3.414$ ,  $b = c \cdot (c - 1) \approx 8.243$ , and  $a = 2 - c \approx 1.414$ .
14. Yes. A bucket split will now result in  $r - 1$ ,  $r$ , or  $r + 1$  new buckets, whereas previously  $r$  new buckets were always created.
15. A second-degree polynomial can be written as  $(a \cdot x + b) \cdot x + c$ , which requires four floating-point operations, whereas  $a + b/(c - x)$  only requires three.
16.  $p(y) = \log_2(y + dy) - \log_2 y = \log_2(1 + dy/y) \approx dy/(y \cdot \ln 2)$ . This makes use of the fact that  $\log_2 x = \ln x / \ln 2$  and  $\ln(1 + x) \approx x$  for small  $x$ .
17. From the assumption about the expected value, there exists a constant  $c_1$  such that  $\tau(y) = c_1/(y \cdot \ln 2)$ . The average storage utilization factor (i.e., overall value) is  $\alpha$ , and solving the equation  $\int_1^2 (c_1/(y \cdot \ln 2)) \cdot dy = \alpha$  yields  $c_1 = \alpha$ .
18. From the assumption that there exists a pair of constants  $c_2$  and  $c_3$  such that  $q(y) = c_2 \cdot \tau(y) = c_2 \cdot \alpha/(y \cdot \ln 2) = c_3/y$ . The value of  $c_3$  is obtained by noting that the probability of landing on a bucket address in  $[y, y + dy]$  is  $q(y) \cdot dy$ , and the probability of landing on some bucket in  $[1, 2]$  is 1. Solving the equation  $\int_1^2 (c_3/y) \cdot dy = 1$  yields  $c_3 = 1/\ln 2$ .
19. From Exercise 6 in Appendix B, the expected number of key value comparisons for a successful search for a bucket at address  $y$  with a storage utilization factor of  $\tau(y)$  is  $1 + \tau(y)/2$ . The expected cost of a successful search is then  $\int_1^2 (1 + \tau(y)/2) \cdot q(y) \cdot dy = 1 + \alpha/(4 \cdot (\ln 2)^2) = 1 + (\alpha/2) \cdot 1.041$ .
20. From Exercise 6 in Appendix B, the expected number of key value comparisons for an unsuccessful search for a bucket at address  $y$  with a storage utilization factor of  $\tau(y)$  is  $\tau(y)$ . The expected cost of a successful search is then  $\int_1^2 \tau(y) \cdot q(y) \cdot dy = \alpha/(2 \cdot (\ln 2)^2) = \alpha \cdot 1.041$ .
21. This situation arises with a probability of  $1/\alpha$ —that is, for every  $1/\alpha$  of the record insertions. The expected number of records in the first bucket is  $\tau(1) = \alpha/\ln 2$ , and thus the expected number of extra hashing operations is  $\tau(1)/\alpha = 1/\ln 2 = 1.443$ .
22. Instances of  $\ln 2$  are replaced by  $\ln r$ .
23. See [384].
24. Using Cartesian coordinates, the arc length for the function  $y = f(x)$  is  $\int \sqrt{1 + (f'(x))^2} dx$ .  $f'(x)$  can be rewritten as  $dy/dx$ . Making the substitutions  $x = \rho \cos \theta$ ,  $y = \rho \sin \theta$ , and  $\rho = e^{j\theta}$  leads to the integral  $\sqrt{1 + f^2} \cdot \int e^{j\theta} \cdot d\theta$ . The value of this integral is  $(\sqrt{1 + j^2/j}) \cdot e^{j\theta}$ , which is  $\rho \cdot \sqrt{1 + j^2} < /f$ .

---

Each reference is followed by one or more keywords. It is also followed by a list of the sections in which it is referenced. The format is “F”, “D”, or “A”, followed by the section number. “F” corresponds to this book, “D” corresponds to 1637, and “A” corresponds to 1636. “F.P”, “D.P”, and “A.P” denote the appropriate preface. “D.L” and “A.L” denote the corresponding appendices describing the pseudo-code language. The four appendices in this book are referenced by their corresponding one-letter label. “A” denotes the appendix describing the B-tree; “B” denotes the appendix describing linear hashing; “C” denotes the appendix describing spiral hashing; and “D” denotes the appendix describing the pseudo-code language. All references that are cited in the solutions to the exercises are associated with the section in which the exercise is found and are distinguished from the actual section that contains the exercise by the suffix “s”. The indexes in this book are referenced by the following two-letter labels. “X.K” denotes the Reference Keyword Index. “X.A” denotes the Author and Credit Index. “X.S” denotes the Subject Index. In the case of this book, additional details are available by providing the page numbers within parentheses following the section number.

# Reference Keyword Index

---

Each keyword is followed by a set of numbers corresponding to the references in the bibliography with which it is associated. The result is an inverted file [1046] (see Section 1.1 in Chapter 1). The categories “general,” “high-dimensional data,” “lines,” “points,” “rectangles,” “regions,” “surfaces,” and “volumes” have been omitted since they have too many entries to be useful.

- 1-2 brother tree [1430]
- 2-3 tree [874, 2046]
  
- A-tree [1607]
- AdaBoost [105–108, 648, 1682]
- adaptive k-d tree [650]
- adaptively sampled distance fields (ADF) [654–655, 707, 1482]
- AESA [1535, 1929–1930]
- aggregate nearest neighbor [1463]
- aggregation query [351, 1203, 1560, 1853, 2055]
- ALGOL [1346]
- ALGOL W [137]
- algorithms [27, 422, 1043–1046, 1705]
- all nearest neighbors query [134, 226, 297, 396, 605, 1908, 2030, 2066]
- American Sign Language (ASL) images [1796]
- antialiasing [42, 1149]
- APL [928]
- approximate nearest neighbor [97–100, 202, 207, 265, 346, 387, 400, 450, 517, 608, 700, 709, 799, 882–884, 921–924, 995, 1032, 1097, 1158, 1226, 1229–1230, 1286, 1319, 1507, 1523, 1604, 1737, 1971, 1989, 2064]
- approximate Voronoi diagram (AVD) [97–98, 799]
- arc tree [776, 780]
- arrangements [543]
- array representation [477]
- artificial intelligence [1594]
- ATree [222]
- AVL tree [15]
  
- B\*-tree [414]
- B<sup>+</sup>-tree [2, 414]
- B-tree [57, 59, 143–144, 414, 746, 817, 874, 1091, 1151, 1165]
  
- balanced binary search tree [69, 766, 874, 1858, 1912–1913]
- balltree [1399–1400]
- BANG file [640–641, 645–646, 1438]
- BAR tree [490, 516–517]
- BBD-tree [100, 207, 1319]
- BD-tree [440–443, 1091, 1386–1388, 1605]
- beam tracing [436]
- best-first nearest neighbor algorithm [821, 846, 848, 853–854, 1286, 1643, 1672]
- Bézier curve [1669]
- biased B-tree [163]
- bin method [1976]
- Binary Searchable Polygonal Representation (BSPR) [293]
- binomial heap [1943]
- bintree [411, 890–891, 1041, 1052, 1088, 1436, 1658, 1661–1662, 1828, 1830, 1835–1836, 1920]
- bioinformatics database [1180, 1235–1236, 1299]
- bisector tree [978]
- bitemporal data [218]
- bk-tree [283]
- BLG-tree [1411]
- BLISS [2027]
- block-nested loop join [733]
- BoostMap [105–108]
- boundary following [493, 526, 1110, 1620, 1970]
- boundary model (BRep) [40, 139–141, 457, 767, 973, 1012, 1233, 1322, 1349, 1351, 1580, 1766, 1977–1979]
- bounded quadtree (BQT) [1100, 1496]
- branch-and-bound nearest neighbor algorithm [666, 986, 1103, 1374, 1586]
- BSP tree [18–19, 302–303, 375, 382, 438, 522, 657–658, 730, 941, 1218, 1229–1230, 1255, 1353–1359, 1409–1410, 1412, 1475–1476, 1735, 1809, 1869, 1916]
- bucket PR quadtree [1258, 1361–1362]
- bucket rectangle PM quadtree [887, 1985–1986]
- buddy system [1042]
- buddy-tree [44, 1087, 1706, 1708, 1710]
- buffer management [380]
- buffer tree [85]
- bulk insertion [347, 381, 985, 1587]
- bulk loading [85, 87, 187, 194–195, 347, 386, 679, 704, 849, 852, 856, 1154, 1160]
- BV-tree [36, 642–644, 1640]
  
- C [1017]
- C++ [1805]
- Cartesian tree [1944]
- cell tree [769–771, 774, 777–778]
- chain code [252–253, 313, 506, 526, 638, 1110, 1290, 1620, 1754]
- Chord method [1846–1848]
- closest pair problem [206]
- clustering [48, 200]
- collision detection [198, 298–299, 564, 895–896, 1038, 1206]
- color quantization [102]
- combinatorial algorithms [1551]
- combined index [1214]
- common subcube elimination [1969]
- compiler design [28]
- compositing [1503]
- compression [199, 518, 1039, 1148, 1250, 1646]
- computational geometry [196, 230, 499, 539–540, 625, 1130, 1282, 1325, 1423–1424, 1509, 1511, 1738, 1882, 1884–1885]
- computed tomography [802]
- computer graphics [239–240, 499, 622, 1568, 1666–1667]

computer-aided design (CAD) [527]  
 concurrency [316, 575, 1066, 1369, 1433, 1437]  
 concurrent Prolog [532]  
 cone tree [352]  
 configuration space [268]  
 conforming Delaunay tetrahedralization [1296, 1329, 1753]  
 conforming Delaunay triangulation [545, 1328, 1333, 1592, 1600]  
 conforming tetrahedralization [120, 335, 341, 959, 1593]  
 conjugation tree [546]  
 connected component labeling [3, 494–495, 623, 659, 683, 688, 800, 814, 918, 1215, 1217, 1469, 1575, 1623, 1657, 1659–1661, 1701, 1902, 1904, 2044]  
 constrained Delaunay triangulation [361, 464, 1127, 1131]  
 constrained nearest neighbor [606]  
 constrained triangulation [968]  
 constraint database [266, 1559, 2073]  
 constraint spatial database [818]  
 constructive solid geometry (CSG) [92, 104, 298–299, 552, 703, 1014, 1143–1144, 1555, 1557–1558, 1581, 1876, 1935, 2019, 2021–2022, 2028–2029]  
 contractiveness [844, 850, 855]  
 convex difference tree (CDT) [1541–1542, 1878]  
 convex hull [743, 1510]  
 convex region [337, 751]  
 corner stitching [1245, 1439, 1741]  
 corner table [1580]  
 corner transformation [1787–1788, 2057]  
 cost model [186, 223, 227, 390, 712–713, 768, 892, 1856, 1866–1868]  
 CSG tree [1352, 1658, 1662]  
 cubetree [1587]  
 CUR-tree [1578]  
 curse of dimensionality [159, 212, 331, 333, 719, 838, 924, 1062, 1447]  
  
*d*-dimensional quadtree [471, 585, 913, 1519, 1948]  
 D-tree [2035–2036, 2070]  
 data fusion [64–65]  
 data mining [200, 797]  
 data structure visualization [243–246, 1330]  
 data warehousing [329]  
 data-parallel algorithms [210, 217, 860–862, 865, 867–869]  
 database systems [418, 554, 1613, 1899, 1974]  
 decoupling [642–644, 1640, 1952, 2043]  
 Delaunay graph [947]  
 Delaunay tree [229]  
 Delaunay triangulation (DT) [204, 229, 474, 563, 667, 765, 767, 947, 990, 998, 1260, 1268, 1322, 1422, 1883, 1964]  
 depth-first nearest neighbor algorithm [360, 376, 530, 650, 666, 955, 986, 1103, 1199, 1270, 1272, 1374, 1586, 1639, 1643, 2052]  
 DF-expression [970, 1004–1007, 1395, 1431, 2018]  
 digital elevation model (DEM) [312, 1243]  
 digital geometry [1034, 1572]  
 digital searching [251, 635]  
 digital terrain model (DTM) [1691]  
 dimension reduction [23–24, 318, 431, 956, 988, 1171]  
 Discrete Fourier Transform (DFT) [26, 2026]  
 distance join [423, 845, 847, 1060, 1756, 1800–1801]  
 distance matrix [123, 130, 1291–1292, 1533, 1535, 1743, 1929–1930, 1932, 1951]  
 distance semijoin [605, 847, 931, 1067, 1173, 1674, 1756, 2030, 2041–2042]  
 distributed indexing [1188–1189, 1846–1848]  
 divided k-d tree [1075]  
 divided-leaf octal tree [1915]  
 double Gray order [582]  
 doubly chained tree (DCT) [305, 961, 996, 1817]  
 Douglas-Peucker algorithm [508, 965–966]  
 DR-tree [1142]  
 duplicate removal [76, 80, 498]  
 dynamic hashing [559, 1104]  
 dynamic point location [103, 142, 357, 362, 365, 652–653, 727, 1441, 1512–1513, 1821]  
 dynamic programming [492]  
 dynamic storage allocation [1042]  
 dynamic z hashing [906]  
 dynamically quantized pyramid (DQP) [1425, 1777]  
 dynamically quantized space (DQS) [1421, 1425]  
  
 ECDF tree [180]  
 economics [1468]  
 edge enhancement [1537]  
 edge pyramid [1762]  
 edge quadtree [654–655, 707, 1482, 1762, 1961]  
 edge-EXCELL [1822, 1824]  
 edit distance [796, 1156, 1780]  
 Elias algorithm [1566]

 Escher drawings [427]  
 Euclidean matching problem [113, 179, 926, 993, 1552, 1906]  
 Euler number [523]  
 EXCELL [57, 617, 1822, 1824–1827, 1829, 1834, 1837]  
 expanded MX-CIF quadtree [9]  
  
 extended octree [115–116, 271–272, 1349–1352, 2020]  
 extendible hashing [57, 579, 617, 1040, 1202, 1823, 1825]  
 external memory representations [1933]  
  
 face octree [270, 274, 654–655, 707, 975, 1482, 1497–1498, 1784, 1881]  
 fair-split tree [297]  
 farthest point pair [799]  
 Fast Fourier Transform (FFT) [421]  
 FastMap [105–108, 587, 850, 855, 886, 1950, 1955, 2045]  
 feature-based queries [72, 1921, 1953]  
 Fibonacci heap [636]  
 Fibonacci numbers [987]  
 fieldtree [628, 630, 1901]  
 filter tree [1720]  
 filter-and-refine [569, 1416]  
 finite element analysis [204–205, 417, 1011, 1013–1014, 1147, 1506, 1561, 1751, 1769, 1981, 2051]  
 fixed-queries array [331]  
 fixed-queries tree [118]  
 FLEX [1008]  
 flow analysis [811]  
 forests of quadtrees [697, 969, 1003, 1093, 1532, 1547, 1629]  
 fractal dimension [161, 584, 586, 1062, 1225, 1309, 1447]  
 fractal landscape modeling [830]  
 fractional cascading [339–340, 653]  
 functional programming [336, 819]  
 fuzzy logic [450, 2064]  
  
 Gabriel graph (GG) [667, 947]  
 game programming [198, 475–476, 564, 1025, 1456, 1890]  
 GBD-tree [1388]  
 generalization [508, 1269]  
 Generalized Bulk Insertion (GBI) [381]  
 geographic information systems (GIS) [9, 127, 284, 489, 672, 773, 1113, 1238, 1240, 1335, 1410–1411, 1455, 1562, 1576–1577, 1644, 1648–1651, 1653, 1732, 1806, 2023]  
 geometree [902]  
 geometric modeling [131, 596, 716, 1316, 1962]  
 geometric probability [1673]  
 geometry [239–240, 1786]  
 gh-tree [473, 1897]  
 GiST [66, 70, 704, 817, 1066, 1403]  
 global illumination [2005]  
 GNAT [255]  
 GPU [739, 1146, 1815]  
 graphical search and replace [1096]  
 graphs [491, 801]  
 Gray code [581, 745]  
 grid file [57, 150, 215, 839–840, 1077–1078, 1154, 1160, 1376, 1385, 1428, 1437, 1549–1550, 1582, 1612]  
 grid-partition index [2070]

HAL tree [1927]  
 half-edge representation [301, 1979]  
 halfplanar range search [543, 546, 2048]  
 hardware [30, 119, 238, 487, 496, 524, 594, 903, 1098, 1246, 1264, 1294–1295, 1521, 1872, 2003]  
 Hausdorff distance [394, 911, 1031]  
 hB-tree [574–575, 1201, 1614]  
 hexagonal tiling [158, 234, 285, 706, 1149, 1293]  
 hidden-line elimination [1818, 1959–1960, 1980]  
 hidden-surface elimination [201, 941, 1354, 1475, 1494, 1818, 1961, 1980]  
 hierarchical face clustering [481, 693, 695, 980, 2004–2005]  
 hierarchical radiosity [2005]  
 Hilbert R-tree [984]  
 Hilbert tree [1121]  
 Hilbert-packed R-tree [983]  
 hinted quadtree [1101]  
 Hough transform [938, 1122, 1159, 1421, 1425, 1777]  
 Huffman code [897]  
 HV/VH tree [1100]  
 hybrid tree [315, 317]  
 hypervolumes [471, 585, 913, 933, 1137, 1519, 1948, 2050]  
  
 image database [323, 759, 1108–1109, 1172, 1591]  
 image dilation [43, 53, 58, 1252–1253, 1730]  
 image invariants [845]  
 image processing [1508, 1574]  
 image synthesis [92, 420, 515]  
 iMinMax [940, 1403, 1408, 2058–2059]  
 incremental nearest neighbor algorithm [66, 186, 264, 387, 821, 844, 846–848, 851, 853–854, 1672, 1971]  
 information retrieval [1611]  
 interference detection [298–299, 338, 735, 1527]  
 interval arithmetic [34–35, 405, 413, 1051, 1314, 1321, 1545]  
 interval tree [357, 534, 538, 934]  
 intervals [59, 216, 364, 560, 588, 637, 1209, 1708, 1895, 2057]  
 IPL–V [1365]  
 IQ-tree [185]  
 ISAM [705]  
 isosurface octree [1995]  
  
 JAVA [93, 243–246]  
  
 k-center problem [203, 445, 601, 723, 859, 1311]  
 k-d tree [50, 151, 153, 164, 168, 171–172, 181, 264, 297, 322, 432, 439–440, 478–480, 483, 490, 512, 517, 528, 530, 548, 673–674, 676, 802, 822–825, 880–881, 960, 1028, 1114, 1132, 1204, 1258, 1331, 1334, 1399, 1571, 1758–1759, 1767–1768, 1797, 1808, 1999, 2077]  
 k-d-B-tree [317, 643, 1091, 1412, 1567]  
 k-DOP [1038]  
 k-means problem [1174, 1219]  
 k-median problem [325]  
 K-structure [1026]  
 kB-tree [786–787, 1077–1078]  
 kB<sup>+</sup>-tree [1076]  
 KD2-tree [1410, 1412]  
 KD2B-tree [1410, 1412]  
 kNN graph [1704]  
  
 LAESA [1292, 1533]  
 Las Vegas randomized algorithm [397–398, 1318]  
 lath [973]  
 layered dag [541]  
 layered tree [1911]  
 lazy evaluation [287, 292]  
 least square quadtree [1248]  
 level compression [51, 1379]  
 level of detail (LOD) [702, 1212, 1864, 1900]  
 line clipping [434]  
 line intersection problem [507, 1185, 1596]  
 line quadtree [1663–1664]  
 linear algebra [578]  
 linear file [953]  
 linear hashing [282, 793, 906, 1040, 1084, 1105–1107, 1187–1188, 1323, 1414, 1420, 1428, 1433, 1435]  
 linear programming [1257, 1280–1281, 1711, 1982]  
 link-cut tree [1776]  
 Lipschitz embedding [237, 426, 595, 631, 850, 855, 886, 962, 1181, 1736]  
 LISP [1263, 1570]  
 locality sensitive hashing (LSH) [510, 700, 709, 922–924, 1523, 1737]  
 location-based queries [72, 1921]  
 loose octree [1901]  
 loose quadtree [1901]  
 lossless compression [1629]  
 LSD tree [821, 823–826, 829]  
  
 M-tree [386, 388–390, 1236, 1311, 1888–1889, 2065]  
 machine learning [105–108, 648, 1682]  
 map conflation [155, 248, 344, 1598–1599, 1601, 1958, 2033]  
 map overlay [291]  
 map projections [14, 1782]  
 marching cube algorithm [1745]  
 mathematical modeling [701]  
 matrix methods [1, 647, 721, 858, 1785, 1804, 2006–2011]  
 maximum clique problem [1126]  
 mb-tree [278, 1383]  
 mb\*-tree [1383]  
 MD-tree [1337–1338]  
 mean shift analysis [358, 700]  
 measure problem [637, 1029, 1145, 1445]  
  
 medial axis transformation (MAT) [221]  
 medical image database [1063–1064, 1485]  
 mesh generation [204–205, 417, 1506]  
 mesh simplification [481, 980]  
 metric space embedding [105–108, 237, 426, 510, 587, 595, 631, 700, 709, 844, 850, 855, 886, 922–924, 962, 1032, 1090, 1097, 1181, 1523, 1737, 1879, 1950, 1955, 2045, 2056]  
 metric spaces [118, 123, 130, 136, 241, 249, 255, 278, 283, 304, 330–332, 334, 346, 376, 386, 388–390, 401, 445, 473, 610, 656, 666, 699, 756, 853–854, 882–884, 940, 974, 978, 1235–1236, 1291–1292, 1347–1348, 1383, 1533, 1535, 1604, 1641, 1704, 1743, 1861, 1887–1889, 1896–1897, 1929–1930, 1932, 1934, 1951, 2052–2054, 2059, 2065]  
 metric tree [1311, 1896–1897]  
 MetricMap [1950, 1955, 2045]  
 minimum bounding box [125, 189, 266, 504, 639, 735, 999, 1019, 1038, 1081, 1135, 1527, 1548, 1589, 1687–1688, 1692, 1923]  
 minimum bounding hypersphere [556–557, 799, 999, 1257, 1280–1281, 1399, 1982, 1991]  
 minimum spanning forest [562]  
 minimum spanning tree (MST) [947]  
 minimum-ambiguity k-d tree [1226, 1228]  
 minimum-weight matching problem [133, 1907]  
 moments [2025]  
 Monte Carlo randomized algorithm [1318]  
 Morton order [1317, 1471–1472, 1478]  
 motion estimation [1819]  
 motion planning [268, 599, 663, 833, 1206, 1700, 2015]  
 moving objects [16, 18, 20–21, 25, 162, 295–296, 300, 348, 351, 624, 781, 790, 889, 930–931, 949–950, 1055–1057, 1305–1306, 1320, 1493, 1524, 1543–1544, 1560, 1609–1610, 1789, 1851, 1855, 1863, 2013–2014, 2034, 2061, 2067]  
 multiattribute tree (MAT) [305, 728, 996, 1133, 1167, 1584, 1686]  
 multidimensional B-tree (MDBT) [1077–1078, 1434, 1686]  
 multidimensional directory (MDD) [1183, 1271]  
 multidimensional extendible hashing (MDEH) [1288, 1428]  
 multidimensional scaling (MDS) [1090, 1879, 2056]  
 multilayer grid file [1773]  
 multilevel grid file [1020–1021, 1087, 1710, 1987]  
 multimedia database [135, 1807]  
 multipaging [1287–1288]  
 multiple storage quadtree [269, 466]

multiprocessing [327, 749, 944, 1182, 1685]  
 multiresolution image processing [1573]  
 multiresolution modeling [391–392, 459, 461–462, 465, 469, 692–693, 695, 812, 1791, 1936, 2005]  
 multitriangulation [460]  
 .mvp-tree [241, 1235]  
 MX octree [552, 1273, 1349]  
 MX quadtree [289, 451, 901, 904–905, 1070, 1150, 1175, 1401, 1751]  
 MX-CIF quadtree [2, 8, 1009, 1100, 1340–1341, 1496, 1720, 1901]  
  
 N order [1992]  
 N-body problem [41, 50, 68, 126, 297, 571, 744, 753–755, 1001, 1221, 1608]  
 nearest foreign neighbor problem [2047]  
 nearest neighbor [25, 61, 130, 136, 162, 165, 182, 184, 189, 192, 212, 224, 236, 278, 283, 304, 314, 318–319, 356, 377, 379, 398–399, 401, 403, 497, 528, 610, 649, 656, 719, 756, 838, 842, 863–864, 930, 949, 968, 974, 978, 1000, 1053–1054, 1062–1064, 1067–1068, 1271, 1291–1292, 1306, 1320, 1330–1332, 1347, 1364, 1383, 1461–1462, 1464–1466, 1493, 1533–1534, 1543, 1566, 1713–1714, 1716, 1743, 1797, 1825, 1838, 1848, 1851, 1856, 1861, 1870, 1896–1897, 1929–1930, 1932, 1941, 1991, 2034–2036, 2054, 2061, 2063, 2070, 2077]  
 neighbor finding [684, 710, 891, 1136–1138, 1162, 1625, 1634–1635, 1652, 1696, 1792, 1816, 1893, 1942]  
 nested interpolation-based grid file (NIBGF) [1438]  
 network algorithms [1859]  
 network optimization [1119]  
 nonmanifold objects [301, 457, 979, 1140, 1979]  
 numerical methods [687, 721, 1515]  
  
 OBBTree [735]  
 object hierarchy [22, 66, 85–86, 1640]  
 object recognition [91, 1811]  
 object-oriented spatial database [1419]  
 online analytic processing (OLAP) [329, 1587]  
 operations research [836]  
 optics [1880]  
 optimal region quadtree [757, 1161]  
 optimized k-d tree [1444]  
 optimized point quadtree [1444]  
 orthogonal polygon [565, 569]  
 os-tree [1226, 1230]  
 oversized shelf [771, 777–778]  
  
 P-tree [939]  
 packed R-tree [44, 698, 1588]  
 packing constraint [1227]  
 parallel coordinates [925]  
 parallel processing [46, 209, 213, 373, 470–472, 511, 524, 898–899, 916, 997, 1027, 1047–1048, 1098, 1160, 1249, 1283, 1465, 1719, 1928, 1972, 2008, 2071–2072]  
 partial match query [172, 231, 322, 530, 582, 621, 1531]  
 partial ordering [319]  
 partial-entity structure [1140]  
 particle simulation [41, 50, 68, 126, 571, 744, 753–755, 1001, 1221, 1608]  
 PASCAL [952]  
 path compression [51, 396, 1379]  
 path planning [981, 1590]  
 Patricia trie [792, 1315]  
 pattern recognition [514, 665]  
 Peano-Hilbert order [591, 616, 734, 835, 937, 1190–1191, 1481]  
 peer-to-peer indexing [122, 136, 675, 1189]  
 peer-to-peer R-tree [1307]  
 peer-to-peer spatial indexing [676, 1307, 1846–1848]  
 perceptrons [1298]  
 perimeter computation [1622, 1721]

- reflectance [420, 1880]
- region octree [31–32, 82, 94, 328, 345, 367–371, 374, 415, 503, 633, 685, 689–691, 814, 830, 873, 912, 915, 932–933, 1027, 1095, 1116, 1146, 1166, 1262, 1273–1279, 1308, 1381–1382, 1392–1393, 1427, 1452, 1504–1505, 1668, 1671, 1745, 1763, 1765, 1792, 1799, 1836, 1841, 1924–1926, 1949, 1983, 1988, 2039–2040, 2049, 2069]
- region quadtree [3–4, 138, 154, 208, 287–288, 290–292, 328, 355, 366, 368, 370–371, 373, 383, 424, 430, 449, 469, 472, 488, 493, 523, 525–526, 532, 577, 583, 659, 677–678, 683–684, 686–688, 690, 900, 916, 997, 1035–1036, 1039, 1094, 1141, 1162–1163, 1165, 1168, 1240, 1242, 1244, 1249–1250, 1261, 1283–1284, 1294, 1301–1302, 1308, 1339–1340, 1343–1344, 1371, 1393–1397, 1483, 1538, 1540, 1576–1577, 1622–1624, 1627, 1631, 1647–1651, 1653, 1659, 1668, 1695, 1719, 1722, 1731–1733, 1754, 1761, 1764, 1783, 1806, 1892–1893, 1902–1904, 1914, 1920, 1922, 1969–1970, 1997–1998, 2002, 2017–2018, 2024–2025, 2044, 2049, 2072, 2075]
- region quadtree construction [758, 1110, 1619–1621, 1729]
- relational join [733]
- relative neighborhood graph (RNG) [947, 1422, 1883]
- restricted bintree [513, 576, 651, 810, 1118, 1176, 1259, 1522, 1564–1565]
- restricted quadtree [205, 702, 1193, 1300, 1312–1313, 1453–1454, 1751, 1771–1772, 1840, 1900, 1939–1940, 1981]
- reverse nearest neighbor (RNN) [162, 1060–1061, 1674, 1800–1801, 1854, 2041–2042]
- RMD-tree [1337]
- ROAESA [1932]
- robotics [527, 696, 1378]
- RR<sub>1</sub> quadtree [1722]
- RR<sub>2</sub> quadtree [1722]
- runlength encoding [1595, 1621, 1627]
- S\*-tree [1345]
- S<sup>+</sup>-tree [970]
- S-tree [22, 970]
- SAIL [1553]
- sampling strategies [1397]
- SAND [71, 73, 568, 570, 1644]
- scan conversion [752]
- Schönhardt Twisted Prism [1694]
- scripting language [568, 570]
- sector tree [352]
- segment tree [166, 183, 216, 277, 1441, 1452, 1774–1775, 1910]
- selectivity estimation [12–13, 47, 78–79, 160–161, 219, 223, 444, 592, 768, 1170, 1327, 1717, 1887]
- separating chain method [1128]
- sequential scan [185, 315, 607–608, 1971–1973]
- set cover problem [385]
- set union algorithm [1857, 1860]
- shading [349, 729, 731, 736, 1380, 1494, 1994]
- shape approximation [1539]
- shape retrieval [1704]
- shortest path algorithm [377, 491, 612, 715, 781, 893, 958, 1053, 1464, 1672, 1736, 1748, 1945]
- similarity join [225, 227, 1073, 1755]
- similarity searching [23–24, 61–62, 122, 135, 184, 191, 228, 249, 333, 342, 348, 431, 709, 826, 844, 851, 854, 988, 1000, 1010, 1071, 1083, 1108–1109, 1164, 1172, 1180, 1485, 1606, 1641, 1713, 1715–1716, 1770, 1873, 1989–1991]
- simple QSF-tree [2057]
- simplification [392, 394, 469, 692, 795, 875, 1031, 1205, 1862, 1864, 1919]
- SIMULA [437]
- Singular Value Decomposition (SVD) [321, 468, 988, 1873, 2026]
- skip list [69, 561, 1204, 1520, 1712]
- skip quadtree [561]
- skyline cube [1479, 2062]
- skyline query [236, 319, 379, 712–713, 1068, 1462, 1468, 1479, 1838, 2062]
- sliding-midpoint k-d tree [1226–1228, 1319]
- Slim-tree [1888–1889]
- smoothing [1540]
- solid modeling [870, 1143–1144, 1232, 1457, 1555–1558, 1581, 1935]
- SP-GiST [70, 704]
- space requirements [430, 525, 583, 585, 757, 1161, 1175, 1244, 1254, 1343–1344, 1371, 1668, 1695, 1724, 1727, 1920, 1948]
- space-filling curve [39, 101, 132–133, 294, 412, 590–591, 616, 718, 725, 734, 835, 937, 984, 1111–1112, 1164, 1190–1192, 1241, 1304, 1309, 1317, 1471–1472, 1478, 1481, 1603, 1698, 1992, 2012]
- SparseMap [850, 855, 886]
- Spatial Approximation tree (sa-tree) [853, 1347–1348, 1704]
- spatial data mining [72, 74, 572, 1173, 1367–1368, 1839, 1953–1954]
- spatial database [5, 13, 149, 161, 258, 260, 775, 783–785, 789, 844, 929, 1080, 1238, 1473, 1546, 1554, 1562, 1645, 1683, 1746–1747, 1931, 1937–1938, 1963, 1966, 2023]
- spatial join [7, 47, 81, 83, 88–89, 148, 150, 160, 256, 259, 261–262, 424, 444, 498, 560, 592, 772, 779, 845, 860–862, 866, 892–894, 934–935, 1020, 1072, 1195–1198, 1207, 1222–1224, 1415, 1417, 1458–1459, 1467, 1470, 1474, 1815, 1867, 1923, 2071, 2073–2074, 2076]
- spatial join index [1210, 1582, 1750]
- spatial k-d tree [1404, 1406–1407]
- spatial networks [377, 491, 605, 612, 715, 781, 949, 958, 1053–1054, 1181, 1464, 1493, 1672, 1736, 1748–1749, 1945, 2055]
- spatial query optimization [75, 78–79, 444, 566, 1405]
- spatial reasoning [64, 446]
- spatiotemporal database [20–21, 127, 156, 790, 950, 1203, 1209, 1305, 1614, 1693, 1895, 2037]
- spatiotemporal pattern retrieval [794]
- spatiotemporal range query [1544]
- sphere tree [895–896, 1410, 1412, 1527, 1991]
- spherical representation [1138]
- spiral hashing [324, 384, 1106, 1247, 1323–1324]
- splines [131]
- split-and-merge segmentation [879, 1495]
- SPY-TEC [1124–1125]
- SR-tree [999]
- SS-tree [1991]
- star-vertex data structure [979]

Steiner points [1296, 1329, 1333, 1600, 1753]  
 STLT method [347]  
 STR method [1153]  
 Strassen's algorithm [1785]  
 streaming [544]  
 strip tree [121, 735, 965–966, 1927]  
 support vector machines (SVM) [281, 1917]  
 surface simplification [391, 550–551, 693, 695, 737, 763, 876, 878, 1049–1050, 1123, 1212, 1569, 2004–2005, 2031–2032]  
 survey [91, 112–113, 165, 168, 173, 200, 224, 334, 345, 364, 401, 414, 452, 457, 499, 539–540, 559, 625, 629, 638, 670, 692, 742, 747, 776, 784, 812, 854, 923, 935, 963, 1122, 1130, 1143, 1147–1148, 1200, 1203, 1208, 1256, 1335, 1357–1358, 1375, 1384, 1442, 1487, 1490, 1535, 1555–1558, 1603, 1614–1615, 1628, 1632–1633, 1638, 1641–1642, 1645, 1647, 1666–1667, 1700, 1709, 1747, 1798, 1811, 1818, 1831, 1882, 1885, 1933, 1935, 1938, 2013]  
 symmetric structure [2016]

Tcl [568, 570]  
 template quadtree [1231]  
 temporal database [59, 951, 1092]  
 ternary hierarchical triangular decomposition [454–455]  
 ternary system [57]  
 tetrahedralizations [275, 809, 1136, 1328, 1694, 1752, 1820]  
 textures [263, 1146]  
 threads [1030]  
 threshold selection [2024]  
 TID [1702–1703]  
 tile tree [1265]  
 tiling [29, 157, 724, 761–762]  
 time dimension [663, 708, 711, 933, 1658, 2050]  
 time-parametric R-tree [295–296]  
 time-series database [26, 348, 588]  
 TLAESA [1291]  
 top-*k* query [306, 2074]  
 topological relations [1458, 1460]  
 topological sort [976]  
 topological sweep [493]  
 topology [1326]  
 topology simplification [550]  
 TPR-tree [1610, 1851]  
 TPR\*-tree [1851, 1855]  
 TR\*-tree [1692]  
 transformation technique [589, 822, 827, 937, 1418, 1449, 1787–1788, 2057]  
 traveling salesman problem [1120]  
 treap [69, 1712]  
 treecode [1608]  
 treemap [153, 478–480, 960, 1334, 1758–1759]

tri-cell [589]  
 triacon hierarchy [520]  
 triangle collapse [795]  
 triangle meshes [124, 301, 457, 513, 576, 651, 810, 979, 1176, 1259, 1564–1565, 1679]  
 triangle strip [467, 549]  
 triangle table [714, 806, 1580]  
 triangular quadtree [521]  
 triangulated irregular network (TIN) [354, 458, 967, 1186, 1243, 1454, 1487, 1677, 1864, 2060]  
 triangulations [97–98, 124, 205, 211, 354, 453, 456, 460, 463, 465, 702, 714, 717, 760, 806, 808, 815, 834, 1138, 1147, 1155, 1373, 1453, 1522, 1580, 1597, 1677–1681, 1791, 1821, 1840, 1886, 1965]  
 trie [51, 251, 621, 635]  
 turning angle [1108–1109]  
 TV-tree [1171]  
 twin grid file [907–908]  
 two-dimensional runlength encoding [1115]

U order [1192, 1698]  
 U-tree [1849]  
 uniform grid [632, 634, 1374]  
 uniform hashing [1484]  
 user interface [547, 1096, 1644, 1937]

VA<sup>+</sup>-file [607–608]  
 VA-file [185, 228, 607–608, 1972–1973]  
 VAMSplit k-d tree [1989, 1991]  
 VAMSplit R-tree [1989]  
 VASCO [243–246]  
 vector quantization [356, 747, 1174, 1194, 1219, 1534]  
 vertex clustering [1205, 1579]  
 vertex decimation [1049–1050]  
 vertex pair collapse [875]  
 vertex representation [565–567, 569, 1744]  
 vertex simplification [837]  
 video database [1057]  
 view-dependent simplification [551, 876]  
 visual computing [1372]  
 visualization [925, 1759]  
 Voronoi diagram [97–98, 112, 189, 192, 255, 474, 497, 740, 765, 767, 807, 978, 990, 1054, 1226, 1229–1230, 1322, 1332, 1389, 1616, 1870, 1941]  
 Voronoi tree [473]  
 vp-tree [304, 332, 376, 656, 1861, 1897, 1934, 2052–2053]

wavelets [760]  
 well-separated pair decomposition [297]  
 window query [11, 56, 77, 84, 1342, 1448, 1451, 1892]  
 winged-edge representation [139–141, 457, 613, 973, 979, 1322, 1580, 1977–1978]

X-tree [188, 190]  
 X-Y tree [153, 478–480, 960, 1334, 1758–1759]  
 XXL [193]

Z order [1417, 1420]  
 z-buffer [515, 752]

# Author and Credit Index

---

When the page number of an index entry refers to a credit (such as an acknowledgement of a solution or of aid in the preparation of the book), then the page number is in italics. Index entries corresponding to authors indicate the page numbers on which a work of the corresponding author is either cited or appears in the bibliography. A page range for an individual indicates that each page in the range cites a work of the corresponding author, or is part of the bibliography in which case it contains at least one work of the corresponding author.

---

# Subject Index

---

When the page number of an index entry refers to a definition, then the page number is in italics. When the index entry appears in a footnote, then the letter “n” is appended to the page number. A page range for a topic indicates that either the topic is discussed in the given page range or that each page in the range mentions the topic.

## 0

0-balanced quadtree, *405, 407, 814*

## 1

1-2 brother tree, *280n*

1-balanced quadtree, *405, 407*

1-irregular quadtree, *405*

1DSEARCH, *16*

1nf. *See* first normal form (1nf)

## 2

2-3 tree, *65, 442, 718, 722*

2-3-4 tree, *442, 722, 722*

2-d Fibonacci condition, *223, 223, 225, 782–783*

2-d range tree. *See also* two-dimensional range tree

2DSEARCH, *17*

2nf. *See* second normal form (2nf)

## 3

(3,0)-AVD, *367, 582, 584–585, 584, 853*

3nf. *See* third normal form (3nf)

## 4

4-adjacent

blocks, *217n*

locations (pixels), *200n*

4-shape, *230*

## 7

7-shape, *231*

## 8

8-adjacent

blocks, *217n*

locations (pixels), *200n*

## 9

9-shape, *230*

## A

A-series paper, *783*

A-tree, *283n, 573*

A\*-algorithm, *347, 493, 535*

AABB. *See* axis-aligned bounding box (AABB)

ABOVE field
