Editorial Project Manager: Anna Valutkevich
Production Project Manager: Mohana Natarajan
Cover Designer: Vicky Pearson

Typeset by SPi Global, India

Table of Contents

Chapter 1 Introduction 1
Philip T. Krein

Section I: Power Electronic Devices

Chapter 2 Semiconductor Diodes and Transistors 15
Tiago Davi C. Busarello, Marcelo G. Simões and José A. Pomilio

Chapter 3 Thyristors 49
Tanya K. Gachovska, Jerry L. Hudgins, Angus Bryant, Patrick Palmer and Subbaraya Yuvarajan

Chapter 4 Static Induction Devices 83
Bogdan M. Wilamowski

Chapter 5 SiC and GaN Power Semiconductor Devices 95
Tanya K. Gachovska and Jerry L. Hudgins

Chapter 6 Power Electronic Modules 157
Enrico Santi, Soheila Eskandari, Bo Tian and Kang Peng

Section II: Power Conversion

Chapter 7 Diode Rectifiers 177
Yim-Shu Lee and Martin H.L. Chow

Chapter 8 Single-Phase Controlled Rectifiers 209
Kishore N. Mude

Chapter 9 Three-Phase Controlled Rectifiers 233
Muhammad H. Rashid

Chapter 10 DC-DC Converters 275
Dariusz Czarkowski

Chapter 11 Inverters 289
Nimrod Vázquez and Joaquín Vaquero López

Chapter 12 Resonant and Soft-Switching Converters 339
Muhammad H. Rashid, Shu Yuen (Ron) Hui and Henry Shu-Hung Chung

Chapter 13 Multilevel Power Converters 385
Leon M. Tolbert and Xiaojie Shi

Chapter 14 AC-AC Converters 417
Mohammad Ali, Atif Iqbal and Mohammad Rizwan Khan

Chapter 15 Multiphase Converters 457
Atif Iqbal, Shaikh Moinoddin, Salman Ahmad, Mohammad Ali, Adil Sarwar and Kishore N. Mude

Chapter 16 Power Factor Correction Circuits 529
Abdallah Kouzou

Chapter 17 Magnetic Circuit Design for Power Electronics 571
William G. Hurley, Maeve C. Duffy, Jesus Acero, Ziwei Ouyang and Jun Zhang

Section III: General Applications

Chapter 18 Solid-State Pulsed Power Modulators and Capacitor Charging Applications 593
José Fernando Silva, Luis Redondo and William C. Dillard

Chapter 19 Uninterruptible Power Supplies 641
Adel Nasiri and Seyed Ahmad Hamidi

Chapter 20 Power Supplies 659
Yuk M. Lai

Chapter 21 Electronic Ballasts 685
Jose Marcos Alonso

Chapter 22 Wireless Power Transfer 711
Mohammad Etemadrezaei

Section IV: Power Generation and Distribution

Chapter 23 Energy Sources 725
Alireza Khaligh and Omer C. Onar

Chapter 24 Photovoltaic System Conversion 767
Nimrod Vázquez and Jeziel Vázquez

Chapter 25 Power Electronics for Renewable Energy Sources 783
Syed M. Islam, Chem V. Nayar, Ahmed Abu-Siada and Md Mubashwar Hasan

Chapter 26 Electric Power Transmission 829
Muhammad H. Rashid, Zahrul F. Hussien, Azlan A. Rahim and Norazlina Abdullah

Chapter 27 HVDC Transmission 847
Vijay K. Sood

Chapter 28 Flexible AC Transmission Systems 885
Edson H. Watanabe, Francisco K. deAraújo Lima, Robson F. daSilva Dias, Maurício Aredes, Pedro G. Barbosa, Silvangela L.S. Lima Barcelos and Gilson Santos, Jr.

Section V: Motor Drive

Chapter 29 Drive Types and Specifications 913
Yahya Shakweh

Chapter 30 Motor Drives 945
Muhammed F. Rahman, Dean Patterson, Adrian Cheok and Robert Betz

Chapter 31 Fundamentals of Power Electronics Controlled Electric Propulsion 1023
Shailendra Jain and Lalit Kumar

Chapter 32 Automotive Applications of Power Electronics 1067
David J. Perreault, Khurram K. Afridi and Iftikhar A. Khan

Chapter 33 Fuel-Cell Systems for Transportations 1091
Mehmet Uzunoglu and Mohammad S. Alam

Chapter 34 Wireless Charging of Electric Vehicles 1113
Chun T. Rim

Section VI: Control

Chapter 35 Linear and Nonlinear Control of Switching Power Converters 1141
José Fernando Silva and Sónia F. Pinto

Chapter 36 Fuzzy-Logic Applications in Electric Drives and Power Electronics 1221
Abdul R. Ofoli

Chapter 37 Artificial Neural Network Applications in Power Electronics and Electric Drives 1245
Baburaj Karanayil and Muhammed F. Rahman

Chapter 38 Novel AI-Based Soft Computing Applications in Motor Drives 1261
Adel M. Sharaf and Adel A.A. Elgammal

Chapter 39 DSP-Based Control of Variable Speed Drives 1303
Hamid A. Toliyat, Mehdi Abolhassani, Peyman Niazi and Lei Hao

Chapter 40 Predictive Control of Power Electronic Converters 1325
Sertac Bayhan and Haitham Abu-Rub

Section VII: Power Quality and EMI Issues

Chapter 41 Active Power Filters 1341
Luis Morán, Juan Dixon and Miguel Torres

Chapter 42 EMI Effects of Power Converters 1381
Andrzej M. Trzynadlowski

Chapter 43 Power Electronics Standards 1397
Yuri Khersonsky

Section VIII: Simulation and Packaging

Chapter 44 Computer Simulation of Power Electronics and Motor Drives 1403
Michael Giesselmann

Chapter 45 Design for Reliability of Power Electronic Systems 1423
Yongheng Yang, Huai Wang, Ariya Sangwongwanich and Frede Blaabjerg

Chapter 46 Thermal Modeling and Analysis of Power Electronic Components and Systems 1441
Peter R. Wilson

Index 1451

1.1 Power Electronics Defined[1]

It has been said that people do not use electricity, but rather they use communication, light, mechanical work, entertainment, and all the tangible benefits of energy and electronics. In this sense, electrical engineering as a discipline is much involved in energy conversion and information. In the general world of electronics engineering, the circuits engineers design and use are intended to convert information. This is true of both analog and digital circuit design. In radio-frequency applications, energy and information are on more equal footing, but the main function of any circuit is information transfer.

What about the conversion and control of energy itself? Energy is a critical need in every human endeavor. The capabilities and flexibility of modern electronics must be brought to bear to meet the challenges of reliable, efficient energy. Electronic circuits and systems can be applied to the challenges of energy conversion and management. This is the framework of *power electronics*, a discipline defined in terms of *electrical energy conversion, applications*, and *electronic devices*. More specifically,

> **Definition** Power electronics involves the study of electronic circuits intended to control the flow of electrical energy. These circuits handle power flow at levels much higher than the individual device ratings.

Rectifiers are typical examples of circuits that meet this definition. Inverters (a general term for dc-ac converters) and dc-dc converters for power supplies are also common applications. As shown in Fig. 1.1, power electronics represents a median point at which the topics of energy systems, electronics, and control converge and combine [1]. Any useful circuit design for an energy application must address issues of devices, control, and systems, as well as of the energy itself. Among the unique aspects of power electronics are its emphasis on large semiconductor devices, the application of magnetic devices for energy storage, special control methods that must be applied to nonlinear systems, and its fundamental place as a central component of today's energy systems and alternative resources. In any study of electrical engineering, power electronics must be placed on a par with digital, analog, and radio-frequency electronics to reflect the distinctive design methods and unique challenges.

Applications of power electronics continue to expand. It is not possible to build practical computers, mobile phones,

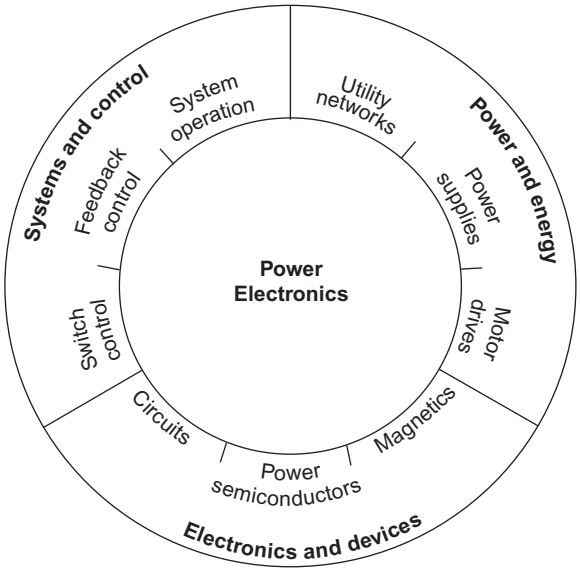

FIG. 1.1 Control, energy, and power electronics are interrelated.

handheld devices, cars, airplanes, industrial processes, and a host of other everyday products without power electronics. Alternative energy systems such as wind generators, solar power, fuel cells, and others require power electronics to function. Technology advances such as electric and hybrid transportation, laptop computers, microwave ovens, flat-panel displays, LED lighting, and hundreds of other innovations were not possible until advances in power electronics enabled their implementation. Although no one can predict the future, it is certain that power electronics will be at the heart of fundamental energy innovations.

The history of power electronics [2–5] has been closely allied with advances in electronic devices that provide the capability to handle high power levels. Since about 1990, devices have become so capable that a transition from a "device-driven" field to an "application-driven" field continues. This transition has been based on two factors: (1) Advanced semiconductors with suitable power ratings exist for almost every application of wide interest, and (2) the general push toward miniaturization is bringing advanced power electronics into a growing variety of products. Although the devices continue to improve, especially related to the use of wide bandgap semiconductor materials, their development generally tends to follow innovative applications.

1.2 Key Characteristics

All power electronic circuits manage the flow of electrical energy between an electrical source and a load. The parts in a circuit must direct electrical flows, not impede them. A general power conversion system is shown in Fig. 1.2. The power converter in the middle controls the energy flow between

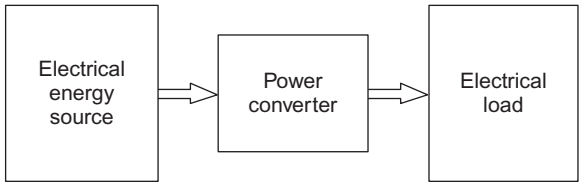

FIG. 1.2 General system for electric power conversion. (From P. T. Krein, Elements of Power Electronics, Oxford University Press, New York, 1998, Copyright 1998, Oxford University Press, used with permission.)

a source and a load. For our purposes, the power converter will be implemented with a power electronic circuit. Because a power converter appears between a source and a load, any energy used within the converter is lost to the overall system. A crucial point emerges: to build a power converter, we should consider only lossless components. A realistic converter design must approach 100% efficiency.

A power converter connected between a source and a load also affects system reliability. If the energy source is perfectly reliable (it is available all the time), then a failure in the converter affects the user (the load) just as if the energy source had failed. An unreliable power converter creates an unreliable system. To put this in perspective, consider that a typical American household loses electric power only a few minutes a year. Energy is available 99.999% of the time. A converter must be better than this to prevent system degradation. An ideal converter implementation will not suffer any failures over its application lifetime. Extreme high reliability can be a more difficult objective than high efficiency.

1.2.1 The Efficiency Objective—The Switch

A circuit element as simple as a light switch reminds us that the extreme requirements in power electronics are not especially novel. Ideally, when a switch is on, it has zero voltage drop and will carry any current imposed on it. When a switch is off, it blocks the flow of current regardless of the voltage across it. The *device power*, the product of the switch voltage and current, is identically zero at all times. A switch therefore controls energy flow with no loss. In addition, reliability is also high. Household light switches perform over decades of use and perhaps 100,000 operations. Unfortunately, a mechanical switch does not meet all practical needs. A switch in a power supply may function 100,000 times each second. Even the best mechanical switch will not last beyond a few million cycles. Semiconductor switches (without this limitation) are the devices of choice in power converters.

A circuit built from ideal switches will be lossless. As a result, switches are the main components of power converters, and many people equate power electronics with the study of switching power converters. Magnetic transformers and lossless storage elements such as capacitors and inductors are also

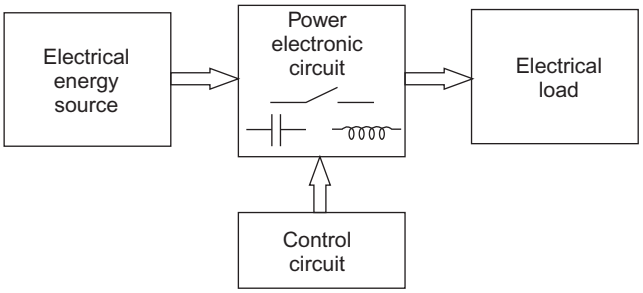

FIG. 1.3 A basic power electronic system. (From P. T. Krein, Elements of Power Electronics, Oxford University Press, New York, 1998, Copyright 1998, Oxford University Press, used with permission.)

valid components for use in power converters. The complete concept, shown in Fig. 1.3, represents a *power electronic system*. Such a system consists of an electrical energy source, an electrical load, a *power electronic circuit*, and a control function.

The power electronic circuit contains switches, lossless energy storage elements, and magnetic transformers. The controls take information from the source, the load, and the designer and then determine how the switches operate to achieve the desired conversion. The controls are built up with low-power analog and digital electronics.

Switching devices are selected based on their *power handling* rating—the product of their voltage and current ratings—rather than on power dissipation ratings. This contrasts with other applications of electronics, in which power dissipation ratings dominate. For instance, a typical stereo receiver performs a conversion from ac line input to audio output. Many audio amplifiers do not use the techniques of power electronics, and the semiconductor devices do not act as switches. A commercial 100 W amplifier, using a class A, B, or AB design, usually employs transistors big enough to dissipate the full 100 W, and the circuit is likely to be <10% energy efficient in normal use. In contrast, *switching amplifiers,* class D, E, or F, use the techniques of power electronics. They provide dramatic efficiency improvements. A home theater system implemented with switching amplifiers can exceed 90% energy efficiency in a small package. The amplifiers can even be packed inside the loudspeakers.

Switches can reach extreme power levels, far beyond what might be expected for a given size. Consider the following examples:

Example 1.1 The NTP30N20 is a metal-oxide-semiconductor field-effect transistor (MOSFET) with a drain current rating of 30 A, a maximum drain-source breakdown voltage of 200 V, and a rated power dissipation of up to 200 W under ideal conditions. Without a heat sink, however, the device can tolerate no more than 2.5 W of dissipation. For power electronics purposes, the power handling rating is $30\ \text{A} \times 200\ \text{V} = 6\ \text{kW}$. Several manufacturers have developed controllers for domestic refrigerators, air conditioners, and high-end machine tools based on this and similar devices. The second part of the definition of power electronics in Section 1.1 points out that the circuits handle power at levels much higher than that of the ratings of individual devices. Here, a device is used to handle 6000 W—compared with its individual rating of no more than 200 W. The ratio 30:1 is high, but not unusual in power electronics contexts. In contrast, the same ratio in a "linear" audio amplifier is close to unity.

Example 1.2 The IGW60T120 is an insulated-gate bipolar transistor (IGBT)—a relative of the bipolar transistor that has been developed specifically for power electronics—rated for 1200 V and 60 A. Its power handling rating is 72 kW that is sufficient for a set of them to control an electric or hybrid car.

1.2.2 The Reliability Objective—Simplicity and Integration

High-power applications lead to interesting issues. In an inverter, the semiconductors often manipulate 30 times their power dissipation capability or more, which implies that only about 3% of the power being controlled is lost. A small design error, unexpected thermal problem, or minor change in layout could alter this somewhat. For instance, if the loss turns out to be 4% rather than 3%, the device stresses are 33% higher, and quick failure is likely to occur. The first issue for reliability in power electronic circuits is to keep device voltage, current, and power dissipation levels well within rating limits. This is challenging when power handling levels are high.

The second issue for reliability is simplicity. It is well established in electronics design that the more parts there are in a system, the more likely it is to fail. Power electronic circuits tend to have few parts, especially in the main energy flow paths. Necessary operations must be carried out through shrewd use of these parts. Often, this means that sophisticated control strategies are applied to seemingly simple conversion circuits.

The third issue for reliability is integration. One way to avoid the reliability-complexity trade-off is to integrate multiple components and functions together. A microprocessor, for example, might contain millions of gates. All interconnections and signals flow within a single chip, and the reliability is nearly that of a single part. Integrated power electronic modules [6] achieve this. Manufacturers package multiple switching devices, with their interconnections and protection components, together as a unit. Control circuits for converters are also integrated as much as possible to keep the reliability high. The package itself is a factor in reliability, and one that is a subject of active research. Many semiconductor packages include small bonding wires that can be susceptible to thermal or vibration damage. The small geometries also tend to enhance electromagnetic interference among the internal circuit components.

1.3 Trends in Power Supplies

Two distinct trends drive electronic power supplies, one of the major classes of power electronic circuits. At the high end, microprocessors, memory chips, and other advanced digital circuits require increasing power levels and increasing performance at very low voltage. It is a challenge to deliver 100 A or more efficiently at voltages that can be less than 1 V. These types of power supplies are expected to deliver precise voltages, even though the load can change by an order of magnitude in nanoseconds.

At the other end are portable devices with rechargeable batteries. The power supplies for these devices and for other consumer products must be cheap and efficient. It is increasingly important to use the best possible power electronics design techniques for these supplies to save energy while minimizing costs and matching many different global standards. Efficiency standards such as the Energy Star program place stringent requirements on a wide range of low-end power supplies.

In the past, bulky "linear" power supplies were designed with transformers and rectifiers from the ac line frequency to provide dc voltages for electronic circuits. In a well-designed power electronic system today, called a *switch-mode power supply*, an ac source from a wall outlet (which could be nearly anywhere in the world) is rectified without direct transformation. The resulting high dc voltage is converted through a dc-dc converter to the 1, 3, 5, and 12 V or other levels required. A personal computer commonly requires multiple 3.3 and 5 V supplies, 12 V supplies, additional levels, and a separate converter for 1 V delivery to the microprocessor. This is in addition to supplies for the video display or peripheral devices. Only a switch-mode supply can support such complex requirements with acceptable costs.

Switch-mode supplies often take advantage of MOSFET semiconductor technology. Trends toward high reliability, low cost, and miniaturization have reached the point where a 5 V power supply sold today might last more than 1,000,000 h (more than a century), provide 100 W of output in a package with volume no more than 15 cm^3, and sell for a price less than US$ 0.10/W. This type of supply brings an interesting dilemma: the ac line cord to plug it in takes up more space than the power supply itself. Innovative concepts such as integrating a power supply within a connection cable or using a block the size of a typical plug are becoming common.

Device technology for power supplies is being driven by expanding needs in the automotive and telecommunication industries and in markets for portable equipment. Power conversion for transportation must be cost effective yet rugged enough to survive the high vibration and wide temperature range to which a truck or passenger car is exposed. Global communication is possible only when sophisticated equipment can be used almost anywhere. Electricity supplies are neither reliable nor consistent throughout much of the world. Although voltage swings in the domestic ac supply in North America are often ±5% around a nominal value, in many developing nations, the swing can be ±25%—when power is available. Power converters for communications equipment must tolerate these swings and must also be able to make use of a wide range of possible backup sources. Designers are challenged to obtain maximum performance from small batteries and to create equipment with minimal energy requirements with power supplies that can operate anywhere in the world.

1.4 Conversion Examples

1.4.1 Single-Switch Circuits

Electrical energy sources take the form of dc voltage sources at various values, sinusoidal ac sources and polyphase sources, among others. A power electronic circuit might be asked to transfer energy between two different dc voltage levels, between an ac source and a dc load or between sources at different frequencies. It might be used to adjust an output voltage or power level, drive a nonlinear load, or control a load current. In this section, a few basic converter arrangements are introduced, and energy conservation provides a tool for analysis.

Example 1.3 Consider the circuit shown in Fig. 1.4. It contains an ac source, a switch, and a resistive load. It is a simple power electronic system.

Let us assign a (somewhat arbitrary) control scheme to the switch. What if the switch is turned on whenever $V_{ac} > 0$ and turned off otherwise? The input and output voltage waveforms are shown in Fig. 1.5. The input has a time average of 0 and root-mean-square (RMS) value equal to $V_{peak}/\sqrt{2}$,

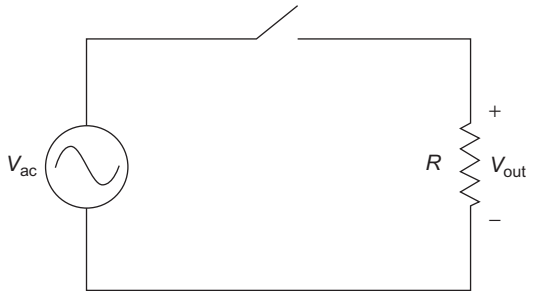

FIG. 1.4 A simple power electronic system. (From P. T. Krein, Elements of Power Electronics, Oxford University Press, New York, 1998, Copyright 1998, Oxford University Press, used with permission.)

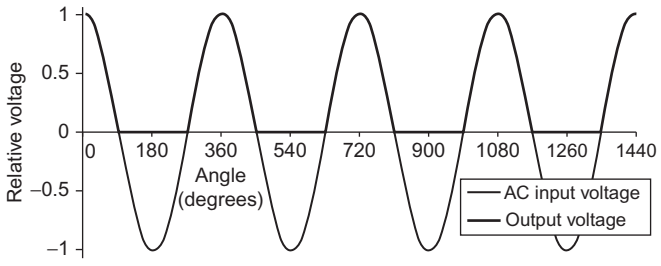

FIG. 1.5 Input and output waveforms for Example 1.5.

where V_{peak} is the maximum value of V_{ac}. The output has a nonzero average value given by

$$\langle v_{out}(t)\rangle = \frac{1}{2\pi}\left(\int_{-\pi/2}^{\pi/2} V_{peak}\cos\theta\,d\theta + \int_{\pi/2}^{3\pi/2} 0\,d\theta\right) = \frac{V_{peak}}{\pi} = 0.3183\,V_{peak} \tag{1.1}$$

and an RMS value equal to $V_{peak}/2$. Since the output has nonzero dc voltage content, the circuit can be used as an ac-dc converter. To make it more useful, a low-pass filter would be added between the output and the load to smooth out the ac portion. This filter needs to be lossless and will be constructed from only inductors and capacitors.

The circuit in Example 1.3 acts as a half-wave rectifier with a resistive load. With the hypothesized switch action, a diode can substitute for the ideal switch. The example confirms that a simple switching circuit can perform power conversion functions. But note that a diode is not, in general, the same as an ideal switch. A diode places restrictions on the current direction, but a true switch would not. An ideal switch allows control over whether it is on or off. In contrast, a diode's operation is constrained by circuit variables.

Consider a second half-wave circuit, now with a series $L-R$ load, shown in Fig. 1.6:

Example 1.4 A series diode $L-R$ circuit has ac voltage source input. This circuit operates much differently than the half-wave rectifier with resistive load. A diode will be on if forward-biased and off if reverse-biased. In this circuit, when the diode is off, the current will be zero. Whenever the diode is on, the circuit is the ac source with $L-R$ load. Let the ac voltage be $V_0\cos(\omega t)$. From Kirchhoff's voltage law (KVL),

$$V_0\cos(\omega t) = L\frac{di}{dt} + Ri.$$

Let us assume that the diode is initially off (this assumption is arbitrary, and we will check it as the example is solved). If the diode is off, the diode current is $i=0$, and the voltage across the diode will be v_{ac}. The diode will become forward-biased when v_{ac} becomes positive, so it will turn on when the input voltage makes a zero crossing in the positive direction. This allows us to establish initial conditions for the circuit, $i(t_0)=0, t_0=-\pi/(2\omega)$. The differential equation can be solved in a conventional way to give

$$i(t) = V_0\left[\frac{\omega L}{R^2+\omega^2L^2}\exp\left(\frac{-t}{\tau}-\frac{\pi}{2\omega\tau}\right) + \frac{R}{R^2+\omega^2L^2}\cos(\omega t) + \frac{\omega L}{R^2+\omega^2L^2}\sin(\omega t)\right] \tag{1.2}$$

where τ is the time constant L/R. What about when the diode is turned off? The first guess might be that the diode turns off when the voltage becomes negative, which is not correct. From the solution, we can determine that the current is not zero when the voltage first becomes negative. If the switch attempts to turn off, it must instantly drop the inductor current to zero. The derivative of current in the inductor, di/dt, would become negative infinite. The inductor voltage $L(di/dt)$ similarly becomes negative infinite, and the devices are destroyed. What really happens is that the falling current allows the inductor to maintain forward bias on the diode. The diode will turn off only when the *current* reaches zero. A diode has definite properties that determine the circuit action, and both the voltage and current are relevant. Fig. 1.7 shows the input and output waveforms for a time constant τ equal to about one-third of the ac waveform period.

1.4.2 The Method of Energy Balance

Any circuit must satisfy conservation of energy. In a lossless power electronic circuit, energy is delivered from source to load, possibly through an intermediate storage step. The energy flow must balance over time such that the energy drawn from the source matches that delivered to the load. The converter in Fig. 1.8 serves as an example of how the method of energy balance can be used to analyze circuit operation.

Example 1.5 The switches in the circuit of Fig. 1.8 are controlled cyclically to operate in alternation: when the

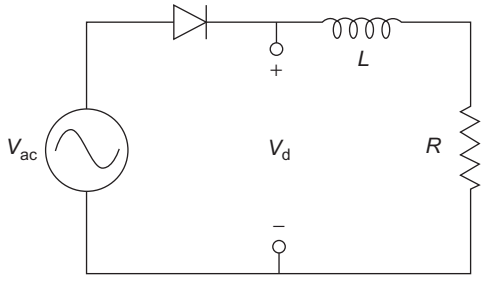

FIG. 1.6 Half-wave rectifier with $L-R$ load for Example 1.5.

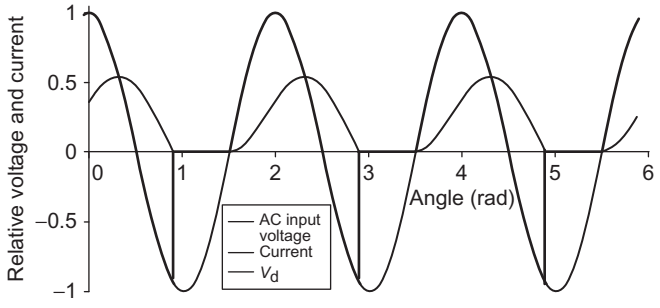

FIG. 1.7 Input and output waveforms for Example 1.5.

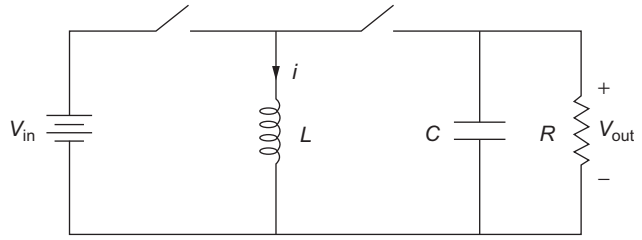

FIG. 1.8 Energy transfer switching circuit for Example 1.5. (From P. T. Krein, Elements of Power Electronics, Oxford University Press, New York, 1998, Copyright 1998, Oxford University Press, Inc., used with permission.)

left switch is on, the right switch is off and so on. What does the circuit do if each switch operates half the time? The inductor and capacitor have large values.

When the left switch is on, the source voltage V_{in} appears across the inductor. When the right switch is on, the output voltage V_{out} appears across the inductor. If this circuit is to be viewed as a useful converter, the inductor should receive energy from the source and then deliver it to the load without loss. Over time, this means that energy does not build up in the inductor, but instead flows through on average. The power into the inductor, therefore, must equal the power out, at least over a cycle. Therefore, the *average* power in must equal the *average* power out of the inductor. Let us denote the inductor current as i. The input is a constant voltage source. Because L is large, this constant voltage source will not be able to change the inductor current quickly, and we can assume that the inductor current is also constant. The average power into L over the cycle period T is

$$P_{in} = \frac{1}{T}\int_0^{T/2} V_{in} i \, dt = \frac{V_{in} i}{2}. \tag{1.3}$$

For the average power out of L, we must be careful about current directions. The current *out* of the inductor will have a value $-i$. The average output power is

$$P_{out} = \frac{1}{T}\int_{T/2}^{T} -i V_{out} \, dt = -\frac{V_{out} i}{2} \tag{1.4}$$

For this circuit to be viewed useful as a converter, the net energy should flow from the source to the load over time. The power conservation relationship $P_{in} = P_{out}$ requires that $V_{out} = -V_{in}$.

The method of energy balance shows that, when operated as described in the example, the circuit shown in Fig. 1.8 serves as a polarity reverser. The output voltage magnitude is the same as that of the input, but the output polarity is negative with respect to the reference node. The circuit is often used to generate a negative supply for analog circuits and other applications from a single positive input source. Other output voltage magnitudes can be achieved at the output if the switches alternate at unequal times.

If the inductor in the polarity reversal circuit is moved instead to the input, a step-up function is obtained. Consider the circuit shown in Fig. 1.9 in the following example.

Example 1.6 The switches shown in Fig. 1.9 are controlled cyclically in alternation. The left switch is on for two-thirds of each cycle and the right switch for the remaining one-third of each cycle. Determine the relationship between V_{in} and V_{out}. The inductor's energy should not build up when the circuit is operating normally as a converter.

A power balance calculation can be used to relate the input and output voltages. Let i be the inductor current. When the left switch is on, power is injected into the inductor. Its average value is

$$P_{in} = \frac{1}{T}\int_0^{2T/3} V_{in} i \, dt = \frac{2V_{in} i}{3}. \tag{1.5}$$

Power leaves the inductor when the right switch is on. Care must be taken with respect to polarities, and the current should be set negative to represent output power. The result is

$$P_{out} = \frac{1}{T}\int_{2T/3}^{T} -(V_{in} - V_{out}) i \, dt = -\frac{V_{in} i}{3} + \frac{V_{out} i}{3}. \tag{1.6}$$

When the input and output power are equated,

$$\frac{2V_{in} i}{3} = -\frac{V_{in} i}{3} + \frac{V_{out} i}{3}, \quad \text{and} \quad 3V_{in} = V_{out} \tag{1.7}$$

and the output voltage is found to be triple the input. Many seasoned engineers find the dc-dc step-up function shown in Fig. 1.9 to be surprising. It is just one example of such action, though. Others (including flyback circuits related to Fig. 1.8) are used in systems ranging from controlled power supplies to spark ignitions for automobiles.

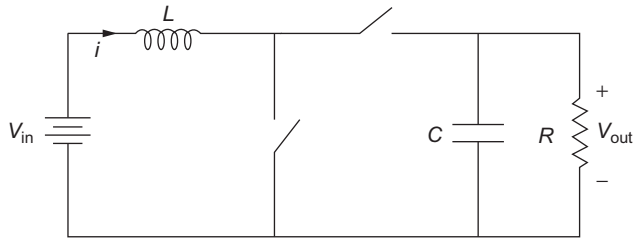

FIG. 1.9 Switching converter Example 1.6. (From P. T. Krein, Elements of Power Electronics, Oxford University Press, New York, 1998, Copyright 1998, Oxford University Press, used with permission.)

The circuits in the preceding examples have few components, provide useful conversion functions, and are efficient. If the switching devices are ideal, each circuit is lossless. Over the history of power electronics, development has tended to flow around the discovery of such circuits: a circuit with a particular conversion function is discovered, analyzed, and applied. As the circuit moves from laboratory testing to a complete commercial product, control and protection functions are added. The power portion of the circuit remains close to the original idea. The natural question arises as to whether a systematic approach to conversion is possible: can we start with a desired function and design an appropriate converter, rather than starting from the converter and working backward toward the application? What underlying principles can be applied to design and analysis? In this chapter, a few of the key concepts are introduced. Note that, although many of the circuits look deceptively simple, all these circuits are nonlinear systems with unusual behavior.

1.5 Tools for Analysis and Design

1.5.1 The Switch Matrix

The most readily apparent difference between a power electronic circuit and other types of electronic circuits is the switch action. In contrast to a digital circuit, the switches do not indicate a logic level. Control is effected by determining the times at which switches should operate. Whether there is just one switch or a large group, there is a complexity limit: if a converter has m inputs and n outputs, even the densest possible collection of switches would have a single switch between each input and output line. The $m \times n$ switches in the circuit can be arranged according to their connections. The pattern suggests a matrix, as shown in Fig. 1.10.

Power electronic circuits fall into two broad classes [2]:

1. Direct switch matrix circuits. In these circuits, energy storage elements are connected to the matrix only at the input and output terminals. The storage elements effectively become part of the source or the load. In the literature, ac-ac versions of these circuits are sometimes called *matrix converters.*
2. Indirect switch matrix circuits, also termed *embedded* converters. These circuits, like the polarity-reverser example, have energy storage elements connected *within* the matrix structure. Indirect switch matrix circuits are most commonly analyzed as a cascade connection of direct switch matrix circuits with storage in between.

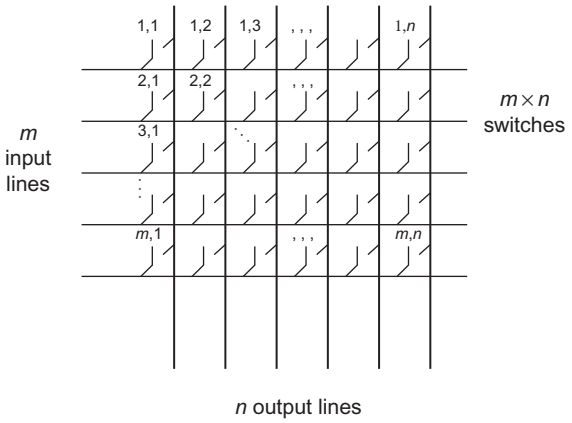

FIG. 1.10 The general switch matrix.

The switch matrices in realistic applications are small. A 2×2 switch matrix, for example, covers all possible cases with a single-port input source and a two-terminal load. The matrix is commonly drawn as the *H-bridge* shown in Fig. 1.11. A three-phase bridge rectifier is shown in Fig. 1.12. There are three possible inputs, and the two terminals of the dc circuit provide outputs, which gives a 3×2 switch matrix. In a computer power supply with five separate dc loads, the switch matrix could be 2×10. Very few practical converters have more than 24 switches, and most designs use fewer than 12.

A switch matrix provides a way to organize devices for a given application. It also helps us focus on three major task

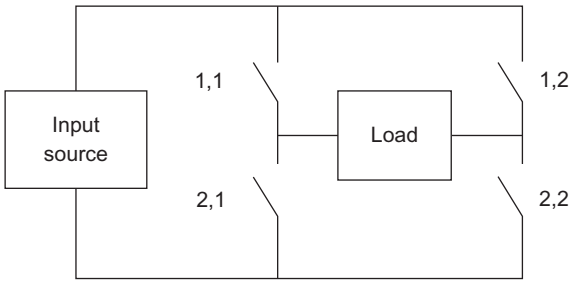

FIG. 1.11 H-bridge configuration of a 2×2 switch matrix.

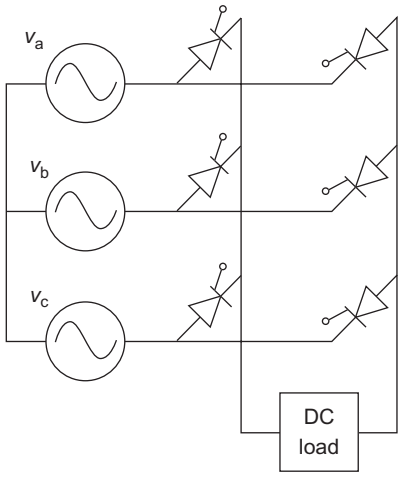

FIG. 1.12 Three-phase bridge rectifier circuit, a 3×2 switch matrix.

areas, which must be addressed individually and effectively in order to produce a useful power electronic system:

- The "hardware" task—Build a switch matrix. This involves the selection of appropriate semiconductor switches and the auxiliary elements that drive and protect them.
- The "software" task—Operate the matrix to achieve the desired conversion. All operational decisions are implemented by adjusting switch timing.
- The "interface" task—Add energy storage elements to provide the filters or intermediate storage necessary to meet the application requirements. Lossless filters with simple structures are required.

In a rectifier or other converter, we must choose the electronic parts, how to operate them, and how best to filter the output to satisfy the needs of the load.

1.5.2 Implications of Kirchhoff's Voltage and Current Laws

A major challenge of switch circuits is their capacity to "violate" circuit laws. First, consider the simple circuits shown in Fig. 1.13. We might try the circuit shown in Fig. 1.13A for ac-dc conversion, but there is a problem. According to Kirchhoff's voltage law (KVL), the "sum of voltage drops around a closed loop is zero." However, with the switch closed, the sum of voltages around the loop is not zero. In reality, this is not a valid result. Instead, a very large current will flow and cause a large $I \cdot R$ drop in the wires. KVL *will* be satisfied by the wire voltage drop, but a fire or, better yet, fuse action, might result. There is, however, nothing that would prevent an operator from trying to close the switch. KVL, then, implies a crucial restriction: a switch matrix must not attempt to interconnect unequal voltage sources directly. Notice that a wire or dead short can be thought of as a voltage source with $V = 0$, so KVL is a generalization of avoiding shorts across an individual voltage source.

A similar constraint holds for Kirchhoff's current law (KCL) that states that "currents into a node must sum to zero." When current sources are present in a converter, we must avoid any attempts to violate KCL. In Fig. 1.13B, if the current sources are different and if the switch is opened, the sum of the currents into the node will not be zero. In a real circuit, high voltages will build up and cause an arc to create another current path. This situation has real potential for damage, and a fuse will not help. As a result, KCL implies the restriction that a switch matrix must not attempt to interconnect unequal current sources directly. An open circuit can be thought of as a current source with $I = 0$, so KCL applies to the problem of opening an individual current source.

In contrast to conventional circuits, in which KVL and KCL are automatically satisfied, switches do not "know" KVL or KCL. If a designer forgets to check and accidentally shorts two voltages or breaks a current source connection, some problem or damage will result. KVL and KCL place necessary constraints on the operation of a switch matrix. In the case of voltage sources, switches must not act to create short-circuit paths among unlike sources. In the case of KCL, switches must act to provide a path for currents. These constraints drastically reduce the number of valid switch-operating conditions in a switch matrix, thereby leading to manageable operating design problems.

When energy storage is included, there are interesting implications of the circuit law restrictions. Fig. 1.14 shows two "circuit law problems." In Fig. 1.14A, the voltage source will cause the inductor current to ramp up indefinitely, since $V = L\mathrm{d}i/\mathrm{d}t$. We might consider this to be a "KVL problem" because the long-term effect is similar to shorting the source. In Fig. 1.14B, the current source will cause the capacitor voltage to ramp toward infinity. This causes a "KCL problem"; eventually, an arc will be formed to create an additional current path, just as if the current source had been opened. However, these connections are not problematic if they are only temporary. It should be evident that an inductor will not support dc voltage, and a capacitor will not support dc current. On average, over an extended time interval, the voltage across an inductor must be zero, and the current into a capacitor must be zero.

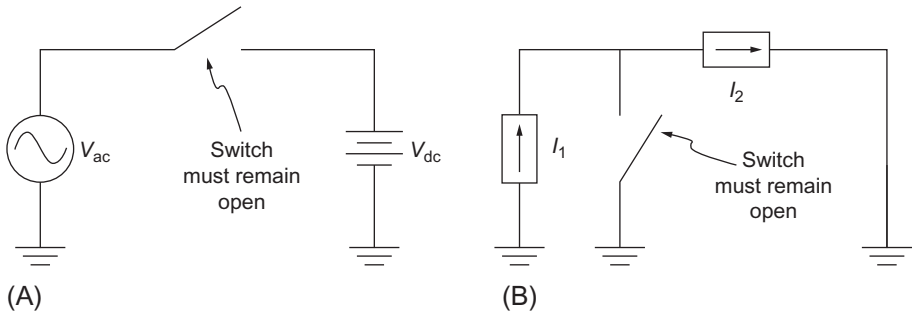

FIG. 1.13 Hypothetical power converters, (A) possible ac-dc converter and (B) possible dc-dc converter. (From P. T. Krein, Elements of Power Electronics, Oxford University Press, New York, 1998, Copyright 1998, Oxford University Press, used with permission.)

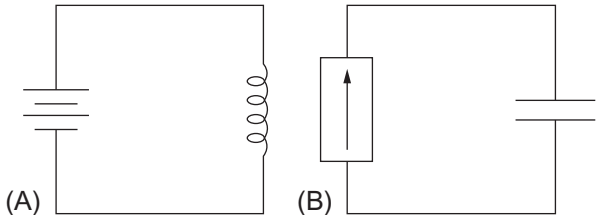

FIG. 1.14 Short-term KVL and KCL problems in energy storage circuits: (A) An inductor cannot sustain dc voltage indefinitely, and (B) a capacitor cannot sustain dc current indefinitely.

1.5.3 Resolving the Hardware Problem—Semiconductor Devices

A switch is either on or off. When on, an ideal switch will carry any current in any direction. When off, it will never carry current, no matter what voltage is applied. It is entirely lossless and changes from its on-state to its off-state instantaneously. A *real switch* can only approximate an ideal switch. The following are the aspects of real switches that differ from the ideal:

- Limits on the amount and direction of on-state current.
- A nonzero on-state voltage drop (such as a diode forward voltage).
- Some levels of leakage current when the device is supposed to be off.
- Limitations on the voltage that can be applied when off.
- Operating speed. The duration of transition between the on-states and off-states is important.

The degree to which the properties of an ideal switch must be met by a real switch depends on the application. For example, a diode can easily be used to conduct dc current; the fact that it conducts only in one direction is often an advantage, not a weakness.

Many different types of semiconductors have been applied in power electronics. In general, these fall into three groups:

1. Diodes, which are used in rectifiers, dc-dc converters, and in a wide range of supporting roles.
2. Transistors, which in general are suitable for control of single-polarity circuits. Several types of transistors are applied to power converters. The insulated-gate bipolar transistor (IGBT) type is unique to power electronics and has good characteristics for applications such as inverters.
3. Thyristors, which are multijunction semiconductor devices with latching behavior. In general, thyristors can be switched with short pulses and then maintain their state until current is removed. The characteristics are especially well suited to high-power controllable rectifiers, but they have been applied to all power conversion applications.

Some of the features of the most common power semiconductors are listed in Table 1.1. The table shows a wide variety of speeds and rating levels. As a rule, faster speeds apply to lower ratings. For each device type, cost tends to increase both for faster devices and for devices with higher power handling capacity.

TABLE 1.1 Examples of semiconductor devices used in power electronics

Device type	Characteristics of power devices
Diode	Current ratings from under 1 A to more than 5000 A. Voltage ratings from 10 V to 10 kV or more. The fastest power devices switch in <10 ns, whereas the slowest require 100 μs or more. The function of a diode applies in rectifiers and dc-dc circuits
BJT	(Bipolar junction transistor) Conducts collector current (in one direction) when sufficient base current is applied. The function applies to dc-dc circuits. Power BJTs for switching have been supplanted by FETs and IGBTs
FET	(Field-effect transistor) Conducts drain current when sufficient gate voltage is applied. Power FETs (nearly always enhancement-mode MOSFETs) have a parallel connected reverse diode by virtue of their construction. Ratings from about 0.5 A to about 150 A and 20 V up to 1200 V. Switching times are fast, from 20 ns or less up to 200 ns. The function applies to dc-dc conversion, where the FET is in wide use, and to inverters
IGBT	(Insulated-gate bipolar transistor) A transistor that has the function of a BJT with its base driven by an FET. Faster than a BJT of similar ratings and easy to use. Ratings from 10 A to more than 600 A, with voltages of 600–4500 V. The IGBT is common in inverters from about 1–200 kW or more. It is found almost exclusively in power electronic applications
SCR	(Silicon-controlled rectifier) A thyristor that conducts like a diode after a gate pulse is applied. Turns off only when current becomes zero. Prevents current flow until a pulse appears. Ratings from 10 A up to more than 5000 A and from 200 V up to 6 kV. Switching requires 1–200 μs. Widely used for controlled rectifiers. The SCR is found almost exclusively in power electronic applications and is the most common member of the thyristor family
GTO	(Gate turn-off thyristor) An SCR that can be turned off by sending a negative pulse to its gate terminal. The ratings approach those of SCRs, and the speeds are similar as well
TRIAC	A semiconductor constructed to resemble two SCRs connected in reverse parallel. Ratings from 2 to 50 A and 200–800 V. Used in lamp dimmers, home appliances, and hand tools. Not as rugged as many other device types, but convenient for many ac applications
IGCT	(Integrated gate-commutated thyristor) A combination device that includes a high-power GTO and external electronics to control it. This device is a member of a larger family of combination devices, in which multiple semiconductor chips packaged together perform a single power function. The IGCT provides a high-performance switch for power levels above 1 MW

Conducting direction and blocking behavior are fundamentally tied to the device type, and these basic characteristics constrain the choice of device for a given conversion function. Consider again a diode. It carries current in only one direction and always blocks current in the other direction. Ideally, the diode exhibits no forward voltage drop or off-state leakage current. Although an ideal diode lacks the many features of an

ideal switch, it is an important switching device. Other real devices operate with polarity limits on current and voltage and have corresponding ideal counterparts. It is convenient to define a special type of switch to represent this behavior, the *restricted switch*:

> **Definition** A restricted switch is an ideal switch with the addition of restrictions on the direction of current flow and voltage polarity. The ideal diode is one example of a restricted switch.

The diode always permits current flow in one direction, while blocking flow in the other direction. It therefore represents a *forward-conducting reverse-blocking* restricted switch and operates in one quadrant on a graph of device current versus voltage. This *unipolar* function is automatic; the two diode terminals provide all the necessary information for switch action. Other restricted switches require a third *gate*-terminal to determine their state. Consider the polarity possibilities given in Table 1.2. Additional functions such as bidirectional-conducting reverse-blocking can be obtained by reverse connection of one of the five types in the table.

The quadrant operation shown in the table indicates polarities. For example, the current in a diode will be positive when on, and the voltage will be negative when off. This means diode operation is restricted to the single quadrant comprising the upper vertical (current) axis and the left horizontal (voltage) axis. Other combinations appear in the table. Symbols for restricted switches can be built up by interpreting the diode's triangle as the current-carrying direction and the bar as the blocking direction. Five types of symbols can be drawn as shown in Table 1.2. These symbols are used infrequently but are useful for showing the polarity behavior of switching devices. A circuit drawn with restricted switches represents an idealized power converter.

TABLE 1.2 The types of restricted switches

Action	Device	Quadrants	Restricted switch symbol	Device symbol
Carries current in one direction, blocks in the other (forward-conducting reverse-blocking)	Diode			
Carries or blocks current in one direction (forward-conducting forward-blocking)	BJT, IGBT			
Carries in one direction or blocks in both directions (forward-conducting bidirectional-blocking)	GTO			
Carries in both directions but blocks only in one direction (bidirectional-conducting forward-blocking)	FET			
Fully bidirectional	Ideal switch			

Restricted switch concepts guide the selection of devices. For example, consider an inverter intended to deliver ac load current from a dc voltage source. A switch matrix built to perform this function must be able to manipulate ac current and dc voltage. Regardless of the physical arrangement of the matrix, we would expect bidirectional-conducting forward-blocking switches to be useful for this conversion. This is a correct result: modern inverters operating from dc voltage sources are built with field effect transistors (FETs) or with IGBTs packaged with reverse-parallel diodes. As new power devices are introduced to the market, it is straightforward to determine what types of converters will use them.

1.5.4 Resolving the Software Problem—Switching Functions

The physical $m \times n$ switch matrix can be associated with a mathematical $m \times n$ *switch state matrix*. Each element of this matrix, called a *switching function*, shows whether the corresponding physical device is on or off:

> **Definition** A *switching function*, $q(t)$, has a value of 1 when the corresponding physical switch is on and 0 when it is off. Switching functions are discrete-valued functions of time, and control of switching devices can be represented with them.

Fig. 1.15 shows a typical switching function. It is periodic, with period T, representing the likely repetitive switch action in a power converter. For convenience, it is drawn on a relative time scale that begins at 0 and draws out the square wave period by period. The actual timing is arbitrary, so the center of the first pulse is defined as a specified time t_0 in the figure. In many converters, the switching function is generated as an actual control voltage signal that might drive the gate of an FET or IGBT.

The timing of switch action is the only alternative for control of a power converter. Because switch action can be represented with a discrete-valued switching function, timing can be

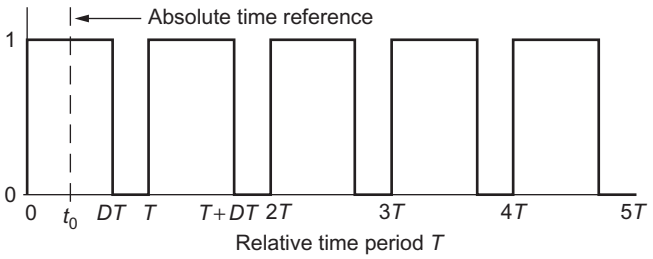

FIG. 1.15 A generic switching function with period T, duty ratio D, and time reference t_0.

represented within the switching function framework. On the basis of Fig. 1.15, a generic switching function can be characterized completely with three parameters:

1. The *duty ratio*, D, is the fraction of time during which the switch is on. For control purposes, the on-time interval or pulse width can be adjusted to achieve a desired result. We can term this adjustment process *pulse-width modulation* (PWM), perhaps the most important process for implementing control in power converters.
2. The frequency $f_{\text{switch}} = 1/T$ (with radian frequency $\omega = 2\pi f_{\text{switch}}$) is most often constant, although not in all applications. For control purposes, frequency can be adjusted. This strategy is sometimes used in low-power-dc-dc converters to manage wide load ranges. In other converters, frequency control is unusual because the operating frequency is often dictated by the application.
3. The time delay t_0 or phase $\varphi_0 = \omega t_0$. Rectifiers often use *phase control* to provide a range of adjustment. Phase-shifted bridge circuits are common for high-power dc-dc conversion. A few specialized ac-ac converter applications use phase modulation.

With just three parameters to vary, there are relatively few possible ways to control any power electronic circuit. Inverters and dc-dc converters usually rely on duty ratio adjustment (PWM) to alter their behavior. Phase control is common in controlled rectifier applications.

Switching functions are powerful tools for the general representation of converter action [7]. The most widely used control approaches derive from averages of switching functions [2,8]. Their utility comes from their application in writing circuit equations. For example, in the boost converter shown in Fig. 1.9, the loop and node equations change depending on which switch is acting at a given moment. The two possible circuit configurations each have distinct equations. Switching functions allow them to be combined. By assigning switching functions $q_1(t)$ and $q_2(t)$ to the left- and right-switching devices, respectively, we obtain

$$\begin{aligned} &q_1\left(V_{\text{in}} - L\frac{\mathrm{d}i_L}{\mathrm{d}t} = 0\right), \\ &q_1\left(C\frac{\mathrm{d}v_C}{\mathrm{d}t} + \frac{v_C}{R} = 0\right), \text{ left switch on} \end{aligned} \tag{1.8}$$

$$\begin{aligned} &q_2\left(V_{\text{in}} - L\frac{\mathrm{d}i_L}{\mathrm{d}t} = v_C\right), \\ &q_2\left(C\frac{\mathrm{d}v_C}{\mathrm{d}t} + \frac{v_C}{R} = i_L\right), \text{ right switch on} \end{aligned} \tag{1.9}$$

Because the switches alternate and the switching functions must be 0 or 1, these sets of equations can be combined to give

$$V_{\text{in}} - L\frac{\mathrm{d}i_{\text{L}}}{\mathrm{d}t} = q_2 v_{\text{C}}, \quad C\frac{\mathrm{d}v_{\text{C}}}{\mathrm{d}t} + \frac{v_{\text{C}}}{R} = q_2 i_{\text{L}} \tag{1.10}$$

The combined expressions are simpler and easier to analyze than the original equations.

For control purposes, the average of equations such as Eq. (1.10) often proceeds with the replacement of switching functions q with duty ratios d. The discrete-time action of a switching function thus will be represented by an average duty ratio parameter. Switching functions, advantages gained by averaging, and control approaches such as PWM are discussed at length in several chapters in this handbook.

1.5.5 Resolving the Interface Problem—Lossless Filter Design

Lossless filters for power electronic applications are sometimes called smoothing filters [9]. In applications in which dc outputs are of interest, such filters are commonly implemented as simple low-pass LC structures. The analysis is facilitated because in most cases the residual output waveform, termed ripple, has a predictable shape. Filter design for rectifiers or dc-dc converters is a question of choosing storage elements large enough to keep ripple low, but not so large that the whole circuit becomes unwieldy or expensive.

Filter design is more challenging when ac outputs are desired. In some cases, this is again an issue of low-pass filter design. However, in many applications, low-pass filters are not adequate to meet low noise requirements. In these situations, active filters can be used. In power electronics, the term active filter refers to lossless switching converters that actively inject or remove energy moment by moment to compensate for distortion. The circuits (discussed in Chapter 41—active filters in this handbook) are not related to the linear active filter op-amp circuits used in analog signal processing. In ac applications, there is a continuing opportunity for innovation in filter design.

1.6 Sample Applications

Although power electronics is becoming universal for electronic systems, a few emerging applications have generated wide interest. Some are discussed briefly here to introduce the breadth of activity in the field.

A hybrid or fully electric vehicle typically has two major power electronic systems and dozens or even hundreds of smaller ones [10]. The two large units are the inverter, which controls the electric drive motor, and a rectifier, which manages battery charging. Smaller systems include motor controllers in electric power-steering units, lighting electronics for solid-state lamps, controllers for small motors that actuate everything from windshield wipers to DVD players, and power supplies for the host of microcontrollers embedded in a modern car. As plug-in hybrid and electric cars continue to develop, the efficiency and sophistication of battery chargers and drive motor controllers will increase.

In a hybrid car, a typical inverter rating is about 50 kW. Fully electric automobiles have inverter ratings to about 200 kW. Hybrid and electric drive power levels increase from there to include multimegawatt inverters that power high-speed trains.

At the other power extreme, designers have been working on small power electronic systems that extract energy from various ambient sources for local purposes [11]. These energy harvesting applications are an emerging growth area. An example application is a corrosion sensor, built into a highway bridge that gathers energy from vibration. The vibration energy is converted and stored and then used for intermittent communication with a central monitoring computer. Typical power levels can be less than 0.001 W.

Solar, wind, and other alternative energy resources are tightly linked to power electronics. A typical solar panel produces about 30 V dc, with tolerances from 20 to 40 V or more. This randomly changing dc source must be converted to clean, tightly regulated ac voltage that synchronizes to the electricity grid and delivers energy. Solar inverter efficiency, reliability, and cost are major factors in successful energy innovation. A dual application, meaning that energy flows in the opposite direction but that many other characteristics are shared, is that of solid-state lighting [12]. In that case, flexible control of a dc current must be provided from an ac grid source.

For wind energy [13], a typical large-scale wind turbine can produce 2 MW of variable-frequency ac power. The frequency and voltage vary rapidly according to wind speed. This power must be converted to fixed frequency and voltage for grid interconnection.

1.7 Summary

Power electronics is the study of electronic circuits for the control and conversion of electrical energy. The technology is a critical part of our energy infrastructure and is central for a wide range of uses of electricity. For power electronics design, we consider only those circuits and devices that, in principle, introduce no loss and achieve near-perfect reliability. The two key characteristics of high efficiency and high reliability are implemented with switching circuits, supplemented with energy storage. Switching circuits can be organized as switch matrices. This facilitates their analysis and design.

In a power electronic system, the three primary challenges are the hardware problem of implementing a switch matrix, the software problem of deciding how to operate that matrix, and the interface problem of removing unwanted distortion and providing the user with the desired clean power source. The hardware is implemented with a few special types of power semiconductors. These include several types of transistors, especially FETs and IGBTs, and several types of thyristors, especially SCRs and GTOs. The software problem can be represented in terms of switching functions. The frequency, duty ratio, and phase of switching functions are available for operational purposes. The interface problem is addressed by means of lossless filter circuits. Most often, these are lossless LC passive filters to smooth out ripple or reduce harmonics. Active filter circuits also have been applied to make dynamic corrections in power conversion waveforms.

Improvements in devices and advances in control concepts have led to steady improvements in power electronic circuits and systems. This is driving tremendous expansion of applications. Personal computers, for example, would be unwieldy and inefficient without power electronic dc supplies. Mobile devices and laptop computers would be impractical. High-efficiency lighting, motor controls, and a wide range of industrial controls depend on power electronics. Strong growth is occurring in transportation applications, in lighting, in dc power supplies for portable devices, in high-end converters for advanced microprocessors, and in alternative and renewable energy. During the next generation, we will reach a time when almost all electrical energy is processed through power electronics somewhere in the path from generation to end use [14].

2.1 Semiconductor Diode

Understanding a semiconductor diode makes possible to understand other complex devices. A semiconductor diode is a structure containing a PN junction that, within its voltage and current rates, allows the conduction of current only in one direction. If the P region experiences a higher potential compared with the region N, the diode is said to be forward-biased, and a current can flow through the diode. On the other hand, if the region N experiences a higher voltage compared with the region P, the diode is said to be reversed-biased. In this case, no current flows through the diode. Fig. 2.1 shows a simplified illustration of such a diode structure.

The regions P and N are united by a metallurgical connection. When a negative voltage is applied between the PN junctions, this voltage appears at the depletion area due to the fact that this area presents higher resistance compared with the rest of the structure. Such voltage makes the electrons in the N region to travel to the P region and vice versa, creating a so-called potential barrier, which, in turn, defines the size of the depletion area. The potential barrier opposes the electron and hole movements across the junction. The potential is approximately 0.7 and 0.3 V for silicon and germanium diodes, respectively, and it is defined as threshold voltage [1].

When a positive voltage higher than the threshold is applied between the PN junctions, the potential barrier is reduced, minimizing the depletion area, and the carriers are free to conduct through the regions, leading the diode to be forward-biased.

Diodes in electric circuits are represented by the symbol depicted in Fig. 2.2. The terminals of the diode are known as anode (A) that corresponds to the P region and cathode (K) that corresponds to the N region. The conventional current

and voltage references through a diode are also shown. The electron flow is in the opposite direction related to the current reference.

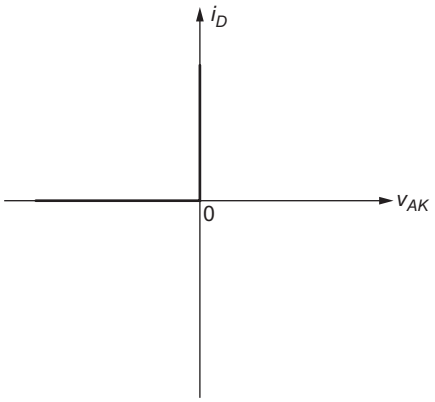

FIG. 2.3 Static characteristic of an ideal diode.

2.1.1 Static Characteristics

The static characteristic of an ideal diode is portrayed in Fig. 2.3. For voltages $v_{AK} > 0$, the diode conducts with current i_F under null voltage. Consequently, the diode can be represented as a short circuit. For voltages $v_{AK} < 0$, the diode holds a negative voltage, and it does not conduct any current. Therefore, the diode can be represented by an open circuit.

The use of an ideal diode in analyzing circuits is accepted in power electronic applications, since it is necessary only to know if the diode is forward- or reversed-biased. However, in applications where a deeper analysis is required, it is necessary to consider the diode real features. Fig. 2.4A presents the static characteristic of a real diode. The characteristic curve is not on scale for better visualization. The first quadrant is the region where the diode is forward-biased. In this case, the diode is in ON state. The third quadrant is the region of reverse bias. Thus, the diode is in OFF state. Fig. 2.4B presents a more realistic diode structure with its layers length.

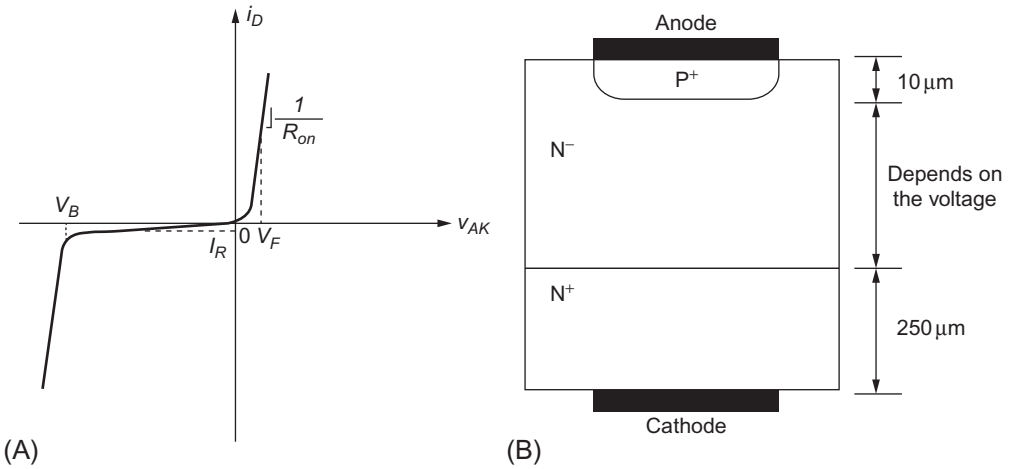

FIG. 2.4 (A) Static characteristic of a real diode and (B) more realistic diode structure.

The following details can be highlighted from the previous chart [2]:

- *Forward voltage, V_F*: The voltage drop across the diode, from terminal *A* to *K*, at a specific current when the diode is forward-biased.
- *Breakdown voltage, V_B*: The maximum reverse voltage across the diode before the diode starts reverse conduction and gets severe damaged. The point at *Vb* is also known as avalanche point.
- *Reverse current I_R*: The current at a particular reverse voltage. This current is usually in the range of μA and hardly taken into account in analysis of power electronic circuits.
- *Conduction resistance R_{ON}*: The equivalent resistance presented by the diode when forward-biased and conducting current. The inverse of this resistance is the slope of the curve in forward region. This characteristic is more relevant in high-voltage devices in which the semiconductor length is larger.

A more complete diode model, during conduction, is shown in Fig. 2.5.

2.1.2 Dynamic Characteristics

The static characteristics of a diode are valid for analysis in steady-state condition, with the diode completely in the state ON or OFF. For the period when the diode is changing between these states, the diode presents a dynamic behavior. Fig. 2.6 presents the circuit used to analyze the turn-on and turn-off characteristic of a power diode. The turn-on process is defined by the change from the OFF to ON state, while the turn-off process is the change from ON to OFF state. The voltage source is supposed to produce a square waveform. The inductor represents the inductive effect of the circuit (ration of the magnetic flux and current) that is present in any electric circuit. The inductance value can be very low, depending on the circuit topology, but can have an important rule to limit the di/dt.

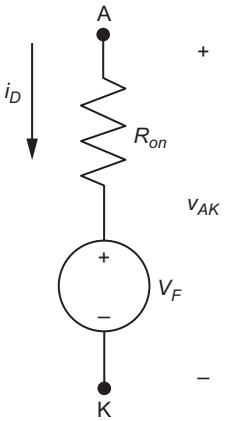

FIG. 2.5 Equivalent circuit of a real diode when forward-biased.

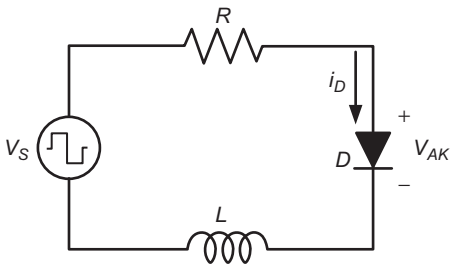

FIG. 2.6 Circuit used to analyze the switching characteristic of a power diode.

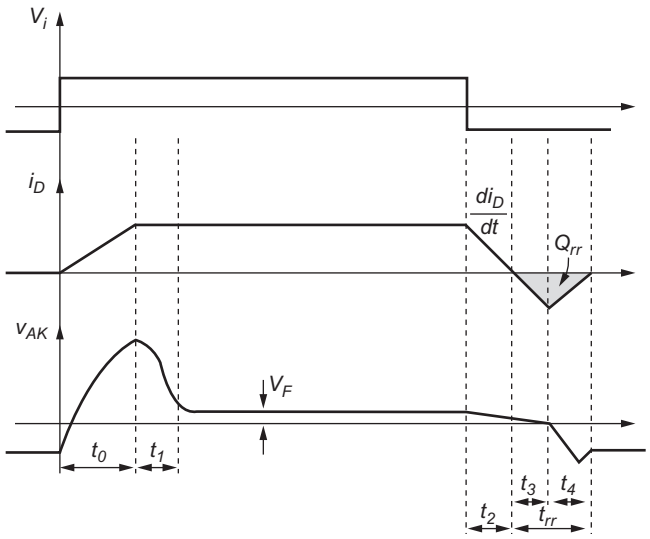

FIG. 2.7 Typical dynamic behavior for the voltage and current of a diode during the turn-on and turn-off periods.

Fig. 2.7 presents a typical dynamic behavior for the voltage and current of a diode during the turn-on and turn-off intervals. The waveform can change slightly from diode to diode and based on intrinsic properties and also if the circuit contains inductive load.

The time intervals highlighted in the figure are defined as follows:

- *Time interval t_0*: The time interval t_0 begins when the voltage source changes its value from negative to positive, initializing the turn-on process. During t_0, the storage charges in the depletion area are removed. The diode current begins to rise, while the diode voltage suffers a peak due to the fact that there is no enough injection of carriers into the depletion area and also due to the resistance of the N region.
- *Time interval t_1*: At this interval, the injection of carriers is completed, and the diode voltage falls to the forward voltage. In power diodes, the intervals t_0 and t_1 are in the range of ten to hundreds of nanoseconds. At the end of t_1, the turn-on process is completed.

- *Time interval* t_2: The interval t_2 begins when the voltage source changes in value from positive to negative, initializing the turn-off process. The minority carriers (electrons in P region and holes in N region) must be removed before the formation of the potential barrier, during such time the diode keeps conducting. The diode voltage falls slightly due to the fall in the resistance R_{ON}.
- *Time interval* t_3: The interval t_3 keeps the behavior of the previous interval, but the diode current is achieving negative current. When the current achieves its negative peak, the minority carriers were reversed, and the diode begins to be reversed-biased.
- *Time interval* t_4: The interval t_4 is the time required for the current to achieve null value, recharging the depletion area. The voltage across de diode suffers an overvoltage mainly due to the parasitic inductances found in the circuit.
- *Time interval* t_{rr}: The time interval t_{rr} is the sum of the intervals t_3 and t_4 and it is known as reverse recovery time. The area under the t-axis in the current waveform is equivalent to the so-called reverse recovery charge.

The reverse recovery time is an important parameter to decide the switching frequency of applications involving diodes. The reverse recovery time must finish before the diode can be forward-biased again. The lower the t_{rr} is, the faster the diode can be switched. Diodes with low reverse recovery time are known as fast diodes or sometimes ultrafast diodes.

Another important feature concerning reverse recovery process is how severe the diode current behaves during the reverse recovery time. For this purpose, the terms soft- and hard-recovery diodes are used. Soft-recovery diodes present slow current fall, while hard-recovery diodes present fast current fall. A slow current fall is more attractive because the voltage produced at the parasitic inductances is lower compared with other case.

2.1.3 Common Types of Diodes

Diodes can be classified into the following major types [2,3]:

Small signal diode: This type of diode has a niche of application in low-power rectifiers, limiters, amplifiers, and in waveshaping. These applications are low-voltage, low-current devices. Forward voltage, reverse breakdown voltage, and reverse recovery current and time are parameters that must be known by a designer when applying small signal diode in power electronic applications.

Power rectifier diode: This type of diode has high forward current and high reverse breakdown voltage capabilities. They are suited for power applications like rectifiers, inverters, and power supplies. The thermal resistance is an important factor for a designer, since these diodes usually require heat sink for heat dissipation.

Zener diode: This type of diode is mainly used in voltage regulation. It operates on the reverse-biased mode. A current called zener current conducts through it in order to clamp the voltage. The behavior on the breakdown voltage is designed to support the dissipation without damaging the device.

Schottky diodes: The aforementioned diodes have an ohmic behavior in the contact between the metal terminal and the semiconductor. Schottky diodes are formed by allocating a thin film of metal directly to the semiconductor material. As result, the behavior in the referred region has a rectifier effect. The forward voltage drop in Schottky diodes is usually 0.3 V, and they are used in low-voltage applications.

2.1.4 Evaluating the Dynamic Characteristics of Real Diodes

In order to visualize how is the real reverse recovery behavior of some types of diodes, the circuit shown in Fig. 2.8 was built. The circuit is composed by a square-wave source. A fast diode (SK3GL04), a slow rectifier diode (1N5404), and a Schottky diode (1N5818) are connected in the circuit through the switches Sw1, Sw2, and Sw3, respectively. A resistor R is used as load. Switch Sw4 is used to insert or remove an inductor in the circuit. Initially, this switch Sw4 is ON, bypassing the inductor. Each diode is analyzed individually in the circuit.

Fig. 2.9 shows the current of each diode during the turn-off process. For the fast and Schottky diodes, the reverse recovery time is in the range of 2–3 μs. For the slow rectifier diode, the time is approximately 10 μs, and the reserve recovery charge is considerably higher than those for the other diodes. The negative current is limited by the external resistance. It is clear that the rectifier diode can be used only in low-frequency applications with low *dv/dt*, as in 50 and 60 Hz AC systems.

Fig. 2.10 shows the current and voltage in the small signal diode when the switch Sw_4 is OFF, inserting the inductor in the circuit. Both waveforms oscillate during the reverse recovery time. The oscillation in the voltage may lead the diode to be forward-biased improperly if its value reaches higher value than the threshold.

2.1.5 Series and Parallel Connection of Power Diodes

Two important parameters of power diodes concerning voltage ratings are repetitive peak inverse voltage (V_{RRM}) and nonrepetitive peak inverse voltage. The first states about the capability of the diode in holding reverse voltage in a sustained manner.

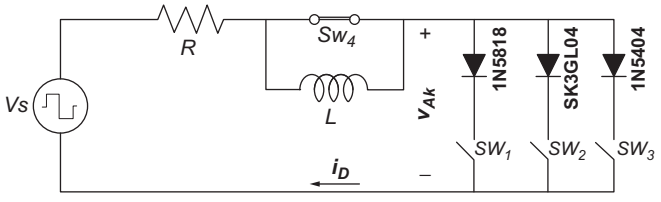

FIG. 2.8 Circuit used to evaluate the real reverse recovery behavior of diodes.

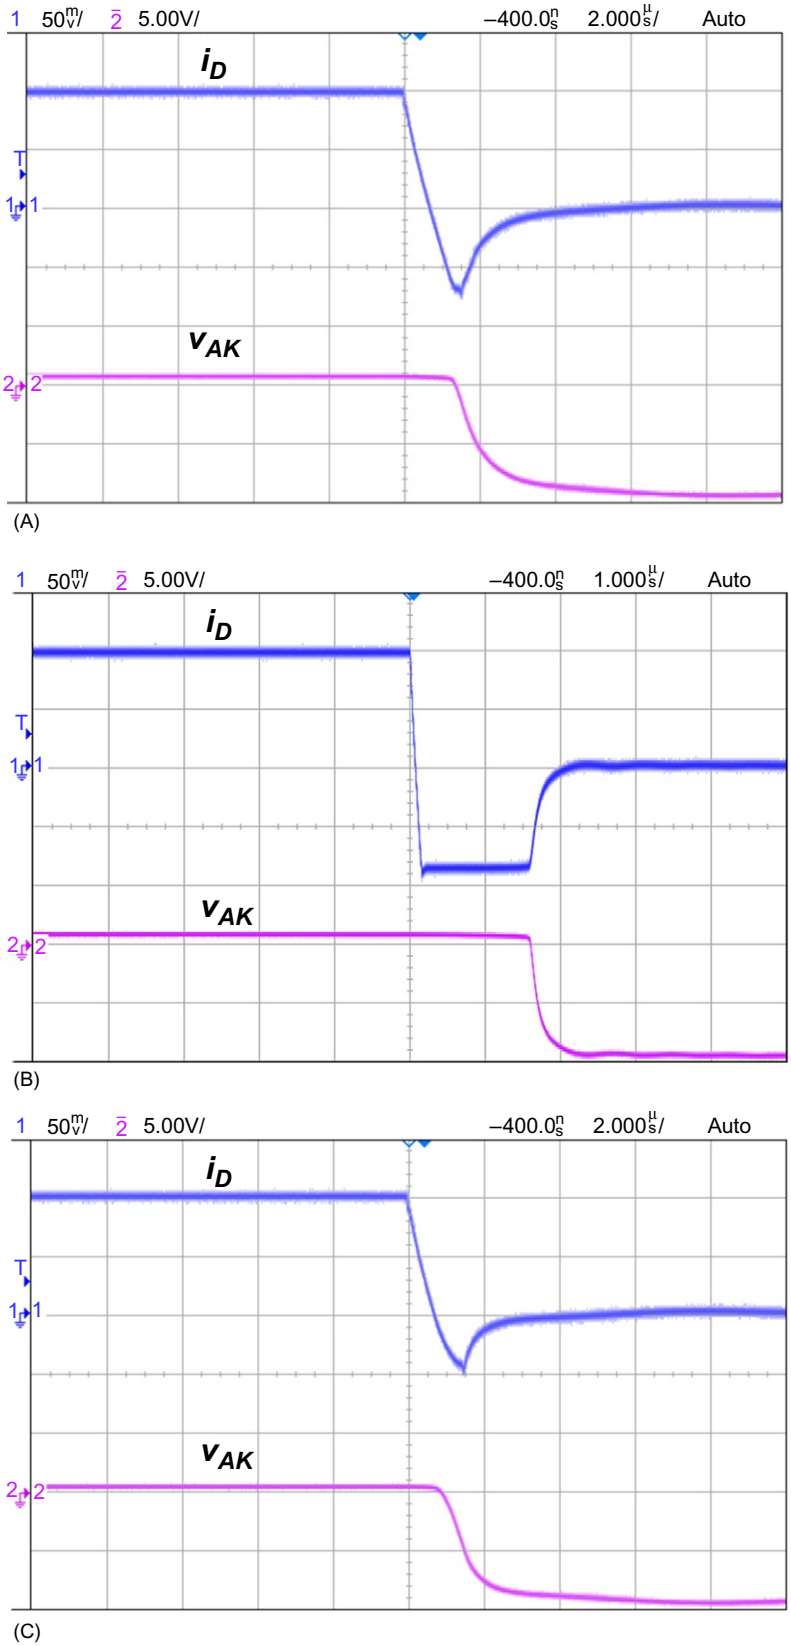

FIG. 2.9 Current of each diode during the turn-off process. (A) SK3GL04 (fast diode) SW1 is ON, (B) 1N5404 (rectifier) SW2 is ON, and (C) 1N5818 (Schottky) SW3 is ON.

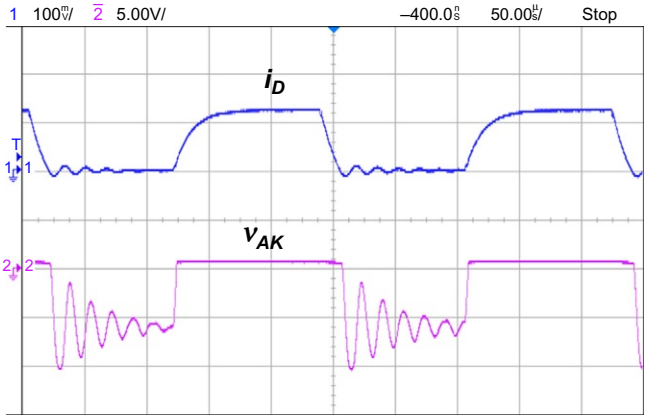

FIG. 2.10 Current and voltage in the small signal diode when the switch *Sw4* is OFF.

The second is the capability of the diode in holding reverse voltage that occurs occasionally.

Concerning current rating, power diodes have the following parameters: average current, RMS current, and peak current. These parameters vary in accordance to the diode temperature. Therefore, by properly dissipating the heat of a diode, the current capability is better utilized.

When an application requires current or voltage ratings that is beyond its capability, parallel or series shall be considered. Connecting diodes in series gives a structure with high-voltage rating, once the voltage will be divided among them. On the other hand, connecting diodes in parallel allows a high-current rating, once the current is divided among the diodes. The major concern in making series or parallel connection is to match their parameters, especially in reverse recovery properties. Otherwise, voltage and current unbalance may occur among the diodes.

In order to overcome such unbalance in series connection, a bank of resistor and capacitor is placed in parallel with the diode string. Fig. 2.11 presents the series connection of diodes with banks of resistor and capacitors. During the transitions, the capacitors equalize the voltage. During the OFF state, the resistive path equally divides the total voltage. The current through the resistor must be higher than the diode reverse leakage current [2].

The A–K points are the terminals of a fictitious high-voltage capacity diode. Ideally, when reverse-biased, the reverse voltage is dived equally among the three diodes.

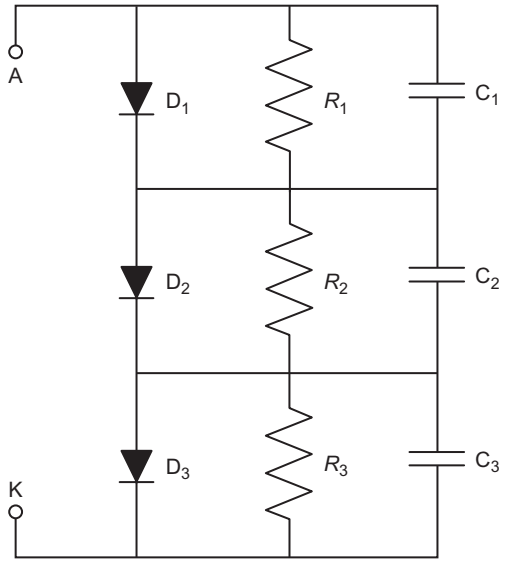

FIG. 2.11 Series connection of diodes with resistor and capacitors for equalization.

The parallel connection of diodes is intended to divide a current equally through the diodes. However, if one diode turns on before the others, the entire current passes through it. Such occurrence may destroy the diode. In order to overcome that, a resistor can be connected in series with each diode. The resistor limits the current in case one diode turns on before the others. Including a resistor is series with each diode decreases considerably the efficiency of the circuit.

For both parallel and series connection of diodes, a special attention must be paid concerning the construction of the printed circuit board (PCB) layout. Parasitic inductances can cause a diode to be forward-biased before the other. Therefore, the layout must be designed aiming an equal parasitic inductance in the path where diodes are being associated in parallel and series.

2.1.6 Typical Application of Diodes

2.1.6.1 Rectifiers

Diodes are widely used as rectifiers. Fig. 2.12 presents the half- and full-wave single-phase rectifiers. An input transformer (not

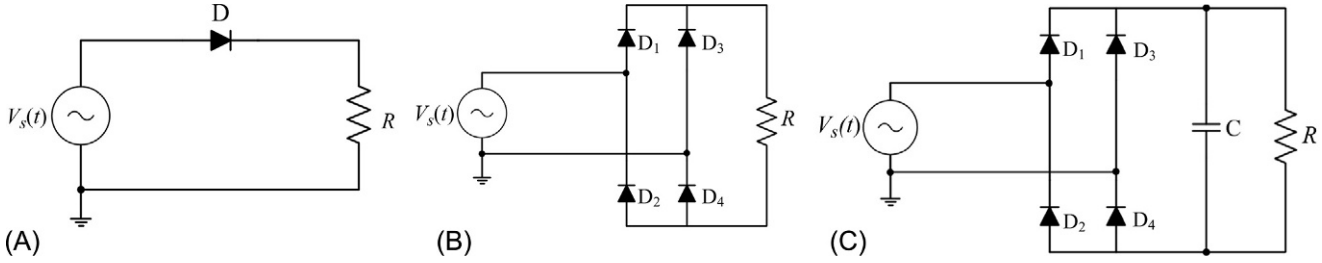

FIG. 2.12 (A) Half-wave rectifier, (B) full-wave rectifier, and (C) full-wave rectifier with capacitor.

shown) can be placed at the input of rectifiers for isolation and voltage leveling purpose. The use of a half-wave rectifier is exclusively for low-power applications, once the average input current is not zero. A capacitor can be used at the output of full-wave rectifier in order to minimize the voltage ripple.

The diodes make only the positive voltage to appear across the load. Fig. 2.13 presents the output voltage for the half-wave, full-wave, and full-wave rectifier with capacitor. In this case, the diodes are considered ideal with no forward voltage drop.

2.1.6.2 Freewheeling

A diode can be used as a freewheeling path for keeping an inductor current conducting continuously. Fig. 2.14 presents a DC–DC converter where the diode operates as freewheeling path. The switch represents a transistor. Without the diode, the inductor would cause an extremely high *dv/dt* across it when the transistor changes from ON to OFF state. Such high *dv/dt* would appear across the transistor, probably destructing it. However, the diode allows a path to the inductor current avoiding high *dv/dt*. The voltage produced by the inductor current will be high enough to directly polarize the diode. In this converter, this voltage is just higher than the output voltage. The transistor and the diode are considered ideal.

Fig. 2.15 presents the inductor current, the transistor current, and the diode current. Notice that the inductor current passes through the transistor when this is ON and through the diode when the transistor is OFF.

2.1.6.3 Voltage Multiplier

Fig. 2.16 presents a voltage multiplier circuit with the output voltage four times higher than the amplitude of the input voltage, neglecting the diode voltage drops. This circuit is used when a higher voltage compared with the input is required. The transformer in this case is used only for isolation.

2.1.7 PSPICE Model

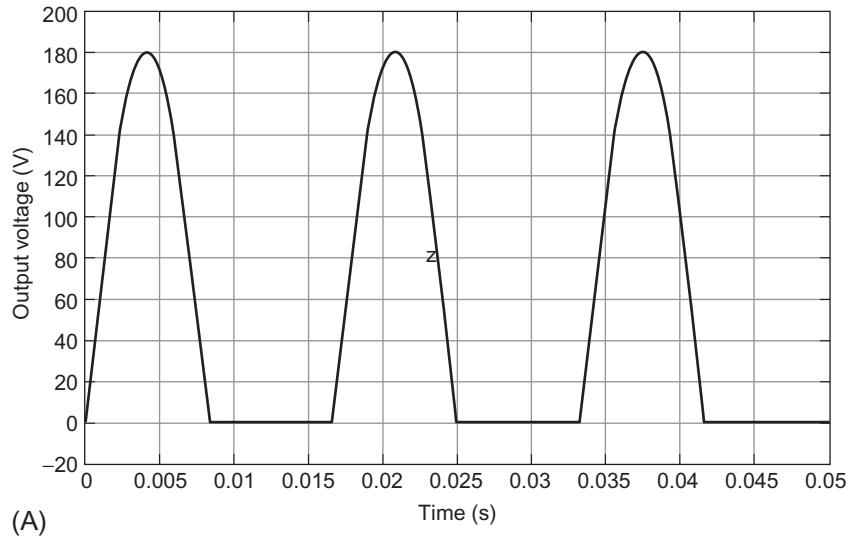
SPICE is a general-purpose circuit platform that can be used to simulate electronic and electric circuits [4]. SPICE was originally developed at the Electronics Research Laboratory of the University of California, Berkeley (1975). The name stands for simulation program for integrated circuits emphasis. A circuit must be specified in terms of element names, element values, nodes, variable parameters, and sources. SPICE can do several types of circuit analyses:

- Nonlinear DC analysis, calculating the DC transference
- Nonlinear transient analysis—calculates signals as a function of time
- Linear AC analysis—computes the Bode plots as a function of frequency
- Noise analysis
- Sensitivity analysis
- Distortion analysis
- Fourier analysis
- Monte Carlo analysis

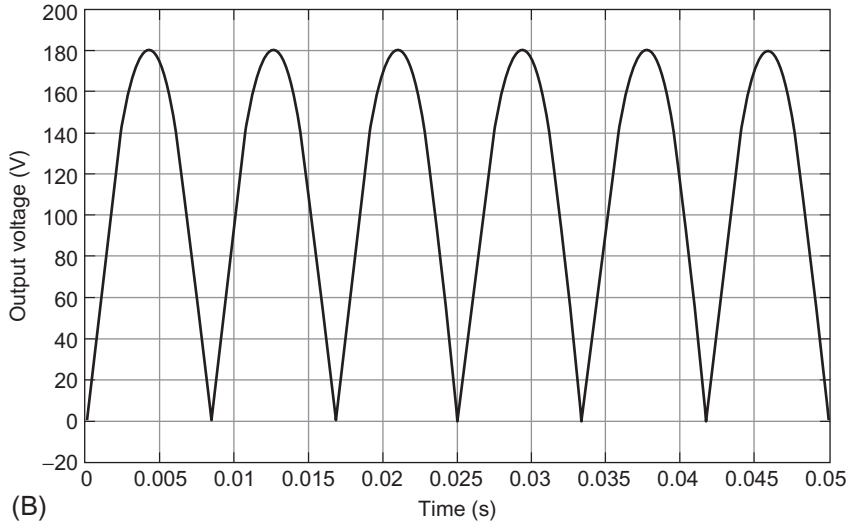
In addition, PSPICE has analog and digital libraries of standard components such as operational amplifiers, digital gates, and flip-flops. This makes it a useful tool for a wide range of analog and digital applications. An input file, called source file, consists of three parts: (1) data statements, with description of the components and the interconnections; (2) control statements, which tells SPICE what type of analysis to perform; and (3) output statements, with specifications that outputs are to be printed or plotted. Two other statements are required: the title statement and the end statement. The title statement is the first line and can contain any information, while the end statement is always .END. In addition, there are also comment statements that must begin with an asterisk (*) and are ignored by SPICE.

A set of device model parameters is defined on a separate .MODEL card and assigned to a unique model name. Parameter values are defined by appending the parameter name, followed by an equal sign and its value. Model parameters without specific value are assigned the default values.

As an example, the model parameter for the Schottky diode 1N5818 is given by the following text:



```
.MODEL 1N5818 D (IS=263u RS=73.1m BV=30.0 IBV=1.00m+
CJO=203p M=0.333 N=1.90 TT=4.32u )
```



The definition of each parameter is given in Table 2.1. The description of the parameter is beyond the scope of this chapter.

The designer will have to decide, depending on the application or the study, if he or she should use of a more or a less sophisticated model of diodes in their circuit simulation.

2.2 Power Bipolar Transistor

The first transistor was created in 1948 by a team of physicists at the Bell Telephone Laboratories and soon became a semiconductor device of major importance. In addition of becoming an important switch for power electronic applications, all microprocessors, microcontrollers, and FPGAs have in their microelectronic design a transistor to implement the required logic circuits. Before the transistor was developed, amplification was achieved with vacuum tubes or magnetic devices. Even though there are now integrated circuits with millions of transistors, the flow and control of all the electric energy still require single transistors. Therefore, power semiconductor switches constitute the heart of modern power electronics. Depending on the application, such devices should have larger voltage or current ratings, instant turn-on and turn-off characteristics, very low-voltage drop when fully on, zero leakage current in blocking condition, and ruggedness to switch highly inductive loads, which are measured in terms of the safe operation area (SOA) and reverse-biased second breakdown,

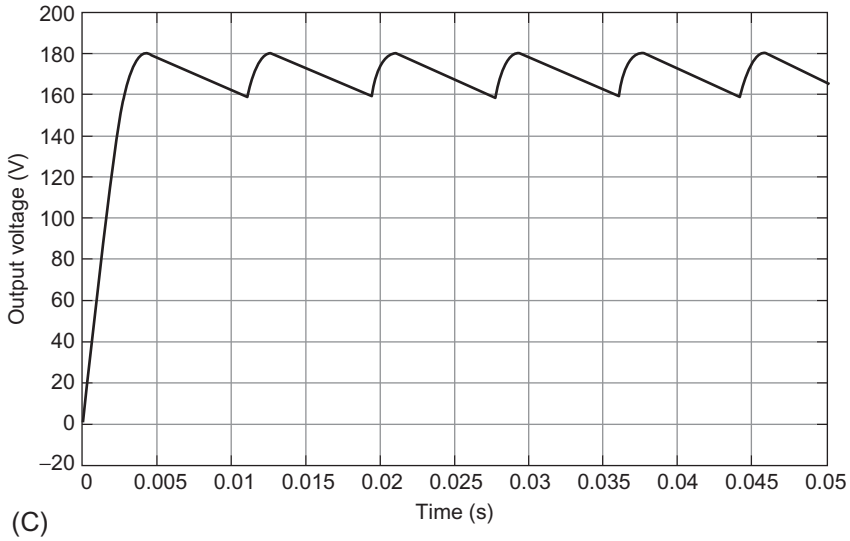


FIG. 2.13 (A) Half-wave rectifier, (B) full-wave rectifier, and (C) full-wave rectifier with capacitor.

high-temperature and radiation capabilities, and high reliability. The right combination of such features restricts the devices suitability to certain applications. High-voltage and high-current ratings permit applications in large motor drives, induction heating, renewable energy inverters, high-voltage DC (HVDC) converters, static reactive energy compensators, and active filters. On the other hand, low-voltage and high-frequency applications concern switching mode power supplies, resonant converters, and motion control systems. Low frequency with high-current and high-voltage devices are restricted to cycloconverter-fed and multimegawatt drives [5,6].

Bipolar junction transistors (BJT) are used to be the traditional component for driving several of those industrial applications. However, insulated gate bipolar transistor (IGBT) and metal-oxide-semiconductor field-effect transistor (MOSFET) technology have progressed so that they are viable replacements for the BJT. However, BJTs still have performance areas in which they may be preferably used, especially when the cost is the main concern.

2.2.1 Basic Structure and Operation

The BJT consists of a three-region structure of N-type and P-type semiconductor materials. It can be constructed as NPN and PNP. Fig. 2.17 shows the physical structure of a planar NPN BJT. The operation is closely related to that of a junction diode where in normal conditions the PN junction between the base and emitter is forward-biased ($V_{BE} > 0$) causing electrons to be injected from the emitter into the base. Since the base region is thin, the electrons travel across it arriving at the reverse-biased base-collector junction ($V_{BC} < 0$) where there is an electric field (depletion region). Upon arrival at this junction, the electrons are pulled across the depletion region and draw into the collector. These electrons flow through the collector region and out the collector contact. Because electrons are negative carriers, their motion constitutes positive current flowing into the external collector terminal. Even though the forward-biased base-emitter junction injects holes from base to emitter, they do not contribute to the collector current, but result in a net current flow component into the base from the external base terminal. Therefore, the emitter current is composed of those two components: electrons destined to be injected across the base-emitter junction and holes injected from the base into the emitter.

The emitter current is exponentially related to the base-emitter voltage according to (2.1):

$$i_E = i_{E0}\left(e^{V_{BE}/\eta V_T} - 1\right) \tag{2.1}$$

where i_E is the saturation current of the base-emitter junction that is a function of the doping levels, temperature, and the area

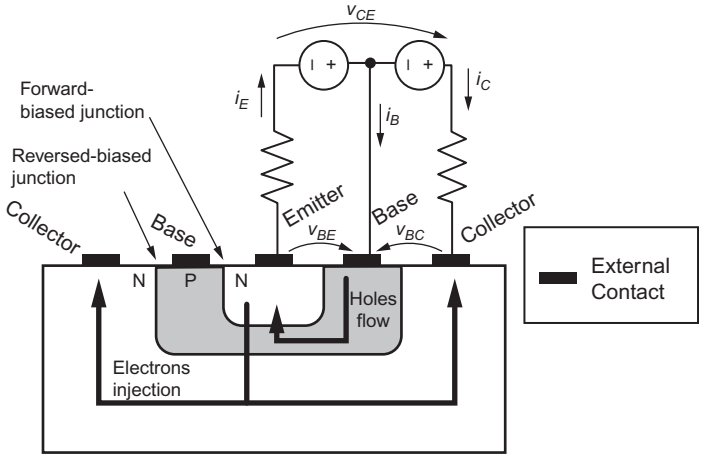

FIG. 2.17 Structure of a planar bipolar junction transistor.

of the base-emitter junction; V_T is the thermal voltage Kt/q; and η is the emission coefficient. The electron current arriving at the collector junction can be expressed as a fraction α of the total current crossing the base-emitter junction as shown in (2.2):

$$i_C = \alpha i_E \tag{2.2}$$

Since the transistor is a three-terminal device, i_E is equal to $i_C + i_B$; hence, the base current can be expressed as the remaining fraction, given by (2.3):

$$i_B = (1-\alpha) i_E \tag{2.3}$$

The collector and base currents are thus related by the ratio given in (2.4):

$$\frac{i_C}{i_B} = \frac{\alpha}{1-\alpha} = \beta \tag{2.4}$$

The values of α and β for a given transistor depend primarily on the doping densities in the base, collector, and emitter regions and on the device geometry. Carrier recombination and temperature also affect the values for both parameters. A power transistor requires a large blocking voltage in the OFF state and a high-current capability in the ON state. A vertically oriented four-layer structure as shown in Fig. 2.18 is preferable because it maximizes the cross-sectional area through which the current flows, reducing the on-state resistance and power dissipation in the device. There is an intermediate collector region with moderate doping. The emitter region is controlled so as to have a homogenous electric field.

Optimization of doping and base thickness is required to achieve high breakdown voltage and amplification capabilities. Power transistors have their emitter and base interleaved to reduce parasitic ohmic resistance in the base current path and also to improve the device for second breakdown failure. The transistor is usually designed to maximize the emitter periphery per unit area of silicon, for the purpose of achieving the highest current gain at a specific current level. In order to ensure those features, transistors have the greatest possible safety margin; they are designed to dissipate substantial power and, thus, have low thermal resistance. It is for this reason, among others, that the chip area must be large and that the emitter periphery per unit area is sometimes not optimized. Most transistor manufacturers use aluminum metallization, since it has many attractive advantages, among these are ease of application by vapor deposition and ease of definition by photolithography. A major problem with aluminum is that only a thin layer can be applied by normal vapor deposition techniques. Thus, when high currents are applied along the emitter fingers, a voltage drop occurs along them, and the injection efficiency on the portions of the periphery that are furthest from the emitter contact is reduced. This limits the amount of current each finger can conduct. If copper metallization is used, then it is possible to reduce the resistance from the emitter contact to the operating regions of the transistors (the emitter periphery).

From a circuit point of view, Eqs. (2.1)–(2.4) are used to relate the variables of the BJT input port (formed by base and emitter) to the output port (collector and emitter). The circuit symbols are shown in Fig. 2.19. Most of the power electronic applications use NPN transistor because electrons move faster than holes, and therefore, NPN transistors have considerable faster commutation times compared with the equivalent PNP transistors.

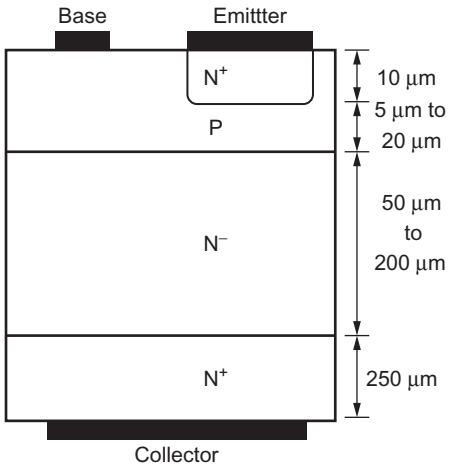

FIG. 2.18 Power transistor vertical structure.

2.2.2 Static Characteristics

The static ratings determine the maximum allowable limits of current and voltage. The absolute voltage limit mechanism is concerned to the avalanche such that thermal runaway does not occur. Forward current ratings are specified at which the junction temperature does not exceed a rated value. Fig. 2.20 shows the base current i_B plotted as a function of the base-emitter voltage V_{BE}. The V_f voltage is around 0.7 V for silicon BJTs.

Fig. 2.21 depicts the collector current i_C as a function of the collector-emitter voltage V_{CE} with i_B as the controlling variable. The curves are distinguished each other by the value of the base

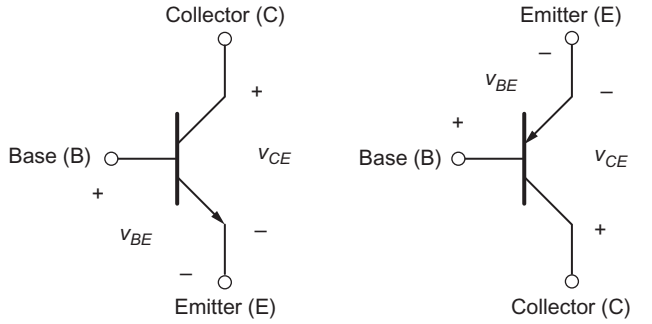

FIG. 2.19 Circuit symbols, (A) NPN transistor and (B) PNP transistor.

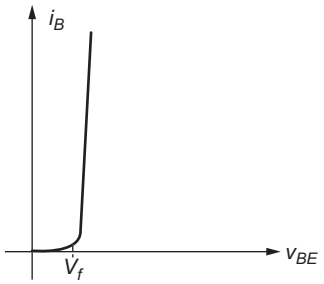

FIG. 2.20 Base current plotted as a function of the base-emitter voltage.

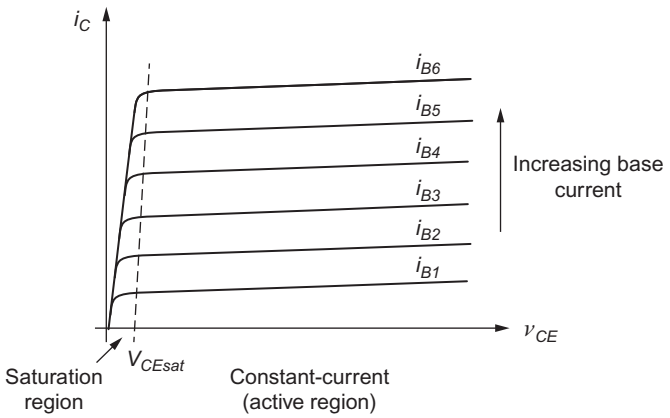

FIG. 2.21 Collector current as a function of the collector-emitter voltage with the base current as the controlling variable.

current. A small base current drives the flow of a much larger current between collector and emitter; such gain called beta (Eq. 2.4) depends upon temperature, V_{CE}, and i_C.

The active region is defined where flat, horizontal portions of voltage-current curves show "constant" i_C current, because the collector current does not change significantly with V_{CE} for a given i_B. Those portions are used for transistors operating as linear amplifiers. In this region, as the voltage and current can present high values, the dissipated power is high. Switching power electronic systems on the other hand requires transistors to operate either in the saturation region where V_{CE} is small or in the cutoff region where the current is zero and the voltage is uphold by the device. In both situations, the dissipated power is low. The crossing of the active region must be as fast as possible to minimize the losses and the consequent temperature increase. The saturation region is characterized by the forward-biased of base-collector junction, and it occurs when $V_{CE} < 0.7V$.

High-voltage BJTs typically have low-current gain, and hence, Darlington-connected devices, as indicated in Fig. 2.22, are commonly used.

Considering gains β_1 and β_2 for each one of those transistors, the Darlington connection will have total gain of $\beta_1 + \beta_2 + \beta_1\beta_2$. Diode D_1 speeds up the turn-off process, by allowing the base driver to remove the stored charge on the T_2 base.

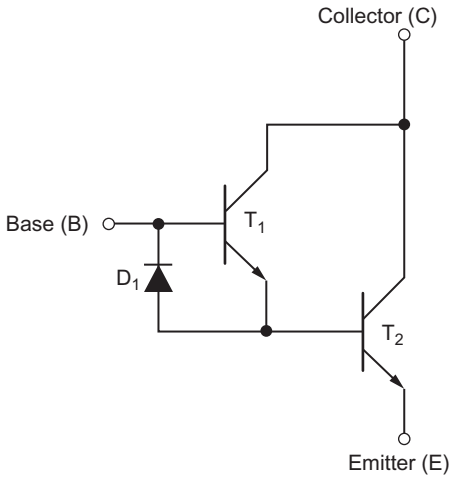

FIG. 2.22 Darlington-connected BJTs.

Vertical-structure power transistors have an additional region of operation called quasi saturation, indicated in the characteristic curve of Fig. 2.23. Such feature is a consequence of the lightly doped collector drift region (N^-) where the collector-base junction supports a low reverse bias. If the transistor enters in the hard-saturation region, the on-state power dissipation is minimized but has to be traded off with the fact that in quasi saturation, the stored charges are smaller. At high collector currents, beta gain decreases with increased temperature, and with quasi-saturation operation, such negative feedback allows careful device paralleling. Two mechanisms on microelectronic level determine the fall off in beta, namely, conductivity modulation and emitter crowding.

Concerning the voltage, there is a region called primary breakdown due to conventional avalanche of the collector-base junction and the attendant large flow of current. The BV_{SUS} is the limit for primary breakdown; it is the maximum collector-emitter voltage that can be sustained across the transistor when it is carrying collector current. The BV_{SUS} is lower than BV_{CEO} or BV_{CBO} that measure the transistor's voltage standoff capability when the base current is zero or negative. The bipolar

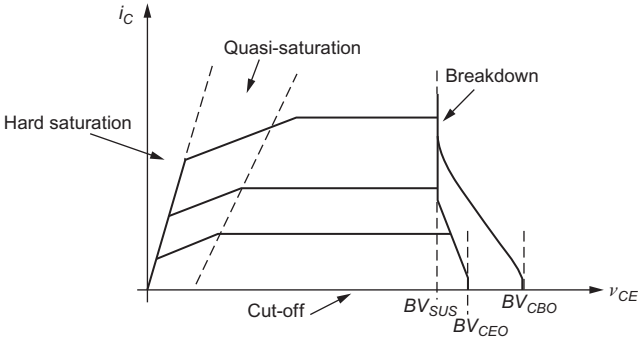

FIG. 2.23 Voltage-current characteristics for a vertical power transistor.

transistor has another potential failure mode called second breakdown, which shows as a precipitous drop in the collector-emitter voltage at large currents. Because the power dissipation is not uniformly spread over the device, but it is rather concentrated on regions, a local gradient of temperature can rise very quickly. Such thermal runaway brings hot spots that can eventually melt and recrystallize the silicon resulting in the device destruction. The key to avoid second breakdown is to (1) keep power dissipation under control, (2) use a controlled rate of change of base current during turnoff, (3) use of protective snubbers circuitry, and (4) position the switching trajectory within the SOA boundaries [2,5,7].

2.2.3 Safe Operation Area

In order to describe the maximum values of current and voltage the transistor should hold, two diagrams are used: the forward-bias safe operating area (FBSOA), known also simply as SOA, given in Fig. 2.24, and the reverse-bias safe operating area (RBSOA) shown in Fig. 2.25.

In the FBSOA, the current I_{CM} is the maximum current of the device; there is a boundary defining the maximum thermal dissipation and a margin defining the second breakdown limitation. Those regions are expanded for switching mode operation. Inductive load generates higher peak energy at turnoff than its resistive counterpart. It is then possible to have a secondary breakdown failure if RBSOA is exceeded.

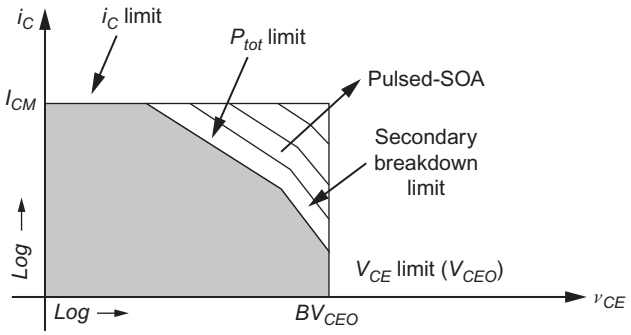

FIG. 2.24 Forward-bias safe operating area (FBSOA).

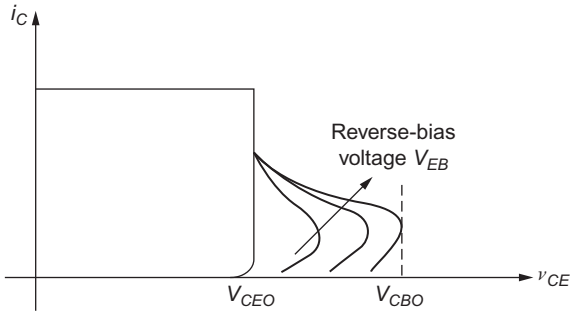

FIG. 2.25 Reverse-bias safe operating area (RBSOA).

A reverse base current helps the cutoff characteristics expanding RBSOA. The RBSOA curve shows that for voltages below V_{CEO}, the safe area is independent of reverse-bias voltage V_{EB} and is only limited by the device collector current, whereas above V_{CEO}, the collector current must be under control depending upon the applied reverse-bias voltage; in addition, temperature effects derate the SOA.

Ability for the transistor to switch high currents reliably is thus determined by its peak power handling capabilities. This ability is dependent upon the transistor's current and thermal density throughout the active region. In order to optimize the SOA capability, the current density and thermal density must be low. In general, it is a hot spot occurring at the weakest area of the transistor that will cause a device to fail due to second breakdown phenomenon. Although a wide base width will limit the current density across the base region, good heat sinking directly under the collector will enable the transistor to withstand high peak power. When the power and heat are spread over a large silicon area, these destructive tendencies are held to a minimum, and the transistor will have the highest SOA capability.

When the transistor is ON, one can ignore the base current losses and calculate the power dissipation on the ON state (conduction losses) by (2.5). Hard saturation minimizes collector-emitter voltage, decreasing on-state losses:

$$P_{ON} = I_C V_{CE(sat)} \tag{2.5}$$

2.2.4 Switching Characteristics

Switching characteristics are important to define the device commutation from conduction (ON) to blocking (OFF) states. Such transition is of paramount importance also because most of the losses are due to high-frequency switching. Fig. 2.26A presents the switching characteristics of a BJT under resistive load. Index "r" refers to the rising time (from 10 to 90% of maximum value); for example, t_{ri} is the current rise time. The falling time is indexed by "f"; the parameter t_f is the current falling time, that is, when the transistor is blocking such time corresponds to crossing from the saturation to the cutoff state. Fig. 2.26B presents operation points over the static characteristic curves. The thicker line indicates the trajectory of how the BJT passes through the cutoff region to the saturation region. Initially, the collector-emitter voltage is equal to VCC. At the end, the BJT is at the saturation region. The BJT passes through the active region in a linear manner.

In order to reduce t_f, the base current for blocking must be negative, and the device must be kept in quasi saturation to minimize the stored charges. The delay time is denoted by t_d, corresponding to the time to discharge the capacitance of base-emitter junction, which can be reduced with a larger current base with high slope. Storage time (t_s) is a very important parameter for BJT transistor. It is the required time to

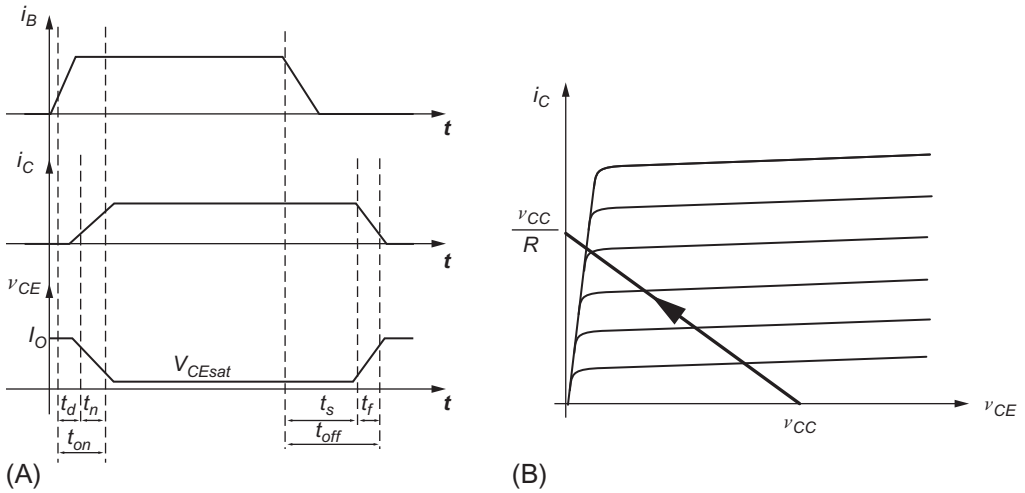

FIG. 2.26 (A) Switching characteristics of a BJT under resistive load and (B) the trajectory over the static characteristic curves under resistive load.

neutralize the minority carriers stored in the collector and base. Storage time and switching losses are key points to deal extensively with bipolar power transistors.

Fig. 2.27 presents switching characteristics of a BJT with inductive load. The waveforms slightly change compared with the previous case. The collector current presents overshoot due to the required reversed recover current of a diode connected across the inductive load. The power waveform is also shown in order to present how the power losses in a transistor. The losses are defined as switching losses and conduction losses. With inductive load, at turn-on, the collector-emitter voltage falls only after the collector current reaches the load current level. At the turnoff, the collector-emitter voltage varies quickly, allowing the collector current to start to decrease. Fig. 2.27B presents the trajectory over the static characteristic curves.

Most advantageous operation in BJT is achieved when fast transitions are optimized. Such requirement minimizes switching losses. Therefore, a good bipolar drive circuit highly influences the transistor performance. A base drive circuit should provide a high forward base drive current (I_{B1}) as indicated in Fig. 2.28 to ensure the power semiconductor turn-on quickly. Base drive current should keep the BJT close to the saturation to minimize forward conduction losses, but a level I_{B2} would maintain the transistor in a quasi-saturation condition, avoiding excess of charges in the base. Controllable slope and reverse current I_{BR} sweeps out stored charges in the transistor base, speeding up the device turnoff.

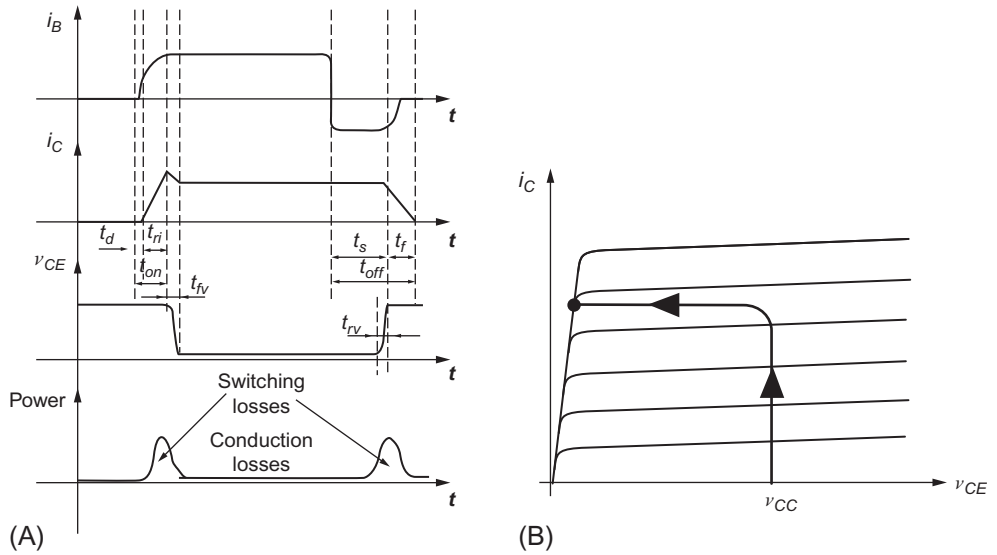

FIG. 2.27 (A) Switching characteristics of a BJT with inductive load and (B) the trajectory over the static characteristic curves under inductive load.

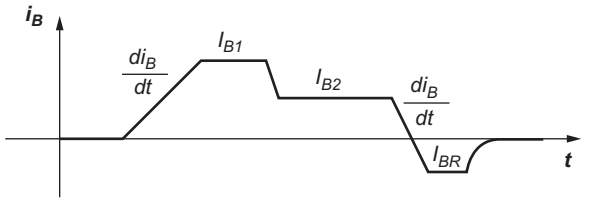

FIG. 2.28 Recommended base current for BJT driving.

2.2.5 Transistor Base Driver Circuits

Several circuits have been suggested to successfully command transistors for operating in power electronic switching systems. Such circuits try to satisfy the following requirements: supply the right collector current, adapt the base current to the collector current, and extract a reverse current from base to speed up the device blocking. A good base driver reduces the commutation times and total losses, increasing efficiency and operating frequency. Depending upon the grounding requirements between the control and the power circuits, the base drive might be isolated or nonisolated types. Fig. 2.29 shows a nonisolated circuit. When T_1 is switched on, T_2 is driven, and diode D_1 is forward-biased providing a reverse bias keeping T_3 off. The base current I_B is positive and saturates the power transistor T_P. When T_1 is switched off, T_3 switches on due to the negative path provided by R_3 and $-V_{CC}$, providing a negative current for switching off the power transistor T_P.

When a negative power supply is not provided for the base drive, a simple circuit like Fig. 2.30 can be used in low-power applications (low-power motors, small DC-DC converters, relays, and pulsed circuits). When the input signal is high, T_1 switches on, and a positive current goes to T_P keeping the capacitor charged with the zener voltage; when the input signal goes low, T_2 provides a path for the discharge of the capacitor,

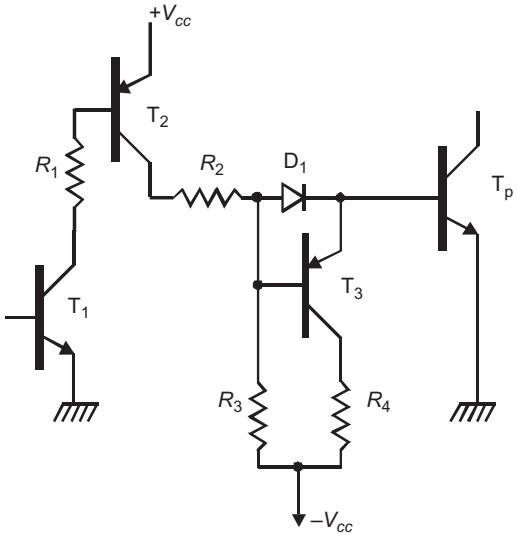

FIG. 2.29 Nonisolated base driver.

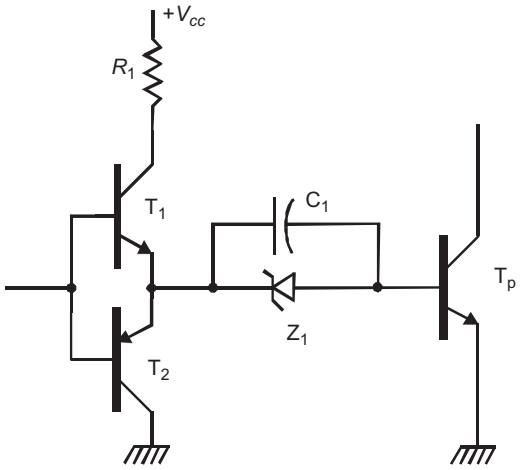

FIG. 2.30 Base command without negative power supply.

imposing a pulsed negative current from the base-emitter junction of T_P.

A combination of large reverse base drive and antisaturation techniques may be used to reduce storage time to almost zero. A circuit called Baker's clamp may be employed as illustrated in Fig. 2.31. When the transistor is on, its base is two diode drops below the input. Assuming that diodes D_2 and D_3 have a forward-bias voltage of about 0.7 V, then, the base will be 1.4 V below the input terminal. Due to diode D_1, the collector is one diode drop or 0.7 V below the input. Therefore, the collector will always be more positive than the base by 0.7 V, staying out of saturation, and because collector voltage increases, the gain β also increases a little bit. Diode D_4 provides a negative path for the reverse base current.

Several situations require ground isolation, off-line operation, and floating transistor topology. In addition, safety needs may call for an isolated base drive circuit. Numerous circuits

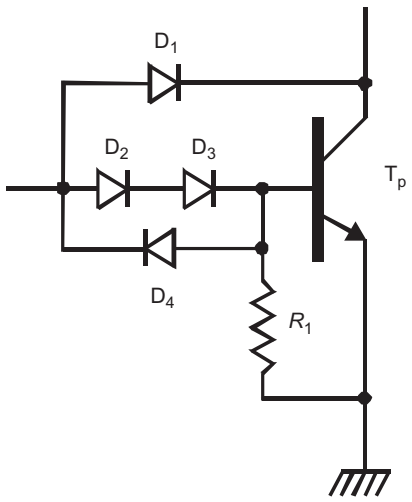

FIG. 2.31 Antisaturation diodes (Baker's clamp) improve power transistor storage time.

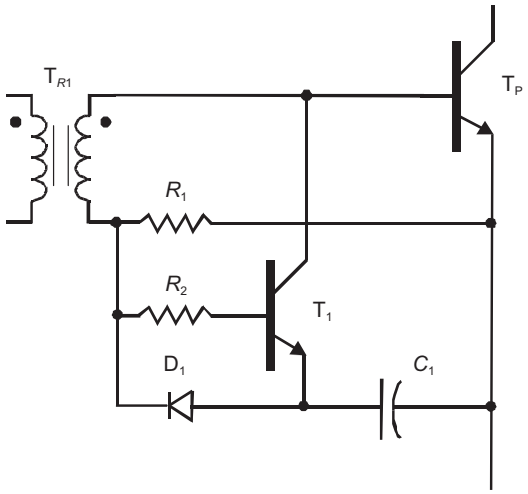

FIG. 2.32 Isolated base drive circuit.

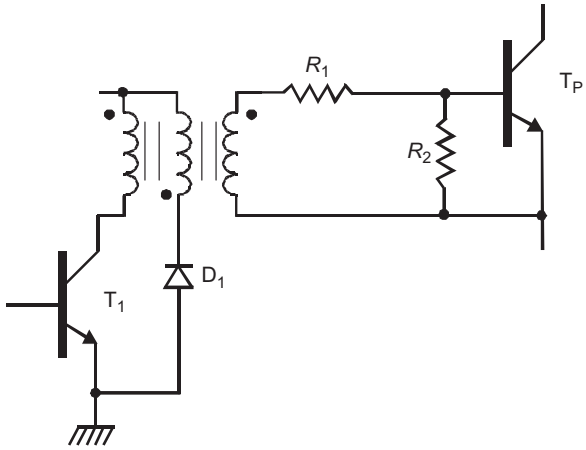

FIG. 2.33 Transformer-coupled base drive with tertiary winding transformer.

have been demonstrated in switching power supplies isolated topologies, usually integrating base drive requirements with their power transformers. Isolated base drive circuits may provide either constant current or proportional current excitation. A very popular base drive circuit for floating switching transistor is shown in Fig. 2.32. When a positive voltage is impressed on the secondary winding (V_S) of T_{R1}, a positive current flows into the base of the power transistor T_P, which switches on (resistor R_1 limits the base current). The capacitor C_1 is charged by $(V_S - V_{D1} - V_{BE})$, and T_1 is kept blocked because the diode D_1 reverse biases T_1 base-emitter. When V_S is zipped off, the capacitor voltage V_C brings the emitter of T_1 to a negative potential with respect to its base. Therefore, T_1 is excited so as to switch on and start pulling a reverse current from T_P base.

Another very effective circuit is shown in Fig. 2.33 with a minimum number of components. The base transformer has a tertiary winding that uses the energy stored in the transformer to generate the reverse base current during the turn-off command. Other configurations are also possible by adding to the isolated circuits the Baker clamp diodes or zener diodes with paralleled capacitors.

Sophisticated isolated base drive circuits can be used to provide proportional base drive currents where it is possible to control the value of β, keeping it constant for all collector currents leading to shorter storage time. Fig. 2.34 shows one of the possible ways to realize a proportional base drive circuit. When transistor T_1 turns on, the transformer T_{R1} is in negative saturation, and the power transistor T_P is off. During the time that T_1 is on, a current flows through winding N_1, limited by

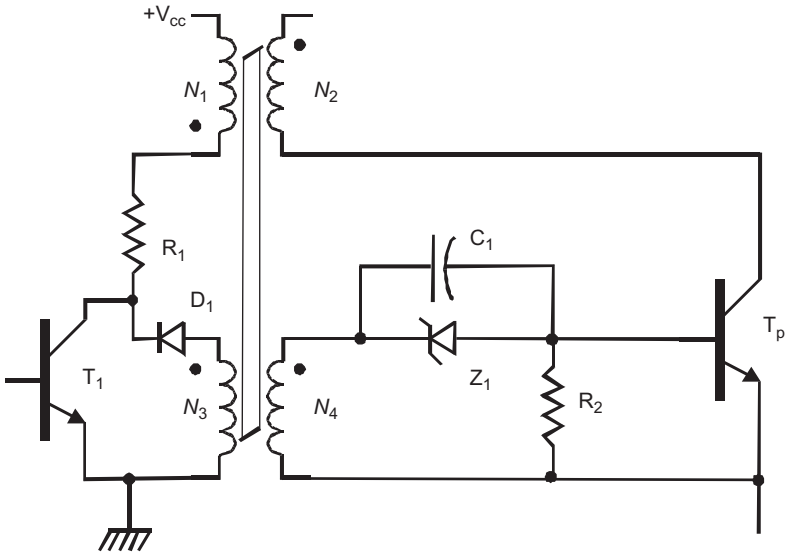

FIG. 2.34 Proportional base drive circuit.

resistor R_1, storing energy in the transformer and holding it into saturation. When the transistor T_1 turns off, the energy stored in N_1 is transferred to winding N_4, pulling the core from negative to positive saturation. The windings N_2 and N_4 will withstand as a current source, the transistor T_P will stay on, and the gain β will be imposed by the turn ratio given by (2.6):

$$\beta = \frac{N_4}{N_2} \tag{2.6}$$

In order to use the proportional drive given in Fig. 2.35, careful design of the transformer must be done, so as to have flux balanced, which will keep core under saturation. The transistor gain must be somewhat higher than the value imposed by the transformer turns ratio, which requires cautious device matching.

The most critical portion of the switching cycle occurs during transistor turnoff, since normally reverse base current is made very large in order to minimize storage time. Such conditions may avalanche the base-emitter junction leading to failure. There are two options to prevent this behavior: turning off the transistor at low values of collector-emitter voltage (which is not practical in most of the applications) or reducing collector current with rising collector voltage, implemented by *RC* protective networks called snubbers. Therefore, an *RC* snubber network can be used to divert the collector current during the turnoff, improving the RBSOA. In addition, the snubber circuit dissipates a fair amount of switching power relieving the transistor. Fig. 2.35 shows a turn-off snubber network. When the power transistor is off, the capacitor *C* is charged through diode D_1. Such collector current flows temporarily into the capacitor as the collector-voltage rises; as the power transistor turns on, the capacitor discharges through the resistor *R* back into the transistor.

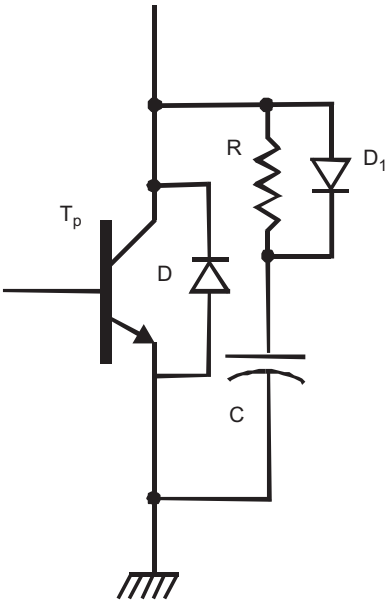

FIG. 2.35 Turn-off snubber network.

2.2.6 BJT Applications

Bipolar junction power transistors are applied to a variety of power electronic functions, switching mode power supplies, and motor drivers [8,9]. A buck-boost converter is exemplified in Fig. 2.36. The BJT operates in the cutoff and saturation regions. This converter can present a higher or lower voltage on its output terminal related to its input voltage source. This depends on the duty cycle of the BJT. The duty cycle is defined as the time a transistor keeps ON over a switching period. For duty cycles lower than 0.5, the buck-boost output voltage is lower than the input voltage. On the other hand, for duty cycles higher than 0.5, the output voltage is higher than the input voltage. The buck-boost converter has also a feature of presenting a contrary polarity on its output terminal related to the input voltage.

BJT are also commonly applied in chopper drivers. These circuits are connected between a fixed-voltage dc source and a dc motor to vary the armature voltage. In addition to armature voltage control, a dc chopper can provide regenerative braking of the motors and can return energy back to the supply. This energy-saving feature is attractive to transportation systems as mass rapid transit (MRT); chopper drives are also used in battery electric vehicles. A dc motor can be operated in one of the four quadrants by controlling the armature or field voltages (or currents). It is often required to reverse the armature or field terminals in order to operate the motor in the desired quadrant. Fig. 2.37 shows a circuit arrangement of a chopper-fed dc separately excited motor. By varying the duty cycle, the power flow to the motor (and speed) can be controlled.

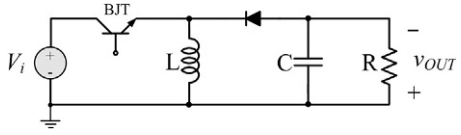

FIG. 2.36 Buck-boost converter with BJT.

TABLE 2.2 Parameter definition of a BJT model

Parameter	Definition
IS	Saturation current
XTI	IS temperature effect exponent
EG	Bandgap voltage (barrier height)
VAF	Forward early voltage
BF	Ideal maximum forward beta
NE	Base-emitter leakage emission coefficient
ISE	Base-emitter leakage saturation current
IKF	Corner for forward beta high-current roll-off
XTB	Forward and reverse beta temperature coefficient
BR	Ideal maximum reverse beta
NC	Base-collector leakage emission coefficient
ISC	Base-collector leakage saturation current
IKR	Corner for reverse beta high-current roll-off
RC	Collector ohmic resistance
CJC	Base-collector zero-bias P–N capacitance
MJC	Base-collector P–N grading factor
VJC	Base-collector built-in potential
FC	Forward-bias depletion capacitor coefficient
CJE	Base-emitter zero-bias P–N capacitance
MJE	Base-emitter P–N grading factor
VJE	Base-emitter built-in potential
TR	Ideal reverse transit time
TF	Ideal forward transit time
ITF	Transit-time dependency on Ic
VTF	Transit-time dependency on Vbc
XTF	Transit-time bias dependence coefficient
RB	Zero-bias (maximum) base resistance

2.2.7 PSPICE Model

The PSPICE model for the BJT is based on the integral-charge model of Gummel and Poon. However, if the Gummel-Poon parameters are not specified, the model reduces to piecewise-linear Ebers-Moll model as depicted in the following text for the 2N2222A NPN transistor [2]:

```
.MODEL Q2N2222A NPN (IS=14.34F XTI=3 EG=1.11
VAF=74.03 BF=255.9 NE=1.307 ISE=14.34 F IKF=.2847
XTB=1.5 BR=6.092 NC=2 ISC=0 IKR=0 RC=1 CJC=7.306P
MJC=.3416 VJC=.75 FC=.5 CJE=22.01P MJE=.377 VJE=.75
TR=46.91 N TF=411.1P ITF=.6 VTF=1.7 XTF=3 RB=10)
```

In either case, charge-storage effects, ohmic resistances, and current-dependent output conductance may be included.

The definition of each parameter is given in Table 2.2 [4].

2.3 Power MOSFET

The MOSFET technology became available by the early 1980s. The novelty of MOSFET over the BJT was the fact that MOSFET uses only majority carriers in conduction and it is commanded by voltage signal instead of current, as in BJT. Additionally, the manner how the electric terminals are constructed presented a great advancement in producing high-speed transistors. Actually, power MOSFET can switch at around 1 MHz. All these features resulted in a different physical behavior of MOSFET compared with BJT [6,10].

2.3.1 Basic Structure

Fig. 2.38 presents a basic structure of a vertical N-channel MOSFET. The MOSFET has three terminals called drain (D), source (S), and gate (G). The gate terminal is isolated from the rest of the semiconductor by means of a SiO_2 layer. The PN junction represents a diode from source to drain terminals. This diode conducts when the drain-source voltage is negative. Additionally, this diode holds the reverse voltage applied to the MOSFET. The MOSFET operates as a transistor when the drain-source voltage is positive.

In case of a positive gate-source voltage, the gate potential repels the positive charges in the P regions and attracts free electrons. When such voltage reaches a threshold voltage, a complete path between source and drain is formed, called channel. This allows a current to be conducted through the drain and source. As the gate-source voltage increases, more carriers are attracted, and more current can be conducted. The carriers are only electrons in the N^+ source region along the channel and in the drain (N^+ and N^-) regions. Fig. 2.39 presents a vertical MOSFET with the N-channel created.

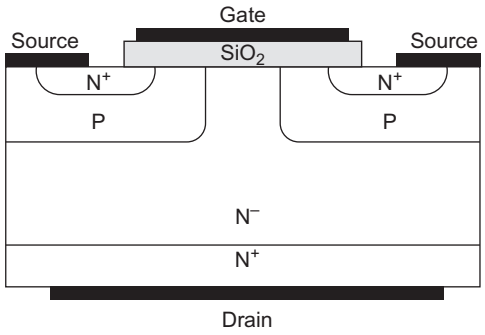

FIG. 2.38 Basic structure of a vertical N-channel MOSFET.

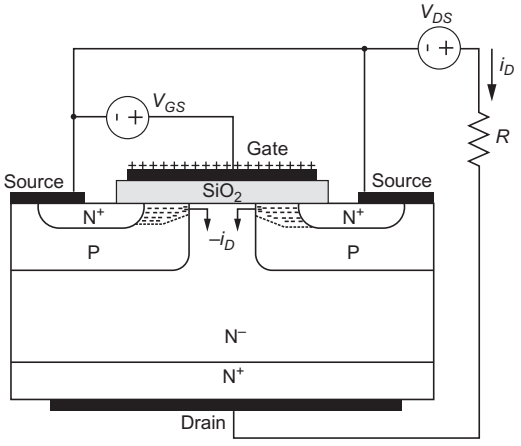

FIG. 2.39 Vertical MOSFET with the N-channel created.

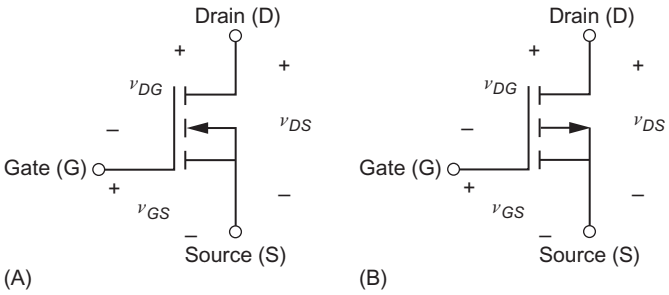

FIG. 2.40 MOSFET symbols for (A) N-channel and (B) P-channel types.

Fig. 2.40 presents the MOSFET symbols for P- and N-channel types. The voltages across the terminals are highlighted.

2.3.2 Static Characteristics

Fig. 2.41 presents the static characteristics of an N-channel MOSFET. The chart shows three regions of operation. In power electronic applications, the MOSFET is preferentially operated in the ohmic and cutoff regions, once either the drain-source voltage or the drain current is small, compared with the active region, thus reducing the power losses. In the active region, the MOSFET operates as an amplifier. *BV* is the breakdown voltage, which is the maximum allowable drain-source voltage across the MOSFET before failure.

2.3.2.1 Ohmic Region

In the ohmic region, also known as triode region or constant resistance region, the channel of the MOSFET behaves like a constant resistance. Such resistance is called R_{DSon}, and it is linearly proportional to drain-source voltage and the drain current. The value of R_{DSon} can vary from some milliohms (low-voltage device) to few ohms (high-voltage device). The manufactures usually inform the value of R_{DSon} on their datasheets. The value of R_{DSon}, together with the drain current, determines the conduction power losses of the MOSFET.

The MOSFET operates at the ohmic region when the constraint shown in (2.7) is satisfied:

$$v_{DS} < v_{GS} - V_{TH} \quad and \quad v_{GS} > V_{TH} \tag{2.7}$$

2.3.2.2 Cut-off Region

The cutoff region is characterized by the absence of the channel formation. This happens when the gate-source voltage is lower than the threshold voltage, as stated in (2.8):

$$v_{DS} > 0 \quad and \quad v_{GS} < V_{TH} \tag{2.8}$$

In this case, no current flows through the drain and source terminals of the MOSFET.

2.3.2.3 Active Region

The active region is also known as saturation region in MOSFETs. However, naming it as saturation region may be misunderstood as the saturation region of BJT. Therefore, throughout this chapter, the name active region is used.

The active region is characterized by a constant drain current, controlled by the gate-source voltage. The MOSFET operates at the active region when the constraint stated in (2.9) is satisfied. In this case, the channel width limits the current flow:

$$v_{DS} > v_{GS} - V_{TH} \quad and \quad v_{GS} > V_{TH} \tag{2.9}$$

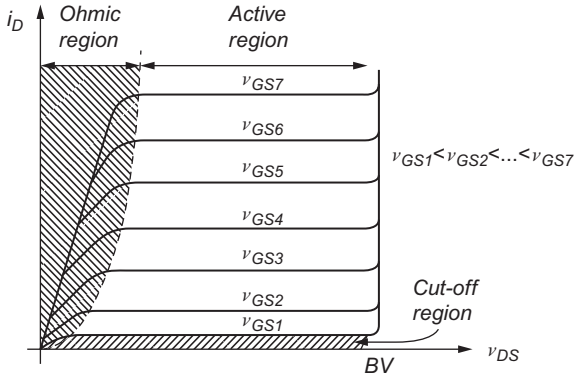

FIG. 2.41 Static characteristics for an N-channel enhancement-type MOSFET.

2.3.3 Switching Characteristics

In order to understand the switching characteristics, the MOSFET is represented by an equivalent circuit model shown in Fig. 2.42. The model consists of a voltage-controlled current source and internal capacitances located among the MOSFET terminals.

The internal capacitances are the gate-drain capacitance C_{GD}, the gate-source capacitance C_{GS}, and the drain-

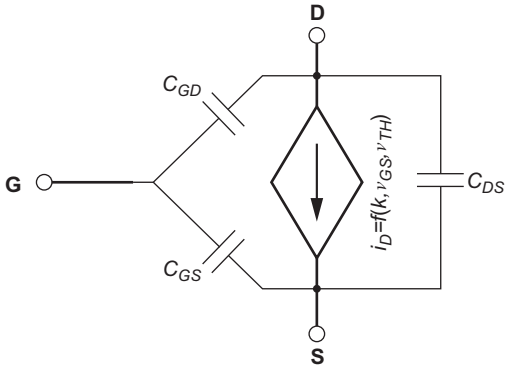

FIG. 2.42 Equivalent circuit model for a MOSFET.

sourcecapacitance C_{DS}. These are nonlinear capacitances that vary according to the MOSFET structure and bias voltage.

The voltage-controlled current source is mathematically approximated by (2.10):

$$\begin{cases} i_D = k\left[2(v_{GS} - V_{TH})v_{DS} - {v_{DS}}^2\right] & \textit{for ohmic region} \\ i_D = k(v_{GS} - V_{TH})^2 & \textit{for active region} \\ i_D = 0 & \textit{for cut} - \textit{off region} \end{cases} \quad (2.10)$$

where k is a constant that depends on the MOSFET construction.

From (2.7) to (2.9), the drain-to-source voltage at the boundary between the active and ohmic region is given by (2.11):

$$v_{DS} = v_{GS} - V_{TH} \quad (2.11)$$

Therefore, (2.10) results in (2.12):

$$i_D = k{v_{DS}}^2 \quad (2.12)$$

From (2.12), the MOSFET input transfer characteristic can be obtained. Fig. 2.43 presents the input transfer function characteristics, valid for the active region. G_m is the slope for an operation point with a v_{GS} voltage and i_D current.

In the ohmic region, the MOSFET can be represented by the circuit shown in Fig. 2.44.

2.3.3.1 Turn-on Analysis

The circuit used to analyze the turn-on and turn-off characteristics of a MOSFET is shown in Fig. 2.45. The circuit contains a DC source (+Vcc), a MOSFET, an inductor (L), a resistor (R), a diode (D), and the gate driver, which is composed of the voltage source V_g and the resistor R_G. The diode is considered ideal (without reverse recovery behavior). The inductor is the load of the circuit. Its inductance value is large enough so that the current thought it is considered constant. The diode is used to supply a path for the load current when the MOSFET is off.

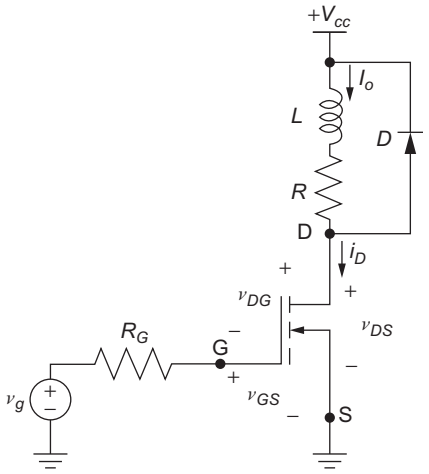

FIG. 2.45 Circuit used to analyze the turn-on and turn-off characteristics of a MOSFET.

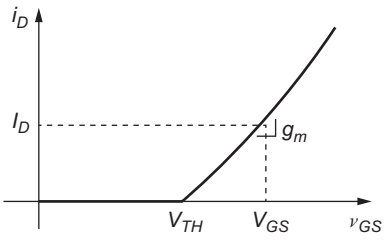

FIG. 2.43 Input transfer function characteristics for a MOSFET.

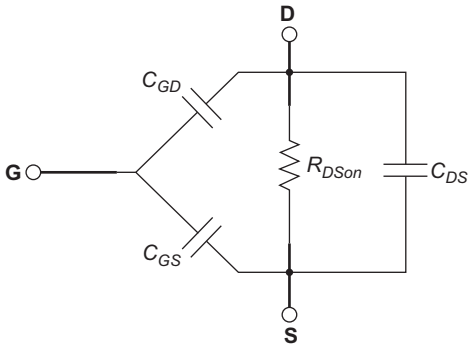

FIG. 2.44 Equivalent circuit valid for the ohmic region.

Fig. 2.46 presents waveforms during the turn-on. The x-axis is divided into four intervals, as follows:

Initially, the MOSFET is in the cutoff region. Thus, the drain current is null, and the drain-to-source voltage is equal to the +Vcc. This makes the gate-drain capacitance to be charged. The interval t_1 begins with the voltage source V_G going from zero to its nominal value. The gate-source capacitance begins to be charged through the resistor R_G, while the gate-drain capacitance begins to be discharged. The drain current keeps null until the gate-to-source voltage reaches the threshold voltage. The time interval t_1 ends when the gate-source voltage

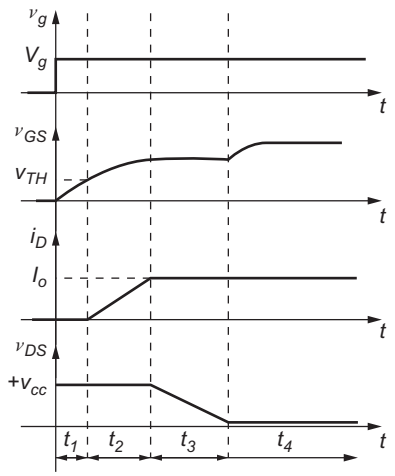

FIG. 2.46 Waveforms during the turn-on process.

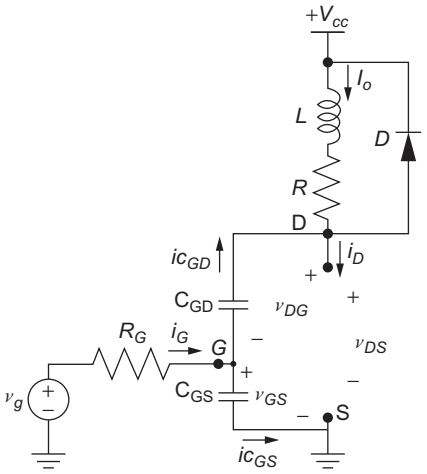

FIG. 2.47 Equivalent circuit for the interval t_1.

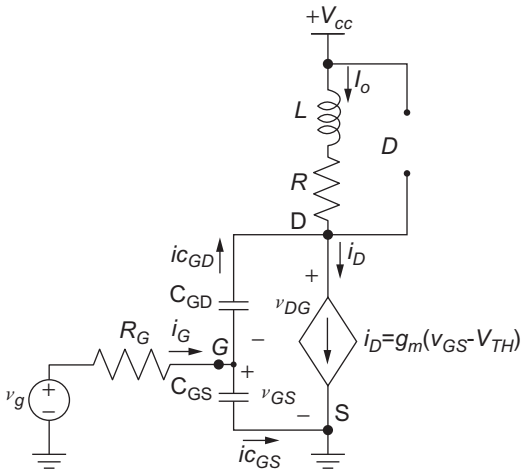

FIG. 2.49 Equivalent circuit for the interval t_3.

reaches the threshold voltage. Once the MOSFET leaves the cutoff region at this moment, the interval t_1 represents the turn-on delay time. Fig. 2.47 presents the equivalent circuit for the time interval t_1. Since the diode is ON, the drain-source voltage does not change.

At the beginning of the interval t_2, the gate-source voltage is higher than the threshold voltage, and the MOSFET starts conducting. The diode keeps conducting, while the drain current is lower than I_o. The gate-source voltage remains growing, while the drain-source voltage keeps unchanged. Fig. 2.48 presents the equivalent circuit for the time interval t_2. The diode was replaced by a short circuit in order to emphasize its conduction state.

The interval t_3 begins when the load current is conducted entirely through the MOSFET ($i_D = I_o$), turning off the diode. The drain-source voltage falls throughout this interval, reaching its minimum value at the end. The gate-drain capacitance is discharged by the gate current. Its voltage varies together with the drain-source voltage. Fig. 2.49 shows the equivalent circuit for the time interval t_3. The diode was replaced by an open circuit.

The interval t_4 begins when the drain-source voltage reaches its minimum value, which is given by (2.13):

$$v_{DS} = I_o R_{DSon} \tag{2.13}$$

The gate current finishes charging the gate-source capacitance, the gate-source voltages reaches its nominal value, and the MOSFET entered into the ohmic region. Fig. 2.50 presents the equivalent circuit for the time interval t_4.

During intervals t_2 and t_3, the MOSFET is passing through the active region with considerable drain-source voltage and drain current. As a result, power dissipation occurs during these intervals, contributing to the switching losses.

2.3.3.2 Turn-off Analysis

In order to analyze the turn-off characteristic, the same circuit shown in Fig. 2.45 was adopted. The MOSFET is initially

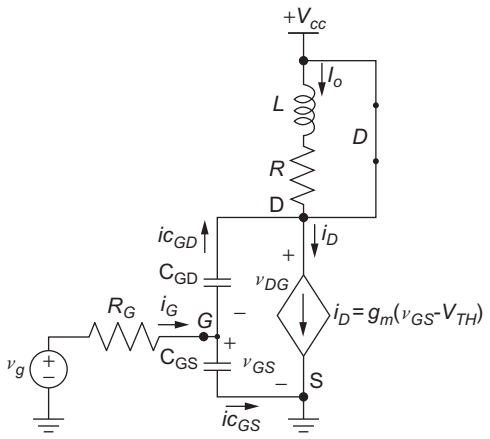

FIG. 2.48 Equivalent circuit for the interval t_2.

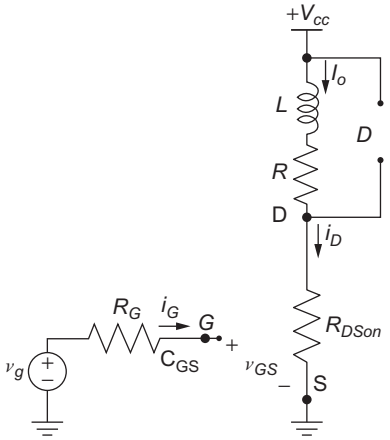

FIG. 2.50 Equivalent circuit for the interval t_4.

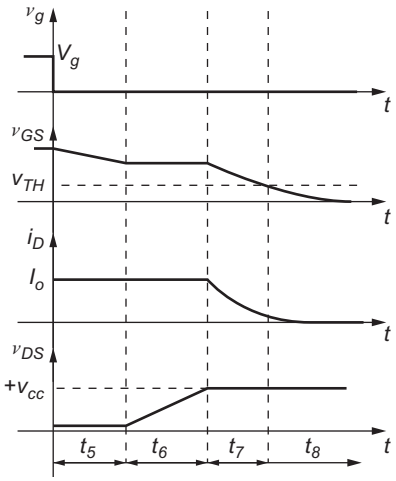

FIG. 2.51 Waveforms during the turn-off process.

considered in the ohmic region with the values shown in the waveform of Fig. 2.46. Fig. 2.51 presents the waveforms during the turn-off switching.

The turnoff of the MOSFET begins when the source Vg is set to zero (a negative voltage is also possible). During interval t_5, the gate-source voltage begins to fall, discharging the gate-source capacitance and charging the gate-drain capacitance. The drain current and the drain-source voltage keep unchanged.

During interval t_6, the drain-source voltage rises, while the gate-source voltage keeps constant. At the end of interval t_6, the drain-source voltage reaches the value of the DC source (+Vcc), turning on the diode, and the drain current begins to fall.

The interval t_7 corresponds to the time required to the gate-source voltage to reach the threshold voltage. After that, the drain current is null, and the MOSFET is in the cutoff region.

Similarly to the turn-on behavior, the intervals t_6 and t_7 present considerable drain current and drain-source voltage, contributing to the switching losses.

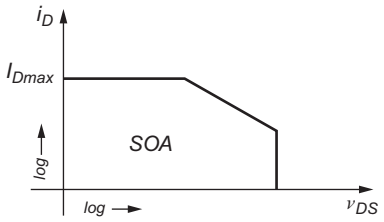

FIG. 2.52 Safe operation area of the MOSFET.

2.3.4 Safe Operation Area

The SOA of the MOSFET is shown in Fig. 2.52. The area SOA shows the values of drain current, and drain-source voltage can hold without destructive failure. MOSFETs do not present the second breakdown.

2.3.5 MOSFET Applications

The majority of applications of BJT can also be employed with MOSFET, especially those in DC–DC converters. Nevertheless, MOSFETs have been widely used in the field of electric vehicles [11]. Fig. 2.53 presents a typical bidirectional DC charger for electric vehicles using MOSFETs. The left side of the high-frequency transformer is the charger. The right side is the battery and the converter of the electric vehicle.

2.3.6 PSPICE Model

The following text presents the PSPICE model for the MOSFET IRFBC30:

```

The definition of each parameter is given in Table 2.3 [4].

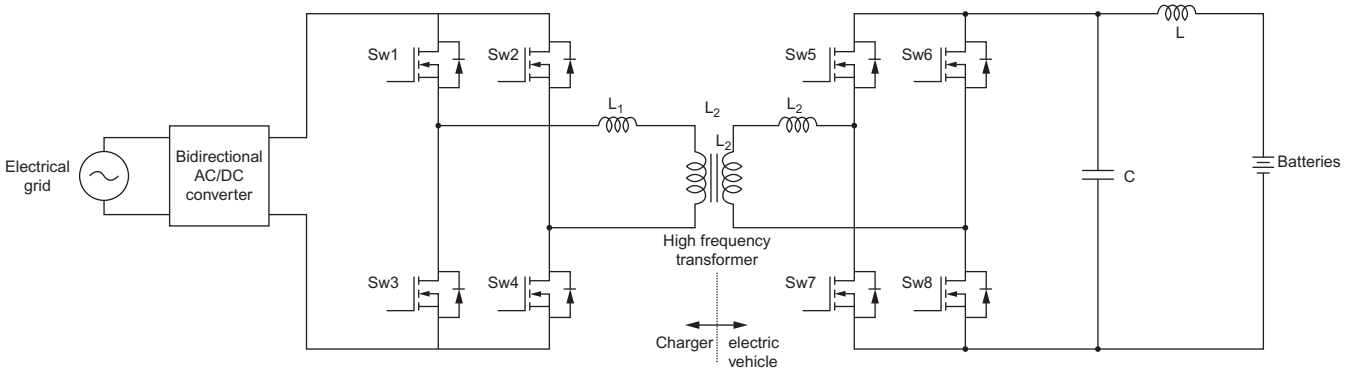

FIG. 2.53 Typical bidirectional DC charger for electric vehicles using MOSFET.

TABLE 2.3 Parameter definition of a MOSFET model

Parameter	Definition
Level	Model type (1, 2, or 3)
Gamma	Bulk threshold parameter
Delta	Width effect on threshold
Eta	Static feedback (LEVEL = 3)
Kappa	Saturation field factor (LEVEL = 3)
Vmax	Maximum drift velocity
Xj	Metallurgical junction depth
Tox	Oxide thickness
Uo	Surface mobility
Phi	Surface potential
R_s	Source ohmic resistance
K_p	Transconductance
W	Channel width
L	Channel length
V_{to}	Zero-bias threshold voltage
R_d	Drain ohmic resistance
R_{ds}	Drain-source shunt resistance
C_{bd}	Bulk-drain zero-bias P–N capacitance
P_b	Bulk P–N potential
Mj	Bulk P–N bottom grading coefficient
Fc	Bulk P–N forward-bias capacitance coefficient
Cgso	Gate-source overlap capacitance/channel width
Cgdo	Gate-drain overlap capacitance/channel width
Rg	Gate ohmic resistance
IS	Bulk P–N saturation current
N	Bulk emission coefficient n
T_t	Transit time

2.4 Insulated Gate Bipolar Transistor

The IGBT is a device that integrates the advantage of having low on-voltage from BJT with the advantage of having an insulated-gate input from MOSFET. Such integration makes the IGBT a device with some superior characteristics compared with the BJT or MOSFET, with relative high switching speed. The IGBT can be gated like a MOSFET, and the output current is handled in a manner similar to the BJT. IGBTs do not have the body diode found in MOSFET. Thus, an external fast recovery diode is usually mounted in the same package for holding high reverse voltage.

2.4.1 Basic Structure

Fig. 2.54 presents a basic structure of a vertical IGBT. The IGBT has three terminal called collector (C), emitter (E), and gate (G). The gate terminal is isolated from the rest of the semiconductor by means of a SiO_2 layer. The P+, N+N−, and P junctions constitute a parasitic BJT. By the application of a positive voltage higher than the threshold between the gate and emitter, the N-channel is created, similar to MOSFET, providing a path for a current from the collector to the emitter terminal. As the junctions P+N+ are forward-biased, it injects carriers into the N region, enhancing the conductivity and reducing the voltage drop along this region. This is the main

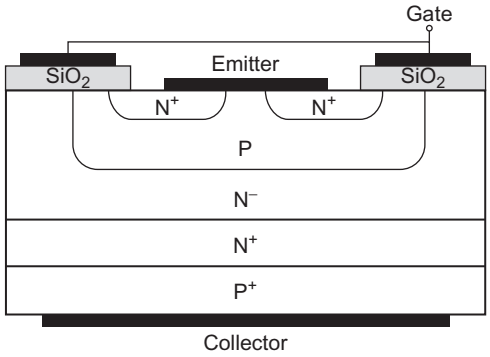

FIG. 2.54 Basic structure of a vertical IGBT.

difference between IGBT and MOSFET. The PN junction blocks reverse voltage when the IGBT is off. In spite of P-channel be possible, as its commutation intrinsically slower than N-channel, it is not convenient for power applications.

Fig. 2.55 presents the symbol for an N-channel type IGBT. The symbol is similar to a BJT, except that the gate terminal is insulated from the rest of the device. Other symbols for IGBT can be found in the literature.

2.4.2 Static Characteristics

Fig. 2.56 presents the static characteristic of an N-channel IGBT. The curves are similar to that for BJT, except that the

controlling variable is the gate-emitter voltage. *BV* is the breakdown voltage.

2.4.3 Switching Characteristics

2.4.3.1 Turn-on Analysis

The turn-on process of IGBT is similar to that for MOSFET, once the IGBT has the insulated-gate terminal. However, the v_{CE} typically falls slower compared with a MOSFET with the same ratings. Fig. 2.57 presents the waveforms during the turn-on process of an IGBT. The circuit used to analyze these waveforms is that shown in Fig. 2.43, except that the MOSFET is replaced by an IGBT.

2.4.3.2 Turn-off Analysis

The turn-off process of IGBT depends on the removal of carriers that came from the P+ region. Since IGBT has insulated gate, such removal cannot be made through the gate terminal. The solution is the inclusion of the N+ layer, which the recombination tax is faster than the N-layer. By diffusion, the storage charges in the N-layer are extinguished, reestablishing the potential barrier. Fig. 2.58 presents the waveforms during the turn-off process of an IGBT.

2.4.4 IGBT Applications

IGBTs have a vast field of application. One of the most relevant is in DC-AC converters, known also as inverters. Such inverters are usually applied in uninterrupted power supplies, motor drivers, and grid interfaces for connecting renewable sources into the distribution/transmission systems [1,3,8,11]. Fig. 2.59 presents a single-phase inverter using IGBTs with LC filter. The inverter has a DC source as input. The terminals A and B are the output of the inverter. The inductor and capacitor are used to filter the high-frequency components of the inverter output voltage. When an induction motor is used as load, the LC filter can be removed, since the motor windings work as filter for the current.

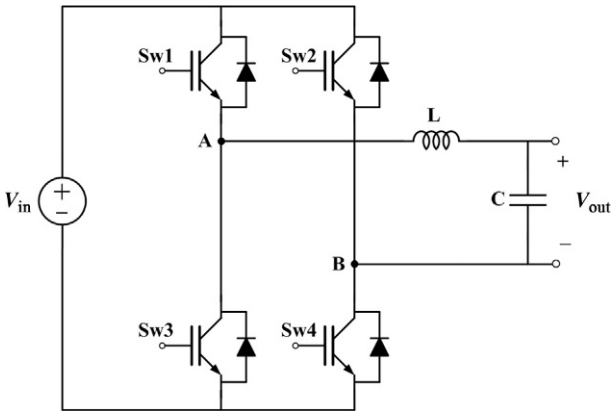

FIG. 2.59 Single-phase inverter using IGBTs with LC filter.

Another field of application of IGBT-based inverters is in power quality improvements. Fig. 2.60 presents a unified power quality conditioner (UPQC) [12] with electronic converters using IGBTs. The UPQC is composed of series and shunt active filters. The first is used to filter the voltage applied to the load, while the second is used to filter the harmonic current produced by the load.

2.4.5 PSPICE Model

The following text presents the PSPICE model for the IGBT IXGT32N170A:

```
.MODEL IXGT32N170A NIGBT (+ TAU=63.552E-9 + KP=14.397 +

KF=.5005 + CGS=38.737E-9 + COXD=88.530E-9 + VTD=-5)
```

The definition of each parameter is given in Table 2.4 [4].

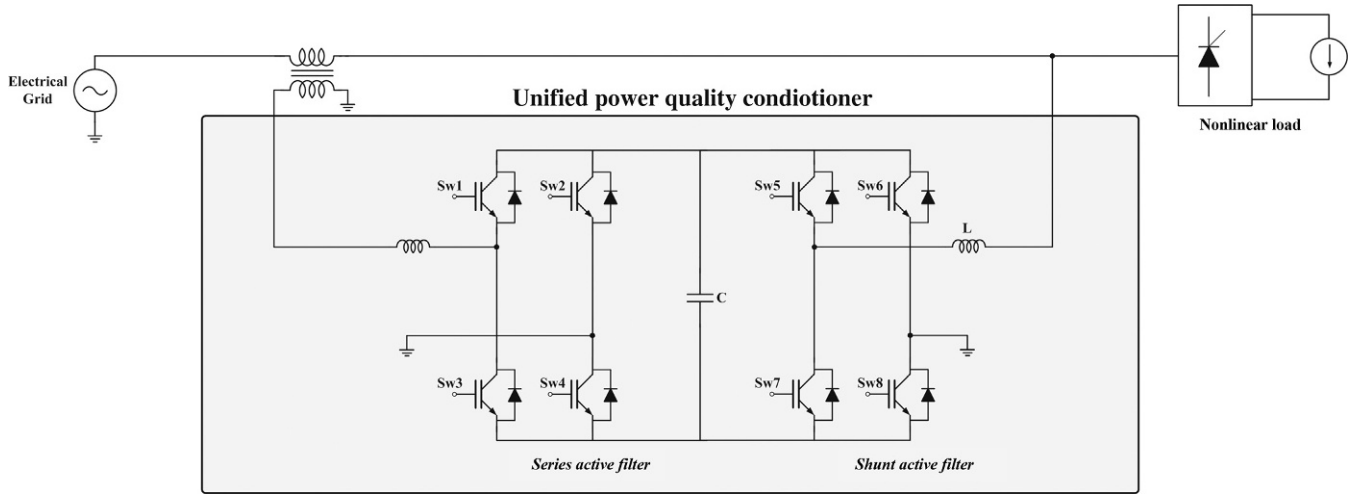

FIG. 2.60 Unified power quality conditioner (UPQC) with electronics converters using IGBTs.

TABLE 2.4 2.4 Parameter definition of a IGBT model

Parameter	Definition
TAU	Ambipolar recombination lifetime
KP	MOS transconductance
AREA	Area of the device
AGD	Gate-drain overlap area
WB	Metallurgical base width
VT	Threshold voltage
MUN	Electron mobility
MUP	Hole mobility
BVF	Avalanche uniformity factor
KF	Triode region factor
CGS	Gate-source capacitance
COXD	Gate-drain overlap oxide capacitance
VTD	Gate-drain overlap depletion threshold

2.5 Swtiching evaluation of a Real MOSFET

In order to verify real switching characteristics of a MOSFET, the circuit shown in Fig. 2.61 was built. The MOSFET is connected to a circuit composed of the main source (Vcc) and an *RL* load. The switch Sw1 is used to insert or remove the inductance of the load. The diode *D* is used as freewheeling path for the load. The gate driver is composed of a square-wave source (V_g), a resistor, a potentiometer, a capacitor, and a switch Sw2, used to insert or remove the capacitor. The potentiometer can vary from 0 to 1 k**Ω**. The MOSFET is the IRF530.

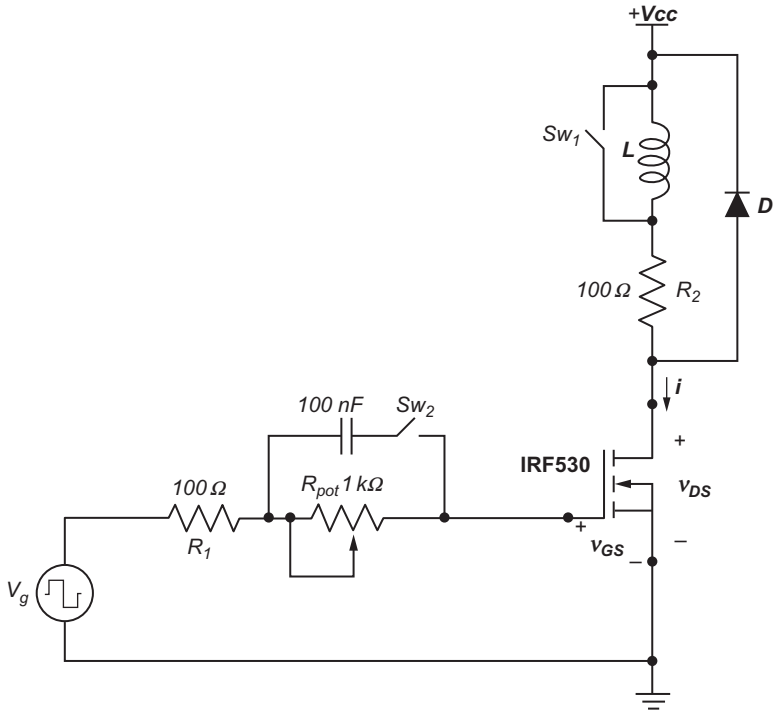

FIG. 2.61 Circuit used to verify real switching characteristics of transistors.

2.5.1 Results for Sw1 ON and Sw2 OFF and *Rpot* at the Maximum Resistance

The switch Sw1 is ON, bypassing the inductor *L*. The switch Sw2 is OFF, disconnecting the capacitor of the gate driver. The R_{pot} is at its maximum resistance. Fig. 2.62 presents waveforms for V_g source and the drain-source voltage. The V_g source goes from −3 to +10 V with frequency equal to 5 kHz.

Fig. 2.63 presents details of the turn-on process. The V_g source changes from −3 to 10 V almost instantaneously. The turn-on delay of the MOSFET is measured from the moment where the V_g source begins to rise until the drain-source voltage begins to fall. Therefore, the turn-on delay for the MOSFET is 0.7 µs.

Fig. 2.64 presents details of the turn-off process. Similarly, the V_g source changes almost instantaneously from +10 to −3 V, and the turn-off delay is measured from the moment the V_g source begins to fall until the moment the drain-source voltage begins to rise. The turn-off delay for the MOSFET is 1.5 µs.

Fig. 2.65 presents the drain-source voltage and the gate-source voltage during the turn-on process. The threshold voltage of the MOSFET is evident. As soon as the threshold is achieved, the drain-source voltage begins to fall.

Fig. 2.66 presents the drain-source voltage and the gate-source voltage during the turn-off process.

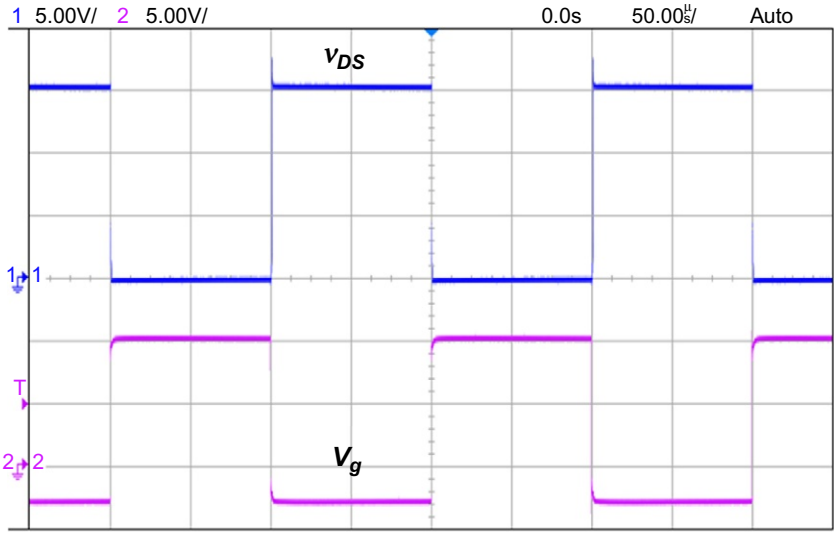

FIG. 2.62 Waveforms for Vg source and the drain-source voltage.

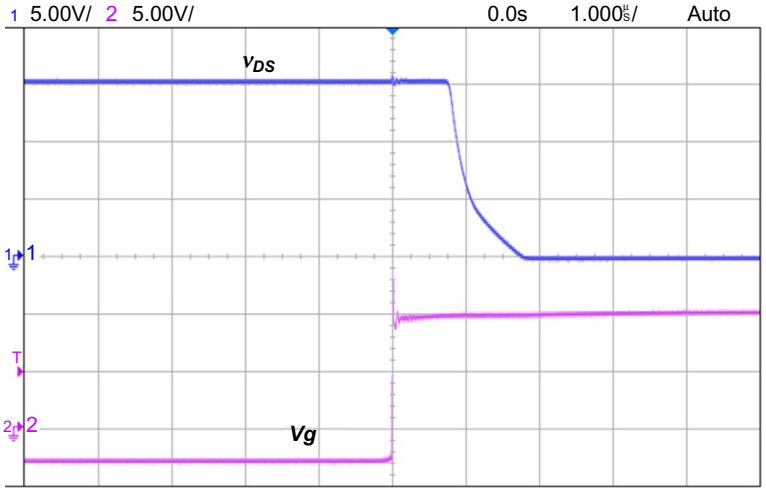

FIG. 2.63 Details of the turn-on process for Sw1 ON and Sw2 OFF and *Rpot* at the maximum resistance.

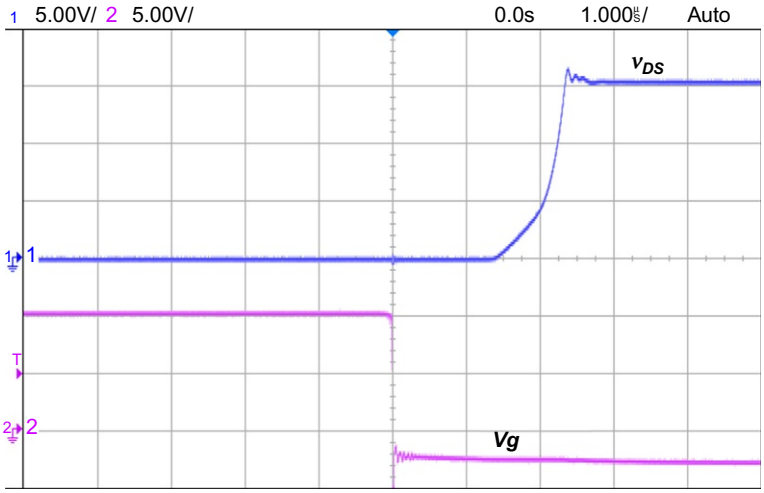

FIG. 2.64 Details of turn-off process for Sw1 ON and Sw2 OFF and *Rpot* at the maximum resistance.

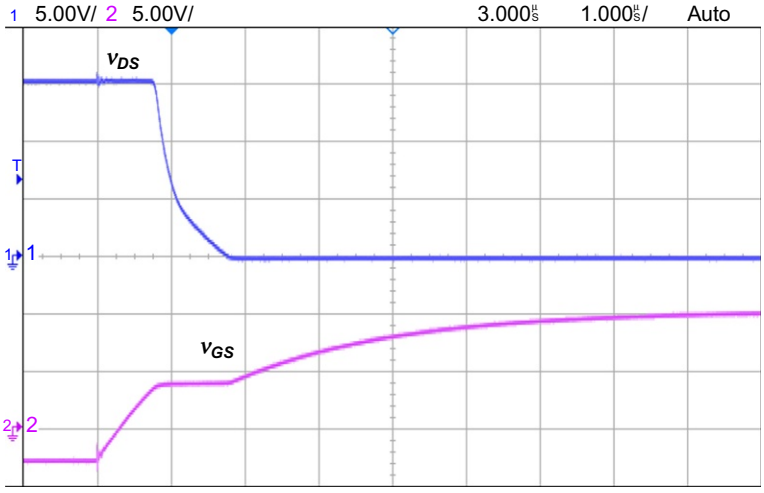

FIG. 2.65 Drain-source voltage and the gate-source voltage during the turn-on process for Sw1 ON and Sw2 OFF and *Rpot* at the maximum resistance.

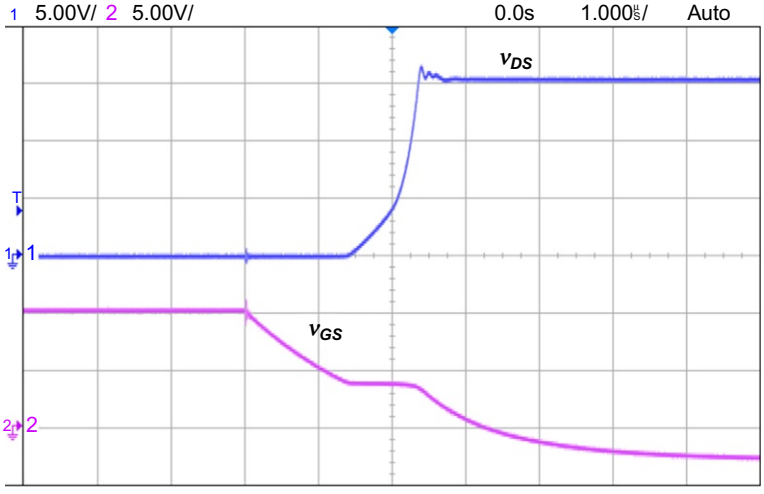

FIG. 2.66 Drain-source voltage and the gate-source during the turn-off process for Sw1 ON and Sw2 OFF and R_{pot} at the maximum resistance.

2.5.2 Results for Sw1 ON and Sw2 OFF and *Rpot* at the Minimum Resistance

The R_{pot} is set to its minimum resistance (0 Ω). Fig. 2.67 presents the details of the turn-on process. The turn-on delay of the MOSFET is approximately 0.15 µs. The delay is lower compared with the previous case. Since the R_{pot} is at its minimum resistance, the gate-driver resistance is made only by R_1, resulting in a lower time constant for charging the MOSFET capacitance. Consequently, the turn-on process is faster.

Fig. 2.68 presents the details of the turn-off process. The turn-off delay of the MOSFET is 0.3 µs.

Fig. 2.69 presents the drain-source voltage and the gate-source voltage during the turn-on process.

Fig. 2.70 presents the drain-source voltage and the gate-source voltage during the turn-off process.

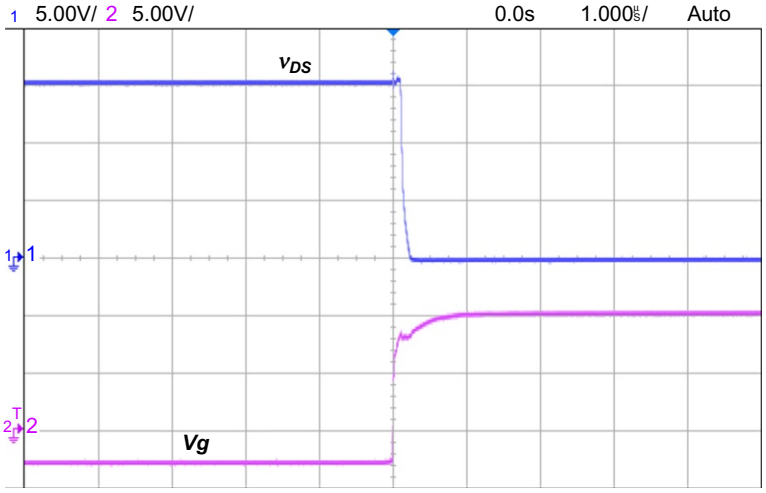

FIG. 2.67 Details of turn-on process for Sw1 ON and Sw5 OFF and *Rpot* at the minimum resistance.

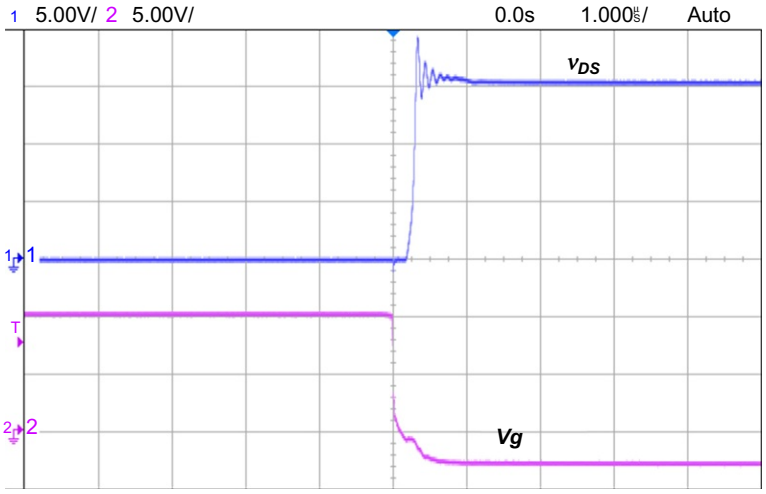

FIG. 2.68 Details of turn-off process for Sw1 ON and Sw5 OFF and R_{pot} at the minimum resistance.

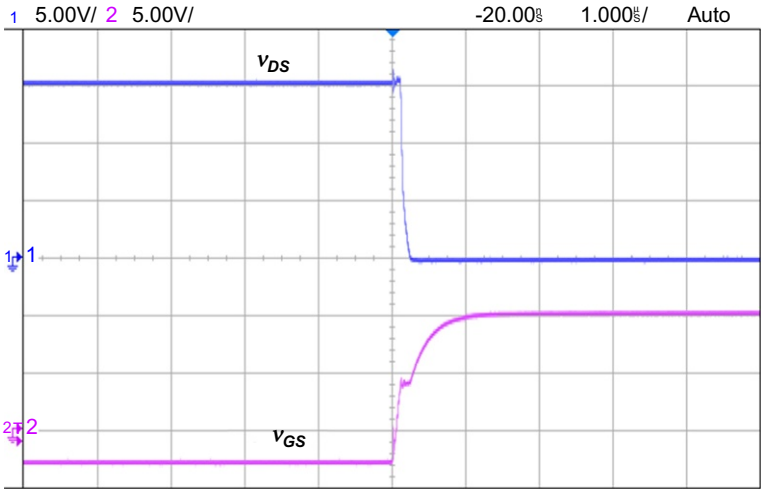

FIG. 2.69 Drain-source voltage and the gate-source voltage during the turn-on process for Sw1 ON and Sw2 OFF and R_{pot} at the maximum resistance.

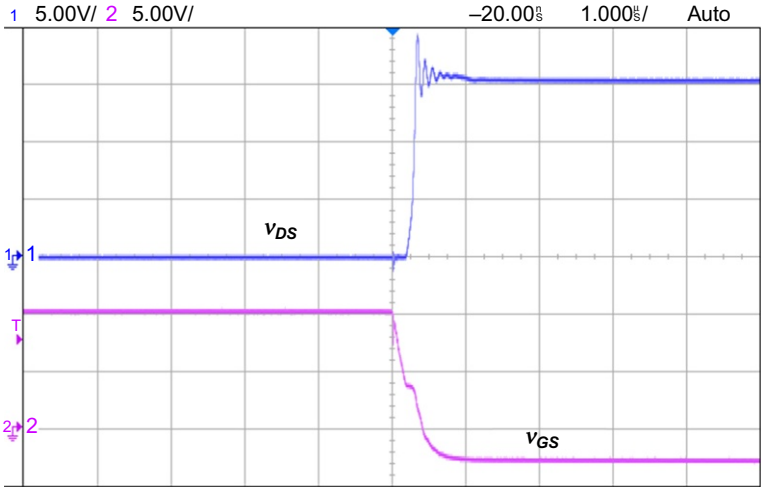

FIG. 2.70 Drain-source voltage and the gate-source during the turn-off process for Sw1 ON and Sw2 OFF and R_{pot} at the maximum resistance.

2.5.3 Results for Sw1 and Sw2 ON and *Rpot* at the Maximum Resistance

The switch Sw2 is now ON, connecting the capacitor to the gate driver. Fig. 2.71 presents the details of the turn-on process. The turn-on delay of the MOSFET is approximately 100 ns. The inclusion of the capacitor makes the transistor faster due to the fact that at initial turn-on process, the capacitor is seen as a short circuit by the voltage source. Thus, the gate current goes through it and charges faster the MOSFET capacitance. As soon as the capacitor is charged, the gate current passes through the potentiometer.

Fig. 2.72 presents the details of the turn-off process. The turn-off of the MOSFET is 200 ns.

2.5.4 Results for Sw1 and Sw2 OFF and *Rpot* at the Maximum Resistance

The switches Sw1 and Sw2 are OFF. The inductor now has effect on the circuit. Fig. 2.73 presents the load current (drain

2.6 Heatsink Thermal Design for Power Semiconductors

In power semiconductor devices, the heat from Joule's effect is produced in the semiconductor wafer. Then, the heat flows to colder environments like the device case and the ambient. This heat flux depends on the temperature gradient and the thermal characteristics of the materials involved.

Usually, an analogy with electric circuit is made to evaluate the heat flow. The average power dissipated in a semiconductor is represented by a current source. The temperatures in junction, case, sink, and ambient are represented by voltage nodes, while the thermal resistances are the circuit resistances. Fig. 2.76 presents the equivalent electric circuit for thermal design, valid for steady-state situation. The heat sink thermal resistances are represented by R_{Tsa}. R_{Tcs} represents the material placed between the semiconductor case and the heat sink. Usually, mica is used. Its thermal resistance is low. The dashed lines indicate that the heat sink will be connected after the electric circuit thermal analysis is performed.

Table 2.5 presents the nomenclature of the equivalent voltage nodes.

Table 2.6 presents the nomenclature of the equivalent resistances.

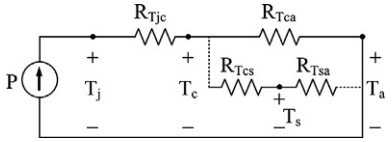

FIG. 2.76 Equivalent electric circuit for thermal design, valid for steady-state situation.

TABLE 2.5 Nomenclature of the equivalent voltage nodes

Parameter	Definition
T_j	Junction temperature
T_c	Case temperature
T_a	Ambient temperature

Parameter	Definition
R_{Tjc}	Junction-to-case resistance
R_{Tca}	Case-to-ambient resistance
R_{Tcs}	Case-to-heat-sink resistance
R_{Tsa}	Heat-sink-to-ambient resistance

The objective of heat-sink thermal design is to guarantee that the semiconductor junction does not exceed its maximum allowed temperature. The ambient temperature is considered constant. The junction-to-case and case-to-ambient resistances are informed by manufactures.

According to Fig. 2.76, the junction temperature is given by (2.14):

$$T_j = T_a + P\left(R_{Tjc} + R_{Tca}\right) \tag{2.14}$$

EXAMPLE 2.1 Find the junction and case temperatures for a semiconductor with the parameters given in Table 2.7.

From Fig. 2.74 and Table 2.7, the case and junction temperatures are given by (2.15) and (2.16), respectively:

$$T_c = T_a + P \cdot R_{Tca} = 240°\text{C} \tag{2.15}$$

$$T_j = T_a + P \cdot R_{Tjc} = 280°\text{C} \tag{2.16}$$

TABLE 2.7 Semiconductor parameters

Parameter	Value	Description
P	20 W	Dissipated power
R_{Tjc}	2°C/W	Obtained from a manufacture catalog
R_{Tca}	10°C/W	Obtained from a manufacture catalog
T_a	40°	Chose by the designer depending on the location
T_{jmax}	120°	Maximum junction temperature before failure. Obtained from a manufacture catalog

2.6.1 Heatsink Design

From the previous example, the value resulted in (2.16) is much higher than the value given in Table 2.7 for the maximum junction temperature. This leads the semiconductor to destruction. Considering the impossibility to reduce the dissipated power and that there is no way to change the thermal resistance, the solution to ovoid the semiconductor destruction is to add a heat sink between the case and ambient with low thermal resistance. The heat sink introduces a low thermal resistance in parallel to the case-to-ambient resistance. This causes a reduction in the case temperature and consequently in the junction temperature. The following example explains hot to design the heat sink.

EXAMPLE 2.2 Design a heat sink for the semiconductor given in Example 2.1.

The design of the heat sink consists on finding the value for the heat-sink-to-ambient resistance R_{Tsa}. From Fig. 2.74 and Table 2.7, the equivalent resistance between the case and the ambient is given by (2.17). The maximum junction temperature is used because the final result in this example will give the maximum heat-sink-to-ambient resistance:

$$R_{Teq} = \frac{T_{jmax} - T_a}{P} - R_{Tjc} = {}^{2°\text{C}}\!/_{W} \tag{2.17}$$

The case-to-heat-sink resistance is given by (2.18), obtained from a manufacture catalog:

$$R_{Tcs} = {}^{0.7°\text{C}}\!/_{W} \tag{2.18}$$

The equivalent resistance is also given by (2.19):

$$R_{Teq} = \frac{R_{Tca}\left(R_{Tcs} + R_{Tsa}\right)}{R_{Tca} + R_{Tcs} + R_{Tsa}} \tag{2.19}$$

Replacing (2.17) and (2.18) in (2.19) and with the values from Table 2.7, the heat-sink-to-ambient resistance is given by (2.20):

$$R_{Tsa} = {}^{1.8°\text{C}}\!/_{W} \tag{2.20}$$

At this point, a manufacture catalog must be examined in order to find a heat sink with the same or lower thermal resistance.

The previous results are valid for steady-state condition and assuming that the power dissipated in the semiconductor is represented by its average value. However, the power may present peaks with value higher than the average. These peaks can be taken into account for the heat-sink design.

The junction temperature calculation considering the power peak is made using an electric quantity called thermal impedance (Z_{Tjc}). Its value is obtained through normalized current found in manufactures catalog. Fig. 2.77 presents typical curves for normalized thermal impedance. The x-axis values are the duration of the pulse over the switching period when the power peak occurs. The impedance is normalized over the junction-to-case thermal resistance.

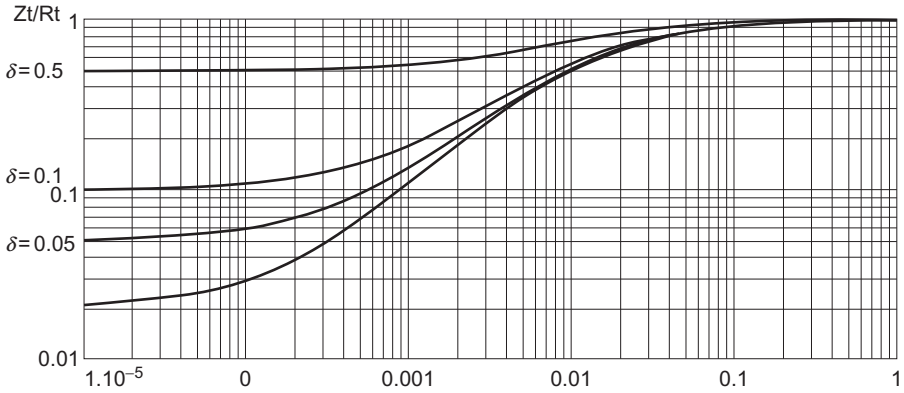

FIG. 2.77 Typical curves for normalized thermal impedance.

The peak junction temperature is given by (2.21):

$$T_{j_pk} = T_c + P_{pk} Z_{Tjc} \tag{2.21}$$

where the index *pk* means peak.

In case the value obtained in (2.21) is higher than the maximum junction temperature, the heat-sink-to-ambient resistance should be recalculated.

2.7 Transistor Selection Criteria

The transistor selection for a power electronic application depends on some criteria. The most common is to identify the required reverse voltage and forward current. Switching frequency appears as criteria directly related to the volume of passive elements, such as inductors and capacitors. For applications with desired low volume, a high-frequency transistor is the best choice. With these criteria defined, the next step is to verify if there are transistors available on the market that satisfies such criteria. Fig. 2.78 presents approximated power rate for currently available BJT, MOSFET, and IGBT, valid for silicon-based transistors [3,13].

Cost and efficiency can also be considered in choosing a transistor. For example, an application where the transistor must hold 500 V and 10 A, according to the previous chart, BJT, MOSFET, or IGBT can be employed. Considering the cost as the main concern, the BJT would likely appear as the best option. On the other hand, if the efficiency is the priority, IGBT is a potential candidate.

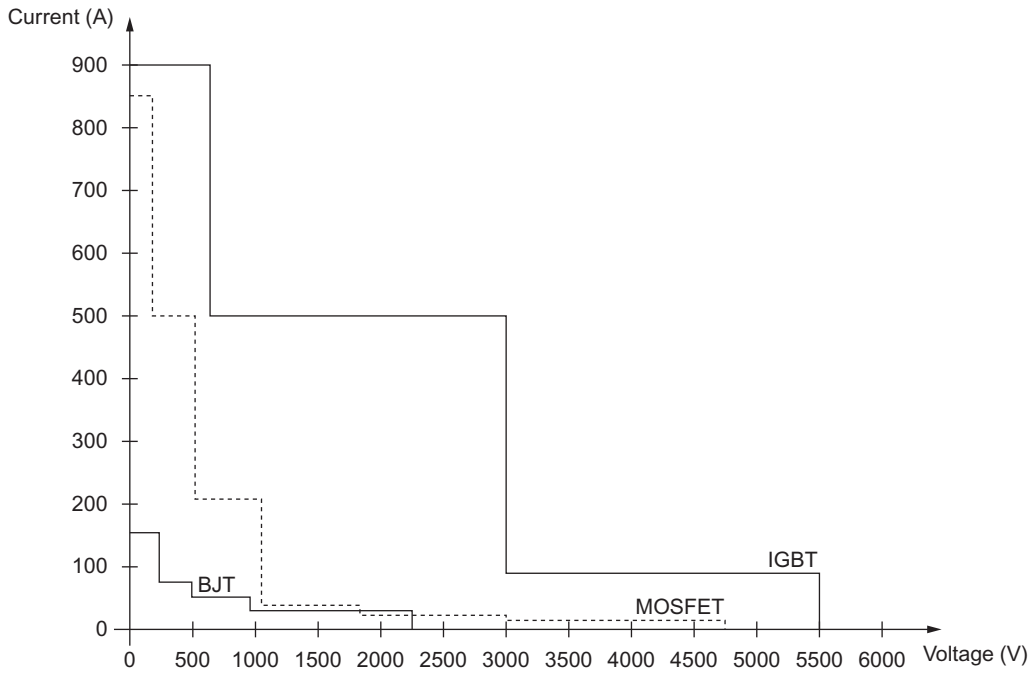

FIG. 2.78 Approximated power rate for currently available BJT, MOSFET, and IGBT.

Efficiency can be exploited taking into account the transistor material. Emerging transistors based on silicon carbide or gallium nitride [6,10,14,15] are a promising technology to enhance the switching behavior and consequently reduce the power losses. Such transistors are considered as wide bandgap power devices. Details of these devices are found in the chapter entitled "Wide Bandgap Materials and Power Semiconductor Devices."

3.1 Introduction

Thyristors are usually three-terminal devices that have four layers of alternating *p*-type and *n*-type material (i.e., three *p*-*n* junctions) comprising its main power handling section. In contrast to the linear relation that exists between load and control currents in a transistor, the thyristor is bistable. The control terminal of the thyristor, called the gate (*G*) electrode, may be connected to an integrated and complex structure as a part of the device. The other two terminals, called the anode (*A*) and cathode (*K*), handle the large applied potentials (often of both polarities) and conduct the major current through the thyristor. The anode and cathode terminals are connected in series with the load to which power is to be controlled.

Thyristors are used to approximate ideal closed (no voltage drop between anode and cathode) or open (no anode current flow) switches for control of power flow in a circuit. This differs from low-level digital switching circuits that are designed to deliver two distinct small voltage levels while conducting small currents (ideally zero). Thyristor circuits must have the capability of delivering large currents and be able to withstand large externally applied voltages. All thyristor types are controllable in switching from a forward-blocking state (positive potential applied to the anode with respect to the cathode, with correspondingly little anode current flow) into a forward-conduction state (large forward anode current flowing, with a small anode-cathode potential drop). Most thyristors have the characteristic that after switching from a forward-blocking state into the forward-conduction state, the gate signal can be removed and the thyristor will remain in its forward-conduction mode. This property is termed "latching" and is an important distinction between thyristors and other types of power electronic devices. Some thyristors are also controllable in switching from forward-conduction back to a forward-blocking state. The particular design of a thyristor will determine its controllability and often its application.

Thyristors are typically used at the highest energy levels in power-conditioning circuits because they are designed to handle the largest currents and voltages of any device technology (systems approximately with voltages above 1 kV or currents

http://dx.doi.org/10.1016/B978-0-12-811407-0.00003-9

above 100 A). Many medium-power circuits (systems operating at less than 1 kV or 100 A) and particularly low-power circuits (systems operating below 100 V or several amperes) generally make use of power bipolar transistors, power metal-oxide-semiconductor field-effect transistors (MOSFETs), or insulated gate bipolar transistors (IGBTs) as the main switching elements because of the relative ease in controlling them. IGBT technology, however, continues to improve and multiple silicon die are commonly packaged together in a module. These modules are replacing thyristors in applications operating up to 3 kV that require controllable turn-off because of easier gate-drive requirements. Power diodes are used throughout all levels of power-conditioning circuits and systems for component protection and wave shaping.

A thyristor used in some ac power circuits (50 or 60 Hz in commercial utilities or 400 Hz in aircraft) to control ac power flow can be made to optimize internal power loss at the expense of switching speed. These thyristors are called phase-control devices, because they are generally turned from a forward-blocking into a forward-conducting state at some specified phase angle of the applied sinusoidal anode-cathode voltage waveform. A second class of thyristors is used in association with dc sources or in converting ac power at one amplitude and frequency into ac power at another amplitude and frequency and must generally switch on and off relatively quickly. A typical application for the second class of thyristors is in converting a dc voltage or current into an ac voltage or current. A circuit that performs this operation is often called an inverter, and the associated thyristors used are referred to as inverter thyristors.

There are four major types of thyristors: (i) the silicon-controlled rectifier (SCR), (ii) the gate turn-off thyristor (GTO) and its close relative the integrated gate-commutated thyristor (IGCT), (iii) the MOS-controlled thyristor (MCT) and its various forms, and (iv) the static induction thyristor (SITh). MCTs are so-named because many parallel enhancement-mode, MOSFET structures of one charge type are integrated into the thyristor for turn-on, and many more MOSFETs of the other charge types are integrated into the thyristor for turn-off. An SITh or field-controlled thyristor (FCTh) has essentially the same construction as a power diode with a gate structure that can pinch-off anode current flow. Although MCTs, derivative forms of the MCT and SIThs, have the advantage of being essentially voltage-controlled devices (i.e., little control current is required for turn-on or turnoff and therefore require simplified control circuits attached to the gate electrode), they are currently only found in niche applications such as pulse power. Detailed discussion of variations of MCTs and SIThs and additional references on these devices are discussed by Hudgins in [1]. Other types of thyristors include the triac (a pair of antiparallel SCRs integrated together to form a bidirectional current switch) and the programmable unijunction transistor (PUT).

The SCRs and GTOs are designed to operate at all power levels. These devices are primarily controlled using electric signals (current), though some types are made to be controlled using optical energy (photons) for turn-on. Subclasses of SCRs and GTOs are reverse conducting types and symmetrical structures that block applied potentials in the reverse and forward polarities. Other variations of GTOs are the gate-commutated turnoff thyristor (GCT), commonly available as the IGCT and the bidirectional-controlled thyristor (BCT).

All power electronic devices must be derated (e.g., power dissipation levels, current conduction, voltage blocking, and switching frequency must be reduced), when operating above room temperature (defined as approximately 25°C). Bipolar-type devices have thermal runaway problems, in that if allowed to conduct unlimited current, these devices will heat up internally causing more current to flow, thus generating more heat and so forth until destruction. Devices that exhibit this behavior are *pin* diodes, bipolar transistors, and thyristors.

Almost all power semiconductor devices are made from silicon (Si). Research and development continues in developing other types of devices in silicon carbide (SiC), gallium nitride (GaN), and related material systems. However, the physical description and general behavior of thyristors is unimportant to the semiconductor material system used, though the discussion and any numbers cited in the chapter will be associated with Si devices.

3.2 Basic Structure and Operation

Fig. 3.1 shows a conceptual view of a typical thyristor with the three *p-n* junctions and the external electrodes labeled. Also shown in the figure is the thyristor circuit symbol used in electric schematics.

A high-resistivity region, n^--base, is present in all thyristors. It is this region, the n^--base and associated junction, J_2 of Fig. 3.1, which must support the large applied forward voltages that occur when the switch is in its off- or forward-blocking state (nonconducting). The n^--base is typically doped with impurity phosphorous atoms at a concentration of 10^{13}–10^{14} cm^{-3}.

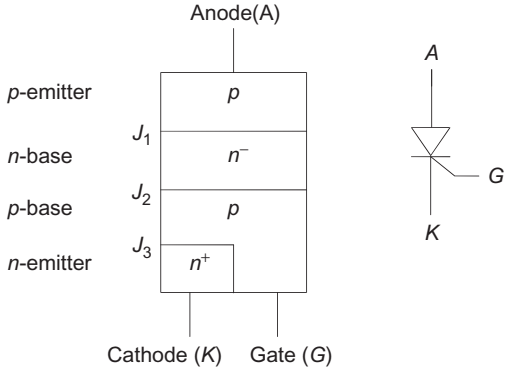

FIG. 3.1 Simple cross section of a typical thyristor and the associated electric schematic symbols.

The n^--base can be tens to hundreds of micrometer thick to support large voltages. High-voltage thyristors are generally made by diffusing aluminum or gallium into both surfaces to create p-doped regions forming deep junctions with the n^--base. The doping profile of the p-regions ranges from about 10^{15} to 10^{17} cm^{-3}. These p-regions can be up to tens of micrometer thick. The cathode region (typically only a few micrometers thick) is formed by using phosphorous atoms at a doping density of 10^{17}–10^{18} cm^{-3}.

The higher the forward-blocking voltage rating of the thyristor, the thicker the n^--base region must be. However, increasing the thickness of this high-resistivity region results in slower turn-on and turn-off (i.e., longer switching times and/or lower frequency of switching cycles because of more stored charge during conduction). For example, a device rated for a forward-blocking voltage of 1 kV will, by its physical construction, switch much more slowly than one rated for 100 V. In addition, the thicker high-resistivity region of the 1 kV device will cause a larger forward voltage drop during conduction than the 100 V device carrying the same current. Impurity atoms, such as platinum or gold, and electron irradiation are used to create charge-carrier recombination sites in the thyristor. The large number of recombination sites reduces the mean carrier lifetime (average time that an electron or hole moves through the Si before recombining with its opposite charge-carrier type). A reduced carrier lifetime shortens the switching times (in particular the turnoff or recovery time) at the expense of increasing the forward conduction drop. There are other effects associated with the relative thickness and layout of the various regions that make up modern thyristors, but the major trade-off between forward-blocking voltage rating and switching times and between forward-blocking voltage rating and forward voltage drop during conduction should be kept in mind. (In signal-level electronics, an analogous trade-off appears as a lowering of amplification (gain) to achieve higher operating frequencies and is often referred to as the gain-bandwidth product.)

Operation of thyristors is as follows. When a positive voltage is applied to the anode (with respect to cathode), the thyristor is in its forward-blocking state. The center junction J_2 (see Fig. 3.1) is reverse biased. In this operating mode, the gate current is held to zero (open circuit). In practice, the gate electrode is biased to a small negative voltage (with respect to the cathode) to reverse bias the GK junction J_3 and prevent charge carriers from being injected into the p-base. In this condition, only thermally generated leakage current flows through the device and can often be approximated as zero in value (the actual value of the leakage current is typically many orders of magnitude lower than the conducted current in the on-state). As long as the forward applied voltage does not exceed the value necessary to cause excessive carrier multiplication in the depletion region around J_2 (avalanche breakdown), the thyristor remains in an off-state (forward-blocking). If the applied voltage exceeds the maximum forward-blocking voltage of the thyristor, it will switch to its on-state. However, this mode of turn-on causes nonuniformity in the current flow, is generally destructive, and should be avoided.

When a positive gate current is injected into the device, J_3 becomes forward biased and electrons are injected from the n-emitter into the p-base. Some of these electrons diffuse across the p-base and get collected in the n^--base. This collected charge causes a change in the bias condition of J_1. The change in bias of J_1 causes holes to be injected from the p-emitter into the n^--base. These holes diffuse across the n^--base and are collected in the p-base. The addition of these collected holes in the p-base acts the same as gate current. The entire process is regenerative and will cause the increase in charge carriers until J_2 also becomes forward biased and the thyristor is latched in its on-state (forward conduction). The regenerative action will take place as long as the gate current is applied in sufficient amount and for a sufficient length of time. This mode of turn-on is considered to be the desired one as it is controlled by the gate signal.

This switching behavior can also be explained in terms of the two-transistor analog shown in Fig. 3.2. The two transistors are regeneratively coupled so that if the sum of their forward current gains (α's) exceeds unity, each drives the other into saturation. Eq. (3.1) describes the condition necessary for the thyristor to move from a forward-blocking state to the forward-conduction state. The forward current gain (expressed as the ratio of collector current to emitter current) of the *pnp* transistor is denoted by α_p and that of the *npn* as α_n. The α's are current dependent and increase slightly as the current increases. The center junction J_2 is reverse biased under forward applied voltage (positive, v_{AK}). The associated electric field in the depletion region around the junction can result in significant carrier multiplication, denoted as a multiplying factor M on the current components, I_{co} and i_G.

$$i_A = \frac{MI_{co} + M\alpha_n i_G}{1 - M(\alpha_n + \alpha_p)} \tag{3.1}$$

In the forward-blocking state, the leakage current I_{co} is small, both α's are small, and their sum is less than unity. Gate current increases the current in both transistors, increasing their α's.

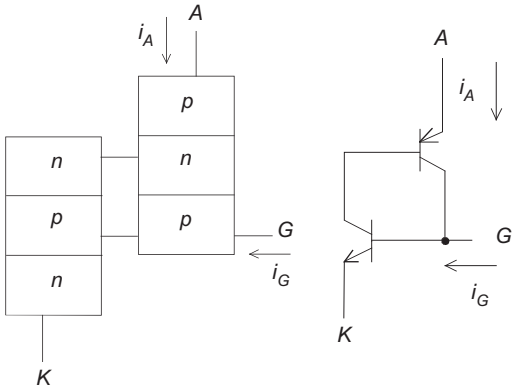

FIG. 3.2 Two-transistor behavioral model of a thyristor.

Collector current in the *npn* transistor acts as base current for the *pnp*, and analogously, the collector current of the *pnp* acts as base current driving the *npn* transistor. When the sum of the two α's equals unity, the thyristor switches to its on-state (latches). This condition can also be reached, without any gate current, by increasing the forward applied voltage so that carrier multiplication ($M \gg 1$) at J_2 increases the internal leakage current, thus increasing the two α's. A third way to increase the α's exists by increasing the device (junction) temperature. Increasing the temperature causes a corresponding increase in the leakage current I_{co} to the point where latching can occur. The typical manifestation of this temperature dependence is to cause an effective lowering of the maximum blocking voltage that can be sustained by the thyristor.

Another way to cause a thyristor to switch from forward-blocking to forward-conduction exists. Under a forward applied voltage, J_2 is reverse biased, while the other two junctions are forward biased in the blocking mode. The reverse-biased junction of J_2 is the dominant capacitance of the three and determines the displacement current that flows. If the rate of increase in the applied $v_{AK}(dv_{AK}/dt)$ is sufficient, it will cause a significant displacement current through the J_2 capacitance. This displacement current can initiate switching similar to an externally applied gate current. This dynamic phenomenon is inherent in all thyristors and causes there to be a limit (dv/dt) to the time rate of applied v_{AK} that can be placed on the device to avoid uncontrolled switching. Alterations to the basic thyristor structure can be produced that increase the dv/dt limit.

Once the thyristor has moved into forward conduction, any applied gate current is superfluous. The thyristor is latched and, for SCRs, cannot be returned to a blocking mode by using the gate terminal. Anode current must be commutated away from the SCR for a sufficient time to allow stored charge in the device to recombine. Only after this recovery time has occurred, can a forward voltage be reapplied (below the dv/dt limit of course), and the SCR again be operated in a forward-blocking mode. If the forward voltage is reapplied before sufficient recovery time has elapsed, the SCR will move back into forward conduction. For GTOs and IGCTs, a large applied reverse gate current (typically in the range of 10%–50% of the anode current for GTOs and 100% of the anode current for IGCTs) applied for a sufficient time can remove enough charge near the GK junction to cause it to turn off. This interrupts the base current to the *pnp* transistor, leaving the *pnp* open base, causing thyristor turn-off. This is similar in principle to use negative base current to quickly turn off a traditional bipolar transistor.

3.3 Static Characteristics

3.3.1 Current–Voltage Curves for Thyristors

A plot of the anode current (i_A) as a function of anode-cathode voltage (v_{AK}) is shown in Fig. 3.3. The forward-blocking mode

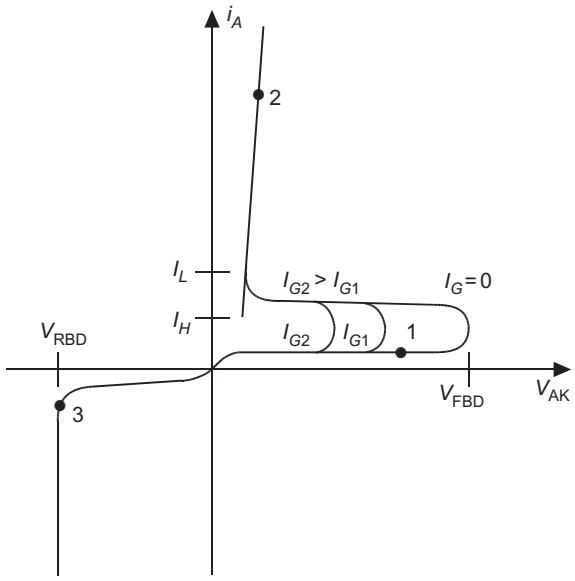

FIG. 3.3 Static characteristic *i-v* curve typical of thyristors.

is shown as the low-current portion of the graph (solid curve around operating point "1"). With zero gate current and positive v_{AK}, the forward characteristic in the off- or blocking state is determined by the center junction J_2, which is reverse biased. At operating point "1," very little current flows (I_{co} only) through the device. However, if the applied voltage exceeds the forward-blocking voltage, the thyristor switches to its on- or conducting state (shown as operating point "2") because of carrier multiplication (M in Eq. (3.1)). The effect of gate current is to lower the blocking voltage at which switching takes place. The thyristor moves rapidly along the negatively sloped portion of the curve until it reaches a stable operating point determined by the external circuit (point "2"). The portion of the graph indicating forward conduction shows the large values of i_A that may be conducted at relatively low values of v_{AK}, similar to a power diode.

As the thyristor moves from forward-blocking to forward-conducting, the external circuit must allow sufficient anode current to flow to keep the device latched. The minimum anode current that will cause the device to remain in forward conduction as it switches from forward-blocking is called the latching current I_L. If the thyristor is already in forward conduction and the anode current is reduced, the device can move its operating mode from forward conduction back to forward-blocking. The minimum value of anode current necessary to keep the device in forward conduction after it has been operating at a high anode current value is called the holding current I_H. The holding current value is lower than the latching current value as indicated in Fig. 3.3.

The reverse thyristor characteristic, quadrant III of Fig. 3.3, is determined by the outer two junctions (J_1 and J_3), which are reverse biased in this operating mode (applied v_{AK} is negative). Symmetrical thyristors are designed so that J_1 will reach reverse

breakdown due to carrier multiplication at an applied reverse potential near the forward breakdown value (operating point "3" in Fig. 3.3). The forward- and reverse-blocking junctions are usually fabricated at the same time with a very long diffusion process (10–50 h) at high temperatures (>1200°C). This process produces symmetrical blocking properties. Wafer-edge termination processing causes the forward-blocking capability to be reduced to about 90% of the reverse-blocking capability. Edge termination is discussed below. Asymmetrical devices are made to optimize forward conduction and turnoff properties and as such reach reverse breakdown at a lower voltage than that applied in the forward direction. This is accomplished by designing the asymmetrical thyristor with a much thinner n^--base than is used in symmetrical structures. The thin n^--base leads to improved properties such as lower forward drop and shorter switching times. Asymmetrical devices are generally used in applications when only forward voltages (positive, v_{AK}) are to be applied (including many inverter designs).

The form of the gate-to-cathode *i-v* characteristic of SCRs, GTOs, and IGCTs is similar to that of a diode. With positive gate bias, the gate-cathode junction is forward biased and permits the flow of a large current in the presence of a low voltage drop. When negative gate voltage is applied to an SCR, the gate-cathode junction is reverse biased and prevents the flow of current until the avalanche breakdown voltage is reached. In a GTO or IGCT, a negative gate voltage is applied to provide a low-impedance path for anode current to flow out of the device instead of out the cathode. In this way, the cathode region (base-emitter junction of the equivalent *npn* transistor) turns off, thus pulling the equivalent *npn* transistor out of conduction. This causes the entire thyristor to return to its blocking state. The problem with the GTO and IGCT is that the gate-drive circuitry is typically required to sink 10%–50% (for the GTO) or 100% (for the IGCT) of the anode current to achieve turn-off.

3.3.2 Edge and Surface Terminations

Thyristors are often made with planar diffusion technology to create the cathode region. Formation of these regions creates cylindrical curvature of the metallurgical gate-cathode junction. Under reverse bias, the curvature of the associated depletion region results in electric field crowding along the curved section of the p^+ diffused region. The field crowding seriously reduces the breakdown potential below that expected for the bulk semiconductor. A floating field ring, an extra *p* diffused region with no electric connection at the surface, is often added to modify the electric field profile and thus reduce it to a value below or at the field strength in the bulk. An illustration of a single floating field ring is shown in Fig. 3.4. The spacing, *W*, between the main anode region and the field ring is critical. Multiple rings can also be employed to further modify the electric field in high-voltage rated thyristors.

Another common method for altering the electric field at the surface is by using a field plate as shown in cross section in Fig. 3.5. By forcing the potential over the oxide to be the same as at the surface of the p^+ region, the depletion region can be extended so that the electric field intensity is reduced near the curved portion of the diffused p^+ region. A common practice is to use field plates with floating field rings to obtain optimum breakdown performance.

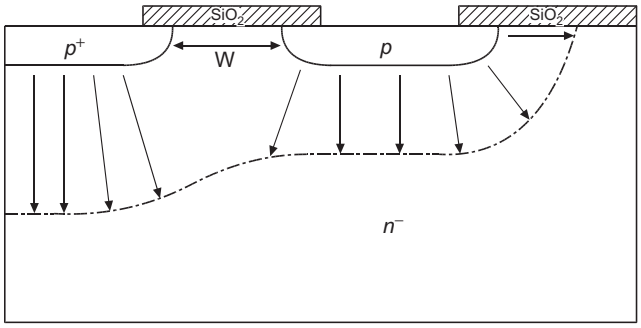

FIG. 3.4 Cross section showing a floating field ring to decrease the electric field intensity near the curved portion of the main anode region (leftmost p^+ region).

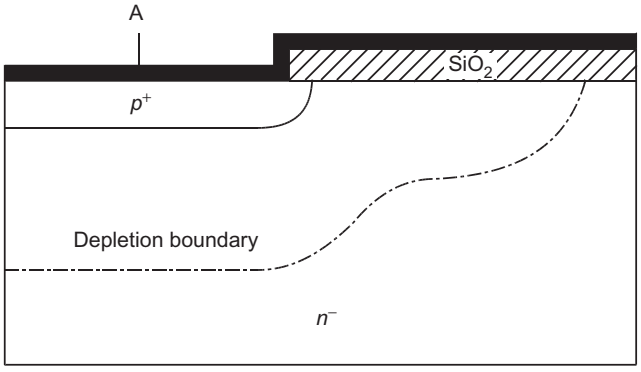

FIG. 3.5 Cross section showing a field plate used to reduce the electric field intensity near the curved portion of the p^+-region (anode).

High-voltage thyristors are made from single wafers of Si and must have edge terminations other than floating field rings or field plates to promote bulk breakdown and limit leakage current at the surface. Controlled bevel angles can be created using lapping and polishing techniques during production of large-area thyristors. Two types of bevel junctions can be created: (i) a positive bevel defined as one in which the junction area decreases when moving from the highly doped to the lightly doped side of the depletion region and (ii) a negative bevel defined as one in which the junction area increases when moving from the highly doped to the lightly doped side of the depletion region. In practice, the negative bevel must be lapped at an extremely shallow angle to reduce the surface field below the field intensity in the bulk. All positive bevel angles between 0 and 90 degrees result in a lower surface field than in the bulk. Fig. 3.6 shows the use of a positive bevel for the J_1 junction and a shallow negative bevel for the J_2 and J_3 junctions on a thyristor

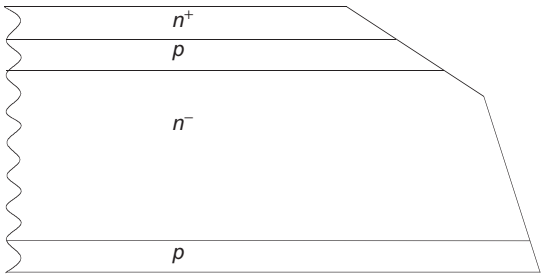

FIG. 3.6 Cross section of a thyristor showing the negative bevel (upper p-n^- and p-n^+ junctions) and positive bevel (lower p-n^- junction) used for edge termination of large-area devices.

cross section to make maximum use of the Si area for conduction and still reduce the surface electric field. Further details of the use of beveling, field plates, and field rings can be found in Ghandi [1] and Baliga [2].

3.3.3 Packaging

Thyristors are available in a wide variety of packages, from small plastic ones for low-power (i.e., TO-247), to stud-mount packages for medium-power, to press pack (also called flat pack) for the highest power devices. The press packs must be mounted under pressure to obtain proper electric and thermal contact between the device and the external metal electrodes. Special force-calibrated clamps are made for this purpose. Large-area thyristors cannot be directly attached to the large copper pole piece of the press pack because of the difference in the coefficient of thermal expansion (CTE), hence the use of a pressure contact for both anode and cathode. Fig. 3.7 shows typical thyristor stud-mount and press-pack packages.

Many medium-power thyristors are appearing in modules where a half- or full bridge (and associated antiparallel diodes) is put together in one package. A power module package should have five characteristics:

(i) Electric isolation of the baseplate from the semiconductor
(ii) Good thermal performance
(iii) Good electric performance
(iv) Long life/high reliability
(v) Low cost

Electric isolation of the baseplate from the semiconductor is necessary in order to contain both halves of a phase leg in one package and for convenience (modules switching different phases can be mounted on one heat sink) and safety (heat sinks can be held at ground potential).

Thermal performance is measured by the maximum temperature rise in the Si die at a given power dissipation level with a fixed heat sink temperature. The lower the die temperature, the better the package. A package with a low thermal resistance from junction-to-sink can operate at higher power densities for the same temperature rise or lower temperatures for the same power dissipation than a more thermally resistive package. While maintaining low device temperature is generally preferable, temperature variation affects majority carrier and bipolar devices differently. Roughly speaking, in a bipolar device such as a thyristor, switching losses increase and conduction losses decrease with increasing temperature. In a majority carrier device, such as a MOSFET, conduction losses increase with increasing temperature. The thermal conductivity of typical materials used in thyristor packages is shown in Table 3.1.

Electric performance refers primarily to the stray inductance in series with the die and the capability of mounting a low-inductance bus to the terminals. Another problem is the minimization of capacitive cross talk from one switch to another, which can cause an abnormal on-state condition by charging the gate of an off-state switch or from a switch to any circuitry in the package (as would be found in a hybrid power module). Capacitive coupling is a major cause of electromagnetic interference (EMI). As the stray inductance of the module and the bus sets a minimum switching loss for the device—because the switch must absorb the stored inductive energy—it is very important to minimize inductance within the module. Reducing the parasitic inductance reduces the high-frequency ringing during transients that is another cause of radiated EMI. Since

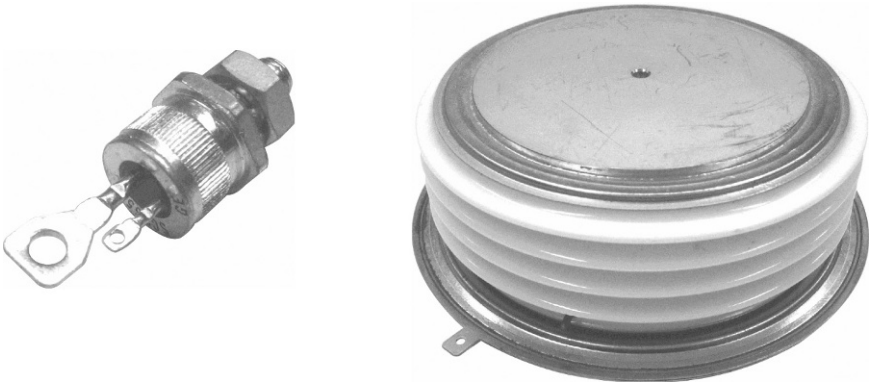

FIG. 3.7 Examples of thyristor packaging: stud-mount (left) and press-pack/capsule (right).

TABLE 3.1 Thermal conductivity of thyristor package materials

Material	Thermal conductivity (W/m·K) at 300 K
Silicon	150

Thermal grease (heat sink compound)	0.75
60/40 solder (Pb/Sn eutectic)	50
95/5 solder (Pb/Sn high temperature)	35

stray inductance can cause large peak voltages during switching transients, minimizing it helps to maintain the device within its safe area of operation.

Long life and high reliability are primarily attained through minimization of thermal cycling, minimization of ambient temperature, and proper design of the transistor stack. Thermal cycling fatigues material interfaces because of CTE mismatch between dissimilar materials. As the materials undergo temperature variation, they expand and contract at different rates that stresses the interface between the layers and can cause interface deterioration (e.g., cracking of solder layers or wire debonding). Chemical degradation processes such as dendrite growth and impurity migration are accelerated with increasing temperature, so keeping the absolute temperature of the device low and minimizing the temperature changes to which it is subjected is important. Typical CTE values for common package materials are given in Table 3.2.

Low cost is achieved in a variety of ways. Both manufacturing and material costs must be taken into account when designing a power module. Materials that are difficult to machine or process, even if they are relatively cheap in raw form (e.g., molybdenum), should be avoided. Manufacturing processes that lower yield also drive up costs. In addition, a part that is very reliable can reduce future costs by reducing the need for repair and replacement.

TABLE 3.2 CTE for thyristor package materials

Material	CTE (μm/m·K) at 300 K
Silicon	4.1

The basic half-bridge module has three power terminals: plus, minus, and phase. Advanced modules differ from traditional high-power commercial modules in several ways. The baseplate is metallized aluminum nitride (AlN) ceramic rather than the typical 0.125 in. thick nickel-plated copper baseplate with a soldered metallized ceramic substrate for electric isolation. This AlN baseplate stack provides a low thermal resistance from die to heat sink. The copper terminal power buses are attached by solder to the devices in a wirebond-free, low-inductance, low-resistance, device interconnect configuration. The balance of the assembly is typical for module manufacturing with attachment of shells, use of dielectric gels, and hard epoxies and adhesive to seal the finished module. Details of the thermal performance of modules and advanced modules can be found in Beker et al. [3] and Godbold et al. [4].

3.4 Dynamic Switching Characteristics

The time rate of rise of anode current (di/dt) during turn-on and the time rate of rise of anode-cathode voltage (dv/dt) during turnoff are important parameters to control for ensuring proper and reliable operation. All thyristors have maximum limits for di/dt and dv/dt that must not be exceeded. Devices capable of conducting large currents in the on-state are necessarily made with large surface areas through which the current flows. During turn-on, localized areas of a device (near the gate region) begin to conduct current. The initial turn-on of an SCR is shown in Fig. 3.8. The cross section illustrates how injected gate current flows to the nearest cathode region, causing this portion of the *npn* transistor to begin conducting. The *pnp* transistor then follows the *npn* into conduction such that anode current begins flowing only in a small portion of the cathode region. If the local current density becomes too large (in excess of several thousand amperes per square centimeter), then self-heating will damage the device. Sufficient time (referred to as plasma spreading time) must be allowed for the entire cathode area to begin conducting before the localized currents become too high. This phenomenon results in a maximum allowable rate of rise of anode current in a thyristor and is referred to as a di/dt limit. In many high-frequency applications, the entire cathode region is never fully in conduction. Prevention of di/dt failure can be accomplished if the rate of increase of conduction area exceeds the di/dt rate such that the internal junction temperature does not exceed a specified critical temperature (typically approximately 350°C). This critical temperature decreases as the blocking voltage increases. Adding series inductance to the thyristor to limit di/dt below its maximum usually causes circuit design problems.

Another way to increase the di/dt rating of a device is to increase the amount of gate-cathode periphery. Inverter SCRs (so-named because of their use in high-frequency power-converter circuits that convert dc to ac, i.e., invert) are designed so that there is a large amount of gate edge adjacent to a

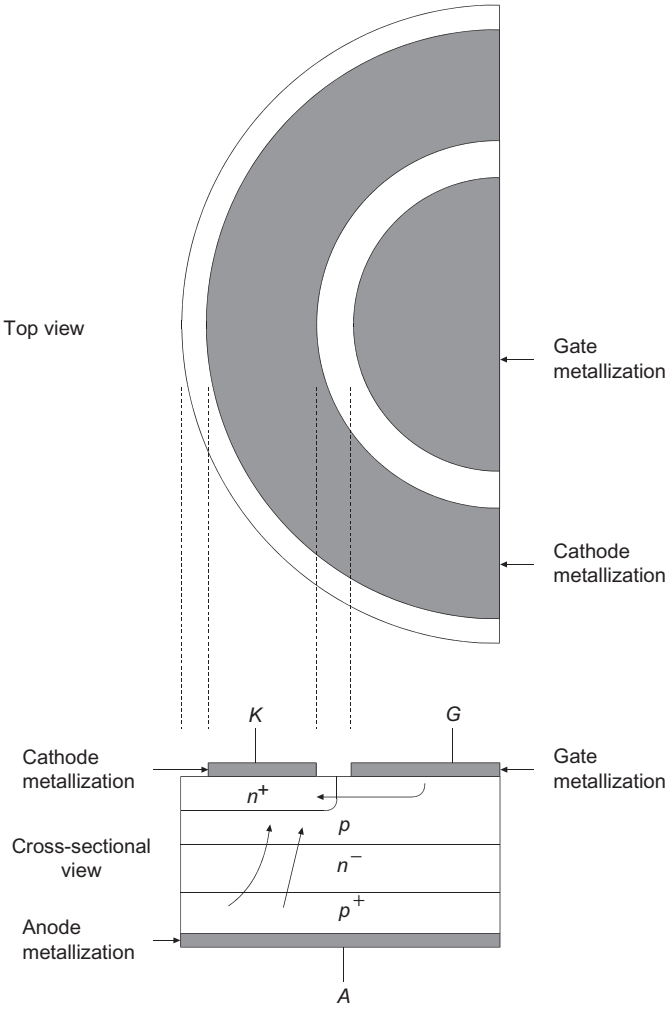

FIG. 3.8 Top view and associated cross section of gate-cathode periphery showing initial turn-on region in a center-fired thyristor.

significant amount of cathode edge. A top surface view of two typical gate-cathode patterns, found in large thyristors, is shown in Fig. 3.9. An inverter SCR often has a stated maximum *di/dt* limit of approximately 2000 A/μs. This value has been shown to be conservative in Hadgins [5], and by using excessive gate current under certain operating conditions, an inverter SCR can be operated reliably at 10,000–20,000 A/μs.

A GTO takes the interdigitation of the gate and cathode to the extreme (Fig. 3.9, left). In Fig. 3.10, a cross section of a GTO shows the amount of interdigitation. A GTO often has cathode islands that are formed by etching the Si. A metal plate can be placed on the top to connect the individual cathodes into a large arrangement of electrically parallel cathodes. The gate metallization is placed so that the gate surrounding each cathode is electrically in parallel as well. This construction not only allows high *di/dt* values to be reached, as in an inverter SCR but also provides the capability to turn off the anode current by shunting it away from the individual cathodes and out of the gate electrode upon reverse biasing of the gate. During turnoff, current is decreasing while voltage across the device is increasing. If the forward voltage becomes too high while sufficient

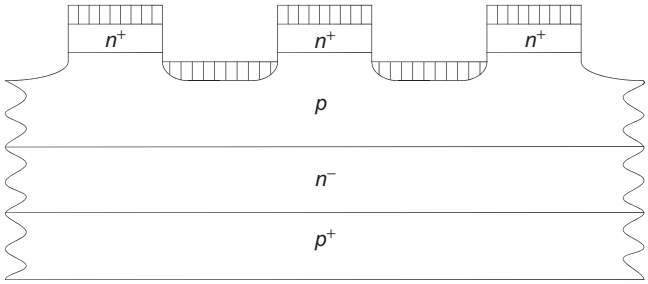

FIG. 3.10 Cross section of a GTO showing the cathode islands and interdigitation with the gate (*p*-base).

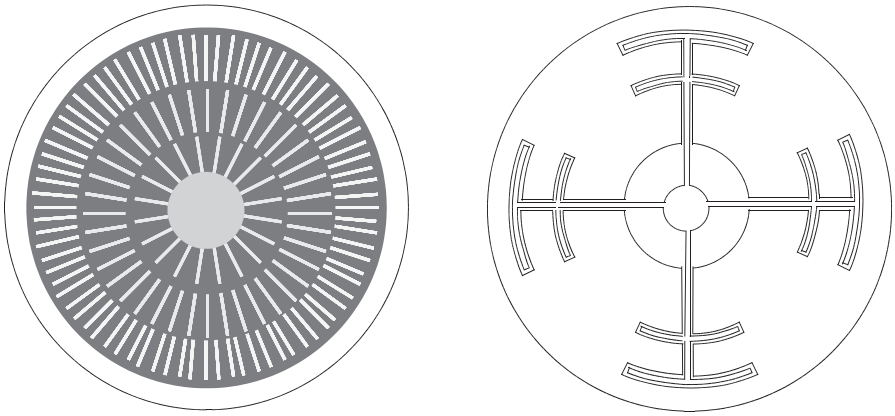

FIG. 3.9 Top view of typical interdigitated gate-cathode patterns used for thyristors.

current is still flowing, then the device will drop back into its conduction mode instead of completing its turn-off cycle. Also, during turnoff, the power dissipation can become excessive if the current and voltage are simultaneously too large. Both of these turn-off problems can damage the device and other portions of the circuit.

Another switching problem that occurs is associated primarily with thyristors, though other power electronic devices suffer some degradation of performance from the same problem. This problem is that thyristors can self-trigger into a forward-conduction mode from a forward-blocking mode if the rate of rise of forward anode-cathode voltage is too large. This triggering method is due to displacement current through the associated junction capacitances (the capacitance at J_2 dominates because it is reverse biased under forward applied voltage). The displacement current contributes to the leakage current I_{co}, shown in Eq. (3.1). The SCRs, GTOs, and IGCTs, therefore, have a maximum dv/dt rating that should not be exceeded (typical values are 100–1000 V/μs). Switching into a reverse-conducting from a reverse-blocking state, due to an applied reverse dv/dt, is not possible because the values of the reverse α's of the equivalent transistors can never be made large enough to cause the necessary feedback (latching) effect. An external capacitor is often placed between the anode and cathode of the thyristor to help control the dv/dt experienced. Capacitors and other components that are used to form such protection circuits, known as snubbers, may be found in all power semiconductor devices.

3.4.1 Cathode Shorts

As the temperature in the thyristor increases above 25°C, the minority carrier lifetime and the corresponding diffusion lengths in the n- and p-bases increase. This leads to an increase in the α's of the equivalent transistors. Discussion of the details of the minority carrier diffusion length and its role in determining the current gain factor α can be found in Sze [6]. Referring to Eq. (3.1), it is seen that a lower applied bias will give a carrier multiplication factor M sufficient to switch the device from forward-blocking into conduction, because of this increase of the α's with increasing temperature. Placing a shunt resistor in parallel with the base-emitter junction of the equivalent npn transistor (shown in Fig. 3.11) will result in an effective current gain, α_{neff}, that is lower than α_n, as given by Eq. (3.2), where v_{GK} is the applied gate-cathode voltage, R_s is the equivalent lumped value for the distributed current shunting structure, and the remaining factors form the appropriate current factor based on the applied bias and characteristics of the gate-cathode junction. The shunt current path is implemented by providing intermittent shorts, called cathode shorts, between the p-base (gate) region and the n^+-emitter (cathode) region in the thyristor as illustrated in Fig. 3.12. The lumped shunt resistance value is in the range of 1–15 Ω as measured from gate to cathode.

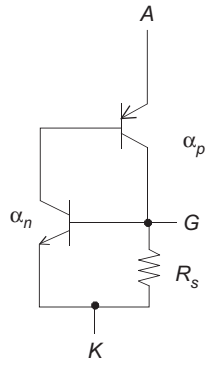

FIG. 3.11 Two-transistor equivalent circuit showing the addition of a resistive shunt path for anode current.

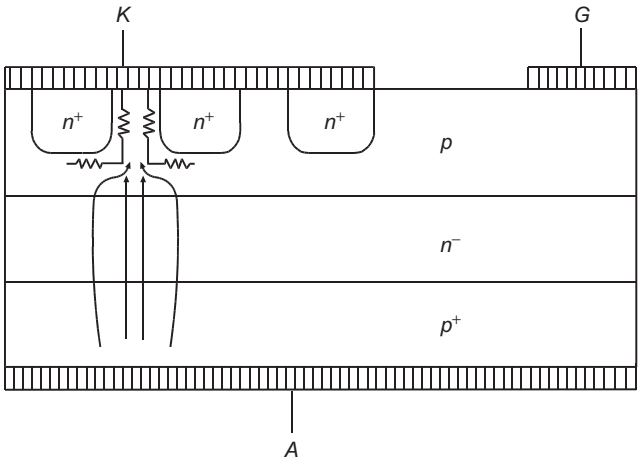

FIG. 3.12 Cross section showing cathode shorts and the resulting resistive shunt path for anode current.

$$\alpha_{neff} = \alpha_n \left(\frac{1}{1 + (v_{GK}\alpha_n)/(R_s i_0 \exp(q v_{GK}/kT))} \right) \tag{3.2}$$

Low values of anode current (e.g., those associated with an increase in temperature under forward-blocking conditions) will flow through the shunt path to the cathode contact, bypassing the n^+-emitter and keeping the device out of its forward-conduction mode. As the anode current becomes large, the potential drop across the shunt resistance will be sufficient to forward bias the gate-cathode junction, J_3, and bring the thyristor into forward conduction. The cathode shorts also provide a path for displacement current to flow without forward-biasing J_3. The dv/dt rating of the thyristor is thus improved and the forward-blocking characteristics by using cathode shorts. However, the shorts do cause a lowering of cathode current handling capability because of the loss of some of the cathode area (n^+-region) to the shorting pattern, an increase in the necessary gate current to obtain switching from forward-blocking to forward conduction and an increase in complexity of manufacturing of the thyristor. The loss of cathode area due to the shorting

structure is from 5% to 20%, depending on the type of thyristor. By careful design of the cathode short windows to the p-base, the holding current can be made lower than the latching current. This is important so that the thyristor will remain in forward conduction when used with varying load impedances.

3.4.2 Anode Shorts

A further increase in forward-blocking capability can be obtained by introducing anode shorts in addition to the cathode shorts. This reduces α_p in a similar manner that cathode shorts reduce α_n. An illustration of this is provided in Fig. 3.13. In this structure, both J_1 and J_3 are shorted (anode and cathode shorts), so that the forward-blocking capability of the thyristor is completely determined by the avalanche breakdown characteristics of J_2. Anode shorts will result in the complete loss of reverse-blocking capability and are only suitable for thyristors used in asymmetrical circuit applications.

3.4.3 Amplifying Gate

The cathode-shorting structure will reduce the gate sensitivity dramatically. To increase this sensitivity and yet retain the benefits of the cathode shorts, a structure called an amplifying gate (or regenerative gate) is used, as shown in Fig. 3.14 (and Fig. 3.9, right). When the gate current (1) is injected into the p-base through the pilot-gate contact, electrons are injected into the p-base by the n^+-emitter with a given emitter injection efficiency. These electrons traverse through the p-base (the time taken for this process is called the transit time) and accumulate near the depletion region. This negative charge accumulation leads to injection of holes from the anode. The device then turns on after a certain delay, dictated by the p-base transit time, and the pilot anode current (2) begins to flow through a small region near the pilot-gate contact as shown in Fig. 3.14.

This flow of pilot anode current corresponds to the initial sharp rise in the anode current waveform (phase I), as shown in Fig. 3.15. The device switching then goes into phase II, during which the anode current remains fairly constant, suggesting that the resistance of the region has reached its lower limit. This is due to the fact that the pilot anode current (2) takes a finite time to traverse through the p-base laterally and become the gate current for the main cathode area. The n^+-emitters start to inject electrons which traverse the p-base vertically and after a certain finite time (transit time of the p-base) reach the depletion region. The total time taken by the lateral traversal of pilot anode current and the electron transit time across the p-base is the reason for observing this characteristic phase II interval. The width of the phase II interval is comparable to the switching delay, suggesting that the p-base transit time is of primary importance. Once the main cathode region turns on, the resistance of the device decreases and the anode current begins to rise again (transition from phase II to III). From this time onward in the switching cycle, the plasma spreading velocity will dictate the rate at which the conduction area will increase. The current density during phases I and II can be quite large, leading to a considerable increase in the local temperature and device failure. The detailed effect of the amplifying gate on the

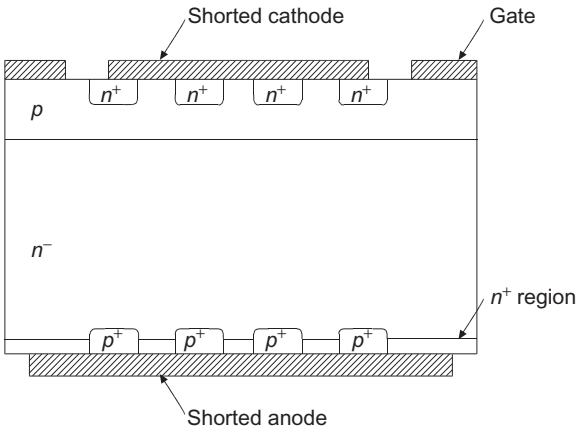

FIG. 3.13 Cross section showing integrated cathode and anode shorts.

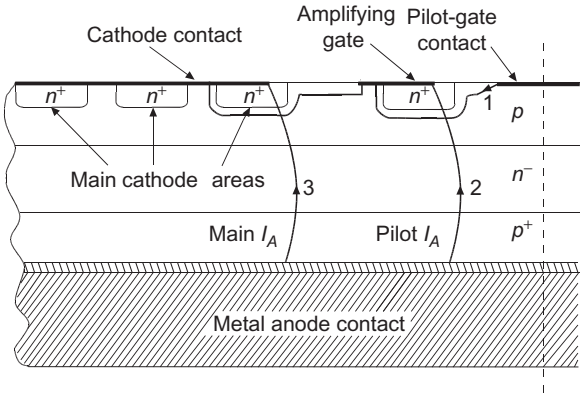

FIG. 3.14 Cross section showing the amplifying gate structure in a thyristor.

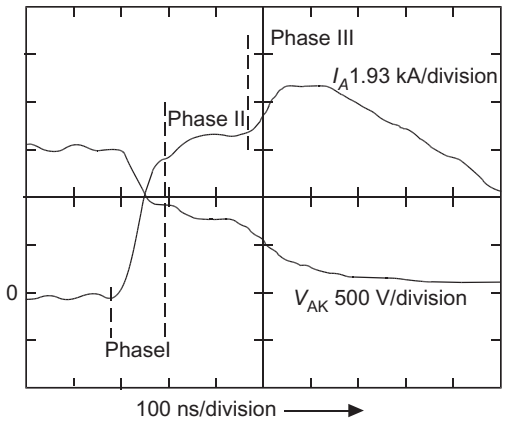

FIG. 3.15 Turn-on waveforms showing the effect of the amplifying gate in the anode current rise.

anode current rise will only be noticed at high levels of *di/dt* (in the range of 1000 A/μs), shown in Fig. 3.15. It can be concluded that the amplifying gate will increase gate sensitivity at the expense of some *di/dt* capability, as demonstrated by Sankaran [7]. This lowering of *di/dt* capability can be somewhat offset by an increase in gate-cathode interdigitation as previously discussed.

3.4.4 Temperature Dependencies

The forward-blocking voltage of an SCR has been shown to be reduced from 1350 V at 25°C to 950 V at −175°C in a near linear fashion [8]. Above 25°C, the forward-blocking capability is again reduced, due to changes in the minority carrier lifetime, which cause the leakage current to increase and the associated breakover voltage to decrease. Several dominant physical parameters associated with semiconductor devices are sensitive to temperature variations, causing their dependent device characteristics to change dramatically. The most important of these parameters are (i) the minority carrier lifetimes (which control the high-level injection lifetimes), (ii) the hole and electron mobilities, (iii) the impact ionization collision cross sections, and (iv) the free-carrier concentrations (primarily the ionized impurity atom concentration). Almost all of the impurity atoms are ionized at temperatures above 0°C, and so further discussion of the temperature effects on ionization is not relevant for normal operation. As the temperature increases above 25°C, the following trends are observed: the carrier lifetimes increase, giving longer recovery times and greater switching losses; the carrier mobilities are reduced, increasing the on-state voltage drop; and at very high temperatures, the intrinsic carrier concentration becomes sufficiently high that the depletion layer will not form and the device cannot switch off. A more detailed discussion of these physical parameters is beyond the scope of this book, but references are listed for those persons interested in pursuing relevant information about temperature effects.

It is well known that charge-carrier recombination events are more efficient at lower temperatures. This shows up as a larger potential drop during forward conduction and a shorter recovery time during turnoff. A plot of the anode current during turnoff, at various temperatures, for a typical GTO is shown in Fig. 3.16.

An approximate relation between the temperature and the forward drop across the n^--base of a thyristor is discussed in detail by Herlet [9] and Hudgins et al. [10]. Temperature-dependent equations relating the anode current density, J_A, and the applied anode-cathode voltage V_{AK} are also given in Ref. [10]; these include the junction potential drops in the device, the temperature dependence of the band-gap energy, and the n^--base potential drop. Data from measurements at forward current densities of approximately 100 A/cm^2 on a GTO rated for 1 kV symmetrical blocking give forward voltage drops of 1.7 V at −50°C and 1.8 V at 150°C.

3.5 Thyristor Parameters

Understanding of a thyristor's maximum ratings and electric characteristics is required for proper application. Use of a manufacturer's data sheet is essential for good design practice. *Ratings* are maximum or minimum values that set limits on device capability. A measure of device performance under specified operating conditions is a *characteristic* of the device. A summary of some of the maximum ratings that must be considered when choosing a thyristor for a given application

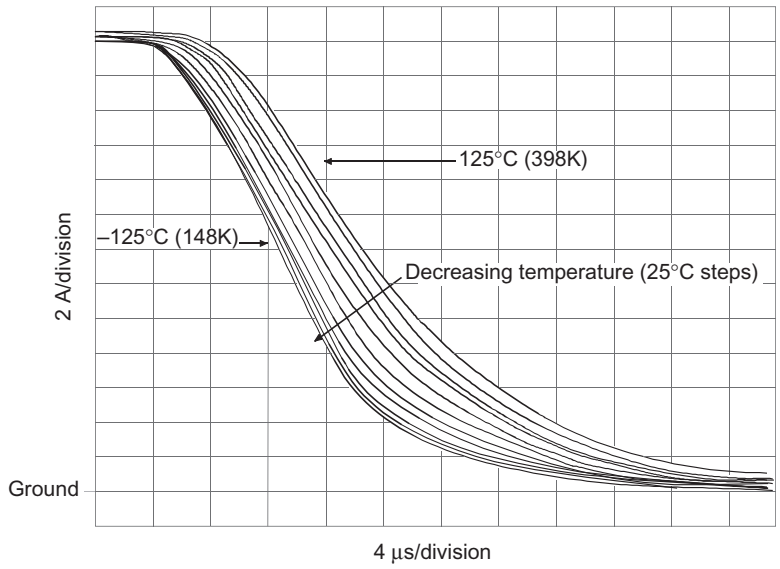

FIG. 3.16 Temperature effect on the anode current tail during turnoff.

TABLE 3.3 Thyristor maximum ratings specified by manufacturers

Symbol	Description
V_{RRM}	Peak repetitive reverse voltage
V_{RSM}	Peak nonrepetitive reverse voltage (transient)
$V_{R(DC)}$	DC reverse-blocking voltage
V_{DRM}	Peak repetitive forward off-state voltage
V_{DSM}	Peak nonrepetitive forward off-state voltage (transient)
$V_{D(DC)}$	DC forward-blocking voltage
$I_{T(RMS)}, I_{F(RMS)}$	RMS forward on-state current
$I_T(AV), I_{F(AV)}$	Average forward on-state current at specified case or junction temperature
$I_{TSM}, I_{F(TSM)}$	Peak one-cycle surge on-state current (values specified at 60 and 50 Hz)
I_{TGQ} (GTO)	Peak controllable current
I^2t	Nonrepetitive pulse overcurrent capability ($t = 8.3$ ms for a 60 Hz half cycle)
P_T	Maximum power dissipation
di/dt	Critical rate of rise of on-state current at specified junction temperature, gate current, and forward-blocking voltage
P_{GM} (P_{FGM} for GTO)	Peak gate power dissipation (forward)
P_{RGM} (GTO)	Peak gate power dissipation (reverse)
$P_{G(AV)}$	Average gate power dissipation
V_{FGM}	Peak forward gate voltage
V_{RGM}	Peak reverse gate voltage
I_{FGM}	Peak forward gate current
I_{RGM} (GTO)	Peak reverse gate current
T_{STG}	Storage temperature
T_j	Junction operating temperature
V_{RMS}	Voltage isolation (modules)

TABLE 3.4 Typical thyristor characteristic maximum and minimum values specified by manufacturers

Symbol	Description
V_{TM}, V_{FM}	Maximum on-state voltage drop (at specified junction temperature and forward current)
I_{DRM}	Maximum forward off-state current (at specified junction temperature and forward voltage)
I_{RRM}	Maximum reverse off-state current (at specified junction temperature and reverse voltage)
dv/dt	Minimum critical rate of rise of off-state voltage at specified junction temperature and forward-blocking voltage level
V_{GT}	Maximum gate trigger voltage (at specified temperature and forward applied voltage)
V_{GD}, V_{GDM}	Maximum gate nontrigger voltage (at specified temperature and forward applied voltage)
I_{GT}	Maximum gate trigger current (at specified temperature and forward applied voltage)
T_{gt} (GTO)	Maximum turn-on time (under specified switching conditions)
T_q	Maximum turn-off time (under specified switching conditions)
t_D	Maximum turn-on delay time (for specified test)
$R_{\Theta(J-C)}$	Maximum junction-to-case thermal resistance
$R_{\Theta(C-S)}$	Maximum case-to-sink thermal resistance (interface lubricated)

is provided in Table 3.3. Thyristor types shown in parentheses indicate a maximum rating unique to that device. Both forward and reverse repetitive and nonrepetitive voltage ratings must be considered, and a properly rated device must be chosen so that the maximum voltage ratings are never exceeded. In most cases, either forward- or reverse-voltage transients in excess of the nonrepetitive maximum ratings result in destruction of the device. The maximum root mean square (RMS) or average current ratings given are usually those which cause the junction to reach its maximum rated temperature. Because the maximum current will depend upon the current waveform and upon thermal conditions external to the device, the rating is usually shown as a function of case temperature and conduction angle. The peak single half-cycle surge-current rating must be considered, and in applications where the thyristor must be protected from damage by overloads, a fuse with an I^2t rating smaller than the maximum rated value for the device must be used. Maximum ratings for both forward and reverse gate voltage, current, and power also must not be exceeded.

The maximum rated operating junction temperature T_J must not be exceeded, since device performance, in particular voltage-blocking capability, will be degraded. Junction temperature cannot be measured directly but must be calculated from a knowledge of steady-state thermal resistance $R_{\Theta(J-C)}$ and the average power dissipation. For transients or surges, the transient thermal impedance ($Z_{\Theta(J-C)}$) curve must be used (provided in manufacturer's data sheets). The maximum average power dissipation P_T is related to the maximum rated operating junction temperature and the case temperature by the steady-state thermal resistance. In general, both the maximum dissipation and its derating with increasing case temperature are provided.

The number and type of thyristor characteristics specified varies widely from one manufacturer to another. Some characteristics are given only as typical values of minima or maxima, while many characteristics are displayed graphically. Table 3.4 summarizes some of the typical characteristics provided as maximum values. The maximum value means that the manufacturer guarantees that the device will not exceed the value given under the specified operating or switching conditions. A minimum value means that the manufacturer guarantees that the device will perform at least, as well as the characteristic given under the specified operating or switching conditions. Thyristor types shown in parenthesis indicate a characteristic unique to that device. Gate conditions of both voltage and current to ensure either nontriggered or triggered device operation are included. The turn-on and turn-off transients of the thyristor are characterized by switching times like the turn-off time listed in Table 3.4. The turn-on transient can be divided into three intervals: (i) gate-delay interval, (ii) turn-on of initial area, and (iii) spreading interval. The gate-delay interval is simply the time between application of a turn-on pulse at the gate and the time the initial cathode area turns on. This delay

TABLE 3.5 Symbols and definitions of major thyristor parameters

R_θ	Thermal Resistance	Specifies the degree of temperature rise per unit of power, measuring junction temperature from a specified external point. Defined when junction power dissipation results in steady-state thermal flow
$R_{\theta(J-A)}$	Junction-to-ambient thermal resistance	The steady-state thermal resistance between the junction and ambient
$R_{\theta(J-C)}$	Junction-to-case thermal resistance	The steady-state thermal resistance between the junction and case surface
$R_{\theta(J-S)}$	Junction-to-sink thermal resistance	The steady-state thermal resistance between the junction and the heat sink mounting surface
$R_{\theta(C-S)}$	Contact thermal resistance	The steady-state thermal resistance between the surface of the case and the heat sink mounting surface
Z_θ	Transient thermal impedance	The change of temperature difference between two specified points or regions at the end of a time interval divided by the step function change in power dissipation at the beginning of the same interval causing the change of temperature difference
$Z_{\theta(J-A)}$	Junction-to-ambient transient thermal impedance	The transient thermal impedance between the junction and ambient
$Z_{\theta(J-C)}$	Junction-to-case transient thermal impedance	The transient thermal impedance between the junction and the case surface
$Z_{\theta(J-S)}$	Junction-to-sink transient thermal impedance	The transient thermal impedance between the junction and the heat sink mounting surface
T_A	Ambient temperature	It is the temperature of the surrounding atmosphere of a device when natural or forced-air cooling is used and is not influenced by heat dissipation of the device
T_S	Sink temperature	The temperature at a specified point on the device heat sink
T_C	Case temperature	The temperature at a specified point on the device case
T_J	Junction temperature	The device junction temperature rating. Specifies the maximum and minimum allowable operation temperatures
T_{STG}	Storage temperature	Specifies the maximum and minimum allowable storage temperatures (with no electric connections)
V_{RRM}	Peak reverse-blocking voltage	Within the rated junction temperature range and with the gate terminal open circuited, specifies the repetitive peak reverse anode-to-cathode voltage applicable on each cycle
V_{RSM}	Transient peak reverse-blocking voltage	Within the rated junction temperature range and with the gate terminal open circuited, specifies the nonrepetitive peak reverse anode-to-cathode voltage applicable for a time width equivalent to less than 5 ms
$V_{R(DC)}$ SCR only	Dc reverse-blocking voltage	Within the rated junction temperature range and with the gate terminal open-circuited, specifies the maximum value for dc anode-to-cathode voltage applicable in the reverse direction

Continued

decreases with increasing gate-drive current and is of the order of a few microseconds. The second interval, the time required for turn-on of the initial area, is quite short, typically less than 1 μs. In general, the initial area turned on is a small percentage of the total useful device area. After the initial area turns on, conduction spreads (spreading interval or plasma spreading time) throughout the device in tens of microseconds for high speed or thyristors. The plasma spreading time may take up to hundreds of microseconds in large-area phase-control devices.

Table 3.5 lists many of the thyristor parameters that appear as listed values or as information on graphs. The definition of each parameter and the test conditions under which they are measured are given in the table as well.

3.6 Types of Thyristors

In recent years, most development effort has gone into continued integration of the gating and control electronics into thyristor modules and the use of MOS technology to create gate structures integrated into the thyristor itself. Many variations of this theme are being developed and some technologies should rise above the others in the years to come. Further details concerning most of the following discussion of thyristor types can be found in [11].

3.6.1 SCRs and GTOs

The highest power handling devices continue to be bipolar thyristors. High-powered thyristors are large diameter devices, some well in excess of 100 mm, and as such have a limitation on the rate of rise of anode current, a di/dt rating. The depletion capacitances around the p-n junctions, in particular the center junction J_2, limit the rate of rise in forward voltage that can be applied even after all the stored charge, introduced during conduction, is removed. The associated displacement current under application of forward voltage during the thyristor blocking state sets a dv/dt limit. Some effort in improving the voltage hold-off capability and overvoltage protection of conventional SCRs is underway by incorporating a lateral high-resistivity region to help dissipate the energy during

TABLE 3.5 Symbols and definitions of major thyristor parameters—cont'd

V_{DRM}	Peak forward-blocking voltage	Within the rated junction temperature range and with the gate terminal open circuited (SCR) or with a specified reverse voltage between the gate and cathode (GTO), specifies the repetitive peak off-state anode-to-cathode voltage applicable on each cycle. This does not apply for transient off-state voltage application
V_{DSM}	Transient peak forward-blocking voltage	Within the rated junction temperature range, and with the gate terminal open circuited (SCR), or with a specified reverse voltage between the gate and cathode (GTO), specifies the nonrepetitive off-state anode-to-cathode voltage applicable for a time width equivalent to less than 5 ms. This gives the maximum instantaneous value for nonrepetitive transient off-state voltage
$V_{D(DC)}$	Dc forward-blocking voltage	Within the rated junction temperature range and with the gate terminal open circuited (SCR) or with a specified reverse voltage between the gate and cathode (GTO), specifies the maximum value for dc anode-to-cathode voltage applicable in the forward direction
dv/dt	Critical rate of rise of off-state voltage $dv/dt = (0.632V_D)/\tau V_D$ is specified off-state voltage τ is time constant for exponential	At the maximum rated junction temperature range, and with the gate terminal open circuited (SCR), or with a specified reverse voltage between the gate and cathode (GTO), this specifies the maximum rate of rise of off-state voltage that will not drive the device from an off-state to an on-state when an exponential off-state voltage of specified amplitude is applied to the device
V_{TM}	Peak on-state voltage	At specified junction temperature, and when on-state current (50 or 60 Hz, half sine wave of specified peak amplitude) is applied to the device, indicates peak value for the resulting voltage drop
$I_{T(RMS)}$	RMS on-state current	At specified case temperature, indicates the RMS value for on-state current that can be continuously applied to the device
$I_{T(AV)}$	Average on-state current	At specified case temperature, and with the device connected to a resistive or inductive load, indicates the average value for forward current (sine half wave, commercial frequency) that can be continuously applied to the device
I_{TSM}	Peak on-state current	Within the rated junction temperature range, indicates the peak value for nonrepetitive on-state current (sine half wave, 50 or 60 Hz). This value indicated for one cycle or as a function of a number of cycles
I^2t	Current-squared time	The maximum, on-state, nonrepetitive short-time thermal capacity of the device and is helpful in selecting a fuse or providing a coordinated protection scheme of the device in the equipment. This rating is intended specifically for operation less than one half cycle of a 180 (degree) conduction angle sinusoidal wave form. The off-state blocking capability cannot be guaranteed at values near the maximum I^2t
di/dt	Critical rate of rise of on-state current	At specified case temperature, specified off-state voltage, specified gate conditions, and at a frequency of less than 60 Hz, indicates the maximum rate of rise of on-state current which the thyristor will withstand when switching from an off-state to an on-state, when using recommended gate drive
I_{RRM}	Peak reverse leakage current	At maximum rated junction temperature, indicates the peak value for reverse current flow when a voltage (sine half wave, 50 or 60 Hz, and having a peak value as specified for repetitive peak reverse-voltage rating) is applied in a reverse direction to the device
I_{DRM}	Peak forward-leakage current	At maximum rated junction temperature, indicates the peak value for off-state current flow when a voltage (sine half wave, 50 or 60 Hz, and having a peak value for repetitive off-state voltage rating) is applied in a forward direction to the device. For a GTO, a reverse voltage between the gate and cathode is specified
P_{GM} (SCR) P_{GFM} (GTO)	Peak gate power dissipation peak gate forward power dissipation	Within the rated junction temperature range, indicates the peak value for maximum allowable power dissipation over a specified time period, when the device is in forward conduction between the gate and cathode
$P_{G(AV)}$	Average gate power dissipation	Within the rated junction temperature range, indicates the average value for maximum allowable power dissipation when the device is forward-conducting between the gate and cathode

TABLE 3.5 Symbols and definitions of major thyristor parameters—cont'd

P_{GRM} GTO only	Peak gate reverse power dissipation	Within the rated junction temperature range, indicates the peak value for maximum allowable power dissipation in the reverse direction between the gate and cathode, over a specified time period
$P_{GR(AV)}$ GTO only	Average gate reverse power dissipation	Within the rated junction temperature range, indicates the average value for maximum allowable power dissipation in the reverse direction between the gate and cathode
I_{GFM}	Peak forward gate current	Within the rated junction temperature range, indicates the peak value for forward current flow between the gate and cathode
I_{GRM} GTO only	Peak reverse gate current	Within the rated junction temperature range, indicates peak value for reverse current that can be conducted between the gate and cathode
V_{GRM}	Peak reverse gate voltage	Within the rated junction temperature range, indicates the peak value for reverse voltage applied between the gate and cathode
V_{GFM}	Peak forward gate voltage	Within the rated junction temperature range, indicates the peak value for forward voltage applied between the gate and cathode
I_{GT}	Gate current to trigger	At a junction temperature of 25°C, and with a specified off-voltage, and a specified load resistance, indicates the minimum gate dc current required to switch the thyristor from an off-state to an on-state
V_{GT}	Gate voltage to trigger	At a junction temperature of 25°C, and with a specified off-state voltage, and a specified load resistance, indicates the minimum dc gate voltage required to switch the thyristor from an off-state to an on-state
V_{GDM} SCR only	Nontriggering gate voltage	At maximum rated junction temperature, and with a specified off-state voltage applied to the device, indicates the maximum dc gate voltage which will not switch the device from an off-state to an on-state
I_{TGQ} GTO only	Gate-controlled turn-off current	Under specified conditions, indicates the instantaneous value for on-current usable in gate control, specified immediately prior to device turn-off
R_θ	Thermal resistance	Specifies the degree of temperature rise per unit of power, measuring junction temperature from a specified external point. Defined when junction power dissipation results in steady-state thermal flow
t_{on} SCR only	Turn-on time	At specified junction temperature, and with a peak repetitive off-state voltage of half rated value, followed by device turn-on using specified gate current, and when specified on-state current of specified di/dt flows, indicated as the time required for the applied off-state voltage to drop to 10% of its initial value after gate current application. Delay time is the term used to define the time required for applied voltage to drop to 90% of its initial value following gate-current application. The time required for the voltage level to drop from 90% to 10% of its initial value is referred to as rise time. The sum of both these defines turn-on time
T_q SCR only	Turn-off time	Specified at maximum rated junction temperature. Device set up to conduct on-state current, followed by application of specified reverse anode-cathode voltage to quench on-state current and then increasing the anode-cathode voltage at a specified rate of rise as determined by circuit conditions controlling the point where the specified off-state voltage is reached. Turn-off time defines the minimum time which the device will hold its off-state, starting from the time on-state current reached zero until the time forward voltage is again applied (i.e., applied anode-cathode voltage becomes positive again)
t_{gt} GTO only	Turn-on time	When applying forward current to the gate, indicates the time required to switch the device from an off-state to an on-state
t_{qt} GTO only	Turn-off time	When applying reverse current to the gate, indicates the time required to switch the device from an on-state to an off-state

breakover. Most effort, though, is being placed in the further development of high-performance GTOs and IGCTs because of their controllability and to a lesser extent in optically triggered structures that feature gate circuit isolation.

High-voltage GTOs with symmetrical blocking capability require thick n^--base regions to support the high electric field. The addition of an n^+ buffer layer next to the p^+-anode allows high-voltage forward-blocking and a low forward voltage drop during conduction because of the thinner n^--base required. Cylindrical anode shorts have been incorporated to facilitate excess carrier removal from the n^--base during turnoff and still retain the high blocking capability. This device structure can control 200 A, operating at 900 Hz, with a 6 kV hold-off. Some of the design trade-off between the n^--base width and turn-off energy losses in these structures has been determined. A similar GTO incorporating an n^+-buffer layer and a *pin* structure has

been fabricated that can control up to 1 kA (at a forward drop of 4 V) with a forward-blocking capability of 8 kV. A reverse conducting GTO has been fabricated that can block 6 kV in the forward direction, interrupt a peak current of 3 kA, and has a turn-off gain of about 5.

The IGCT is a modified GTO structure. It is designed and manufactured so that it commutates all of the cathode current away from the cathode region and diverts it out of the gate contact. The IGCT is similar to a GTO in structure except that it always has a low-loss *n*-buffer region between the n^--base and *p*-emitter. The IGCT device package is designed to result in a very low parasitic inductance and is integrated with a specially designed gate-drive circuit. The gate drive contains all the necessary *di/dt* and *dv/dt* protection; the only connections required are a low-voltage power supply for the gate drive and an optical signal for controlling the gate. The specially designed gate drive and ring-gate package circuit allows the IGCT to be operated without a snubber circuit and to switch with a higher anode *di/dt* than a similar GTO. At blocking voltages of 4.5 kV and higher, the IGCT provides better performance than a conventional GTO. The speed at which the cathode current is diverted to the gate (di_{GQ}/dt) is directly related to the peak snubberless turn-off capability of the IGCT. The gate-drive circuit can sink current for turn-off at di_{GQ}/dt values in excess of 7000 A/μs. This hard gate drive results in a low charge storage time of about 1 μs. The low storage time and the fail-short mode make the IGCT attractive for high-power, high-voltage series applications; examples include high-power converters in excess of 100 MVA, static volt-ampere reactive (VAR) compensators, and converters for distributed generation such as wind power.

3.6.1.1 On-State Characteristics

In the on-state, the GTO operates in a similar manner to the thyristor. If the anode current remains above the holding current level, then positive gate drive may be reduced to zero, and the GTO will remain in conduction. However, as a result of the turn-off ability of the GTO, it does possess a higher holding current level than the standard thyristor, and in addition, the cathode of the GTO thyristor is subdivided into small finger elements to assist turn-off. Thus, if the GTO thyristor anode current transiently dips below the holding current level, localized regions of the device may turn off, thus forcing a high anode current back into the GTO at a high rate of rise of anode current after this partial turnoff. This situation could be potentially destructive. It is recommended, therefore, that the positive gate drive is not removed during conduction but is held at a value $I_{G(ON)}$, where $I_{G(ON)}$ is greater than the maximum critical trigger current (I_{GT}) over the expected operating temperature range of the GTO thyristor.

Fig. 3.17 shows the typical on-state *V-I* characteristics for a 4000 1A, 4500 V GTO from Dynex range of GTOs [1] at junction temperatures of 25 and 125°C. The curves can be approximated to a straight line of the form

$$V_{TM} = V_0 + IR_0 \tag{3.3}$$

where V_0 = voltage intercept models the voltage across the cathode and anode forward-biased junctions and R_0 = on-state resistance. When average and RMS values of on-state current (I_{TAV}, I_{TRMS}) are known, then the on-state power dissipation P_{ON} can be determined using V_0 and R_0. That is,

$$P_{ON} = V_0 I_{TAV} + R_0 I_{TRMS}^2 \tag{3.4}$$

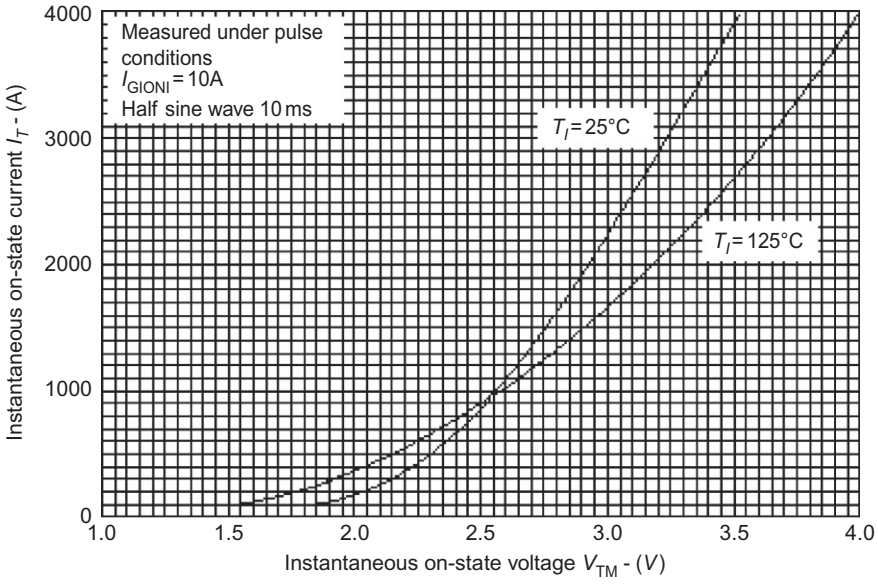

FIG. 3.17 *V-I* characteristics of GTO [12].

3.6.1.2 Off-State Characteristics

Unlike the standard thyristor, the GTO does not include cathode emitter shorts to prevent nongated turn-on effects due to dv/dt induced forward-biased leakage current. In the off-state of the GTO, steps should, therefore, be taken to prevent such potentially dangerous triggering. This can be accomplished by either connecting the recommended value of resistance between the gate and the cathode (R_{GK}) or by maintaining a small reverse bias on the gate contact ($V_{RG} = -2$ V). This will prevent the cathode emitter becoming forward biased and therefore sustain the GTO thyristor in the off-state.

The peak off-state voltage is a function of resistance R_{GK}. This is shown in Fig. 3.18. Under ordinary operating conditions, GTOs are biased with a negative gate voltage of around −15 V supplied from the gate-drive unit during the off-state interval. Nevertheless, provision of R_{GK} may be desirable design practice in the event of the gate-drive failure for any reason ($R_{GK} < 1.5\,\Omega$ is recommended for a large GTO). R_{GK} dissipates energy and hence adds to the system losses.

3.6.1.3 Rate of Rise of Off-State Voltage (dv_D/dt)

The rate of rise of off-state voltage (dv_D/dt) depends on the resistance R_{GK} connected between the gate and the cathode and the reverse bias applied between the gate and the cathode. This relationship is shown in Fig. 3.19.

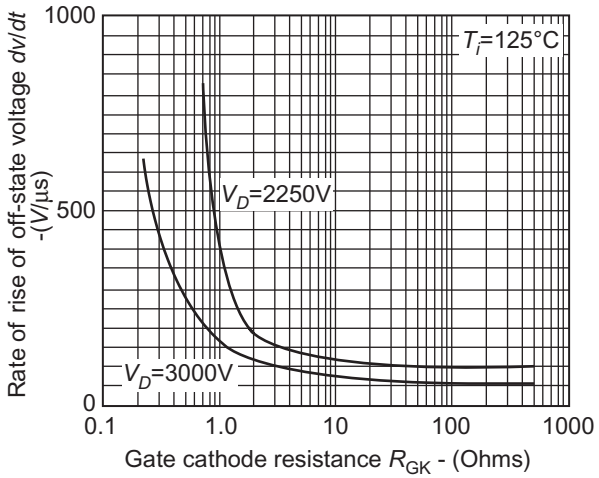

FIG. 3.19 dv_D/dt versus R_{GK} [12].

3.6.1.4 Gate Triggering Characteristics

The gate trigger current (I_{GT}) and the gate trigger voltage (V_{GT}) are both dependent on junction temperature T_j as shown in Fig. 3.20. During the conduction state of the GTO, a certain value of gate current must be supplied, and this value should be larger than the I_{GT} at the lowest junction temperature at which the GTO operates. In dynamic conditions, the specified I_{GT} is not sufficient to trigger the GTO switching from higher

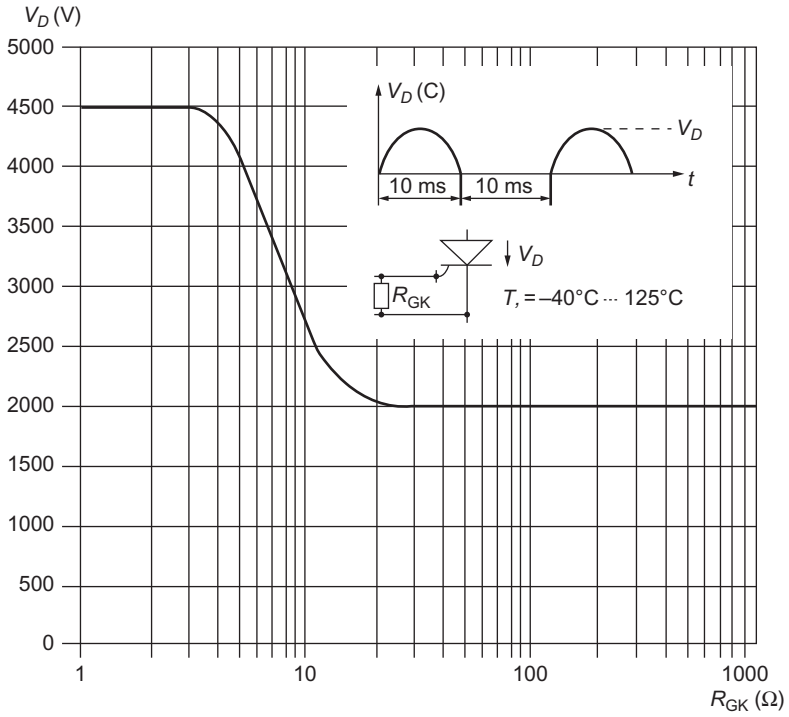

FIG. 3.18 GTO blocking voltage versus R_{GK} [12].

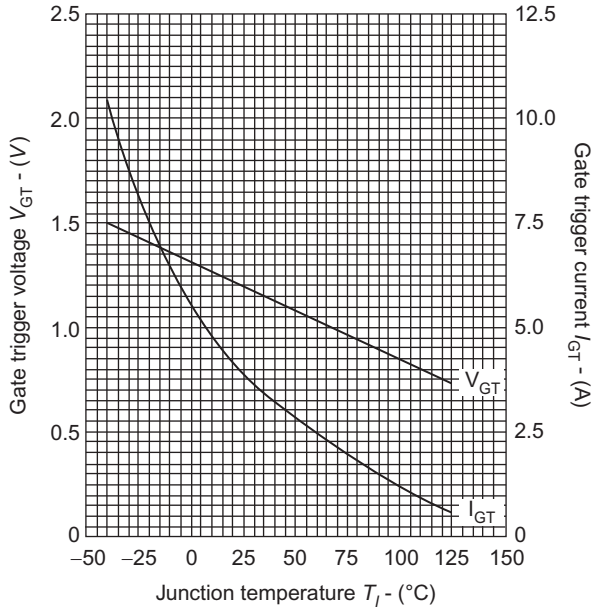

FIG. 3.20 GTO trigger characteristics (see data sheet in Ref. [1]).

voltage and high *di*/*dt*. In practice, a much high peak gate current I_{GM} (in order of 10 times I_{GT}) at T_j min is recommended to obtain good turn-on performance.

3.6.1.5 GTO Switching Phases

The switching process of a GTO thyristor goes through four operating phases.

Turn-on

A GTO has a highly interdigitated gate structure with no regenerative gate. Thus, it requires a large initial gate trigger pulse. A typical turn-on wave diagrams and their important parameters are shown in Fig. 3.21. Minimum and maximum values of I_{GM} can be derived from the device data sheet. A value of di_g/dt is given in device characteristics of the data sheet, against turn-on time. The rate of rise of gate current, di_g/dt will affect the device turn-on losses. The duration of the I_{GM} pulse should not be less than half the minimum on time given in data sheet ratings. A longer period will be required if the anode current *di*/*dt* is low such that I_{GM} is maintained until a sufficient level of anode current is established.

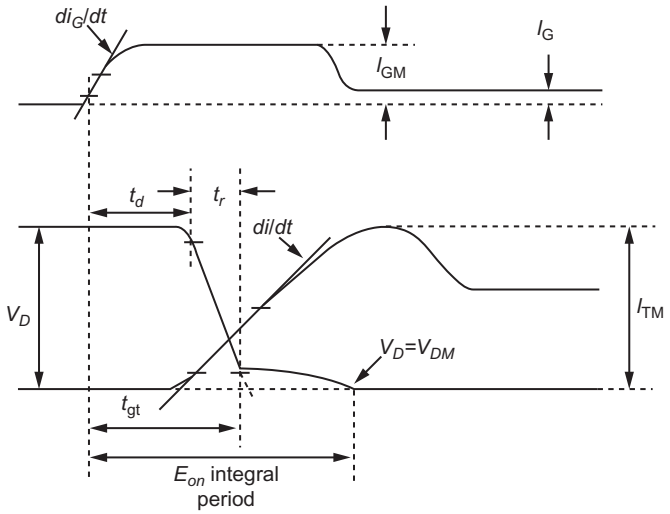

FIG. 3.21 A typical GTO turn-on wave diagrams [13].

On-state

Once the GTO is turned on, forward gate current must be continued for the whole of the conduction period. Otherwise, the device will not remain in conduction during the on-state period. If large negative *di*/*dt* or anode current to reversal occurs in the circuit during the on-state, then higher values of I_G may be required. Much lower values of I_G are, however, required when the device has heated up.

Turn-off

The turn-off performance of a GTO is greatly influenced by the characteristics of the gate turn-off circuit. Thus, the characteristics of the turn-off circuit must match with the device requirements. Fig. 3.22 shows the typical anode and gate currents during the turn-off. The gate turn-off process involves the extraction of the gate charge, the gate avalanche period, and the anode current decay. The amount of the charge extraction is a device parameter and its value is not significantly affected by the external circuit conditions. The initial peak turn-off current and turn-off time, which are important parameters of the turning-off process, depend on the external circuit components. The device data sheet gives typical values for I_{GQ}.

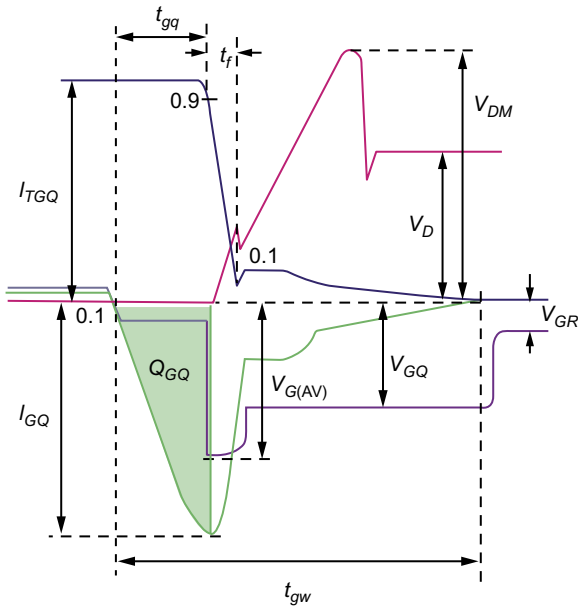

FIG. 3.22 A typical GTO turn-off currents [13].

The turn-off circuit arrangement of a GTO is shown in Fig. 3.22. The turn-off current gain of a GTO is low, typically 6–15. Thus, for a GTO with a turn-off gain of 10, it will require a turn-off gate current of 10 A to turn off an on-state of 100 A. A charged capacitor C is normally used to provide the required turn-off gate current. Inductor L limits the turnoff di/dt of the gate current through the circuit formed by R_1, R_2, SW_1, and L. The gate circuit supply voltage V_{GS} should be selected to give the required value of V_{GQ}. The values of R_1 and R_2 should also be minimized.

Off-state period

During the off-state period, which begins after the fall of the tail current to zero, the gate should ideally remain reverse biased. This reverse bias ensures maximum blocking capability and dv/dt rejection. The reverse bias can be obtained either by keeping SW_1 closed during the whole off-state period or via a higher impedance circuit SW_2 and R_3 provided a minimum negative voltage exits. This higher impedance circuit SW_2 and R_3 must sink the gate leakage current.

In case of a failure of the auxiliary supplies for the gate turn-off circuit, the gate may be in reverses biased condition, and the GTO may not be able to block the voltage. To ensure blocking voltage of the device is maintained, then a minimum gate-cathode resistance (R_{GK}) should be used. The value of R_{GK} for a given line voltage can be derived from the data sheet.

3.6.1.6 GTO SPICModel

A GTO may be modeled with two transistors shown in Fig. 3.2. However, a GTO model [14] consisting of two thyristors, which are connected in parallel, yields improved on-state, turn-on, and turn-off characteristics. The model is shown in Fig. 3.23 with four transistors.

When the anode-to-cathode voltage V_{AK} is positive and there is no gate voltage, the GTO model will be in the off-state like a standard thyristor. If a positive voltage (V_{AK}) is applied to the anode with respect to the cathode and no gate pulse applied, $I_{B1} = I_{B2} = 0$ and therefore $I_{C1} = I_{C2} = 0$. Thus, no anode current will flow, $I_A = I_K = 0$.

When a small voltage is applied to the gate, then I_{B2} is nonzero, and therefore, both $I_{C1} = I_{C2} = 0$ are nonzero. Thus, the internal circuit will conduct, and there will a current flow from the anode to the cathode.

When a negative gate pulse is applied to the GTO model, the PNP junction near to the cathode will behave as a diode. The diode will be reverse biased since the gate voltage is negative with to the cathode. Therefore, the GTO will stop conduction.

When the anode-to-cathode voltage is negative, that is, the anode voltage is negative with respect to the cathode, the GTO model will act like a reverse biased diode. This is because the PNP transistor will see a negative voltage at the emitter and the NPN transistor will see a positive voltage at the emitter. Therefore, both transistors will be in the off-state and hence the GTO will not conduct. The SPICE subcircuit description of the GTO model will be as follows:

Subcircuit		1		2	3	GTO subcircuit definition
*Terminal			Anode	Cathode	Gate	
Q1	5	4	1 DMOD1		PNP	PNP transistor with model DMOD1
Q3	7	6	1 DMOD1		PNP	
Q2	4	5	2 DMOD2		NPN	PNP transistor with model DMOD2
Q4	6	7	2 DMOD2		NPN	
R1	7	5	10 Ω			
R2	6	4	10 Ω			
R3	3	7	10 Ω			
MODEL		DMOD1			PNP	Model statement for a PNP transistor
MODEL		DMOD2			NPN	Model statement for an NPN transistor
ENDS						End of subcircuit definition

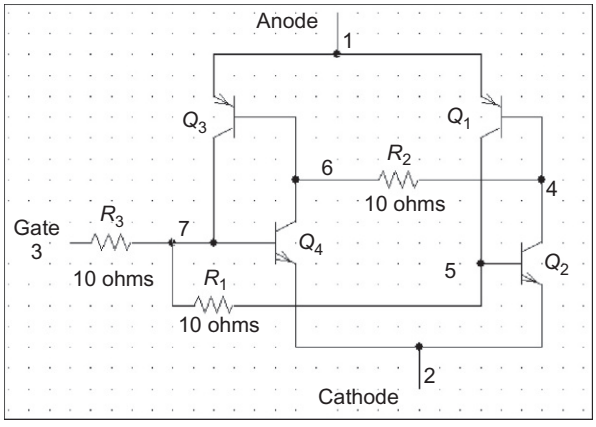

FIG. 3.23 Four-transistor GTO model.

3.6.2 MOS-Controlled Thyristors

An effort to combine the advantages of bipolar junction and field-effect structures has resulted in hybrid devices such as the IGBT and the MOS-controlled thyristor (MCT). While an IGBT is an improvement over a bipolar junction transistor (BJT) using a MOSFET to turn-on and turn-off current, an MCT is an improvement over a thyristor with a pair of MOSFETs to turn-on and turn-off current. The MCT overcomes several of the limitations of the existing power devices and promises to be a better switch for the future.

The cross section of the p-type MCT unit cell is given in Fig. 3.24. When the MCT is in its forward-blocking state and

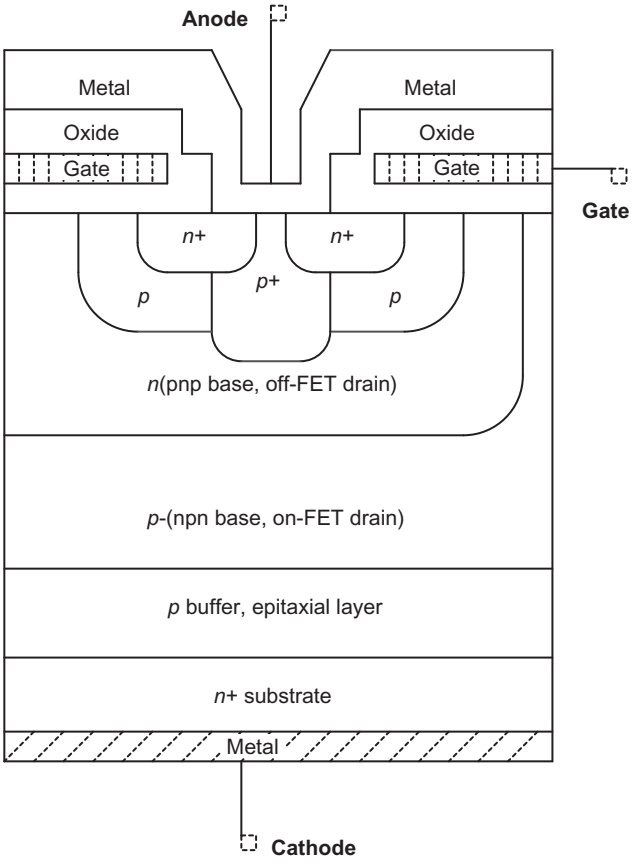

FIG. 3.24 Cross section of unit cell of a *p*-type MCT.

a negative gate-anode voltage is applied, an inversion layer is formed in the *n*-doped material that allows holes to flow laterally from the *p*-emitter (*p*-channel FET source) through the channel to the *p*-base (*p*-channel FET drain). This hole flow is the base current for the *npn* transistor. The *n*-emitter then injects electrons which are collected in the n^--base, causing the *p*-emitter to inject holes into the n^--base so that the *pnp* transistor is turned on and latches the MCT. The MCT is brought out of conduction by applying a positive gate-anode voltage. This signal creates an inversion layer that diverts electrons in the n^--base away from the *p*-emitter and into the heavily doped *n*-region at the anode. This *n*-channel FET current amounts to a diversion of the *pnp* transistor base current so that its base-emitter junction turns off. Holes are then no longer available for collection by the *p*-base. The elimination of this hole current (*npn* transistor base current) causes the *npn* transistor to turn off. The remaining stored charge recombines and returns the MCT to its blocking state.

The seeming variability in fabrication of the turn-off FET structure continues to limit the performance of MCTs, particularly current interruption capability, though these devices can handle two to five times the conduction current density of IGBTs. Numerical modeling and its experimental verification show that ensembles of cells are sensitive to current filamentation during turnoff. All MCT device designs suffer from the problem of current interruption capability. Turn-on is relatively simple, by comparison; both the turn-on and conduction properties of the MCT approach the one-dimensional thyristor limit.

Other variations on the MCT structure have been demonstrated, namely, the emitter switched thyristor (EST) and the dual-gate emitter switched thyristor (DG-EST) [15]. These comprise integrated lateral MOSFET structures that connect a floating thyristor *n*-emitter region to an n^+ thyristor cathode region. The MOS channels are in series with the floating *n*-emitter region, allowing triggering of the thyristor with electrons from the n^--base and interruption of the current to initiate turn-off. The DG-EST behaves as a dual-mode device, with the two gates allowing an IGBT mode to operate during switching and a thyristor mode to operate in the on-state.

3.6.2.1 Equivalent Circuit and Switching Characteristics

The SCR is a four-layer *pnpn* device with a control gate, and applying a positive gate pulse turns it on when it is forward biased. The regenerative action in the device helps to speed up the turn-on process and to keep it in the "ON" state even after the gate pulse is removed. The MCT uses an auxiliary MOS device (PMOSFET) to turn-on, and this simplifies the gate control. The turn-on has all the characteristics of a power MOSFET. The turnoff is accomplished using another MOSFET (NMOSFET), which essentially diverts the base current of one of the BJTs and breaks the regeneration.

The transistor-level equivalent circuit of a P-channel MCT and the circuit symbol are shown in Fig. 3.25. The MCT is modeled as an SCR merged with a pair of MOSFETs. The SCR consists of the bipolar junction transistors (BJTs) Q_1 and Q_2, which are interconnected to provide regenerative feedback such that the transistors drive each other into saturation. Of the two MOSFETs, the PMOS located between the collector and emitter of Q_2 helps to turn the SCR on, and the NMOS located across the base-emitter junction of Q_2 turns it off. In the actual fabrication, each MCT is made up of a large number (~100,000) cells, each of which contains a wide-base *npn* transistor and a narrow-base *pnp* transistor. While each *pnp* transistor in a cell is provided with an *N*-channel MOSFET across its emitter and base, only a small percentage (~4%) of *pnp* transistors are provided with P-channel MOSFETs across their emitters and collectors. The small percentage of PMOS cells in an MCT provides just enough current for turn-on and the large number of NMOS cells provide plenty of current for turnoff.

3.6.2.2 Turn-On and Turn-Off

When the MCT is in the forward-blocking state, it can be turned on by applying a negative pulse to its gate with respect to the anode. The negative pulse turns on the PMOSFET (On-FET) whose drain current flows through the base-emitter

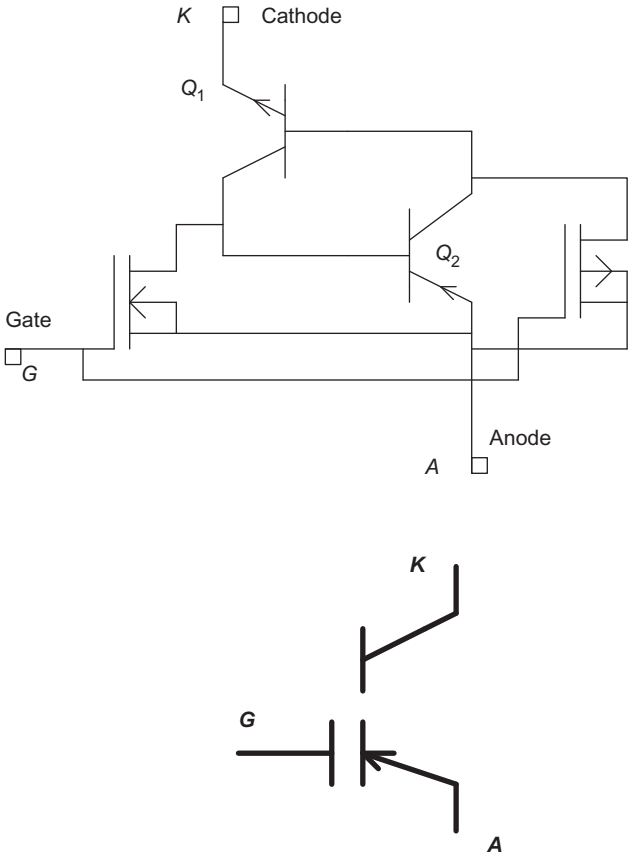

FIG. 3.25 Equivalent circuit and symbol of an MCT.

junction of Q_1 (*npn*), thereby turning it on. The regenerative action within $Q_1 - Q_2$ turns the MCT on into full conduction within a very short time and maintains it even after the gate pulse is removed. The MCT turns on without a plasma spreading phase, giving a high *di/dt* capability and ease of overcurrent protection. The on-state resistance of an MCT is slightly higher than that of an equivalent thyristor because of the degradation of the injection efficiency of the n^+-emitter/*p*-base junction. Also, the peak current rating of an MCT is much higher than its average or *rms* current rating.

An MCT will remain in the "ON" state until the device current is reversed or a turn-off pulse is applied to its gate. Applying a positive pulse to its gate turns off a conducting MCT. The positive pulse turns on the NMOSFET (Off-FET), thereby diverting the base current of Q_2 (*pnp*) away to the anode of the MCT and breaking the latching action of the SCR. This stops the regenerative feedback within the SCR and turns the MCT off. All the cells within the device are to be turned off at the same time to avoid a sudden increase in current density. When the Off-FETs are turned on, the SCR section is heavily shorted and this results in a high *dv/dt* rating for the MCT. The highest current that can be turned off with the application of a gate bias is called the "maximum controllable current." The MCT can be gate controlled if the device current is less than the maximum controllable current. For smaller device currents, the width of the turn-off pulse is not critical. However, for larger currents, the gate pulse has to be wider and more often has to occupy the entire off-period of the switch.

3.6.2.3 Comparison of MCT and Other Power Devices

An MCT can be compared with a power MOSFET, a power BJT, and an IGBT of similar voltage and current ratings. The operation of the devices is compared under on-state, off-state, and transient conditions. The comparison is simple and very comprehensive.

The current density of an MCT is ≈70% higher than that of an IGBT having the same total current [16]. During its on-state, an MCT has a lower conduction drop compared with other devices. This is attributed to the reduced cell size and the absence of emitter shorts present in the SCR within the MCT. The MCT also has a modest negative temperature coefficient at lower currents with the temperature coefficient turning positive at larger current [16]. Fig. 3.26 shows the conduction drop as a function of current density. The forward drop of a 50 A MCT at 25°C is around 1.1 V, while that for a comparable IGBT is over 2.5 V. The equivalent voltage drop calculated from the value of r_{DS}(ON) for a power MOSFET will be much higher. However, the power MOSFET has a much lower delay time (30 ns) compared with that of an MCT (300 ns). The turn-on of a power MOSFET can be so much faster than an MCT or an IGBT; therefore, the switching losses would be negligible compared with the conduction losses. The turn-on of an IGBT is intentionally slowed down to control the reverse recovery of the freewheeling diode used in inductive switching circuits [17].

The MCT can be manufactured for a wide range of blocking voltages. Turn-off speeds of MCTs are supposed to be higher as initially predicted. The turn-on performance of Generation-2 MCTs is reported to be better compared with Generation-1 devices. Even though the Generation-1 MCTs have higher turn-off times compared with IGBTs, the newer ones with higher radiation (hardening) dosage have comparable turn-off times. At present, extensive development activity in IGBTs

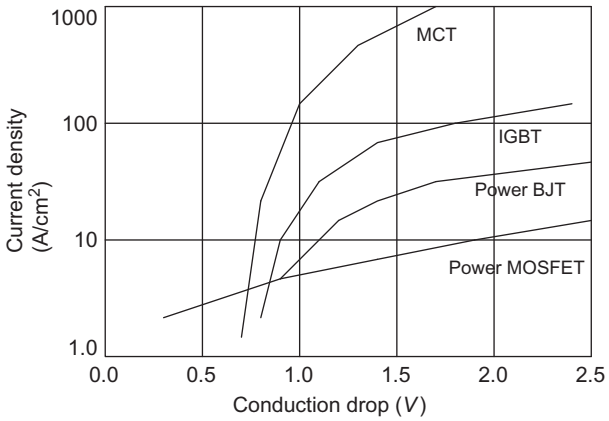

FIG. 3.26 Comparison of forward drop for different devices.

has resulted in high-speed switched mode power supply (SMPS) IGBTs that can operate at switching speeds ≈150 kHz [18]. The turn-off delay time and the fall time for an MCT are much higher compared with a power MOSFET, and they are found to increase with temperature [16]. Power MOSFETs become attractive at switching frequencies above 200 kHz, and they have the lowest turn-off losses among the three devices.

The turn-off safe operating area (SOA) is better in the case of an IGBT than an MCT. For an MCT, the full switching current is sustainable at ≈50%–60% of the breakdown voltage rating, while for an IGBT, it is about 80%. The use of capacitive snubbers becomes necessary to shape the turn-off locus of an MCT. The addition of even a small capacitor improves the SOA considerably.

The MCT has a MOS gate similar to a power MOSFET or an IGBT, and hence, it is easy to control. In a PMCT, the gate voltage must be applied with respect to its anode. A negative voltage below the threshold of the On-FET must be applied to turn on the MCT. The gate voltage should fall within the specified steady-state limits in order to give a reasonably low delay time and to avoid any gate damage due to overvoltage [17]. Similar to a GTO, the gate voltage rise time has to be limited to avoid hot spots (current crowding) in the MCT cells. A gate voltage less than −5 V for turnoff and greater than 10 V for turn-on ensures proper operation of the MCT. The latching of the MCT requires that the gate voltage be held at a positive level in order to keep the MCT turned off.

Because the peak-to-peak voltage levels required for driving the MCT exceed those of other gate-controlled devices, the use of commercial drivers is limited. The MCT can be turned on and off using a push-pull pair with discrete NMOS-PMOS devices, which, in turn, are driven by commercial integrated circuits (ICs). However, some drivers developed by MCT manufacturers are not commercially available [17].

A Baker's clamp push-pull can also be used to generate gate pulses of negative and positive polarity of adjustable width for driving the MCT [19–21]. The Baker's clamp ensures that the push-pull transistors will be in the quasisaturated state prior to turnoff, and this results in a fast switching action. Also, the negative feedback built into the circuit ensures satisfactory operation against variations in load and temperature. A similar circuit with a push-pull transistor pair in parallel with a pair of power BJTs is available [22]. An intermediate section, with a BJT that is either cut off or saturated, provides −10 V and +15 V through potential division.

3.6.2.4 Protection of MCTs

Paralleling of MCTs

Similar to power MOSFETs, MCTs can be operated in parallel. Several MCTs can be paralleled to form larger modules with only slight derating of the individual devices provided the devices are matched for proper current sharing. In particular, the forward voltage drops of individual devices have to be matched closely.

Overcurrent protection

The anode-to-cathode voltage in an MCT increases with its anode current, and this property can be used to develop a protection scheme against overcurrent [19,20]. The gate pulses to the MCT are blocked when the anode current and hence the anode-to-cathode voltage exceed a preset value. A Schmitt trigger comparator is used to allow gate pulses to the MCT when it is in the process of turning on, during which time the anode voltage is relatively large and decreasing.

Snubbers

As with any other power device, the MCT is to be protected against switching-induced transient voltage and current spikes by using suitable snubbers. The snubbers modify the voltage and current transients during switching such that the switching trajectory is confined within the SOA. When the MCT is operated at high frequencies, the snubber increases the switching loss due to the delayed voltage and current responses. The power circuit of an MCT chopper including an improved snubber circuit is shown in Fig. 3.27 [19,21]. The turn-on snubber consists of L_s and DL_S, and the turn-off snubber consists of R_s, C_s, and DL_S. The series-connected turn-on snubber reduces the rate of change of the anode current dI_A/dt. The MCT does not support V_s until the current through the freewheeling diode reaches zero at turn-on. The turn-off snubber helps to reduce the peak power and the total power dissipated by the MCT by reducing the voltage across the MCT when the anode current decays to zero. The analysis and design of the snubber and the effect of the snubber on switching loss and EMI are given in Refs. [19] and [21]. An alternative snubber configuration for the two MCTs in an ac-ac converter has also been reported [22]. This snubber uses only one capacitor and one inductor for both the MCT switches (PMCT and NMCT) in a power-converter leg.

Simulation model of an MCT

The operation of power converters can be analyzed using PSPICE and other simulation software. As it is a new device,

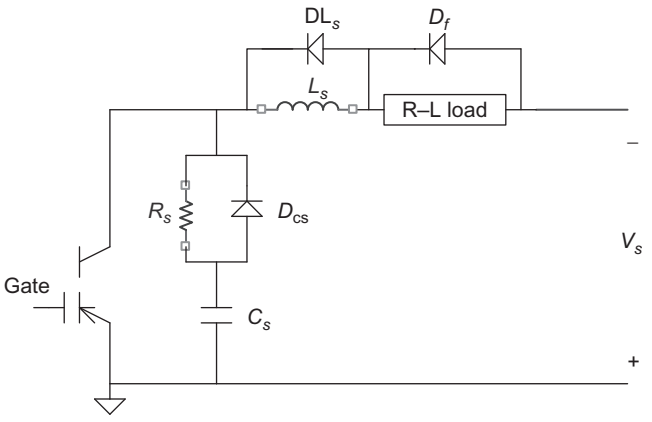

FIG. 3.27 An MCT chopper with turn-on and turn-off snubbers.

models of MCTs are not provided as part of the simulation libraries. However, an appropriate model for the MCT would be helpful in predicting the performance of novel converter topologies and in designing the control and protection circuits. Such a model must be simple enough to keep the simulation time and effort at a minimum and must represent most of the device properties that affect the circuit operation. The PSPICE models for Harris PMCTs are provided by the manufacturer and can be downloaded from the internet. However, a simple model presenting most of the characteristics of an MCT is available [23,24]. It is derived from the transistor-level equivalent circuit of the MCT by expanding the SCR model already reported the literature. The improved model [24] is capable of simulating the breakover and breakdown characteristics of an MCT and can be used for the simulation of high-frequency converters.

3.6.3 Generation-1 and Generation-2 MCTs

The Generation-1 MCTs were commercially introduced by Harris Semiconductors in 1992. However, the development of Generation-2 MCTs is continuing. In Gen-2 MCTs, each cell has its own turn-on field-effect transistor (FET). Preliminary test results in Generation-2 devices and a comparison of their performance with those of Generation-1 devices and high-speed IGBTs are available [25,26]. The Generation-2 MCTs have a lower forward drop compared with the Generation-1 MCTs. They also have a higher *di/dt* rating for a given value of capacitor used for discharge. During hard switching, the fall time and the switching losses are lower for the Gen-2 MCTs. The Gen-2 MCTs have the same conduction loss characteristics as Gen-1 with drastic reductions in turn-off switching times and losses [27].

Under zero-current switching conditions, Gen-2 MCTs have negligible switching losses [27]. Under zero-voltage switching, the turn-off losses in a Gen-2 device are one-half to one-fourth (depending on temperature and current level) the turn-off losses in Gen-1 devices. In all soft-switching applications, the predominant loss, namely, the conduction loss, reduces drastically allowing the use of fewer switches in a module.

3.6.4 *N*-channel MCT

The PMCT discussed in this chapter uses an NMOSFET for turnoff, and this results in a higher turn-off current capability. The PMCT can only replace a P-channel IGBT and inherits all the limitations of a P-channel IGBT. The results of a 2-D simulation show that the NMCT can have a higher controllable current [27]. It is reported that NMCT versions of almost all Harris PMCTs have been fabricated for analyzing the potential for a commercial product [17]. The NMCTs are also being evaluated for use in zero-current soft-switching applications. However, the initial results are not quite encouraging in that the peak turn-off current of an NMCT is one-half to one-third of the value achievable in a PMCT. It is hoped that the NMCTs will eventually have a lower switching loss and a larger SOA as compared with PMCTs and IGBTs.

3.6.5 Base Resistance-Controlled Thyristor [28]

The base resistance-controlled thyristor (BRT) is another gate-controlled device that is similar to the MCT but with a different structure. The Off-FET is not integrated within the *p*-base region but is formed within the n^--base region. The diverter region is a shallow *p*-type junction formed adjacent to the *p*-base region of the thyristor. The fabrication process is simpler for this type of structure. The transistor-level equivalent circuit of a BRT is shown in Fig. 3.28.

The BRT will be in the forward-blocking state with a positive voltage applied to the anode and with a zero gate bias. The forward-blocking voltage will be equal to the breakdown voltage of the open-base *pnp* transistor. A positive gate bias turns on the BRT. At low current levels, the device behaves similarly to an IGBT. When the anode current increases, the operation changes to thyristor mode resulting in a low forward drop. Applying a negative voltage to its gate turns off the BRT. During the turn-off process, the anode current is diverted from the n^+ emitter to the diverter. The BRT has a current tail during turnoff that is similar to an MCT or an IGBT.

3.6.6 MOS Turn-off Thyristor [29]

The MOS turn-off (MTO) thyristor or the MTOT is a replacement for the GTO and it requires a much smaller gate drive. It is more efficient than a GTO; it can have a maximum blocking voltage of about 9 kV, and it will be used to build power converters in the 1–20 MVA range. Silicon Power Corporation (SPCO) manufactures the device.

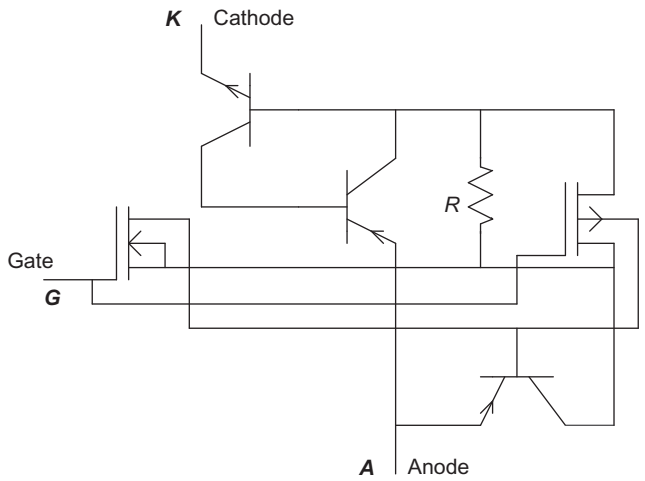

FIG. 3.28 Equivalent circuit of base resistance-controlled thyristor (BRT).

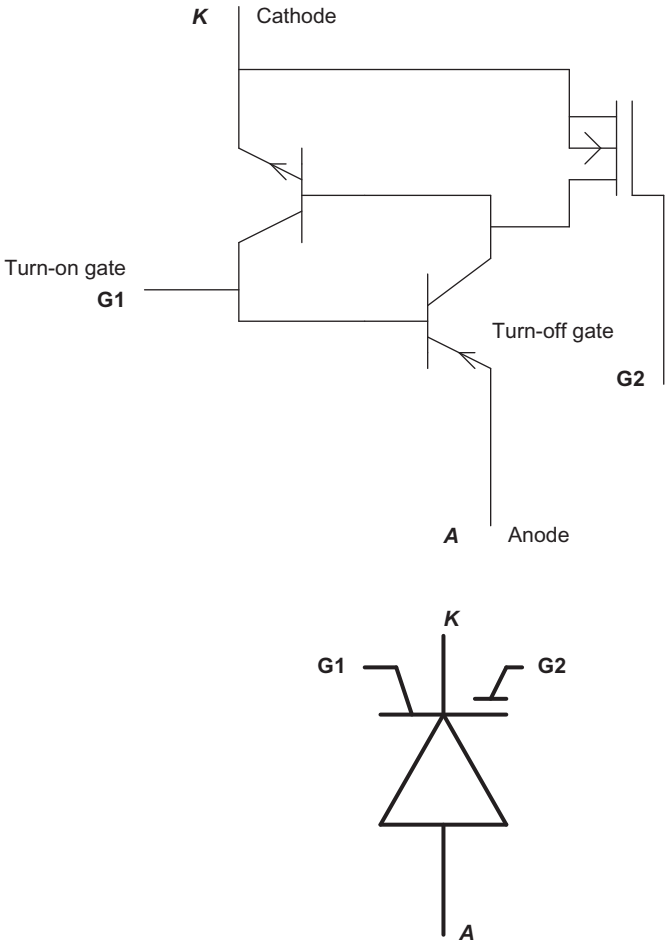

FIG. 3.29 Equivalent circuit and symbol of a MOS turn-off (MTO) thyristor.

The transistor-level equivalent circuit of the MTOT (hybrid design) and the circuit symbol are shown in Fig. 3.29. Applying a current pulse at the turn-on gate (G_1), as with a conventional GTO, turns on the MTOT. The turn-on action, including regeneration, is similar to a conventional SCR. Applying a positive voltage pulse to the turn-off gate (G_2), as with an MCT, turns off the MTOT. The voltage pulse turns on the FET, thereby shorting the emitter and base of the *npn* transistor and breaking the regenerative action. The MTOT is a faster switch than a GTO in that it is turned off with a reduced storage time compared with a GTO. The disk-type construction allows double-sided cooling.

3.6.7 Static Induction Thyristors

An SITh or FCTh has a cross section similar to that shown in Fig. 3.30. Other SITh configurations have surface-gate structures. The device is essentially a *pin* diode with a gate structure that can pinch-off anode current flow. High-power SIThs have a subsurface gate (buried-gate) structure to allow larger cathode

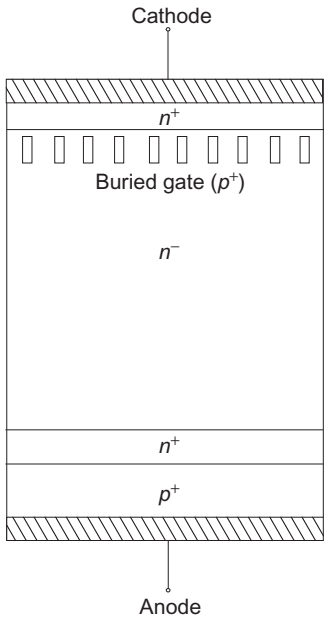

FIG. 3.30 Cross section of an SITh or FCT.

areas to be utilized, and hence, larger current densities are possible.

Planar gate devices have been fabricated with blocking capabilities of up to 1.2 kV and conduction currents of 200 A, while step-gate (trench-gate) structures have been produced that are able to block up to 4 kV and conduct 400 A. Similar devices with a "Verigrid" structure have been demonstrated that can block 2 kV and conduct 200 A, with claims of up to 3.5 kV blocking and 200 A conduction. Buried-gate devices that block 2.5 kV and conduct 300 A have also been fabricated. Recently, there has been a resurgence of interest in these devices for fabrication in SiC.

3.6.8 Optically Triggered Thyristors

Optically gated thyristors have traditionally been used in power utility applications where series stacks of devices are necessary to achieve the high voltages required. Isolation between gate-drive circuits for circuits such as static VAR compensators and high-voltage dc-ac inverters (for use in high-voltage dc (HVDC) transmission) has driven the development of this class of devices, which are typically available in ratings from 5 to 8 kV. The cross section is similar to that shown in Fig. 3.31, showing the photosensitive region and the amplifying gate structures. Light-triggered thyristors (LTTs) may also integrate overvoltage protection.

One of the most recent devices can block 6 kV forward and reverse, conduct 2.5 kA average current, and maintain a di/dt capability of 300 A/μs and a dv/dt capability of 3000 V/μs, with a required trigger power of 10 mW. An integrated light-triggered and light-quenched SITh has been produced that

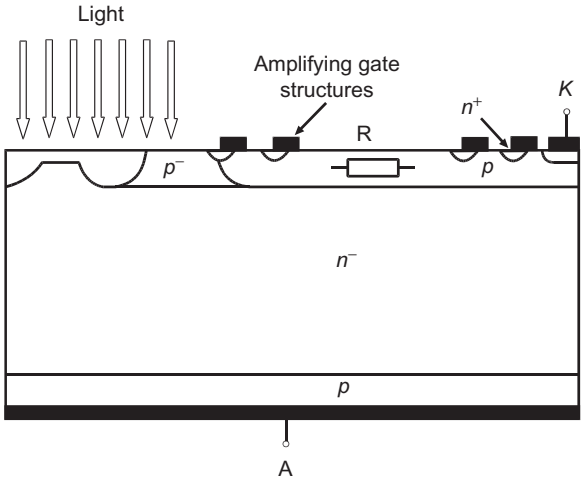

FIG. 3.31 Cross section of a light-triggered thyristors (LTT).

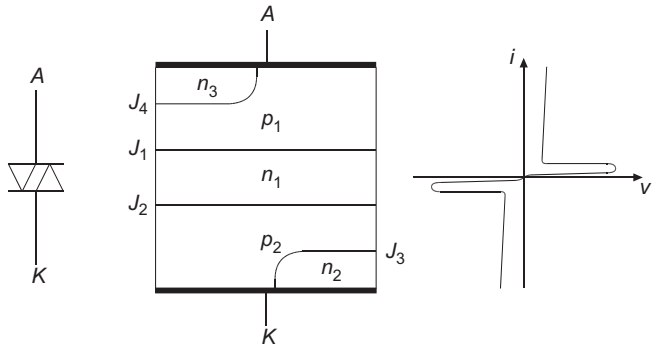

FIG. 3.33 Cross section and *i-v* plot of a diac.

can block 1.2 kV and conduct up to 20 A (at a forward drop of 2.5 V). This device is an integration of a normally off buried-gate static induction photo-thyristor and a normally off *p*-channel darlington surface-gate static induction phototransistor. The optical trigger and quenching power required is less than 5 and 0.2 mW, respectively.

3.6.9 Bi-directional Controlled Thyristors

The BCT is an integrated assembly of two antiparallel thyristors on one Si wafer. The intended applications for this switch are VAR compensators, static switches, soft starters, and motor drives. These devices are rated up to 6.5 kV blocking. Cross talk between the two halves has been minimized. A cross section of the BCT is shown in Fig. 3.32. Note that each surface has a cathode and an anode (opposite devices). The small gate-cathode periphery necessarily restricts the BCT to low-frequency applications because of its *di/dt* limit.

Low-power devices similar to the BCT, but in existence for many years, are the diac and triac. A simplified cross section of a diac is shown in Fig. 3.33. A positive voltage applied to the anode with respect to the cathode forward biases J_1, while reverse biasing J_2. J_4 and J_3 are shorted by the metal contacts. When J_2 is biased to breakdown, a lateral current flows in the p_2 region. This lateral flow forward biases the edge of J_3, causing carrier injection. The result is that the device switches into its thyristor mode and latches. Applying a reverse voltage causes the opposite behavior at each junction, but with the same result. Fig. 3.33 also shows the *i-v* plot for a diac.

The addition of a gate connection, to form a triac, allows the breakover to be controlled at a lower forward voltage. Fig. 3.34 shows the structure for the triac. Unlike the diac, this is not symmetrical, resulting in differing forward and reverse breakover voltages for a given gate voltage. The device is fired by applying a gate pulse of the same polarity relative to MT1 as that of MT2.

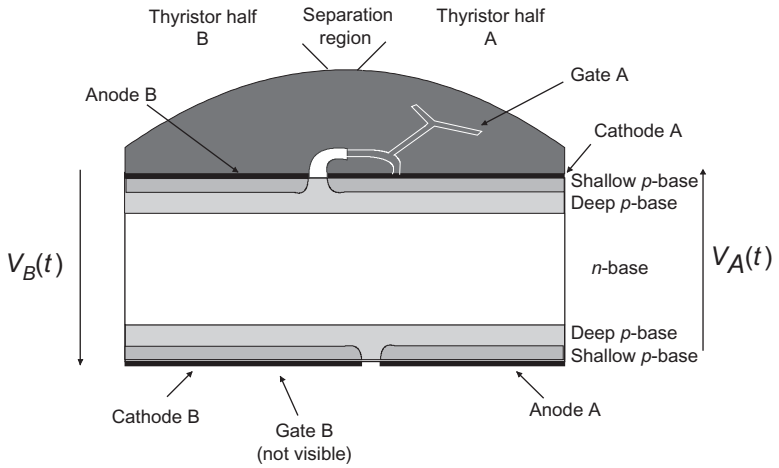

FIG. 3.32 Cross section of a bidirectional control thyristor (BCT).

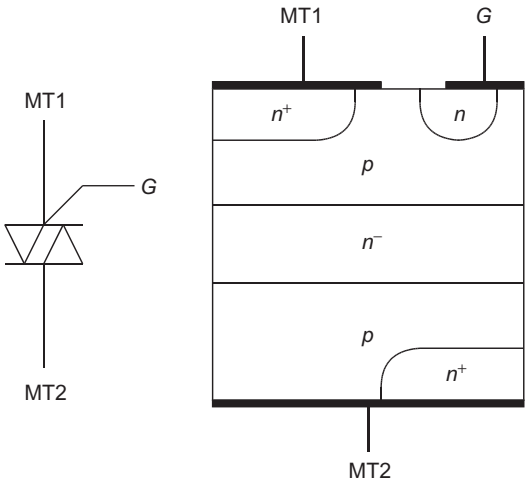

FIG. 3.34 Cross section of a triac.

3.7 Gate Drive Requirements

3.7.1 Snubber Circuits

To protect a thyristor, from a large *di/dt* during turn-on and a large *dv/dt* during turnoff, a snubber circuit is needed. A general snubber topology is shown in Fig. 3.35. The turn-on snubber is made by inductance L_1 (often, L_1 is stray inductance only). This protects the thyristor from a large *di/dt* during the turn-on process. The auxiliary circuit made by R_1 and D_1 allows the discharging of L_1 when the thyristor is turned off. The turn-off snubber is made by resistor R_2 and capacitance C_2. This circuit protects a GTO from large *dv/dt* during the turn-off process. The auxiliary circuit made by D_2 and R_2 allows the discharging of C_2 when the thyristor is turned on. The circuit of capacitance C_2 and inductance L_1 also limits the value of *dv/dt* across the thyristor during forward-blocking. In addition, L_1 protects the thyristor from reverse overcurrents. R_1 and diodes D_1, D_2, are usually omitted in ac circuits with converter-grade thyristors. A similar second set of *L*, *C*, and *R* may be used around this circuit in HVDC applications.

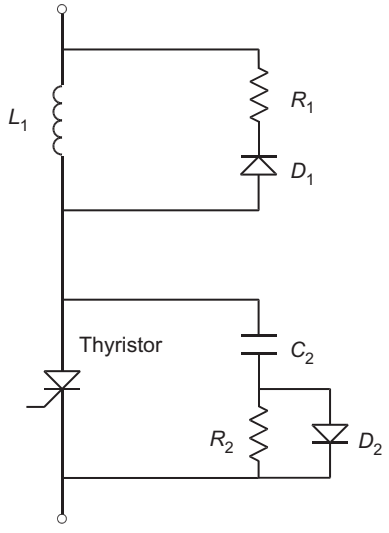

FIG. 3.35 Turn-on (top elements) and turn-off (bottom elements) snubber circuits for thyristors.

3.7.2 Gate Circuits

It is possible to turn on a thyristor by injecting a current pulse into its gate. This process is known as gating, triggering, or firing the thyristor. The most important restrictions are on the maximum peak and duration of the gate pulse current. In order to allow a fast turn-on and a correspondingly large anode *di/dt* during the turn-on process, a large gate current pulse is supplied during the initial turn-on phase with a large di_G/dt. The gate current is kept on, at lower value, for some times after the thyristor turned on in order to avoid unwanted turn-off of the device; this is known as the "back-porch" current. A shaped gate current waveform of this type is shown in Fig. 3.36.

Fig. 3.37 shows typical gate *i-v* characteristics for the maximum and minimum operating temperatures. The dashed line represents the minimum gate current and corresponding gate voltage needed to ensure that the thyristor will be triggered at various operating temperatures. It is also known as the locus of minimum firing points. On the data sheet, it is possible find a line representing the maximum operating power of the thyristor gating internal circuit. The straight line, between V_{GG} and V_{GG}/R_G, represents the current voltage characteristic of the equivalent trigger circuit. If the equivalent trigger circuit line intercepts the two gate *i-v* characteristics for the maximum and minimum operating temperatures between where they intercept the dashed lines (minimum gate current to trigger and maximum gate power dissipation), then the trigger circuit is able to turn-on the thyristor at any operating temperature without destroying or damaging the device.

In order to keep the power circuit and the control circuit electrically unconnected, the gate signal generator and the gate of the thyristor are often connected through a transformer.

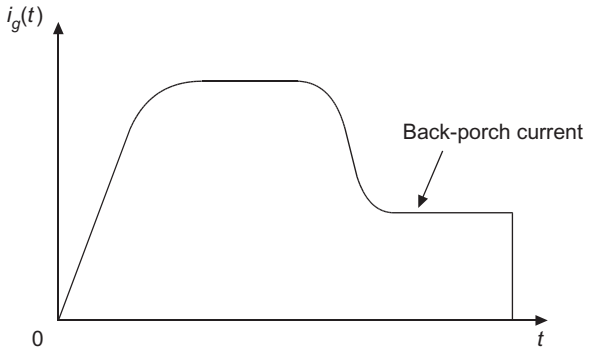

FIG. 3.36 Gate current waveform showing large initial current followed by a suitable back-porch value.

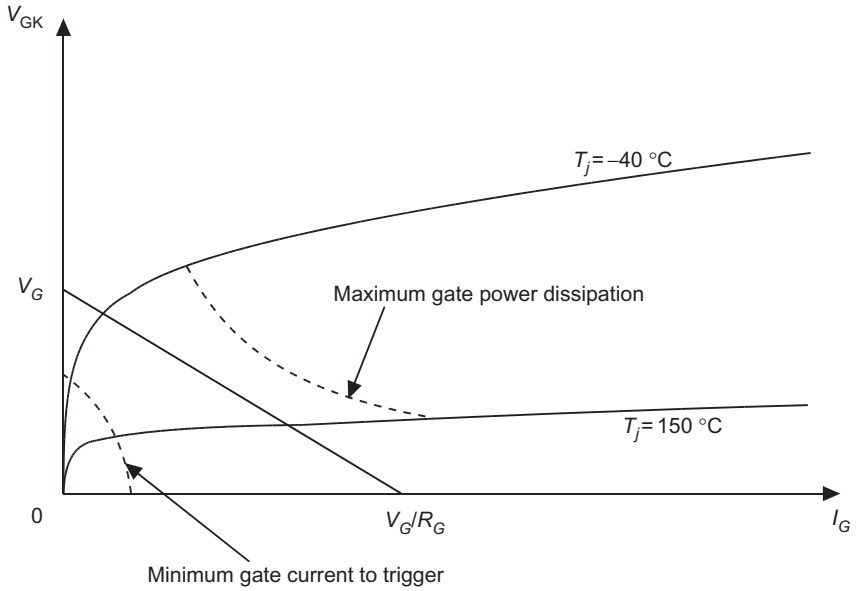

FIG. 3.37 Gate *i-v* curve for a typical thyristor.

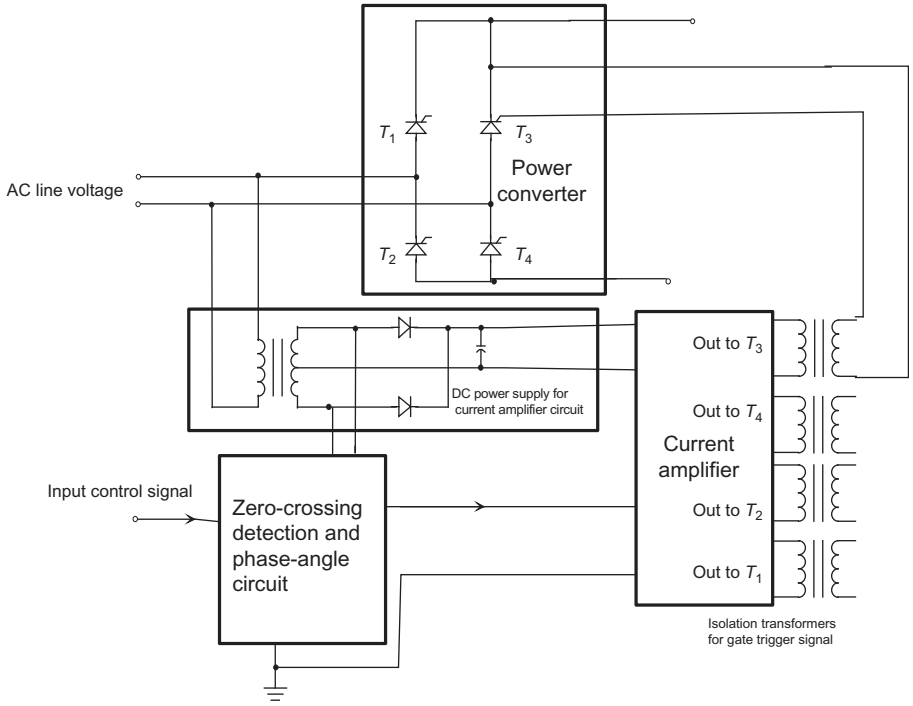

FIG. 3.38 Block diagram of a transformer-isolated gate-drive circuit.

There is a transformer winding for each thyristor, and in this way, unwanted short circuits between devices are avoided. A general block diagram of a thyristor gate trigger circuit is shown in Fig. 3.38. This application is for a standard bridge configuration often used in power converters.

Another problem can arise if the load impedance is high, particularly if the load is inductive and the supply voltage is low. In this situation, the latching current may not be reached during the trigger pulse. A possible solution to this problem could be the use of a longer current pulse. However, such a solution is not attractive because of the presence of the isolation transformer. An alternative solution is the generation of a series of short pulses that last for the same duration as a single long pulse. A single short pulse, a single long pulse, and a series of

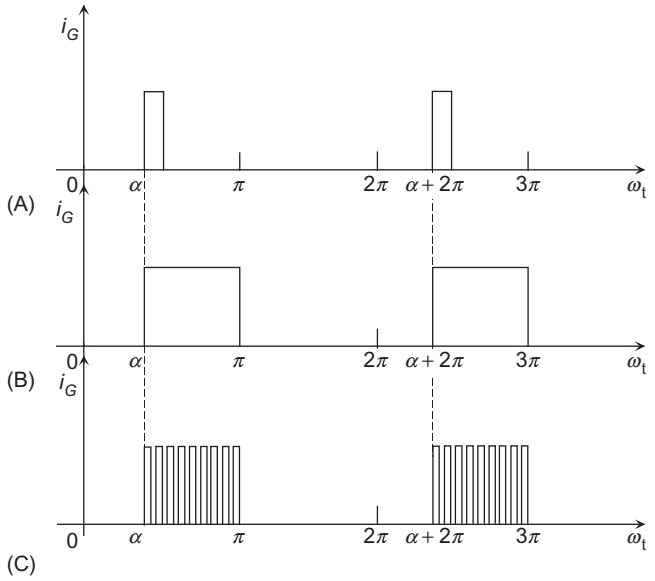

FIG. 3.39 Multiple gate pulses used as an alternative to one long current pulse.

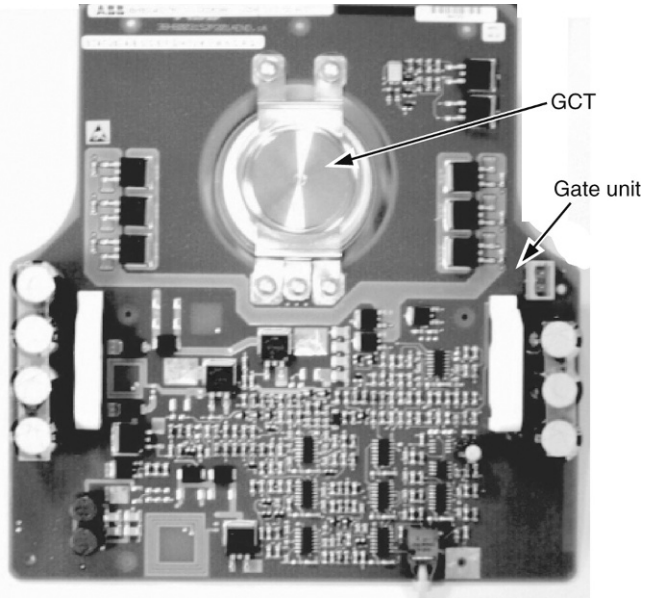

FIG. 3.40 Typical layout of an IGCT gate drive.

short pulses are shown in Fig. 3.39. Reliable gating of the thyristor is essential in many applications.

There are many gate trigger circuits that use optical isolation between the logic-level electronics and a drive stage (typically MOSFETs) configured in a push-pull output. The dc power supply voltage for the drive stage is provided through transformer isolation. Many device manufacturers supply drive circuits available on printed circuit (PC) boards or diagrams of suggested circuits.

IGCT gate drives consist of an integrated module to which the thyristor is connected via a low-inductance mounting; an example is given in Fig. 3.40. Multiple MOSFETs and capacitors connected in parallel may be used to source or sink the necessary currents to turn the device on or off. Logic in the module controls the gate drive from a fiber-optic trigger input and provides diagnostic feedback from a fiber-optic output. A simple power supply connection is also required.

Values for each cell of a multicell GTO model

Model component	Symbol	Value
Delay resistor	R	1 μΩ
Delay capacitor	C	1 nF
Mutual coupling inductance	M	10 nH
Gate contact resistance	R_{GC}	1 mΩ
Cathode contact resistance	R_{KC}	1 mΩ

Other GTO thyristor models have been developed that offer improved accuracy at the expense of increased complexity. The model by Tseng et al. [30] includes charge storage effects in the n^--base, and its application to a multicell model, as in Fig. 3.14, has been demonstrated successfully. Models for the IGCT, based on the lumped-charge approach [31] and the Fourier-based solution of the ambipolar diffusion equation (ADE) [32], have also been developed.

3.8 Applications

The most important application of thyristors is for line-frequency phase-controlled rectifiers. This family includes several topologies, of which one of the most important is used to construct HVDC transmission systems. A single-phase controlled rectifier is shown in Fig. 3.41.

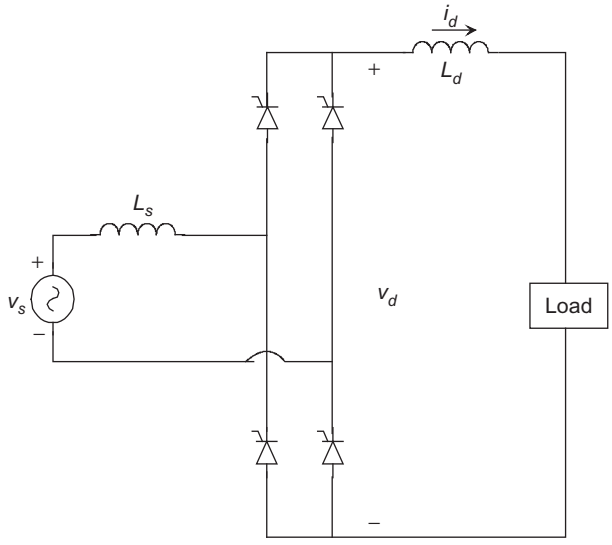

FIG. 3.41 Single-phase controlled rectifier circuit.

The use of thyristors instead of diodes allows the average output voltage to be controlled by appropriate gating of the thyristors. If the gate signals to the thyristors were continuously applied, the thyristors in Fig. 3.41 would behave as diodes. If no gate currents are supplied, they behave as open circuits. Gate current can be applied any time (phase delay) after the forward voltage becomes positive. Using this phase-control feature, it is possible to produce an average dc output voltage less than the average output voltage obtained from an uncontrolled diode rectifier.

3.8.1 DC–AC Utility Inverters

Three-phase converters can be made in different ways, according to the system in which they are employed. The basic circuit used to construct these topologies—the three-phase controlled rectifier—is shown in Fig. 3.42.

Starting from this basic configuration, it is possible to construct more complex circuits in order to obtain high-voltage or high-current outputs or just to reduce the output ripple by constructing a multiphase converter. One of the most important systems using the topology shown in Fig. 3.42 as a basic circuit is the HVDC system represented in Fig. 3.43. This system is made by two converters, a transmission line, and two ac systems. Each converter terminal is made of two poles. Each pole is made by two six-pulse line-frequency converters connected through Δ–Y and Y–Y transformers in order to obtain a 12-pulse converter and a reduced output ripple. The filters are required to reduce the current harmonics generated by the converter.

When a large amount of current and relatively low voltage is required, it is possible to connect in parallel, using a specially designed inductor, two six-pulse line-frequency converters connected through Δ–Y and Y–Y transformers. The special inductor is designed to absorb the voltage between the two converters and to provide a pole to the load. This topology is shown in Fig. 3.44. This configuration is often known as a 12-pulse converter. Higher pulse numbers may also be found.

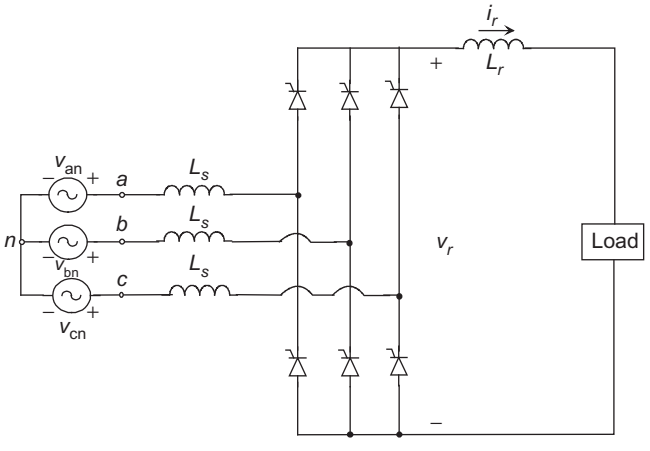

FIG. 3.42 A three-phase controlled bridge circuit used as a basic topology for many converter systems.

3.8.2 Motor Control

Another important application of thyristors is in motor control circuits. Historically, thyristors have been used heavily in traction, although most new designs are now based on IGBTs. Such motor control circuits broadly fall into four types: (i) chopper control of a dc motor from a dc supply, (ii) single- or three-phase converter control of a dc motor from an ac supply, (iii) inverter control of an ac synchronous or induction machine from a dc supply, and (iv) cycloconverter control of an ac machine from an ac supply. An example of a GTO chopper is given in Fig. 3.45. $L_1, R_1, D_1,$ and C_1 are the turn-on snubber; $R_2, D_2,$ and C_2 are the turn-off snubber; finally, R_3 and D_3 form the snubber for the freewheel diode D_3. A thyristor cycloconverter is shown in Fig. 3.46; the waveforms show the fundamental component of the output voltage for one phase. Three double converters are used to produce a three-phase variable-frequency, variable voltage sinusoidal output for driving ac motors. However, the limited frequency range (less than a third of the line frequency) restricts the application to large, low-speed machines at high powers.

A single- or three-phase thyristor converter (controlled rectifier) may be used to provide a variable dc supply for controlling a dc motor. Such a converter may also be used as the front end of a three-phase induction motor drive. The variable voltage, variable-frequency motor drive requires a dc supply, which is supplied by the thyristor converter. The drive may use a square wave or PWM voltage source inverter (VSI) or a current source inverter (CSI). Fig. 3.47 shows a square wave or PWM VSI with a controlled rectifier on the input side. The switch block inverter may be made of thyristors (usually GTOs or IGCTs) for high power, although most new designs now use IGBTs. Low-power motor controllers generally use IGBT inverters.

In motor control, thyristors are also used in CSI topologies. When the motor is controlled by a CSI, a controlled rectifier is also needed on the input side. Fig. 3.48 shows a typical CSI inverter. The capacitors are needed to force the current in the thyristors to zero at each switching event. This is not needed when using GTOs. This inverter topology does not need any additional circuitry to provide the regenerative braking (energy recovery when slowing the motor). Historically, two back-to-back connected line-frequency thyristor converters have been employed to allow bidirectional power flow and thus regenerative braking. Use of antiparallel GTOs with symmetrical blocking capability, or the use of diodes in series with each asymmetrical GTO, reduces the number of power devices needed, but greatly increases the control complexity.

3.8.3 VAR Compensators and Static Switching Systems

Thyristors are also used to switch capacitors or inductors in order to control the reactive power in the system. Such arrangements may also be used in phase-balancing circuits for balancing the load fed from a three-phase supply. Examples of these circuits are shown in Fig. 3.49. These circuits act as static VAR controllers. The topology represented on the left of Fig. 3.49 is called a thyristor-controlled inductor (TCI), and it acts as a variable inductor where the inductive VAR supplied can be varied quickly. Because the system may require either inductive or capacitive VAR compensation, it is possible to connect a bank of capacitors in parallel with a TCI. The topology shown on the

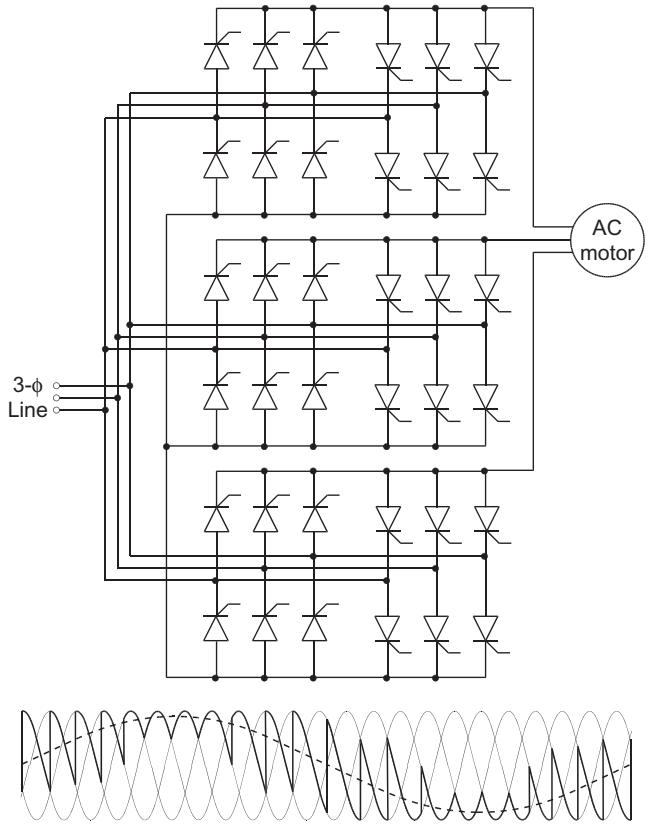

FIG. 3.46 Cycloconverter for control of large ac machines.

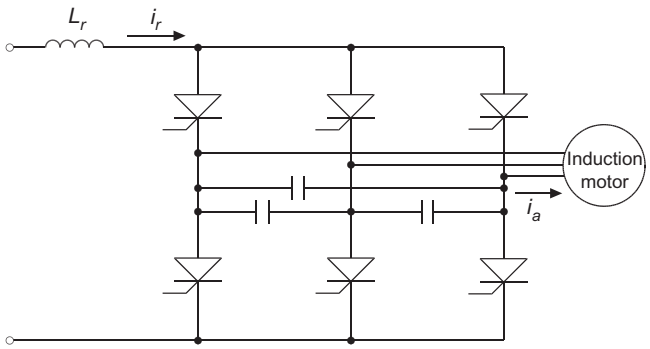

FIG. 3.48 CSI on the output section of a motor drive system using capacitors for power factor correction.

right of Fig. 3.49 is called a thyristor-switched capacitor (TSC). Capacitors can be switched out by blocking the gate pulse of all thyristors in the circuit. The problem of this topology is the voltage across the capacitors at the thyristor turnoff. At turn-on the thyristor must be gated at the instant of the maximum ac voltage to avoid large overcurrents. Many recent SVCs have used GTOs.

A similar application of thyristors is in solid-state fault current limiters and circuit breakers. In normal operation, the thyristors are continuously gated. However, under fault conditions, they are switched rapidly to increase the series impedance in the load and to limit the fault current. Key advantages are the flexibility of the current limiting, which is independent of the location of the fault and the change in load impedance, the reduction in fault level of the supply, and a smaller voltage sag during a short-circuit fault.

A less important application of thyristors is as a static transfer switch, used to improve the reliability of uninterruptible power supplies (UPS) as shown in Fig. 3.50. There are two modes of using the thyristors. The first leaves the load permanently connected to the UPS system and in case of emergency disconnects the load from the UPS and connects it directly to the power line. The second mode is opposite to the first one. Under normal conditions, the load is permanently connected to the power line, and in event of a line outage, the load is disconnected from the power line and connected to the UPS system.

3.8.4 Lighting Control Circuits

An important circuit used in lighting control is the dimmer, based on a triac and shown in Fig. 3.51. The *R-C* network applies a phase shift to the gate voltage, delaying the triggering of the triac. Varying the resistance controls the firing angle of the triac and therefore the voltage across the load. The diac is used to provide symmetrical triggering for the positive and negative half cycles, due to the nonsymmetrical nature of the triac. This ensures symmetrical waveforms and elimination of even harmonics. An *L-C* filter is often used to reduce any remaining harmonics.

4.1 Introduction

Static induction devices were invented in 1975 by Nishizawa [1], and for many years, Japan was the only country where static induction family devices were successfully fabricated. Static induction transistor (SIT) can be considered as a short channel junction field effect transistor (JFET) device operating in prepunch-through region. The number of devices in this family is growing with time. The SIT can operate with the power over 100 kW at 100 kHz and above 150 W at 3 GHz [2]. These devices may operate up to THz frequencies [3,4]. Static induction transistor logic (SITL) had 100 times smaller switching energy than its I^2L competitor [5,6]. Static induction thyristor has many advantages over the traditional silicon-controlled rectifier (SCR), and static induction diod (SID) exhibits high switching speed, large reverse voltage, and low forward voltage drops [7].

4.2 Theory of Static Induction Devices

The cross section of the SIT is shown in Fig. 4.1, while its characteristics are shown in Fig. 4.2. An induced electrostatically potential barrier controls the current in static induction devices. The derivations of formulas will be done for an n-channel device, but the obtained results, with a little modification, can also be applied to p-channel devices. For a small electric field existing in the vicinity of the potential barrier, the drift and diffusion current can be approximated by

$$J_n = -qn(x)\mu_n \frac{d\varphi(x)}{dx} + qD_n \frac{dn(x)}{dx} \tag{4.1}$$

where $D_n = \mu_n V_T$ and $V_T = kT/q$. By multiplying both sides of the equation by $\exp(-\varphi(x)/V_T)$ and rearranging

$$J_n \exp\left(-\frac{\varphi(x)}{V_T}\right) = qD_n \frac{d}{dx}\left[n(x)\exp\left(-\frac{\varphi(x)}{V_T}\right)\right] \tag{4.2}$$

Integrating from x_1 to x_2, one can obtain

$$J_n = qD_n \frac{n(x_2)\exp(-\varphi(x_2)/V_T) - n(x_1)\exp(-\varphi(x_1)/V_T)}{\int_{x_1}^{x_2} \exp(-\varphi(x)/V_T)dx} \tag{4.3}$$

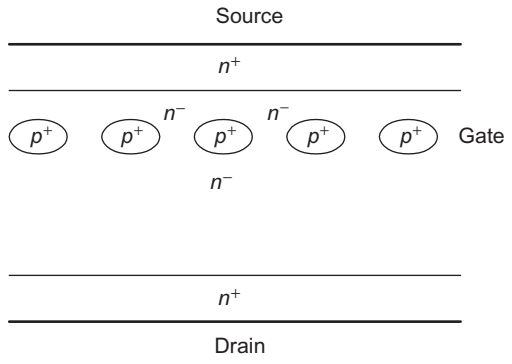

FIG. 4.1 Cross section of the static induction transistor.

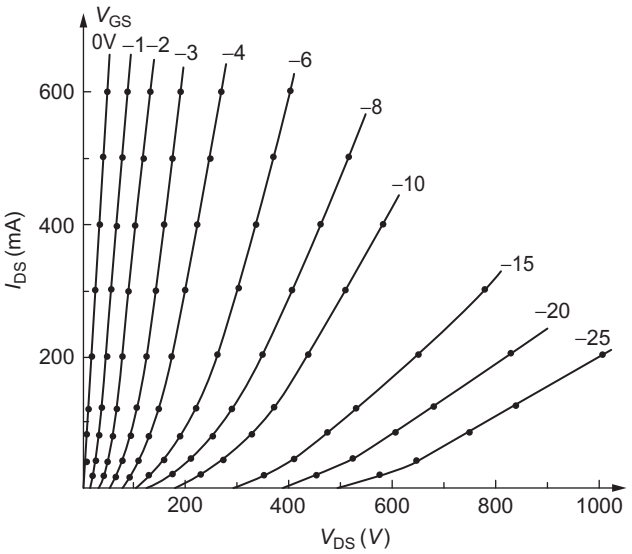

FIG. 4.2 Characteristics of the early SIT design [1].

With the following boundary conditions

$$\varphi(x_1)=0;\ \ n(x_1)=N_S$$
$$\varphi(x_2)=V_D;\ \ n(x_2)N_D \tag{4.4}$$

Eq. (4.3) reduces to

$$J_n=\frac{qD_nN_S}{\int_{x_1}^{x_2}\exp\left(-\varphi(x)/V_T\right)dx} \tag{4.5}$$

Note that the above equations derived for SIT can also be used to find current in any devices controlled by a potential barrier, such as a bipolar transistor, an MOS transistor operation in subthreshold mode, or a Schottky diode.

4.3 Characteristics of SIT

Samples of the potential distribution in the SI devices are shown in Fig. 4.3 [7]. The vicinity of the potential barrier can be approximated using parabolic formulas (Fig. 4.4) along and across the channel [8,9].

$$\varphi(x)=\Phi\left[1-\left(2\frac{x}{L}-1\right)^2\right] \tag{4.6}$$

$$\varphi(y)=\Phi\left[1-\left(2\frac{y}{W}-1\right)^2\right] \tag{4.7}$$

Integrating Eq. (4.5) first along the channel and then across the channel yields a very simple formula for drain currents in n-channel SITs:

$$I_D=qD_pN_SZ\frac{W}{L}\exp\left(\frac{\Phi}{V_T}\right) \tag{4.8}$$

where Φ is the potential barrier height in reference to the source potential, N_S is the electron concentration at the source, W/L ratio describes the shape of the potential saddle in vicinity of the barrier, and Z is the length of the source strip.

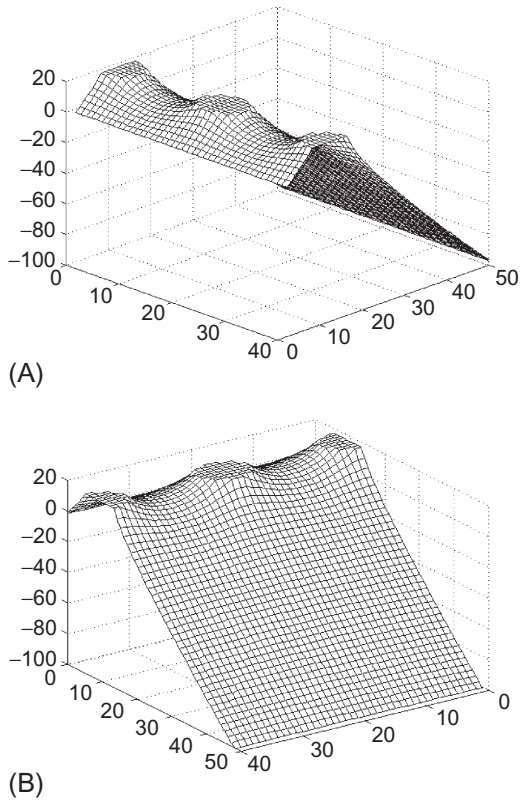

FIG. 4.3 Potential distribution in SIT: (A) view from the source side and (B) view from the drain side.

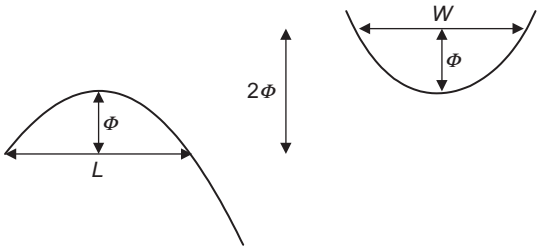

FIG. 4.4 Potential distribution in the vicinity of the barrier approximated by parabolic shapes.

Since barrier height Φ can be a linear function of gate and drain voltages, therefore,

$$I_D = qD_pN_SZ\frac{W}{L}\exp\left(a(V_{GS} + bV_{DS} + \Phi_0)/V_T\right) \tag{4.9}$$

The above equation describes characteristics of SIT for small current range. For large current levels, the device current is controlled by the space charge of moving carriers. In the one-dimensional case, the potential distribution is described by the Poisson equation:

$$\frac{d^2\varphi}{dx_2} = -\frac{\rho(x)}{\varepsilon_{Si}\varepsilon_0} = \frac{I_{DS}}{Av(x)} \tag{4.10}$$

where A is the effective device cross section and $v(x)$ is carrier velocity. For a small electric field, $v(x) = \mu E(x)$, and the solution of Eq. (4.10) is

$$I_{DS} = \frac{9}{8}V_{DS}^2\mu\varepsilon_{Si}\varepsilon_0\frac{A}{L^3} \tag{4.11}$$

and for a large electric field, $v(x) = \text{const}$, and Eq. (4.10) results in

$$I_{DS} = 2V_{DS}v_{sat}\varepsilon_{Si}\varepsilon_0\frac{A}{L^2} \tag{4.12}$$

where L is the channel length and $v_{sat} \asymp 10^{11}$ μm/s is the carrier saturation velocity. In practical devices, the current-voltage relationship is described by an exponential relationship, Eq. (4.9); for small currents, a quadratic relationship, Eq. (4.11); and finally for large voltages by an almost linear relationship, Eq. (4.12). SIT characteristics drawn in linear and logarithmic scales are shown in Figs. 4.5 and 4.6, respectively.

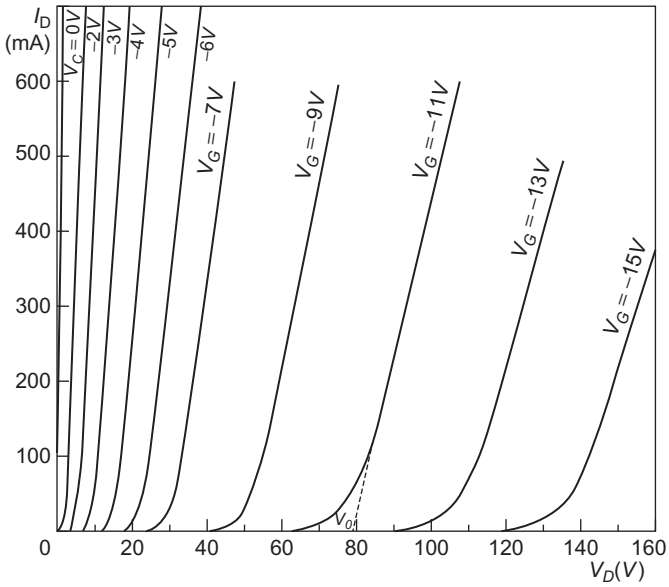

FIG. 4.5 Characteristics of the SIT drawn in a linear scale.

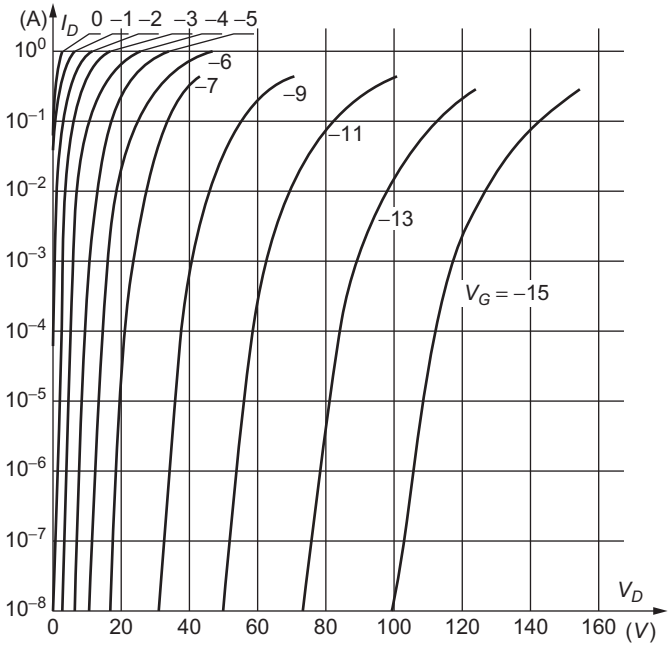

FIG. 4.6 Characteristics of the SIT drawn in a logarithmic scale.

4.4 Bipolar Mode Operation of SI devices (BSIT)

The bipolar mode of operation of SIT was first reported in 1976 by Nishizawa and Wilamowski [5,6]. Several complex theories for the bipolar mode of operation were developed [10–14], but actually, the simple formula given by Eq. (4.5) works well not only for the typical mode of the SIT operation but also for the bipolar mode of the SIT operation. Furthermore, the same formula works very well for the classical bipolar transistors. Typical characteristics of the SI transistor operating in normal and in bipolar modes are shown in Figs. 4.7 and 4.8.

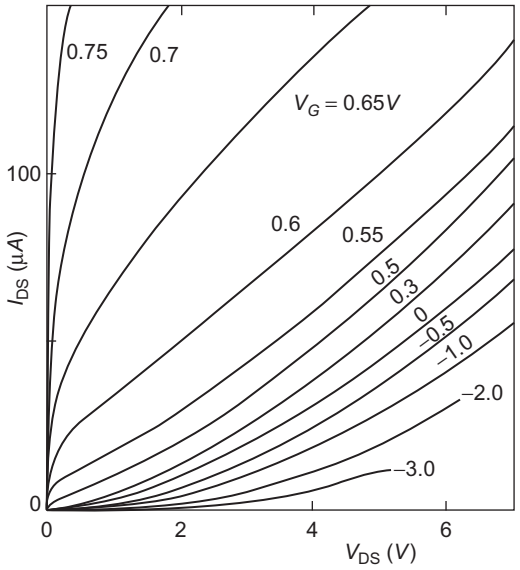

FIG. 4.7 Small-size SIT transistor characteristics, operating in both the normal and bipolar modes, $I_D = f(V_{DS})$ with V_{GS} as a parameter.

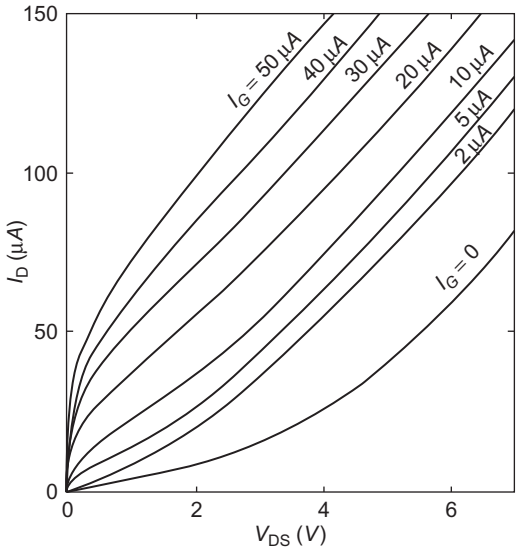

FIG. 4.8 Small-size SIT transistor characteristics, operating in both the normal and bipolar modes, $I_D = f(V_{DS})$ with I_G as a parameter.

A potential barrier controls the current in the SIT, and it is given by

$$J_n = \frac{qD_n N_S}{\int_{x_1}^{x_2} \exp\left(-\frac{\varphi(x)}{V_T}\right) dx} \tag{4.13}$$

where $\phi(x)$ is the profile of the potential barrier along the channel.

For example, in the case of *npn* bipolar transistors, the potential distribution across the base in reference to emitter potential at the reference impurity level $N_E = N_S$ is described by

$$\varphi(x) = V_T \ln\left(\frac{N_B(x)N_S}{n_i^2}\right) \exp\left(-\frac{V_{BE}}{V_T}\right) \tag{4.14}$$

After inserting Eq. (4.14) into Eq. (4.13), one can obtain the well-known equation for electron current injected into the base:

$$J_n = \frac{qD_n n_i^2}{\int_{x_1}^{x_2} N_B(x)dx} \exp\left(\frac{V_{BE}}{V_T}\right) \tag{4.15}$$

If Eq. (4.13) is valid for SIT and BJT, then one may assume that it is also valid for the bipolar mode of operation of the SIT transistor. This is a well-known equation for the collector current in the bipolar transistor, but this time, it was derived using the concept of the current flow through the potential barrier.

4.5 Emitters for Static Induction Devices

One of the disadvantages of the SIT is the relatively flat shape of the potential barrier (Fig. 4.9A). This leads to slow, diffusion-based transport of carriers in the vicinity of the potential barrier. The carrier transit time can be estimated using the formula

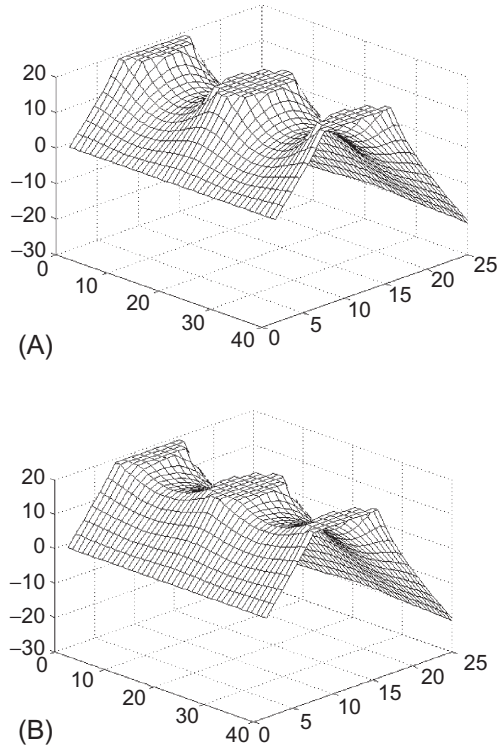

FIG. 4.9 Potential distributions in SIT: (A) traditional and (B) with sharp potential barrier.

$$t_{\text{transit}} = \frac{l_{\text{eff}}^2}{D} \tag{4.16}$$

where l_{eff} is the effective length of the channel and $D = \mu V_T$ is the diffusion constant. In the case of a traditional SIT transistor, this channel length is about 2 μm, while in the case of SIT transistors with sharper barriers (Fig. 4.9B), the channel length is reduced to about 0.2 μm. The corresponding transient times are 2 ns and 20 ps, respectively.

Potential distributions shown in Fig. 4.3 are valid for SIT with an emitter made of a traditional *p-n* junction. A much narrower potential barrier can be obtained when the other type of emitter is being used. There are two well-known emitters, (1) *p-n* junction (Fig. 4.10A) and (2) Schottky junction (Fig. 4.10B). For silicon devices, *p-n* junctions have a forward voltage drop of 0.7–0.8 V, while Schottky emitters have 0.2–0.3 V only. Since the Schottky diode is a majority carrier device, the carrier storage effect is negligible.

Another interesting emitter structure is shown in Fig. 4.10C. This emitter has all the advantages of the Schottky diode, with majority carrier injection, even though it is fabricated out of *p-n* junctions.

The concept of static induction devices can be used independently of the type of emitter shown in Fig. 4.10. With Schottky-type and punch-through-type emitters, the potential barrier is much narrower, and this results in faster response time and larger current gain in the bipolar mode of operation.

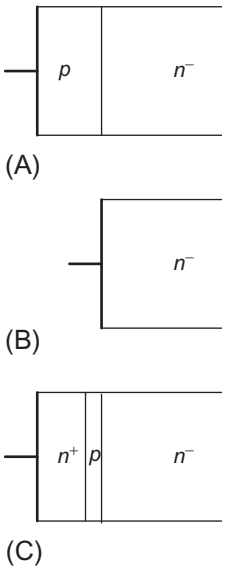

FIG. 4.10 Various structures of emitters: (A) *p-n* junction including heterostructure with SiGe materials, (B) Schottky junction, and (C) punch-through emitter (in normal operation condition, the *p* region is depleted from carriers).

4.6 Static Induction Diode

The bipolar mode of operation of SIT can also be used to obtain diodes with low forward voltage drop and negligible carrier storage effect [10,11,13,15]. A SID can be obtained by shorting a gate to the emitter of the SIT [16,17]. Such diode has all the advantages of the SIT such as thermal stability and short switching time. The cross section of such diode is shown in Fig. 4.11.

The quality of the SID can be further improved with more sophisticated emitters (Fig. 4.10B and C). The SI diode with Schottky emitter was described by Wilamowski in 1983 [18] (Fig. 4.12). A similar structure was later published by Baliga [19].

4.7 Lateral Punch-Through Transistor

Fabrications of SI transistors usually require very sophisticated technology. It is much simpler to fabricate a lateral punch-through transistor (LPTT), which operates on the same principle and has similar characteristics [20] (Fig. 4.13). The cross section of the LPTT is shown in Fig. 4.14.

4.8 Static Induction Transistor Logic

The SITL was proposed by Nishizawa and Wilamowski [5,6]. This logic circuit has almost 100 times better power-delay product than its I^2L competitor. Such drastic improvement of the power-delay product is possible because the SITL structure has a significantly smaller junction parasitic capacitance and also the voltage swing is reduced. Figs. 4.15 and 4.16 illustrate the concept of SITL. Measured characteristics of

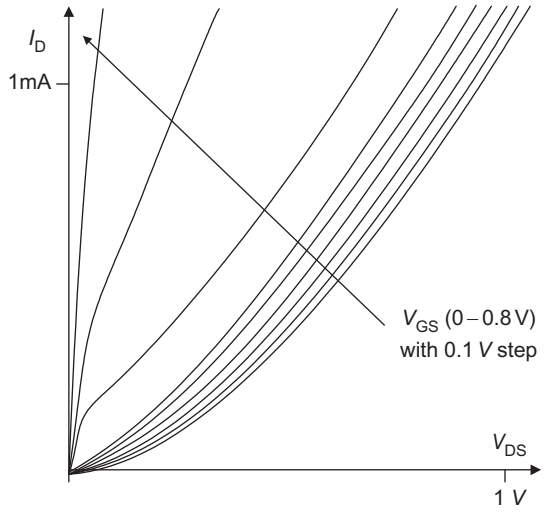

FIG. 4.17 Measured characteristics of *n*-channel transistor of the logic circuit of Fig. 4.16.

n-channel transistor of the static induction logic are shown in Fig. 4.17.

4.9 BJT Saturation Protected by SIT

The SI transistor can also be used instead of a Schottky diode to protect a bipolar junction transistor against saturation [21]. This leads to faster switching time. The concept is shown in Figs. 4.13 and 4.18. Note that this approach is advantageous to the solution with Schottky diode, since it does not require additional area on a chip and it does not introduce additional capacitance between the base and the collector. The base-collector capacitance is always enlarged by the Miller effect, and this leads to slower switching in the case of the solution with the Schottky diode.

4.10 Static Induction MOS Transistor

The punch-through transistor with MOS-controlled gate was described in 1983 [22,23]. In the structure in Fig. 4.19A, current

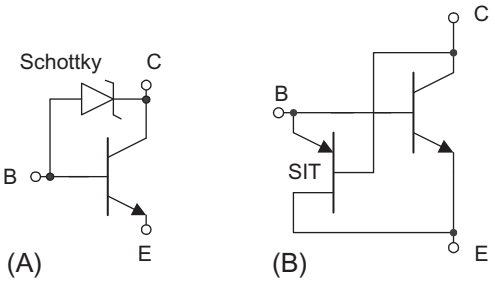

FIG. 4.18 Protection of bipolar transistor against deep saturation: (A) using Schottky diode and (B) using SIT.

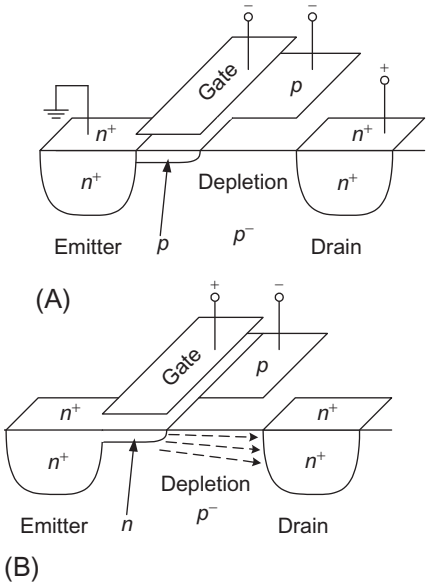

FIG. 4.19 MOS-controlled punch-through transistor: (A) transistor in the punch-through mode for the negative gate potential and (B) transistor in the on-state for the positive gate potential.

can flow in a similar fashion as in the LPTT [20]. In this mode of operation, carriers are moving far from the surface with a velocity close to the saturation velocity. The real advantage of such structure is the very low gate capacitance.

Another implementation of static induction MOS transistor (SIMOS) is shown in Fig. 4.20. The buried p^+ layer is connected to the substrate, which has a large negative potential. As a result, the potential barrier is high, and the emitter-drain current cannot flow. The punch-through current may start to flow

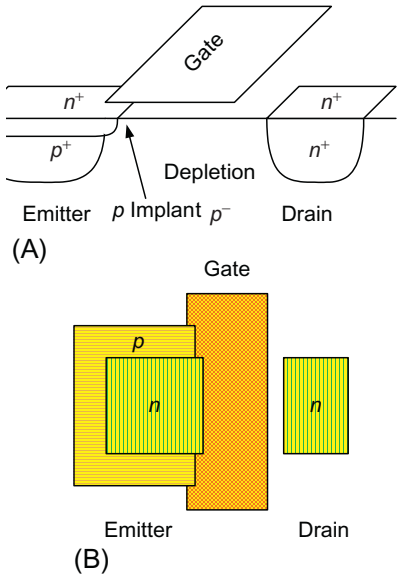

FIG. 4.20 Static induction MOS structure: (A) cross section and (B) top view.

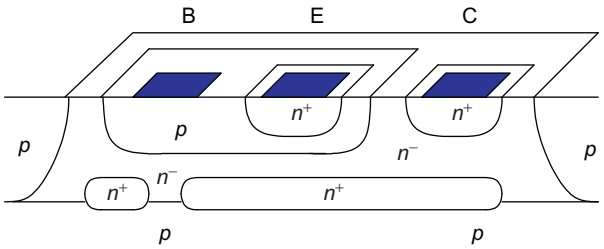

FIG. 4.21 Cross sections of bipolar transistors protected against deep saturation using SIT.

when the positive voltage is applied to the gate, and in this way, the potential barrier is lowered. The *p*-implant layer is depleted, and due to the high horizontal electric field under the gate, there is no charge accumulation under this gate. Such a transistor has several advantages over the traditional MOS transistor (Fig. 4.21).

1. The gate capacitance is very small, since there is no accumulation layer under the gate.
2. Carriers are moving with a velocity close to saturation velocity.
3. Much lower substrate doping and the existing depletion layer lead to much smaller drain capacitance.

The device operates in a similar fashion as MOS transistor in subthreshold conditions, but this process occurs at much higher current levels. Such "bipolar mode" of operation may have many advantages in VLSI applications.

4.11 Space Charge Limiting Load (SCLL)

Using the concept of the space charge-limited current flow, it is possible to fabricate very large resistors on a very small area. Moreover, these resistors have a very small parasitic capacitance. For example, a 50 kΩ resistor requires only several square μm when a 2 μm feature size technology is used [7].

Depending on the value of the electric field, the device current is described by the following two equations. For a small electric field, $v(x) = \mu E(x)$:

$$I_{DS} = \frac{9}{8} V_{DS}^2 \mu \varepsilon_{Si} \varepsilon_0 \frac{A}{L^3} \tag{4.17}$$

For a large electric field, $v(x) = \text{const}$:

$$I_{DS} = 2 V_{DS} v_{sat} \varepsilon_{Si} \varepsilon_0 \frac{A}{L^2} \tag{4.18}$$

Moreover, these resistors, which are based on the space charge limit flow, have a very small parasitic capacitance (Fig. 4.22).

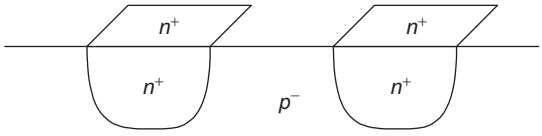

FIG. 4.22 Space charge limiting load (SCLL).

4.12 Power MOS Transistors

Power MOS transistors are being used for fast switching power supplies and for switching power converters. They can be driven with relatively small power, and switching frequencies could be very high. High switching frequencies lead to compact circuit implementations with small inductors and small capacitances. Basically, only two technologies, DMOS and VMOS, are used for power MOS devices as shown in Figs. 4.23 and 4.24.

A more popular structure is the DMOS shown in Fig. 4.24. This structure also uses the SIT concept. Note that for large drain voltages, the *n*-region is depleted from carriers, and statically induced electric field in the vicinity of the virtual drain is significantly reduced. As a result, this transistor may withstand much larger drain voltages, and also the effect of channel length modulation is significantly reduced. The later effect leads to larger output resistances of the transistor. Therefore, the drain current is less sensitive to drain voltage variations. The structure in Fig. 4.24 can be considered as a composition of the MOS transistor and the SIT transistor as is shown in Fig. 4.25.

The major disadvantage of power MOS transistors is relatively large drain series resistance and much smaller

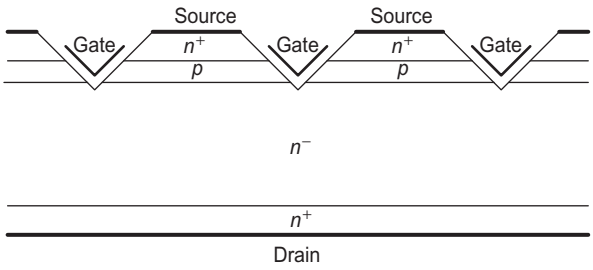

FIG. 4.23 Cross section of the VMOS transistor.

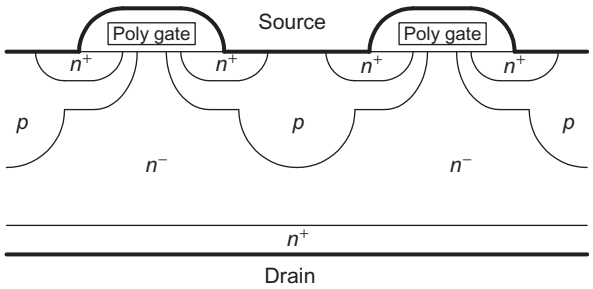

FIG. 4.24 Cross section of the DMOS transistor.

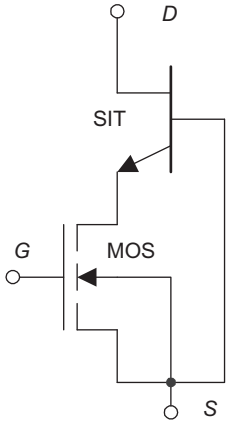

FIG. 4.25 Equivalent diagram with MOS and SIT of the structure of Fig. 4.24.

transconductance in comparison with bipolar transistors. Both of these parameters can be improved dramatically by a simple change of the type of drain, in the case of *n*-channel device from *n*-type to *p*-type drain. This way, the integrated structure is being built where its equivalent diagram consists of MOS transistor integrated with bipolar transistor. Such structure has β times larger transconductance (β is the current gain of bipolar transistor) and much smaller series resistance due to the conductivity modulation effect caused by holes injected into lightly doped drain region. Such device is known as insulated-gate bipolar transistors (IGBT) as shown in Fig. 4.26. Their main disadvantage is large switching time limited primarily by poor switching performance of bipolar transistor. Another difficulty is related to a possible latch-up action of a four-layer $n^+pn^-p^+$ structure. This undesired effect could be suppressed by using heavily doped p^+ region in the base of NPN structure, which leads to significant reduction of the current gain of this parasitic transistor. The gain of other PNP transistor must be kept large, so the transconductance of the entire device is large too. The IGBT transistor has breakdown voltages up to 1500 V; turn off times are in range 0.1–0.5 μs. They may operate with currents above 100 A with a forward voltage drop about 3 V.

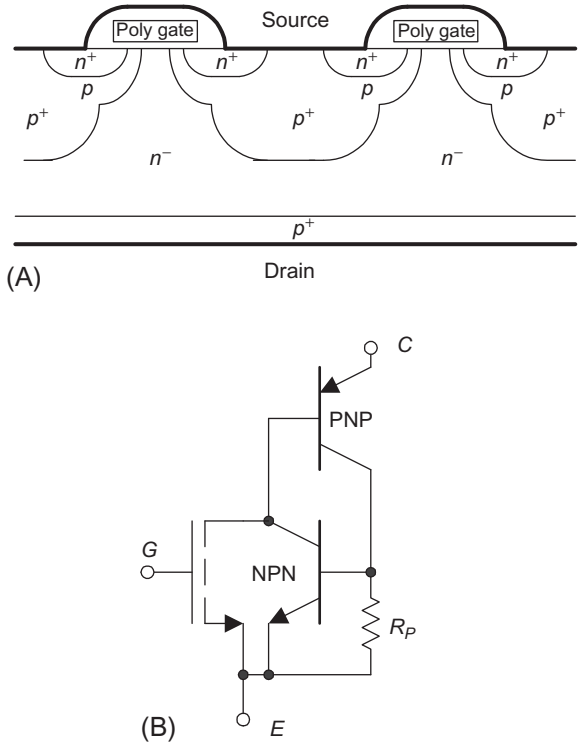

FIG. 4.26 Insulated-gate bipolar transistor (IGBT), (A) cross section and (B) equivalent diagram.

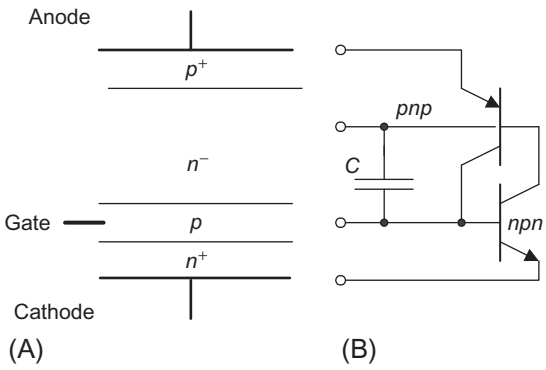

FIG. 4.27 Silicon control rectifier: (A) cross section and (B) equivalent diagram.

4.13 Static Induction Thyristor

There are several special semiconductor devices dedicated to high power applications. The most popular is thyristor known also as silicon control rectifier (SCR). This device has a four-layer structure as shown in Fig. 4.27A, and it can be considered as two transistors *npn* and *pnp* connected as shown in Fig. 4.27B.

In normal mode of operation (anode has positive potential), only one junction is reverse-biased, and it can be represented by capacitance *C*. A spike of anode voltage can therefore get through capacitor *C*, and it can trigger SCR. This behavior is not acceptable in practical application, and therefore, a different device structure is being used as is shown in Fig. 4.28. Note that by shorting gate to cathode by resistor *R*, it is much more difficult to trigger the *npn* transistor by spike of anode voltage. This way, rapid change of anode voltages is not able to trigger thyristor. Therefore, this structure has a very large *dv/dt* parameter.

When NPN transistor is replaced with SI transistor, parameters of a thyristor can be significantly improved. For example, with breaking voltage in the range of 5 kV and current of 600 A,

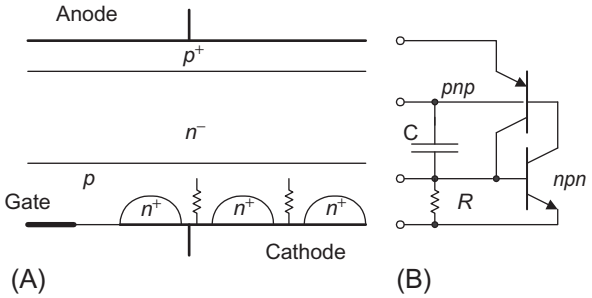

FIG. 4.28 Silicon control rectifier with larger *dv/dt* parameter: (A) cross section and (B) equivalent diagram.

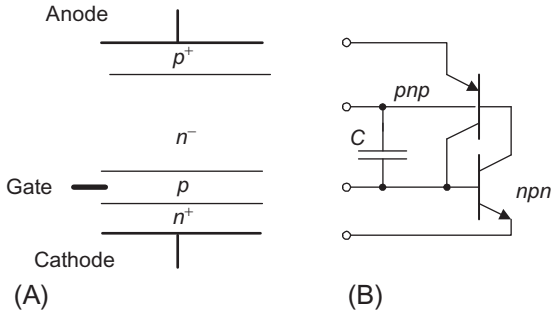

FIG. 4.30 GTO-SIT: (A) cross section and (B) equivalent diagram.

the switching on time can be as short as 100 ns, and *dv/dt* parameter can be as large as 50 kV/s [15,24].

Most of the SCRs sold in the market comprise an integrated structure composed of two or more thyristors. This structure has both large *dv/dt* and *di/dt* parameters. This structure consists of internal thyristor that significantly amplifies the gate signal.

One can notice that the classical thyristor as shown in Fig. 4.27 can be turned off by the gate voltage, while integrated SCR shown in Fig. 4.29 can be only turned off by reducing anode current to zero. Most of the SCRs sold in the market have an integrated structure composed of two or more thyristors. This structure has both large *dv/dt* and *di/dt* parameters.

4.14 Gate Turn Off Thyristor

For the dc operation, it is important to have a thyristor that can be turned off by the gate voltage. Such thyristor has a structure similar to the one shown in Fig. 4.27. It is important, however, to have significantly different current gains β for *pnp* and *npn* transistors. The current gain of *npn* transistor should be as large as possible, and the current gain of *pnp* transistor should be small. The product of β_{npn} and β_{pnp} should be larger than one. This can be easily implemented using SI structure as shown in Fig. 4.30.

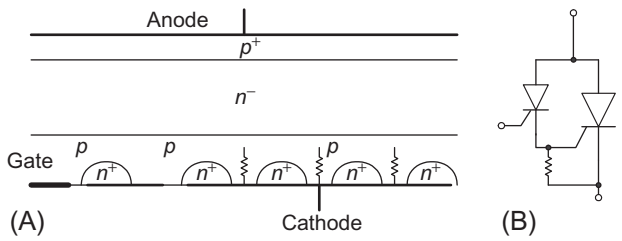

FIG. 4.29 Integrated structure of silicon control rectifier: (A) cross section and (B) equivalent diagram.

5.1 Background

Power semiconductor devices are key components of power electronics technology, used primarily as switches or rectifiers in circuits and systems. Currently, more than 70% of all electric energy consumed is processed by power electronics. The main function of power electronics is to control and transfer the flow of electric energy from one form to another and in a form that is suitable to the user. Semiconductor devices are widespread and can be found in almost every electric and electronic piece of equipment or product. Their power range depends on the application and can be from milliwatts to megawatts. Power devices have a significant impact on the economy as they determine system cost and efficiency.

The invention of the transistor in 1947 by Shockley, Bardeen, and Brattain [1] allowed direct solid-state control of electricity for the first time. However, the application of transistors for controlling electric power was limited until the invention of the thyristor in the late 1950s [2]. Although the thyristor has limited switching capability, it cannot be turned off by external control. Thyristors have been used for the design of different applications, such as control of direct current (DC) motors. The first power bipolar junction transistor (BJT) with substantial power handling capabilities was introduced in the 1960s. The device overcame some of the limitations of the thyristor because it could be switched on or off by applying an external signal.

Further developments of the thyristor led to the realization of a fully controllable switching device, a thyristor that can be turned off using a specialized gate design within the thyristor (GTO) [3]. This enables the GTO to be used in more complex power conversion technology that is capable of controlling power more directly and efficiently. This significant development greatly enhanced power electronics technology.

The metal-oxide-silicon field-effect transistor (MOSFET) was the next major device introduced in the 1970s [4]. It has minimal drive requirements due to its insulated gate. Also, the MOSFET is a voltage-controllable device having high input impedance and fast switching response. MOSFETs are unipolar majority carrier devices that give them a faster switching speed than the BJT or thyristor. On the other hand, the power handling capabilities of the MOSFET are low compared with the thyristor because of high ON-state resistance associated with high blocking voltage.

In the early 1980s, a new process technology was developed allowing MOSFET and BJT technology to be integrated on the same chip [5]. A new device, the insulated-gate bipolar transistor (IGBT), was introduced. IGBTs possess the advantages of both devices: faster switching (inherited from MOSFET) and lower specific ON-state resistance (from the PNP BJT). Improvements in design and technology have made IGBTs popular replacements for BJTs and low- to medium-power

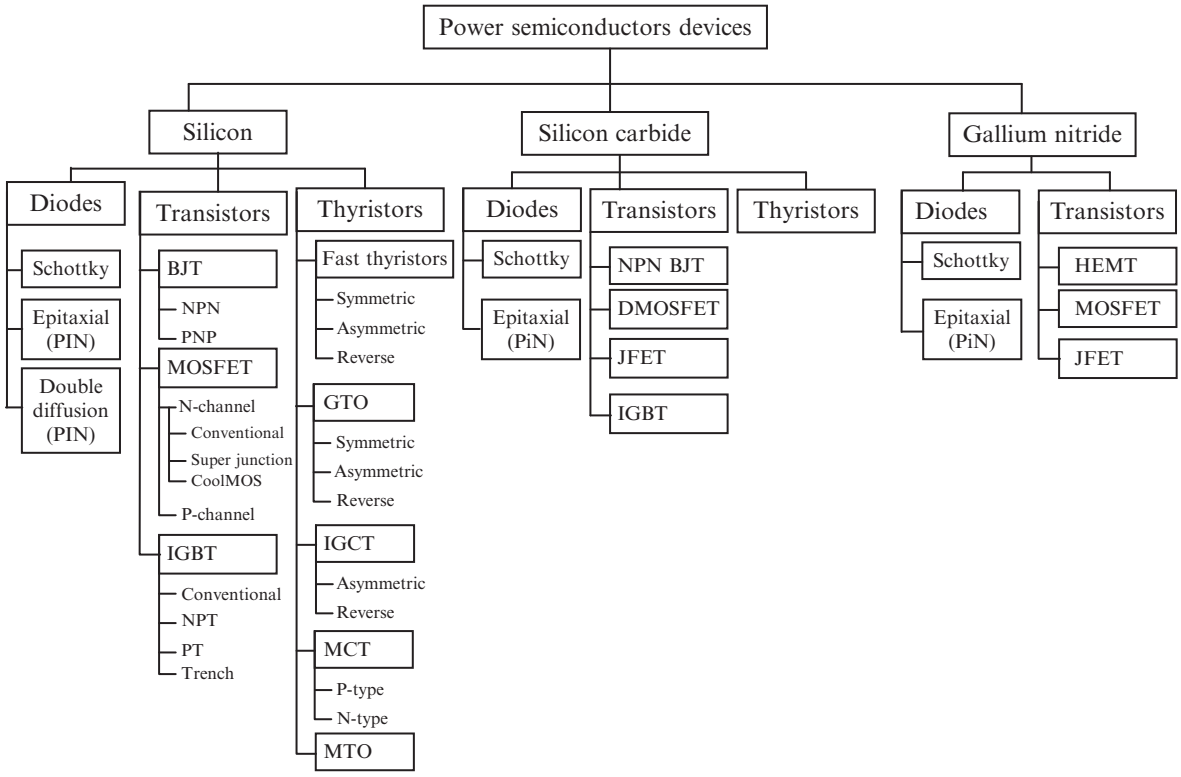

FIG. 5.1 Most important power semiconductor devices on the market along with silicon carbide and gallium nitride power devices that have been developed and studied in recent years.

thyristor technology. The IGBT is presently the dominate semiconductor device for most medium-power applications.

Fig. 5.1 summarizes the most important power silicon (Si) semiconductor devices on the market along with silicon carbide (SiC) and gallium nitride (GaN) power devices that are on the market and others that have been developed and studied in recent years in various semiconductor laboratories. Due to many decades of development, fabrication, and optimization of a large variety of Si devices and a large material abundance, high manufacturing capability, and extremely low cost, Si is still the most used element for production of power semiconductor devices.

Based on their structure, power devices can be classified as diodes, transistors, and thyristors. Si Schottky diodes are typically used for high switching frequencies at low breakdown voltage (BV), $BV \leq 100$ V; the fast switching epitaxial PiN diodes are used for $BV \leq 600 \div 1200$ V, and double-diffused PiN diodes are applied at higher voltages, $BV \geq 1000$ V.

Silicon BJTs have been completely replaced by MOSFETs and IGBTs. By introducing an extra P-doping region in the MOSFET drift region, a high breakdown voltage is achieved with much higher drift doping, which results in a drastic reduction (5–10 times) in specific ON-resistance for the same chip area in a voltage range of $BV = 600$–1000 V.

Large-area Si devices capable of handling thousands of amperes and kilovolts are now available on the market. Metal-oxide-semiconductor (MOS) gate devices, such as IGBTs, are designed using two different structures: punch-through (PT) and nonpunch-through (NPT). Both types of IGBTs can handle voltage up to 3.3 kV and current up to 1.2 kA [6]. IGBT modules for 6.5 kV and 0.6 kA are also available.

Silicon GTOs and thyristors are still widely used for very high-power applications. FMCC group is currently selling asymmetrical GTO thyristors for 4.5 kV and 26 kA [7]. The devices are optimized for low conduction losses, and the switching frequency is in the range of 200–500 Hz for most applications. All GTOs require snubbers for protection during turn-on and turn-off switching. Significant improvement to the GTO structure, including a gate driver, an integrated inverse diode, and better packaging, resulted in a new semiconductor device, the integrated gate-commutated thyristor (IGCT). The IGCTs have much faster turn-off times than GTOs. This allows them to operate at higher frequencies—up to several kilohertz—for very short periods of time. However, the typical IGCT operating frequency is up to 500 Hz due to high switching losses at higher frequencies. Asymmetrical IGCTs, optimized for snubberless turnoff, can operate at 6.5 kV and 4.2 kA. Metal-oxide-semiconductor-controlled thyristors (MCTs) and MOS turn-off thyristors (MTOs) have been proposed, but the market demand for these devices is very low at this time [8].

The need for high-voltage, high-power-density devices operating at high frequencies and junction temperatures higher than 150°C is growing, especially for advanced power electronics. Silicon-based devices are not able to meet these requirements without connecting, in series and in parallel, to a large number of devices using costly active or passive snubbers and expensive cooling systems [9]. For this reason, the limitations of Si material properties for power devices have been debated during the last decade; and wide bandgap semiconductors, such as those made of SiC and GaN, have attracted considerable attention.

Significant research into SiC and GaN as materials for semiconductor devices has been carried out during the last 20 years. Their wide bandgap energy enables the devices to operate at elevated temperatures (600°C) while retaining low leakage current. The higher breakdown strength for a given blocking voltage of SiC and GaN results in smaller drift layers or channel lengths as compared with Si devices. As a result, the storage of the minority carriers or the input and output capacitance and, therefore, the associated switching losses at a given switching frequency are reduced. This leads to an increase of the switching frequency to 0.5–1 MHz with acceptable switching losses, which significantly reduces the size and cost of the passive components in power electronic systems.

Regardless of the advantages that SiC and GaN materials possess, they have not been adopted for manufacturing of the entire family of high-power devices. Difficulty with crystal growth, the presence of crystal defects, such as micropipes and dislocations, and the absence of abundant wafer suppliers have all contributed to a lack of progress in the fabrication of SiC and GaN power devices by the commercial sector [10]. Several industrial research groups and university labs have been working on improving the material properties and development of SiC and GaN power devices. In September 2001, two companies advertised the commercial availability of SiC Schottky diodes: Infineon (from 600 V up to 6 A or from 300 V up to 10 A) and Microsemi (100-200-480 V, 1A) [11]. Five years later, in February 2006, the first commercially available GaN high-electron-mobility transistor (HEMT) products were launched by Eudyna Devices (now Sumitomo Electric Device Innovations USA, Inc.) [12]. Since then, new SiC and GaN devices and new companies have been introduced to the market. In the next sections, the physical properties of SiC and GaN materials are compared with Si material, and the new devices are discussed.

5.2 Silicon Carbide and Gallium Nitride Materials

This chapter includes details on the physical and electric characteristics of SiC and GaN materials and highlights on the advantageous properties of power semiconductor devices fabricated from them.

5.2.1 Silicon Carbide Polytypes

SiC is known as a classical polytypic substance existing in more than 250 polytypes; the common polytypes are 6H, 15R, 4H, and 3C [13]. The letters H, C, and R denote the overall lattice type as being hexagonal, cubic, or rhombohedral, respectively. All polytypes have a hexagonal frame with a carbon (C) atom positioned at the center of the mass of the tetragonal structure outlined by the four neighboring Si atoms, and the distance between a C atom to each of the Si atoms is the same [14].

Polytypes are formed by stacking SiC molecules on top of each other in a certain order. The stacking order between succeeding double layers of C and Si atoms determines the difference between polytypes. During substrate manufacturing for semiconductor devices, it is important that the entire wafer is a single polytype. Growth conditions during substrate production should be stable because any instability in the growing process leads to spontaneous switching from one polytype to another. This will alter the electric properties of the material and act as a nucleation site for defects such as micropipes [15].

Currently, two SiC polytypes are accepted in SiC device research: 6H-SiC and 4H-SiC. Before the introduction of 4H-SiC wafers in 1994, 6H-SiC was the dominant polytype. Since then, both polytypes have been used in research; but recently, 4H-SiC has become the more dominant polytype. This is because the charge-carrier mobilities in 4H-SiC are identical along the two planes of the semiconductor, whereas the 6H-SiC polytype exhibits anisotropy, which means that the mobilities of the material in the two planes are not the same.

5.2.2 Gallium Nitride Crystal Structures

Gallium nitride is found in three crystal structures: wurtzite, zinc blende, and rock salt. At ambient conditions, GaN crystalizes in a wurtzite-type structure [16], while the zinc-blende and rock-salt cubic GaN structures are metastable structures [17] at normal conditions. The zinc-blende GaN structure is formed during a film preparation process [18], while the rock-salt cubic GaN structure is formed under ultrahigh pressure of at least 37 GPa, and when the pressure is completely released, the rock-salt structure transfers back to the wurtzite structure [19]. The zinc-blende GaN structure is not an equilibrium phase, and the growth of it would cost extra energy [20]. The wurtzite crystal structure of GaN material exhibits a variety of material properties, such as spontaneous polarization and piezoelectric polarization effects, which are very important in the design of GaN heterostructure devices [21]. Also, the GaN wurtzite crystal structure has a wider bandgap than the zinc-blende structure [22], which is also an advantage for using the wurtzite structure in the fabrication of power devices.

5.2.2.1 Silicon Carbide and Gallium Nitride Physical and Electrical Properties

Silicon carbide and GaN materials display a wide range of properties, such as high breakdown electric field strength, high

TABLE 5.1 Physical properties for various semiconductors

saturated drift velocity, and high thermal stability, which make it attractive for use as a material for semiconductor devices. Table 5.1 summarizes some of these properties for the most popular wide bandgap semiconductors and Si. Some of the properties that benefit power semiconductor devices are strongly dependent on the bandgap. These properties are critical electric field, intrinsic carrier concentration, and to a lesser extent mobility and conductivity.

Silicon carbide is from the IV–IV group semiconductor family and has an indirect bandgap. Every SiC polytype has a different bandgap. Gallium nitride is from the III–V semiconductor family and has a direct bandgap. The bandgaps of 4H-SiC and GaN wurtzite-type structures at room temperature are 3.23 and 3.39 eV [25], which are more than three times higher than the bandgap of Si.

5.2.2.2 Critical Electric Field

The specific ON-state resistance, R_{SP-ON}, is an important device parameter for determining the device conduction losses. It is based on the critical electric field of the material, ε_c. Knowing the energy bandgap of the material, the critical electric field can be calculated. An expression for the critical electric field as a function of the bandgap energy for the indirect bandgap materials, such as SiC, is [30]

$$\varepsilon_c = 2.38 \times 10^5 E_G^2 \tag{5.1}$$

and an expression for the critical electric field for the direct bandgap materials, such as GaN, is [30]

$$\varepsilon_c = 1.73 \times 10^5 E_G^{2.5} \tag{5.2}$$

There is no dependence on the background doping included in these expressions because the voltage blocking capability, during the OFF-state of power electronic devices, depends on the property of the lightly doped drift region [30]. For Si, an expression for a relationship between the critical electric field, ε_c, and the bandgap, E_G, [31] is

$$\varepsilon_c = 1.02 \times 10^7 \sqrt{\frac{q}{\varepsilon_0 \varepsilon_r}} N_{N^-}^{1/8} E_G^{3/4} \tag{5.3}$$

where N_N^- is the doping concentration in the lightly doped drift region, N^- region; q is the unity electric charge ($\cong 1.6 \times 10^{-19}$), $\varepsilon_0 = 8.85 \times 10^{-14}$ F/cm; and ε_r is the Si dielectric constant. Assuming that the doping concentration in the lightly doped drift region, N^- region, is approximately 5×10^{13} cm^{-3}, the electric field can be represented by the formula:

$$\varepsilon_c = 2.5 \times 10^5 E_G^{3/4} \tag{5.4}$$

The critical electric fields of SiC and GaN materials are high as compared with Si because they have wider bandgaps. A wider bandgap of SiC or GaN material indicates that the energy required to break a bond is significantly higher than the energy required for the Si material. This allows a larger electric field to be applied before the avalanche of a multitude of ionized carriers occurs in the semiconductor. A more than 10 times higher critical electric field for SiC and GaN materials compared with Si allows power devices to be designed with thinner, more highly doped drift regions to achieve similar blocking voltages.

The specific ON-resistance can be related to the breakdown voltage, BV; electron mobility, μ_n; relative permittivity, ε_r; and bandgap energy, E_G.

For Si, the specific ON-resistance can be calculated by the following equation [32]:

$$R_{SP-ON} = \frac{1.716 \times 10^{-6} \varepsilon_r BV^{2.5} E_G^{-3}}{\mu_n} \tag{5.5}$$

For SiC, the specific ON-resistance is [33]

$$R_{SP-ON} = \frac{3.351 \times 10^{-3} BV^2 E_G^{-6}}{\varepsilon_r \mu_n} \tag{5.6}$$

For GaN, the specific ON-resistance is [33]

$$R_{SP-ON} = \frac{8.725 \times 10^{-3} BV^2 E_G^{-7.5}}{\varepsilon_r \mu_n} \tag{5.7}$$

Fig. 5.2 presents a theoretical, specific ON-state resistance of blocking regions designed for certain breakdown voltages in Si, 4H-SiC, and GaN under optimum punch-through conditions using Eqs. (5.5)–(5.7).

From Fig. 5.2 and Eqs. (5.5)–(5.7), it can be deduced that, for the same blocking voltage, SiC and GaN devices offer specific ON-resistance that is more than 350 times lower than their Si counterparts. The doping concentration also affects the

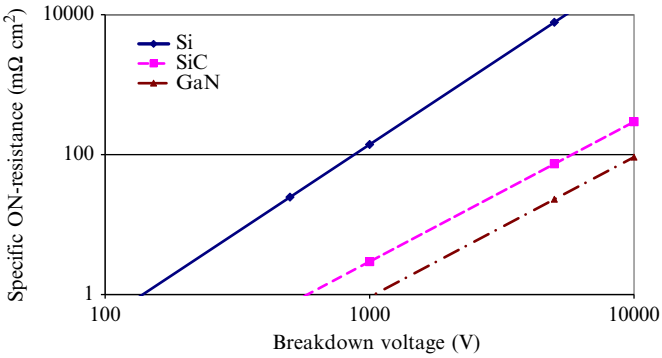

FIG. 5.2 Specific ON-state resistance of the blocking regions in function of the breakdown voltages for Si, 4H-SiC, and GaN.

blocking voltage. For the same blocking voltage, the background doping in a SiC and a GaN device can be 10–100 times higher than that of a Si device. An increase in doping concentration will also lead to a decrease in specific ON-resistance. This is one of the most important advantages of high-voltage SiC and GaN devices because for the same blocking voltage, the ON-resistance is much lower. The fact that the devices can be made thinner and more highly doped means that SiC and GaN devices have the capability of operating at a higher frequency. Thinner devices are faster because the carriers do not have to travel as far through the device and have less volume of stored charge (bipolar devices).

5.2.2.3 Intrinsic Carrier Concentration

The intrinsic carrier concentration of a semiconductor completely free of impurities and defects is the number of excited electrons from the valence band occupying energy-momentum states in the conduction band (and also the number of excited holes in the valence band) per unit volume. It is given by the equation:

$$n_i = (N_C N_V)^{\frac{1}{2}} e^{-\frac{E_G}{2kT}} \tag{5.8}$$

where N_C and N_V are the effective density of states in the conduction and in the valence band, respectively; E_G is the energy bandgap; k is Boltzmann's constant (1.381×10^{-23} J K^{-1}); and T is the absolute temperature in Kelvin, and it is assumed that $kT \leq E_G/5$.

Due to the wide bandgaps of SiC and GaN materials, their room-temperature intrinsic carrier concentrations are very small, $\sim 8.2 \times 10^{-9}$ cm^{-3} for SiC and 1.6×10^{-10} for GaN, while the intrinsic carrier concentration of Si is 1.45×10^{10} cm^{-3}. Wide bandgap semiconductors have the advantage of operating at high temperature and radiation fluxes because degradation effects due to thermally generated carriers are small. As the temperature increases, the electron's thermal energy in the valence band increases leading to a condition where any effects due to impurity doping are negated. This condition at elevated temperatures effectively causes the semiconductor to act as if it were intrinsic (no impurity doping). The temperature at which this condition occurs for Si is about 150°C, while SiC has a wide bandgap, and the valence electrons require more thermal energy to move from valence to conducting band. This intrinsic temperature for SiC is ~900°C.

Radiation energy/particle flux can also excite an electron and make it move to the conducting band. Similar to temperature, a wide bandgap material will require more radiation energy to free an electron from the conducting band.

As a result of a wide bandgap, devices built with SiC and GaN can endure more heat and radiation without losing their designed electric properties. Devices using the wide bandgap materials can theoretically operate in extreme conditions where Si-based devices cannot.

5.2.2.4 Saturated Drift Velocity

The saturated drift velocity is also one of the most important device-related characteristics of a semiconductor because it determines the frequency limits of power devices and, consequently, the range of their most efficient use. The high-frequency capability of a semiconductor material is directly proportional to the material drift velocity. The drift velocity of 4H-SiC (2×10^7 cm s^{-1}) and a GaN wurtzite crystal structure (2.2×10^7 cm s^{-1}) is approximately twice as large as the drift velocity of Si (10^7 cm s^{-1}); hence, it is expected that 4H-SiC- and GaN-based power devices could be switched at significantly higher frequencies as compared with their Si counterparts. In addition, a higher drift velocity allows charge in the depletion region to be removed faster; therefore, the switching losses are smaller since the reverse recovery current is smaller, and the reverse recovery time is shorter.

5.2.2.5 Thermal Stability

As was mentioned previously, one of the advantages of 4H-SiC- and GaN-based semiconductor devices is that they can operate at high temperatures due to the wide bandgap. Besides this, 4H-SiC has another thermal advantage—significantly high thermal conductivity, $\lambda_{SiC} = 4.9$ W cm^{-1} K^{-1}, compared with the conductivity of Si, $\lambda_{Si} = 1.5$ W cm^{-1} K^{-1}. This means that SiC-based devices can operate at higher power densities. The thermal conductivity of GaN, $\lambda_{GaN} = 1.3$ W cm^{-1} K^{-1}, is approximately equal to the thermal conductivity of Si. For low-power-density applications, the losses are not much larger, and the device temperature does not exceed the maximum operating junction temperature. Therefore, GaN devices can be built on Si substrates. Silicon is an important material in these applications because there are high quantities of inexpensive Si substrates available compared, for example, with SiC substrates. Thus, the use of Si as a substrate material is desirable, primarily for cost reasons. However, using Si substrates for GaN devices also introduces a number of critical issues due to the lattice mismatch and the difference in the thermal expansion coefficients, which affect the quality and device reliability [34]. For high-power-density applications, the GaN devices should be grown on a SiC substrate.

The junction-to-case thermal resistance $\left(R_{th-jc}\right)$ of a device is calculated by the following equation:

$$R_{th-jc} = \frac{d}{\lambda A} \tag{5.9}$$

where d is the length (cm), in the direction of the heat flow, and A is the cross-sectional area (cm^2) perpendicular to the direction of heat flow. Since the 4H-SiC thermal conductivity is three times higher as compared with Si, the junction-to-case thermal resistances of 4H-SiC devices are three times lower than their Si counterparts. Lower R_{th-jc} indicates that the heat generated in a 4H-SiC substrate during the operation could more easily flow (diffuse) to the case, to the heat sink, and then to the environment. Therefore, the advantage of 4H-SiC devices or GaN devices on SiC substrate is faster heat dissipation, reducing the requirement for a heavy heat sink and complex thermal packaging. There is also a real benefit in terms of long-term reliability due to potentially lower thermal stresses.

5.2.2.6 Coefficient of Thermal Expansion

All materials change their size when subjected to a temperature change as long as the pressure is held constant. The coefficient of thermal expansion (CTE) describes a change in the size of an object with a change in the temperature. It is the fractional change in the volume of the object per degree change in temperature at a constant pressure. During the design of high-power semiconductor devices, it is necessary for the semiconductor CTE to closely match the package substrate CTE to minimize shear stresses at material interfaces.

The CTE of 4H-SiC is 5.2 ppm K^{-1}, and the CTE of GaN is from 3.2 to 5.6 ppm K^{-1} [25]. The two coefficients are significantly larger than the CTE of Si (2.6 ppm K^{-1}). The CTE of most package materials is higher than 4.5 ppm K^{-1}. The best matches of the package materials and 4H-SiC and GaN are AlN substrate (4.5 ppm K^{-1}), beryllia (BeO) substrate (6.1 ppm K^{-1}), and alumina (Al_2O_3) substrate (6.5 ppm K^{-1}).

5.2.2.7 Figure of Merit

To compare the performance of power semiconductor technologies and devices, two groups of figures of merit (FOMs) are used. The first group includes FOMs that are functions of the intrinsic material parameters, and they are used to compare technologies or materials. A larger FOM number, for the first group, represents better performance. The second group includes FOMs that are functions of the device parameters. They are used to compare device performance in a power system. A smaller FOM number, for the second group, means better device performance.

FOM for materials and technology

The Baliga high-frequency figure of merit (BHFFOM) is derived to compare the performance of power semiconductor devices operating at high frequencies. Baliga relates the power losses of the devices to the intrinsic material parameters and shows that the switching loss of a power semiconductor device depends on the electron mobility, μ_n, and the critical electric field, ε_C. The BHFFOM is given by the following equation [35]:

$$\text{BHFFOM} = \mu_n \varepsilon_c^2 \sqrt{\frac{V_G}{4BV^3}} \tag{5.10}$$

where V_G is gate drive voltage. For high-frequency operation, the power losses can be reduced by using semiconductors with a larger mobility and critical electric field for breakdown [35]. The FOMs for 4H-SiC and a GaN wurtzite crystal structure normalized to Si are given in Table 5.2. For calculation of BHFFOMs, it is assumed that the gate drive voltage, V_G, and the breakdown voltage, BV, are the same for Si, 4H-SiC, and GaN devices. The results show an 81.6 times bigger BHFFOM for 4H-SiC compared with Si and a 197.1 bigger BHFFOM for GaN compared with Si. Therefore, significant performance improvement for high-frequency operation can be achieved by replacing Si with SiC and GaN.

Johnson's figure of merit (JFOM) shows that the performance limits and power-frequency limits of a power device are set by the intrinsic material parameters, such as the critical electric field, ε_c, and its electron saturation velocity [36]:

$$\text{JFOM} = \frac{\varepsilon_C^2 v_{sat}^2}{4\pi^2} \tag{5.11}$$

For high-power and high-frequency operation, the devices should be based on semiconductor materials with both large breakdown voltage and high electron velocity. Therefore, wide bandgap materials, like GaN and SiC, are having higher critical electric fields and electron saturation velocities and, therefore, higher JFOM. Table 5.2 provides calculated JFOM results for 4H-SiC and GaN wurtzite crystal structure normalized to Si, which confirms that 4H-SiC and GaN have 488 and 1284 times higher JFOM, respectively, compared with Si.

In Ref. [37], JFOM is also presented as a function of the cut-off frequency, f_T, which is related to the effective saturation velocity and the breakdown voltage, BV, that can be related to the critical electric field.

$$\text{JFOM} = \frac{2}{\alpha} f_T BV \tag{5.12}$$

TABLE 5.2 Figures of merit for 4H-SiC and a GaN wurtzite crystal structure normalized to Si

FOM	Si	4H-SiC	GaN
BHFFOM	1	81.6	197
JFOM	1	488	1284
BFOM	1	6.15	8.97

The FOMs discussed above are connected to the switching losses of power devices. Power losses of semiconductor devices also include static or ON-state losses, which depend on the specific ON-resistance of the devices. Baliga related the specific ON-resistance to the breakdown voltage, BV; electron mobility, μ_n; relative permittivity ε_r; and critical electric field, ε_c, by the following equation [38]:

$$R_{SP-ON} = \frac{4BV^2}{\varepsilon_r \mu_n \varepsilon_c} \tag{5.13}$$

The denominator of Eq. (5.13) is known as the Baliga figure of merit (BFOM) for resistivity or ON-losses:

$$\text{BFOM} = \varepsilon_r \mu_n \varepsilon_c \tag{5.14}$$

Table 5.2 also gives the calculated results for the BFOM for 4H-SiC and a GaN wurtzite crystal structure normalized to Si. The results confirm that 4H-SiC and GaN have better FOM indexes, that is, 6.15 and 8.97 times higher, respectively, compared with Si.

The ability of GaN to form heterojunctions makes it superior compared with SiC for transistors, although the two materials have similar breakdown fields and saturation electron velocities. GaN can be used to fabricate HEMTs, whereas SiC is currently only used to fabricate metal-semiconductor field-effect transistors (MESFETs) and power MOSFETs. Significantly high mobility (2500 $\text{cm}^2\,\text{Vs}^{-1}$ [39]) in the two-dimensional electron gas (2DEG) and high carrier concentration for HEMTs leads to low channel resistance, which is especially important for high-frequency operation in power switching applications .

FOM for devices

Designers of power electronic systems are using FOMs that are related to the device's parameters. The lower the index value of these FOMs, the better the device performance. Two devices with the same value perform the same in a given application.

The switching losses figure of merit (SLFOM) is used to evaluate the switching performance of field-effect transistors (FETs). SLFOM is a product of the specific ON-resistance of a device, R_{SP-ON}, and its gate to drain charge, Q_{GD}, [40]:

$$\text{SLFOM} = R_{SP-ON} Q_{GD} \tag{5.15}$$

The gate-to-drain charge, Q_{GD}, of an FET is a main parameter of the turn-on loss of a FET. Some companies, for example, provide the gate-to-drain charge, Q_{GD}, and gate-to-source charge, Q_{GS} [41]. In this case, a more accurate value of SLFOM can be obtained [42]:

$$\text{SLFOM} = R_{SP-ON} Q_{SW} \tag{5.16}$$

where Q_{SW} is known as the switching charge, and it is equal to the sum of Q_{GD} and Q_{GS}. The charge Q_{GS} is the portion of the gate-to-source charge from the device threshold voltage to the gate plateau voltage, which controls the current rise and fall of the device. Since SiC and GaN have a bigger bandgap than Si, their channel width is smaller, and, therefore, their gate-to-drain and gate-to-source capacitance are smaller. Consequently, their gate-to-drain charge and gate-to-source, Q_{GD} and Q_{GS}, are smaller. Also, as mentioned above, R_{SP-ON} of SiC and GaN devices is smaller than R_{SP-ON} of Si devices. Therefore, the SLFOMs of SiC and GaN devices are smaller than the SLFOM of a Si device.

The conduction loss figure of merit (CLFOM) is used to evaluate a FETs' performance. CLFOM is a product of ON-state resistance, R_{SP-ON}, and total gate charge, Q_G [43]:

$$\text{CLFOM} = R_{SP-ON} Q_G \tag{5.17}$$

For a given MOSFET technology, both parameters, R_{SP-ON} and Q_G, are opposite of each other. A device with a lower ON-state resistance has a higher gate charge and vice versa [44]. The ON-state resistance, total gate charge, and switching charge are not constants. The ON-state resistance and total gate charge values depend on the gate-source voltage, V_{GS}, and are also influenced by the junction temperature, T_J. Furthermore, the ON-state resistance of a MOSFET depends on the drain current, I_D, while the total gate charge depends on the drain-source voltage, V_{DS}. The switching charge, Q_{SW}, also depends on the drain-source voltage, V_{DS}.

A proper comparison of devices using SLFOM and CLFOMs is possible when it is made under the same conditions [44]. The more proper CLFOM is given in [43] and [44]:

$$\begin{aligned}\text{SLFOM}(V_{GS}, T_J, I_D, V_{DS}) = {} & R_{SP-ON}(V_{GS}, T_J, I_D) \\ & \times Q_{SW}(V_{GS}, T_J, V_{DS})\end{aligned} \tag{5.18}$$

$$\begin{aligned}\text{CLFOM}(V_{GS}, T_J, I_D, V_{DS}) = {} & R_{SP-ON}(V_{GS}, T_J, I_D) \\ & \times Q_G(V_{GS}, T_J, V_{DS})\end{aligned} \tag{5.19}$$

The SLFOM and CLFOM for Si, SiC, and GaN devices on the market are given in Table 5.3. Although a fair comparison between the devices cannot be done because for the same blocking voltage, they are designed for different drain currents; the SiC and GaN devices have better FOMs than the Si device. A device with a higher drain current will have a bigger area and, therefore, a higher gate-to-source and gate-to-drain capacitance and a high switching charge. It will also have smaller ON-resistance. For breaking voltage equal to 650 V, the smallest figure of merit has the GaN Systems GaN device. The two Cree devices, C3M0065090J and CPM2-1700-0045B, are designed for 900 and 1700 V, correspondingly, but the 900 V device has higher ON-resistance, 65 Ω, compared with the 1700 V device with an ON-resistance of 45 Ω. The low ON-resistance of the 1700 V device can be due to the higher design's drain current than the 900 V device. Also, the 1700 V device is more mature. The maturation of the SiC and GaN technology will result in new devices with smaller FOMs, which will be more attractive for power electronic applications.

TABLE 5.3 Parameters and FOMs for Si, SiC, and GaN devices

Material	Part number	Company (reference)	VB (V)	I_D (A)	R_{SP_ON} (mΩ)	Q_{SW} (nC)	Q_G (nC)	SLFOM	CLFOM

5.3 SiC Power Devices

5.3.1 Introduction

Due to the significant improvements in SiC material growth technology, SiC-based power devices are available for high-power, high-temperature, and high-frequency applications. Three types of SiC power devices, diodes, transistors, and thyristors, have been designed, modeled, and characterized during the last two decades. Some of them are on the market, and others are in a development stage. Designers are trying to improve the performance of these devices and optimize their FOM parameters to obtain the best ratio between conduction and switching losses, resulting in higher system efficiency [51]. The physics and important parameters of SiC power devices are discussed in this chapter.

5.3.2 SiC Power Diodes

The power diodes are the key components used in power electronic applications. A power diode is often used as a parallel diode to the switch body diode for decreasing the switching losses. Basically, SiC power diodes can be classified into three types: (1) SiC Schottky diode; (2) SiC PiN diode; and (3) SiC merged PN-Schottky diode (MPS), also called a junction barrier Schottky (JBS) diode.

5.3.2.1 SiC Schottky Diode

The SiC Schottky diode was the first SiC device on the market by Infineon Technologies (from 600 V up to 6 A or from 300 V up to 10 A) and Microsemi (100-200-480 V, 1 A) [11]. Now, 15 years later, from 1700 V up to 50 A with zero reverse recovery, zero forward recovery, high-frequency operation, temperature-independent switching behavior, extremely fast switching, and positive temperature coefficient on the forward voltage, V_F, diodes are available [52]. The commercially available Si Schottky diodes are usually rated at maximum breakdown voltages of <100 V [53]. Beyond this limit, Si Schottky diodes cannot compete with Si PiN diodes due to the unacceptably large ON-state resistance of Schottky diodes and the voltage blocking limit due to barrier lowering.

An advantage of high-power SiC Schottky diodes is that they have zero reverse recovery charge since they are majority carrier devices. The reverse recovery current peak is very small compared with a fast Si PiN diode leading to significantly lower turn-OFF losses. The reverse recovery current is due to the displacement current from the junction capacitance. Since the dynamic characteristic of a Schottky diode is capacitive in nature, the reverse recovery characteristic of a SiC Schottky diode is independent from forward current, di/dt, and device junction temperature [54].

A power SiC Schottky diode is formed by the junction of a semiconductor (SiC) with a metal (titanium (Ti), nickel (Ni), gold (Au), or platinum (Pt)) that forms a Schottky barrier. The semiconductor is grown on a substrate that forms an ohmic contact with another metal, as shown in Fig. 5.3.

A Schottky diode is a unipolar device, which means that the current conduction is governed only by majority carriers (electrons). Similar to a Si Schottky diode, the forward voltage of SiC, V_F, is one of the important parameters when selecting a Schottky diode. It is a function of temperature, Schottky barrier height, and drift region resistance. A dependence of the voltage drop and the current density, J_F, is given by the following equation:

$$V_F = \frac{nkT}{q} \ln\left(\frac{J_F}{A^* T^2}\right) + \phi_B/q + R_{SP_ON} J_F \tag{5.20}$$

where n is the ideality factor. For an ideal device, n is equal to one, while for a real device, n is larger than 1 and can be assumed to be between 1 and 1.3. Boltzmann's constant is k, q is the electron charge, T is the absolute temperature, and A^* is Richardson's constant with theoretical values of 146 A cm^{-2}K^{-2} for 4H-SiC [55] and 110 A cm^{-2}K^{-2} for Si. For the same current density and at room temperature (300 K), the voltage of the first member of the right side of Eq. (5.20) for SiC will be 7 mV smaller.

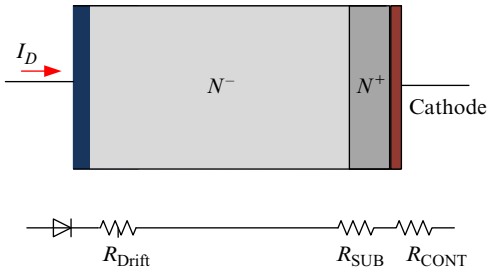

FIG. 5.3 Schottky diode structure and simple model.

The potential barrier at the metal-semiconductor interface, ϕ_B, given in Eq. (5.20), is known as the Schottky barrier height. It can be calculated by the equation:

$$\phi_B = \phi_m - \chi \tag{5.21}$$

where ϕ_m is the work function of the metal and χ is the material's electron affinity. The measured and calculated barrier heights for selected metal/4H-SiC junctions are listed in Table 5.4 [56,57]. Titanium/silicon carbide has the smallest barrier height. The measured barrier heights depend on the surface polarity of SiC (Si- and C-face) and often differ from the calculated values.

The Schottky barrier heights for selected metal/Si junction [58] are provided in Table 5.5. The maximum barrier heights of a Si device are significantly small compared with the minimum barrier heights of a SiC device. The difference between the barrier height of Ti/SiC and Ti/Si is larger than 0.56 V. Due to the high barrier height of a SiC device, the contribution of the barrier height to the forward voltage drop is higher, though the contribution from the specific on-resistance is lower. However, barrier height lowering will occur at high applied electric fields and result in a device design change for SiC diodes, just as in Si diodes, to PiN structures.

In Eq. (5.20), R_{SP_ON} is the total specific resistance. It is a sum of the ohmic contact resistance, R_{CONT}; the substrate resistance, R_{SUB}; and the drift region resistance, R_{Drift} [59]:

$$R_{SP_ON} = R_{CONT} + R_{SUB} + R_{Drift} \tag{5.22}$$

For silicon carbide devices, the substrate has higher resistance, and R_{SUB} must be included in the analysis. The new SiC devices are fabricated with a thin substrate for a lower forward voltage and improved thermal performance [54]; therefore, the resistance will be smaller. The ohmic contact resistance, R_{CONT}, is the resistance between the contact of the drift region and the cathode. It may also make a substantial contribution to the ON-state voltage drop. The drift region resistance, R_{Drift}, can be determined by the drift layer thickness and doping concentration, W_D and N_D, and the electron mobility, μ_n, according to the following equation:

$$R_{Drift} = \frac{W_D}{q\mu_n N_D} \tag{5.23}$$

The drift region resistance, R_{Drift}, can also be given as an expression in terms of the designed blocking voltage, V_B, and critical electric field, E_C:

$$R_{Drift} = \frac{4V_B^2}{2qE_C^3} \tag{5.24}$$

The drift region resistance increases quadratically with blocking voltage; therefore, the ON-state losses will increase significantly with an increase of the blocking voltage. Since conductivity modulation effects are not inherent to Schottky diodes, the drift region resistance will be significantly high for high-voltage diodes. In [60], a 3 kV 4H-SiC Schottky diode with a diameter of 1 mm and ON-resistance of 34 mΩ cm^{-2} (1.08 Ω) is reported, which is significantly high. For high blocking voltage, a PiN diode is preferred.

Another important parameter of a Schottky diode is the reverse leakage current. If the reverse leakage current is high when the reverse voltage is high, the power dissipated by it leads to an increase in the diode temperature. Since the reverse leakage current is sensitive to the junction temperature, increasing the limits of the power dissipation initiates a positive feedback for the temperature leading to permanent damage of the device [61]. Therefore, optimizing the diode parameters to obtain low leakage current is an important concern for a device designer.

Two mechanisms significantly contribute to the reverse leakage current operating at a high reverse voltage: the thermionic emission over the potential barrier and quantum mechanical tunneling of the carriers through a potential barrier. When reverse voltage, V_R, is applied, the leakage current due to the thermionic effect is

$$I_L = AA^*T^2 e^{-\frac{q\phi_B}{kT}}\left(e^{-\frac{qV_R}{kT}} - 1\right) \tag{5.25}$$

where A is the Schottky diode cross-sectional area and other parameters are as previously described. Increasing the reverse voltage higher than $3kT/q$ for moderately doped semiconductors decreases the Schottky barrier and causes the reverse leakage current to increase. Therefore, for a reverse voltage higher than $3kT/q$, the leakage current equation should include the barrier lowering $\Delta\phi_B$:

$$I_L = AA^*T^2 e^{-\frac{q\phi_B}{kT}} e^{-\frac{q\Delta\phi_B}{kT}}\left(e^{-\frac{qV_R}{kT}} - 1\right) \tag{5.26}$$

The barrier lowering depends on the maximum electric field, E_M, at the metal-semiconductor interface and the semiconductor relative permittivity [61]:

TABLE 5.4 Measured and calculated values of barrier heights for selected metal/4H-SiC junctions

Metals		Ti	Ni	Au
Measured	ϕ_B/q (Si-face), V	1.12	1.69	1.81
	ϕ_B/q (C-face), V	1.25	1.87	2.07
Calculated	ϕ_B/q, V	1.06	1.63	1.69

TABLE 5.5 Schottky barrier heights for selected metal/Si junctions

Metal	Mg	Ti	Cr	W	Mo	Pd	Au	Pt
ϕ_B/q, V	0.4	0.5	0.61	0.67	0.68	0.77	0.88	0.9

$$\Delta\phi_B = \sqrt{\frac{qE_M}{4\pi\varepsilon_r}} \tag{5.27}$$

For a one-dimensional Schottky junction, the maximum electric field, E_M, is related to the applied reverse bias voltage, V_R, by the following equation:

$$E_M = \sqrt{\frac{2qN_D}{\varepsilon_r}(V_R - V_{bi})} \tag{5.28}$$

Since the barrier lowering increases as the reverse bias voltage increases, the leakage current also increases. The second mechanism that contributes to the increase of the leaking current is the tunneling current. Since SiC has a wide bandgap and, therefore, a high critical electric field, the SiC Schottky diodes are designed to stand significantly higher electric fields on the metal-semiconductor interface compared with Si diodes. The SiC Schottky diodes can experience very high electric fields, higher than 2 MV cm^{-1}, which will contribute to a significant increase of the leakage current. A more rapid increase in leakage current observed in SiC Schottky diodes can be expressed with the thermionic emission model [59]:

$$I_L = A^*T^2 e^{-\frac{q\phi_B}{kT}} e^{-\frac{q\Delta\phi_B}{kT}} e^{C_T E_M^2}\left(e^{-\frac{qV_R}{kT}} - 1\right) \tag{5.29}$$

where C_T is a tunneling coefficient. Since the forward voltage drop of a SiC Schottky diode and the leakage current increase as the design breakdown voltage increases, PiN and merged PN-Schottky diodes should be used for applications using higher-voltage SiC.

5.3.2.2 SiC PiN Diode

The advantage of a SiC PiN diode is low specific resistance R_{SP_ON}, during high current conduction, due to high-level injection of minority carriers in the lightly doped drift region resulting in conductivity modulation. However, conductivity modulation causes significant reverse recovery current during switching, which is undesirable because it causes additional turn-ON loss in the active switch. At voltage ratings from 10 to 20 kV, 4H-SiC PiN diodes offer the best trade-off between ON-state voltage drop, switching losses, and high-temperature performance as compared with Si PiN and SiC Schottky/JBS diodes [62].

Different research groups have worked on designing, fabricating, and characterizing SiC PiN diodes, but the maturity of PiN diodes is not sufficient enough to be marketable. In 2001, a high-voltage PiN diode in SiC with a blocking voltage of over 19 kV was reported [63]. It has a forward voltage drop of 6.5 V at 100 A cm^{-2}. Also in 2002, the design, fabrication, and high-temperature characteristics of 4H-SiC PiN rectifiers with 5, 6, and 10 kV blocking voltage were reported [64]. For the 10 kV rectifier, a forward voltage drop of <4.8 V was observed at 100 A cm^{-2} in the entire 25–200°C temperature range. Also in [62], 12.9 kV SiC PiN diodes with ultralow ON-state voltage drop and differential ON-resistance of 3.75 V and 3.3 mΩ cm^{-2} at 100 A cm^{-2}, respectively, were reported. It has also been reported in the literature that Schottky and PiN SiC diodes have significantly less reverse current than the conventional fast or ultrafast Si diode [65].

SiC PiN diodes consist of a highly doped N-type substrate, a lightly doped N-type epitaxial layer, known as the drift region, and a highly doped P-type region for the anode, which is shown in Fig. 5.4. The most important parameter for a power SiC PiN diode is the voltage drop, V_{AK}, across it during the conduction state. It is composed of five components, including the voltages across the junctions, J_1 and J_2, the voltage across the two depletion regions, V_{d1} and V_{d2}, and the voltage across the drift region, V_{N^-}.

$$V_{AK} = V_{j1} + V_{j2} - V_{d1} - V_{d2} + V_{N^-} \tag{5.30}$$

Different models have been used to calculate the voltage drop across the diode and the current passing through it. A level-3 model for modeling a power diode using a Fourier-based solution for the ambipolar diffusion equation (ADE) of the lightly doped N^- drift region is given in [66]. In their model, the PiN diode is divided into three regions, and the basic equations governing the behavior of semiconductor devices are used to analyze the operation of the diode. The diode current, I_D, and the electron, hole, and displacement currents at junctions J_1 and J_2 (I_{n1}, I_{p1}, I_{disp1} and I_{n2}, I_{p2}, I_{disp2}) and their direction are shown in Fig. 5.4. The P^+ and N^+ emitters are assumed to be minority sinks.

Since the P^+ emitter region is highly doped, high-level injection exists during the ON-state, and therefore, there is a significant electron concentration adjacent to the P^+N^- junction. As a result of this high concentration, electrons flow into the P^+ emitter and recombine with the holes. The resulting electron current due to the emitter recombination is

$$I_{n1} = qAh_p p_{x1}^2 \tag{5.31}$$

where p_{x1} is the hole concentration at the junction, J_1. The recombination parameter, h_p, is calculated by the following equation:

$$h_P = \frac{1}{N_P}\sqrt{\frac{D_{n_P}}{\tau_{n_P}}} \tag{5.32}$$

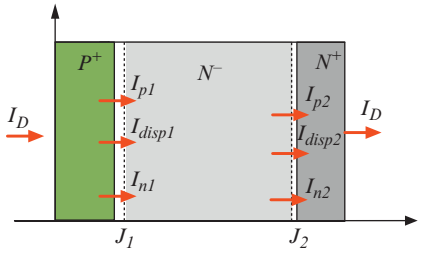

FIG. 5.4 Schematic structure of a $P^+N^-N^+$ power diode.

where N_P is the emitter doping concentration and D_{nP} and τ_{nP} are the electron diffusivities and lifetime. The current continuity at junction J_1 (Fig. 5.4) requires that

$$I_D = I_{n1} + I_{p1} + I_{dis1} \tag{5.33}$$

The junction voltage of junction J_1 is [32]

$$V_{j1} = V_T \ln\left(\frac{p_{x1} N_{N^-}}{n_i^2}\right) \tag{5.34}$$

where V_T is the thermal voltage (kT/q).

A high-power diode has a thick, lightly doped drift region for supporting high blocking voltage. A simple charge control modeling approach cannot be applied for the drift region, since the transient duration is comparable with or shorter than the transient time of the charge carriers. In this case, the charge dynamics in the drift region can be described by the continuity and the transport equations. To simplify the analysis, the charge profile in the thick, lightly doped drift region is assumed to be one-dimensional for more than 90% of its volume. Also, high-level injection in the drift region during most of the time of the transient and ON-state can be assumed. Under these assumptions and quasineutrality, the one-dimensional ADE describing the carrier dynamics in the majority of this region is given by the equation:

$$D_{N^-}\frac{\partial^2 p(x,t)}{\partial x^2} = \frac{p(x,t)}{\tau_{N^-}} + \frac{\partial p(x,t)}{\partial t} \tag{5.35}$$

where D_{N^-} is the ambipolar diffusion coefficient, τ_{N^-} is the high-level carrier lifetime within the drift region, and $p(x,t)$ is the excess carrier concentration. Different methods can be used to solve the ADE. In [66], Fourier analysis is used to solve the ADE. The basic idea of the Fourier-based solution is to separate excess carrier concentration $p(x,t)$into its space and time functions. According to Leturcq [67], the excess carrier concentration, $p(x,t)$, can be represented as a discrete cosine Fourier series:

$$p(x,t) = p_0(t) + \sum_{k=1}^{\infty} p_k(t)\cos\left[\frac{k\pi(x-x_1)}{x_2-x_1}\right] \tag{5.36}$$

where the Fourier series coefficients $p_k(t)$ are

$$\begin{aligned} p_0(t) &= \frac{1}{x_2-x_1}\int_{x_1}^{x_2} p(x,t)dx \\ p_k(t) &= \frac{2}{x_2-x_1}\int_{x_1}^{x_2} p(x,t)\cos\left(\frac{k\pi(x-x_1)}{x_2-x_1}\right)dx \end{aligned} \tag{5.37}$$

By substituting the carrier concentration in the Fourier series from Eq. (5.37) into the ADE, Eq. (5.35), the amplitude of the Fourier series $p_k(t)$ can be determined in a group of first-order differential equations. This requires employing the boundary conditions at the edges of the drift region. The required boundary conditions are the boundaries of the regions (x_1 and x_2), their differentials (dx_1/dt and dx_2/dt), and the carrier density gradients at x_1 and x_2 given by the equations:

$$\left.\frac{\partial p}{\partial x}\right|_{X_1} = \frac{1}{2qA}\left(\frac{I_n}{D_n} - \frac{I_p}{D_p}\right)\Bigg|_{X_1} \text{ and } \left.\frac{\partial p}{\partial x}\right|_{X_2} = \frac{1}{2Aq}\left(\frac{I_n}{D_n} - \frac{I_p}{D_p}\right)\Bigg|_{X_2} \tag{5.38}$$

where D_n and D_p are electron and hole diffusivities, I_n and I_p are electron and hole currents, and A is the active device area. The solution to the ADE is given by the following differential equations as each of them refers to a harmonic, p_k, of the carrier charge density, $p(x)$:

For $k > 0$

$$\begin{aligned} &D_{N^-}\left[\left.\frac{\partial p(x,t)}{\partial x}\right|_{x2}(-1)^k - \left.\frac{\partial p(x,t)}{\partial x}\right|_{x1}\right] \\ &= \frac{x_2-x_1}{2}\left(\frac{dp_k(t)}{dt} + \left[\frac{1}{\tau} + \frac{D_{N^-}k^2\pi^2}{(x_2-x_1)^2}\right]p_k(t)\right) \\ &+ \left(\sum_{\substack{n=1 \\ n\neq k}}^{\infty}\frac{n^2}{n^2-k^2}\left[\frac{dx_1}{dt} - (-1)^{n+k}\frac{dx_2}{dt}\right]p_n(t) + \frac{p_k(t)}{4}\left(\frac{dx_1}{dt} - \frac{dx_2}{dt}\right)\right) \end{aligned}$$

For $k = 0$,

$$\begin{aligned} D_{N^-}\left[\left.\frac{\partial p(x,t)}{\partial x}\right|_{x_2} - \left.\frac{\partial p(x,t)}{\partial x}\right|_{x_1}\right] &= (x_2-x_1)\left(\frac{dp_0(t)}{dt} + \frac{p_0(t)}{\tau}\right) \\ &+ \sum_{n=1}^{\infty}\left[\frac{dx_1}{dt} - (-1)^n\frac{dx_2}{dt}\right]p_n(t) \end{aligned} \tag{5.39}$$

At the boundary, x_1 and x_2, the carrier densities, p_{x1} and p_{x2}, are calculated using Eqs. (5.40), (5.41), respectively:

$$p_{x1} = \sum_{k=1}^{n}(-1)^k p_k \tag{5.40}$$

$$p_{x2} = \sum_{k=1}^{n} p_k \tag{5.41}$$

The current continuity equation at junction J_2 is

$$I_{n2} = I_D - I_{p2} - I_{disp2} \tag{5.42}$$

Assuming that

$$\frac{1}{D_n} + \frac{1}{D_p} = \frac{D_n + D_p}{D_n D_p} = \frac{2}{D_{N^-}} \text{ and } D\left(\frac{1}{D_n} - \frac{1}{D_p}\right) = \frac{D_n - D_p}{D_n + D_p} = D_{diff} \tag{5.43}$$

and using the current continuity equations at junctions J_1, Eq. (5.33), and J_2, Eq. (5.42), the left side of Eq. (5.39), for even and odd numbers of k, can be calculated by the following equations:

$$I_{even} = D\left(\left.\frac{\partial p}{\partial x}\right|_{x_2} - \left.\frac{\partial p}{\partial x}\right|_{x_1}\right) = \frac{1}{2qA}\begin{vmatrix} I_D \\ I_{p2} \\ I_{n1} \\ I_{disp1} \\ I_{disp2} \end{vmatrix}\begin{vmatrix} 2 & -2 & -2 & -\frac{D}{D_p} & -\frac{D}{D_n} \end{vmatrix}$$

$$I_{odd} = D\left(\left.\frac{\partial p}{\partial x}\right|_{x_2} - \left.\frac{\partial p}{\partial x}\right|_{x_1}\right) = \frac{1}{2qA}\begin{vmatrix} I_D \\ I_{p2} \\ I_{n1} \\ I_{disp1} \\ I_{disp2} \end{vmatrix}\begin{vmatrix} -2D_{diff} & 2 & 2 & -\frac{D}{D_p} & \frac{D}{D_n} \end{vmatrix} \tag{5.44}$$

The depletion layer voltages, V_{d1} and V_{d2}, across the P^+N^- and N^- N depletion layers are derived using a feedback from the boundary carrier densities, p_{x1} and p_{x2}:

$$V_{d1} = \begin{cases} 0 & \text{if } p_{x1} > 0, \\ -K_{FV}p_{x1} & \text{otherwise.} \end{cases}$$
$$V_{d2} = \begin{cases} 0 & \text{if } p_{x2} > 0, \\ -K_{FV}p_{x2} & \text{otherwise.} \end{cases} \tag{5.45}$$

The feedback constant, K_{FV}, is set to 10^{-12}, which gives good convergence and minimal error. The same value of K_{FV} is used to calculate the depletion layer voltages of a diode and an IGBT in [68].

The depletion widths, W_{d1} and W_{d2}, are

$$W_{d1} = \sqrt{\frac{2\varepsilon V_{d1}}{qN_{N^-} + \frac{|I_{p1}|}{Av_{sat}}}}$$
$$W_{d2} = \sqrt{\frac{2\varepsilon V_{d2}}{qN_{N^-} + \frac{|I_{n2}|}{Av_{sat}}}} \tag{5.46}$$

The boundary positions, x_1 and x_2, are

$$x_1 = W_{d1}$$
$$x_2 = W_{N^-} - W_{d2} \tag{5.47}$$

The displacement currents, I_{disp1} and I_{disp2}, at junctions J_1 and J_2 are

$$I_{disp1} = C_{J1}\frac{dV_{d1}}{dt} = \varepsilon A\frac{1}{W_{d1}}\frac{dV_{d1}}{dt}$$
$$I_{disp2} = C_{J2}\frac{dV_{d2}}{dt} = \varepsilon A\frac{1}{W_{d2}}\frac{dV_{d2}}{dt} \tag{5.48}$$

The voltage drop in the lightly doped drift region, V_{N^-}, can be calculated based on electron and hole currents passing through it. The current transport equations are

$$J_n = q\mu_n n\mathcal{E} + q\mu_n \nabla n \tag{5.49}$$

$$J_p = q\mu_n n\mathcal{E} - q\mu p\nabla p \tag{5.50}$$

Due to conductivity modulation, it can be assumed that the concentration of the electrons in the drift region is

$$n = p + N_{N^-} \tag{5.51}$$

Including the doping concentration, N_{N^-} is necessary, especially during the switching when the drift region has low conductivity due to the low-level injection.

Summing the current transport equations and including the Einstein relation ($D_p/\mu_p = kT/q$) and Eq. (5.51), the total current density is

$$J = qE\left(p\left(\mu_n + \mu_p\right) + \mu_n N_{N^-}\right) + qV_T\left(\mu_n - \mu_p\right)\frac{\partial p}{\partial x} \tag{5.52}$$

The electric field, $\mathcal{E}$, is

$$\mathcal{E} = \frac{J}{q\left(p\left(\mu_n + \mu_p\right) + \mu_n N_{N^-}\right)} - \frac{V_T\left(\mu_n - \mu_p\right)}{p\left(\mu_n + \mu_p\right) + \mu_n N_{N^-}}\frac{\partial p}{\partial x} \tag{5.53}$$

The drift region voltage drop is calculated by integrating the electric field between the two boundaries, x_1 and x_2:

$$V_{N^-} = \frac{J}{q}\int_{x_1}^{x_2}\frac{dx}{p\left(\mu_n + \mu_p\right) + \mu_n N_{N^-}} - \int_{p_{x1}}^{p_{x2}}\frac{V_T\left(\mu_n - \mu_p\right)}{p\left(\mu_n + \mu_p\right) + \mu_n N_{N^-}}\partial p \tag{5.54}$$

The voltage drop in the lightly doped drift region, V_{N^-}, is composed of two components: a resistive voltage drop due to the resistivity of the lightly doped drift region and voltage due to the diffusion across the drift region. The first integral of Eq. (5.54) cannot be solved analytically from the Fourier series relation because the carrier densities must be calculated for each point along the drift region and then substituted in Eq. (5.54). Instead, the drift region is divided into segments of equal width. It is desirable that the number of segments, M, be equal to the number of the terms in the Fourier series used to calculate the carrier densities. The width of a segment is calculated by the equation:

$$\Delta x = \frac{x_2 - x_1}{M - 1} \tag{5.55}$$

The carrier distribution in every point is calculated by the inverse Fourier transformation. The carrier distribution between two points is assumed to be a linear approximation (Fig. 5.5):

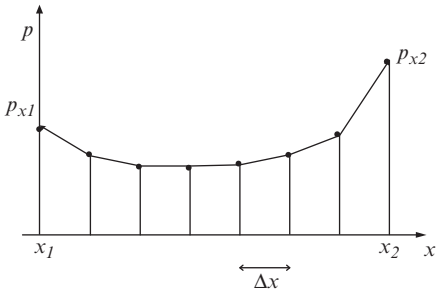

FIG. 5.5 The carrier distribution in the drift region during the ON-state.

$$p_T = p_{T1} + (p_{T2} - p_{T1})\frac{x}{\Delta x} \tag{5.56}$$

The resistive voltage drop for every segment, V_{seg}, is calculated by

$$V_{seg} = \frac{J}{q\left(\mu_n + \mu_p\right)} \int_0^{\Delta x} \frac{dx}{p_T} = \frac{J}{q\left(\mu_n + \mu_p\right)} \frac{\Delta x}{p_{T2} - p_{T1}} \ln\left(\frac{p_{T2}}{p_{T1}}\right) \tag{5.57}$$

For $p_{T1} = p_{T2} = p_T$, Eq. (5.57) is not defined. Using L'Hôpital's rule for this case, the voltage drop of the segment is

$$V_{seg} = \frac{J}{q\left(\mu_n + \mu_p\right)} \frac{\Delta x}{p_T} \tag{5.58}$$

These two cases for calculating V_{seg} are generalized in [68] as follows:

$$V_{seg} = \begin{cases} \dfrac{J}{q\left(\mu_n + \mu_p\right)} \dfrac{\Delta x}{p_{T2} - p_{T1}} \ln\left(\dfrac{p_{T2}}{p_{T1}}\right) & \text{if } |p_{T2} - p_{T1}| \\ & \geq 0.00005(p_{T2} - p_{T1}), \\ \dfrac{J}{q\left(\mu_n + \mu_p\right)} \dfrac{\Delta x}{p_T} & \text{otherwise.} \end{cases} \tag{5.59}$$

and the voltage drop, V_{N^-}, of the silicon rectifier is

$$V_{N^-} \approx \frac{I}{qA\left(\mu_n + \mu_p\right)} \frac{x_2 - x_1}{M-1} \sum_{k=0}^{M-1} \left[\frac{1}{p_{T(k)} - p_{T(k-1)}} \ln\left(\frac{p_{T(k)}}{p_{T(k-1)}}\right)\right] - V_T\left(\frac{\mu_n - \mu_p}{\mu_n + \mu_p}\right) \ln\left(\frac{p_{x2}}{p_{x1}}\right) \tag{5.60}$$

where I is the current passing through the drift region, A is its cross-sectional area, and M is the number of terms of the Fourier series, and the carrier distribution, $p_{T(k)}$, is calculated by

$$p_{T(k)} = p\left(x_1 + \frac{k(x_2 - x_1)}{M-1}\right) + \frac{\mu_n N_B}{\mu_n + \mu_p} \tag{5.61}$$

The N^+ emitter region, shown in Fig. 5.4, has a high doping concentration, and therefore, there is a significant hole concentration adjacent to the N^- N^+ junction. Due to the high-level injection during the ON-state, electrons from the N^+ region are injected into the lightly doped drift region, and high concentration holes flow into the highly doped N^+ emitter region. The holes recombine with the electrons, and the resulting hole current due to the emitter recombination is

$$I_{p2} = qAh_n p_{x2}^2 \tag{5.62}$$

The recombination parameter, h_n, depends on the emitter doping levels, N_{N^+}; the minority carrier diffusivities, $D_{p_{N^+}}$; and the holes' lifetime, $\tau_{p_{N^+}}$ [69]; and it is calculated by the equation:

$$h_n = \frac{1}{N_{N^+}} \sqrt{\frac{D_{p_{N^+}}}{\tau_{p_{N^+}}}} \tag{5.63}$$

The junction voltage, V_{J2}, is [32]

$$V_{j2} = V_T \ln\left(\frac{p_{x2}}{N_{N^-}}\right) \tag{5.64}$$

Summing the two junction voltages from Eqs. (5.34), (5.64), the total junction voltage, $V_{j12,}$ is

$$V_{j12} = V_T \ln\frac{p_{x1}p_{x2}}{n_i^2} = V_T \ln p_{x1}p_{x2} - 2V_T \ln(n_i) \tag{5.65}$$

The total junction voltage, V_{j12}, does not directly depend on the doping concentration of the lightly doped drift region, N_{N^-}. However, there is a dependency between the boundary values of the excess charge concentrations, p_{x1} and p_{x2}, and the impurity doping level that then determines junction voltage values. To obtain the minimum forward voltage drop during conduction, V_F, the minimum width of the drift region, corresponding to the minimum doping concentration, should be used. However, the results from the simulation given in [70] do not agree with this simple assertion from Eq. (5.65). The simulation results show that increasing the doping concentration, N_{N^-}, for the same breakdown voltage leads to a decrease of V_{AK} to a minimum value, after which further increases in the doping concentration cause an increase in the forward voltage drop. Higher doping concentrations, N_{N^-}, lead to reduced injection efficiencies of the higher doped P^+ and N^+ emitters into the drift region and, therefore, decrease the values of the carrier densities, p_{x1} and p_{x2}, at the region boundaries. It can be seen, from Eq. (5.65), that as the boundary charge concentrations are reduced, the contribution of the junction voltages to the total forward drop tend to cause a reduction in V_{AK}. Also, the total junction voltage, V_{j12}, depends on the intrinsic carrier concentration. Since the intrinsic carrier concentration of Si is $\sim 10^{10}$ cm^{-3}, the second member of Eq. (5.65) is $2V_T \ln(n_i) \approx 20V_T \ln(10)$ and will be subtracted to calculate the total junction voltage of a Si diode. The intrinsic carrier concentration of

SiC is $\sim 10^{-10}$ cm^{-3}, and the second member of Eq. (5.65) is $2V_T \ln(n_i) \approx -20V_T \ln(10)$ and will be added to calculate the total junction voltage of a SiC diode. For the same carrier densities, p_{x1} and p_{x2}, the total junction voltage of SiC will be approximately 2.38 V due to a lower intrinsic carrier concentration as compared with Si, which explains the experimental results of the IV characteristics of Si and SiC diodes. The forward voltage drop for a high-voltage Si diode is no more than 1.5 V, while for a SiC diode, the voltage drop is higher than 3 V. In [71], it is shown that for low-voltage devices (<6.5 kV), the forward voltage drop will be smaller for Si, as compared with SiC devices, while for high-voltage devices, the opposite is true.

Since for the same blocking voltage, the lightly doped drift region of a SiC diode is thinner than the lightly doped drift region of a Si diode, the stored charge will be smaller, the reverse recovery current will be smaller, and consequently, the switching losses will be smaller. Therefore, the power application designer should carefully calculate the losses and choose the best diode for the application.

5.3.2.3 SiC Junction Barrier Schottky Diode

As mentioned above, a SiC PiN diode has a large forward voltage drop (about 3 V) due to the wide bandgap energy. For low- and medium-voltage applications, 600–6000 V, the forward drop becomes a significant part of ON-state losses in SiC PiN diodes. On the other hand, when using a Si Schottky diode as a rectifier, the forward voltage drop is in the range of 1–1.5 V. Reverse leakage current depends on the blocking voltage, and for the same blocking voltage, the leakage current is significantly higher than that of a SiC PiN diode.

The JBS diode combines the benefits of the Schottky and PiN diode. It was first demonstrated in silicon [72] as a Schottky structure with a P$^+$N junction grid integrated into its drift region. As of 2016, JBCs can be found on the market for 600, 1200, and 1700 V reverse-blocking ratings.

Schematic cross sections of a JBS structure are shown in Fig. 5.6. It combines Schottky and PiN diodes, as illustrated, with P$^+$-well embedded in the N- epilayer. During the forward conduction mode, JBS behaves as a Schottky diode. The current flows from the anode to cathode due to the majority carriers (electrons) flowing through the multiple conductive channels under the Schottky contact. In normal operation, the Schottky current dominates, and the analysis for the forward current can be based on thermionic emission theory for Schottky junctions.

The forward voltage drop in the function of current density is determined by the metal-semiconductor Schottky barrier height. The expression for the current density has to be modified to allow for the area taken up by the P$^+$ regions in the structure [32]:

$$V_{FS} = \frac{nkT}{q} \ln\left(\frac{J_F}{A^* T^2}\right) + \phi_B + R_{SP_ON} J_{FS} \tag{5.66}$$

where J_{FS} is the current density across the Schottky barrier calculated by the following equation:

$$J_{FS} = \frac{m+s}{2d} J_{FC} \tag{5.67}$$

where s is the diffusion width of the P^+ regions, m is the masked regions (spacing between P^+ regions), and $2d$ is the actual area of the Schottky diode. The simulation results given in [73] show that the smallest spacing between P$^+$ regions results in the lowest electric field and the lowest forward voltage drop. For calculating the ON-state resistance, R_{SP_ON}, of a JBS diode, it should be taken into account that the current will pass through a different area. The equation for the ON-state resistance, R_{SP_ON}, is based on current spreading from the top $2d$ to the bottom $(m+s)$ [32]:

$$R_{SP_ON} = \rho \frac{(x_j + W)(m+s)}{m+s-2d} \ln\left(\frac{m+s}{2d}\right) \tag{5.68}$$

In Eq. (5.68), ρ is the resistivity of the epilayer, x_j is the P^+ region thickness, and W is the depletion layer width:

$$W = \sqrt{\frac{2\varepsilon_r}{N_D}(V_{bi} - V_F)} \tag{5.69}$$

The reverse leakage current has two components: one that is due to the injection of carriers across the Schottky barrier and another that is due to space-charge generation and diffusion currents [32]. The first expression is derived by modifying Eq. (5.26) to allow for the area taken up by the P$^+$ regions in the structure:

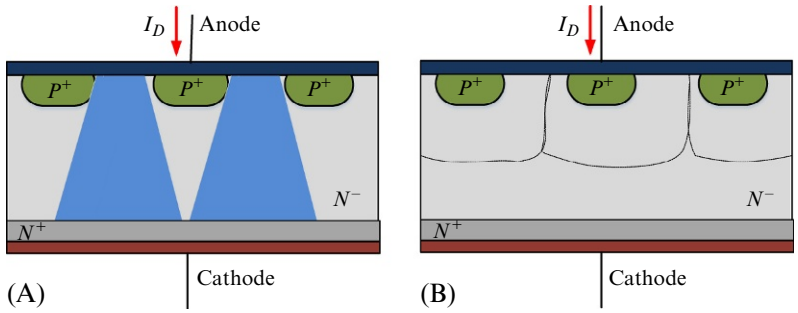

FIG. 5.6 Structure of a power JBS diode under (A) forward and (B) reverse bias.

$$I_{L_{SCH}} = \frac{2d}{m+s} A^* T^2 e^{-\frac{q\phi_B}{kT}} e^{-\frac{q\Delta\phi_B}{kT}} \left(e^{-\frac{qV_R}{kT}} - 1 \right) \tag{5.70}$$

The barrier lowering, $\Delta\phi_B$, is calculated by Eq. (5.27) where E_M is the electric field at the Schottky barrier. Applying negative voltage to a JBS causes its P^+N junctions to become reverse-biased, and the depletion layers spread into the channel. Increasing the negative voltage leads to pinch-off of the Schottky barrier and forms a potential barrier that limits the electric field at the Schottky contact, while the drift region supports further increase in voltage. The electric field is approximately constant once the channel potential barrier forms and pinch-off occurs. Further increases in reverse voltage are not reflected in the electric field; therefore, the electric field can be expressed by the pinch-off voltage, V_p:

$$E_M = \sqrt{\frac{2qN_D}{\varepsilon_r}(V_P + V_{bi})} \tag{5.71}$$

The size of the spacing between the P^+ regions should be optimized so that pinch-off is reached before the electric field at the Schottky contact increases to the point where excessive leakage currents occur due to tunneling currents and ON-resistance is not so big [73].

The second component of the leakage current is due to the P^+N junction:

$$I_{L_{P^+N}} = q\sqrt{\frac{D_p}{\tau_p}}\frac{n_i^2}{N_D} + q\frac{n_i W}{\tau_P} \tag{5.72}$$

where D_p and τ_p are hole diffusivity and lifetime in the N region with a width and doping concentration of W and N_D. Since the intrinsic carrier concentration of SiC (10^{-10}) is small compared with Si (10^{10} cm^{-3}), the leakage current of a SiC JBS due to the P^+N junction is significantly smaller and can be neglected. The presence of P^+ implanted regions improves the current surge capability and dv/dt and di/dt ratings for JBS diodes [73].

When a SiC JBS is designed to block high voltage, the N region is significantly thick and lightly doped; therefore, the forward voltage drop will be significantly large, especially for high current. The high-voltage JBS operates at two operation modes: JBS and MPS, depending on the forward-bias voltage level. When the bias voltage is not high enough to turn on the inherent PiN diode ($V_F < 3$ V), only the Schottky part is conducting. As the forward bias increases ($V_F > 3$ V), the minority carriers start to be injected into the N- layer from the P^+-well and modulate the conductivity of the epilayer resulting in a low resistance in series with the Schottky region. As a result, the ON-state current density in the high-voltage JBS during the MPS mode becomes ever larger than that for a PiN diode. The storage charge during the MPS mode is significantly smaller than that in the PiN diode, and therefore, the reverse recovery behavior of the high-voltage JBSs will be significantly superior to those for PiN diodes. The peak reverse current will be smaller, and therefore, the switching losses, and the stresses in the switch controlling the reverse recovery will be smaller.

If the high-voltage JBS is designed so that the space between the PN junctions within the cell is significantly small, a potential barrier under the Schottky region can be formed. The leakage current will be small since the lowering effect of the Schottky barrier will not be observed.

5.3.3 SiC MOSFET

For Si power MOSFETs (breakdown voltage higher than 200 V), the ON-resistance becomes dominated by the drift region resistance leading to an increase in the ON-state voltage drop and conducting losses. Novel Si structures have allowed the breakdown voltage to extend to 600 V, but the specific on-resistance is still reasonably large, which limits high-frequency operation. Theoretically, the much lower drift region resistance in SiC would allow development of power MOSFETs with higher breakdown voltages and smaller switching and conducting losses.

Since the introduction of the first SiC power double diffusion MOSFET (DMOSFET) in 1996 [74], different devices have been designed, characterized, and studied to improve their performance. Some SiC MOSFETs developed since that time are provided in Table 5.6. Since 1996, blocking voltages have increased from 0.76 to 14 kV. For a long period of time, the power MOSFET structures developed in Si could not be directly employed for SiC devices due to the following reasons.

The first is that in low-voltage devices, the ON-resistance is caused by the low mobility of inversion electrons at the SiO_2/4H-SiC interface. It was found, however, that the electric quality of the interface can be improved dramatically by postoxidation annealing in nitric oxide (NO) that leads to an increase in the inversion layer electron mobility and a corresponding reduction in channel resistivity [91]. Also, the introduction of a

self-aligned process reduces the channel resistance, and therefore, the specific ON-resistance of a well-fabricated power device is no longer limited by the channel resistance [92].

The second reason is that a high electric field in the insulator, silicon dioxide (SiO_2) of a silicon carbide MOSFET, can cause the device to fail during the blocking mode. The problem is aggravated at the trench corners leading to rupture of the gate oxide at higher drain voltages [93], thus restricting the maximum operating voltage. It can be prevented by using a buried P^+ layer to shield the channel region [94]. As a result, the electric field in the gate oxide is reduced, increasing the reliability of the SiC MOSFETs.

The third reason is that the injection of electrons into the oxide can take place when the electrons in the semiconductor gain sufficient energy to surmount the potential barrier between the SiC and SiO_2. This can cause shifting of the threshold voltage of the MOSFET leading to reliability problems.

Many companies have invested extensively in research and development of SiC MOSFETS, and most of the problems have been solved. Now, 1700 V devices can be found on the market [46]. At the ECCE 2011 Phoenix conference, Cree Inc. presented a new 12 kV SiC MOSFET ready for production.

A common structure for a SiC MOSFET is the double diffused or DMOSFET (Fig. 5.7), which has high switching speed and durability. It is a vertical device with a planar gate. The name is taken from the fabrication technique that involves double diffusion through the same opening: one for creating the P region and the other for the N source. DMOSFET has a very short channel length, L_{CH}, for achieving high transconductance and gain and also for high frequency response [95]. The current capability of a device can be improved by increasing the device aspect ratio L_{CH}/W_{CH}, where W_{CH} is the channel width. The voltage capability can be improved by decreasing the doping concentration or the thickness of the lightly doped drift region.

Applying a positive voltage to the gate higher than the threshold voltage, V_{th}, creates an inversion layer (channel) on the top of the P-base region connecting the source to the junction field-effect transistor (JFET) region. An accumulation layer under the gate oxide at the top of the JFET region is also formed, providing current that spreads from the channel into the JFET region. The electron current flows through the channel and then continues to the path with the smallest resistance, that is, through the accumulation layer. After leaving the accumulation layer, the current flows downward and sideways toward the drain electrode [95].

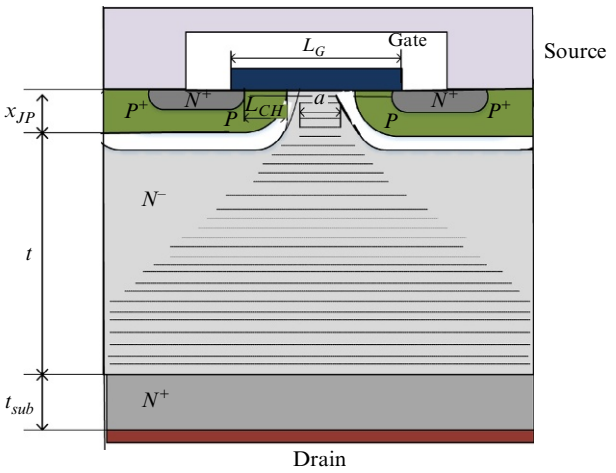

FIG. 5.7 Structure of a power DMOSFET.

For small values of the channel voltage, $V_{CH} < V_{CHsat}$, the DMOSFET has an approximately constant ON-state resistance with a value that is the sum of the channel and drift region resistance. The drain current, I_D, is

$$I_D = \frac{\mu_{CH} C_{OX} W_{CH}}{2L_{CH}} \left[2(V_{GS} - V_{th}) V_{CH} - V_{CH}^2\right] \tag{5.73}$$

where μ_{CH} is the inversion layer mobility (channel mobility), C_{OX} is the oxide capacitance per unit area, and V_{GS} is the gate-source voltage. The channel voltage, V_{CH}, is calculated by the equation:

$$V_{CH} = V_{DS} - I_D\left(R_{JFET} + R_{Drift}\right) \tag{5.74}$$

where R_{JFET} and R_{Drift} are JFET resistance and drift region resistances, respectively. The JFET resistance, R_{JFET}, is the resistance of the lightly doped N region that is under the accumulation layer formed under the gate electrode. The cross-sectional area of the JFET region through which the current flow increases slightly with distance, but for simplicity of analysis, a uniform cross section for the current flow can be assumed. If the JFET region is assumed to extend from the gate to the bottom of the P-base junction, x_{JP}, (P-region thickness), the resistance of the JFET region can be calculated by Eq. (5.75) [38]:

$$R_{JFET} = \frac{\rho_{JFET} x_{JP}}{Z\, a} \tag{5.75}$$

where Z is the length of the cell in the orthogonal direction to the cross section shown in Fig. 5.7, ρ_{JFET} is the resistivity of the JFET region depending on the doping concentration of the JFET region and calculated by

$$\rho_{JFET} = \frac{1}{q Z N_{JEFT}} \tag{5.76}$$

and a in Eq. (5.75) is the width of the channel flow. The width can be related to the device structural parameters gate width, W_G, and the width of the P-base L_{CH} by the equation:

$$a = W_G - 2L_{CH} - 2W_0 \tag{5.77}$$

where W_0 is the zero-bias depletion region width:

$$W_0 = \sqrt{\frac{2\varepsilon_{SiC} N_P V_{bi}}{q N_{JEFT}(N_{JEFT} + N_P)}} \tag{5.78}$$

Since $N_{JEFT} \ll N_P$, the equation for the zero-bias depletion region width can be simplified to

$$W_0 = \sqrt{\frac{2\varepsilon_{SiC} V_{bi}}{q N_{JEFT}}} \tag{5.79}$$

The built-in voltage depends on the doping concentration of both sides of the PN junction:

$$V_{bi} = \frac{kT}{q} \ln\left(\frac{N_P N_{JFET}}{n_i^2}\right) \tag{5.80}$$

The intrinsic carrier concentration for SiC is significantly small compared with Si; therefore, the built-in voltage and drift region resistance will be larger. The parameter P-region thickness can be used to optimize the JFET region.

The drift region is under the JFET region. Since there is no depletion region to restrict the current in the drift region from spreading, it will spread, and therefore, the cross-sectional area will increase. If it is assumed that the cross-sectional width, X_D, for current flow increases by an angle of 45 degrees, and this width is smaller than the width of the cell, W_{Cell}; the drift region resistance can be calculated by the following equation:

$$R_{JFET} = \frac{\rho_{Drift}}{2Z} \ln\left(\frac{a+2t}{a}\right) \tag{5.81}$$

where ρ_{drift} is the resistivity of the drift region and t is the thickness of the drift region. For the same breakdown voltage, the drift region thickness of a Si device is big as compared with a SiC device. The SiC device can also be highly doped; therefore, the drift region resistance for a SiC device will be small as compared with the drift region of a Si device.

At high drain-source voltage, $V_{DS} > V_{DSsat} = V_{GS} - V_{th}$, the saturation of the current is observed. At least three mechanisms of current saturation in a DMOSFET occur: channel pinch-off, carrier saturation velocity in the high-electric-field regions, and the so-called parasitic JFET effect [96] that prevents the current from flowing uniformly in the JFET region. During saturation, the current is constrained to flow in a narrow JFET channel. The drain current can be calculated by the following equation:

$$I_D = \frac{\mu_{CH} C_{OX} W_{CH}}{2L_{CH}} V_{CHsat}^2 \tag{5.82}$$

where the channel resistance, R_{CH}, and the accumulation layer resistance, R_A, should be included in the calculation of the saturation voltage. The channel resistance depends on the inversion layer mobility, μ_{CH} and can be calculated by

$$R_{CH} = \frac{L_{CH}}{\mu_{CH} C_{OX}(V_{GS-} V_{th})} \tag{5.83}$$

The accumulation layer resistance, R_A, depends on the accumulation layer length, L_A, and the electron mobility in the accumulation layer, μ_A:

$$R_A = \frac{L_A}{\mu_A C_{OX}(V_{GS-} V_{th})} \tag{5.84}$$

The accumulation layer length, L_A, is

$$L_A = \frac{L_G}{2} - x_{JP} \tag{5.85}$$

where L_G is the gate length. For modeling the dynamic characteristics of a power SiC DMOSFET, the nonlinear gate-to-drain capacitance, C_{GD}, should be calculated as follows:

$$C_{GD} = \frac{C_{OX} C_{Dep}}{C_{OX} + C_{Dep}} \tag{5.86}$$

where C_{Dep} is the depletion region capacitance that is formed under the gate oxide.

$$C_{Dep} = \frac{\varepsilon_{SiC} Z(L_G - 2x_{JP})}{W_{Dep}} \tag{5.87}$$

where the depletion width, $W_{Dep,}$ depends on the drain bias, V_D, and can be calculated by the following equation:

$$W_{Dep} = \frac{\varepsilon_{SiC}}{C_{OX}} \left(\sqrt{1 + \frac{2V_D C_{OX}^2}{q\varepsilon_{SiC} N_{JFET}}} - 1\right) \tag{5.88}$$

From Eqs. (5.87), (5.88), the depletion capacitance, C_{Dep}, decreases as the drain bias voltage V_D, increases.

5.3.4 SiC JFET

The SiC JFET has some benefits, such as a resistive forward characteristic in the first and third quadrants and a monolithic integrated body diode. It is comparable with available SiC Schottky diodes in terms of stored charge, low output capacitance, low gate charge, and low switching losses that makes it attractive for use.

The first commercialized SiC transistor was normally the ON JFET from SemiSouth Laboratories and SiCED Electronics Development. They were easy to implement as there were no reliability issues with gate oxide as with SiC MOSFETs. The JFETs are only depletion-mode, normally ON-type devices that conduct current at zero gate voltage and are fully blocked when the gate voltage is below the pinch-off voltage. The most successful JFET type, in terms of voltage and current ratings, has been the lateral channel JFET (LCJFET), shown in Fig. 5.8 The LCJFET allows optimization of the channel parameters and is easy to fabricate. Due to the combined lateral-vertical channel design, the LCJFET has significantly reduced Miller capacitance. A parasitic diode formed with the buried P region and the N drift region can be used as a freewheeling diode without an external antiparallel diode. Also, the current through the channels can flow in the reverse direction when enough gate-source voltage is applied; therefore, the LCJFET can work in synchronous rectification circuits.

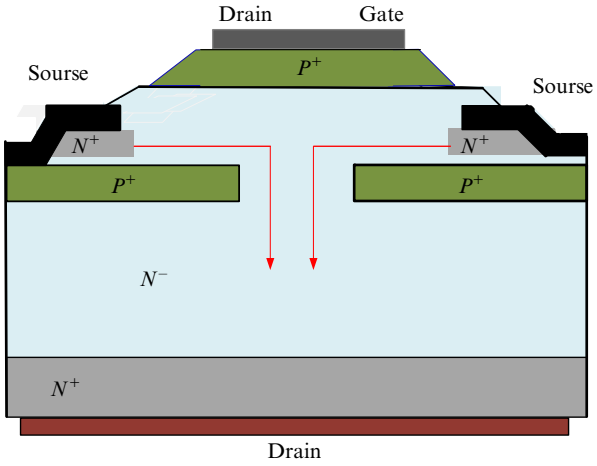

FIG. 5.8 Lateral channel SiC JFET.

When JFETs are ON, they exhibit constant resistance that can be minimized by increasing the gate voltage slightly higher than zero. A normally-ON device is not easy to use in a power application because losing the control can cause undesired conduction of the switch and, consequently, can lead to shoot-through current damaging the circuit [97].

A cascode configuration, shown in Fig. 5.9, composed of a SiC JFET and a series-connected low-voltage Si MOSFET, can overcome the problem and make a normally-ON JFET behave similarly to a conventional MOSFET. Typically, a 30 V MOSFET with very low ON-resistance controls the JFET conduction. When the two devices are conducting, the conduction losses of the MOSFET will be insignificant. When the Si MOSFET is turned on, the gate-source voltage of the JFET becomes zero, allowing current to pass from the drain to the source. The forward characteristics of a cascode configuration are determined by the gate-source voltage applied to the MOSFET.

During the OFF-state, the cascode exhibits a rugged avalanche behavior. Since in a cascode configuration the control device is a low-voltage Si MOSFET, it is easy to replace a power device with a cascode configuration packed as one device, because the control is made with the same voltage levels. The temperature coefficient of the ON-resistance of a SiC JFET is positive, which naturally protects the device from overshooting during high-temperature operation. However, there are some limitations with a cascode configuration. The maximum operating temperature in a cascode configuration is limited by the Si MOSFET, the Si MOSFET internal body diode shows a low dv/dt rating, limiting the switching frequency of the JFET, and the conduction losses are higher since the two devices are connected in series [98].

To overcome these limitations, gate drivers that can block a JFET have been designed. The driver output voltage swings from zero to negative voltage. The negative voltage level is less than the maximum pinch-off voltage of the device and, therefore, could cause a gate avalanche condition. In order to limit uncontrolled avalanche current, a parallel circuit, that includes a resistor, capacitor, and diode connected in series to the JFET gate, can be used. This parallel circuit is capable of limiting the avalanche current but supplying the high gate current peaks required for fast switching [99]. A disadvantage of using a special JFET driver is that a negative supply voltage should be provided to the drive circuit that complicates the control circuit of the device. Also, replacing a power device with a JFET in a power application is more complicated because the driver and the control are also affected.

In 2011, normally OFF vertical channel JFETs (VCJFETs) compatible with standard gate drive circuitry and featuring a positive temperature coefficient for ease in paralleling were commercially available. VCJFETs were based on a patented vertical channel trench structure from SemiSouth Laboratories, Inc. A typical high-voltage VCJFET is shown in Fig. 5.10.

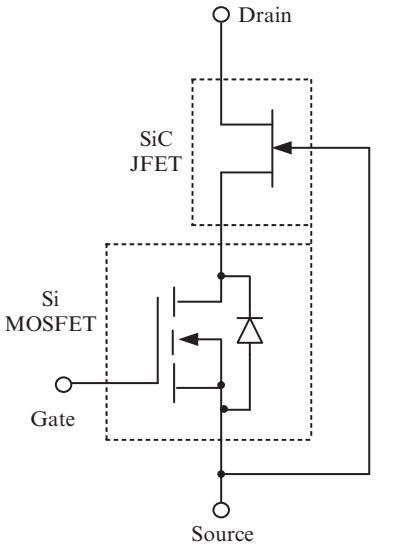

FIG. 5.9 SiC JFET/Si low-voltage MOSFET cascode configuration.

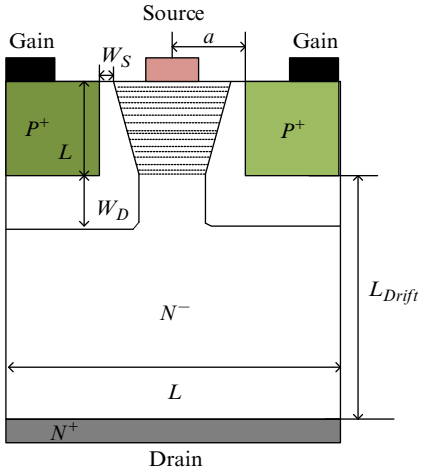

FIG. 5.10 SiC VCJFET cross section.

When the channel voltage is smaller ($V_{CH} < V_{CHsat}$), a VCJFET works in the linear region and has an approximately constant ON-state resistance; the value of which is the sum of the channel and drift region resistance. The drain current, I_D, can be calculated by the following equation [100]:

$$I_D = I_P \left[\frac{3V_{CH}}{V_P} - \frac{2}{V_P^{3/2}} \left[(V_{CH} - V_{GS} + V_{bi})^{3/2} - (V_{bi} - V_{GS})^{3/2} \right] \right] \tag{5.89}$$

where I_P is the pinch-off current depending on the channel parameters, such as electron mobility, μ_n; doping concentration, N_{CH}; VCJFET thickness, Z; half of the width of the channel region, a; and the effective length of the channel. The pinch-off current is calculated by the following equation:

$$I_P = \frac{q^2 \mu_n N_{CH}^2 Z a^3}{3\varepsilon_{SiC} L_{eff}} \tag{5.90}$$

Since the drift region of a high-voltage SiC VCJFET is designed to support high voltage, the drift region is thick and lightly doped. Hence, the drift resistance will be significantly higher than other resistance through which the drain current is flowing. Therefore, the drift resistance should be included for calculating the channel voltage, V_{CH}:

$$V_{CH} = V_{DS} - I_D R_{Drift} \tag{5.91}$$

where R_{Drift} is the drift resistance. To simplify the expression for calculating the drift resistance, the current spreading effect of the current coming from the channel can be neglected; then, the drift resistance can be calculated as the resistance of the rectangular area in the drift region under the channel:

$$R_{Drift} = \frac{L_{Drift} - W_D}{q\mu_n N_{Drift} Z W_{Drift}} \tag{5.92}$$

where L_{Drift} and W_{Drift} are the drift region thickness and the width and N_{Drift} is the doping concentration of the lightly doped drift region.

The pinch-off voltage depends on the channel parameters and can be calculated by the equation:

$$V_P = \frac{qN_{CH}a^2}{2\varepsilon_{SiC}} \tag{5.93}$$

The built-in voltage is

$$V_{bi} = \frac{kT}{q} \ln\left(\frac{N_{CH}N_P}{n_i^2}\right) \tag{5.94}$$

where N_P is the doping concentration of the gate.

When the channel voltage is increased so that $V_{CH} > V_{CHsat}$, the drain current saturates. The saturation current is defined by the following equation:

$$V_{CHsat} = V_P - V_{GS} + V_{bi} \tag{5.95}$$

There are two reasons for the drain current to saturate. One reason is that the depletion region becomes progressively wider toward the drain side causing a reduction of channel width and an increase of channel resistance. The other reason is that due to the presence of a high electric field in the channel, the carrier velocity saturates. The saturated drain current, I_{DSAT}, can be calculated by the equation [100]:

$$I_{DSAT} = I_P \left[1 - 3\frac{V_{bi} - V_{GS}}{V_P} + 2\left(\frac{V_{bi} - V_{GS}}{V_P}\right)^{3/2} [1 + \lambda(V_{CH} - V_{CHSAT})] \right] \tag{5.96}$$

The multiplication term $[1 + \lambda(V_{CH} - V_{CHSAT})]$ in Eq. (5.96) is used to account for the channel modulation effect.

A benefit of a VCJFET is that it can be used in directions, forward and reverse, in a converter circuit. The reverse I–V characteristics do not saturate as do the forward I–V characteristics. The reason for this is that when the drain current is in the reverse direction, $V_{GD} > V_{GS}$, the channel closes so the drain side will be wide open. As a result, as V_{SD} increases, the channel is never pinched off when $V_{GS} > V_{th}$, while when $V_{GS} < V_{th}$, the channel is always pinched off on the side of the source and wide open on the drain side. Therefore, it is possible for a VCJFET to be used for freewheeling, although no parasitic diode is formed between the source and the drain [101].

In order to model the switching losses of a VCJFET, the capacitance between gate and source, C_{GS}, and the capacitance between gate and drain, C_{GD}, should be known. The gate-source capacitance is

$$C_{GS} = \frac{K_{GS}\varepsilon_{SiC}A_{GS}}{W_S} \tag{5.97}$$

where K_{GS} is the coupling area, the coefficient of the gate and source; A_{GS} is the coupling area between gate and source; and W_S is the depletion width between the gate and source. The depletion width can be calculated by

$$W_S = \sqrt{\frac{2\varepsilon_{SiC}}{qN_{CH}}}(V_{bi} - V_{GS}) \tag{5.98}$$

The gate-to-drain capacitance is

$$C_{GD} = \frac{\varepsilon_{SiC}A_{GD}}{W_D} \tag{5.99}$$

where the width of the depletion region between the gate and the drain is

$$W_D = \sqrt{\frac{2\varepsilon_{SiC}}{qN_{CH}}}(V_{CH} + V_{bi} - V_{GS}) \tag{5.100}$$

TABLE 5.7 Parameters and FOMs for 1200 V SiC devices

Type	Part number	Company	I_D (A)	R_{SP-ON} (mΩ)	Q_{SW} (nC)	Q_G (nC)	SLFOM	CLFOM
JFET	IJW120R100T1 [102]	Infineon	26	100	48	72	4800	7200
MOSFET	SCT3017AL [103]	Cree	40	52	65	115	3380	5980

Some of the parameters of SiC JFETs and MOSFETs are presented in Table 5.7 as their switching losses FOM (SLFOM) and conduction losses FOM (CLFOM). The MOSFET FOMs are smaller although the MOSFET current is higher. In 2009, it was stated that a SiC MOSFET would be the device of choice as soon as the SiO_2/SiC interface and reliability issues were resolved [104]. The two companies that were producing JFETs no longer exist. Infineon Technologies discontinued their JFET products. Other SiC companies are more interested in production and development of SiC MOSFETs; therefore, the future of the SiC JFET is still unknown.

5.3.5 SiC BJT

Power BJTs in SiC are very attractive for power switching applications due to their very low specific ON-resistance and high-temperature operation with high power densities [105]. The common-emitter gain, β; the specific on-resistance, R_{SP_ON}; and the open-base breakdown voltage, BV_{CEO}, are important parameters that should be accounted for in choosing a device for a power application. The current gain should be high enough to reduce the base current that controls the BJT. Considerable work has been done to improve device performance. One of the main challenges is to increase the current gain of 4H-SiC BJTs [106] that is limited by the surface recombination [105]. Reducing the surface recombination current by optimizing the surface passivation improves the current gain [107]. Also, the common-emitter current gain can be improved by increasing the minority carrier lifetime in the base and emitter regions [108]. The maximum current gain for high-voltage SiC BJTs that has been reported in the literature is 335 for a 600 V device [109].

To increase the blocking voltage, the growth of high-purity SiC homoepitaxial thin films on SiC single-crystal wafers is required to form N^-N^+ wafer structures [110]. The maximum open-base breakdown voltage, BV_{CEO}, for a SiC BJT was reported to be 6 kV, but the gain was only 3 [111]. Further work is necessary to improve the design and to develop a new processing technology so that an increase in BV_{CEO} can be achieved without sacrificing the current gain of the transistor. Also, the conduction and switching power losses should be minimized. The conduction losses depend on the collector-emitter voltage and the collector current.

The voltage drop, V_{CE}, across the high-power SiC BJT is composed of six components, including the voltages across the junctions, J_0, J_1, and pseudojunction, J_2; the voltage across the two depletion regions, V_{d1} and V_{d2}; and the voltage across the carrier storage region (CSR), V_{N^-}:

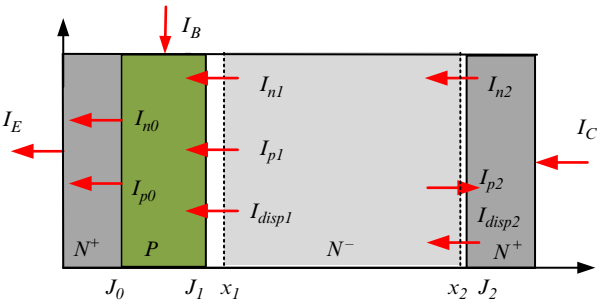

FIG. 5.11 One-dimensional cross section of a power BJT showing the hole and electron currents in each region.

$$V_{CE} = V_{j0} + V_{j1} + V_{j2} - V_{d1} - V_{d2} + V_{N^-} \tag{5.101}$$

A basic one-dimensional structure of a power BJT is illustrated in Fig. 5.11. The BJT is divided into four regions: N^+ emitter, P base, N^- drift, and N^+ collector. The external (emitter base and collector currents, I_E, I_B, and I_C) and internal electron and hole and displacement currents (at junctions J_0—I_{n0}, I_{p0}; J_1—I_{n1}, I_p, and I_{disp1}; and J_2—I_{n2}, I_{p2}, and I_{disp2}) are indicated for each region.

The N^+ emitter layer of a power BJT can be simply characterized as a hole sink. The hole current at the junction, J_0, is obtained by the following equation:

$$I_{p0} = qAh_n n_{B0} P_B \tag{5.102}$$

where n_{B0} is the electron concentration at junction J_0 and P_B is the base doping concentration. The N^+ emitter recombination parameter, h_n, depends on emitter properties, such as doping level (N_E), hole diffusivity (D_p), and hole minority lifetime (τ_p). The electron current component at junction J_0 is determined by

$$I_{n0} = I_C - I_{p0} \tag{5.103}$$

and the voltage drop across junction J_0 is

$$V_{j0} = V_T \ln\left(\frac{n_{B0}(n_{B0} + P_B)}{n_i^2}\right) \tag{5.104}$$

The equation for the P-base region can be used to derive the boundary current at junction J_1. The lumped-charge method is used to model the behavior in the base region due to its moderate doping level and comparatively narrow base width. The injected carrier distribution in the base region during conduction is shown in Fig. 5.12.

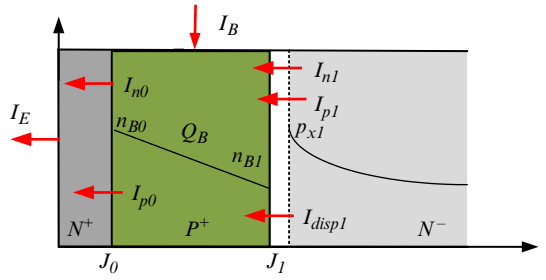

FIG. 5.12 Charge distribution and boundary current components in P base.

Using the continuity equation for the base region, the injected minority carrier charge is described by the relation:

$$\frac{dQ_B}{dt}+\frac{Q_B}{\tau_{BHL}}=I_{n0}-I_{n1}=I_B+I_{p1}+I_{disp1}-I_{p0} \tag{5.105}$$

where τ_{BHL} is the high-level lifetime in the P-base region.

The total electron charge in the base is expressed as

$$Q_B=\frac{n_{B0}+n_{B1}}{2}qAW_B \tag{5.106}$$

where W_B is the base width. The electron concentration at the base region boundary on the collector side, n_{B1}, is related to the excess carrier concentration, p_{x1}, by the doping concentration of the base, P_B, by the equation:

$$n_{B1}=\frac{p_{x1}^2}{P_B} \tag{5.107}$$

Since the diffusion length in the base region is much greater than the base width, the gradient of the electron concentration is approximately linear, giving the electron current at the base-collector junction, J_1, as

$$I_{n1}=qD_nA\frac{n_{B0}-n_{B1}}{W_B} \tag{5.108}$$

The base-emitter voltage V_{BE} is calculated by the equation:

$$V_{BE}=V_T\ln\left(\frac{n_{B0}P_B}{n_i^2}+1\right) \tag{5.109}$$

The voltage drop in N^- drift region is calculated during the ON-state in a manner similar to that of a PiN diode. The injected excess carrier concentration is determined by the ADE. As for all power switches, high-level injection and quasi-neutral conditions exist. Under high-level injection conditions, the ADE for the lightly doped drift describes the carrier dynamics of the majority carriers:

$$D\frac{\partial^2p(x,t)}{\partial x^2}=\frac{p(x,t)}{\tau}+\frac{\partial p(x,t)}{\partial t} \tag{5.110}$$

where D is the ambipolar diffusion coefficient, τ is the high-level carrier lifetime within the drift region, and $p(x, t)$ is the excess carrier concentration. The Fourier series solution of the ADE is given by the following first-order differential equations as each of them refers to a harmonic, $p_k(t)$, of the total minority carrier density, $p(x,t)$:

For $k>0$

$$\begin{aligned}&D\left[\left.\frac{\partial p(x,t)}{\partial x}\right|_{x_2}(-1)^k-\left.\frac{\partial p(x,t)}{\partial x}\right|_{x_1}\right]\\&=\frac{x_2-x_1}{2}\left(\frac{dp_k(t)}{dt}+\left[\frac{1}{\tau}+\frac{Dk^2\pi^2}{(x_2-x_1)^2}\right]p_k(t)\right)\\&+\left(\sum_{\substack{n=1\\n\neq k}}^{\infty}\frac{n^2}{n^2-k^2}\left[\frac{dx_1}{dt}-(-1)^{n+k}\frac{dx_2}{dt}\right]p_n(t)+\frac{p_k}{4}\left(\frac{dx_1}{dt}-\frac{dx_2}{dt}\right)\right)\end{aligned} \tag{5.111}$$

for $k=0$

$$\begin{aligned}D\left[\left.\frac{\partial p(x,t)}{\partial x}\right|_{x_2}-\left.\frac{\partial p(x,t)}{\partial x}\right|_{x_1}\right]&=(x_2-x_1)\frac{dp_0(t)}{dt}+\frac{p_0(t)}{\tau}\\&+\sum_{n=1}^{\infty}\left[\frac{dx_1}{dt}-(-1)^n\frac{dx_2}{dt}\right]p_n(t)\end{aligned}$$

The solution to the ADE is determined by using the boundary conditions at the edges of the charge storage region. The representation requires the width of the undepleted region and the hole and electron currents at the boundaries of the drift region, which give the gradients of the carrier concentrations at x_1 and x_2, respectively. For the given direction of the currents (Fig. 5.13), the required boundary conditions are given by the equations:

$$\left.\frac{\partial p}{\partial x}\right|_{x_1}=\frac{1}{2q}\left(\frac{J_n}{D_n}+\frac{J_p}{D_p}\right)\Bigg|_{x_1}\text{ and }\left.\frac{\partial p}{\partial x}\right|_{x_2}=\frac{1}{2q}\left(\frac{J_n}{D_n}+\frac{J_p}{D_p}\right)\Bigg|_{x_2} \tag{5.112}$$

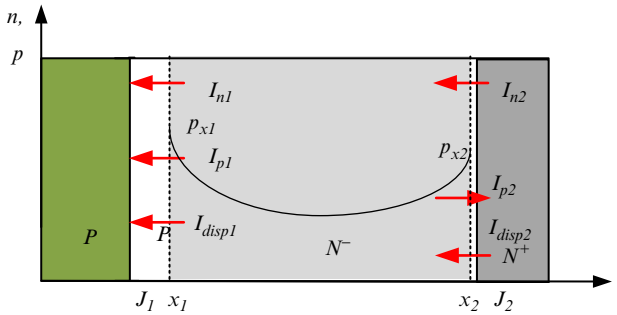

FIG. 5.13 Charge distribution and boundary current components in N^- collector.

Using the boundary condition Equation (5.112), the left side of Eq. (5.111), for even and odd numbers of k, can be calculated by the following equations:

$$I_{even} = D\left(\left.\frac{\partial p}{\partial x}\right|_{x_2} - \left.\frac{\partial p}{\partial x}\right|_{x_1}\right) = \frac{1}{2qA}\begin{vmatrix} I_{n1} \\ I_{p1} \\ I_{n2} \\ I_{p2} \end{vmatrix}\begin{vmatrix} -\frac{D}{D_n} - \frac{D}{D_p} + \frac{D}{D_n} + \frac{D}{D_p} \end{vmatrix} \tag{5.113}$$

$$I_{odd} = D\left(\left.\frac{\partial p}{\partial x}\right|_{x_2} - \left.\frac{\partial p}{\partial x}\right|_{x_1}\right) = -\frac{1}{2qA}\begin{vmatrix} I_{n1} \\ I_{p1} \\ I_{n2} \\ I_{p2} \end{vmatrix}\begin{vmatrix} \frac{D}{D_n} & \frac{D}{D_p} & \frac{D}{D_n} & \frac{D}{D_p} \end{vmatrix} \tag{5.114}$$

The boundary carrier densities, p_{x1} and p_{x2}, at the boundaries, x_1 and x_2, are calculated using the equations:

$$p_{x_1} = \sum_{k=1}^{n} p_k \text{ and } p_{x_2} = \sum_{k=1}^{n} (-1)^k p_k \tag{5.115}$$

The voltages across the N^-N^+ and N^-P^+ depletion layers, V_{d1} and V_{d2}, are calculated by the following equations:

$$\begin{aligned} V_{d1} &= \begin{cases} 0 & \text{if } p_{x1} > 0, \\ -K_{FV} p_{x1} & \text{otherwise.} \end{cases} \\ V_{d2} &= \begin{cases} 0 & \text{if } p_{x1} > 0, \\ -K_{FV} p_{x2} & \text{otherwise.} \end{cases} \end{aligned} \tag{5.116}$$

The feedback constant, K_{FV}, is set to 10^{-12}, which gives good convergence and minimal error [68]. The associated depletion widths, W_{d1} and W_{d2}, are calculated using a step doping concentration change on each side of the junction:

$$\begin{aligned} W_{d1} &= \sqrt{\frac{2\varepsilon V_{d1}}{qN_{N^-} + \frac{|I_c|}{A v_{sat}}}} \\ W_{d2} &= \sqrt{\frac{2\varepsilon V_{d2}}{qN_{N^-} + \frac{|I_c|}{A v_{sat}}}} \end{aligned} \tag{5.117}$$

The boundary positions, x_1 and x_2, are calculated by

$$\begin{aligned} x_1 &= W_{d1} \\ x_2 &= W_{N^-} - W_{d2} \end{aligned} \tag{5.118}$$

The displacement currents, I_{disp1} and I_{disp2}, are due to the changing depletion widths at junctions J_1 and J_2:

$$\begin{aligned} I_{disp1} &= C_{J1}\frac{dV_{d1}}{dt} = \varepsilon A \frac{1}{W_{d1}}\frac{dV_{d1}}{dt} \\ I_{disp2} &= C_{J2}\frac{dV_{d2}}{dt} = \varepsilon A \frac{1}{W_{d2}}\frac{dV_{d2}}{dt} \end{aligned} \tag{5.119}$$

The voltages across junctions J_1 and J_2 are

$$\begin{aligned} V_{j1} &= 2V_T \ln\left(\frac{p_1}{n_i}\right) \\ V_{j2} &= V_T \ln\left(\frac{p_{x2}}{N_C}\right) \end{aligned} \tag{5.120}$$

The voltage drop across the carrier storage region, V_{N^-}, is calculated based on the injected carrier concentration discussed in Section 5.3.2.2.

$$\begin{aligned} V_{N^-} \approx & \frac{I_C}{qA\left(\mu_n + \mu_p\right)} \frac{x_2 - x_1}{M-1} \sum_{\kappa=0}^{M-1} \left[\frac{1}{p_{T(k)} - p_{T(k-1)}} \ln\left(\frac{p_{T(k)}}{p_{T(k-1)}}\right)\right] \\ & + V_T \left(\frac{\mu_n - \mu_p}{\mu_n + \mu_p}\right) \ln\left(\frac{p_{x2}}{p_{x1}}\right) \end{aligned} \tag{5.121}$$

where the carrier distribution, $p_{T(k)}$, is calculated as

$$p_{T(k)} = p\left(x_1 + \frac{k(x_2 - x_1)}{M-1}\right) + \frac{\mu_n N_{N^-}}{\mu_n + \mu_p} \tag{5.122}$$

The N^+ collector region has similar properties to the N^+ emitter region as it also can be presented as a hole sink. The hole current at junction J_2 is obtained by the equation:

$$I_{p2} = qAh_n p_{x2}^2 \tag{5.123}$$

The electron current at junction J_2 is

$$I_{n2} = I_c + I_{p2} - I_{disp2} \tag{5.124}$$

During the ON-state, the voltages across the N^-N^+ and N^-P^+ depletion layers, V_{d1} and V_{d2}, are equal to zero, and the collector-emitter voltage is

$$V_{CE} = V_{j0} + V_{j1} + V_{j2} + V_{N^-} \tag{5.125}$$

Substituting the junctions' voltages from Eqs. (5.104), (5.120) in Eq. (5.125) and simplifying, the following equation will be obtained:

$$V_{CE} = V_T \ln\left(n_{B0}(n_{B0} + P_B)p_{x1}^2 \frac{p_{x2}}{N_C}\right) + 4V_T \ln\left(\frac{1}{n_i}\right) + V_{N^-} \tag{5.126}$$

Since the thickness of the lightly doped drift region of a SiC BJT is smaller than the lightly doped drift region of a Si device, their boundary carrier densities, p_{x1} and p_{x2}, at the boundaries, x_1 and x_2, are bigger [71]. Therefore, for the same doping concentration of the four regions of a power SiC BJT and a power Si BJT, the first term of Eq. (5.126) for a SiC device is big compared with a Si one. Also, if it is assumed that the intrinsic carrier concentrations of Si and SiC are 10^{10} and 10^{-10} cm^{-3} and

the thermal voltage, $V_T = 0.256$, the second term of a Si device is a negative number (approximately −2.36 V) that will subtract from the first term and make collector-emitter voltage smaller, while for a SiC BJT, the second term is a positive number (∼2.36 V) that will add to the first term and make the collector-emitter voltage bigger. Only the voltage drop in the lightly doped drift region for SiC will be small compared with a Si one, since the thickness in Si is significantly larger and the doping concentration in Si is lower. To have benefits of conductivity modulation and therefore small ON-resistance, SiC BJTs similar to SiC PiN diode should be designed for higher than 4 kV [112]. Also, the BJT is a bipolar device having minority and majority carrier flowing during operation; therefore, the drift region stores charge that decreases the device switching speed and thus can only operate at switching frequencies less than can be obtained with a MOSFET structure.

5.3.6 SiC IGBT

As previously mentioned, the rapid improvement in 4H-SiC material quality and the maturing of SiC device processing in recent years have enabled the development of high-voltage SiC power devices (MOSFETs and JFETs). However, the ON-resistance of SiC MOSFETs and JFETs rapidly increases as the blocking voltage and operating junction temperature increase because they are unipolar devices and conductivity modulation is not happening in the lightly doped drift region. This makes the conduction loss of the unipolar devices unacceptable for applications with a blocking voltage higher than 10 kV. For these applications, bipolar devices are preferred because they have been shown to have a small voltage drop due to strong conductivity modulation in their drift regions [113].

Simple gate drive interfaces make 4H-SiC IGBTs attractive devices. Chronologically, the first fabricated and characterized IGBTs were *P*-channel because there was a practical limitation in producing the low resistivity P^+-type SiC substrate required for fabricating *N*-channel IGBTs [114]. But with the advantages of the SiC technology, *N*-channel IGBTs have been built. Both *N*- and *P*-channel SiC IGBTs have demonstrated high blocking voltage capability, as the first IGBT fabricated in 2006 had a blocking voltage of 5.8 kV. Since then, different IGBTs have been built; for example, 12 kV *P*-channel IGBTs with 14 mΩ cm^2 ON-resistance [115], 13 kV *N*-channel IGBTs with 22 mΩ cm^2 ON-resistance [116], and 20 kV self-aligned *P*-channel DMOS-IGBTs have been reported [117]. The 20 kV *P*-channel IGBT has a less than 15 times a smaller voltage drop at 31 A cm^{-2} current density compared with a theoretical MOSFET with the same blocking voltage [117]. The last reported IGBT with ultrahigh blocking voltage of 27 kV was reported in 2015 [118].

Different SiC device research groups have been working on optimizing the IGBT parameters and fabricating and characterizing devices so that soon IGBTs will be on the market. For a given blocking voltage, a trade-off between conduction and switching loses should be made to optimize the IGBT parameters. A reason for this is that there is a huge amount of charge stored in the IGBT lightly doped drift region during the ON-state and that has to be removed during turn-OFF [119].

In [120], the device group from Cree Inc. has fabricated a 10 kV MOSFET and an *N*-type IGBT capable of flowing 10 and 4 A, respectively. Both devices were processed identically through the device fabrication process each as a MOS part where the lightly doped drift region had the same length and doping concentration. The only difference between the two devices is that the *N*-channel IGBTs have a moderately doped *N* field-stop (FS) buffer layer and a heavily doped P^+ injector, while the MOSFET has an N^+ substrate. The DC characteristics of the devices were measured, and it was observed that the forward voltage drops of the two structures were the same, ∼5 V.

The switching results indicated that both devices were much faster than the highest voltage, commercially available Si IGBT. The MOSFET turn-OFF transient time was faster than the IGBT turn-OFF time of 140 and 400 ns, respectively. A reason for slow turn-OFF time is that the IGBT is a bipolar device and stores minority and majority charges in the lightly doped drift region that are removed slowly, while the MOSFET is a unipolar device and is not dependent on carrier recombination during turn-OFF. The IGBT turn-OFF transient can be improved by reducing gate resistance and optimizing the internal capacitance and increasing the high-level lifetime.

Seven years later, the Cree Inc. group demonstrated a 20.7 kV *N*-channel IGBT with a forward voltage drop of 6.4 V at a collector current of 20 A and a 17 kV *N*-channel IGBT with a forward voltage drop of 5.7 V at a collector current of 20 A [121]. The two IGBTs were fabricated with the same mask sets and identical fabrication process. Although the lightly doped drift region for the 20.7 kV IGBT was significantly increased in width to support higher voltage, the voltage drop did not increase significantly, which can be attributed to conductivity modulation that takes place during the conduction state of the IGBT. Similar to a SiC PiN diode and a BJT, as an IGBT is a bipolar device, the junction voltage drops are dominant in determining the forward voltage drop with a blocking voltage smaller than 20 kV. The ON-resistance for an IGBT will be dominated by the parasitic resistance, such as channel resistance and the contact resistance, while the resistance of the lightly doped drift region will not be much larger due to high-level injection in the lightly doped drift region leading to conductivity modulation.

Results of a comparison of *N*-channel and *P*-channel SiC IGBTs have shown comparable static characteristics that can be explained by the fact that during the ON-state, an IGBT is operating at high-level injection. Regardless of the structure of an IGBT, the behavior of the carriers in the lightly doped drift region is governed by the ADE:

$$D\frac{\partial^2 p(x,t)}{\partial x^2} = \frac{p(x,t)}{\tau} + \frac{\partial p(x,t)}{\partial t} \tag{5.127}$$

Operating at high-level injection means that the injected carriers in the lightly doped drift region have significantly higher values than the background impurity doping concentration. The electron and hole concentrations in the drift region during the ON-state are equal:

$$p(x,t) = n(x,t) \tag{5.128}$$

Their concentrations depend on the boundary conditions at each end of the drift region, the minority charge-carrier lifetime, and the drift region width. Assuming that *N*-channel and *P*-channel IGBTs are processed identically through the device fabrication process and the gate-source voltage and collector current are the same, then the carrier concentration in the drift region of the two devices will be equal, and therefore, the voltage drop across the drift regions will be the same. The IGBT junction voltages are functions of the doping concentrations, and they will be the same for the identically processed *N*- and *P*-channel IGBTs. Therefore, the total voltage drop for identically processed *N*-channel and *P*-channel SiC IGBTs will be significantly the same when the devices are subjected to the same conditions: gate-source voltage, collector current, and temperature.

On the other hand, *N*-channel IGBTs offer far superior switching characteristics over *P*-channel IGBTs. In Ref. [122], the simulation results of the switching characteristics of *N*-channel and *P*-channel 15 kV SiC IGBTs are given that support this fact. The rate of increase in the collector-emitter voltage of an *N*-channel IGBT is 40 V ns^{-1} and for a *P*-channel IGBT is 5 V ns^{-1}. The current decay for the *N*-channel IGBT is also faster than the current decay for the *P*-channel IGBT. A physical explanation for this is that in the beginning of the turn-OFF process, the collector-emitter voltage, V_{CE}, rises from the forward voltage, V_F, to the DC supply voltage, V_{DC}, and the rate of change of the V_{CE} depends on the rate of removal of the stored charge through the emitter side. During this time, the recombination and displacement currents are significantly smaller than the minority carrier current and can be neglected. The minority current is responsible for the charge removal. As the V_{CE} rises, the depletion region expands toward the collector junction. The minority carriers are swept out through the depletion region, and the majority of carriers are pushed toward the collector where most of them will recombine in the P^+ injector layer for an *N*-channel IGBT or N^+ injector layer for a *P*-channel IGBT [119]. Due to the large rate of change in the minority carrier current, the depletion region expends faster in an *N*-channel IGBT than in a *P*-channel IGBT, and therefore, the collector voltage for *N*-channel an IGBT rises at a faster rate. During the second phase of the turn-OFF process, after the collector-emitter voltage, V_{CE}, reaches the DC supply voltage, V_{DC}, the freewheeling diode is turned ON that allows the collector current to fall down to a value depending on the remaining storage charge. During this time, the V_{CE} overshoots due to the energy stored in the stray inductance in the collector-emitter loop. After that, the collector current depends only on the remaining storage charge, and the recombination rate depends on the high-level carrier lifetime [123]. Since the holes' lifetime is smaller than the electrons' lifetime, the tailing current phase is shorter for an *N*-channel IGBT compared with a *P*-channel IGBT. Also, an *N*-channel IGBT has faster charge extraction due to the large ionization energy of acceptors in 4H-SiC [122]. Since the total losses for an *N*-channel IGBT are smaller compared with a *P*-channel IGBT, further developments in IGBT should be focused on an *N*-channel IGBT [118].

Similar to other power devices, IGBTs consist a thick lightly doped drift region that is required to support high voltage and prevent an avalanche breakdown. The drift region thickness, the doping concentration, and the minority carrier lifetime are important IGBT design parameters. Their values are optimized so that the sum of the conduction and switching losses is minimized for a desired blocking voltage. The drift region thickness and doping concentration are optimized to obtain minimum conduction loses (forward voltage drop) for the same blocking voltage. Increasing the doping concentration requires a thicker drift region to sustain the high voltage and prevent an avalanche breakdown. The minority lifetime effects the conducting and switching losses. An increase in the lifetime enhances the conductivity modulation, and therefore, the forward voltage drop is reduced, while the recombination process becomes slower and results in high switching losses. A compromise between conduction and switching losses should be made to optimize the carrier lifetime in the drift region.

To decrease the drift region thickness for the same IGBT blocking voltage, an FS layer adjacent to the lightly doped drift region is used, making the IGBT an asymmetrical device. In [124], it is shown that a 15 kV *N*-channel symmetrical IGBT does not have an FS layer and the thickness of the drift region is 247 μm, while for an asymmetrical *N*-channel IGBT, the thickness is 150 μm. Therefore, the voltage drop in the lightly doped drift region is significantly smaller for an asymmetrical device. Also, due to the FS layer, the depletion width starts to expand across the whole drift region when an IGBT is switched OFF and a punch-through effect is observed. Therefore, the depletion width that is equal to the drift region thickness should be designed first. The punch-through effect benefits the switching characteristics of an IGBT. After the punch-through, the sweep-out of the excess carriers practically stops, and the charge removal is performed mostly due to the recombination process in the FS layer. Therefore, the current tail disappears under the punch-through condition. The punch-through effect has some disadvantages also. During punch-through, the parasitic capacitance associated with increasing of the V_{CE} turns into a much smaller capacitance instead of a large diffusion capacitance [121]. This capacitance resonates with the parasitic stray inductance in the collector-emitter loop resulting in voltage overshooting and a ringing phenomenon,

which should be carefully considered. The thickness of the FS layer is an important device parameter. Increasing the FS layer thickness results in superior turn-OFF speed but slightly increases the forward voltage drop, while decreasing the FS layer thickness slows down the turn-OFF speed but offers superior conduction capability [125].

To reduce the ON-state resistance of the lightly doped drift region of an N-channel IGBT, some power device designers have inserted a thin, heavily doped N^+ current spreading layer (CSL) beneath the P-type base region, forming a JFET layer between the two P bases. An CSL helps to distribute the electron flow more uniformly, minimizing the current crowding at the top of the drift region and reducing the drift layer resistance. Both regions, CSL and JFET, are formed as N-type epitaxial layers having higher doping concentration than the drift layer. Increasing the doping concentration in the JFET region helps to reduce the ON-state resistance; however, it causes an increase in the electric field at the SiC-SiO_2 interface during the blocking state. Simulation results have shown that for a drift region width higher than 1.6 μm, the oxide field reaches 4 MV cm^{-1} prior to the avalanche breakdown in SiC. Decreasing the JFET width increases the resistance since it pinches off the current path but reduces the cell area; consequently, the effect of the specific ON-resistance is negligible [77]. An optimum width of the JFET region can be determined. When an IGBT has an optimum width, its blocking voltage is limited by the avalanche breakdown for the entire range of the lightly doped drift region. In [126], it is shown that for their design, the optimum width is 1 μm.

To optimize the parameters of a PT IGBT, a physics-based model, given in [127], can be used. For this purpose, the device is divided into five regions, as shown in Fig. 5.14: P emitter (collector terminal), N^+ field-stop layer, N^- drift region, P well, and N^+ emitter. Fig. 5.14 also shows the external currents (emitter and collector currents I_E and I_C), the internal electron and hole currents (at junctions J_0 I_{n0} and I_{p0}, J_1 I_{n_1} and I_{p_1}, and J_2 I_{n_2} and I_{p_2}), and the capacitive currents from the displacement layers (I_{disp_2} and I_{CG}). The IGBT is a gate-controlled device and is used as a controllable switch in power electronic applications. Given its P-N-P-N structure, the IGBT is a voltage bidirectional switch, that is, it can conduct current in one direction only, but it can block the voltage of both polarities. The reverse-blocking capability is rarely used in conventional power converter configurations.

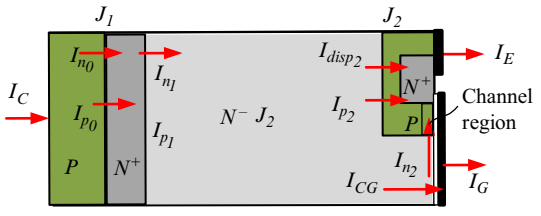

FIG. 5.14 One-dimensional cross section used for modeling of PT IGBT showing the currents in each region.

Frequently, an antiparallel diode is added as a separate chip to accommodate converter configurations, such as the voltage source inverter, which require a current bidirectional switch. In the normal forward blocking operation of the IGBT, a depletion layer is formed at the MOS end of the drift region (at the N^- drift region/P-well junction), while in a reverse-blocking operation, it is formed at the P emitter/drift region junction. In forward blocking, a depletion layer is never formed at the P emitter. For this reason, no displacement current for junction J_0 is included. The model can be easily extended to reverse-blocking IGBTs by allowing a depletion layer at the junction J_0.

The hole and electron currents in the P-emitter layer end of a power IGBT at junctions, J_0, I_{p0}, and I_{n0}, depend on the process happening in the FS layer. The sum of them is equal to the IGBT collector current:

$$I_C = I_{p0} + I_{n0} \tag{5.129}$$

where N_N is the doping concentration of the FS layer.

Adding an FS layer allows a reduction in the drift region thickness for the same blocking voltage and also speeds up the IGBT turn-off process but creates two junctions, J_0 and J_1. Due to electron reverse injection into the P^+ emitter, there is a small electron current I_{n0} at junction J_0. These electrons travel through the buffer layer from the drift region. The hole current, I_{p0}, injected from the P^+ emitter, travels mostly by diffusion through the FS layer. Since the layer is typically quite thin in comparison with the hole diffusion length, L_{p_N}, there is little recombination, and most of the holes reach the drift region. This hole current is I_{p1} and represents the hole injection from the buffer layer into the drift region.

The difference between the two hole currents at junctions J_1 and J_0 is due to the recombination, and it is compensated for by an increase in the electron current, so that the electron current I_{n1} at junction J_1 can be presented by a sum of the recombination component plus the reverse injection electron current I_{n0}. Static conditions are assumed up to now, while under dynamic conditions, an additional hole current component due to variations in the stored charge in the buffer layer should be considered.

Assuming a quasistatic state, the continuity equation of the holes in the buffer layer is then expressed by

$$D_{pN}\frac{d^2p(x)}{dt^2} = \frac{p(x)}{\tau_{pN}} \tag{5.130}$$

where τ_{pN} is the minority lifetime and D_{pN} is the hole diffusivity in the field-stop layer. The solution for the excess hole concentration in the buffer layer is given by

$$p(x) = \frac{\left[p_{N0}\sinh\left(\frac{W_N - x}{L_{pN}}\right) + p_{NW}\sinh\left(\frac{x}{L_{pN}}\right)\right]}{\sinh\left(\frac{W_N}{L_{pN}}\right)} \tag{5.131}$$

where W_N is the width of the buffer layer, p_{N0} and p_{NW} are the hole concentrations at the two edges of the field-stop layer (junctions J_0 and J_1), and L_{pN} is the hole diffusion length.

Under the low-level injection, the minority hole current is mostly diffusion current, so it is expressed as

$$I_p = qAD_{pN}\frac{dp}{dx} \tag{5.132}$$

Thus, the hole current at the junction J_0 is obtained substituting the derivative of Eq. (5.131) for $x = 0$ into Eq. (5.132):

$$I_{p0} = qAD_{pN}\left.\frac{dp}{dx}\right|_{x=0} = \frac{qAD_{pN}}{L_{pN}\sinh\left(\frac{W_N}{L_{pN}}\right)}\left[p_{N0}\cosh\left(\frac{W_N}{L_{pN}}\right) - p_{NW}\right] \tag{5.133}$$

Assuming quasiequilibrium, the reverse injection current I_{n0} at junction J_0 is given by

$$I_{n0} = \frac{AI_{sne}N_N p_{N0}}{n_i^2} \tag{5.134}$$

where I_{sne} is the emitter electron saturation current.

The current continuity at the boundaries of the buffer layer requires that

$$I_C = I_{n0} + I_{p0} = I_{n1} + I_{p1} + I_{dis1} \tag{5.135}$$

Then, the hole concentration at the junction J_1 is obtained by substituting Eqs. (5.133), (5.134) into Eq. (5.135) and then reorganizing the equation to the form:

$$p_{N0} = \left[\frac{AI_{sne}N_N}{n_i^2} + \frac{qAD_{pN}}{L_{pN}\sinh\left(\frac{W_N}{L_{pN}}\right)}\right]^{-1}\left[I_C + \frac{qAD_{pN}}{L_{pN}\sinh\left(\frac{W_N}{L_{pN}}\right)}p_{NW}\right] \tag{5.136}$$

The hole current I_{p1} at junction J_1 is obtained similar to I_{p0}, only $x = W_N$:

$$I_{p1} = qAD_{pN}\left.\frac{dp}{dx}\right|_{x=W_N} = \frac{qAD_{pN}}{L_{pN}\sinh\left(\frac{W_N}{L_{pN}}\right)}\left[p_{N0} - p_{NW}\cosh\left(\frac{W_N}{L_{pN}}\right)\right] + I_{QN} \tag{5.137}$$

The current, I_{QN}, represents the capacitive current due to the variation in the charge Q_N stored in the buffer region:

$$I_{QN} = -\frac{dQ_N}{dt} \tag{5.138}$$

The charge Q_N can be approximated as

$$Q_N = qAW_N\frac{p_{N0} + p_{NW}}{2} \tag{5.139}$$

The hole concentration, p_{NW}, at the boundary between the buffer layer and the drift region is obtained by applying the Boltzmann relationship for the junction J_2 under the assumption of high-level injection in the drift region ($p_{N^-0} >> N_{N^-}$):

$$p_{NW} = \frac{p_{N^-0}(p_{N^-0} + N_{N^-})}{N_N} = \frac{p_{N^-0}^2}{N_N} \tag{5.140}$$

where p_{N^-0} is the hole concentration in the beginning and N_{N^-} is the doping concentration of the N^- drift region.

The voltages across the junctions J_0 and J_1 are

$$V_{J0} = V_T\ln\left(\frac{p_{N0}N_N}{n_i^2}\right) \tag{5.141}$$

$$V_{J1} = V_T\ln\left(\frac{N_{N^-}}{p_{N^-0}}\right) \tag{5.142}$$

The voltage drop in the N^- drift region is calculated during the ON-state. The charge distribution and the boundary current components in the N^- region are shown in Fig. 5.15. The injected excess carrier concentration is determined by the ADE. As for all bipolar power switches, high-level injection and quasineutral conditions exist. Under high-level injection conditions, the ADE (Eq. 5.35) describes the carrier dynamics.

It was mentioned that, during forward blocking of an IGBT, no depletion layer forms at junction J_1; therefore, its thickness, x_1, can be approximated as zero. Therefore, the charge storage region, which operates under high-level injection and is described by the ADE, Eq. (5.35), has $x_1 \equiv 0$ and $\frac{dx_1}{dt} \equiv 0$. The Fourier series solution of the ADE, given by Eq. (5.39), can be simplified to

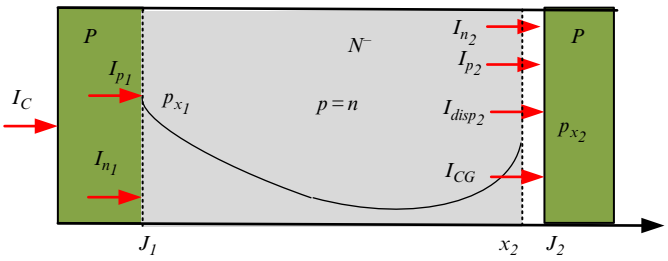

FIG. 5.15 Charge distribution and boundary current components in the N^- region of PT IGBT.

For $k > 0$

$$D_{N^-}\left[\left.\frac{\partial p(x,t)}{\partial x}\right|_{x2}(-1)^k - \left.\frac{\partial p(x,t)}{\partial x}\right|_{x1}\right] = \frac{x_2}{2}\left(\frac{dp_k(t)}{dt} + \left[\frac{1}{\tau} + \frac{D_{N^-}k^2\pi^2}{x_2^2}\right]p_k(t)\right) + \left(\sum_{\substack{n=1 \\ n\neq k}}^{\infty}\frac{n^2}{n^2-k^2}\left[(-1)^{n+k}\frac{dx_2}{dt}\right]p_n(t) + \frac{p_k(t)}{4}\left(\frac{dx_2}{dt}\right)\right) \quad (5.143)$$

For $k = 0$

$$D\left[\left.\frac{\partial p(x,t)}{\partial x}\right|_{x_2} - \left.\frac{\partial p(x,t)}{\partial x}\right|_{x1}\right] = x_2\left(\frac{dp_0(t)}{dt} + \frac{p_0(t)}{\tau}\right) - \sum_{n=1}^{\infty}\left[(-1)^n\frac{dx_2}{dt}\right]p_n(t)$$

The solution to the ADE is determined by using the boundary conditions at the edges of the charge storage region:

$$\left.\frac{\partial p}{\partial x}\right|_{x_1} = \frac{1}{2q}\left(\frac{J_n}{D_n} - \frac{J_p}{D_p}\right)\Bigg|_{x_1} \quad \text{and} \quad \left.\frac{\partial p}{\partial x}\right|_{x_2} = \frac{1}{2q}\left(\frac{J_n}{D_n} - \frac{J_p}{D_p}\right)\Bigg|_{x_2} \quad (5.144)$$

The current continuity equation at junction J_2 is determined by

$$I_C = I_{n_2} + I_{p_2} + I_{disp_2} + I_{CG} \quad (5.145)$$

The electron current at junction J_2 is the MOS channel current:

$$I_{n_2} = I_{mos} \quad (5.146)$$

Substituting Eqs. (5.146) in (5.145) and then in Eq. (5.143), the left side of the solution of the ADE (Eq. 5.143), for even and odd numbers of k, can be calculated by the following equations:

$$I_{odd} = -D\left(\left.\frac{\partial p}{\partial x}\right|_{x_2} + \left.\frac{\partial p}{\partial x}\right|_{x_1}\right) = \begin{vmatrix} I_{n_1} \\ I_{mos} \\ I_C \\ I_{disp_2} \\ I_{CG} \end{vmatrix} \frac{1}{2qA}\begin{vmatrix} 2 & -2 & \frac{2D}{D_p} & -\frac{D}{D_p} & -\frac{D}{D_p} \end{vmatrix}$$

$$I_{even} = D\left(\left.\frac{\partial p}{\partial x}\right|_{x_2} - \left.\frac{\partial p}{\partial x}\right|_{x_1}\right) = \frac{1}{2qA}\begin{vmatrix} I_{n1} \\ I_{mos} \\ I_C \\ I_{disp2} \\ I_{CG} \end{vmatrix} \begin{vmatrix} -2 & +2 & 0 & +\frac{D}{D_p} & +\frac{D}{D_p} \end{vmatrix} \quad (5.147)$$

The boundary carrier densities p_{x1} and p_{x2} at the boundaries x_1 and x_2 are calculated using the equations:

$$p_{x_1} = \sum_{k=0}^{M-1} p_k \quad \text{and} \quad p_{x_2} = \sum_{k=0}^{M-1}(-1)^k p_k \quad (5.148)$$

The voltage across the N^-P depletion layer, V_{d_2}, is calculated by the following equation:

$$V_{d_2} = \begin{cases} 0 & \text{if } p_{x_1} > 0, \\ -K_{FV}p_{x_2} & \text{otherwise.} \end{cases} \quad (5.149)$$

The associated depletion width, W_{d_2}, is calculated using a step doping concentration change on each side of the junction:

$$W_{d_2} = \sqrt{\frac{2\varepsilon V_{d_2}}{qN_{N^-} + \frac{|I_C|}{Av_{sat}}}} \quad (5.150)$$

The boundary position x_2 is calculated by

$$x_2 = W_{N^-} - W_{d_2} \quad (5.151)$$

The displacement current at x_2 is composed of two components: I_{disp_2} flowing into the P well and I_{CG} associated with Miller capacitance and accumulation layer charge. The P-well displacement current is given by

$$I_{disp_2} = C_{J_2}\frac{dV_{d2}}{dt} = \varepsilon A\frac{1}{W_{d_2}}\frac{dV_{d_2}}{dt} \quad (5.152)$$

To calculate the Miller capacitance, it is assumed that the depletion layer extends under the gate from P well and only extends downward through the drift region once the accumulation layer has been removed from the gate in the center of the intercell region. Therefore, the width of the Miller capacitance, W, is

$$W = W_{d2} - l_m - l_1 \quad (5.153)$$

where l_m is an intercell half width and l_1 is a width due to voltage V_{GE}:

$$l_1 = \sqrt{\frac{2\varepsilon V_{GE}}{qN_{N^-}}} \quad (5.154)$$

The Miller capacitance is given by the series combination of the oxide capacitance $C_{ox}Aa_i$ and the depletion capacitance $\frac{\varepsilon Aa_i}{W}$:

$$C_{CG} = \frac{C_{ox}Aa_i}{1 + \frac{C_{ox}}{\varepsilon}W} \quad (5.155)$$

where a_i is the ratio of intercell area to the total die area.

Due to Miller capacitance, the current I_{CG} is

$$I_{CG} = C_{CG}\left(\frac{dV_{d2}}{dt} - \frac{dV_{GE}}{dt}\right) \quad (5.156)$$

where

$$\frac{dV_{GE}}{dt}=\frac{1}{C_{GE}+C_{GC}}\left(I_G+C_{CG}\frac{dV_{d2}}{dt}\right) \tag{5.157}$$

The voltage drop in the carrier storage region V_{N^-} is calculated based on the injected carrier concentration:

$$V_{N^-}\approx\frac{I_C}{qA\left(\mu_n+\mu_p\right)}\frac{x_2-x_1}{M-1}\sum_{\kappa=0}^{M-1}\left[\frac{1}{p_{T(k)}-p_{T(k-1)}}\ln\left(\frac{p_{T(k)}}{p_{T(k-1)}}\right)\right]+V_T\left(\frac{\mu_n-\mu_p}{\mu_n+\mu_p}\right)\ln\left(\frac{p_{x2}}{p_{x1}}\right) \tag{5.158}$$

where the carrier distribution $p_{T(k)}$ is calculated as

$$p_{T(k)}=p\left(x_1+\frac{k(x_2-x_1)}{M-1}\right)+\frac{\mu_n N_{N^-}}{\mu_n+\mu_p} \tag{5.159}$$

IGBTs are used as switches, operating mainly in two stages: ON and OFF. The MOS region can be modeled as a simple MOSFET. During the ON-state, the MOSFET operates either in the triode region or in the saturation region, while during the OFF-state, it operates in cut-OFF. Therefore, during the OFF-state, the gate-source voltage is smaller than the threshold voltage ($V_{GS}<V_{TH}$), and current I_{mos} is zero. During the ON-state, the gate-source voltage is larger than the threshold voltage ($V_{GS}>V_{TH}$), and current I_{mos} is calculated by

$$I_{mos}=\begin{cases}\frac{K_p}{2}\left[2V_{DS}(V_{GS}-V_{TH})-V_{DS}^2\right] & \text{if } V_{DS}\le V_{GS}-V_{TH}\\ \frac{K_p}{2}(V_{GS}-V_{TH})^2 & \text{otherwise}\end{cases} \tag{5.160}$$

The voltage drop V_{CE} across PT IGBT is composed of three components: voltages across the junction J_1, voltage across the two depletion regions V_{d2}, and voltage across the carrier storage region V_{N^-}.

$$V_{CE}=V_{j_1}+V_{d_2}+V_{N^-} \tag{5.161}$$

5.3.7 SiC Thyristor

As the trend of power electronics industry is moving toward high voltage, high current, and high frequency, the conduction and switching losses of the power semiconductor devices should be at an acceptable level. Up to now, SCRs are still the most powerful devices currently available in pulse power applications. A single SCR can block 8 kV and conduct 4 kA, and a GTO can block 6 kV and conduct 6 kA [128]. However, due to the high switching losses of SCRs and GTOs, their maximum operation frequency is limited to 1 kHz. Because of their switching and driving characteristics, the device paralleling for high-power applications is impossible. SCRs and Si GTOs have a positive temperature coefficient and their operating temperature is limited to 100°C junction temperature, since the leakage current increases significantly above that temperature. Typically, this requires expensive active liquid cooling to maintain safe operation conditions. The leakage current of a SiC GTO is extremely small at 300°C and only requires forced air cooling.

SiC GTOs and IGBTs are two devices that can soon be utilized in utility-based power handling equipment, such as flexible AC transmission systems (FACTS) and high-voltage DC transmissions (HVDCT). A 4H-SiC thyristor is a better candidate because it is capable of higher current densities than a SiC IGBT, since the physical mechanism for conductivity modulation is more effective in the thyristor than the IGBT. Also, SiC IGBTs are limited to 150°C junction temperature due to a limitation of the gate oxide reliability.

In the near future, large-area SiC GTOs will be utilized in FACTS and HVDCT due to three main advantages: a smaller number of devices connected in series since they have higher blocking capability (20–30 kV with the present technology), low current leakage, and reduced cooling requirements due to the ability of SiC GTOs to operate at higher junction temperatures (300°C if the packaging issues are solved). However, the thyristor requires more complex external circuitry as it is a current-controlled device.

The first SiC symmetrical thyristors (700 V with a rated current of 6 A and a forward drop of 3.9 V) were demonstrated by Cree, Inc. [129]. Since then, scientists from Cree and other institutions have designed and fabricated different asymmetrical *NPNP* devices. The limitations of the epilayer thickness and device footprint have been the main obstacles for increasing the blocking voltage and the current capability of the devices, but different scientific groups have worked in the last two decades to improve design, fabrication, and characterization of different power semiconductor devices that were used for an evaluation of SiC GTOs from 1.77 kV blocking voltage with 4 V voltage drop at 100 A and 200°C [130] demonstrated in 2005 to a 22 kV blocking voltage with approximately 6.5 V voltage drop at 100 A and 150°C reported 10 years later. The most important developments of this evaluation were increasing the wafer diameter to 5.9″ (150 mm) [131]; the electrically active defects, such as dislocations, point defects, and silicon inclusion, have been drastically reduced; the problem of the foreword voltage drop, V_F, drift due to high density of the basal plane dislocation has been solved by improving the epitaxial growth; and improving the life time of the minority carrier concentration in the lightly doped drift region.

Due to very high blocking voltage (>20 kV) for SiC GTOs, they have a low-doped thick drift region that has high resistivity. In order to obtain significantly low ON-state losses, the ambipolar diffusion length of the minority carriers in the drift region should be significantly large, that is, the minority carrier

lifetime must be made as long as possible. For an *N*-type SiC epilayer, a significant improvement of carrier lifetime has been achieved from 0.69 to 9.5 μs by reducing the $Z_{1/2}$ center via two-step thermal treatment (thermal oxidation and Ar annealing) for a 148 μm N-type epilayer [132]. However, there is some difficulty for enhancement of the carrier lifetimes in *p*-type epilayers [133]. In [134], the lifetime in *P*-type SiC epilayer was improved from 1 to 4 μs by oxidation at 1300°C for 5 h prior to the metal contact processing; however, the carrier lifetime was not uniform across the chip area. The lifetime uniformity can be enhanced by controlling the point defects in SiC by low-energy electron irradiation [132].

Currently, the thyristors are made on N^+ 4H-SiC substrates, because P^+ substrates have higher resistance than the N^+ substrates. Recently, a significant improvement in N^+ 4H-SiC substrate quality has been reported. An IGBT with an ultrahigh blocking voltage of 27 kV was built on N^+ 4H-SiC substrate [118]. For a Si power thyristor to minimize power losses, the epilayer is N^- type. Therefore, in the future, power thyristors will build on P^+ substrate with an N^- epilayer.

To optimize the parameters of the transistor, a physics-based model for GTOs employing a Fourier-based solution for the ambipolar diffusion equation of the N^- lightly doped drift region and a lumped-charge method for the P-base region can be used. A new level-3 physics-based model for GTOs employs a Fourier-based solution for the ambipolar diffusion equation of the lightly doped N^- drift region, and a lumped-charge method for the *P*-base region is provided below. In addition to the external electric characteristics, the model can also provide internal physical and electric information, such as junction voltages, and the charge distribution in the buffer layer and the base regions. Fig. 5.16 shows the schematic structure of a SiC high-power thyristor with the direction of the flowing currents.

A major difficulty in analyzing and modeling the performance of bipolar power devices is due to the different carrier density distribution in the different regions. The behavior of the GTO is modeled by dividing the device into different regions.

The P^+ and N^+ emitter regions have high doping concentration, and therefore, there is a significant electron concentration adjacent to the P^+N junction and a significant hole concentration adjacent to the PN^+ junction due to the equal concentrations of holes and electrons. As a result of these high concentrations, minority carriers flow into the highly doped P^+ and N^+ emitter regions, where they recombine with holes and electrons, respectively. The process is known as emitter recombination. The resulting electron and hole currents due to the recombination are

$$I_{n0} = qAh_p p_{N0}^2 \tag{5.162}$$

$$I_{p3} = qAh_n n_{PW}^2 \tag{5.163}$$

where p_{N0} and n_{PW} are the hole and the electron concentrations at junctions J_0 and J_3, respectively. The recombination parameters, h_p and h_n, calculated by Eqs. (5.32), (5.63), depend on the emitter properties, such as doping level (N_{P^+} and N_{N^+}), electron and hole diffusivities (D_n and D_p), and electron and hole lifetime (τ_n and τ_p). The hole and emitter currents in the P^+ and N^+ emitter regions are

$$I_{p0} = I_A - I_{n0} \tag{5.164}$$

$$I_{n3} = I_A - I_{p3} \tag{5.165}$$

Adding a buffer layer allows a reduction of the drift region thickness for the same blocking voltage and speeds up the thyristor turn-off process, but it creates two junctions, J_1 and J_2. Due to electron reverse injection into the P^+ emitter, there is a small electron current, I_{n0}, at junction J_0. These electrons travel through the buffer layer coming from the drift region. The hole current, I_{p0}, injected from the P^+ emitter travels mostly by diffusion through the buffer layer. Since the buffer layer is typically quite thin in comparison with the diffusion length in the buffer layer, L_{p_N}, there is little recombination in the buffer layer, and most of the hole current reaches the drift region. This current, I_{p1}, presents the hole injection from the buffer layer into the drift region.

The difference between the two hole currents at the junction J_1 and J_0 is due to the recombination, and it is compensated by an increase in the electron current, so that the electron current I_{n1} at junction J_1 can be presented by a sum of the

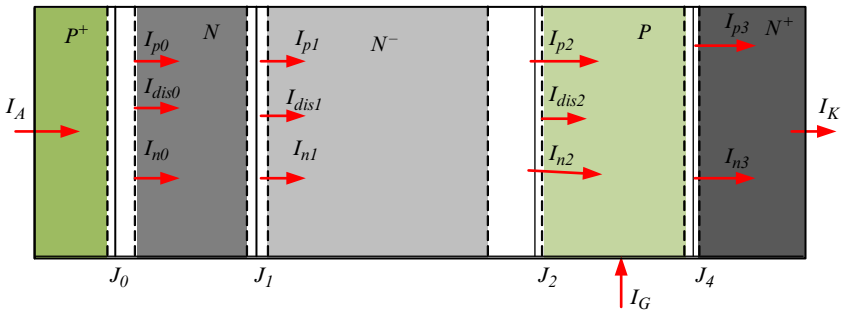

FIG. 5.16 Schematic structure of SiC high-power thyristor.

recombination component plus the reverse injection electron current I_{n0}. Static conditions are assumed up to now, while under the dynamic condition an additional hole current component due to variations in the stored charge in the buffer layer should be consider.

Assuming a quasistatic state, the continuity equation of the holes in the buffer layer is then expressed by

$$D_{pN}\frac{d^2p(x)}{dt^2}=\frac{p(x)}{\tau_{pN}} \tag{5.166}$$

where τ_{pN} is the minority lifetime and D_{pN} is the hole diffusivity in the buffer layer. The solution for the excess hole concentration in the buffer layer is given by

$$p(x)=\frac{\left[p_{N0}\sinh\left(\frac{W_N-x}{L_{pN}}\right)+p_{NW}\sinh\left(\frac{x}{L_{pN}}\right)\right]}{\sinh\left(\frac{W_N}{L_{pN}}\right)} \tag{5.167}$$

where W_N is the width of the buffer layer, p_{N0} and p_{NW} are the hole concentrations at the two edges of the buffer layer (junctions J_0 and J_1), and L_{pN} is the diffusion length of the holes.

Under the low-level injection, the minority hole current is mostly diffusion current, so it is expressed as

$$I_p=qAD_{pN}\frac{dp}{dx} \tag{5.168}$$

Thus, the hole current at the junction J_0 is obtained by substituting the derivative of Eq. (5.167) for $x=0$ into Eq. (5.168):

$$I_{p1}=qAD_{pN}\left.\frac{dp}{dx}\right|_{x=0}=\frac{qAD_{pN}}{L_{pN}\sinh\left(\frac{W_N}{L_{pN}}\right)}\left[p_{N0}\cosh\left(\frac{W_N}{L_{pN}}\right)-p_{NW}\right] \tag{5.169}$$

Assuming quasiequilibrium, the reverse injection current I_{n0}, at junction J_0 is given by

$$I_{n1}=\frac{I_{sne}N_Np_{N0}}{n_i^2} \tag{5.170}$$

where I_{sne} is the emitter electron saturation current, which is usually small, and N_N is the doping concentration of the buffer layer.

The current continuity at the boundaries of the buffer layer requires that

$$I_A=I_{n0}+I_{p0}=I_{n1}+I_{p1}+I_{dis1} \tag{5.171}$$

Then, the hole concentration at the junction J_1 is obtained by substituting Eqs. (5.169), (5.170) into Eq. (5.171) and then reorganizing to the form:

$$p_{N0}=\left[\frac{AI_{sne}N_N}{n_i^2}+\frac{qAD_{pN}}{L_{pN}\sinh\left(\frac{W_N}{L_{pN}}\right)}\right]^{-1}\left[I_A+\frac{qAD_{pN}}{L_{pN}\sinh\left(\frac{W_N}{L_{pN}}\right)}p_{NW}\right] \tag{5.172}$$

The hole current, I_{p1}, at junction J_1 is obtained similar to I_{p0}, only $x=W_N$:

$$I_{p1}=qAD_{pN}\left.\frac{dp}{dx}\right|_{x=W_N}=\frac{qAD_{pN}}{L_{pN}\sinh\left(\frac{W_N}{L_{pN}}\right)}\left[p_{N0}-p_{NW}\cosh\left(\frac{W_N}{L_{pN}}\right)\right]+I_{QN} \tag{5.173}$$

The current, I_{QN}, represents the capacitive current due to the variation in the charge, Q_N, stored in the buffer region.

$$I_{QN}=-\frac{dQ_N}{dt} \tag{5.174}$$

The charge, Q_N, can be approximated as

$$Q_N=qAW_N\frac{p_{N0}+p_{NW}}{2} \tag{5.175}$$

The hole concentration, p_{NW}, at the boundary between the buffer layer and the drift region, is obtained by applying the Boltzmann relationship for the junction J_1 under the assumption of high-level injection in the drift region ($p_{N^-0}>>N_{N^-}$):

$$p_{NW}=\frac{p_{N^-0}(p_{N^-0}+N_{N^-})}{N_N}=\frac{p_{N^-0}^2}{N_N} \tag{5.176}$$

where p_{N^-0} is the hole concentration in the beginning and N_{N^-} is the doping concentration of the N^- drift region that is denoted below as p_{x1}.

The voltages across the junctions, J_0 and J_1, are

$$V_{J1}=V_T\ln\left(\frac{p_{N0}N_N}{n_i^2}\right) \tag{5.177}$$

$$V_{J2}=V_T\ln\left(\frac{N_{N^-}}{p_{N^-0}}\right) \tag{5.178}$$

The GTO thyristor requires a thick drift region to support a high blocking voltage. A simple charge control modeling approach cannot be applied for the drift region because the transient duration compares with or is shorter than the transient time of the charge carriers. In this case, the charge dynamics in the drift region can be described by the continuity and the transport equations. The charge profile in the thick drift region can be assumed as one-dimensional over more than 90% of the volume, which makes the analysis simple. Also, high-level

injection conditions can be assumed during the time of the transient and static state. Under this assumption and quasineutrality, the one-dimensional ambipolar diffusion equation that describes the carrier dynamics in the majority of this region is given by Eq. (5.35). The equations from Section 5.3.2.2 for SiC PiN diodes in Eqs. (5.35)–(5.61) are the same for a power GTO, so it will not be repeated.

The junction voltage V_{J2} between the lightly doped drift region N^- and the P base is

$$V_{J2} = 2V_T \ln\left(\frac{p_{x2}}{n_i}\right) \tag{5.179}$$

The lumped-charge method can be used to model the charge behavior in the base region due to high doping level and comparatively narrow base width. Using the continuity equation for the base region, the injected minority carrier charge can be described by the relation below:

$$\frac{dQ_P}{dt} + \frac{Q_P}{\tau_{PHL}} = I_{n3} - I_{n2} = I_{p2} + I_G + I_{disp2} - I_{p3} \tag{5.180}$$

where τ_{PHL} is the high-level lifetime in the P-base region. The electron concentration at the P-base region boundary, n_{P0}, is related to p_{x2} by the doping concentration of the base, N_P, by the equation:

$$n_{P0} = \frac{p_{x2}^2}{N_P} \tag{5.181}$$

The total electron charge in the base can be expressed as

$$Q_P = \frac{n_{P0} + n_{PW}}{2} qAW_P \tag{5.182}$$

where n_{PW} is the electron concentration at the base region boundary from the N^+ emitter side and W_P is the base width. Since the diffusion length in the P-base region is much greater than the base width, the gradient of the electron concentration may be approximated linearly. Then, the electron current at junction, J_3, is

$$I_{n3} = qD_nA\frac{n_{PW} - n_{P0}}{W_P} \tag{5.183}$$

The junction voltage V_{J3} between the P-base and the N^+ emitter can be calculated by the equation:

$$V_{J2} = V_T \ln\left(\frac{n_{PW}(n_{PW} + N_P)}{n_i^2}\right) \tag{5.184}$$

The voltage drop V_{AK} across the SiC thyristor is composed of seven components including voltages across junctions J_0, J_1, J_2, and J_3, the voltage across the two depletion regions, V_{d1} and V_{d2}, and the voltage across the drift region, V_{N^-}:

$$V_{AK} = V_{J0} + V_{J1} + V_{J2} + V_{J3} + V_{d1} + V_{d2} + V_{N^-} \tag{5.185}$$

5.4 GaN Power Devices

Due to the significant improvements in GaN material growth technology, engineers have utilized different GaN-based power devices in high-frequency and power applications. The device designers are trying to improve performance and reliability and optimize their FOM parameters to obtain high system efficiency. GaN HEMT devices ranging up to 650 V are available on the market. The physics and important parameters of GaN power devices are discussed below.

5.4.1 Lateral GaN Schottky Barrier Diodes

To achieve a high-efficiency, high-density power conversion system, the high-voltage diodes used in a system should have low turn-ON voltage, V_T, low ON-resistance, R_{ON}, low leakage current, and short reverse recovery time. Due to the wide bandgap of GaN and high electron mobility in the 2DEG, AlGaN-/GaN-based lateral Schottky barrier diodes (SBDs) on a Si, sapphire, or SiC substrate have demonstrated superior performance over rectifiers made in other material systems, such as gallium arsenide (GaAs)-based devices. The advantages of lateral GaN-based devices are that they have a very low ON-resistance because of the extremely high electron concentrations in the 2DEG, up to 10–20 times higher that GaAs-based devices. Lateral SBDs have a small junction capacitance compared with conventional Schottky diodes and, therefore, low reverse recovery times. Also, a lateral design approach enables the standard GaN HEMT process flow to be used for integrating a Schottky diode with a high-voltage transistor [135].

A cross section of a typical lateral AlGaN/GaN heterostructure Schottky diode is shown in Fig. 5.17. The epitaxial layers are grown by metal-organic chemical vapor deposition on a substrate, and then, two types of contacts, ohmic and Schottky, are formed.

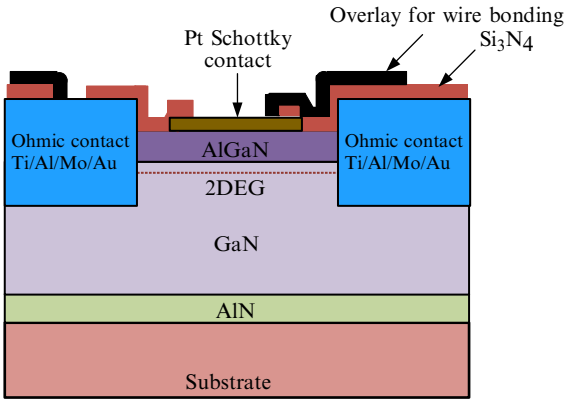

FIG. 5.17 Cross section of a lateral AlGaN/GaN heterostructure Schottky diode (substrate, AlN buffer layer, GaN, and AlGaN).

The quality of the epitaxial GaN depends on the quality of the substrate. Si, sapphire, SiC, and GaN can be used for the substrate. Si substrates have good quality, are significantly large in size, and are inexpensive. They can be used for GaN devices for low-power-density applications, where the losses are not high and the device temperature does not exceed the maximum operating junction temperature. Using a Si substrate for GaN devices introduces a number of critical issues due to the lattice mismatch and the difference in the thermal expansion coefficients, which affects the quality and device reliability [34]. Sapphire substrates are cost-effective and widely used for electronic devices with high power density and high-pulsed-output power densities, but it has a high lattice mismatch to GaN and poor thermal conductivity. Therefore, it is difficult to remove heat produced during operation. For high-power-density applications, the GaN devices should be grown on a SiC substrate since the SiC thermal conductivity is three times higher than Si, which leads to improved heat dissipation. The qualities of SiC substrates have improved significantly in the last few years, but they are still not widely available at low cost. GaN substrates have only recently been developed and used for power devices, although they are most important for optical applications. By using GaN substrates, the lattice mismatch is fully eliminated, but the cost of these substrates is high, and large diameters are not available. GaN layers grown on GaN substrates have low defect densities compared with layers grown on other types of substrate. Therefore, for devices of the same physical dimensions, devices utilizing GaN substrates will exhibit better OFF-state and ON-state characteristics.

Growth of GaN onto a Si or a sapphire substrate offers the very attractive potential for incorporating GaN devices. However, because of the large difference in lattice constant, crystal structure, and thermal expansion coefficient, it is difficult to epitaxially grow GaN. To solve this problem, a buffer layer that minimizes the mismatch between the substrate and GaN allows growth with a quality equal to GaN. Several buffer layer types have been used to grow GaN on Si, for example, SiC [136], AlN [137], GaAs [138] and silicon nitride (Si_3N_4) [139]. An AlN buffer layer is one of the best candidates for obtaining high-quality GaN on a Si substrate. It was found in [140] that a thicker AlN buffer layer resulted in higher crystalline quality of consequently grown GaN film.

The heterostructure consisting of undoped GaN and undoped zinc blende (cubic) ($Al_{0.3}Ga_{0.7}N$) is grown on the AlN buffer layer. Due to spontaneous and piezoelectric polarization, a 2DEG is created in the channel at the AlGaN/GaN interface [141]. The sheet electron density and the mobility in the channel are significantly high, $\sim 10^{13}\,\text{cm}^{-2}$ and $1500\,\text{cm}^2\,(\text{V s})^{-1}$, respectively, which result in low ON-state resistance.

Two types of contacts are formed in a lateral SBD. Metals or alloys such as palladium (Pd), platinum (Pt), indium-platinum (IrPt), palladium-silver (PdAg), and nickel/gold (Ni/Au) that have higher work functions than GaN can be used to form a Schottky barrier to the channel. The Schottky barrier is formed to the AlGaN interfacial layer of an AlGaN/GaN heterostructure. Since the channel has a high electron concentration, the depletion length is significantly shorter than in conventional diodes, although the lateral SBDs have a greater barrier height.

The ohmic contacts of a GaN power device (diodes and transistors), in most cases, represent a metal stack that is formed by thermal evaporation of different metals in multilayers following by rapid thermal annealing. The devices should be optimized to have low specific conduction resistance, and they should also be thermally stable. For *N*-type GaN, metal stacks such as titanium/aluminum/molybdenum/gold (Ti/Al/Mo/Au) and titanium/aluminum/platinum/gold (Ti/Al/Pt/Au) can be used to form ohmic contacts because of their excellent characteristics. A specific contact resistivity as low as $4.7 \times 10^{-7}\,\Omega\,\text{cm}^{-2}$ was obtained by rapid thermal annealing of evaporated Ti/Al/Mo/Au [142]. Also, Ti/Al/Pt/Au contacts on GaN have shown a minimum contact resistivity of $8.4 \times 10^{-5}\,\Omega\,\text{cm}^{-2}$ after annealing [143].

Applying a positive bias, higher than the turn-ON voltage, V_T, to the anode, causes electrons to flow from cathode to the anode. For an applied anode to cathode voltage, V_{AC}, higher than $3kT/q$, the current through the diode is

$$I_A = AA^*T^2 e^{-\frac{q\phi_B}{kT}}\left(e^{-\frac{qV_{AC}}{kT}} - 1\right) \tag{5.186}$$

where A is the Schottky contact area and A^* is the Richardson constant ($26.4\,\text{A cm}^{-2}\text{K}^{-2}$), and the potential barrier at the metal-semiconductor interface, ϕ_B, depends on the work function of the metal or alloy used for the Schottky contact.

As a negative bias is applied to the Schottky contact, a depletion layer between the Schottky contact and the 2DEG is formed. Increasing the negative voltage, the depletion layer expands and the junction capacitance decreases, resulting in a nonlinear capacitance-voltage characteristic [144]. A simple equivalent circuit model of a Schottky/2DEG diode is shown in Fig. 5.18. It consist of a voltage-dependent junction capacitance, C_j, series resistance, R_s, and a shunt capacitance, C_{sh}, [144].

The junction capacitance, C_j, is

$$C_j(V_{AC}) = \frac{W\varepsilon}{\pi} A \ln\left(\frac{\left(R^2 + d_{dep}^2\right)^{1/2} + R}{\left(R^2 + d_{dep}^2\right)^{1/2} - R}\right) \tag{5.187}$$

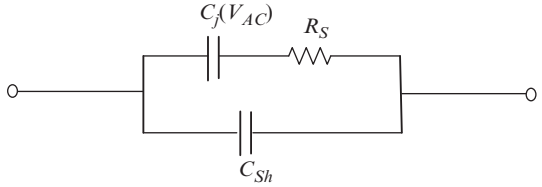

FIG. 5.18 A simple equivalent circuit model of a Schottky diode.

where W is the Schottky contact width and R is the half height of the Schottky metallization. The depletion width d_{dep} is

$$d_{dep}(V_{AC}) = \frac{2\varepsilon(V_{bi} - V_{AC})}{qn_s} \tag{5.188}$$

where V_{bi} is the built-in voltage, V_{AC} is the reverse bias applied voltage, and n_s is the 2DEG sheet charge density. The series resistance, R_s, is a sum of the undepleted channel resistance, R_{CH}, and the ohmic contact resistance, R_{OC}:

$$R_s = R_{CH} + R_{OC} \tag{5.189}$$

The undepleted channel resistance, R_{CH}, is

$$R_{CH} = \frac{L_{AC} - d_{dep}}{q\mu_n n_s W} \tag{5.190}$$

where L_{AC} is the distance between anode and cathode (channel length) and μ_n is the electron mobility in 2DEG. The ohmic contact resistance, R_{OC}, is

$$R_{OC} = \frac{r_{sp}}{W} \tag{5.191}$$

where r_{sp} is the specific contact resistivity. The shunt capacitance, C_{sh}, includes the ohmic contact (pad-to-pad) capacitance and Schottky contact-to-ohmic pad capacitance.

For high-voltage SBDs, the device channels are significantly long. Therefore, it can be assumed that the junction breakdown is caused either by impact ionization or by tunneling. The channel length, L_{AC}, is a very important device parameter for a lateral SBD. By increasing the distance, L_{AC}, larger breakdown voltages can be obtained, but the ON-resistance and, therefore, the conduction losses will be higher.

Different technologies have been studied to improve SBD performance. One of them uses an anode composed of two metals with different work functions. In this case, two types of contacts are formed: a Schottky and an ohmic, as shown in Fig. 5.19.

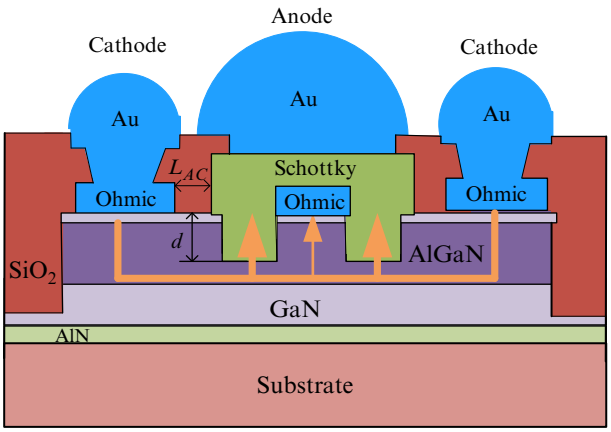

FIG. 5.19 A Schottky diode with recessed dual anode metal.

The low work function metal reduces the turn-ON voltage, V_T, and the high work function metal at the edge of the anode reduces the reverse leakage current and maintains the breakdown voltage. In [145], it is shown that the turn-ON voltage of the SBD is reduced from 1.47 to 0.57 V by employing the dual metal anode, and the breakdown voltages are virtually unaffected.

Another technology that can be used to reduce the turn-on voltage, V_T, without an increase in the leakage current is recess etching in the anode region of an SBD. The etching process must be well controlled because uneven etched surface morphologies can result in an increase in the surface leakage current [146]. A combination of an ohmic anode and a recessed Schottky gate, as shown in Fig. 5.19, is responsible for the low turn-ON voltage and an increase in the forward current. No breakdown-voltage degradation has been observed. In comparison with a conventional SBD, the forward current at 1.5 V is increased by two to three times in the SBD with a recessed dual anode metal, resulting in a breakdown voltage of 1440 V. The reason for this is that when a small positive voltage is applied to the anode, electrons flow from the cathode to the anode ohmic metal. Increasing the anode voltage so that the Schottky contact under the recessed anode region is turned on causes electrons to also flow through the Schottky metal. Additional electrons passing through the anode ohmic contact lead to very low turn-ON voltage, V_T, and high forward current.

The recess depth, d, is an important design parameter for a Schottky GaN device. For devices with a higher value than the optimum recessed depth, the electrons tend to flow through the Schottky metal instead of through the anode ohmic metal so that the electrons flowing to the anode ohmic metal are suppressed. The blocking voltage is not affected by the recess depth. In [146], it is reported that an AlGaN/GaN on Si SBD with dual metal and 16 nm recess depth with 0.34 V turn-ON voltage, V_T, has an anode current, I_A, (at 1.5 V) equal to 1.63 A. A SBD with a maximum breakdown voltage of 1.9 kV was reported by [147].

Researchers have reaped the benefits of GaN lateral Schottky diodes, such as low turn-ON voltage, V_T; low ON-resistance, R_{ON}; low leakage current; and low reverse recovery times. Improvements in the reliability of the GaN lateral Schottky diodes will make them the best candidates for high-power applications.

5.4.2 Vertical GaN PiN Diodes

GaN vertical devices have been studied extensively because of their potential to sustain high breakdown voltage without enlarging the chip area [148] and hence increasing the number of dies on a wafer. Also, vertical GaN devices have the potential to achieve a higher power at high temperature (150°C) than the lateral devices, especially for higher breakdown voltages and higher scaling level designs [149]. Vertical devices have high current capability and do not suffer from the thermal management issues associated with thin-film surfaces [150].

The reliability and performance of GaN-based devices depends on the defect density. GaN layers grown on foreign substrates (e.g., Si or SiC) create difficulties for realizing vertical devices because of higher defect densities ($>10^8$–10^9 cm^{-2}) created. For fabricating devices with high breakdown-voltage capability, low leakage current, and high reliability, it is very important that the epitaxial layers have a low defect density. GaN layers grown on a GaN bulk substrate have significantly low defect densities ($<10^6$ cm^{-2}), but the bulk GaN substrates are too expensive and currently have small diameters, which are the main challenges for the commercialization of the GaN vertical devices, although they have shown high performance. Scientists from different universities and companies are conducting ongoing research into improving the quality and increasing the size of the GaN substrates. The research is mostly driven by the optoelectronics industry in two directions: scalability and price reduction. Since there are already multiple suppliers of bulk GaN substrates, the development of GaN vertical power devices will increase soon.

In Fig. 5.20, a cross section of a vertical GaN PiN diode is shown. Similar to Si and SiC PiN diodes, a GaN PiN diode consists of a heavily doped N^+ region, a lightly doped drift region, and a heavily doped P^+ region. When a GaN vertical diode is built on GaN substrate, the substrate has a high electron concentration (1.5–2×10^{18} cm^{-3}) and plays a role as a heavily doped N^+ region. Some researchers have built a GaN vertical diode on a Si substrate. In this case, due to the lattice mismatch and differences in the thermal expansion coefficients between Si and GaN, a buffer layer of AlN/GaN or AlGaN is grown between the substrate and the epitaxial layer. The buffer layer improves the quality of the epitaxial layer grown on top of it. Then, a heavily Si-doped N-GaN layer (2×10^{18} cm^{-3}) is grown.

As mentioned earlier for N-type GaN, metal stacks, such as Ti/Al/Mo/Au, Ti/Al/Pt/Au, and others, can be used to form low-resistivity stable ohmic contacts because of their excellent characteristics. Obtaining stable contacts with low resistivity for P-type GaN is more difficult due to the wide bandgap of GaN. Since the work function of P-type semiconductors is larger and for a wide bandgap it will be pronounced, a metal with a larger work function [151] is required to align the metal and semiconductor Fermi levels. Metal stacks, such as Ni/Au, Pd/Au, Ni/Pd/Au, and others, can be used for these ohmic contacts. An alloy of Ni/Pd/Au is reported to have good ohmic contact with a low specific resistance of 4.5×10^{-6} Ω cm^2 [152].

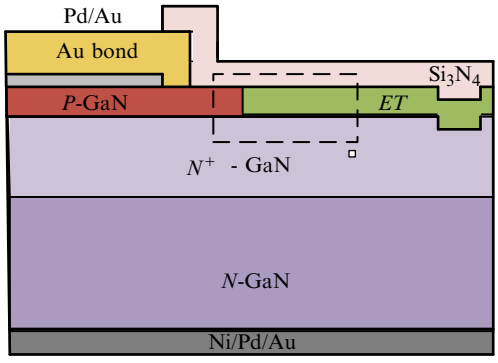

FIG. 5.20 A cross section of a vertical GaN PiN diode.

For the same breakdown voltage, the thickness of the lightly doped drift region N^- of a GaN vertical PiN diode is smaller than the thickness of Si and SiC PiN diodes, while GaN PiN diodes can have a higher doping concentration in the lightly doped drift region than SiC and Si. Shown in Fig. 5.21 are the calculated results for the minimum width of the lightly doped drift region as a function of the doping concentration for a PiN structure for different applied voltages and different

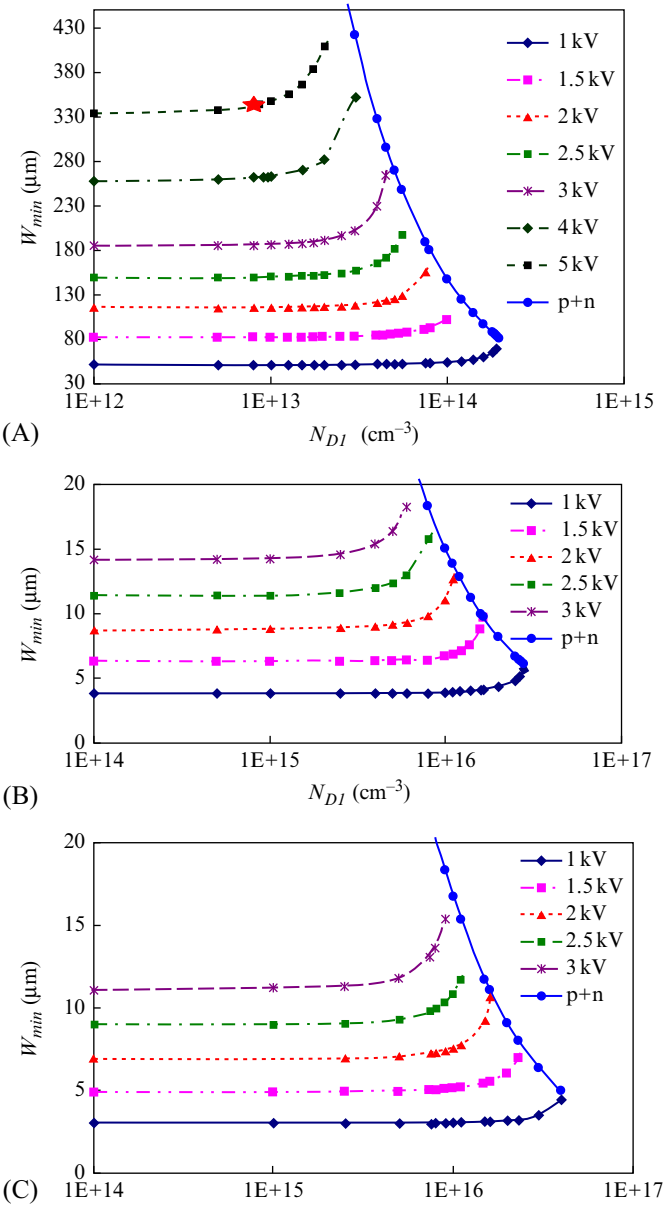

FIG. 5.21 The minimum width of the lightly doped drift region (W_{min}) as a function of doping concentration (N_{D1}) for a P^+N diode and a $P^+N^-N^+$ structure for different applied voltages and different semiconductor materials: (A) Si, (B) 4H-SiC, and (C) GaN.

semiconductor materials: Si, 4H-SiC, and GaN [153]. For a 3 kV GaN diode, the thickness of the lightly doped drift region is ~12 μm, and the doping concentration for this thickness is $\sim 10^{16}$ cm^{-3}. For a SiC device, the thickness and the doping concentration for a 3 kV device are 15 μm and $\sim 7 \times 10^{15}$ cm^{-3}, while for a Si device the thickness and the doping concentration for a 3 kV device are 200 μm and $\sim 8 \times 10^{13}$ cm^{-3}. In [154], a vertical GaN 2.6 kV power diode is described with a lightly doped drift region width and doping concentration of 15 μm and $\sim 8 \times 10^{13}$ cm^{-3}, which support the calculated results given in [153]. On the drift region, a heavily magnesium (Mg)-doped P^+-type GaN layer is grown. The layer's impurity concentration is higher than 2×10^{17} cm^{-3}, depending on the diode design.

A level-3 model introduced in Section 5.3.2.2 can be used for modeling a GaN PiN power diode. The most important parameter for a power GaN PiN diode is the voltage drop, V_{AK}, across it during the conduction state. It is composed of five components, including the voltages across the junctions, J_1 and J_2; the voltage across the two depletion regions, V_{d1} and V_{d2}; and the voltage across the drift region, V_{N^-}:

$$V_{AK} = V_{j1} + V_{j2} - V_{d1} - V_{d2} + V_{N^-} \tag{5.192}$$

Although the lightly doped drift region of a GaN PiN diode is significantly thinner than the lightly doped drift region of a Si PiN diode and the carrier concentration in the drift region is considerably higher in a GaN device, the voltage drop across a 5 kV GaN device, at a current smaller than 50 A, is larger than the voltage drop of a Si diode. The published data for the turn-ON voltage at room temperature of a GaN diode are larger than 3 V [150,155–157]. The reason for the higher turn-ON voltage of a GaN PiN diode is similar to the reason for that in a SiC PiN diode. SiC and GaN are wide bandgap materials, and their intrinsic carrier concentration, n_i, at room temperature is significantly smaller than the carrier concentration of Si. The junction voltage of junction J_1 is a dominant term in Eq. (5.192), especially for the diodes with a breakdown voltage smaller than 5 kV. The junction voltage of junction J_1 is

$$V_{j1} = V_T \mathrm{In}\left(\frac{p_{x1} N_{N^-}}{n_i^2}\right) \tag{5.193}$$

where V_T is the thermal voltage (kT/q), p_{x1} is the excess carrier concentration of the lightly doped drift region at the junction J_1, and N_{N^-} is the doping concentration of the lightly doped drift region. The total junction voltage V_{j12}, which is a sum of the voltages of the junctions J_1 and J_2, V_{j1} and V_{j2}:

$$V_{j12} = V_T \ln\left(\frac{p_{x1} p_{x2}}{n_i^2}\right) \tag{5.194}$$

The total junction voltage, Vj_{12}, does not directly depend on the doping concentration of the lightly doped drift region, N_{N^-}. However, there is a dependency between the boundary values of the excess charge concentrations, p_{x1} and p_{x2}, and the impurity doping level that determines the junction voltage values. Also, the excess carrier concentrations, p_{x1} and p_{x2}, depend on the emitter recombination parameters that can be assumed as constants for calculating the total forward voltage drop.

To obtain the minimum forward voltage drop, V_{AK}, during conduction time, the minimum width of the drift region, corresponding to the minimum doping concentration, should be used. However, the results from the simulation given in [153] do not agree with this simple assertion. Increasing the doping concentration, $\boldsymbol{N_{N^-}}$,for the same breakdown voltage leads to a decrease of V_{AK} to a minimum value, after which further increases in the doping concentration cause an increase in the forward voltage drop. A higher doping concentration, $\boldsymbol{N_{N^-}}$, reduces the injection efficiencies of the higher doped P^+ and N^+ emitters into the drift region and, therefore, decreases the values of the excess carrier densities, p_{x1} and p_{x2}, at the region boundaries. From Eq. (5.194), it can be seen that as the boundary charge concentrations are reduced, the total junction voltage, Vj_{12}, also reduces, as shown in Fig. 5.22.

Although higher doping concentrations, N_{N^-}, lead to a decrease in the values of the excess carrier densities, p_{x1} and p_{x2}, the voltage drop across the drift region, V_{N^-}, has a minimum value. The forward voltage drop, V_{AK}, also has a minimum.

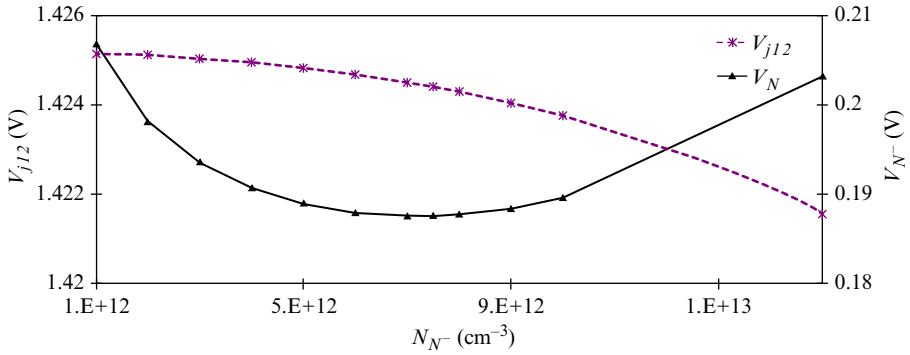

FIG. 5.22 The simulation results of a Si PiN structure for a designed breakdown voltage of 5 kV, given in [148]: the total junction voltage, Vj_{12}, and the voltage drop across the drift region, V_{N^-}, as a function of the doping concentration of the lightly doped drift region, $\boldsymbol{N_{N^-}}$.

The simulation results for optimizing the doping concentration to minimize the forward voltage drop, V_{AK}, of a 5 kV Si PiN diode would lead to a reduction in the forward drop of more than 12%, while for SiC and GaN PiN diodes the reduction in the forward voltage drop for a concentration below 10^{15} cm^{-3} is <1% [153]. Hence, the optimization of the concentration of the lightly doped drift region for SiC and GaN is not necessary.

Fabricating GaN devices with high breakdown voltages requires a low-doped drift region and edge-termination (ET) structures that do not limit device performance. ET plays a key role in determining the device breakdown voltage. The purpose of the ET structures is to spread out the electric field at the edge of the junction such that there is no region with a very high electric field that can damage the device. The lack of good ET reduces the breakdown voltage significantly below the ideal limits due to field crowding at the edges that leads to an avalanche breakdown. To improve device performance, the electric field crowding at the edges should be minimized. Different ET techniques have been used for different types of GaN devices. One of them is smoothing of the equipotential contours at the edge of the device resulting in a manageable electric field [158]. A field-plate structure consisting of a SiN_x passivation layer and a Ti/Au bilayer can be used for the ET [159]. When the metal contact is extended over a surface dielectric layer, for example, SiO_2, the depletion region boundary is extended, and therefore, the electric field crowding is reduced [160]. Another ET technique for reducing electric field crowding is the formation of a P^+ floating ring or guard ring [160]. In [161], a simple ET technique is used to achieve nearly ideal parallel plane breakdown voltage for GaN devices. The technique involves implanting a neutral species on the edges of devices to form a highly resistive, amorphous layer. ET is obtained by using argon implantation, increasing the breakdown voltage of GaN Schottky barrier diodes from 300 V for unterminated diodes to 1650 V after ET.

Improving the quality and the size of the GaN substrate, improving the quality of the epitaxial layers, and choosing the right ET technique will help the device designer to fabricate a high-voltage GaN PiN diode (>10 kV) that will switch quickly and have a smaller forward voltage drop than the Si PiN diode.

5.4.3 GaN JFET

The breakdown voltage of a lateral transistor depends mainly on the channel parameters. In order to maintain low ON-resistance, R_{ON}, the device width and the space between the gate and the drain should be increased, which limits the breakdown voltage to 1 kV and increases the need for more sophisticated device structures for managing the electric field and also increases the device capacitance. In a vertical device, the breakdown voltage depends on the deposition region parameters, and it is easier to scale up for high current and voltage. Vertical devices allow greater power density, lower capacitance, and generally better performance.

Two types of JFETs are considered in this book: a vertical JFET (VJEFT) and a lateral channel JFET with a vertical drift region (LC-VJFET).

5.4.3.1 Vertical JFET

Two cross sections of vertical GaN JFETs are depicted in Fig. 5.23. The first one has a rectangular channel, and the second has trapezoidal channels. Depending on the doping levels and physical dimensions of a VJFET, the transistor can be designed to operate as a normally-ON or normally-OFF device. A normally-OFF device is preferable because it will prevent current from flowing when no voltage is applied to the gate, and therefore, it can be easily utilized in power applications.

A cascode circuit, shown in Fig. 5.24, includes a high-voltage, normally-ON GaN JFET with a low-voltage MOSFET that can operate as a normally-OFF high-voltage device. The high-voltage GaN VJFET is a normally-ON device and has a negative threshold voltage, and the low-voltage MOSFET is capable of blocking ~30 V with a standard power MOSFET threshold voltage. The cascode circuit has the gate-driving characteristics

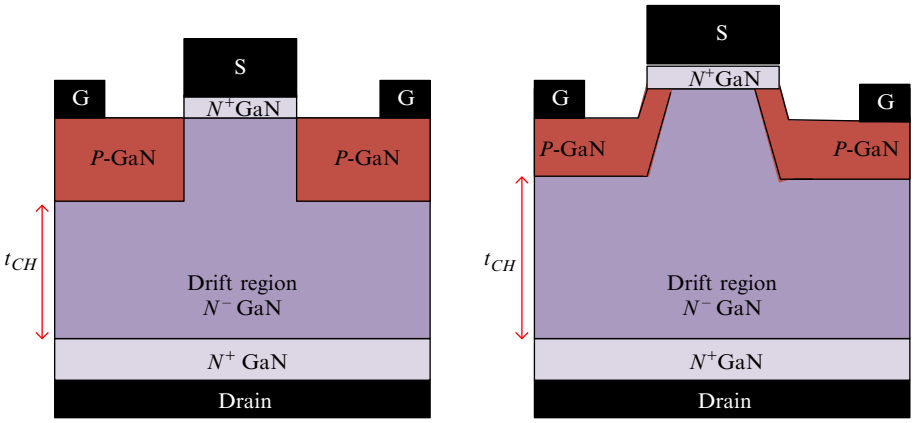

FIG. 5.23 A cross section of a vertical JFET with rectangular and trapezoidal channels.

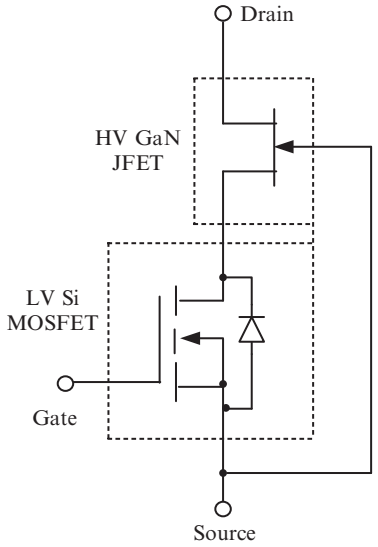

FIG. 5.24 A cascode circuit including a high-voltage JFET and low-voltage MOSFET.

of the standard power MOSFET and the current/voltage capability of the high-voltage GaN VJFET. Since the MOSFET is a low-voltage device, its ON-resistance, R_{DS_ON}, is significantly smaller than in the GaN JFET, and the associated losses will be insignificant.

A VJFET consists of a heavily doped N^+ region, a lightly doped N^- drift region, and a channel region that is formed between two heavily doped P^+ regions. On the top of the channel region is the heavily doped N^+ region. For a normally-OFF device and with no voltage applied to the gates ($V_{GS}=0$), the channel is fully depleted of carriers due to a significantly high doping concentration of the heavily doped P^+ regions and the significantly low doping concentration in the channel. The depletion region width depends on the doping concentrations of the channel and heavily doped P^+ region, N_{CH} and N_P; GaN permittivity, ε; built-in voltage, V_{bi}; and gate-source voltage, V_{GS}:

$$W \approx \frac{\varepsilon}{q}\frac{N_{CH}N_P}{N_{CH}+N_P}(V_{bi}-V_{GS}) \tag{5.195}$$

The built-in voltage is calculated by the equation:

$$V_{bi}=\frac{kT}{q}ln\left(\frac{N_{CH}N_P}{n_i^2}\right) \tag{5.196}$$

where k *is* Boltzmann's constant, T is the temperature in Kelvin, q is unit electric charge, and n_i is the GaN intrinsic carrier concentration. If a positive voltage is applied to the gates, the depletion region width decreases, creating no resistive path for the current, and the current passes through the channel from the drain to the source.

For a normally-ON device and no voltage applied to the gates ($V_{GS}=0$), the channel is not depleted, and the current passes through the channel from the drain to the source. When a negative voltage, with a magnitude higher than the threshold voltage, is applied to the gate, the depletion region is extended and prevents current from passing through the channel.

When a GaN VJFET is built on GaN substrate, the substrate has high electron concentration and plays the role as a heavily doped N^+ region. Other substrates, such as Si or SiC, can be used for building of a GaN VJFET.

Epitaxial layers are grown on the top of the GaN substrate or the buffer layer for devices made with other substrates. The VJFET GaN epitaxial layers can have nonuniform doping concentration as a function of the thickness of the different layers, which can be used for optimizing a device's performance [162]. The drift region thickness and the doping concentration are designed to carry the majority of the drain-source voltage, V_{DS}. The drift region concentration can be in the range of 10^{14}–10^{16} cm^{-3}. The gates are formed on the top of the heavily doped P^+ regions, whose thickness, t_{CH}, determines the channel thickness. The doping concentration in the channel can be equal to or less than the doping concentration of the drift region. The doping concentration in the channel depends on the desired threshold voltage of the VJFET.

In Fig. 5.23, the channel has a rectangular shape. There are JFETs where the channels can be designed to have a trapezoidal shape. The trapezoidal-shaped channel can improve the performance by enabling better control of the electric field near the location where the channel sidewall and the upper surface meet [162]. The width of the channel, W_{CH}, for a rectangular channel or the bottom base for a trapezoidal-shaped channel can vary depending on numerous factors, such as desired functionality (normally-ON or normally-OFF device) and the channel doping concentration. The width and the thickness of the channel, W_{CH} and t_{CH}, should be optimized so that a very small leakage current flows from the source to the drain while maintaining a low ON-state resistance, R_{ON}.

Simulation results given in [163] showed that the ON-state resistance, R_{ON}, can be reduced by increasing the channel doping concentration and width, but in this case, the breakdown voltage is reduced, a positive threshold voltage is compromised, and a normally-OFF operation is hard to achieve. The threshold voltage, V_T, is very sensitive to the channel width, W_{CH}. In order to achieve a positive threshold voltage, V_T, the channel width should be smaller than 1 μm, which leads to a high ON-state resistance, R_{ON}. To obtain a better trade-off between the threshold voltage, V_T, and ON-state resistance, R_{ON}, a lateral channel JFET with a vertical drift region is proposed.

5.4.3.2 Lateral Channel JFET With Vertical Drift Region

A cross section of a lateral channel GaN JFET with a vertical drift region (LC VJFET) is shown in Fig. 5.25. Similar to VJFET, the doping levels and physical dimensions of an LC VJFET determine the transistor functionality to operate as a normally-ON or normally-OFF device. A normally-OFF device

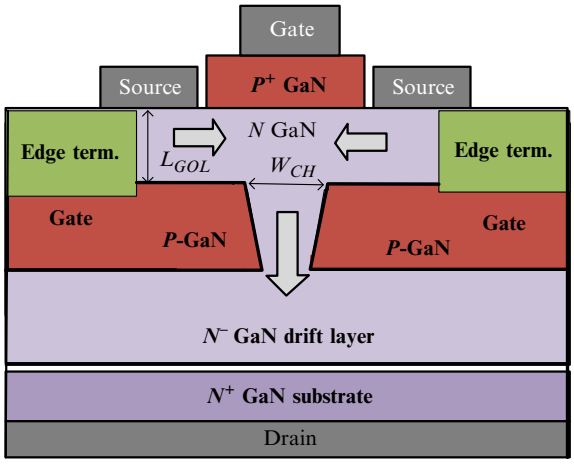

FIG. 5.25 A cross section of a lateral channel JFET with a vertical drift region.

is preferable, but the cascode configuration shown in Fig. 5.24 has the gate-driving characteristic of the low-voltage MOSFET and the current/voltage capability of the high-voltage LC VJFET, which can be used for a normally-ON device.

The LC VJFET has three regions of interest. First is the core of the device, which includes the device channel and the gate region. The second region includes the lightly doped drift region and the substrate, and the third region is the edge termination and the isolation region.

A GaN LC VJFET can be built on a heavily doped GaN substrate, but other substrates, such as Si or SiC, can also be used. However, in this case, a buffer layer from AlN/GaN, AlGaN, or other suitable materials should be grown between the substrate and the epitaxial layer to improve the quality of the epitaxial layer grown on top of it. The breakdown voltage of an LC VJFET is determined by the doping concentration and thickness of the lightly doped drift region and also the proper edge-termination techniques. For a kV-rated device, the doping concentration of the lightly doped drift region is in the range of 10^{15}–10^{16} cm^{-3}. The lightly doped drift region provides a region through which current flows from the drain to source during the ON-state, but during the OFF-state, the drift region provides a region for supporting the electric field by the voltage gradient between the source or gate and the drain [164].

The channel of the LC-VJFET is composed of two parts: a vertical and a lateral conductive region. A blocking *P*-type GaN layer, with a significantly high impurity concentration in the range of 10^{17}–10^{19} cm^{-3}, is used to form the two regions. The blocking layer supports the vertical electric field and causes the current to flow in the lateral area of the channel. The length of the overlap, L_{GOL}, between the gate and the blocking layer is an important parameter. This is exactly the effective gate that modulates the lateral channel width and changes the conductivity of the channel. When the length of the overlap, L_{GOL}, is smaller than the optimum value, leakage current in the device increases as the channel is not fully pinched OFF, and some electrons flow from the source to the drain. But increasing the length of the overlap, L_{GOL}, more than the optimum value causes the ON-state resistance of the device to increase [163].

The vertical channel region is a continuation of the lightly doped drift region. The vertical channel thickness and doping concentration should be optimized with two constraints: minimizing the LC-VJFET ON-resistance when the device is turned ON and providing proper pinch-OFF so that no current passes through the channel when the device is turned OFF. The channel width, W_{CH}, is also an important design parameter that determines the functionality of the device as a normally-ON or normally-OFF design. If the channel width, W_{CH}, is significantly large, the path of the current from the drain to the source will be low resistance, but in this circumstance, pinch-OFF of the channel is more difficult to achieve.

On the top of the channel, a heavily doped P^+-type GaN layer is deposited and patterned to form the gate. The blocking *P*-type GaN layer, together with the gate, can control the device by the PN junctions formed with the *N*-type channel. In some designs, the gate and the blocking layer are electrically tied to form a buried *P*-type gate.

The edge-termination scheme used in the transistors is similar to those schemes used in PiN junction diodes. The potential applied to the top metal is spread over a distance that is typically greater than the thickness of the lightly doped drift region. For this purpose, two separate implant steps are used. Smoothing the equipotential contours at the device edges results in better management of the electric field on the device surface and prevents the device from breaking down prematurely [165]. In this case, if a breakdown occurs, it will be due to an avalanche breakdown.

The operation of an LC-VJFET depends on the design. For a normally-OFF device, where no voltage is applied to the gates ($V_{GS}=0$), the channel is fully depleted of carriers due to a significantly high doping concentration of the heavily doped P^+ gate and the blocking *P*-type GaN layer from one side and a significantly low doping concentration in the channel from the other side. Two depletion regions are formed: one from the *PN* junction of the P^+ gate and the *N*-channel and the second one from the blocking *P*-type GaN layer and the *N*-channel. The two depletion widths can be calculated using Eq. (5.195) by substituting the corresponding doped concentrations. The total depletion width, *W*, is a sum of the depletion width of the two junctions. When a positive voltage is applied to the gates, the depletion width, *W*, decreases, and current passes through the channel from the drain to the source. For a normally-ON device with no voltage applied to the gates ($V_{GS}=0$), the channel is not depleted, and the current flows through the channel from the drain to the source. When a negative voltage, with a magnitude higher than the threshold voltage, is applied to the gate, the two depletion regions are expanded and prevent current from passing through the channel.

The simulation results given in [163] show that there is a higher degree of coupling between the ON-resistance, R_{ON}, and the threshold voltage, V_T, in the LC VJFET than in the VJFET. Therefore, a low ON-state resistance can be obtained with a thinner and more highly doped *N*-GaN channel.

5.4.4 GaN MOSFET

In the last 10 years, research on the design, fabrication, and characterization of high-voltage GaN MOSFETs has been based on both lateral and vertical structures: the fabrication process for a lateral high-voltage MOSFET is simpler than the vertical MOSFET since a thick, lightly doped drift region is necessary for a vertical structure. For the same breakdown voltage, a lateral device has a larger area than a vertical device. Therefore, the chip size of a lateral MOSFET is bigger. However, a Si substrate can be used for growth of lateral devices, which are larger and cheaper, while GaN substrates are normally used for vertical MOSFETs, which are smaller and more expensive. Other substrates, such as Si or SiC can also be used for vertical devices, but a buffer layer should be grown between the substrate and the epitaxial layer to improve the quality of the epitaxial layer, which increases the device cost.

5.4.4.1 Vertical Trench MOSFET

Fig. 5.26 shows a cross section of a high-voltage GaN vertical trench MOSFET. Most of the vertical GaN high-voltage MOSFETs are built on a low-defect-density GaN substrate, which is the MOSFET drain. The substrate doping concentration is higher than 10^{18} cm^{-3}. A lightly doped N^- drift region is grown on the top of the substrate by metal-organic vapor deposition. The doping concentration of the drift region is in the range of 10^{14}–10^{16} cm^{-3}, and its thickness depends on the desired breakdown voltage. The area of the drift region depends on its thickness. It should be chosen to allow spreading of the current in the drift region, thereby decreasing the drift region ON-resistance. The value of the thickness and the doping concentration of the lightly doped drift region can be optimized so that the sum of the conduction and the switching losses of the device can be minimized.

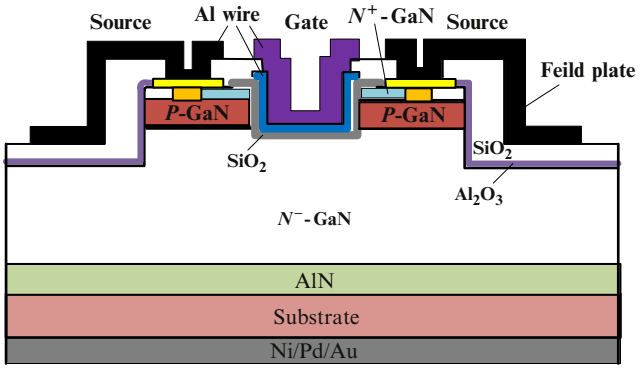

FIG. 5.26 A cross section of a vertical trench MOSFET.

A *P*-type base layer with a thickness smaller than 1 μm is grown on the top of the drift region. The thickness of the *P*-layer is the channel length of the device or the effective gate of the device. The doping concentration of the base is higher than the drift region, and it is in the range of 10^{17}–10^{19} cm^{-3}. On the top of the base layer, a selective area regrowth of a heavily doped N^+-type layer is grown to form the MOSFET source. SiO_2 can be used as the regrowth mask. The doping concentration of the N^+-type layer is higher than 3×10^{18} cm^{-3}, and the thickness is smaller than 0.5 μm. Usually for GaN devices, Si is used as the dopant for the formation of *N*-type layers, and Mg is used for *P*-type.

The gate trench is then formed by etching part of the two MOSFET layers, *P* base and N^+ source. A SiO_2 layer, as a dielectric interlayer, is deposited on the sidewall and the bottom of the trench by plasma-enhanced chemical vapor deposition, and then, the metal is deposited to form the gate electrode. The vertical sidewall of the trench should be well smoothed and cleaned to achieve high inversion layer mobility and, therefore, low resistivity of the channel [38]. Also, the trench bottom plays a crucial role in achieving superior electric performance and highly reliable operation. Therefore, the trench bottom should be a little bit rounded, which will reduce the P-well pinching effect, and as a result, the pinching resistance under the gate-drain area is decreased [166].

To improve the OFF-state characteristic, such as the breakdown voltage of a trench MOSFET, a field-plate edge-termination technique can be used to reduce the electric field at the edge of the *PN* junction around the isolation mesa periphery [167]. The field plate consists of the extended wiring electrode for the source electrode. The field-plate electrode completely overlaps the *PN* junction from the side, and therefore, the potential crowding at the edge of the *PN* junction is effectively reduced. While an improvement of the ON-state characteristic, such as the ON-resistance can be achieved by reducing the cell pitch size, improving the dielectric/semiconductor interface quality, and optimizing the drift layer growth condition which will enhance the electron mobility.

The operation of a high-voltage GaN trench MOSFET is similar to the operation of Si and SiC trench MOSFETs. When a positive voltage higher than the threshold voltage is applied between the gate and the source of the device, an *N*-channel region is formed on the surface of the *P* base that provides a conducting path between the source and drain terminals. If the gate to source voltage is below the threshold voltage, the transistor is turned off, and only a very small leakage current is passing from the drain to the source of the transistor. In theory, the threshold voltage of a MOSFET is defined as the voltage applied between the gate and source that creates an inversion layer of minority carriers with a concentration higher than the base. According to [168], the threshold voltage is

$$V_{th} = \Phi_S + \frac{\varepsilon_{GaN}}{\varepsilon_{SiO_2}} t_{SiO_2} \sqrt{\frac{2qN_P}{\varepsilon_{GaN}\varepsilon_0}\Phi_S} \tag{5.197}$$

where ε_{GaN} and ε_{SiO_2} are the permittivity of GaN and SiO_2, respectively; t_{SiO_2} is the thickness of the SiO_2; and N_P is the doping concentration of the base. The surface potential at the P base is Φ_S. At the deposition-inversion transition point, the surface potential is

$$\Phi_S = 2\Phi_F = \frac{2kT}{q} \ln\left(\frac{N_P}{n_i}\right) \tag{5.198}$$

For the same doping concentration of the P base and SiO_2 layer thickness, the calculated threshold voltage for a GaN device should be larger than the threshold voltages of SiC and Si devices because of the significantly low intrinsic carrier concentration of GaN. The simulation result for the threshold voltage of a trench GaN MOSFET (P-base doping concentration 3×10^{19} cm^{-3}) obtained from a one-dimensional, self-consistent Schrödinger-Poisson solver is 26 V, while the experimental result for the same device is significantly lower at 8 V [169]. Other researchers, [170–172], have also reported low experimental threshold voltage values compared with theoretical values. Differences between the simulation and experimental results can be due to the sidewall etch damage of the P base, which can cause nitrogen vacancies to form and behave as donors [169]. Research about decreasing the sidewall etch damage, better smoothing, and cleaning after sidewall etching is being conducted, which will increase the threshold voltage and provide better noise immunity to prevent false turn-on.

In 2016, at the 28th International Symposium on Power Semiconductor Devices and ICs, a state-of-the-art GaN trench MOSFET, with a breakdown voltage of 1.6 kV and a high current operation exceeding 10 A for a single-cell device, was reported [167]. The breakdown voltage of the device was improved from 1.2 to 1.6 kV by applying a field-plate edge-termination technique around the isolation mesa of the transistor. The specific ON-resistance, R_{ON}, of the single cell, measured when a gate-source voltage, V_{GS}, of 40 V was applied, was 2.7 mΩ cm^2. The threshold voltage of the trench MOSFET was reported to be 3.5 V. The authors also showed the switching characteristics for a double-pulse switching experiment (see Fig. 5.27). From the switching characteristics, the rise and fall time, t_r and t_f, were determined to be 19 and 10 ns, respectively, when the supply voltage, V_{DD}, was 400 V and the drain current, I_D, was around 10–14 A. Also, the turn-on and turn-off switching losses were calculated to be 90 and 12 μJ, respectively, which suggests that the fabricated vertical GaN trench MOSFETs are suitable for use in high-power applications with high-frequency switching.

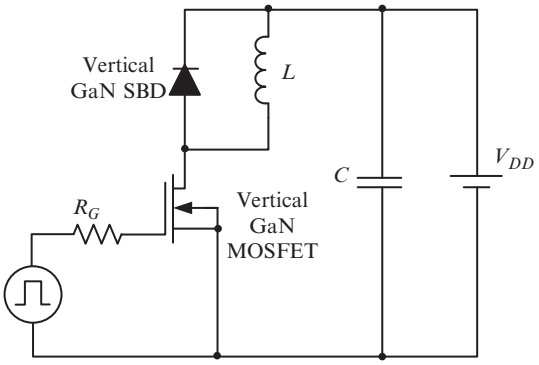

FIG. 5.27 Schematic circuit diagram for double-pulse switching measurement using the fabricated vertical GaN MOSFET and the internally developed vertical GaN SBD [162].

5.4.4.2 Lateral MOSFET

Lateral MOSFETs have a significantly simpler structure than the vertical ones because during fabrication, no heavy etching is used for the gate and no thick, lightly doped drift region is grown. Also, the three terminals, the source, gate, and drain, are placed on the top surface, which is suitable for power-integrated circuits where the power transistor is monolithically integrated with control circuits on the same chip. However, for the same blocking voltage, the length of the channel of a lateral MOSFET is longer, and therefore, the area of the device is larger than the area of a vertical trench MOSFET. Similar to the vertical MOSFET, the lateral MOSFET is normally an OFF device.

A cross section of a GaN lateral MOSFET is shown in Fig. 5.28. Different substrates, such as sapphire, SiC, and GaN, have been used for fabricating lateral MOSFETs. A P-type Mg-doped GaN layer is grown by metal-organic chemical vapor deposition on top of the substrate. For better growth of the P-doped layer, a buffer layer between the substrate and the P layer is grown. A SiO_2 thin layer is grown on top of the P layer to form the MOS structure of the transistor and to suppress any damage or pollution due to ion

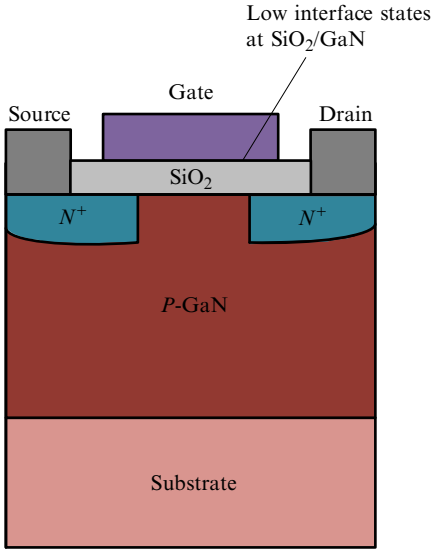

FIG. 5.28 A cross section of a GaN lateral MOSFET.

implantation. The ion implantation is used to place Si ions in the P layer and to form heavily doped N^+ source and drain regions. In the end, low-resistance contact layers are formed on the drain, source, and the gate.

The breakdown of a lateral MOSFET is mainly determined by the thickness of the SiO_2 layer. Since the drain has a high doping concentration, the voltage drop of the drain region is significantly smaller. Therefore, the potential of the region of the drain under the gate is approximately equal to the applied voltage on the drain. When the gate-source voltage is smaller than the threshold voltage and the drain-source voltage is significantly high, a breakdown can occur in the gate oxide. A schematic of a lateral GaN MOSFET during the OFF-state and its potential and electric field in function of the position is shown in Fig. 5.29. During the OFF-state, the gate and source are connected to the ground, and high voltage is applied to the drain with respect to the source. The electric field between the drain and the gate is significantly high because of the small thickness of the SiO_2 layer, while the channel length is significantly larger. Therefore, the electric field between the drain and source is smaller. Also, the resistance of the SiO_2 layer is larger than the channel resistance. For these reasons, almost all of the electric field is concentrated on the gate oxide, a result of the breakdown near point 1 in Fig. 5.29 [173].

The electric field in the region between the gate and the drain is significantly higher and, therefore, limits the voltage applied between the drain and the source. To spread the electric field and decrease its value in the region between the gate and the drain, a lightly doped N^- layer, known as the reduced surface field (RESURF) layer, is used by different scientific groups to increase the breakdown voltage of a lateral device. The RESURF concept was introduced by Appels and Vaes for the first time [174]. A RESURF layer increases the breakdown voltage of lateral MOSFETs and increases the ON-state resistance since the layer should be long and lightly doped. Another aspect of a long, lateral drift layer is the additional required chip area, which increases the cost of the devices. For a given breakdown voltage, the optimal parameters of a RESURF layer, the length and doping concentration, should be determined. A trade-off between blocking voltage and ON-state resistance should be found.

A lateral GaN MOSFET with a RESURF layer during the OFF-state and its potential and electric field as a function of the position is shown in Fig. 5.30. During the OFF-state, a big part of the electric field of the MOSFET with a RESURF layer is concentrated on the two sides of the RESURF layer, and some part is in the RESURF layer. Therefore, for the same breakdown voltage, the electric field in the gate oxide layer for a MOSFET with a RESURF layer will be significantly smaller than the electric field in the gate oxide layer for a conventional MOSFET. To ensure long-term reliability of a MOSFET, the electric field in the gate oxide layer should be kept below 3 MV cm^{-1}. A lateral GaN MOSFET with RESURF, with a high blocking capability of 1550 V and an operation current of 2.5 A, is reported in [172]. To further reduce the surface electric field and maintain a high breakdown voltage, two RESURF regions are required. A lateral GaN with two RESURF regions is shown in Fig. 5.31. The RESURF1 region is near the gate and has a low implant dose. Lowering the implant dose in RESURF1 will reduce the electric field of the oxide near to the gate. The RESURF2 region is near the drain and has a high implant dose. The higher implant dose in the RESURF2 region will support high breakdown voltage. In [175], an enhancement mode N-channel lateral GaN high-voltage MOSFET with two RESURF regions is presented, with a breakdown voltage of 2.5 kV and a specific on-resistance of 30 mΩ cm^{-2}. Further

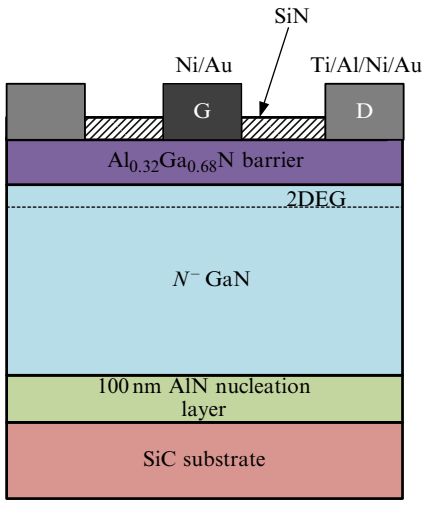

FIG. 5.32 A cross section of a conventional GaN HEMT.

improvement of lateral GaN MOSFETs can be accomplished by improving the quality of the SiO_2/GaN interface and reducing the resistance of the contacts. If the SiO_2/GaN interface has poor quality, the electrons passing through the channel are captured at interface states leading to a decrease in electron mobility and, therefore, an increase in channel resistance. Annealing at temperatures higher than 900°C after depositing SiO_2 has been used to decrease interface state density [173,176,177].

Simulation results for GaN MOSFET devices of similar dimension with a RESURF region (field-plate structure) and a GaN HEMT are given in [177]. From the simulation results, it is concluded that both devices are capable of producing similar ON-state modes of operation and achieve similar effective mobility at equivalently larger electric fields. However, during subthreshold operation, the GaN MOSFET is shown to contain a much lower carrier concentration than the GaN heterostructure field-effect transistor (HFET). As a result, the breakdown avalanche effect in the GaN MOSFET is roughly five times larger than the GaN HFET for devices of similar dimensions, 3500 and 600 V, respectively. Therefore, implementing the MOS structure with the high quality of the SiO_2/GaN interface can potentially resolve fundamental constraints for high-voltage power applications caused by current device architects.

5.4.5 GaN HEMT

5.4.5.1 GaN HEMT Structure

A GaN HEMT is a field-effect transistor in which two layers of different bandgaps and polarizations (GaN and AlGaN) are grown upon one another forming a heterojunction. As a consequence, in the vicinity of the heterojunction, positive charge is induced at the interface due to both spontaneous and piezoelectric type of polarization. Free electrons are transferred from the AlGaN layer, having higher conduction band energy, to the GaN layer, where the conduction band energy is lower, thus occupying a lower energy state and compensating for the induced positive charge [178]. The number of electrons is larger, especially if AlGaN is doped with impurities. Accumulated electrons along the heterojunction in a quantum well are usually referred to as two-dimensional electron gas (2DEG). The 2DEG is located in the channel of the HEMT, where current flows between the drain and the source controlled by the gate.

A cross section of a conventional GaN HEMT is shown in Fig. 5.32. HEMTs have been successfully grown on Si [179], sapphire [180], SiC [181], and GaN [182] substrates. SiC and sapphire substrates were the first used for HEMTs because of the existing experience in the light-emitting diode (LED) industry. However, successful growth of GaN HEMTs on Si substrates with parameters similar to HEMTs on SiC substrate has been reported lately. This is attractive to industry since Si substrates are available in large sizes and at low cost. Since SiC has three times the thermal conductivity of Si, HEMT transistors for low-power applications can be built on Si substrates, while for high-power applications, SiC substrates are preferred. The epitaxial layer grown on GaN substrates will not have a mismatch problem, but these substrates are extremely costly and small in size.

For HEMTs grown on foreign substrates, an intermediate, nucleation, or buffer layer is essential to the growth of quality GaN on the substrate. The morphology and crystal quality of a buffer layer play a critical role in determining the quality of epitaxial growth [183]. Aluminum nitride can be used as a nucleation layer. Metal-organic chemical vapor deposition and metal-organic molecular beam epitaxy methods can be used to form the AlN buffer layer. In [184], it is shown that there is no distinct difference between the GaN grown on a buffer layer obtained by the two methods.

The GaN epilayer grown on the top of the buffer layer is known as a channel layer because a channel is formed within.

The channel layer is grown mostly by metal-organic chemical vapor deposition along the [0001] direction to benefit from the spontaneous polarization within the GaN wurtzite crystal. The temperature for growing the GaN epilayer is also important to the quality of the layer. As the temperature increases, the defect density and surface roughness decreases, which may be attributed to the improvement in the surface mobility and activities of source spaces on the substrate [184].

On the top of the channel layer, a barrier layer with a higher bandgap and lower electron affinity, compared with the GaN channel layer, is grown. The buffer layer can be fabricated with a group-III nitride material, such as $Al_xGa_yIn_{1-x-y}N$, where $0 \leqq x \leqq 1$, $0 \leqq y \leqq 1$ and $x+y \leqq 1$ [185]. The thickness of the AlGaN barrier layer and the aluminum composition can be optimized so that a significant carrier concentration is induced and a 2DEG can be formed.

A passivation layer is deposited on the top of the barrier layer between the gate and the source and the second passivation layer between the drain and the gate. The layers may be initially formed as a single layer that is subsequently etched through to form the gate [185]. Different dielectric materials can be used, such as SiN, SiO_2, Si, Ge, MgO_x, MgN_x, ZnO, SiN_X, and SiO_x, but usually, SiN is used. The deposition temperature and post-annealing temperature of the passivation layer are important for controlling dynamic ON-state resistance degradation. The results given in [186] indicate that the SiN/AlGaN interface trap density is reduced by increasing the deposition temperature and also by increasing the postannealing temperature. Therefore, the current collapse in terms of dynamic ON-state resistance is also reduced.

As illustrated in Fig. 5.32, a conventional AlGaN/GaN HEMT has typically been fabricated with coplanar metal contacts. The source and drain electrodes are ohmic contacts providing low resistance and nonrectifying behavior, while the gate contact is intended to be a nonohmic Schottky barrier contact that controls the carrier concentration in the channel and blocks the current at large reverse voltages. Since the Schottky gate electrode and the 2DEG are separated by the AlGaN layer, the gate leakage current should be suppressed, but a relatively large gate leakage current is usually observed in the devices due to the defects near or at the surface of the AlGaN layer. The defects are formed during the epitaxial layer growth and by interface reaction between the metal and AlGaN layers interacting due to thermal treatments during the fabrication processes. Different materials have been used to create Schottky gate electrodes: Ni, Cu, Pt, and W. Pure metals have poor thermal stability on the AlGaN layer, while using electrodes with compound nitrides, such as TiN, the gate leakage current and the current collapse are suppressed to some extent. A characterization and comparison of poly-Si and TiN gate electrodes have shown advantages in reducing the leakage current and robustness against reverse-bias stressing of the poly-Si gate electrode [187].

Forming all three contacts on the same epitaxial layer may result in compromises between these characteristics. Therefore, there is a trade-off in device design, when selecting the doping and composition of the AlGaN barrier layer, between optimizing the source and drain ohmic contacts while optimizing the nonohmic gate contact [185]. Furthermore, high-power HEMTs should be optimized to provide as much current-carrying capability as possible to the region under the gate electrode while allowing the gate to block as high voltage as possible. Hence, it may be useful to have differences in the regions between the source and gate, under the gate, and between the gate and drain in order to modify the amount of energy band bending. Modifying the band bending will change the amount of the sheet region charge and the electric field profile within the device.

To improve electric performance together with reliability, new advanced structures have been designed and characterized. Introducing a field plate between the gate and drain electrodes enables electric field modulation. As a result, the electric field profile is reshaped, and the electric field is spread along the device's channel. Under the field plate, a depletion zone is formed so that the maximum peak value of the electric field at the drain side of the gate edge is reduced. Therefore, using a field-plate structure increases the device breakdown voltage, since the maximum electric field is distributed across the region among the gate and drain [188].

The phenomenon known as current collapse is associated with surface states in GaN-based HEMTs. It is caused by electrons trapped by defects in the GaN layer and the interface between the passivation film and the AlGaN barrier layer. Since, the electric field at the gate edge has a maximum value, it strongly affects the current collapse due to the acceleration of the electrons in the channel. The ON-resistance increase caused by the current collapse phenomena strongly depends on the gate-edge electric field. The results given in [189] show that the ON-state resistance increase caused by the current collapse phenomena is dramatically reduced by a field plate since the gate-edge electric field is reduced by the field-plate electrode.

The electron mobility in the 2DEG of an AlGaN/GaN heterostructure is an important transport parameter that characterizes the quality of the structure and determines the HEMT performance [190]. The 2DEG mobility is limited by a combination of various scattering mechanisms such as background impurities, polarization effects, degeneracy, interface roughness scattering, dislocations, scattering by acoustic and optical phonons, remote modulation doping scattering, and alloy disorder [191] and [192].

The electron mobility in the 2DEG is a function of the sheet electron density, N_S, at the heterointerface over a wide temperature range. It increases with an increase in the sheet electron density, N_s, up to a maximum value and decreases with further increases in the density, N_S. At a high sheet electron density in AlGaN/GaN heterostructures, the electrons spill from the quantum well near the heterointerface and occupy the delocalized states in the channel, leading to a reduction of the electron mobility. In this case, less effective screening and more

pronounced ionized impurity scattering were observed when electrons occupied a much wider doped region near the heterointerface [193].

The sheet electron density near the AlGaN/GaN heterointerface is mainly contributed by the electrons induced by the doped AlGaN barrier and from the electrons generated by the piezoelectric effect. The sheet density of 2DEG is expressed as [194]:

$$N_S = \frac{1}{q}\left(\sigma_{AlGaN} - \frac{\varepsilon_{AlGaN}}{d_{AlGaN}}\Delta V_{AlGaN}\right) \tag{5.199}$$

where σ_{AlGaN} is the sheet charge density that is induced by AlGaN polarization, q is the electron charge, and ε_{AlGaN} and d_{AlGaN} are the dielectric constant and the thickness of the AlGaN barrier. The potential drop, $\Delta V_{AlGaN,}$ can be calculated as

$$\Delta V_{AlGaN} = q\Phi_b - E_F - \Delta E_C \tag{5.200}$$

where Φ_b is the surface barrier height, E_F is the Fermi level position with respect to the GaN conduction band edge at the AlGaN/GaN interface, and ΔE_C is the conduction band discontinuity between GaN and AlGaN, as shown in Fig. 5.33.

To decrease the sheet electron density, N_s, and improve the performance of the HEMT, a GaN capping layer placed between the barrier layer of AlGaN and the passivation layer of SiN is deposited as shown in Fig. 5.34. Strong polarization-induced electric fields are present in the AlGaN buffer layer and in the GaN capping layer that affect the 2DEC sheet density, depending on the thickness of the GaN capping layer. Experimental results given in [195] and the simulation results given in [196] show that the presence of a GaN capping layer results in a monotonic decrease of the sheet electron density with increases in the capping layer thickness. Decreasing the 2DEG sheet density results in modification of the electron scattering mechanisms and, therefore, modification in the mobility too. The experimental and simulation results show that as the thickness of the GaN capping layer increases, the electron mobility increases monotonically to a maximum point, where further increases in the capping layer thickness will cause the mobility to decrease slightly and eventually saturate [195] and [196].

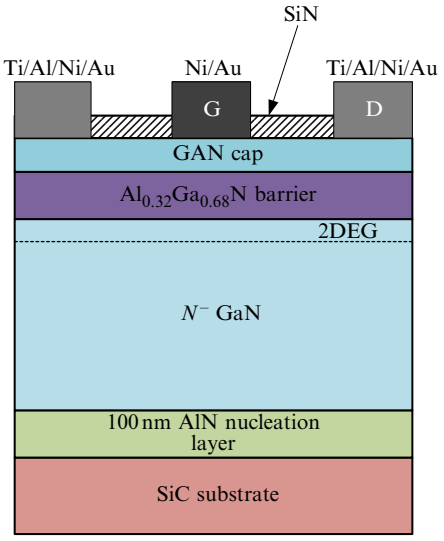

FIG. 5.34 A cross section of an advanced GaN HEMT structure.

The 2DEG sheet resistance of the GaN/AlGaN/GaN structure can be calculated by the following equation [194]:

$$N_S = \frac{d_{GaN}\sigma_{GaN} + d_{AlGaN}\sigma_{AlGaN}}{q(d_{GaN} + d_{AlGaN})} - \frac{\varepsilon_{GaN}}{q}(q\Phi_b + E_F) \tag{5.201}$$

where σ_{GaN} is the sheet charge density that is induced by the GaN polarization and ε_{GaN} and d_{GaN} are dielectric constant and the thickness of the GaN capping layer, respectively. The surface barrier height, $\Phi_{b,}$ and the Fermi level position, $E_{F,}$ are shown in Fig. 5.35.

To achieve better HEMT performance, a thin AlN (~1 nm) interlayer at the AlGaN/GaN interface is added in some advanced structures. The insertion of the thin AlN interlayer suppresses the penetration of the wave function into the barrier and effectively removes alloy scattering and pushes out most of

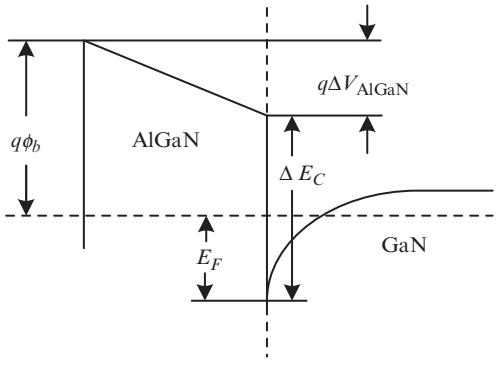

FIG. 5.33 Conduction band diagram of an AlGaN/GaN heterostructure [195].

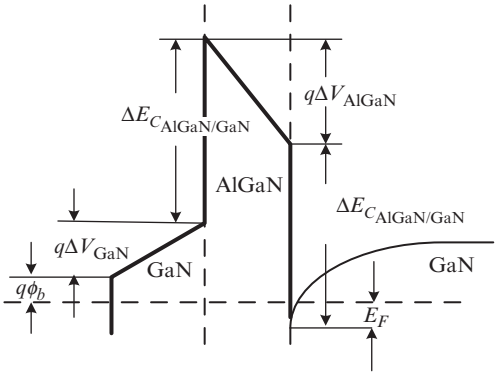

FIG. 5.35 Conduction band diagram of a GaN/AlGaN/GaN heterostructure [195].

the 2DEG from the barrier. The small finite part that still penetrates the barrier is not affected by the allow scattering [197]. Also, additional polarization due to the AlN interlayer is observed. As a result, the sheet charge density and mobility are improved as compared with the conventional AlGaN/GaN heterostructure having equivalent AlGaN parameters.

At small drain bias, V_{DS}, the conductivity between the source and drain, known as 2DEG conductivity, is proportional to the product of channel mobility, μ, and the sheet electron density, N_S:

$$g_{SD} = \frac{I_D}{V_{DS}} = q\mu N_S \frac{L}{W} \tag{5.202}$$

where I_D is the drain current and L and W are the length and width of the gate. Therefore, insertion of an AlN layer increases the conductivity. In [198], it is reported that introduction of an AlN interlayer improved the ON-state resistance and current, R_{ON} and I_{ON}, by 10 %.

The 2DEG sheet resistance of GaN/AlN/AlGaN structure can be calculated by the following equation according to [194]:

$$N_S = \frac{d_{AlGaN}\sigma_{AlGaN} + d_{AlN}\sigma_{AlN}}{q(d_{AlGaN} + d_{AlN})} - \frac{\varepsilon}{q}\left(q\Phi_b + E_F - \Delta E_{C\,\frac{AlN}{GaN}} + \Delta E_{C\,\frac{AlGaN}{GaN}}\right) \tag{5.203}$$

where σ_{AlN} is the sheet charge density that is induced by AlN polarization and ε_{AlN} and d_{AlN} are the dielectric constant and thickness of the AlN capping layer, respectively. The surface barrier height, $\Phi_{b,}$ and the Fermi level position, $E_{F,}$ of the GaN/AlN/AlGaN structure are shown in Fig. 5.36.

A critical requirement of the power switch is that it has low ON-resistance, R_{ON}, immediately after switching from OFF-state to ON-state. The ON-resistance, R_{ON}, of a HEMT is expressed by the following equation:

$$R_{ON} = 2R_C + R_S + R_D + R_{CH} \tag{5.204}$$

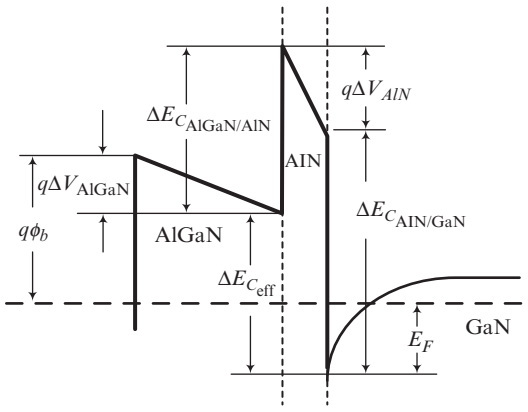

FIG. 5.36 Conduction band diagram of a GaN/AlN/AlGaN heterostructure [195].

where R_C is the source and drain contact resistance, R_S, is the parasitic source resistance, R_D, is the parasitic drain resistance, and R_{CH} is the channel resistance. The carrier trapping at the surface and the buffer traps degrade the device performance. In a GaN HEMT, the parasitic charge moving in and out of the traps affects the density of the 2DEG and causes ON-resistance degradation. To characterize the dynamic ON-resistance of a HEMT, a switching test should be performed using Fig. 5.37. The gate source of the device is connected to a pulsed generator that can switch the device from OFF- to ON-state. During the OFF-state, high-voltage V_{DD} is applied to the device. The load resistance, R_L, is connected in series with the device under test, and it is adjusted so that the ON-state resistance is measured in the linear region. The turn-ON and turn-OFF time are fixed during the experiment. Turn-OFF time should be long enough, typically larger than 10 ms, so the device under test cools down and its temperature does not affect the results. The ON-time is larger than the time at which the dynamic resistance is measured or the time at which the drain current, I_D, saturates.

The transient drain current through the device, $i_D(t)$, and the drain-source voltage, $v_{DS(t)}$, are recorded, and the resistance is calculated for different times by the equation:

$$R_{ON_{Dyn}}(t) = \frac{v_{DS(t)}}{i_D(t)} \tag{5.205}$$

The static ON-resistance, $R_{ONstatic,}$ is calculated by the same equation; only the saturated values for the current and the voltage are used. The experiment and calculation can be repeated for different values of the load resistance (i.e., different drain current). In Fig. 5.38A is a sketch of the gate-source voltage applied to the device under test, the drain-source voltage and the drain current. While in Fig. 5.38B showed a sketch of the dependency of drain current I_D, as a function of drain-source voltage, V_{DS}, for times t_1 and $_{t2}$ and different values of the load resistance.

The current collapse can be defined as a normalized dynamic ON-resistance (i.e., a ratio of the dynamic resistance value to its static value). The ratio can be used to compare the performances of HEMTs.

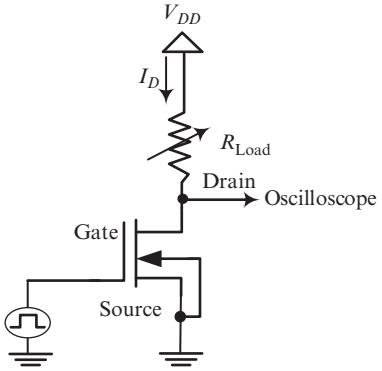

FIG. 5.37 Pulsed test circuit for dynamic ON-resistance measurement.

(B) Dependency of drain current I_D, as a function of drain-source voltage, V_{DS}, for times t_1 and t_2 and different values of the load resistance.

5.4.5.2 GaN HEMT DC Characteristics

The current-voltage characteristics of a HEMT are related to the density variation of the 2DEG where 2DEG depends on the gate-source voltage, V_{GS}, applied to the HEMT. Moreover, any changes of V_{GS} have an effect on the electron mobility in the channel. A HEMT has three modes of operation: linear, saturation, and cut-OFF. For power applications and the linear mode of operation, the low-field mobility of the electrons in 2DEG, μ_n, is used to calculate the drain current, while when the drain-source voltage increases, the mobility of the electrons in the 2DEG decreases. In this case, a simple model for high field mobility, μ_n^{HV}, based on the geometry of the HEMT structure is used:

$$\mu_n^{HV} = \frac{\mu_n}{1 + \dfrac{\mu_n V_{DS}}{L_{CH} v_{sat}}} \tag{5.206}$$

where L_{CH} is the channel length and v_{sat} is the saturation velocity. The drain current, i_D, is proportional to the density of electrons in the channel [199]:

$$i_D(x) = \frac{W}{L_{CH}} \mu_n C_{GS} \frac{dv}{dx} \tag{5.207}$$

where W is the channel width. The drain current can be obtained by integrating the current along the channel. If the source and drain contact resistances are neglected and the boundary conditions are used,

$$v_{x=0} = 0 \text{ and } v_{x=L_{CH}} = V_{DS} \tag{5.208}$$

then the drain current in the linear regime of operation is

$$I_D = \frac{W}{L_{CH}} \mu_n C_{GS} \left[(V_{GS} - V_{th}) V_{DS} - V_{DS}^2 \right] \tag{5.209}$$

where C_{GS} is the gate-to-source capacitance and V_{th} is the threshold voltage. In the saturation regime of operation, the drain current is

$$I_D = \frac{W}{L_{CH}} \mu_n C_{GS} (V_{GS} - V_{th})^2 \tag{5.210}$$

5.4.5.3 GaN HEMT Design Considerations

To improve the performance and also protect GaN HEMTs from damage, the designer should take into account some very important concerns and benefits.

The threshold voltages of GaN HEMTs are low compared with the Si and SiC MOSFETs. Some of the HEMT devices start to conduct current at significantly low gate-source voltage (1.4 V) that makes it difficult to ensure that the device turns OFF, especially at low temperatures (the threshold voltage decreases as the temperature drops). Negative voltage should be used in this case to ensure turn-OFF of the device. This behavior indicates that the threshold voltage has a positive temperature coefficient. HEMTs are unipolar devices (i.e., no minority carriers are involved during conduction). Therefore, there is no reverse recovery charge and thus very small reverse recovery losses.

As it can be seen in Figs. 5.32 and 5.34, GaN HEMTs do not have an intrinsic body diode as in Si and SiC MOSFETs. However, they have a so-called "body-diode" effect that makes the device conduct under applied reverse voltages. The mechanism for an enhancement GaN HEMT to behave as a diode during turn-OFF is as follows [200]. When the gate-source voltage is zero and the drain-source voltage is positive, no channel is created, and therefore, current is not flowing. As the drain-source voltage starts to become negative, a positive bias on the gate relative to the drift region is formed, injecting electrons under the gate. The gate-to-drain voltage starts to increase, and when it reaches the threshold voltage, there will be a significant amount of electrons under the gate to form a conduction channel.

The temperature coefficient of the ON-state resistance, R_{ON}, of a GaN HEMT is positive, similar to Si and SiC MOSFETs, but the magnitude is small compared with a Si MOSFET and approximately in the same range as a SiC MOSFET.

Since GaN HEMTs have high switching speed, the voltage slew rate may be more than ten to hundreds of volts per nanosecond, and the current slew rate may be more than 10 A s^{-1}. Such a high slew rate may lead to the so-called Miller effect (i.e., undesirable or parasitic turn-ON of the power transistor and that creates a short circuit that will cause significant damage resulting in destruction of the HEMT).

Shown in Fig. 5.39A is a synchronous buck converter. If the upper HEMT is switched ON, the lower one has to be OFF in order to avoid a shoot-through condition and, therefore, possible failure of the HEMT due to overcurrent.

The mechanism of the parasitic switching for the synchronous buck can be explained with the capacitive voltage divider formed between the gate to drain and gate to source of the low-side transistor (Fig. 5.39B). The gate-source voltage of the low-side transistor is

$$V_{GS} = \frac{C_{GD}}{C_{GD} + C_{GS}} V_{SW} \tag{5.211}$$

where C_{GD} and C_{GS} are the gate-drain and gate-source capacitances, respectively, and V_{SW} is the switching node voltage. Although the gate of the low HEMT is set to zero by the driver circuit, there is a possibility that the low-side HEMT turns ON because of the fast change in the switching voltage. The rate of change of the voltage at the switching node, V_{SW}, is approximately V_{in}/t_r, where V_{in} is the converter input voltage and t_r is the rise time. The voltage slew causes a current to flow through gate-to-drain capacitance of the low-side HEMT:

$$i_{C_{GD}} = C_{GD} \frac{dV_{SW}}{dt} \tag{5.212}$$

This current flows into the equivalent impedance of driver pull-down resistance in series with the gate resistance and both of them in parallel to the gate-source capacitance of the low HEMT. If the gate-source voltage during the rise time of the high side transistor is higher than the threshold voltage, the low HEMT will turn ON parasitically. One way to prevent this from happening is to split the gate pull-up and pull-down connection in the driver and allowing for the insertion of discrete resistors, if needed. The low (OFF-state) pull-down resistance should be a lower resistance value than the pull-up resistance value. If the driver does not support a separate turn-OFF resistor, a diode in parallel can be used, as shown in Fig. 5.40.

The high slew rate may also cause ringing and, in some cases, damage if the common source inductance, L_S, is not minimized. The source current, i_S, is the sum of the drain and the gate currents. Any voltage induced on the common source inductance $\left(L_S \frac{di_S}{dt}\right)$ will show up as ringing in the gate-source voltage. To address this issue, one company developed packages with exceptionally low internal inductance by implementing source-sense or Kelvin connection, but the external inductance that contributes to the ringing should also be minimized. Shown in Fig. 5.41 is a Kelvin connection at the source of a HEMT where the ground return of the gate driver is connected directly to the source on the die internal to the package by a star-point connection. In this case, the external parasitic inductances and resistances in the gate loop will be minimized, and the high slew rate of the drain current during turn-ON switching cannot influence the gate current loop.

However, the (PCB) layout should be carefully considered to minimize the effect of the parasitic inductance. For this purpose, the designers should keep the connection from the output of the driver to the HEMT gate and from the Kelvin connection

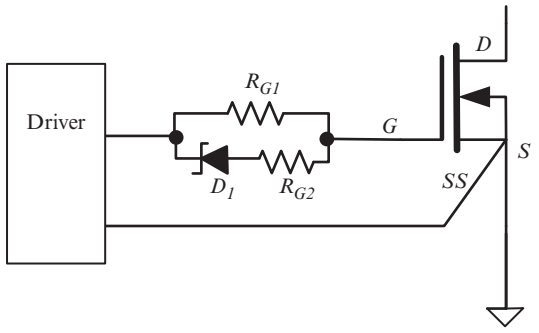

FIG. 5.40 Separate turn-ON and turn-OFF resistors to control parasitic turn-on of low-side HEMT.

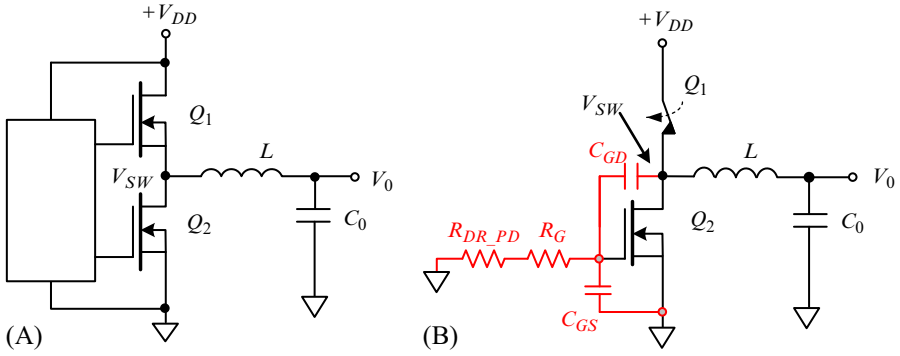

FIG. 5.39 Synchronous buck converter (A) idea and (B) parasitic resistance and capacitance included.

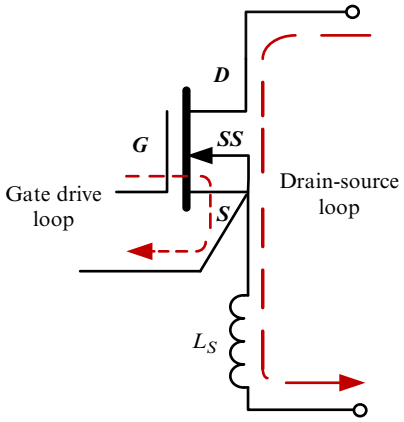

FIG. 5.41 Source-sense or Kelvin connection at the HEMT source.

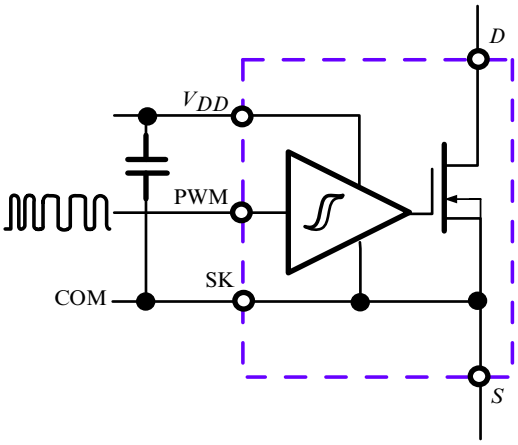

FIG. 5.43 Gate drive and logic circuits with GaN power FETs on a single chip.

to the gate return path of the driver as short as possible. To reduce the wire parasitic inductance, the two paths should be on separate board layers physically over each other. In this case, the magnetic flux generated by two current flows will cancel each other and will lower the parasitic inductance. Also, the connection for the decoupling capacitor of the driver power supply should be short.

During the fast switching transition, the Miller capacitance combined with parasitic inductance in the gate-source loop may induce over- or undershoot voltage spikes that could possibly exceed the maximum gate-source voltage rating of the device. This can be avoided by optimizing the PCB layout, but if the spikes still remain after overvoltage clamping a Zener diode and a capacitor in parallel is included as it shown in Fig. 5.42A can be used [201]. If a negative gate-source voltage is used to turn OFF the HEMT, the overvoltage clamp will have two Zener diodes connected back to back as shown in Fig. 5.42B. For effective clamping, the diode and the capacitor should be placed as close to the device gate as possible.

To enable high switching, high power density, and low system cost, some companies are fabricating a gate drive and logic circuit with GaN power FETs on a single chip, as shown in Fig. 5.43. The advantages of this type of arrangement are that there is no gate-loop parasitic inductance and, therefore, the output signal will be absent of ringing; has a fast rise-time gate signal; and the ability to have rail-to-rail gate signal values. Plus, it offers high-frequency operation with minimal propagation delay [202].

Unlike many conventional Si MOSFETs, the GaN HEMTs are not avalanche rated at the breakdown at the drain-source junction. Therefore, in order to maintain reliability, the maximum drain-source voltage, V_{DS}, should be guaranteed by design. For some topologies, Si MOSFETs can be directly substituted for GaN HEMTs with the same breakdown voltage. An example of this type of topology is a full bridge converter controlled as a dual synchronous buck, as shown in Fig. 5.44 [203].

While for some resonance topologies, Si MOSFETs cannot be replaced with GaN HEMTs that have the same breakdown voltage. Shown in Fig. 5.45 is a resonant-reset forward converter.

After the switch turns OFF, the magnetizing current reverses in a sinusoidal fashion set by the magnetizing inductance, L_m,

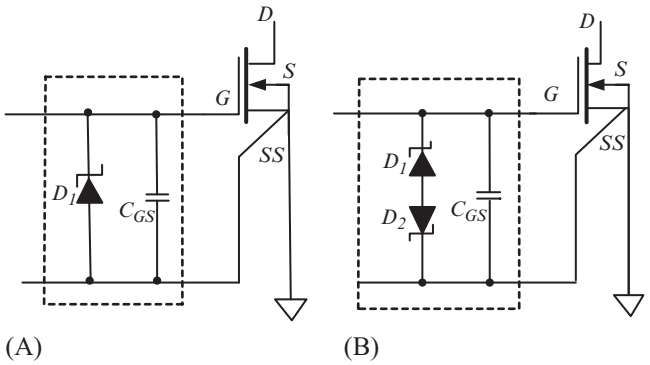

FIG. 5.42 Gate overvoltage clamping using Zener diodes and capacitor: (A) zero voltage is applied to turn OFF the HEMT, (B) negative voltage is applied to turn OFF the HEMT.

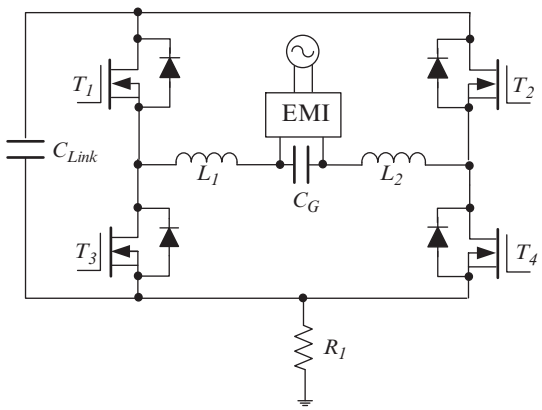

FIG. 5.44 A dual synchronous buck converter.

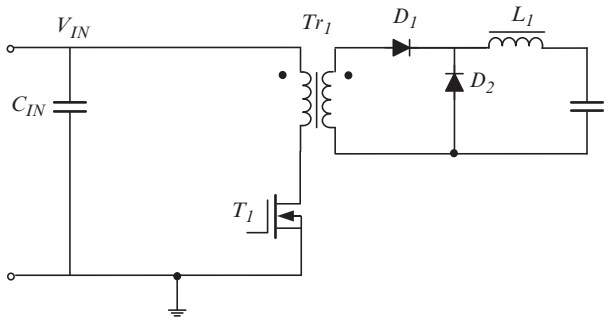

FIG. 5.45 A resonant-reset forward converter.

and the resonance capacitance, C_R. The resonance capacitance, C_R, is a sum of all capacitances across the primary winding of the transformer including the reflected diode capacitance, C_D:

$$C_R = C_D\left(\frac{N_S}{N_P}\right)^2 + C_{DS} + C_T \tag{5.213}$$

where C_{DS} is the switch drain-source capacitance, C_T is transformer primary windings capacitance, and N_S/N_P is the transformer winding ratio. The drain-source capacitance, C_{DS}, is dominant in this expression. The drain-source peak voltage, V_{DSpeak}, of the switch depends on the characteristic impedance $\sqrt{L_m/C_R}$ and can be calculated by the equation:

$$V_{DSpeak} = V_{in} + V_P = V_{in} + I_{Ppeak}\sqrt{\frac{L_m}{C_R}} \tag{5.214}$$

where the peak primary current is

$$I_{Ppeak} = \frac{1}{2}\frac{V_{in}t_{ON}}{L_m} \tag{5.215}$$

From the last three equations, it can be concluded that if only switches are different in the circuit shown in Fig. 5.45, the maximum drain-to-source voltage that will be applied to the switch depends on the drain-source capacitance, C_{DS}. Since GaN HEMTs have significantly smaller capacitance, the peak voltage, V_P, will be significantly larger, and therefore, the peak drain-source voltage will correspondingly be larger. In order to maintain maximum reliability, GaN HEMTs should be rated for higher voltages than the Si MOSFETs in any particular application.

Although GaN high-power HEMTs have significantly low switching and conduction power losses, compared with MOSFETs in Si or SiC, during high-power and high-frequency operation, their temperature is increased. Thermal management is another very important consideration for designers. The current fabrication methodology of HEMT structures implies that the gate, drain, and source connections must be made on the same side of the die. For this reason, necessary isolation gaps must be included between these contacts as this mounting technique results in a higher thermal resistance. To improve the thermal resistance, the package of HEMTs has a thermal pad on the bottom side that is connected to the substrate through high-density microvias with copper providing the low thermal resistance path. To optimize the device performance, the thermal pad must always be connected to the source. For most effective cooling, a heat sink can be attached to the PCB bottom copper pad with the recommended thermally conductive interface pad or film between the heat sink and the bottom copper pad. Also, the top copper layer should be a 2 oz or thicker layer. A PCB with four or more internal layers is desirable. To improve the heat transfer is to add plated, through-hole thermal vias between conductive layers, but no vias should be placed under the solder bars unless they are microvias and completely filled with copper [200]. Vias with holes located directly under the gate, source, or drain solder bars will reduce the transistor's temperature cycling performance. In Fig. 5.46, a cross-sectional view of the GaN HEMT package and thermal dissipation path through the PCB, vias, and the heat sink is shown [204].

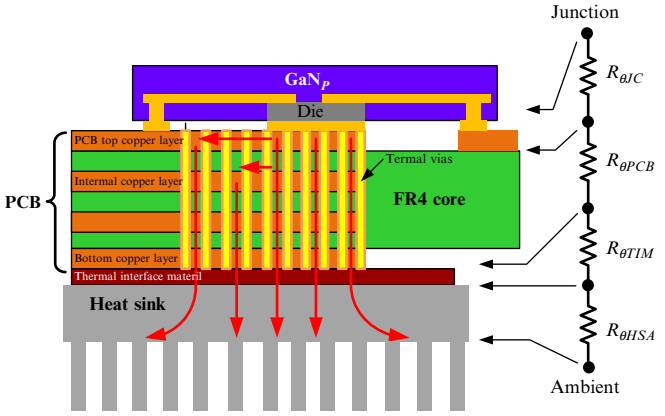

FIG. 5.46 A cross-sectional view of a GaN HEMT package and thermal dissipation path [203].

Appendix Lightly Doped Drift Region Thickness

One of the requirements for choosing a proper power electronic device for a converter is that it must possess a low specific ON-resistance. The specific ON-resistance of a bipolar device is related to the width and doping concentration of the lightly doped drift region (N^- base). This means that the doping concentration and the width of the low-doped base region in a bipolar device must be carefully considered to achieve a desired avalanche breakdown voltage and ON-resistance (conduction characteristics).

The avalanche breakdown voltage, V_{BD}, for an abrupt parallel plate junction, is a function of the background doping and the semiconductor properties, such as dielectric constant,

energy bandgap, and impact ionization coefficient. Breakdown occurs when the carrier multiplication becomes greater than unity. Impact ionization coefficients empirically describe the exponential relationship of the applied electric field and associated charge-carrier creation. The impact ionization coefficients for electrons and holes have different values, and values for semiconductor materials of interest are obtained empirically. The general ionization coefficient has been determined to have a theoretical form that is exponential and represented by [205]:

$$\alpha_i = A_i e^{-\left(\frac{b_i}{\mathcal{E}}\right)^{m_i}} \tag{A.1}$$

where $\mathcal{E}$ is the electric field (V cm^{-1}), A_i is the amplitude parameter (cm^{-1}), b_i is the ionization energy parameter related to the mean free path between collisions (V cm^{-1}), and m_i is an additional fit parameter for use with a multitude of semiconductor materials [205,206]. These parameter values depend on the semiconductor material, and they are different for electrons or holes. For Si, 6H-SiC, and GaN, m_i has been determined to be 1 for both electrons and holes [205,206].

Near the breakdown condition, a small error is introduced by equating the impact ionization coefficients of electrons and holes to an effective ionization coefficient, α_{eff}. In this case, the breakdown voltage is defined as the applied voltage at which the summed effects described by the ionization coefficient acting over the depletion width, W, create more free charge carriers. The boundary at breakdown is when the integral Eq. (A.2) achieves a value of unity [207]. The associated breakdown condition in terms of the effective ionization coefficient is:

$$\int_0^W \alpha_{eff}\, dx = 1 \tag{A.2}$$

Evaluation of this integral using Eq. (A.1) is very difficult; and no analytical expressions result, thus limiting its usefulness for device design. However, a simplified (and purely empirical) polynomial expression for the ionization coefficient in terms of the electric field is widely used [207]:

$$\alpha_{eff} = K\mathcal{E}^7 \tag{A.3}$$

The two previous fit parameters, A_i and b_i, are absorbed into the prefactor, K. The coefficient, K, is expressed in terms of new parameters, A, b, and m, that are averages of the previous A_i, b_i, and m_i values, expressed in Eq. (A.1) for holes and electrons [206]:

$$K = 9 \times 10^{-38} \frac{A 216^m}{b^{0.85} E_G^{15}} \tag{A.4}$$

where E_G is the bandgap energy (eV) for the semiconductor material of interest.

For a one-sided abrupt P^+-N junction, the electric field and the voltage across the lightly doped region are functions of the depletion distance and depend on the impurity doping concentration, N_{D1}, in the lightly doped N-base and the depleted N-base width, W. The electric field and voltage relations are presented in Eqs. (A.5), (A.6), respectively.

$$\mathcal{E}(x) = \frac{q}{\varepsilon} N_{D1}(W - x) \tag{A.5}$$

$$V(x) = \frac{q}{2\varepsilon} N_{D1}(W - x)^2 \tag{A.6}$$

The maximum electric field is observed at junction ($x = 0$). Using this and substituting Eq. (A.5) in Eq. (A.3) and then substituting into the integral Eq. (A.2), one can obtain the minimum width of the depletion layer, $W_{\min}$, at breakdown [206].

$$W_{\min} = \left(\frac{K}{8}\frac{q^7}{\varepsilon^7} N_{D1}^7\right)^{-\frac{1}{8}} \tag{A.7}$$

The corresponding breakdown voltage can then be determined from Eq. (A.6) as

$$V_{BD} = \left(2K\frac{q^3}{\varepsilon^3} {N_{D1}}^3\right)^{-1/4} \tag{A.8}$$

It should be noted that the permittivity is correctly placed in the denominator in Eq. (A.8), not in the numerator as was presented in the expressions from [206].

To reduce the lightly doped region width and maintain the same breakdown voltage requires the addition of a highly doped N^+ buffer layer at the end of the drift (N-base) region to create a $P^+N^-N^+$ structure. This will modify the expressions for the minimum width of the depletion layer, $W_{\min}$, and the corresponding breakdown voltage, V_{BD}. Reducing the width of the base region will decrease the effective on-resistance during conduction and reduce the volume of stored charge, thus decreasing the turn-OFF (and turn-ON) time.

To reduce the thickness of the drift region for the same blocking voltage, a heavily doped N^+-type buffer layer should be added to the end of the drift region to create a $P^+N^-N^+$ structure Fig. A.1B. Due to the high doping level in the buffer layer, the gradient of the electric field will be steep and positive, in the same way as in the P-type region. The electric field has maximum value at the P^+N^- junction. The electric field in the drift region will decrease gradually with no requirement for an excessive depletion layer width. The phenomenon that occurs when the depletion layer extends across the entire drift region is known as punch-through.

Consider a two-dimensional $P^+N^-N^+$ structure under equilibrium conditions with the doping profile sketched in Fig. A.1. The electric field in the different regions can be obtained by substituting the charge densities into Poisson's equations and then integrating:

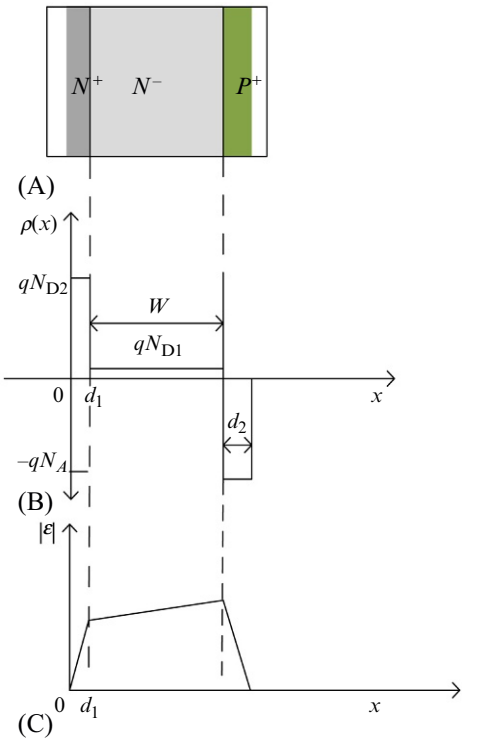

FIG. A.1 (A) A $P^+N^-N^+$ structure highlighting the depleting region under a large reverse applied voltage, (B) doping profile of the $P^+N^-N^+$ structure with charge density as a function of position, and (C) electric field as a function of position.

$$\mathcal{E}=\begin{cases}(q/\varepsilon)N_{D2}x & 0\le x\le d_1\\ (q/\varepsilon)(N_{D1}x+d_1(N_{D2}-N_{D1})) & d_1\le x\le d_1+W\\ (q/\varepsilon)N_A(d_1+W+d_2-x) & d_1+W\le x\le d_1+W+d_2\\ 0 & x\le 0 \text{ and } d_1+W+d_2\le x\end{cases} \tag{A.9}$$

where the respective impurity doping concentrations for the $N^+N^-P^+$ regions are N_{D2}, N_{D1}, and N_A. The corresponding depletion region thicknesses of each section are d_1, W, and d_2.

The maximum electric field of the $P^+N^-N^+$ structure will be at the N^-P^+ junction $(x=d_1+W)$. Charge neutrality from Eq. (A.9) gives the depletion thickness, d_2 of the P^+ region as

$$d_2=(N_{D1}W+N_{D2}d_1)/N_A \tag{A.10}$$

Since $\mathcal{E}=-dV/dx$, the electric potential applied to the structure is obtained by integrating the electric field from 0 to d_1+W+d_2 resulting in

$$V_{appl}=\frac{q}{\varepsilon}\left[\frac{N_{D2}^2+N_{D2}N_A}{2N_A}d_1^2+\left(\frac{N_{D1}N_{D2}}{N_A}+N_{D2}\right)d_1W+\left(\frac{N_{D1}^2+N_AN_{D1}}{2N_A}\right)W^2\right] \tag{A.11}$$

Substituting Eqs. (A.11) into (A.10) and using the result to calculate the ionization coefficient Eq. (A.3), we can reevaluate the ionization integral Eq. (A.2) as

$$N_{D2}^7d_1^8+\frac{N_{D2}^8d_1^8}{N_A}+\left(\frac{N_{D1}}{N_A}+1\right)(8N_{D2}^7d_1^7W+28N_{D1}N_{D2}^6d_1^6W^2+56N_{D1}^2N_{D2}^5d_1^5W^3+70N_{D1}^3N_{D2}^4d_1^4W^4+56N_{D1}^4N_{D2}^3d_1^3W^5+28N_{D1}^5N_{D2}^2d_1^2W^6+8N_{D1}^6N_{D2}d_1W^7+N_{D1}^7W^8)=\frac{8\varepsilon^7}{Kq^7} \tag{A.12}$$

For a given breakdown voltage, BV, the thicknesses of the drift region, W, can be calculated numerically using Eqs. (A.11), (A.12).

Nomenclature

a	Width of channel flow, cm
a_i	Ratio of intercell area to total die area
A	Cross-sectional active device area, cm^2
A*	Richardson's constant
A_{GS}	Coupling area between gate and source, cm^2
A_i, b_i, and m_i	Amplitude parameter (cm^{-1}), ionization energy parameter ($V\ cm^{-1}$), and fit parameter
BV	Breakdown voltage, kV
BV_{CEO}	Maximum open-base breakdown voltage of BJT, kV
C, C_n, and C_p	Auger coefficients, $cm^6\ s^{-1}$
C_{Dep}	Depletion region capacitance, F
C_j	Junction capacitance, F
C_{GD}	Gate-to-drain capacitance, F
C_{OX}	Oxide capacitance per unit area, $F\ cm^{-2}$
C_{SH}	Shunt capacitance, F
C_T	Tunneling coefficient
d	Length from junction to case, cm
d	Recess depth, cm
d_{dep}	Depletion width, cm
d_1, W, and d_2	Depletion region thicknesses of each section of $N^+N^-P^+$ regions, respectively, cm
D	Ambipolar diffusivity, cm^2s^{-1}
D_n and D_p	Electron and hole diffusivities, cm^2s^{-1}
D_{N^-}	Ambipolar diffusion coefficient in N^- region, cm^2s^{-1}
D_{pN}	Hole diffusivity in field-stop N layer, cm^2s^{-1}
D_{pN+}	Minority carrier diffusivities in N^- region, cm^2s^{-1}
E_C	Critical electric field, $V\ cm^{-1}$
E_G	Bandgap energy, eV
E_M	Electric field at Schottky barrier, $V\ cm^{-1}$
E_M	Maximum electric field, $V\ cm^{-1}$
f_T	Cutoff frequency, Hz
h_n and h_p	Electron and hole recombination parameters, $cm^{-4}s^{-1}$
I	Current passing through drift region, A
I_{CG}	Displacement layer, A

I_D	Drain current, A
I_D	Diode current, A
I_{disp1} and I_{disp2}	Displacement currents, A
I_E, I_B, I_C	Emitter, base, and collector currents, A
I_{mos}	MOS current, A
I_n and I_p	Electron and hole currents, A
I_{n0}, I_{n1}, and I_{n2}	Electron current at junctions J_0, J_1, and J_2, A
I_{p0}, I_{p1}, and I_{p2}	Electron current at junctions J_0, J_1, and J_2, A
I_{QN}	Capacitive current, A
I_{sne}	Emitter electron saturation current, A
Ip	Pinch-off current, A
J_0, J_1, J_2, J_3	Junctions
J_F	Current density, A cm^{-2}
J_{FS}	Current density across the Schottky barrier, A cm^{-2}
$J_{n((N^+N^-)}$, $J_{n((PN^-)}$	Electron carrier densities at the N^+N^- and PN^- junctions, A cm^{-2}
k and n	Harmonic indexes for CSR carrier density of Fourier series representation
k	Boltzmann's constant (1.381×10^{-23} J K^{-1})
K	Coefficient
K_{FV}	Feedback constant
K_{GS}	Coupling area coefficient between gate and source
L_A	Accumulation layer length, cm
L_{CH}	DMOSFET channel length, cm
L_{DRIFT}	Drift region thickness, cm
L_{PN}	Hole diffusion length, cm
l_m	Intercell half width, cm
l_1	Width due to voltage V_{GE}, cm
M	Number of the terms of the Fourier series
M	Number of segments
N^-	Drift region
N^+	Field-stop layer
N^+	Emitter
N_A	Acceptor doping concentration, cm^{-3}
N_{B0}	Electron concentration at junction J_0, cm^{-3}
N_C	Effective density of state in conduction band, cm^{-3}
N_{CH}	Channel doping concentration, cm^{-3}
N_D	Donor doping concentration, cm^{-3}
N_{DRIFT}	Doping concentration of lightly doped drift region, cm^{-3}
N_{D1}	Doping concentration in the lightly doped N-base, cm^{-3}
N_{D2}, N_{D1} , N_A	Doping concentration in the $N^+N^-P^+$ regions, respectively, cm^{-3}
N_E	Emitter doping concentration, cm^{-3}
N_{JEFT}	Doping concentration in the *JFET* region, cm^{-3}
N_N	Doping concentration of buffer layer, cm^{-3}
N_N^-	Doping concentration in the N^- region, cm^{-3}
N_p	Emitter doping concentration, cm^{-3}
N_p	Doping concentration of gate, cm^{-3}
N_S	Number of effectively available states per unit volume, cm^{-3}
N_V	Effective density of state in valence band, cm^{-3}
n	Electron carrier concentration, cm^{-3}
N_{B1}	Electron concentration base-region boundary, cm^{-3}
n	Ideality factor
n_i	Intrinsic carrier concentration, cm^{-3}
n_{PO}	Electron concentration P-base region boundary, cm^{-3}
n_0 … n_7	Nodes in lumped-charge model, cm^{-3}
n_{pw}	Electron concentration at junction J_3, cm^{-3}
n_{pw}	Electron concentration at base region boundary from N^- emitter side, cm^{-3}
n_s	2DEG sheet charge density, cm^{-3}
P	P emitter
P	P well
P_B	Base doping concentration, cm^{-3}
p	Hole carrier concentration, cm^{-3}
P_{DRIFT}	Hole concentration of drift region, cm^{-3}
$p(x)$	Ambipolar carrier density as a function of position, cm^{-3}
$p(x,t)$	Excess carrier concentration, cm^{-3}
$p(x,t)$	Ambipolar carrier density as a function of position and time, cm^{-3}
$p_0(t)$	DC Fourier series component of the carrier storage region (CSR), cm^{-3}
P_{JFET}	Doping concentration of JFET region, cm^{-3}
$p_k(t)$, $p_n(t)$—k- or $n^{-\text{th}}$	Fourier series component of CSR carrier density profile, cm^{-3}
P_{N-}	Hole concentration in N^- region, cm^{-3}
p_{NO}	Hole concentration at the boundary between buffer layer and drift region, cm^{-3}
p_{NO}, p_{NW}	Hole concentrations at two edges of field-stop layer, cm^{-3}
$p_{T(k)}$	Carrier distribution, cm^{-3}
p_{T1}, p_{T2}, and p_{T1}	Carrier densities of the two points of a segment and the carrier density of the segment, cm^{-3}
p_{x1} and p_{x2}	Excess carrier concentrations at the two boundaries of the drift region, junctions J_1 and J_2, cm^{-3}
q	Unit electric charge (≅1.6×10−19C)
R	Half height of Schottky metallization, cm
R_A	Accumulation layer resistance, Ω
R_{AUG}	Auger recombination rate, cm^{-3}s^{-1}
R_{CH}	Channel resistance, Ω
R_{CONT}	Ohmic contact resistance, Ω
R_{DRIFT}	Drift region resistance, Ω
R_{JFET}	Junction field-effect transistor resistance, Ω
R_{OC}	Ohmic contact resistance, Ω
R_{ON}	ON-resistance, Ω
R_s	Series resistance, Ω
r_{sp}	Specific contact resistivity, mΩ cm^2
R_{SP_ON}	Specific ON-resistance, mΩ cm^2
R_{SRH}	Shockley-Read-Hall carrier recombination rate, cm^{-3}s^{-1}
$R_{(th-jc)}$	Junction-to-case thermal resistance, K kW^{-1}
T	Absolute temperature, K
T_j	Junction temperature, K
V_{AC}	Anode cathode voltage, V
V_{AK}	Voltage drop during conduction state, V
V_B	Blocking voltage, V
V_{BE}	Base-emitter voltage, V
V_{bi}	Built-in voltage, V
V_{CE}	Collector-emitter voltage, V

V_{CH}	Channel voltage, V
V_{d1} and V_{d2}	Depletion layer voltages, V
V_D	Drain bias, V
V_{DC}	DC supply voltage, V
V_{DS}	Drain-source voltage, V
V_F	Forward voltage drop, V
V_G	Gate drive voltage, V
V_{GE}	Gate emitter voltage, V
V_{GS}	Gate-source voltage, V
V_{N^-}	Carrier storage region voltage, V
V_{N^-}	Drift region voltage drop, V
V_{j0}, V_{j1}, and V_{j2}	Voltage drop at junctions J_0, J_1, and J_2, V
V_{j12}	Total junction voltage, V
V_R	Reverse voltage, V
v_{sat}	Saturation velocity, cm s^{-1}
V_{seg}	Resistive voltage drop of a segment, V
V_T	Thermal voltage, V
V_{th}	Threshold voltage, V
W	Depletion layer width, cm
W	Miller capacitance width, cm
W	Schottky contact width, cm
W_B	Base width, cm
W_{CH}	DMOSFET channel width, cm
W_D	Drift layer thickness, cm
W_{d1} and W_{d2}	Depletion widths, cm
W_{DEP}	Depletion region width, cm
W_{DRIFT}	Drift region width, cm
W_g	Gate width, cm
W_I	Intrinsic layer width, cm
W_{min}	Minimum width of the depletion layer of *N*-base, cm
W_N	Width of buffer layer, cm
W_P	Base region width, cm
W_S	Depletion width between gate and source, cm
W_0	Zero bias depletion region width, cm
W_1, W_2, W	Widths of the depletion region on the N^- and P sides of the junction and total depletion layer, cm
χ	SiC electron affinity, eV
x_D	Cross-sectional width, cm
x_j	P^+ region thickness, cm
x_{JP}	P-base junction thickness, cm
x_1	Thickness, cm
x_1 and x_2	Boundary positions of the carrier storage region, cm
z	Length of cell in the orthogonal direction to the cross section
z	Width in vertical to paper direction, cm
α_i, and α_{eff}	General ionization coefficient, effective ionization coefficient, cm^{-1}
β	Common-emitter gain
ε	Electric field strength, V cm^{-1}
ε_C	Critical electric field strength, V cm^{-1}
ε_r	*Si* Dielectric constant
ε_r	Relative permittivity
ε	Material permittivity, Fcm^{-1}
λ	Thermal conductivity, W cm^{-1} K^{-1}
μ_{CH}	Inversion layer mobility, $cm^2V^{-1}s^{-1}$
μ_n and μ_p	Electron and hole mobilities, $cm^2V^{-1}s^{-1}$
τ	High-level carrier lifetime, s
τ_n, τ_p, and τ_{HL}	Electron, hole, and high-level injection lifetimes, s
τ_{PHL}	High-level lifetime in P-base region, s
τ_{pN}	Minority lifetime in *N* region, s
τ_{N^-}	Electron lifetime in N^- region, s
ψ	Potential, V
ρ	Resistivity of the epilayer, Ω cm^{-2}
Q_G	Total gate charge, C
Q_{GD}	Gate-to-drain charge, C
Q_{GS}	Gate-to-source charge, C
Q_{GS}	Charge in buffer region, C
Q_N	Charge in buffer region, C
Q_{SW}	Switching charge, C
ϕ_m	Work function of the metal, eV

Acronyms/Initialisms

ac	Alternating current
ADE	Ambipolar diffusion equation
AlN	Aluminum nitride
AlGaN	Aluminum gallium nitride
Al_2O_3	Alumina
Au	Gold
BeO	Beryllia
BHFFOM	Baliga high-frequency figure of merit
BJT	Bipolar junction transistor
C	Carbon
C	Cubic
CLFOM	Conduction loss figure of merit
CS	Carrier storage
CSL	Current spreading layer
CSR	Carrier storage region
CTE	Coefficient of thermal expansion
DC	Direct current
DMOSFET	Double diffusion metal-oxide-semiconductor field-effect transistor
ET	Edge termination
FACTS	Flexible AC transmission systems
FET	Field-effect transistor
FOM	Figure of merit
FS	Field stop
GaN	Gallium nitride
GaAs	Gallium arsenide
Ge	Germanium
GTO	Gate turn-off thyristor
H	Hexagonal
HEMT	High-electron-mobility transistor
HFET	Heterostructure field-effect transistor
HVDCT	High-voltage DC transmission
ICM	Integral charge control model
IGBT	Insulated-gate bipolar transistor
IGCT	Integrated gate-commutated thyristor
IrPt	Indium-platinum
JBS	Junction barrier Schottky diode
JFET	Junction field-effect transistor
JFOM	Johnson's figure of merit
LC-JFET	Lateral channel junction field-effect transistor

LED	Light-emitting diode
MCT	MOS-controlled thyristors
MESFET	Metal-semiconductor field-effect transistor
Mg	Magnesium
Mo	Molybdenum
MOS	Metal-oxide-semiconductor
MOSFET	Metal-oxide-semiconductor field-effect transistor
MPS	Merged PN-Schottky diode
MTO	MOS turn-off thyristor
Ni	Nickel
Ni/Au	Nickel/gold
NO	Nitric oxide
NPT	Nonpunch-through
PCB	Printed circuit board
PiN	*P*, intrinsic and *N*-doped regions
Pd	Palladium
PdAg	Palladium-silver
Pt	Platinum
PNP	*P*-, *N*-, and *P*-doped regions
PT	Punch-through
R	Rhombohedral
RC	Resistor-capacitor
RESURF	Reduced surface field
SBD	Schottky barrier diode
SCR	Silicon-controlled rectifier
Si	Silicon
SiC	Silicon carbide
Si_3N_4	Silicon nitride
SiO_2	Silicon dioxide
SLFOM	Switching losses figure of merit
SRH	Shockley-Read-Hall
T	Titanium
2DEG	Two-dimensional electron gas
VCJFET	Vertical channel junction field-effect transistor
VJFET	Vertical junction gate field-effect transistors

6.1 Introduction

A power electronic module or power module is an assembly containing several power components, mostly power semiconductor devices, properly internally interconnected to perform a power conversion function. It is an integrated building block for the realization of a power converter with a reduced number of external components required. Control electronics such as gate drivers, sensing, and protection functions may be included inside the power module package. In this case, the term intelligent power module (IPM) is commonly used. From the electric standpoint, the power module reduces parasitic elements in the interconnection of the power semiconductor devices due to the tight physical integration. From the thermal standpoint, the power module usually has a thermally conductive baseplate that can be bolted to a heat sink or a cold plate to remove the loss heat generated as a result of power converter operation. From the mechanical standpoint, it provides a robust mechanical package for the power components inside. In conclusion, a power module is an electro-thermo-mechanical device optimized for power converter operation. Using a power module may simplify the design of a power converter because the power module design provides a robust mechanical structure and guarantees proper operation from an electric and thermal point of view as long as the module datasheet specifications and guidelines are followed. Power modules are typically used at higher power levels, where a discrete component implementation would require paralleling of several power semiconductor devices.

Advantages of power modules are tight integration of multiple power semiconductor devices, high current and power ratings because multiple power semiconductor dies can be paralleled inside the module, good thermal management, and mechanical robustness. Probably, the biggest advantage is the reduction of parasitic elements, in particular parasitic inductances, due to the tight integration. These parasitic elements cause additional losses and overshoot and ringing during converter operation, which cause electromagnetic interference (EMI) issues. The parasitic element reduction allows switching converter operation at higher frequency, which reduces passive

filtering element size, and may provide additional system-level advantages, such as quiet converter operation at switching frequencies above the audible range.

The main disadvantage of power modules is probably a higher cost compared with discrete devices. A second disadvantage is that a specific application may require characteristics not available in commercial modules on the market.

In this article, power electronic modules will be described mostly from the point of view of a power module user, somebody who wants to use a power module to realize a power converter rather than the point of view of the designer of a power module.

In Section 6.2, the differences between discrete devices and modules are discussed. Section 6.3 gives an example of a power module. Section 6.4 briefly describes the manufacturing process of power modules. Section 6.5 describes various types of modules and the types of power semiconductor devices used in them. Section 6.6 discusses thermal management and Section 6.7 module reliability. Finally, Section 6.8 provides design guidelines and considerations for the use of power modules.

6.2 Discrete Power Devices Versus Power Modules

Fig. 6.1 shows a photo of two discrete semiconductor components—a power metal-oxide-semiconductor field-effect transistor (MOSFET) and a diode—and a power module. The power module is a half-bridge configuration realized with silicon insulated-gate bipolar transistors (IGBTs). The module ratings are from 1200 V to 100 A. Notice that the power module has multiple power and control connections. The module of Fig. 6.1 has three large screw-type power connections for the power terminals and four smaller pin-type connections on top for the IGBT gate terminals. The bottom of the module has a metal baseplate that can be bolted to a heat sink for thermal management. Two of the baseplate holes for heat sink mount can be clearly seen at the bottom. Notice that a discrete component contains a single power semiconductor device in an individual package, whereas the power module contains multiple power semiconductor devices. A second difference is that for discrete devices, the metal plate for heat sink connection, if provided like in the discrete MOSFET of Fig. 6.1, is typically nonisolated, whereas in the power module, all semiconductor devices are thermally coupled to the baseplate but are electrically isolated from it. In the TO220 discrete MOSFET, the metal tab is electrically connected to the drain of the MOSFET, and electric isolation must be provided as part of the heat sink mount.

6.3 An Example of Power Module

In this section, an example of an IGBT half-bridge power module is described. The physical structure of the power module with labeled terminal connections is shown in Fig. 6.2.

The equivalent circuit of the module is shown in Fig. 6.3 with labeled terminals. The top IGBT, called IGBT1, has collector terminal C1 and emitter terminal E1. The gate and emitter Kelvin terminals are called G1K and E1K, respectively (Kelvin contacts are discussed in Section 6.8.3). Labeling is similar for IGBT2, the bottom IGBT. Note that the module contains four distinct semiconductor devices, two IGBTs and

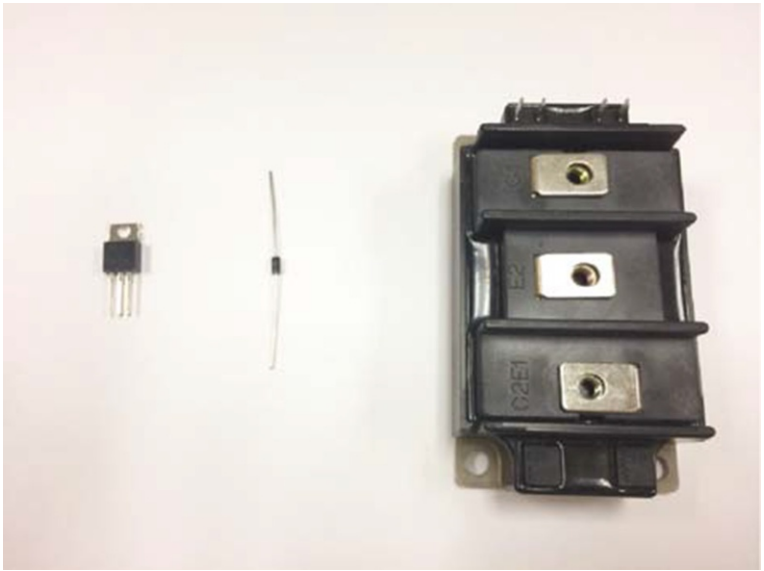

FIG. 6.1 From left to right: photo of a discrete power MOSFET in TO220 package, a discrete leaded diode, and a power electronic module (Toshiba MG100Q2YS1).

FIG. 6.2 Photo of Toshiba MG100Q2YS1 IGBT half-bridge power module with labeled terminals.

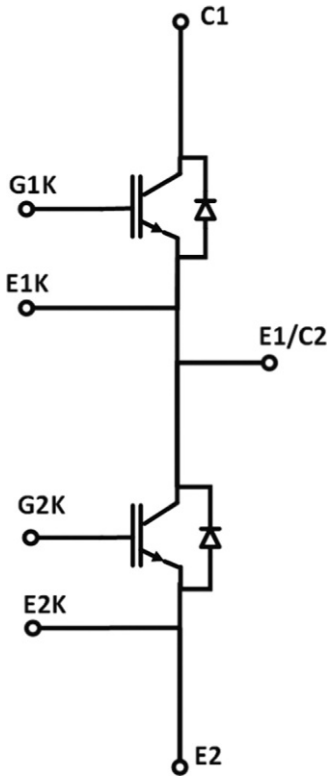

FIG. 6.3 Equivalent circuit of Toshiba MG100Q2YS1 power module.

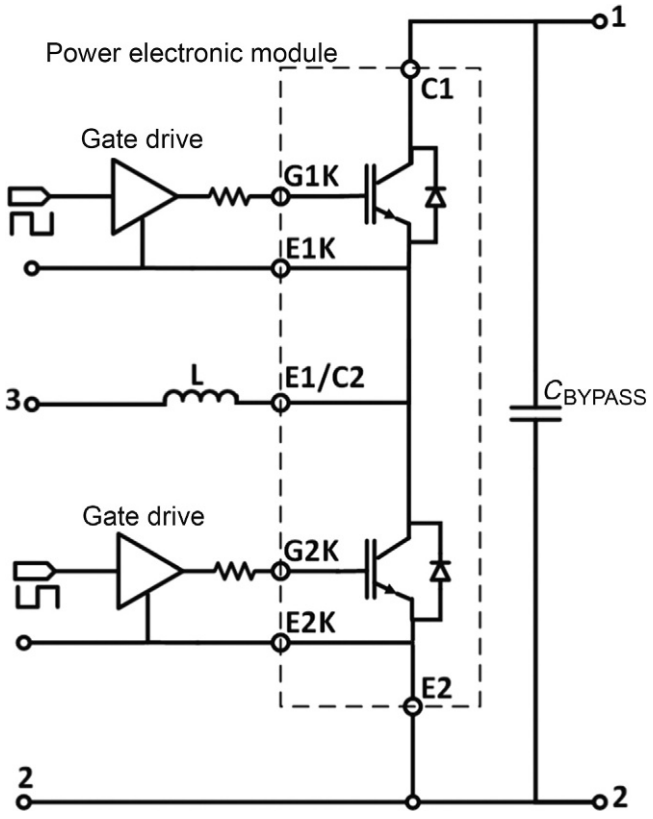

FIG. 6.4 Equivalent circuit of power electronic module with some of the external components needed for switching converter realization.

two diodes. Each of these may consist of a single die or multiple dies connected in parallel to achieve higher current capability.

The IGBT half-bridge power module can be used to realize different switching power converters such as a bidirectional DC-DC converter (buck type in one direction and boost type in the other direction) or a single-phase two-level inverter. Three modules could be combined to create a three-phase inverter, but in that case, using a single three-phase module may be more convenient. Some of the external components required to realize a switching power converter are shown in Fig. 6.4. First of all, gate drivers are required to control the IGBTs. In a switching converter, the two IGBTs are turned on in a complementary fashion, so that, when one IGBT is on, the other one is off. The gate driver controls should introduce a short dead time during which both switches are off to prevent shoot-through, that is, shorting capacitor C_{BYPASS}. Second, a bypass capacitor C_{BYPASS} is required to filter the square-

wave current at the switching frequency drawn by the power module during operation. As will be described later, capacitor C_{BYPASS} should be a high-frequency capacitor and should be placed physically close to the module to minimize interconnection parasitic inductance, which causes overshoot and ringing during switching operation. Finally, an inductor L is required to filter the square-wave voltage at the switching frequency created at node E1/C2 by the switching action. Sources and loads can then be connected to the 1-2 and 3-2 ports.

6.4 Manufacturing Process

As mentioned above, power modules contain multiple power devices internally interconnected to realize a specific power processing function, such as the IGBT half-bridge module package shown in Fig. 6.2. As shown in the equivalent circuit of Fig. 6.3, this module contains multiple IGBT and diode chips interconnected to form a half-bridge topology. Physically, a power module is an integration of semiconductor chips, wire bonds, direct bonded copper (DBC) substrate, solder, baseplate, silicone gel, terminals, housing, and so on as shown in Fig. 6.5. The manufacturing process includes attaching chips on the DBC substrate, bonding wires, attaching the DBC substrate to the baseplate, placing the top housing, and filling it with silicone gel. Each element of the generic power module of Fig. 6.5 has a specific function, and its selection depends on many factors. The semiconductor chips are selected to provide the required voltage and current ratings. The DBC substrate provides electric isolation but good thermal coupling between the chips and the baseplate, so that heat generated on the chips can be efficiently conducted to the baseplate. The top copper layer provides the required electric connections among the bottom terminals of the chips. Wire bonds provide the required electric connections for the top terminals of the chips and connections to the module terminals. The baseplate provides mechanical support for the module and can be connected to a heat sink for heat removal. These elements and the techniques used for power module assembly will be described more in detail in the following subsections.

6.4.1 Semiconductor Chips

The semiconductor chips form the core of a power electronic module. Fig. 6.6 shows the interior of a power electronic module with semiconductor chips mounted on a DBC substrate and interconnected with wire bonds. Semiconductor chips determine the voltage, current, and power ratings of the power module. Power modules with different internal interconnections of semiconductor chips are available to realize different power converter topologies such as half bridge and full bridge. To achieve high-current capability, multiple semiconductor chips can be paralleled inside the module. The performance of power modules in terms of on-resistance, switching speed, and power loss is critically dependent on the semiconductor chip characteristics.

6.4.2 Die Attach

Die attach is the process of attaching a die/chip to a substrate or package. For example, in the power module of Fig. 6.5, the IGBT chip and the diode chip are attached to the top copper layer of the DBC substrate. Note that in case of vertical chip devices, the device power terminals are on opposite sides of the chip, and therefore, the chip current flows through the die attach joint. Die attach is usually accomplished by using one of the following processes: (1) eutectic, (2) solder, (3) adhesive, (4) glass or silver glass:

1) A *eutectic bond* is formed by melting a preform consisting of a mixture or alloy of two or more dissimilar metals in the joint between the die and substrate. The preform has a melting point that is lower than the melting point of its base materials. For example, considering a typical

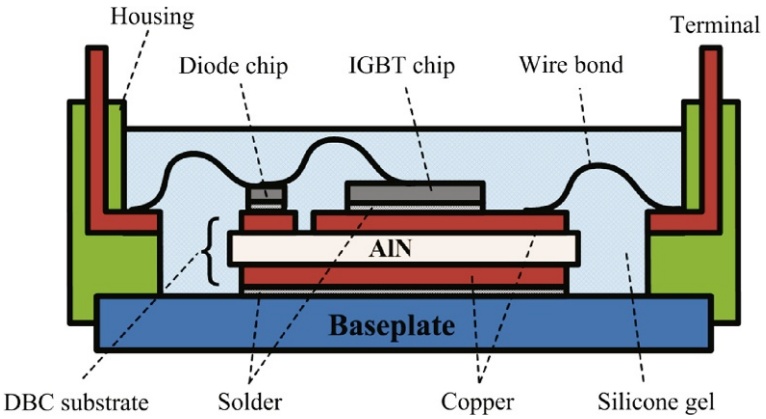

FIG. 6.5 Cross section of IGBT power electronic module.

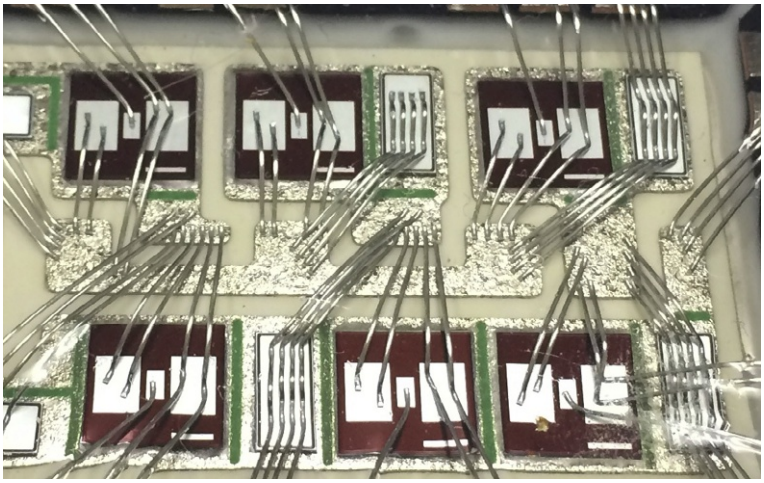

FIG. 6.6 Top view of power module interior showing semiconductor chips mounted on DBC substrate with wire bond interconnections.

preform composed of gold and silicon, the melting point of gold is 1640°C, and the melting point of silicon is 1414°C. However, when the materials are combined in a preform, the melting point drops to 363°C [1].

2) *Solder* is an attaching method commonly used in the semiconductor industry. Solder attach provides good mechanical strength, high thermal conductivity, and good electric conductivity. Lead-based solder has been popular for a long time with advantages of good performance, proved technology, and low cost. However, environmental concerns about the toxic properties of lead have recently arisen. As a result, lead-free solder is gradually replacing lead-based solder in many applications.
3) An *adhesive* bond is formed by attaching the die to the substrate using some type of adhesive material. It can be electrically insulating or conductive depending on the adhesive material used. An advantage of adhesive bonding is that it is performed at room temperature and does not require high temperatures.
4) A *glass bond* is formed by attaching the die to the substrate using glass in paste form. The glass paste may also contain silver particles that enhance thermal and electric conductivity (this is called silver-glass die bonding). The glass bonding process is similar to adhesive bonding. The differences are the material used and the need for heat. Glass bonds are heated to 350–450°C that melts the glass into a low viscosity liquid. The glass hardens as it cools, thereby making the bond [1].

6.4.3 Wire Bonds

The electric connections between the top connections of semiconductor chips and module terminals are realized by wire bonding (shown in Figs. 6.5 and 6.6). Conventional wire bonding materials include aluminum (Al), copper (Cu), and gold (Au). Aluminum is the most common material for power modules because of its low cost and convenient process, especially to form thick wires for high-current capability. Gold has the lowest resistivity and good high-frequency performance and is usually used for integrated circuit and high-frequency devices. Due to limited improvement of resistance in power module and high cost, gold is not commonly used in power modules. The electric properties of copper are intermediate between those of Al and Au, whereas the cost of aluminum is significantly lower than copper. Consequently, Al wire bonds are most common with copper used in special cases.

To satisfy high-current requirements, heavy wire bonding (Fig. 6.7) has been developed. Traditional wire size is smaller than 10 mils (1 mil = 1/1000 in.) in diameter, whereas heavy wire bonding is significantly thicker and can save space on the bonding pad. An alternative solution is ribbon bonding (Fig. 6.8), which has the added advantage of better high-frequency performance [2]. Ribbon bonding is a form of wedge bonding using flat ribbon to replace the round wire. Compared with round wire, ribbon wire can carry higher current at high frequency, where skin effect is the limiting factor, and has smaller effective inductance and less signal cross talk [3].

6.4.4 DBC Substrate

The DBC substrate is an important interface between the electric components in the power module and the external cooling system [4]. It consists of a ceramic insulator layer with copper bonded to one or both sides by a high-temperature melting and diffusion process. DBC substrates provide electric conduction on the top copper layer, electric isolation from top to bottom thanks to the ceramic insulator layer, and outstanding thermal conduction from top to bottom. The top copper layer is etched

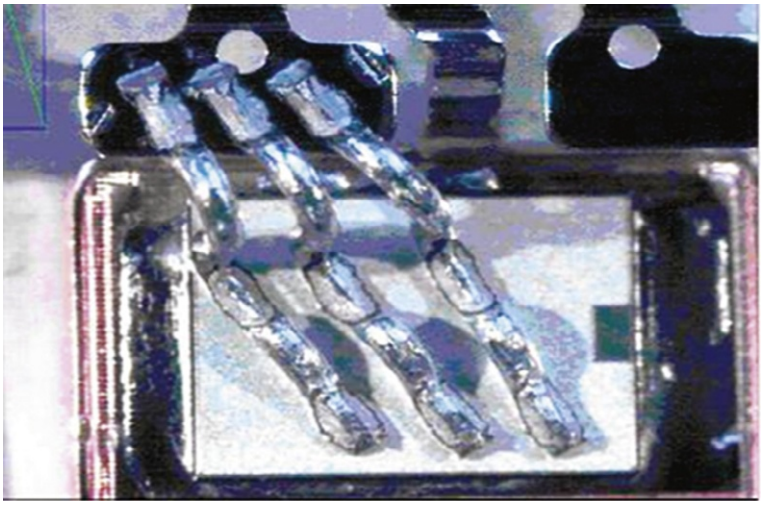

FIG. 6.7 Heavy wire bonding.

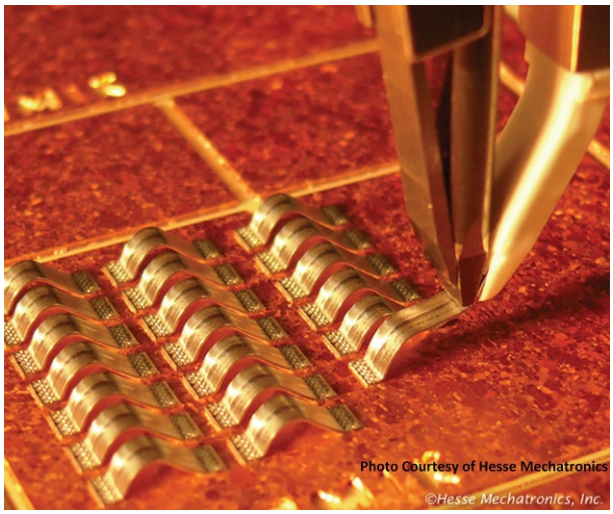

FIG. 6.8 Ribbon bonding.

to form the required electric interconnections and is electrically connected to the backside electrodes of semiconductor chips using one of the die attach techniques described above, most commonly by soldering. The excellent electric isolation is provided by the ceramic material. The two most common choices are alumina (Al_2O_3) and aluminum nitride (AlN). Al_2O_3 is inexpensive and widely used; however, it has the disadvantages of having relatively low thermal conductivity (24–28 W/m K) and of being brittle. Compared with Al_2O_3, AlN is more expensive, but it has better mechanical and thermal performance (thermal conductivity larger than 150 W/m K) and therefore has become popular in high-temperature applications [5]. The bottom copper layer is usually not patterned and is soldered to the baseplate to achieve heat spreading from top to bottom. One important thermal characteristic of DBC substrates is a low coefficient of thermal expansion (CTE), which is close to that of silicon. This ensures good thermal cycling performance and higher reliability.

6.4.5 Baseplate

One of the main functions of the baseplate is to provide mechanical support for the electric components and the DBC substrate. At the same time, it must propagate the heat generated by the semiconductor chips to the external heat sink effectively. A high degree of surface smoothness is also required to guarantee no voids between the baseplate and the DBC substrate, because voids can cause hot spots that will eventually lead to cracking and poor reliability [4]. In order to reduce the thermal resistance of the interface between the baseplate and the heatsink, a thin layer of thermal grease (also called thermal paste or heatsink compound) is applied between the baseplate and the heat sink. The purpose of

the thermal grease is to fill up voids due to interface surface imperfections, because air in these voids acts as an excellent thermal insulator. However, thermal grease is not a good thermal conductor, so a thick layer of thermal grease may actually *increase* the thermal resistance between the baseplate and the heat sink.

CTE mismatch is a key consideration in power module design and needs to be addressed in each connection and attachment between two different materials inside the power module. To improve power module mechanical reliability, adjacent materials should have closely matched CTEs, so that, when the module heats up and cools down during operation, the adjacent materials expand and contract in a similar way, avoiding the development of mechanical stress, which can cause joint failure due to mechanical fatigue. This is particularly important for large-area connections, which may develop larger mechanical stress during thermal cycling. Therefore, the baseplate material should be thermally compatible with the DBC substrate material, and mechanical, chemical, and other factors also need to be considered.

The housing and silicone gel are used to insulate the electric components on the top of the module and prevent contamination. In modern IPMs, thermal sensors are attached to the DBC close to the chips, to measure the real-time junction temperature, which is very useful for device condition monitoring.

6.5 Types of Power Electronic Modules

There are several different types of power electronic modules available on the market today. They come in different shapes and sizes and can be categorized either by the power processing topology used or by the power semiconductor devices used.

6.5.1 A Survey of Power Electronic Module Topologies

A brief survey of power electronic module topologies is now given:

Diode rectifier or thyristor rectifier: Four (or more) diodes or thyristors are connected in a bridge circuit configuration that converts an AC input (typically either single phase or three phase) into a DC output. A full-bridge and a three-phase bridge diode rectifier are shown in Fig. 6.9. For an example of a three-phase module, see Ref. [6].

- Half-bridge, full-bridge, or three-phase (six-pack) power module: Generally, these power modules, shown in Fig. 6.10, are implemented with either power MOSFETs or IGBTs (insulated-gate bipolar transistors). Typically, IGBTs can achieve much higher current and voltage ratings, allowing them to operate at higher power levels with reduced conduction losses, whereas MOSFETs can operate at much higher switching frequencies, making them suitable for application where fast switching and high power density are required. A half-bridge configuration can be used to implement a DC-DC power-bidirectional converter or a single-phase inverter. A full-bridge configuration can be used to implement a full-bridge converter or a three-level single-phase inverter. A six-pack power module can be used to implement a three-phase inverter or a three-phase-controlled rectifier. Note that since all switches are controllable, all these converter topologies are power bidirectional, that is, power can flow in both directions. For an example of a six-pack power module, see Ref. [7].
- Converter-inverter-brake (CIB) module: The module, shown in Fig. 6.11, contains a single-phase or three-phase uncontrolled or half-controlled bridge rectifier (C) plus an inverter (I) and a brake chopper (B). This module contains all power semiconductor devices required to implement a three-phase variable motor drive fed by three-phase power. The three-phase diode rectifier can be used to create a DC bus voltage that supplies the three-phase inverter connected to the three-phase motor. The chopper circuit allows to pulse-width modulate a braking resistor to dissipate energy during regenerative braking. See Ref. [8] for more information about regeneration in motor drives.

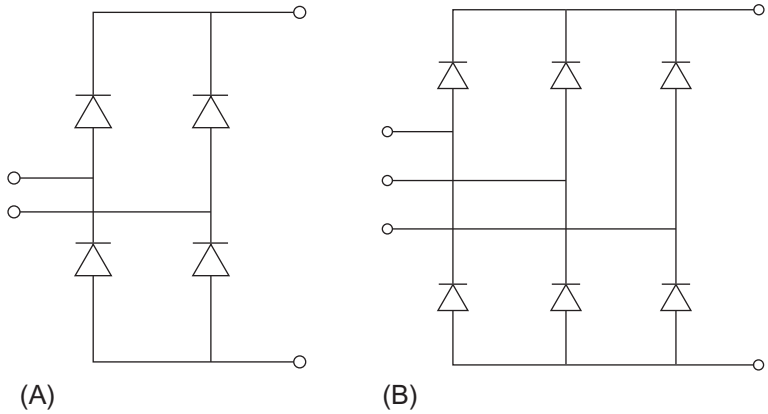

FIG. 6.9 Diode rectifier: single-phase full-bridge (A) and three-phase (B) configuration.

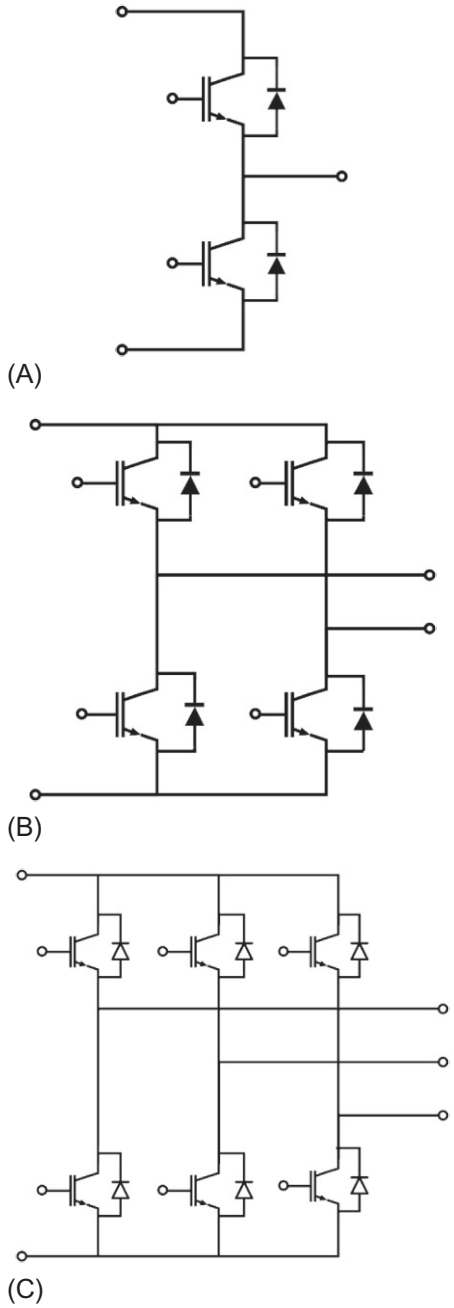

FIG. 6.10 Circuit diagram of a half-bridge (A), full-bridge (B), and a three-phase six-pack power module (C).

- Neutral-point-clamped (NPC) module: Each leg has four power switches connected in series. The applied voltage on the power switch is one-half that of a two-level converter. The NPC topology can allow operation at voltages larger than the voltage rating of a single power device. In addition, NPC converter can achieve lower output current ripples and improve the total harmonic distortion (THD) of the output.
- Power factor correction (PFC) module: PFC module combines a rectifying function and a PFC function in order to reduce the harmonics of the input current and improve power factor.

6.5.2 Power Semiconductor Devices Used in Power Electronic Modules

The most common power semiconductor devices used in power electronic modules are diodes, MOSFETs, IGBTs, and thyristors. Power bipolar junction transistors (BJTs) are less common and are briefly mentioned for completeness.

1. Power diode:

   Power diodes provide uncontrolled rectification of power and are used in applications such as AC-DC converters and variable-frequency drives. Typically, the power diode can be either a P-i-N diode or a Schottky diode.

   The P-i-N diode is a bipolar device having a so-called P-i-N structure, that is, it is a p-n junction with a wide, undoped intrinsic semiconductor layer (i-layer) in the middle to sustain a reverse blocking voltage. Frequently, the midlayer, rather than being intrinsic, has low N-doping and is therefore called N- (N minus) layer. Fig. 6.12 shows the basic structure of a P-i-N diode. In the forward-biased conduction, the diode has a forward conduction drop, which causes conduction loss, and the diode can be modeled as a junction voltage source, equal to the threshold voltage, and a series equivalent resistance that represents the increasing slope in the diode I-V characteristics. In the reverse-biased condition, a small reverse leakage current flows, which increases gradually with the applied reverse voltage. If the applied reverse voltage exceeds a certain voltage, called breakdown voltage, the reverse current becomes very large due to avalanche breakdown, and the diode may be destroyed due to large power dissipation in the device. The advantage of a P-i-N diode is low on-state voltage drop in high-current conduction, due to the minority carrier injection in epitaxial drift region resulting in conductivity modulation. However, the minority carrier injection during conduction causes a large reverse recovery current during diode turnoff, which is not desirable, because it causes additional turn-on loss in the active switch.

   The Schottky diode is a very attractive unipolar device, formed by an electrically nonlinear contact between a metal and a semiconductor bulk region shown in Fig. 6.13. It has low on-state voltage drop, almost zero reverse recovery charge, and extremely high switching

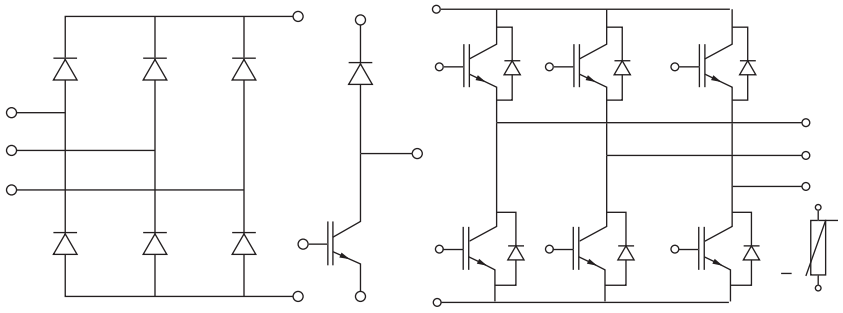

FIG. 6.11 CIB module including a three-phase uncontrolled rectifier, a brake chopper, and a three-phase IGBT inverter. A temperature-sensing thermistor is also included.

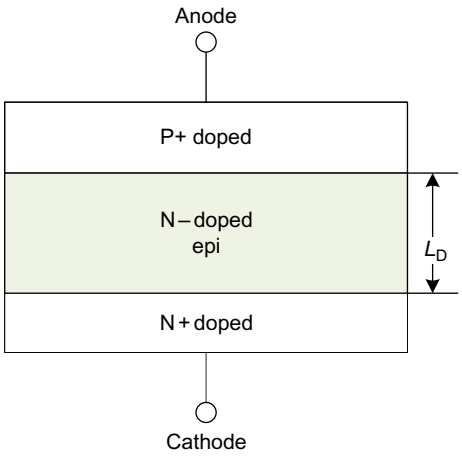

FIG. 6.12 Basic structure of a P-i-N diode.

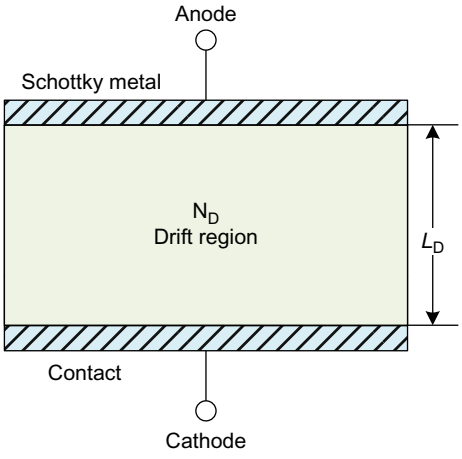

FIG. 6.13 Basic structure of a Schottky diode.

speed, but its reverse leakage current is large especially at high temperature due to its lower built-in potential barrier. Additionally, the breakdown voltage of Schottky diode is limited by the increase of drift region resistance without any conductivity modulation effect.

2. Power MOSFET

The power metal-oxide-semiconductor field-effect transistor (MOSFET) is a unipolar, majority carrier, and voltage-controlled device. It is one of the most commonly used power devices due to its easy gate driving, fast switching speed, and low loss dissipation. Most power MOSFETs feature a vertical structure (a structure of alternating p-type and n-type doping) shown in Fig. 6.14. In most power MOSFETs, the N+ source and P-well junction are shorted to prevent the parasitic bipolar transistor from turning on accidentally. When no gate voltage is applied, the power MOSFET is capable of supporting a drain-source blocking voltage through the reverse-biased P-well and N-epi junction. In high-voltage devices, most of the blocking voltage is supported by the lightly doped N-epi layer.

Generally speaking, the power MOSFET can operate in two different quadrants of its *I-V* characteristics:

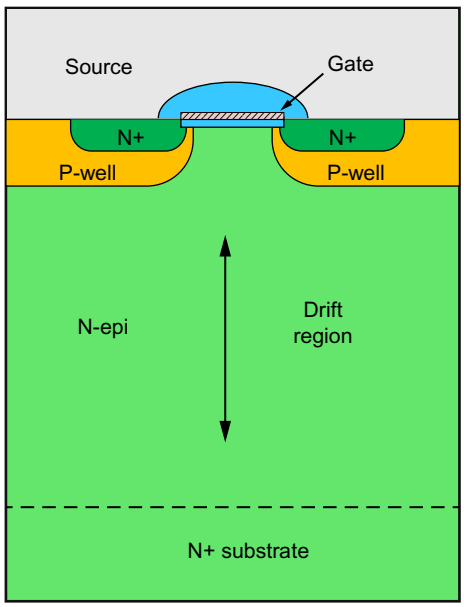

FIG. 6.14 Basic structure of a power MOSFET.

the first quadrant operation and the third quadrant operation. As the gate voltage (V_G) increases above a threshold voltage (V_{th}), the MOSFET starts to conduct current. When the gate voltage V_G is much larger than the threshold voltage V_{th}, the output *I-V* curve appears linear, and the MOSFET channel is fully turned on. Under low gate overdrive, the drain current reaches a saturation value when the MOSFET channel is pinched off.

The MOSFET's switching behavior is highly dependent on the parasitic capacitances gate-to-source C_{gs}, gate-to-drain C_{gd}, and drain-to-source C_{ds}. Gate-to-drain capacitance C_{gd} and drain-to-source C_{ds} are nonlinear and a function of bias voltages.

3. Power IGBT

   The insulated-gate bipolar transistor (IGBT) is a minority carrier device with high input impedance and large current-carrying capability. The IGBT combines the advantages of both power MOSFET and BJT, and it has MOS input characteristics and bipolar output characteristics. The basic structure of a power IGBT is shown in Fig. 6.15.

   The IGBT is widely used in many applications of power electronics, such as motor drives, uninterruptible power supplies (UPS), and power modules, because of the following advantages:
   - A very low on-state voltage drop due to conductivity modulation and very small conduction loss
   - A simple gate driver circuit design due to the MOS gate structure
   - A very large current-carrying capability and smaller chip size for a given conduction current
   - Good forward and reverse voltage blocking capability

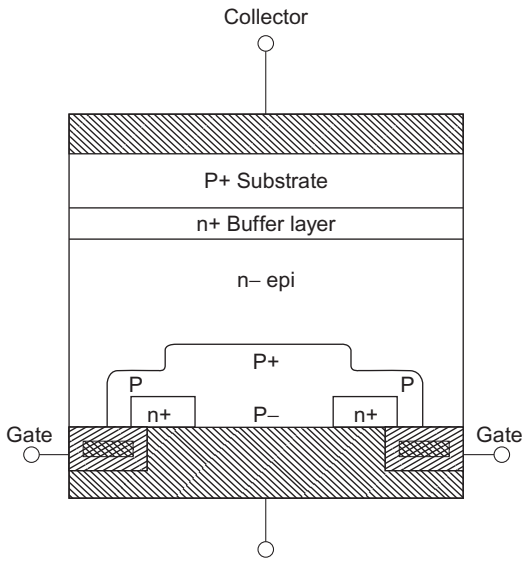

FIG. 6.15 Basic structure of a power IGBT.

   However, the IGBT has some drawbacks, compared with power MOSFET:
   - Slow switching speed, current tailing due to carrier combination
   - Latch-up issue due to the parasitic thyristor structure

   The IGBT is viewed as a serial connection of a MOSFET and a P-i-N diode, and sometimes it is modeled as a wide base PNP transistor driven by a MOSFET in Darlington configuration. In the output I-V characteristics of a power IGBT, the conduction current starts flowing when the gate voltage exceeds the threshold voltage, and collector-source voltage is approximately above 0.7 V.

4. Power Thyristor

   A thyristor is a power device with four alternating layers of p-type and n-type doping and can be turned on by the gate terminal but cannot be turned off by the gate [9]. It has the largest power-handling capability.

5. Power BJT

   The power bipolar transistors (BJT) are conceptually the same as the small-signal BJTs. The main difference is that the active area of power BJT device is much larger resulting in a much higher current handling capability. Power BJTs also have a thick and lightly doped collector region. Such collector regions result in a large blocking voltage.

6.5.3 SiC Power Semiconductor Devices in Power Modules

In recent times, power semiconductor devices using silicon carbide (SiC), a wide bandgap material, rather than silicon have become commercially available. The SiC material has superior material properties for power electronic applications. SiC devices are starting to be used in power modules. In particular, SiC-merged barrier Schottky diodes are used to replace high-voltage P-i-N diodes. The advantage is that, unlike P-i-N diodes, SiC Schottky diodes are majority carrier devices and do not exhibit reverse recovery at turnoff. SiC MOSFETs are also being introduced in modules. Presently, the higher cost of SiC devices limits their adoption.

6.6 Thermal Management of Power Modules

6.6.1 The Purpose of Thermal Management

For a variety of system-level reasons, modern power electronic applications require compact and high-power density power converters. In order to achieve this required miniaturization, higher integration of components and higher switching frequencies, which reduce passive filtering element size, are required. The increase in switching frequency leads to increased power losses and the physical integration makes it harder to remove the loss heat generated. This creates a significant design challenge that requires careful thermal

management. Additionally, in power modules, the power dissipation is concentrated inside the small power semiconductor chips, making heat removal particularly difficult. Power module datasheets specify a maximum allowable junction temperature, that is, temperature at the semiconductor chips inside the module. Exceeding this temperature will lead to module failure. Moreover, lower operating junction temperatures lead to markedly improved module reliability. The maximum junction temperature for current commercially available silicon-based power modules is around 150°C.

Another thermal concern affecting module reliability is thermal cycling, that is, the alternate heating and cooling of the module as a result of varying operating conditions. Excessive thermal cycling leads to aging and early failure of the module. In order to avoid overheating and to improve reliability, a common recommendation is that junction temperature should not exceed 125°C. Therefore, thermal management of power module is necessary to satisfy the thermal requirements described above.

6.6.2 Equivalent Thermal Network of Power Module

Fig. 6.16 shows a cross section of a power electronic module. Power dissipation occurs at the silicon chip due to conduction and switching losses. The heat is conducted through several material layers inside the module until it reaches the baseplate. Fig. 6.16 shows that the heat flows from top to bottom through the top solder layer, the top copper layer, the ceramic substrate, the bottom copper layer, the bottom solder layer, and the baseplate. From the baseplate, the heat exits the module, crosses the thermal grease layer, and reaches the heat sink. In case of air cooling, the heat then transfers by convection to the air surrounding the heat sink. Usually, the heat flow is modeled as being unidimensional with the lateral heat spreading modeled as a spreading angle that increases the heat flow cross section. It should be kept in mind that this approximation introduces a certain error [10]. Each material layer has a certain thermal resistance and thermal capacitance. The temperature gradient across each layer drives the conductive heat transfer. Consequently, the temperature gradually decreases from junction temperature at the silicon chip to ambient temperature T_{AMB}.

The junction temperature in the power module can be estimated by the equivalent Cauer *RC* thermal network shown in Fig. 6.17. In this equivalent model, voltage represents temperature, and current represents heat flow. An *RC* cell represents a specific material layer [11]. The thermal resistance R_i of the *i*th layer is given by

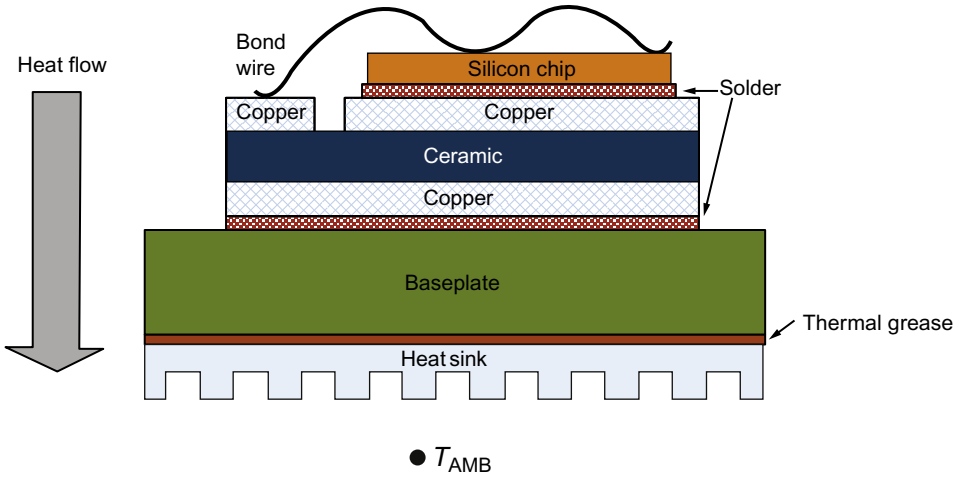

FIG. 6.16 Cross section of power electronic module showing heat flow.

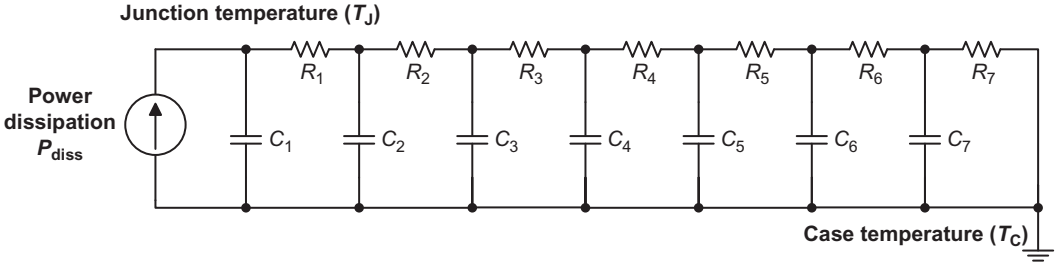

FIG. 6.17 Equivalent Cauer RC thermal network of the power module from junction to case.

$$R_i = \frac{d_i}{k_i A_i} \tag{6.1}$$

where d_i is the ith layer thickness; A_i is the effective cross-sectional area, including a spreading angle for conductors; and k_i is the thermal conductivity of the ith layer.

Thermal capacitance C_i of the ith layer is given by the equation

$$C_i = (c \times \rho \times V)_i \tag{6.2}$$

where c is the constant pressure-specific heat capacity, ρ is the mass density, and V is the effective volume of the ith layer.

According to the equivalent thermal network, the junction temperature T_J is numerically equal to the top left node voltage (the top node of the input current source), while the case temperature T_C represents the reference node voltage of the network. The power module datasheets provide a numerical value for the junction-to-case thermal resistance $R_{th(JC)}$. The term "case" indicates the bottom of the baseplate, where the heat sink is attached. In the equivalent model of Fig. 6.17, $R_{th(JC)}$ is equal to the sum of all thermal resistances R_1 through R_7. The relationship between T_J and T_C is given by the following equation [12]:

$$T_J = T_C + P_{diss} \cdot R_{th(JC)} \tag{6.3}$$

This thermal resistance directly provides the temperature difference between junction and case. To calculate the absolute temperature, it is necessary to calculate the case temperature T_C. This temperature can be calculated based on the selected heat sink, air flow, and ambient temperature T_{AMB}.

As previously mentioned, power modules frequently have a thermal sensor mounted in close proximity of the chips. This gives experimental access to junction temperature in real time [13]. Note that this method can only measure the junction temperature in steady state or for slowly varying thermal transients, because the measured value is accurate only at thermal equilibrium.

According to the thermal network, the junction temperature can be controlled in an acceptable range by applying external cooling to the case of the module.

6.6.3 Cooling Solutions for Power Module

6.6.3.1 Air Cooling

The fin heat sink is a common air cooling solution used in industry, as shown in Fig. 6.18.

For low-power application, a fin heat sink with natural convection is a good choice because no additional device is needed. When the dissipated power is larger, forced convection cooling using an electric fan can be used. However, when the dissipated power density exceeds 100 W/cm^2, the heat sink will not satisfy the cooling requirement, and a more effective cooling method is needed, such as liquid cooling.

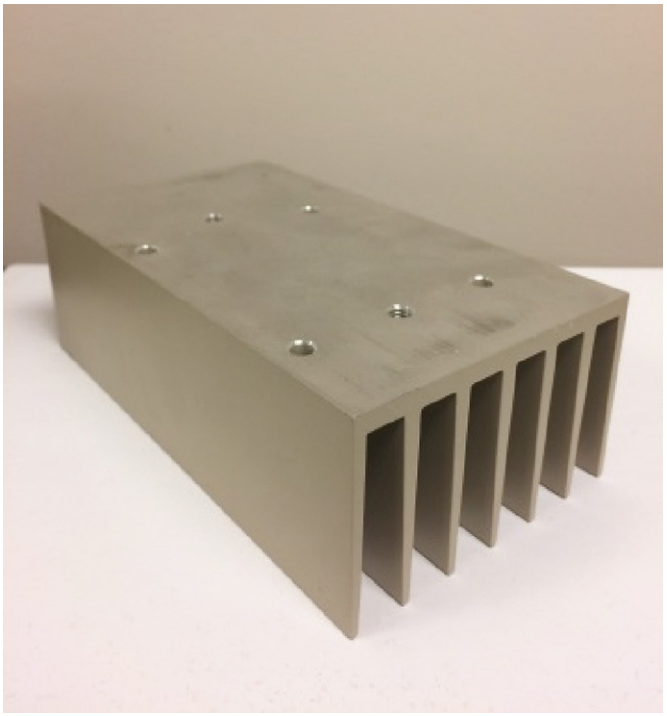

FIG. 6.18 Structure of fin heat sink for power electronics.

6.6.3.2 Liquid Cooling

Liquid cooling has higher thermal transfer efficiency than air cooling and is used in high-power modules. The power module baseplate is thermally connected to a so-called cold plate, which is liquid-cooled. A liquid cooling system is required, as shown in Fig. 6.19. The cooling liquid in the system, such as water, is pumped into the inlet of the cold plate, is heated by the heat flow from the module, flows out from the outlet, and transfers the heat to the cooling radiator. The cold water is gathered in the coolant tank and recirculated. Liquid cooling provides superior thermal performance compared with air cooling, but it incurs additional cost and may affect reliability due to possible coolant leaks.

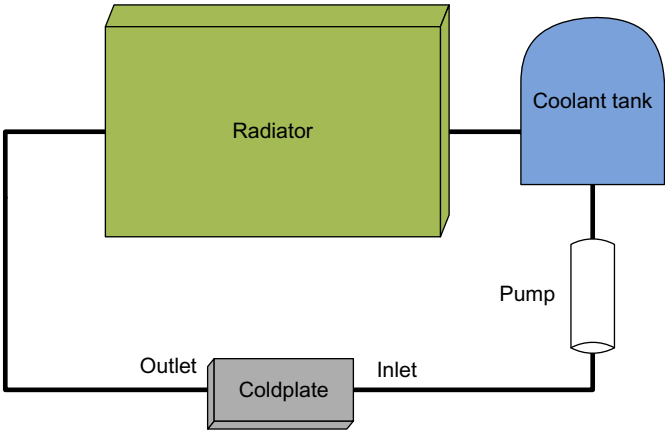

FIG. 6.19 Schematic cold plate and liquid cooling system.

6.6.3.3 Double-Sided Cooling

An approach to increase cooling performance is to remove heat from both sides of the semiconductor dies, instead of removing it from one side only. This approach cannot be used effectively in case of the wire bond package of Fig. 6.16, because the wire bonds prevent heat removal from the top. Consequently, double-sided cooling can be applied only to wire-bond-free power modules. Wire-bond-free packaging techniques include low-temperature attach using double-sided DBC, flip chip solder balls interconnection technology, and press-pack technology. Design complexity, cooling efficiency, electric isolation, and power density must be considered for each case when interfacing the device package with advanced double-sided cooling schemes. The cooling methods are different and depend on the packaging technology used. The double-sided cooling methods are now briefly discussed for the double-sided DBC structure and for the press-pack structure.

6.6.3.4 Double-Sided Cooling Using the DBC Structure

Low-temperature attach techniques have been used to connect IGBT devices to DBC on both sides in order to achieve double-sided liquid cooling. This technique increases cooling performance, but electric isolation via DBC adds thermal resistance. Fig. 6.20 shows a cross section of the double-sided cooling structure with power semiconductors. This package design gave a thermal resistance of 0.087°C/W for a flow rate of 1.6 gal/min [14].

Flip chip solder ball interconnection technology can be used to eliminate cooling interface issues related to wire bonds, but electric isolation requirements limit the efficiency of the cooling system also in this case. Microchannels are integrated directly in the package to provide double-sided cooling. The interface between the device and DBC via solder balls as well as the use of DBC as isolation between the device and heat sinks somewhat reduces the heat transfer from the chip. This cooling and package configuration provides a thermal resistance of 0.09–0.12°C/W for a flow rate range of 0.2–2 gal/min [14]. Fig. 6.21 shows a cross section of the structure.

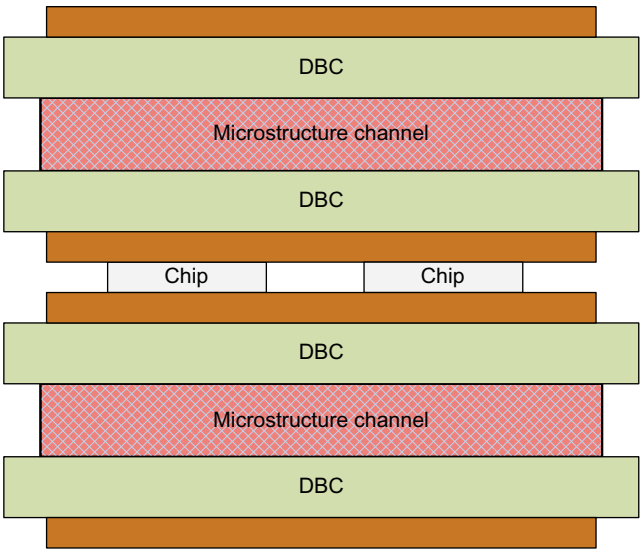

FIG. 6.20 Cross section of the double-sided cooling structure with low temperature joining techniques.

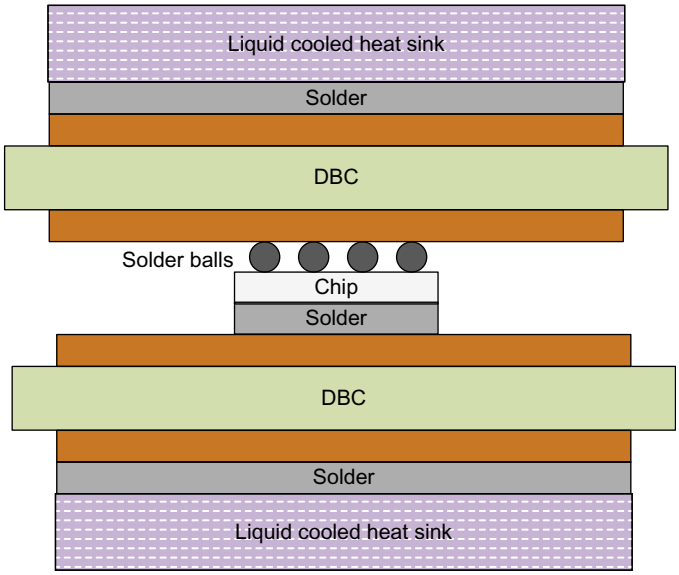

FIG. 6.21 Cross section of the double-sided cooling structure with flip chip solder.

6.6.3.5 Double-Sided Cooling Using the Press-Pack Structure

Press-pack semiconductor packaging technology can also allow advanced double-side cooling schemes. This example uses evaporators on both sides of the semiconductors. This method is promising for applications that use press-pack technology. Fig. 6.22 shows the cross section of the press-pack and double-sided multiphase cooling structure.

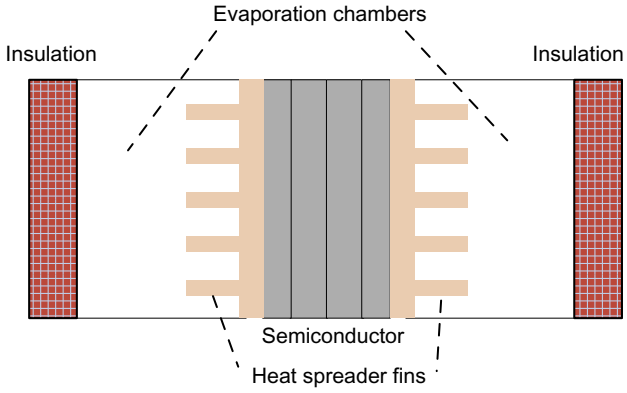

FIG. 6.22 Cross section of the double-sided cooling structure for press pack.

6.7 Reliability of Power Modules

For power electronic applications, reliability of power modules is an important issue. The reliability of power electronics has been improving over the years. As an example, power module failure rate in traction has decreased from 1000 FITs in 1995 to 20 FITs in 2000 (1 FIT = one failure per 10^9 device hours). In recent years, many failure-detecting tests have been proposed or improved, such as solder cracking and bond wire lift-off tests [15].

Thermomechanical stress on power module packaging materials is the most common reason for module failure due to mismatch in the coefficients of thermal expansion (CTE) between different adjacent materials inside the power module package. The structure of a power module, shown in Fig. 6.5, has been described earlier. The most common module failures are due to wire bond lifting, that is, the wire bond detaching from the surface it was bonded to, and solder cracking.

Bond wire lifting is one of the main reasons for power electronic module failures: a crack is formed and grows at the junction between the chip and the bond wire due to mismatch between the CTEs as a result of temperature variations. The difference in the CTEs causes strain at the interface. The strain initiates the crack that grows as a result of successive stress cycles during operation. This is shown in Fig. 6.23. The bond wire lifting failures can be examined by microstructural testing. A discussion of reliability in power modules can be found in [16].

Cracks usually grow from the two end sides during thermal cycles, and the bond wire lifts up when the crack reaches the center. A contributing factor to bond wire failures is magnetic forces induced on the wire bonds by inductive coupling among bond wires.

The second most common failure is related to solder fatigue at a solder joint inside the power module. For example, a failure may occur in the solder joint between a silicon die and the copper substrate, as shown in Fig. 6.24. The failure occurs because of CTE mismatch between the die chip and the substrate, which results in mechanical stress that shifts the solder layers laterally in relation to each other and eventually creates voids.

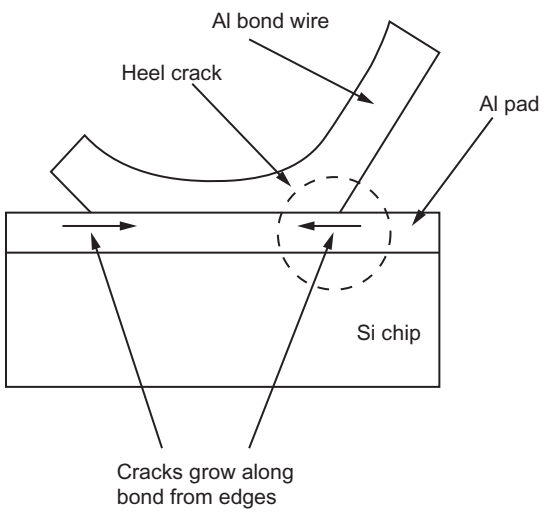

FIG. 6.23 Bond wire lifting resulting from crack propagation.

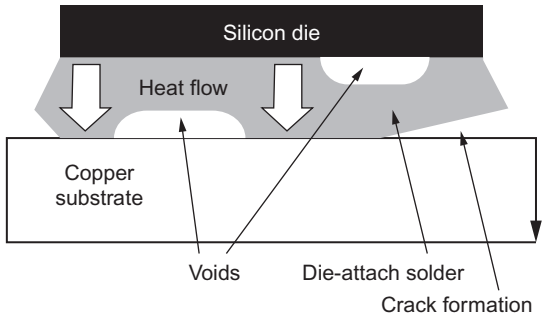

FIG. 6.24 Void and crack formation between die and substrate.

As shown in Fig. 6.24, the voids are a barrier to heat conduction from die to substrate and cause a nonuniform heat distribution. This in turn increases the thermal resistance between die and substrate and damages the die. The stress on the interfaces depends on temperature and increases as temperature increases.

Two different types of thermal stress can be identified, power cycling and thermal cycling. Power cycling refers to temperature variations caused by varying power loss in the devices due to a variation of operating conditions. Thermal cycling is the effect of temperature variations in the environment around the power module.

Power converters usually undergo both types of temperature cycling but with different levels of temperature variation and frequency [16].

6.7.1 Reliability Tests [17]

A power module is exposed to active temperature cycles due to its operation and to passive temperature cycles due to variation of the surrounding environment. Thermal cycling and power cycling tests can be performed to represent these conditions and evaluate reliability:

6.7.1.1 Thermal Cycling Test

In this test, the temperature of the power module is changed as a result of a change in case temperature or of variation of ambient temperature (TST, thermal shock test). No electric stress is applied. This test evaluates lifetime of the solder joints and ability of the device to survive sudden temperature variation.

6.7.1.2 Power Cycling Test

In this test, the ruggedness of semiconductor devices such as IGBTs and MOSFETs is evaluated under thermomechanical stress due to power loss cycling in the internal semiconductor

dies. The variation of temperature is due to periodic variations of load current. This test evaluates reliability under high-temperature operation.

The equivalent test cycles can be evaluated by converting the thermal stress on solder and bond joints due to active and passive thermal stress into reliability test data.

6.8 Design Guidelines and Considerations

In order to utilize a commercially available power module to realize a switching converter for a specific application, the following steps should be followed:

1. *Power module selection based on switching converter specifications*. A power module of the desired topology with the appropriate voltage and current rating should be selected. The type (IGBT, MOSFET, and so on) and characteristics of the power semiconductor devices in the module determine achievable switching frequency. From the manufacturer's datasheets, conduction and switching losses can be estimated.
2. *Electric design*. Referring to Fig. 6.4, the external components required to realize the converter need to be designed. These include bypass capacitor C_{BYPASS}, gate drivers (unless they are already integrated inside the module), power inductor L, and converter control. Some special considerations regarding the first two items, which are specific to power modules, will be discussed below.
3. *Thermal design*. Based on the estimated losses, the thermal design must be completed. The cooling method—natural convection, forced convection, or liquid cooling—is selected and the thermal circuit designed to achieve a desired maximum junction temperature under worst-case conditions.

For a successful design, it is critical to follow the specifications and recommendations in the manufacturer's datasheets. Manufacturers also provide additional design support, such as application notes, technical papers, and online loss calculation software tools for their products.

6.8.1 Bypass Capacitor Considerations

Besides component selection, as is frequently the case in power electronics, proper physical layout is critical. As shown in Fig. 6.25, for the case of a half-bridge converter, the switching loop should be minimized in physical size in order to reduce overshoot and ringing during switching. The objective is to reduce the distributed parasitic inductance of the switching loop, shown as lumped inductance L_{SWITCH} in the figure.

As shown in Fig. 6.4, the switching loop is partially inside the power module, but it is completed by the external capacitor

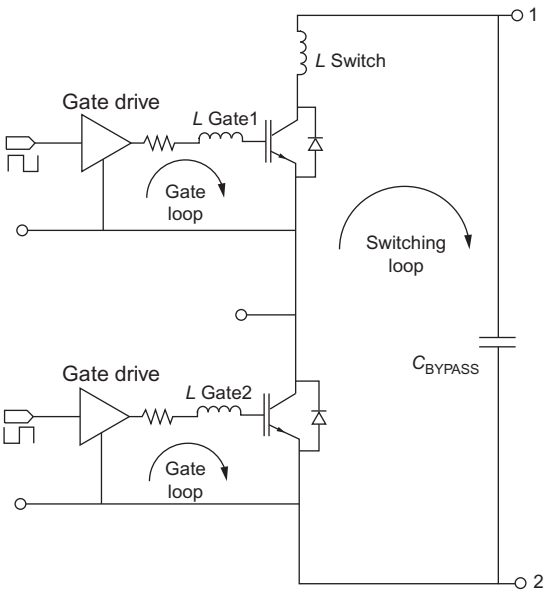

FIG. 6.25 Half-bridge module schematic showing the switching loop and the gate loops that should be minimized for proper converter operation.

C_{BYPASS}. This capacitor should absorb the square-wave current at the switching frequency resulting from switching converter operation. It is critical to use a high-frequency high-current-ripple capacitor. Ceramic or metal film capacitors are appropriate. Polypropylene capacitors are a popular choice. It is critical to mount the bypass capacitor physically close to the module. A laminated bus bar is recommended to reduce parasitic inductance by having closely spaced flat conductors conducting opposite polarity currents.

6.8.2 Gate Driver Design Considerations

The gate driver design is similar to what is commonly done for discrete power semiconductor devices. Based on the total gate charge Q_G from the datasheets and on the desired gate voltage rise and fall time, a gate driver with adequate current capability is selected. The choice of gate resistor is a trade-off: a smaller gate resistor gives faster switching speed with lower switching losses and with increased gate noise immunity, whereas a larger gate resistor gives slower switching speed with reduced switching noise and reduced diode reverse recovery. It should be kept in mind that power modules frequently have internal gate resistances in case of multiple paralleled dies as shown in Fig. 6.26. Resistances R_g are internal to the module and are needed to ensure dynamic current balance. If a single gate resistor was used, there could be an LC oscillation caused by the input capacitances of the two IGBTs resonating with the parasitic inductance of the gate connection. In the case of Fig. 6.26, this resonant path has a $2R_g$ series damping resistance. The module

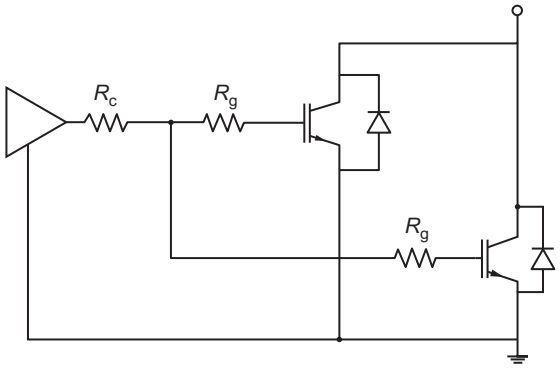

FIG. 6.26 Schematic of bottom switch of power module consisting of two paralleled IGBTs with internal resistances R_g.

datasheets usually provide a recommended external gate resistor range of values.

Regarding layout, it is important to minimize the gate loops shown in Fig. 6.25. A large gate loop causes a large parasitic inductance L_{GATE} that resonates with the IGBT input capacitance causing gate voltage ringing, which may cause spurious IGBT switching. The power module gate contacts should be directly connected to the gate driver printed circuit board if possible.

6.8.3 Gate Kelvin Contacts

Power modules typically have gate Kelvin contacts. It is essential that they be used for the gate drive as shown in Fig. 6.4 in order to have an effective dynamic gate voltage control. Fig. 6.27 shows the case of no emitter Kelvin contact. As a result, there is a parasitic emitter inductance L_E that is part of both the switching

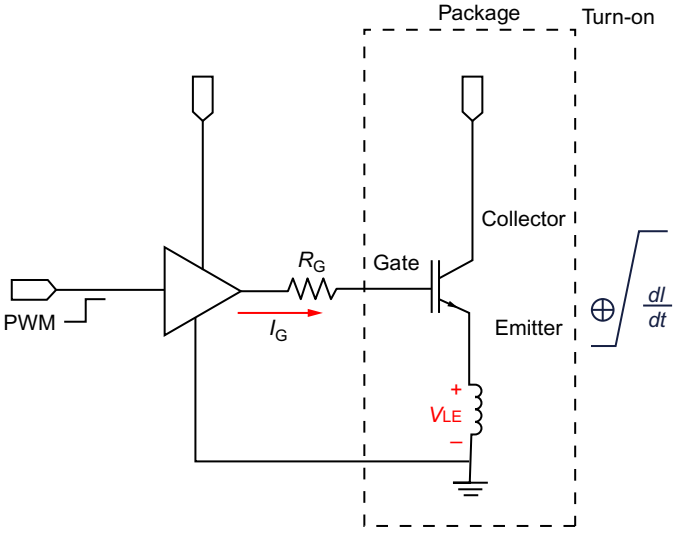

FIG. 6.27 Packaged IGBT without emitter Kelvin contact.

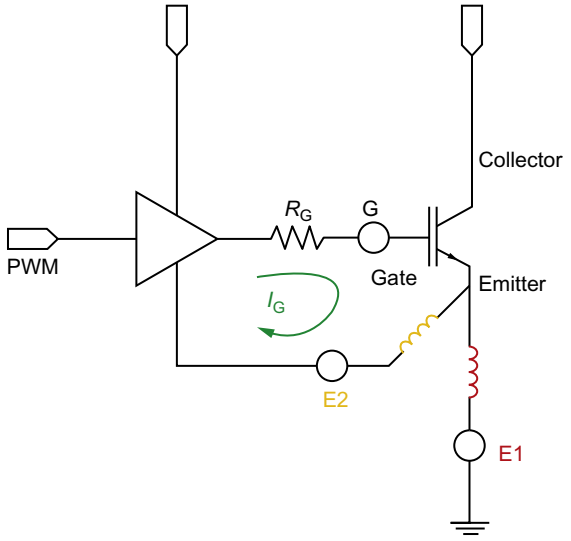

FIG. 6.28 Emitter Kelvin contact E2 is separate from emitter power contact E1.

loop and the gate loop (refer to Fig. 6.25). This inductance conducts the full collector current. During turn-on, the gate drive voltage increases, and the IGBT gradually turns on. The increasing collector current induces a positive voltage v_{LE} on the parasitic emitter inductance that subtracts from the gate driver voltage and slows down the gate-emitter voltage rise. This negative feedback effect is undesirable because it slows down the switching transition and causes the gate driver to have less dynamic control of the actual gate-emitter voltage. A similar negative feedback effect occurs at turnoff, slowing down this transition as well. This problem can be solved by providing a separate emitter Kelvin contact as shown in Fig. 6.28. The power contact emitter inductance (in red) is not part of the gate loop, and the negative feedback effect is eliminated.

Fig. 6.29 shows the inside of a six-pack IGBT power module. On the bottom left side, one can see the power emitter pin and the Kelvin emitter pin. Notice that dedicated wire bonds go from the IGBT chip to the Kelvin emitter pin. These wire bonds conduct only the gate driver current and not the collector current and represent the E2 connection of Fig. 6.28. The figure also shows the IGBT and diode dies, the IGBT gate and emitter pads, the wire bonds, the top copper layer, the ceramic substrate, and the thermistor.

6.8.4 Other Design Considerations

In order to realize a switching converter, other design aspects must be considered, such as protection, sensing, and control implementation. The gate driver may include protections, such as short circuit protection. Current sensing may be implemented for protection and for current mode programming control.

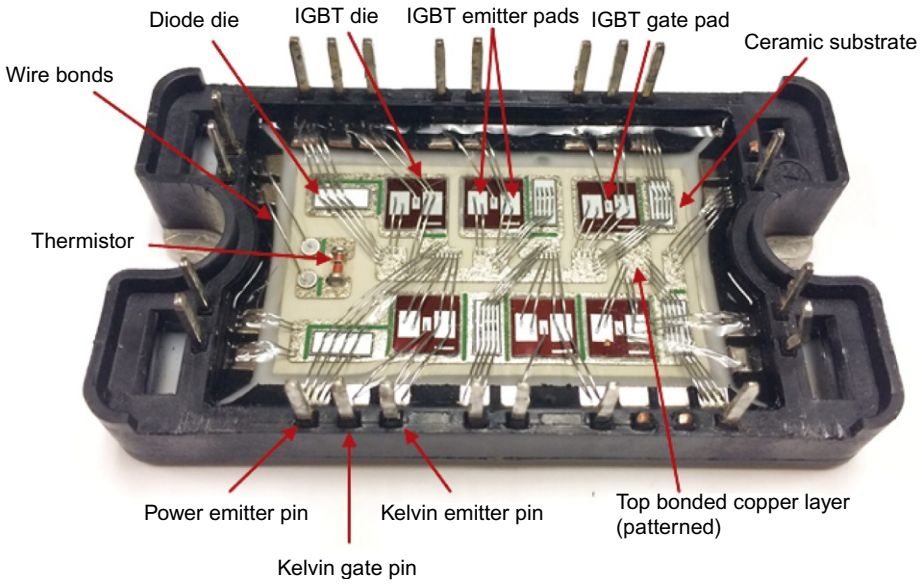

FIG. 6.29 Photo of opened Microsemi APTGF50X60T3G six-pack IGBT power module (from 600 V to 50 A) with several internal features labeled.

Voltage sensing is typically required for control. Either an analog or a digital controller can be used. Snubbers and clamps may be required to reduce switching waveform overshoot and ringing. EMI filters may be required.

7.1 Introduction

This chapter describes the application and design of diode rectifier circuits. It covers single-phase rectifier circuits, three-phase rectifier circuits, polyphase rectifier circuits, and high-frequency rectifier circuits. The objectives of this chapter are the following:

- To enable the readers to understand the operation of typical rectifier circuits
- To enable the readers to appreciate the different qualities of rectifiers required for different applications
- To enable the reader to design practical rectifier circuits

The high-frequency rectifier waveforms given are obtained from PSpice simulations, which take into account the secondary effects of stray and parasitic components. In this way, the waveforms can closely resemble the real ones. These waveforms are particularly useful to help designers determine the practical voltage, current, and other ratings of high-frequency rectifiers.

7.2 Single-Phase Diode Rectifiers

There are two types of single-phase diode rectifier that convert a single-phase ac supply into a dc voltage, namely, single-phase half-wave rectifiers and single-phase full-wave rectifiers. In the following subsections, the operations of these rectifier circuits are examined, and their performances are analyzed and compared in a tabulated form. For the sake of simplicity, the diodes are considered to be ideal, that is, they have zero forward voltage drop and reverse recovery time. This assumption is generally valid for the case of diode rectifiers that use the mains, a low-frequency source, as the input and when the forward voltage drop is small compared with the peak voltage of the mains. Furthermore, it is assumed that the load is purely resistive such that the load voltage and the load current have similar waveforms. In Section 7.5, Filtering Systems in Rectifiers Circuits, the effects of inductive load and capacitive load on a diode rectifier are considered in detail.

7.2.1 Single-Phase Half-Wave Rectifiers

The simplest single-phase diode rectifier is the single-phase half-wave rectifier. A single-phase half-wave rectifier with resistive load is shown in Fig. 7.1. The circuit consists of only one diode that is usually fed with a secondary transformer as shown. During the positive half cycle of the transformer secondary voltage, diode D conducts. During the negative half cycle, diode D stops conducting. Assuming that the transformer has zero internal impedance and provides perfect sinusoidal voltage on its secondary winding, the voltage and current waveforms of resistive load R and the voltage waveform of diode D are shown in Fig. 7.2.

By observing the voltage waveform of diode D in Fig. 7.2, it is clear that the peak inverse voltage (PIV) of diode D is equal to V_m during the negative half cycle of the transformer secondary voltage. Hence, the peak repetitive reverse voltage (V_{RRM}) rating of diode D must be chosen to be higher than V_m to avoid reverse breakdown. In the positive half cycle of the transformer secondary voltage, diode D has a forward current that is equal to the load current; therefore, the peak repetitive forward current (I_{FRM}) rating of diode D must be chosen to be higher than the peak load current, V_m/R, in practice. In addition, the transformer has to carry a dc current that may result in a dc saturation problem of the transformer core.

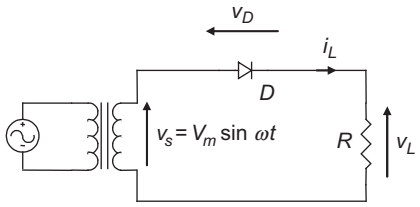

FIG. 7.1 A single-phase half-wave rectifier with resistive load.

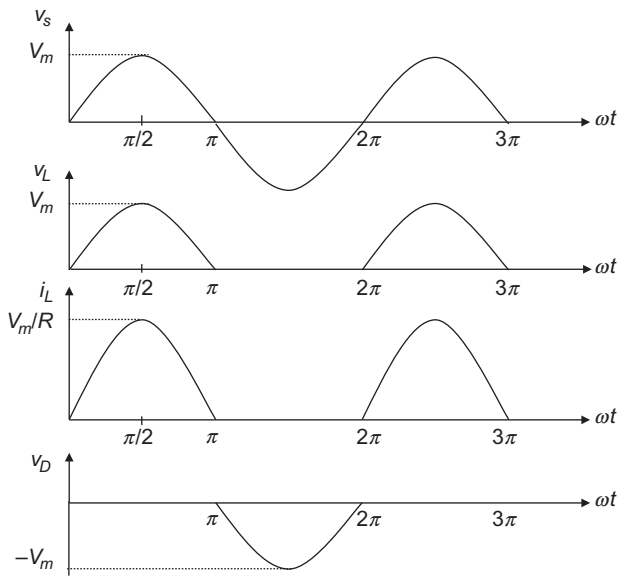

FIG. 7.2 Voltage and current waveforms of the half-wave rectifier with resistive load.

7.2.2 Single-Phase Full-Wave Rectifiers

There are two types of single-phase full-wave rectifier, namely, full-wave rectifiers with center-tapped transformer and bridge rectifiers. A full-wave rectifier with a center-tapped transformer is shown in Fig. 7.3. It is clear that each diode, together with the associated half of the transformer, acts as a half-wave rectifier. The outputs of the two half-wave rectifiers are combined to produce full-wave rectification in the load. As far as the transformer is concerned, the dc currents of the two half-wave rectifiers are equal and opposite, such that there is no dc current for creating a transformer core saturation problem. The voltage and current waveforms of the full-wave rectifier are shown in Fig. 7.4. By observing diode voltage waveforms v_{D_1} and v_{D_2} in Fig. 7.4, it is clear that the PIV of the diodes is equal to $2V_m$ during their blocking state. Hence, the V_{RRM} rating of the diodes must be chosen to be higher than $2V_m$ to avoid reverse breakdown. (Note that, compared with the half-wave rectifier shown in Fig. 7.1, the full-wave rectifier has twice the dc output voltage, as shown in Section 7.2.4.) During its conducting state, each diode has a forward current which is equal to the load current; therefore, the I_{FRM} rating of these diodes must be chosen to be higher than the peak load current, V_m/R, in practice.

Employing four diodes instead of two, a bridge rectifier as shown in Fig. 7.5 can provide full-wave rectification without using a center-tapped transformer. During the positive half cycle of the transformer secondary voltage, the current flows to the load through diodes D_1 and D_2. During the negative half cycle, D_3 and D_4 conduct. The voltage and current waveforms of the bridge rectifier are shown in Fig. 7.6. As with the full-wave rectifier with center-tapped transformer, the I_{FRM} rating of the employed diodes must be chosen to be higher than the peak load current, V_m/R. However, the PIV of the diodes is reduced from $2V_m$ to V_m during their blocking state.

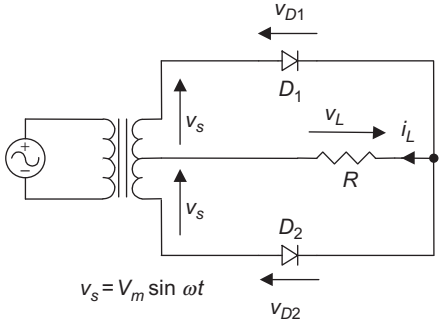

FIG. 7.3 Full-wave rectifier with center-tapped transformer.

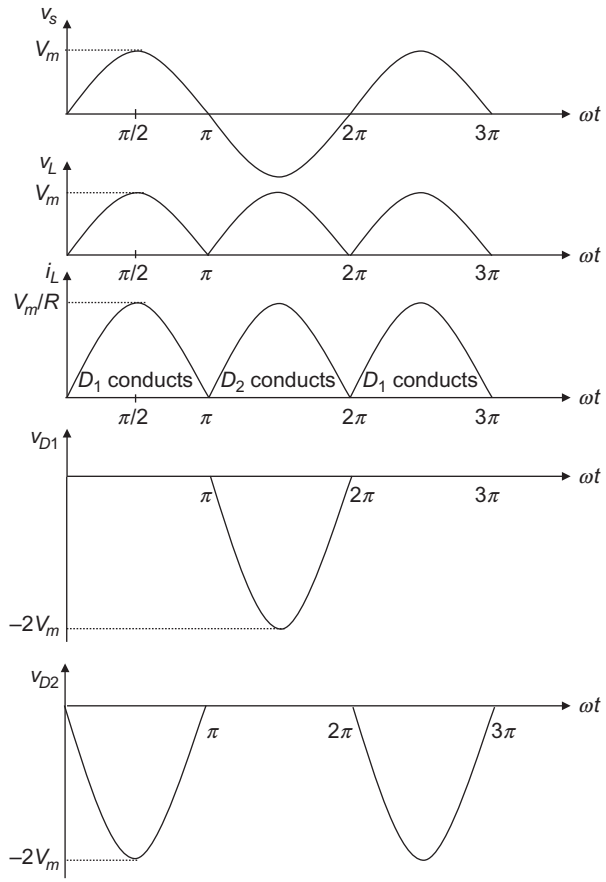

FIG. 7.4 Voltage and current waveforms of the full-wave rectifier with center-tapped transformer.

7.2.3 Performance Parameters

In this subsection, the performance of the rectifiers mentioned above will be evaluated in terms of the following parameters.

7.2.3.1 Voltage Relationships

The average value of the load voltage v_L is V_{dc} and it is defined as

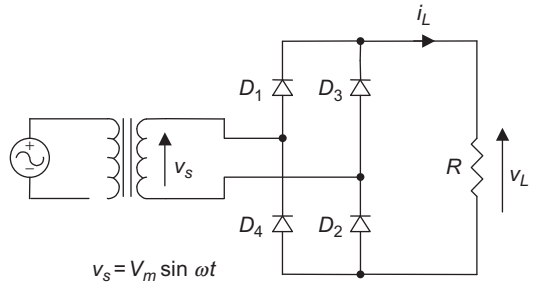

FIG. 7.5 Bridge rectifier.

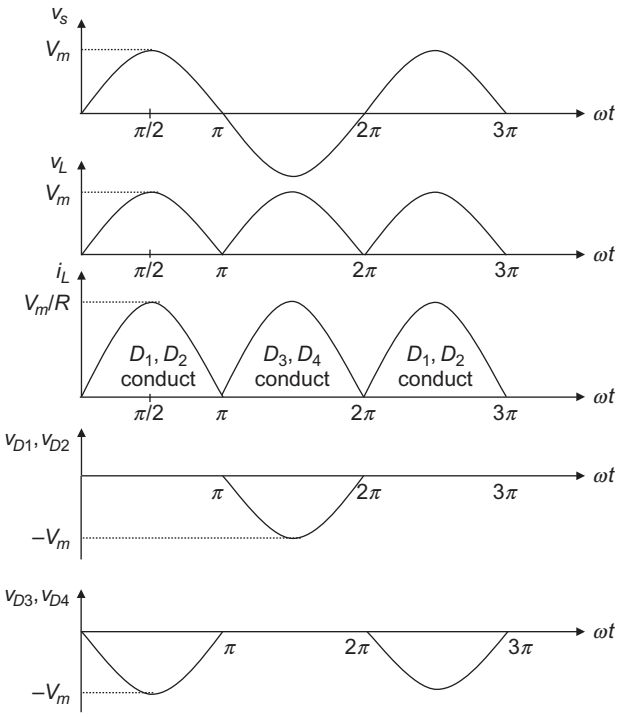

FIG. 7.6 Voltage and current waveforms of the bridge rectifier.

$$V_{dc} = \frac{1}{T}\int_0^T v_L(t)\,dt \tag{7.1}$$

In the case of a half-wave rectifier, Fig. 7.2 indicates that load voltage $v_L(t) = 0$ for the negative half cycle. Note that the angular frequency of the source $\omega = 2\pi/T$, and Eq. (7.1) can be rewritten as

$$V_{dc} = \frac{1}{2\pi}\int_0^{\pi} V_m \sin\omega t\, d(\omega t) \tag{7.2}$$

Therefore,

$$\text{Half-wave} \quad V_{dc} = \frac{V_m}{\pi} = 0.318\ V_m \tag{7.3}$$

In the case of a full-wave rectifier, Figs. 7.4 and 7.6 indicate that $v_L(t) = V_m|\sin\omega t|$ for both the positive and negative half cycles. Hence, Eq. (7.1) can be rewritten as

$$V_{dc} = \frac{1}{\pi}\int_0^{\pi} V_m \sin\omega t\, d(\omega t) \tag{7.4}$$

Therefore,

$$\text{Full-wave} \quad V_{dc} = \frac{2V_m}{\pi} = 0.636\ V_m \tag{7.5}$$

The root-mean-square (rms) value of load voltage v_L is V_L, which is defined as

$$V_L = \left[\frac{1}{T}\int_0^T v_L^2(t)dt\right]^{1/2} \tag{7.6}$$

In the case of a half-wave rectifier, $v_L(t) = 0$ for the negative half cycle; therefore, Eq. (7.6) can be rewritten as

$$V_L = \sqrt{\frac{1}{2\pi}\int_0^{\pi}(V_m \sin\omega t)^2 d(\omega t)} \tag{7.7}$$

or

$$\text{Half-wave} \quad V_L = \frac{V_m}{2} = 0.5V_m \tag{7.8}$$

In the case of a full-wave rectifier, $v_L(t) = V_m|\sin\omega t|$ for both the positive and negative half cycles. Hence, Eq. (7.6) can be rewritten as

$$V_L = \sqrt{\frac{1}{\pi}\int_0^{\pi}(V_m \sin\omega t)^2 d(\omega t)} \tag{7.9}$$

or

$$\text{Full-wave} \quad V_L = \frac{V_m}{\sqrt{2}} = 0.707V_m \tag{7.10}$$

The result of Eq. (7.10) is as expected because the rms value of a full-wave rectified voltage should be equal to that of the original ac voltage.

7.2.3.2 Current Relationships

The average value of load current i_L is I_{dc}, and because load R is purely resistive, it can be found as

$$I_{dc} = \frac{V_{dc}}{R} \tag{7.11}$$

The rms value of load current i_L is I_L, and it can be found as

$$I_L = \frac{V_L}{R} \tag{7.12}$$

In the case of a half-wave rectifier, from Eq. (7.3),

$$\text{Half-wave} \quad I_{dc} = \frac{0.318V_m}{R} \tag{7.13}$$

and from Eq. (7.8),

$$\text{Half-wave} \quad I_L = \frac{0.5V_m}{R} \tag{7.14}$$

In the case of a full-wave rectifier, from Eq. (7.5),

$$\text{Full-wave} \quad I_{dc} = \frac{0.636V_m}{R} \tag{7.15}$$

and from Eq. (7.10),

$$\text{Full-wave} \quad I_L = \frac{0.707V_m}{R} \tag{7.16}$$

7.2.3.3 Rectification Ratio

The rectification ratio, which is a figure of merit for comparing the effectiveness of rectification, is defined as

$$\sigma = \frac{P_{dc}}{P_L} = \frac{V_{dc}T_{dc}}{V_L I_L} \tag{7.17}$$

In the case of a half-wave diode rectifier, the rectification ratio can be determined by substituting Eqs. (7.3), (7.13), (7.8), and (7.14) into Eq. (7.17):

$$\text{Half-wave} \quad \sigma = \frac{(0.318V_m)^2}{(0.5V_m)^2} = 40.5\% \tag{7.18}$$

In the case of a full-wave rectifier, the rectification ratio is obtained by substituting Eqs. (7.5), (7.15), (7.10), and (7.16) into Eq. (7.17):

$$\text{Full-wave} \quad \sigma = \frac{(0.636V_m)^2}{(0.707V_m)^2} = 81\% \tag{7.19}$$

7.2.3.4 Form Factor

The form factor (FF) is defined as the ratio of the root-mean-square value (heating component) of a voltage or current to its average value:

$$\text{FF} = \frac{V_L}{V_{dc}} \quad \text{or} \quad \frac{I_L}{I_{dc}} \tag{7.20}$$

$$\text{Half-wave} \quad \text{FF} = \frac{0.5V_m}{0.318V_m} = 1.57 \tag{7.21}$$

In the case of a full-wave rectifier, the FF can be found by substituting Eqs. (7.16) and (7.15) into Eq. (7.20):

$$\text{Full-wave} \quad \text{FF} = \frac{0.707V_m}{0.636V_m} = 1.11 \tag{7.22}$$

7.2.3.5 Ripple Factor

The ripple factor (RF), which is a measure of the ripple content, is defined as

$$\text{RF} = \frac{V_{ac}}{V_{dc}} \tag{7.23}$$

where V_{ac} is the effective (rms) value of the ac component of load voltage v_L:

$$V_{ac} = \sqrt{V_L^2 - V_{dc}^2} \tag{7.24}$$

Substituting Eq. (7.24) into Eq. (7.23), the RF can be expressed as

$$\text{RF} = \sqrt{\left(\frac{V_L}{V_{dc}}\right)^2 - 1} = \sqrt{\text{FF}^2 - 1} \tag{7.25}$$

In the case of a half-wave rectifier,

$$\text{Half-wave} \quad \text{RF} = \sqrt{1.57^2 - 1} = 1.21 \tag{7.26}$$

In the case of a full-wave rectifier,

$$\text{Full-wave} \quad \text{RF} = \sqrt{1.11^2 - 1} = 0.482 \tag{7.27}$$

7.2.3.6 Transformer Utilization Factor

The transformer utilization factor (TUF), which is a measure of the merit of a rectifier circuit, is defined as the ratio of the dc output power to the transformer volt-ampere (VA) rating required by the secondary winding:

$$\text{TUF} = \frac{P_{dc}}{V_s I_s} = \frac{V_{dc} I_{dc}}{V_s I_s} \tag{7.28}$$

where V_s and I_s are the rms voltage and rms current ratings of the secondary transformer:

$$V_s = \frac{V_m}{\sqrt{2}} = 0.707 V_m \tag{7.29}$$

The rms value of the transformer secondary current I_s is the same as that of the load current I_L. For a half-wave rectifier, I_s can be found from Eq. (7.14):

$$\text{Half-wave} \quad I_s = \frac{0.5 V_m}{R} \tag{7.30}$$

For a full-wave rectifier, I_s is found from Eq. (7.16):

$$\text{Full-wave} \quad I_s = \frac{0.707 V_m}{R} \tag{7.31}$$

Therefore, the TUF of a half-wave rectifier can be obtained by substituting Eqs. (7.3), (7.13), (7.29), and (7.30) into Eq. (7.28):

$$\text{Half-wave} \quad \text{TUF} = \frac{0.318^2}{0.707 \times 0.5} = 0.286 \tag{7.32}$$

The poor TUF of a half-wave rectifier signifies that the transformer employed must have a 3.496 (1/0.286) VA rating in order to deliver 1 W dc output power to the load. In addition, the transformer secondary winding has to carry a dc current that may cause magnetic core saturation. As a result, half-wave rectifiers are used only when the current requirement is small.

In the case of a full-wave rectifier with center-tapped transformer, the circuit can be treated as two half-wave rectifiers operating together. Therefore, the transformer secondary VA rating, $V_s I_s$, is double that of a half-wave rectifier, but the output dc power is increased by a factor of four due to higher rectification ratio as indicated by Eqs. (7.5) and (7.15). Therefore, the TUF of a full-wave rectifier with center-tapped transformer can be found from Eq. (7.32):

$$\text{Full-wave} \quad \text{TUF} = \frac{4 \times 0.318^2}{2 \times 0.707 \times 0.5} = 0.572 \tag{7.33}$$

In the case of a bridge rectifier, it has the highest TUF in single-phase rectifier circuits because the currents flowing in both the primary and secondary windings are continuous sinewaves. By substituting Eqs. (7.5), (7.15), (7.29), and (7.31) into Eq. (7.28), the TUF of a bridge rectifier can be found:

$$\text{Bridge} \quad \text{TUF} = \frac{0.636^2}{(0.707)^2} = 0.81 \tag{7.34}$$

The transformer primary VA rating of a full-wave rectifier is equal to that of a bridge rectifier since the current flowing in the primary winding is also a continuous sinewave.

7.2.3.7 Harmonics

Full-wave rectifier circuits with resistive load do not produce harmonic currents in their transformers. In half-wave rectifiers, harmonic currents are generated. The amplitudes of the harmonic currents of a half-wave rectifier with resistive load, relative to the fundamental, are given in Table 7.1. The extra loss caused by the harmonics in the resistive loaded rectifier circuits is often neglected because it is not high compared with other losses. However, with nonlinear loads, harmonics can cause appreciable loss and other problems such as poor power factor and interference.

7.2.4 Design Considerations

In a practical design, the goal is to achieve a given dc output voltage. Therefore, it is more convenient to put all the design parameters in terms of V_{dc}. For example, the rating and turn ratio of the transformer in a rectifier circuit can be easily determined if the rms input voltage to the rectifier is in terms of the required output voltage V_{dc}.

Denote the rms value of the input voltage to the rectifier as V_s, which is equal to $0.707 V_m$. Based on this relation and Eq. (7.3), the rms input voltage to a half-wave rectifier is found as

$$\text{Half-wave} \quad V_s = 2.22 V_{dc} \tag{7.35}$$

TABLE 7.1 Harmonic percentages of a half-wave rectifier with resistive load

Harmonic	Second	Third	Fourth	Fifth	Sixth	Seventh	Eighth
%	21.2	0	4.2	0	1.8	0	1.01

Similarly, from Eqs. (7.5) and (7.29), the rms input voltage per secondary winding of a full-wave rectifier is found as

$$\text{Full-wave} \quad V_s = 1.11 V_{dc} \tag{7.36}$$

Another important design parameter is the V_{RRM} rating of the diodes employed.

In the case of a half-wave rectifier, from Eq. (7.3),

$$\text{Half-wave} \quad V_{RRM} = V_m = \frac{V_{dc}}{0.318} = 3.14 V_{dc} \tag{7.37}$$

In the case of a full-wave rectifier with center-tapped transformer, from Eq. (7.5),

$$\text{Full-wave} \quad V_{RRM} = 2V_m = \frac{2V_{dc}}{0.636} = 3.14 V_{dc} \tag{7.38}$$

In the case of a bridge rectifier, also from Eq. (7.5),

$$\text{Bridge} \quad V_{RRM} = V_m = \frac{V_{dc}}{0.636} = 1.57 V_{dc} \tag{7.39}$$

It is important to evaluate the I_{FRM} rating of the employed diodes in rectifier circuits.

In the case of a half-wave rectifier, from Eq. (7.13),

$$\text{Half-wave} \quad I_{FRM} = \frac{V_m}{R} = \frac{I_{dc}}{0.318} = 3.41 I_{dc} \tag{7.40}$$

In the case of full-wave rectifiers, from Eq. (7.15),

$$\text{Full-wave} \quad I_{FRM} = \frac{V_m}{R} = \frac{I_{dc}}{0.636} = 1.57 I_{dc} \tag{7.41}$$

The important design parameters of basic single-phase rectifier circuits with resistive loads are summarized in Table 7.2.

7.3 Three-Phase Diode Rectifiers

It has been shown in Section 7.2 that single-phase diode rectifiers require a rather high transformer VA rating for a given dc output power. Therefore, these rectifiers are suitable only for low-to-medium power applications. For power output higher than 15 kW, three-phase or polyphase diode rectifiers should be employed. There are two types of three-phase diode rectifier that convert a three-phase ac supply into a dc voltage, namely, star rectifiers and bridge rectifiers. In the following subsections, the operations of these rectifiers are examined, and their performances are analyzed and compared in tabulated form. For the sake of simplicity, the diodes and the transformers are considered to be ideal, that is, the diodes have zero forward voltage drop and reverse current and the transformers possess no resistance and no leakage inductance. Furthermore, it is assumed that the load is purely resistive, such that the load voltage and the load current have similar waveforms. In Section 7.5, Filtering Systems in Rectifier Circuits, the effects of inductive load and capacitive load on a diode rectifier are considered in detail.

7.3.1 Three-Phase Star Rectifiers

7.3.1.1 Basic Three-Phase Star Rectifier Circuit

A basic three-phase star rectifier circuit is shown in Fig. 7.7. This circuit can be considered as three single-phase half-wave rectifiers combined together. Therefore, it is sometimes referred to as a three-phase half-wave rectifier. The diode in a particular phase conducts during the period when the voltage on that phase is higher than that on the other two phases. The

TABLE 7.2 Important design parameters of basic single-phase rectifier circuits with resistive load

Output ripple frequency f_r	$1f_i$	$2f_i$	$2f_i$

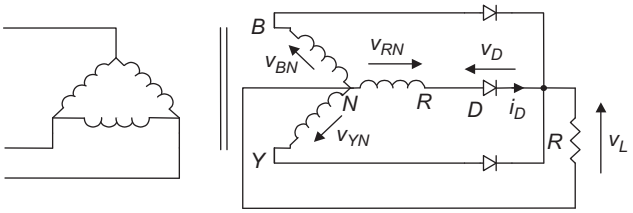

FIG. 7.7 Three-phase star rectifier.

voltage waveforms of each phase and the load are shown in Fig. 7.8. It is clear that, unlike the single-phase rectifier circuit, the conduction angle of each diode is $2\pi/3$, instead of π. This circuit finds uses where the required dc output voltage is relatively low, and the required output current is too large for a practical single-phase system.

Taking phase R as an example, diode D conducts from $\pi/6$ to $5\pi/6$. Therefore, using Eq. (7.1), the average value of the output can be found as

$$V_{dc} = \frac{3}{2\pi}\int_{\pi/6}^{5\pi/6} V_m \sin\theta d\theta \tag{7.42}$$

or

$$V_{dc} = V_m \frac{3}{\pi}\frac{\sqrt{3}}{2} = 0.827V_m \tag{7.43}$$

Similarly, using Eq. (7.6), the rms value of the output voltage can be found as

$$V_L = \sqrt{\frac{3}{2\pi}\int_{\pi/6}^{5\pi/6} (V_m \sin\theta)^2 d\theta} \tag{7.44}$$

or

$$V_L = V_m\sqrt{\frac{3}{2\pi}\left(\frac{\pi}{3} + \frac{\sqrt{3}}{4}\right)} = 0.84V_m \tag{7.45}$$

In addition, the rms current in each transformer secondary winding can also be found as

$$I_s = I_m\sqrt{\frac{1}{2\pi}\left(\frac{\pi}{3} + \frac{\sqrt{3}}{4}\right)} = 0.485I_m \tag{7.46}$$

where $I_m = V_m/R$.

Based on the relationships stated in Eqs. (7.43), (7.45), (7.46), all the important design parameters of the three-phase star rectifier can be evaluated, as listed in Table 7.3, which is given at the end of Section 7.3.2. Note that, as with a single-phase half-wave rectifier, the three-phase star rectifier shown in Fig. 7.7 has direct currents in the secondary windings that can cause a transformer core saturation problem. In addition, the currents in the primary do not sum to zero. Therefore, it is preferable not to have star-connected primary windings.

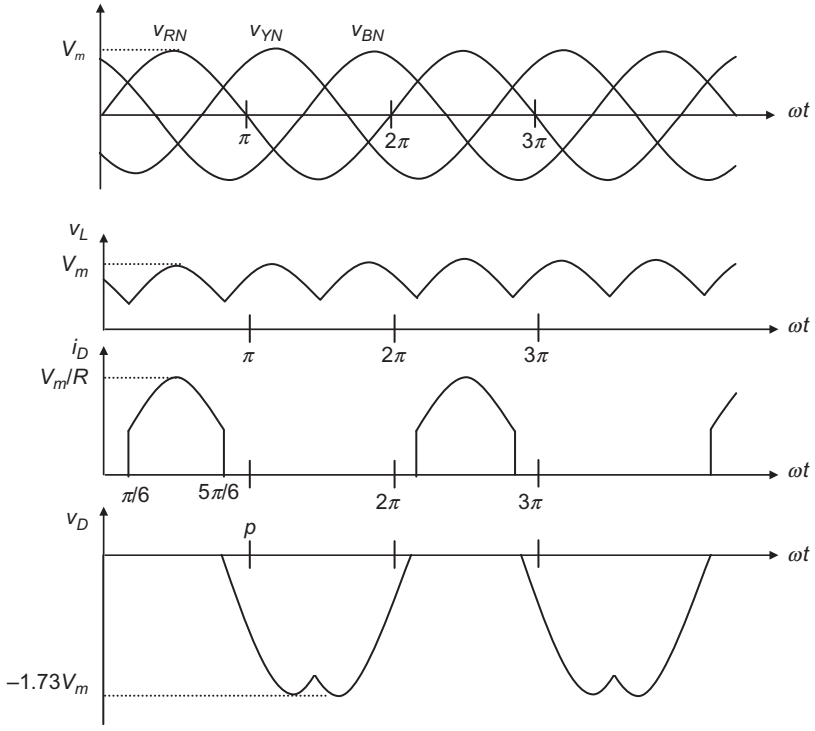

FIG. 7.8 Waveforms of voltage and current of the three-phase star rectifier shown in Fig. 7.7.

7.3.1.2 Three-Phase Interstar Rectifier Circuit

The transformer core saturation problem in the three-phase star rectifier can be avoided by a special arrangement in its secondary windings, known as zigzag connection. The modified circuit is called the three-phase interstar or zigzag rectifier circuit, as shown in Fig. 7.9. Each secondary-phase voltage is obtained from two equal-voltage secondary windings (with a phase displacement of $\pi/3$) connected in series so that the dc magnetizing forces due to the two secondary windings on any limb are equal and opposite. At the expense of extra secondary windings (increasing the transformer secondary rating factor from 1.51 to 1.74 VA/W), this circuit connection eliminates the effects of core saturation and reduces the transformer primary rating factor to the minimum of 1.05 VA/W. Apart from transformer ratings, all the design parameters of this circuit are the same as those of a three-phase star rectifier (therefore not separately listed in Table 7.3). Furthermore, a star-connected primary winding with no neutral connection is equally permissible because the sum of all primary phase currents is zero at all times.

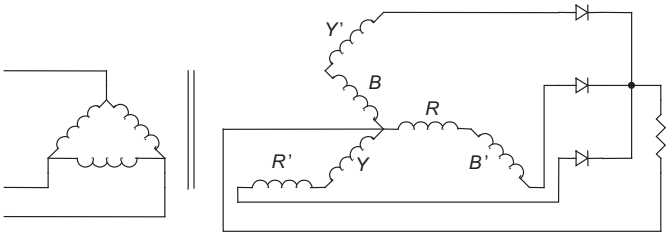

FIG. 7.9 Three-phase interstar rectifier.

7.3.1.3 Three-Phase Double-Star Rectifier With Interphase Transformer

This circuit consists essentially of two three-phase star rectifiers with their neutral points interconnected through an interphase transformer or reactor (Fig. 7.10). The polarities of the corresponding secondary windings in the two interconnected systems are reversed with respect to each other, so that the rectifier output voltage of one three-phase unit is at a minimum when the rectifier output voltage of the other unit is at a maximum as shown in Fig. 7.11. The function of the interphase transformer is to cause the output voltage v_L to be the average of the rectified voltages $v1$ and $v2$ as shown in Fig. 7.11. In addition, the ripple frequency of the output voltage is now six times that of the mains, and therefore, the component size of the filter (if there is any) becomes smaller. In a balanced circuit, the

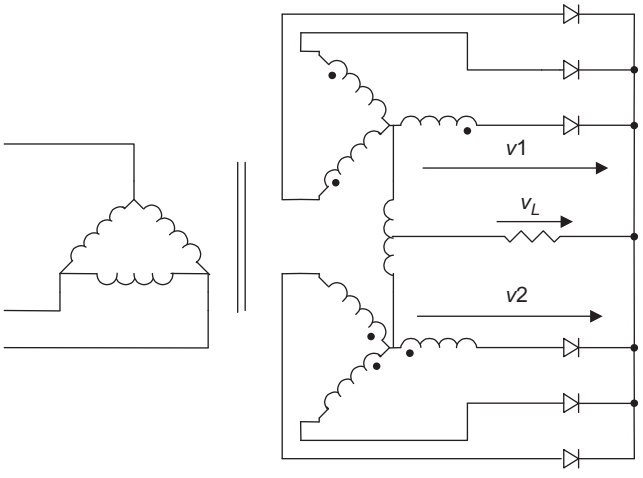

FIG. 7.10 Three-phase double-star rectifier with interphase transformer.

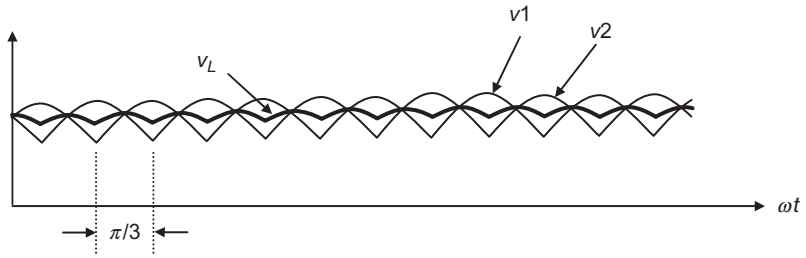

FIG. 7.11 Voltage waveforms of the three-phase double-star rectifier.

output currents of two three-phase units flowing in opposite directions in the interphase transformer winding will produce no dc magnetization current. Similarly, the dc magnetization currents in the secondary windings of two three-phase units cancel each other out.

By virtue of the symmetry of the secondary circuits, the three primary currents add up to zero at all times. Therefore, a star primary winding with no neutral connection would be equally permissible.

7.3.2 Three-Phase Bridge Rectifiers

Three-phase bridge rectifiers are commonly used for high-power applications because they have the highest possible transformer utilization factor for a three-phase system. The circuit of a three-phase bridge rectifier is shown in Fig. 7.12. The diodes are numbered in the order of conduction sequences, and the conduction angle of each diode is $2\pi/3$.

The conduction sequence for diodes is 12, 23, 34, 45, 56, and 61. The voltage and the current waveforms of the three-phase bridge rectifier are shown in Fig. 7.13. The line voltage is 1.73 times the phase voltage of a three-phase star-connected source. It is permissible to use any combination of star- or delta-connected primary and secondary windings because the currents associated with the secondary windings are symmetrical.

Using Eq. (7.1), the average value of the output can be found as

$$V_{dc} = \frac{6}{2\pi}\int_{\pi/3}^{2\pi/3} \sqrt{3}V_m \sin\theta d\theta \tag{7.47}$$

or

$$V_{dc} = V_m \frac{3\sqrt{3}}{\pi} = 1.654V_m \tag{7.48}$$

Similarly, using Eq. (7.6), the rms value of the output voltage can be found as

$$V_L = \sqrt{\frac{9}{\pi}\int_{\pi/3}^{2\pi/3} (V_m \sin\theta)^2 d\theta} \tag{7.49}$$

or

$$V_L = V_m \sqrt{\frac{3}{2} + \frac{9\sqrt{3}}{4\pi}} = 1.655V_m \tag{7.50}$$

In addition, the rms current in each transformer secondary winding can also be found as

$$I_s = I_m \sqrt{\frac{2}{\pi}\left(\frac{\pi}{6} + \frac{\sqrt{3}}{4}\right)} = 0.78I_m \tag{7.51}$$

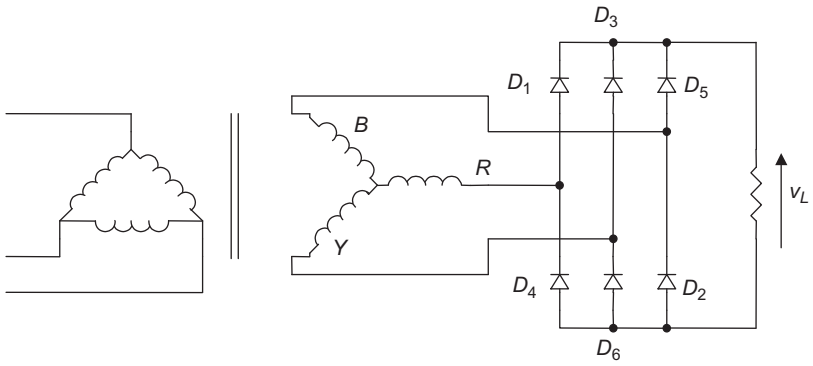

FIG. 7.12 Three-phase bridge rectifier.

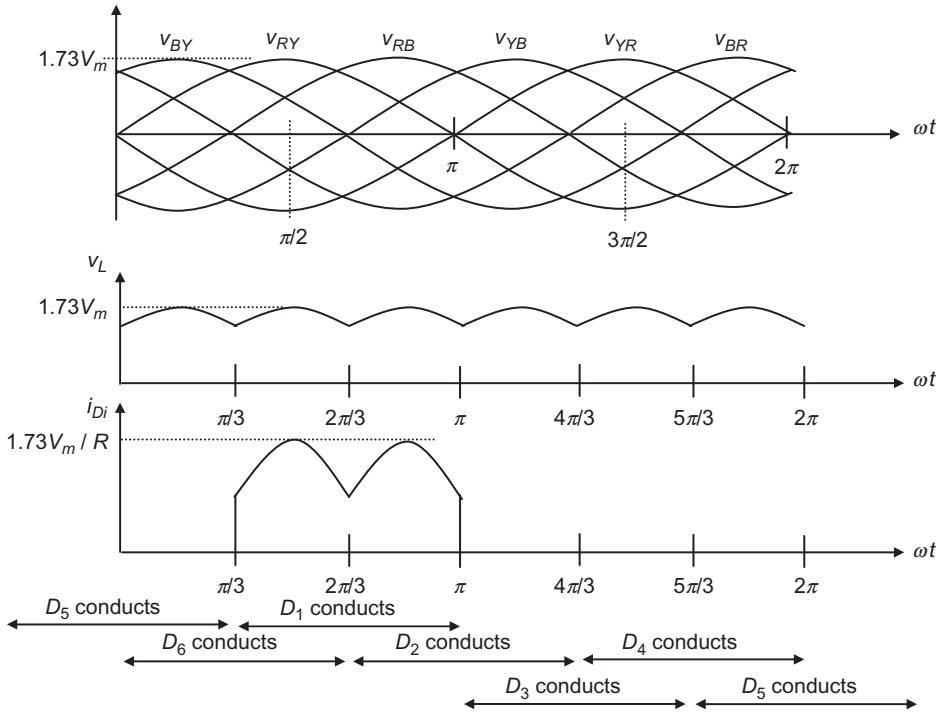

FIG. 7.13 Voltage and current waveforms of the three-phase bridge rectifier.

and the rms current through a diode is

$$I_D = I_m \sqrt{\frac{1}{\pi}\left(\frac{\pi}{6} + \frac{\sqrt{3}}{4}\right)} = 0.552 I_m \tag{7.52}$$

where $I_m = 1.73 V_m / R$.

Based on Eqs. (7.48), (7.50), (7.51), (7.52), all the important design parameters of the three-phase star rectifier can be evaluated, as listed in Table 7.3. The dc output voltage is slightly lower than the peak line voltage or 2.34 times the rms phase voltage. The V_{RRM} rating of the employed diodes is 1.05 times the dc output voltage, and the I_{FRM} rating of the employed diodes is 0.579 times the dc output current. Therefore, this three-phase bridge rectifier is very efficient and popular wherever both dc voltage and current requirements are high. In many applications, no additional filter is required because the output ripple voltage is only 4.2%. Even if a filter is required, the size of the filter is relatively small because the ripple frequency is increased to six times the input frequency.

7.3.3 Operation of Rectifiers With Finite Source Inductance

It has been assumed in the preceding sections that the commutation of current from one diode to the next takes place instantaneously when the interphase voltage assumes the necessary polarity. In practice, this is hardly possible because there are finite inductances associated with the source. For the purpose of discussing the effects of the finite source inductance, a three-phase star rectifier with transformer leakage inductances is shown in Fig. 7.14, where l_1, l_2, and l_3 denote the leakage inductances associated with the transformer secondary windings.

Refer to Fig. 7.15. At the time when v_{YN} is about to become larger than v_{RN}, due to leakage inductance l_1, the current in D_1 cannot fall to zero immediately. Similarly, due to the leakage inductance l_2, the current in D_2 cannot increase immediately to the full value. The result is that both the diodes conduct for a certain period, which is called the overlap (or commutation) angle. The overlap reduces the rectified voltage v_L as shown in the upper voltage waveform of Fig. 7.15. If all the leakage inductances are equal, that is, $l_1 = l_2 = l_3 = l_c$, then the amount of reduction of dc output voltage can be estimated as $mf_i l_c I_{dc}$, where m is the ratio of the lowest ripple frequency to the input frequency.

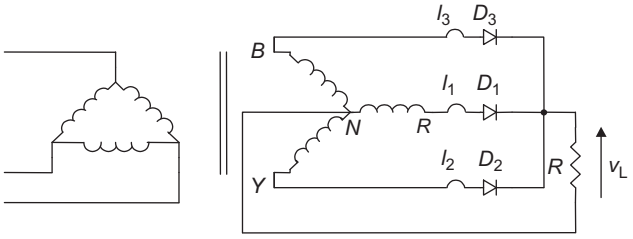

FIG. 7.14 Three-phase star rectifier with the transformer leakage inductances.

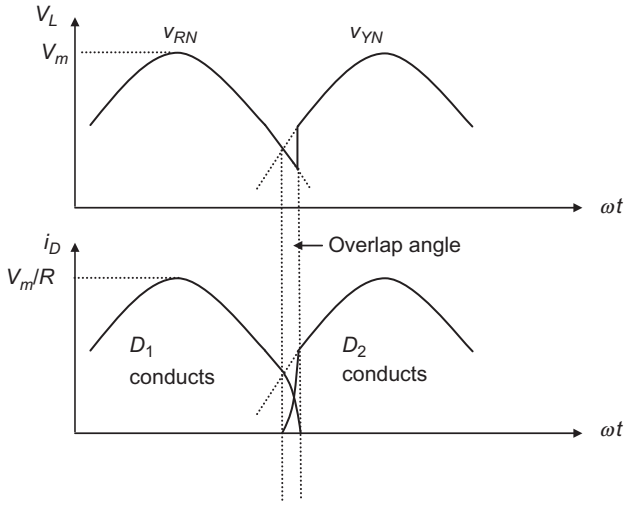

FIG. 7.15 Waveforms during commutation in Fig. 7.14.

For example, for a three-phase star rectifier operating from a 60 Hz supply with an average load current of 50 A, the amount of reduction of the dc output voltage is 2.7 V if the leakage inductance in each secondary winding is 300 μH.

7.4 Poly-Phase Diode Rectifiers

7.4.1 Six-Phase Star Rectifier

A basic six-phase star rectifier circuit is shown in Fig. 7.16. The six-phase voltages on the secondary are obtained by means of a center-tapped arrangement on a star-connected three-phase winding. Therefore, it is sometimes referred to as a three-phase full-wave rectifier. The diode in a particular phase conducts during the period when the voltage on that phase is higher than that on the other phases. The voltage waveforms

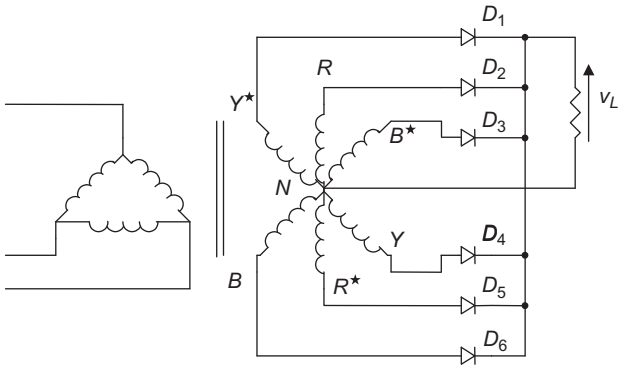

FIG. 7.16 Six-phase star rectifier.

of each phase and the load are shown in Fig. 7.17. It is clear that, unlike the three-phase star rectifier circuit, the conduction angle of each diode is $\pi/3$, instead of $2\pi/3$. Currents flow in only one rectifying element at a time, resulting in a low average current, but a high peak to an average current ratio in the diodes and poor transformer secondary utilization. Nevertheless, the dc currents in the secondary of the six-phase star rectifier cancel in the secondary windings like a full-wave rectifier and, therefore, core saturation is not encountered. This six-phase star circuit is attractive in applications that require a low ripple factor and a common cathode or anode for the rectifiers.

By considering the output voltage provided by v_{RN} between $\pi/3$ and $2\pi/3$, the average value of the output voltage can be found as

$$V_{dc} = \frac{6}{2\pi}\int_{\pi/3}^{2\pi/3} V_m \sin\theta d\theta \tag{7.53}$$

or

$$V_{dc} = V_m \frac{6}{\pi}\frac{1}{2} = 0.955 V_m \tag{7.54}$$

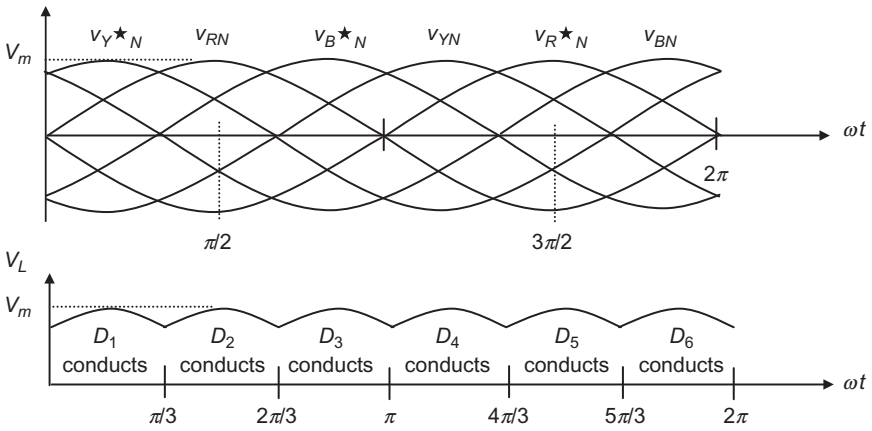

FIG. 7.17 Voltage waveforms of the six-phase star rectifier.

Similarly, the rms value of the output voltage can be found as

$$V_L = \sqrt{\frac{6}{2\pi}\int_{\pi/3}^{2\pi/3} (V_m \sin\theta)^2 d\theta} \tag{7.55}$$

or

$$V_L = V_m\sqrt{\frac{6}{2\pi}\left(\frac{\pi}{6}+\frac{\sqrt{3}}{4}\right)} = 0.956V_m \tag{7.56}$$

In addition, the rms current in each transformer secondary winding can also be found as

$$I_s = I_m\sqrt{\frac{1}{2\pi}\left(\frac{\pi}{6}+\frac{\sqrt{3}}{4}\right)} = 0.39I_m \tag{7.57}$$

where $I_m = V_m/R$.

Based on the relationships stated in Eqs. (7.55)–(7.57), all the important design parameters of the six-phase star rectifier can be evaluated, as listed in Table 7.4 (given at the end of Section 7.4.3).

7.4.2 Six-Phase Series Bridge Rectifier

The star- and delta-connected secondaries have an inherent $\pi/6$-phase displacement between their output voltages. When a star- and a delta-connected bridge rectifier are connected in series as shown in Fig. 7.18, the combined output voltage will have a doubled ripple frequency (12 times that of the mains). The ripple of the combined output voltage will also be reduced from 4.2% (for each individual bridge rectifier) to 1%. The combined bridge rectifier is referred to as a six-phase series bridge rectifier.

In the six-phase series bridge rectifier shown in Fig. 7.18, let V_m^* be the peak voltage of the delta-connected secondary. The peak voltage between the lines of the star-connected secondary is also V_m^*. The peak voltage across the load, denoted as V_m, is equal to $2V_m^* \times \cos(\pi/12)$ or $1.932V_m^*$ because there is $\pi/6$-phase displacement between the secondaries. The ripple frequency is twelve times the mains frequency. The average value of the output voltage can be found as

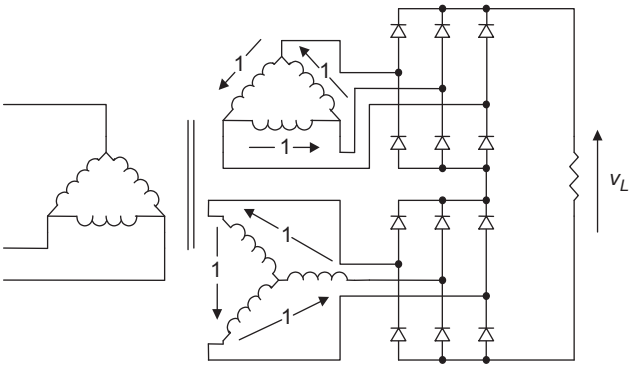

FIG. 7.18 Six-phase series bridge rectifier.

$$V_{dc} = \frac{12}{2\pi}\int_{5\pi/12}^{7\pi/12} V_m \sin\theta d\theta \tag{7.58}$$

or

$$V_{dc} = V_m\frac{12}{\pi}\frac{\sqrt{3}-1}{2\sqrt{2}} = 0.98862V_m \tag{7.59}$$

The rms value of the output voltage can be found as

$$V_L = \sqrt{\frac{12}{2\pi}\int_{5\pi/12}^{7\pi/12} (V_m \sin\theta)^2 d\theta} \tag{7.60}$$

or

$$V_L = V_m\sqrt{\frac{12}{2\pi}\left(\frac{\pi}{12}+\frac{1}{4}\right)} = 0.98867V_m \tag{7.61}$$

TABLE 7.4 Important design parameters of the six-phase rectifier circuits with resistive load

	Six-phase star rectifier	Six-phase series bridge rectifier	Six-phase parallel bridge rectifier (with interphase transformer)
Peak repetitive reverse voltage V_{RRM}	$2.09V_{dc}$	$0.524V_{dc}$	$1.05V_{dc}$
RMS input voltage per transformer leg V_s	$0.74V_{dc}$	$0.37V_{dc}$	$0.715V_{dc}$
Diode average current $I_{F(AV)}$	$0.167I_{dc}$	$0.333I_{dc}$	$0.167I_{dc}$
Peak repetitive forward current I_{FRM}	$6.28I_{F(AV)}$	$3.033I_{F(AV)}$	$3.14I_{F(AV)}$
Diode rms current $I_{F(RMS)}$	$0.409I_{dc}$	$0.576I_{dc}$	$0.409I_{dc}$
Form factor of diode current $I_{F(RMS)}/I_{F(AV)}$	2.45	1.73	2.45
Rectification ratio	0.998	1.00	1.00
Form factor	1.0009	1.00005	1.00005
Ripple factor	0.042	0.01	0.01
Transformer rating primary VA	$1.28P_{dc}$	$1.01P_{dc}$	$1.01P_{dc}$
Transformer rating secondary VA	$1.81P_{dc}$	$1.05P_{dc}$	$1.05P_{dc}$
Output ripple frequency f_r	$6f_i$	$12f_i$	$12f_i$

The rms current in each transformer secondary winding is

$$I_s = I_m\sqrt{\frac{4}{\pi}\left(\frac{\pi}{12}+\frac{1}{4}\right)} = 0.807I_m \tag{7.62}$$

The rms current through a diode is

$$I_s = I_m\sqrt{\frac{2}{\pi}\left(\frac{\pi}{12}+\frac{1}{4}\right)} = 0.57I_m \tag{7.63}$$

where $I_m = V_m/R$.

Based on Eqs. (7.59), (7.61), (7.62), (7.63), all the important design parameters of the six-phase series bridge rectifier can be evaluated, as listed in Table 7.4 (given at the end of Section 7.4.3).

7.4.3 Six-Phase Parallel Bridge Rectifier

The six-phase series bridge rectifier described above is useful for high-output voltage applications. However, for high-output current applications, the six-phase parallel bridge rectifier (with an interphase transformer) shown in Fig. 7.19 should be used.

The function of the interphase transformer is to cause the output voltage v_L to be the average of the rectified voltages $v1$ and $v2$ as shown in Fig. 7.20. As with the six-phase series bridge rectifier, the output ripple frequency of the six-phase parallel bridge rectifier is also 12 times that of the mains. Further filtering on the output voltage is usually not required. Assuming a balanced circuit, the output currents of two three-phase units (flowing in opposite directions in the interphase transformer winding) produce no dc magnetization current.

All the important design parameters of the six-phase parallel rectifiers with interphase transformer are also listed in Table 7.4.

7.5 Filtering Systems in Rectifier Circuits

Filters are commonly employed in rectifier circuits for smoothing out the dc output voltage of the load. They are classified as inductor-input dc filters and capacitor-input dc filters. Inductor-input dc filters are preferred in high-power applications because more efficient transformer operation is obtained due to the reduction in the form factor of the rectifier current. Capacitor-input dc filters can provide volumetrically efficient

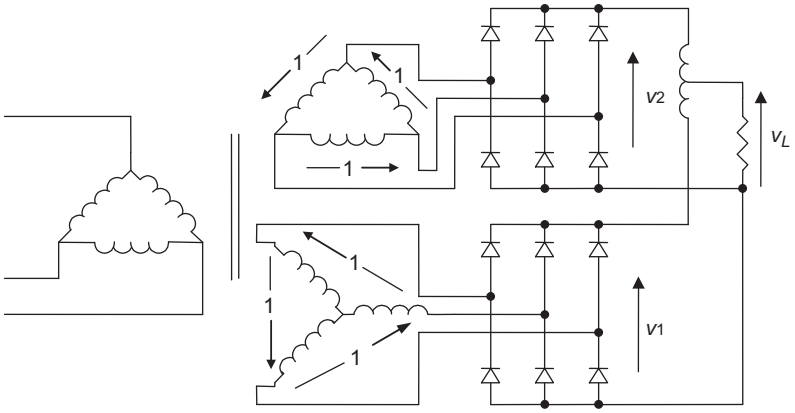

FIG. 7.19 Six-phase parallel bridge rectifier.

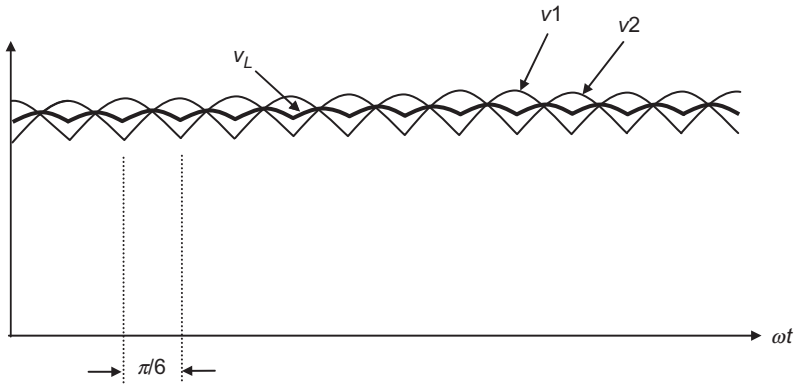

FIG. 7.20 Voltage waveforms of the six-phase bridge rectifier with interphase transformer.

operation, but they demand excessive turn-on and repetitive surge currents. Therefore, capacitor-input dc filters are suitable only for lower-power systems where close regulation is usually achieved by an electronic regulator cascaded with the rectifier.

7.5.1 Inductive-Input DC Filters

The simplest inductive-input dc filter is shown in Fig. 7.21A. The output current of the rectifier can be maintained at a steady value if the inductance of L_f is sufficiently large $(\omega L_f \gg R)$. The filtering action is more effective in heavy load conditions than in light load conditions. If the ripple attenuation is not sufficient even with large values of inductance, an L-section filter as shown in Fig. 7.21B can be used for further filtering. In practice, multiple L-section filters can also be employed if the requirement on the output ripple is very stringent.

For a simple inductive-input dc filter shown in Fig. 7.21A the ripple is reduced by the factor

$$\frac{v_o}{v_L} = \frac{R}{\sqrt{R^2 + (2\pi f_r L_f)^2}} \tag{7.64}$$

where v_L is the ripple voltage before filtering, v_o is the ripple voltage after filtering, and f_r is the ripple frequency.

For the inductive-input dc filter shown in Fig. 7.21B, the amount of reduction in the ripple voltage can be estimated as

$$\frac{v_o}{v_L} = \left| \frac{1}{1 - (2\pi f_r)^2 L_f C_f} \right| \tag{7.65}$$

where f_r is the ripple frequency, if $R \gg 1/2\pi f_r C_f$.

7.5.1.1 Voltage and Current Waveforms of Full-Wave Rectifier With Inductor-Input DC Filter

Fig. 7.22 shows a single-phase full-wave rectifier with an inductor-input dc filter. The voltage and current waveforms are illustrated in Fig. 7.23.

When the inductance of L_f is infinite, the current through the inductor and the output voltage are constant. When inductor L_f is finite, the current through the inductor has a ripple component, as shown by the dotted lines in Fig. 7.23. If the input inductance is too small, the current decreases to zero (becoming discontinuous) during a portion of the time between the peaks of the rectifier output voltage. The minimum value of inductance required to maintain a continuous current is known as the critical inductance L_C.

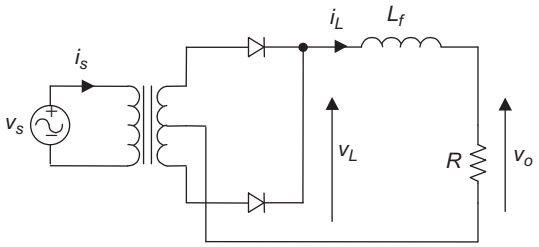

FIG. 7.22 A full-wave rectifier with inductor-input dc filter.

7.5.1.2 Critical Inductance L_C

In the case of single-phase full-wave rectifiers, the critical inductance can be found as

$$\text{Full-wave} \quad L_C = \frac{R}{6\pi f_i} \tag{7.66}$$

where f_i is the input mains frequency.

In the case of polyphase rectifiers, the critical inductance can be found as

$$\text{Poly-phase} \quad L_C = \frac{R}{3\pi m(m^2 - 1) f_i} \tag{7.67}$$

where m is ratio of the lowest ripple frequency to the input frequency, for example, $m = 6$ for a three-phase bridge rectifier.

7.5.1.3 Determining the Input Inductance for a Given Ripple Factor

In practice, the choice of the input inductance depends on the required ripple factor of the output voltage. The ripple voltage of a rectifier without filtering can be found by means of Fourier analysis. For example, the coefficient of the nth harmonic component of the rectified voltage v_L shown in Fig. 7.22 can be expressed as

$$v_{L_n} = \frac{-4V_m}{\pi(n^2 - 1)} \tag{7.68}$$

where $n = 2, 4, 8, \ldots$, etc.

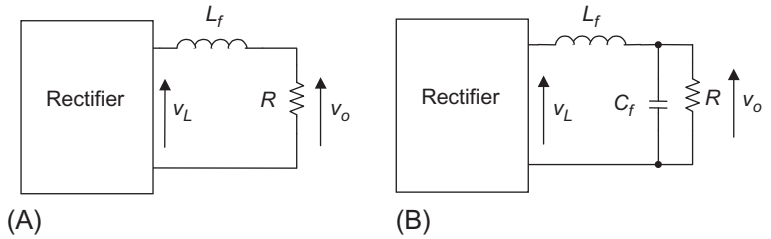

FIG. 7.21 Inductive-input dc filters. (A) Simple inductive-input dc filter. (B) L-section filter.

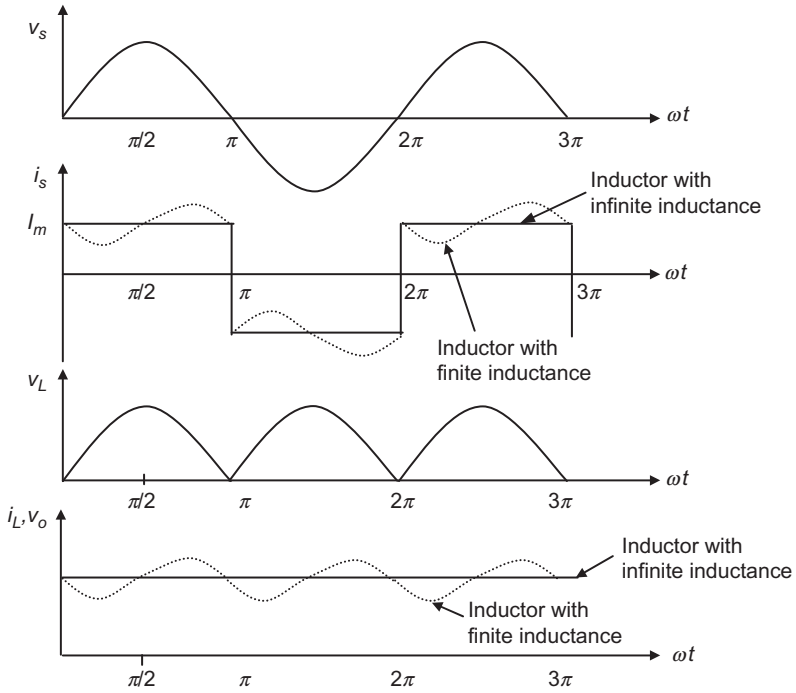

FIG. 7.23 Voltage and current waveforms of full-wave rectifier with inductor-input dc filter.

The dc component of the rectifier voltage is given by Eq. (7.5). Therefore, in addition to Eq. (7.27), the ripple factor can also be expressed as

$$\text{RF} = \sqrt{2 \sum_{n=2,4,8,} \left(\frac{1}{n^2-1}\right)^2} \tag{7.69}$$

Considering only the lowest-order harmonic ($n = 2$), the output ripple factor of a simple inductor-input dc filter (without C_f) can be found, from Eqs. (7.64) and (7.69), as

$$\text{Filtered RF} = \frac{0.4714}{\sqrt{1 + \left(4\pi f_i L_f / R\right)^2}} \tag{7.70}$$

7.5.1.4 Harmonics of the Input Current

In general, the total harmonic distortion (THD) of an input current is defined as

$$\text{THD} = \sqrt{\left(\frac{I_s}{I_{s1}}\right)^2 - 1} \tag{7.71}$$

where I_s is the rms value of the input current and I_{s1} and the rms value of the fundamental component of the input current. The THD can also be expressed as

$$\text{THD} = \sqrt{\sum_{n=2,3,4,} \left(\frac{I_{sn}}{I_{s1}}\right)^2} \tag{7.72}$$

where I_{sn} is the rms value of the nth harmonic component of the input current.

Moreover, the input power factor is defined as

$$\text{PF} = \frac{I_{s1}}{I_s} \cos\phi \tag{7.73}$$

where ϕ is the displacement angle between the fundamental components of the input current and voltage.

Assume that inductor L_f of the circuit shown in Fig. 7.22 has an infinitely large inductance. The input current is then a square wave. This input current contains undesirable higher harmonics that reduce the input power factor of the system. The input current can be easily expressed as

$$i_s = \frac{4I_m}{\pi} \sum_{n=1,3,5,} \frac{1}{n} \sin 2n\pi f_i t \tag{7.74}$$

The rms values of the input current and its fundamental component are I_m and $4I_m/\left(\pi\sqrt{2}\right)$, respectively. Therefore, the THD of the input current of this circuit is 0.484. Since the displacement angle is $\phi = 0$, the power factor is $4/\left(\pi\sqrt{2}\right) = 0.9$.

The power factor of the circuit shown in Fig. 7.22 can be improved by installing an ac filter between the source and the rectifier, as shown in Fig. 7.24.

Considering only the harmonic components, the equivalent circuit of the rectifier given in Fig. 7.24 can be found as shown in Fig. 7.25. The rms value of the nth harmonic current appearing in the supply can then be obtained using the current divider rule:

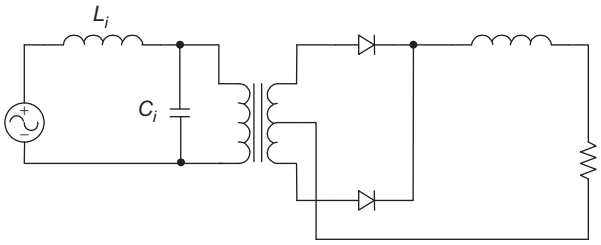

FIG. 7.24 Rectifier with input ac filter.

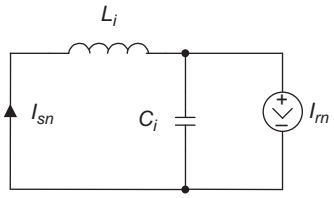

FIG. 7.25 Equivalent circuit for input ac filter.

$$I_{sn} = \left| \frac{1}{1 - (2n\pi f_i)^2 L_i C_i} \right| I_{rn} \tag{7.75}$$

where I_{rn} is the rms value of the nth harmonic current of the rectifier.

Applying Eq. (7.73) and knowing $I_{rn}/I_{r1} = 1/n$ from Eq. (7.74), the THD of the rectifier with input filter shown in Fig. 7.24 can be found as

$$\text{Filtered THD} = \sqrt{\sum_{n=3,5} \frac{1}{n^2} \left| \frac{1}{1 - (2n\pi f_i)^2 L_i C_i} \right|^2} \tag{7.76}$$

The important design parameters of typical single-phase and three-phase rectifiers with inductor-input dc filter are listed in Table 7.5. Note that, in a single-phase half-wave rectifier, a freewheeling diode is required to be connected across the input of the dc filters such that the flow of load current can be maintained during the negative half cycle of the supply voltage.

7.5.2 Capacitive-Input DC Filters

Fig. 7.26 shows a full-wave rectifier with capacitor-input dc filter. The voltage and current waveforms of this rectifier are shown in Fig. 7.27. When the instantaneous voltage of the secondary winding v_s is higher than the instantaneous value of capacitor voltage v_L, either D_1 or D_2 conducts, and the capacitor C is charged up from the transformer. When the instantaneous voltage of the secondary winding v_s falls below the instantaneous value of capacitor voltage v_L, both the diodes are reverse biased and the capacitor C is discharged through load resistance R. The resulting capacitor voltage v_L varies between a maximum value of V_m and a minimum value of $V_m - V_{r(pp)}$ as shown in Fig. 7.27. ($V_{r(pp)}$ is the peak-to-peak ripple voltage.) As shown in Fig. 7.27, the conduction angle θ_c of the diodes becomes smaller when the output ripple voltage decreases. Consequently, the power supply and the diodes suffer from high repetitive surge currents. An LC ac filter, as shown in Fig. 7.24, may be required to improve the input power factor of the rectifier.

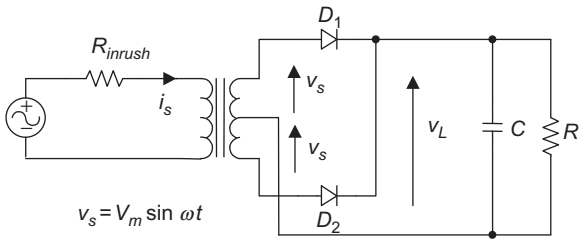

FIG. 7.26 Full-wave rectifier with capacitor-input dc filter.

TABLE 7.5 Important design parameters of typical rectifier circuits with inductor-input dc filter

	Full-wave rectifier with center-tapped transformer	Full-wave bridge rectifier	Three-phase star rectifier	Three-phase bridge rectifier	Three-phase double-star rectifier with interphase transformer
Peak repetitive reverse voltage V_{RRM}	$3.14V_{dc}$	$1.57V_{dc}$	$2.09V_{dc}$	$1.05V_{dc}$	$2.42V_{dc}$
RMS input voltage per transformer leg V_s	$1.11V_{dc}$	$1.11V_{dc}$	$0.885V_{dc}$	$0.428V_{dc}$	$0.885V_{dc}$

Peak repetitive forward current I_{FRM}	$2.00I_{F(AV)}$	$2.00I_{F(AV)}$	$3.00I_{F(AV)}$	$3.00I_{F(AV)}$	$3.00I_{F(AV)}$
Diode rms current $I_{F(RMS)}$	$0.707I_{dc}$	$0.707I_{dc}$	$0.577I_{dc}$	$0.577I_{dc}$	$0.289I_{dc}$
Form factor of diode current $I_{F(RMS)}/I_{F(AV)}$	1.414	1.414	1.73	1.73	1.73
Transformer rating primary VA	$1.11P_{dc}$	$1.11P_{dc}$	$1.21P_{dc}$	$1.05P_{dc}$	$1.05P_{dc}$
Transformer rating secondary VA	$1.57P_{dc}$	$1.11P_{dc}$	$1.48P_{dc}$	$1.05P_{dc}$	$1.48P_{dc}$
Output ripple frequency f_r	$2f_i$	$2f_i$	$3f_i$	$6f_i$	$6f_i$
Ripple component V_r at					
(a) Fundamental	$0.667V_{dc}$	$0.667V_{dc}$	$0.250V_{dc}$	$0.057V_{dc}$	$0.057V_{dc}$
(b) Second harmonic	$0.133V_{dc}$	$0.133V_{dc}$	$0.057V_{dc}$	$0.014V_{dc}$	$0.014V_{dc}$
(c) Third harmonic of the ripple frequency	$0.057V_{dc}$	$0.057V_{dc}$	$0.025V_{dc}$	$0.006V_{dc}$	$0.006V_{dc}$

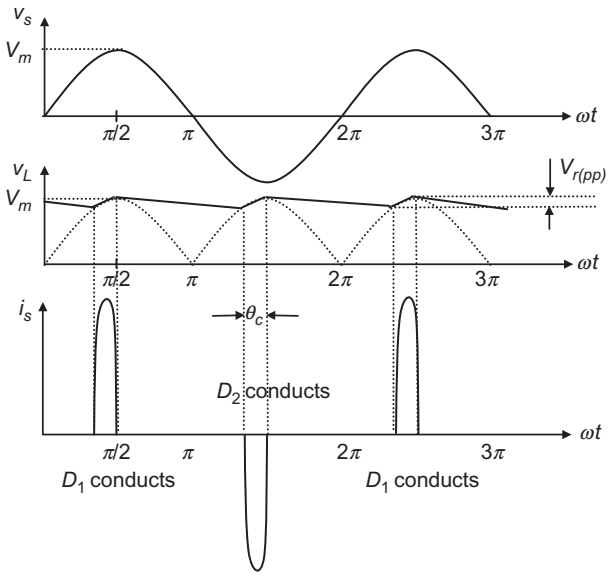

FIG. 7.27 Voltage and current waveforms of the full-wave rectifier with capacitor-input dc filter.

In practice, if the peak-to-peak ripple voltage is small, it can be approximated as

$$V_{r(pp)} = \frac{V_m}{f_r RC} \tag{7.77}$$

where f_r is the output ripple frequency of the rectifier.

Therefore, the average output voltage V_{dc} is given by

$$V_{dc} = V_m\left(1 - \frac{1}{2f_r RC}\right) \tag{7.78}$$

The rms output ripple voltage V_{ac} is approximately given by

$$V_{ac} = \frac{V_m}{2\sqrt{2} f_r RC} \tag{7.79}$$

The ripple factor RF can be found from

$$\text{RF} = \frac{1}{\sqrt{2}(2f_r RC - 1)} \tag{7.80}$$

7.5.2.1 Inrush Current

The resistor R_{inrush} in Fig. 7.26 is used to limit the inrush current imposed on the diodes during the instant when the rectifier is being connected to the supply. The inrush current can be very large because capacitor C has zero charge initially. The worst case occurs when the rectifier is connected to the supply at its maximum voltage. The worst-case inrush current can be estimated from

$$I_{inrush} = \frac{V_m}{R_{sec} + R_{ESR}} \tag{7.81}$$

where R_{sec} is the equivalent resistance looking from the secondary transformer and R_{ESR} is the equivalent series resistance (ESR) of the filtering capacitor. Hence, the employed diode should be able to withstand the inrush current for a half cycle of the input voltage. In other words, the *maximum allowable surge current* (I_{FSM}) rating of the employed diodes must be higher than the inrush current. The equivalent resistance associated with the transformer windings and the filtering capacitor is usually sufficient to limit the inrush current to an acceptable level. However, in cases where the transformer is omitted, for example, the rectifier of an off-line switch-mode supply, resistor R_{inrush} must be added for controlling the inrush current.

Consider as an example, a single-phase bridge rectifier, which is to be connected to a 120 V to 60 Hz source (without transformer). Assume that the I_{FSM} rating of the diodes is 150 A for an interval of 8.3 ms. If the ESR of the filtering capacitor is zero, the value of the resistor for limiting inrush current resistance can be estimated to be 1.13 Ω using Eq. (7.81).

7.6 High-Frequency Diode Rectifier Circuits

In high-frequency converters, diodes perform various functions, such as rectifying, flywheeling, and clamping. One special quality a high-frequency diode must possess is a fast switching speed. In technical terms, it must have a short reverse recovery time and a short forward recovery time.

The reverse recovery time of a diode may be understood as the time a forwardly conducting diode takes to recover to a blocking state when the voltage across it is suddenly reversed (which is known as forced turnoff). The temporary short circuit during the reverse recovery period may result in large reverse current, excessive ringing, and large power dissipation, all of which are highly undesirable.

The forward recovery time of a diode may be understood as the time a nonconducting diode takes to change to the fully on state when a forward current is suddenly forced into it (which is known as forced turn-on). Before the diode reaches the fully on state, the forward voltage drop during the forward recovery time can be significantly higher than the normal on-state voltage drop. This may cause voltage spikes in the circuit.

It should be interesting to note that, as far as circuit operation is concerned, a diode with a long reverse recovery time is similar to a diode with a large parasitic capacitance. A diode with a long forward recovery time is similar to a diode with a large parasitic inductance. (Spikes caused by the slow forward recovery of diodes are often wrongly thought to be caused by leakage inductance.) Comparatively, the adverse effect of a long reverse recovery time is much worse than that of a long forward recovery time.

Among commonly used diodes, the Schottky diode has the shortest forward and reverse recovery times. Schottky diodes

are therefore most suitable for high-frequency applications. However, Schottky diodes have relatively low reverse breakdown voltage (normally lower than 200 V) and large leakage current. If, due to these limitations, Schottky diodes cannot be used, ultrafast diodes should be used in high-frequency converter circuits.

Using the example of a forward converter, the operations of a forward rectifier diode, a flywheel diode, and a clamping diode will be studied in Section 7.6.1. Because of the difficulties encountered in the full analyses taking into account parasitic/stray/leakage components, PSpice simulations are extensively used here to study the following:

- The idealized operation of the converter
- The adverse effects of relatively slow rectifiers (e.g., the so-called ultrafast diodes, which are actually much slower than Schottky diodes)
- The improvement achievable by using high-speed rectifiers (Schottky diodes)
- The effects of leakage inductance of the transformer
- The use of snubber circuits to reduce ringing
- The operation of a practical converter with snubber circuits

Using the example of a flyback converter, the operations of a flyback rectifier diode and a clamping diode will also be studied in Section 7.6.2.

The design considerations for high-frequency diode rectifier circuits will be discussed in Section 7.6.3. Some precautions that must be taken in the interpretation of computer simulation results are briefed in Section 7.6.4.

7.6.1 Forward Rectifier Diode, Flywheel Diode, and Magnetic-Reset Clamping Diode in a Forward Converter

7.6.1.1 Ideal Circuit

Fig. 7.28 shows the basic circuit of a forward converter. Fig. 7.29 shows the idealized steady-state waveforms for continuous-mode operation (the current in L_1 being continuous). These waveforms are obtained from PSpice simulations, based on the following assumptions:

- Rectifier diode D_R, flywheel diode D_F, and magnetic-reset clamping diode D_M are ideal diodes with infinitely fast switching speed.
- Electronic switch $M1$ is an idealized MOS switch with infinitely fast switching speed and

$$\text{On-state resistance} = 0.067\ \Omega$$
$$\text{Off-state resistance} = 1\ \text{M}\Omega$$

  It should be noted that PSpice does not allow a switch to have zero on-state resistance and infinite off-state resistance.
- Transformer T_1 has a coupling coefficient of 0.99999999. PSpice does not accept a coupling coefficient of 1.
- The switching operation of the converter has reached a steady state.

Referring to the circuit shown in Fig. 7.28 and the waveforms shown in Fig. 7.29, the operation of the converter can be explained as follows:

1. For $0 < t < DT$ (D is the duty cycle of the MOS switch M_1 and T is the switching period of the converter. M_1 is turned on when $V1$ (VPULSE) is 15 V and turned off when $V1$(VPULSE) is 0 V).

   The switch M_1 is turned on at $t = 0$.

   The voltage at node 3, denoted as $V(3)$, is

$$V(3) = 0 \quad \text{for} \quad 0 < t < DT \tag{7.82}$$

   The voltage induced at node 6 of the secondary winding L_S is

$$V(6) = V_{IN}\left(N_s/N_p\right) \tag{7.83}$$

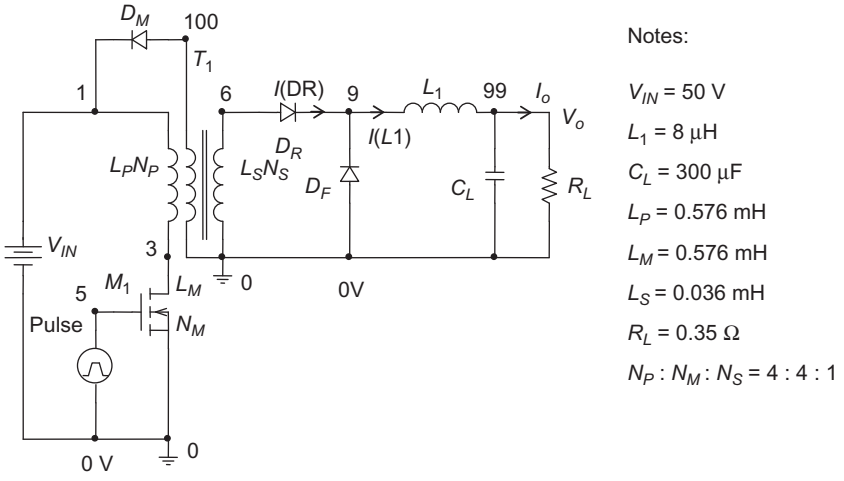

FIG. 7.28 Basic circuit of forward converter.

This voltage drives a current $I(DR)$ (current through rectifier diode D_R) into the output circuit to produce the output voltage V_o. The rate of increase of $I(DR)$ is given by

$$\frac{dI(DR)}{dt} = \left[V_{IN}\frac{N_S}{N_P} - V_o\right]\frac{1}{L_1} \tag{7.84}$$

where V_o is the dc output voltage of the converter.

The flywheel diode D_F is reversely biased by $V(9)$, the voltage at node 9:

$$V(9) = V_{IN}(N_S/N_P) \quad \text{for} \quad 0 < t < DT \tag{7.85}$$

The magnetic-reset clamping diode D_M is reversely biased by the negative voltage at node 100. Assuming that L_M and L_P have the same number of turns, we have

$$V(100) = -V_{IN} \quad \text{for } 0 < t < DT \tag{7.86}$$

A magnetizing current builds up linearly in L_P. This magnetizing current reaches the maximum value of $(V_{IN}DT)/L_P$ at $t = DT$.

2. For $DT < t < 2DT$

The switch M_1 is turned off at $t = DT$.

The collapse of magnetic flux induces a back emf in L_M, which is equal to L_P, to turn-on the clamping diode D_M. The magnetizing current in L_M drops (from the maximum value of $(V_{IN}\ DT)/L_P$, as mentioned above) at the rate of V_{IN}/L_P. It reaches zero at $t = 2DT$.

The back emf induced across L_P is equal to V_{IN}. The voltage at node 3 is

$$V(3) = 2V_{IN} \quad \text{for } DT < t < 2DT \tag{7.87}$$

The back emf across L_S forces D_R to stop conducting.

The inductive current in L_1 forces the flywheel diode D_F to conduct. $I(L1)$ (current through L_1) falls at the rate of

$$\frac{dI(L1)}{dt} = \frac{-V_o}{L_1} \tag{7.88}$$

The voltage across D_R, denoted as $V(6,9)$ (the voltage at node 6 with respect to node 9), is

$$\begin{aligned} V(DR) &= V(6,9) \\ &= -V_{IN}(N_S/N_P) \quad \text{for } DT < t < 2DT \end{aligned} \tag{7.89}$$

3. For $2DT < t < T$

D_M stops conducting at $t = 2DT$. The voltage across L_M then falls to zero.

The voltage across L_P is zero:

$$V(3) = V_{IN} \tag{7.90}$$

The voltage across L_S is also zero:

$$V(6) = 0 \tag{7.91}$$

Inductive current $I(L1)$ continues to fall at the rate of

$$\frac{dI(L1)}{dt} = \frac{-V_o}{L_1} \tag{7.92}$$

The switching cycle restarts when the switch M_1 is turned on again at $t = T$.

From the waveforms shown in Fig. 7.29, the following useful information (for continuous-mode operation) can be found:

- The output voltage V_o is equal to the average value of $V(9)$:

$$V_o = \mathrm{D}\frac{N_S}{N_P}V_{IN} \tag{7.93}$$

- The maximum current in the forward rectifying diode D_R and flywheel diode D_F is

$$\begin{aligned} I(DR)_{max} &= I(DF)_{max} \\ &= I_o + \frac{1}{2}\frac{V_o}{L_1}(1-D)T \end{aligned} \tag{7.94}$$

where $V_o = \mathrm{D}V_{IN}(N_S/N_P)$ and I_o is the output loading current.

- The maximum reverse voltage of D_R and D_F is

$$\begin{aligned} V(DR)_{max} &= V(DF)_{max} \\ &= V(6,9)_{max} = V_{IN}\frac{N_S}{N_P} \end{aligned} \tag{7.95}$$

- The maximum reverse voltage of D_M is

$$V(DM)_{max} = V_{IN} \tag{7.96}$$

- The maximum current in D_M is

$$I(DM)_{max} = DT\frac{V_{IN}}{L_P} \tag{7.97}$$

- The maximum current in the switch $M1$, denoted as $ID(M1)$, is

$$\begin{aligned} ID(M1)_{max} &= \frac{N_S}{N_P}I(DR)_{max} + I(DM)_{max} \\ &= \frac{N_S}{N_P}\left[I_o + \frac{1}{2}\frac{V_o}{L_1}(1-D)T\right] + DT\frac{V_{IN}}{L_P} \end{aligned} \tag{7.98}$$

It should, however, be understood that, due to the nonideal characteristics of practical components, the idealized waveforms shown in Fig. 7.29 cannot actually be achieved in the real world. In the following, the effects of nonideal diodes and transformers will be examined.

7.6.1.2 Circuit Using Ultra-Fast Diodes

Fig. 7.30 shows the waveforms of the forward converter (circuit given in Fig. 7.28) when ultrafast diodes are used as D_M, D_R, and D_F. (Note that ultrafast diodes are actually much slower than Schottky diodes.) The waveforms are obtained by PSpice simulations, based on the following assumptions:

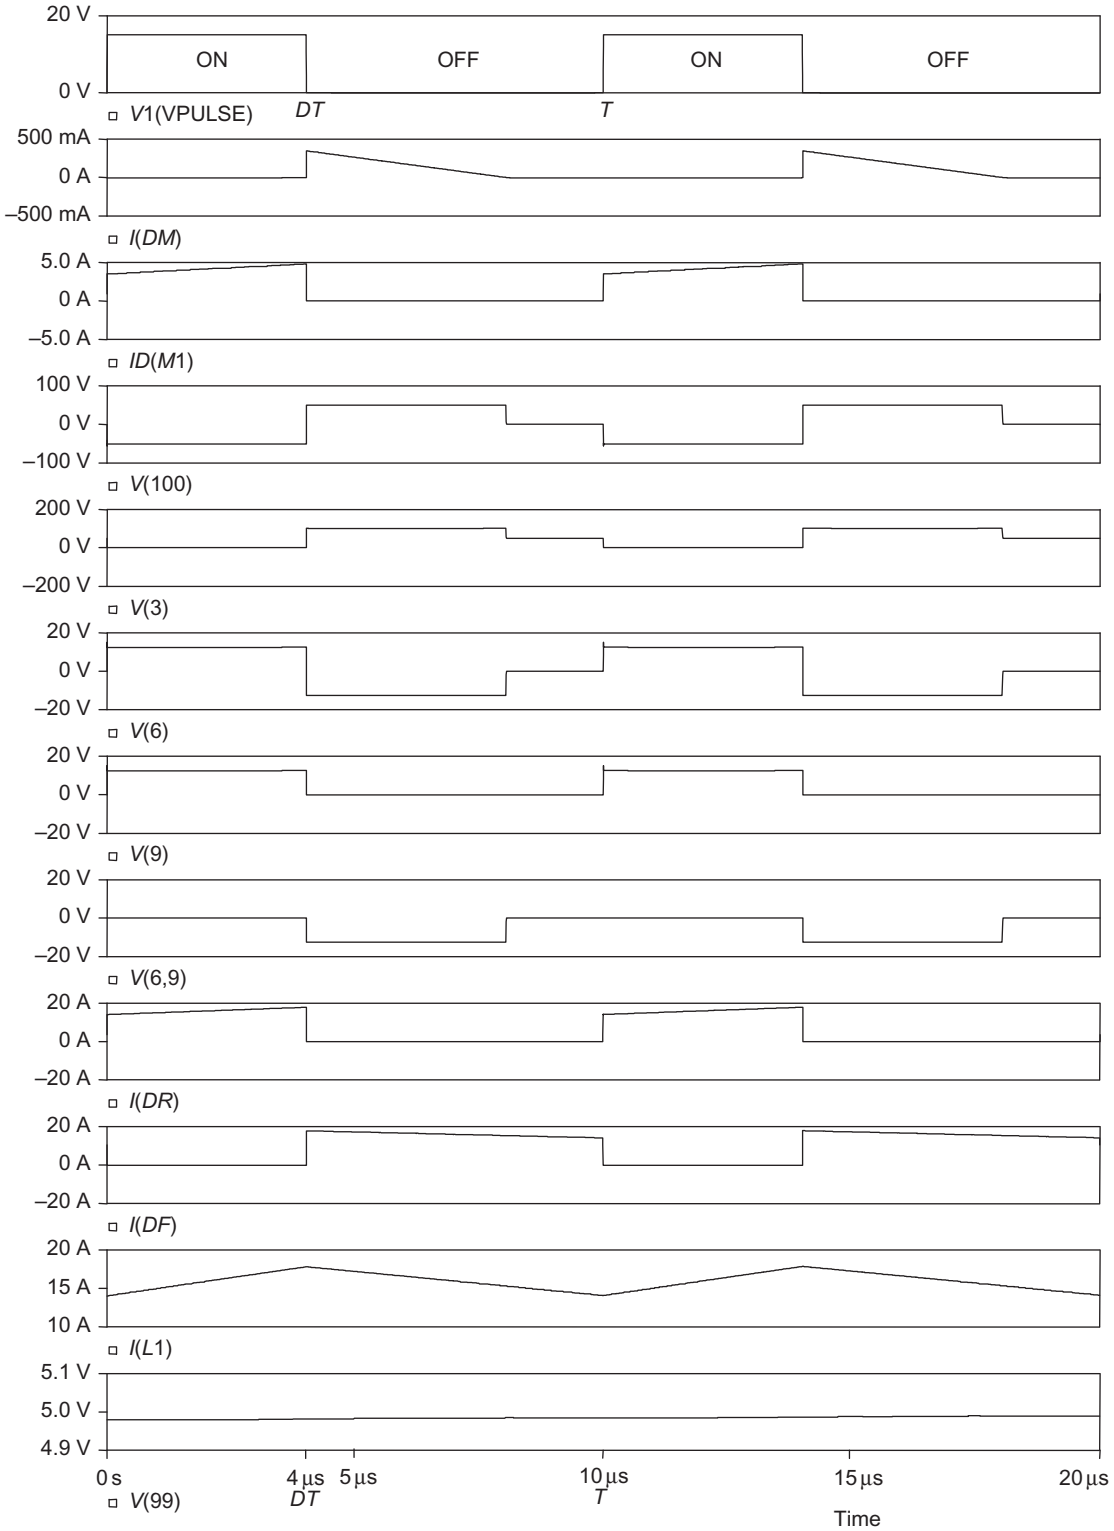

FIG. 7.29 Idealized steady-state waveforms of forward converter for continuous-mode operation.

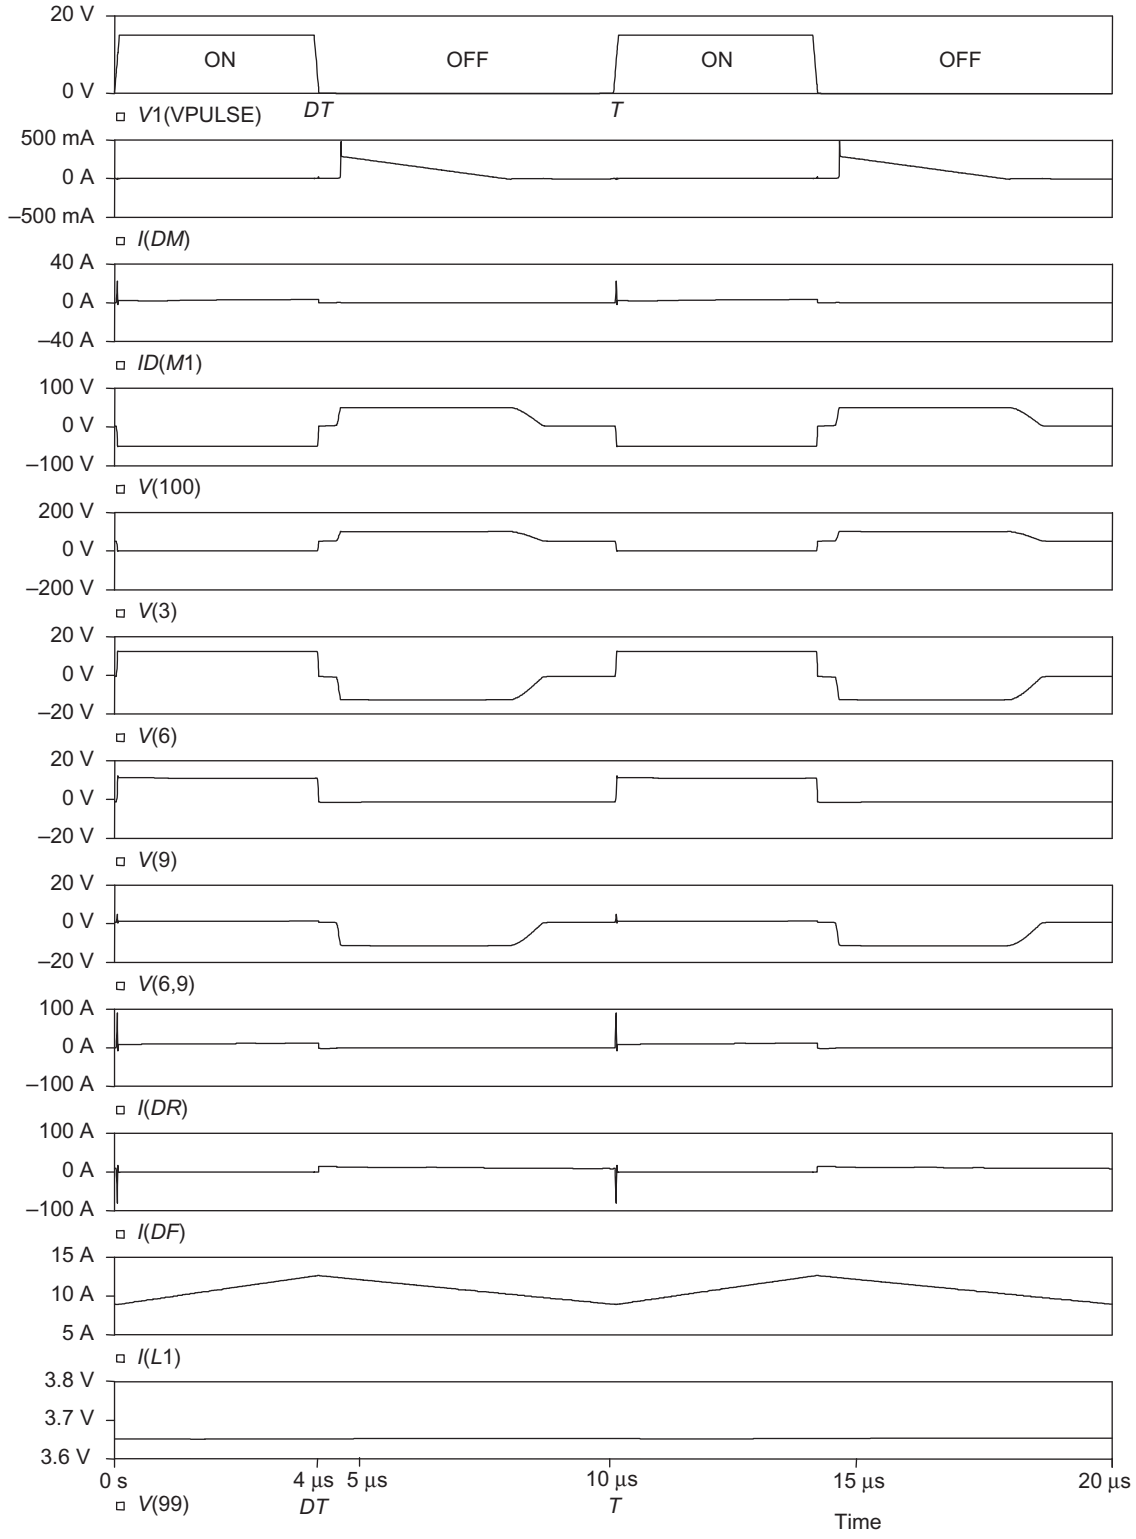

FIG. 7.30 Waveforms of forward converter using "ultrafast" diodes (which are actually much slower than Schottky diodes).

- D_M is an MUR460 ultrafast diode. D_R and D_F are MUR1560 ultrafast diodes.
- M_1 is an IRF640 MOS transistor.
- Transformer T_1 has a coupling coefficient of 0.99999999 (which may be assumed to be 1).
- The switching operation of the converter has reached a steady state.

It is observed that a large spike appears in the current waveforms of diodes D_R and D_F (denoted as *I(DR)* and *I(DF)* in Fig. 7.30) whenever the MOS transistor M_1 is turned on. This is due to the relatively slow reverse recovery of the flywheel diode D_F. During the reverse recovery time, the positive voltage suddenly appearing across L_S (which is equal to $V_{IN}(N_S/N_P)$) drives a large transient current through D_R and D_F. This current spike results in large current stress and power dissipation in D_R, D_F, and M_1.

A method of reducing the current spikes is to use Schottky diodes as D_R and D_F, as described below.

7.6.1.3 Circuit Using Schottky Diodes

In order to reduce the current spikes caused by the slow reverse recovery of rectifiers, Schottky diodes are now used as D_R and D_F. The assumptions made here are (referring to the circuit shown in Fig. 7.28) the following:

- D_R and D_F are MBR2540 Schottky diodes.
- D_M is an MUR460 ultrafast diode.
- M_1 is an IRF640 MOS transistor.
- Transformer T_1 has a coupling coefficient of 0.99999999.
- The switching operation of the converter has reached a steady state.

The new simulated waveforms are given in Fig. 7.31. It is found that, by employing Schottky diodes as D_R and D_F, the amplitudes of the current spikes in *ID(M1)*, *I(DR)*, and *I(DF)* can be reduced to practically zero. This solves the slow-speed problem of ultrafast diodes.

7.6.1.4 Circuit With Practical Transformer

The simulation results given above in Figs. 7.29–7.31 (for the forward converter circuit shown in Fig. 7.28) are based on the assumption that transformer *T*1 has effectively no leakage inductance (with coupling coefficient $K = 0.99999999$). It is, however, found that when a practical transformer (having a slightly lower *K*) is used, severe ringings occur. Fig. 7.32 shows some simulation results to demonstrate this phenomenon, where the following assumptions are made:

- D_R and D_F are MBR2540 Schottky diodes. D_M is an MUR460 ultrafast diode.
- M_1 is an IRF640 MOS transistor.
- Transformer T_1 has a practical coupling coefficient of 0.996.
- The effective winding resistance of L_P is 0.1 Ω. The effective winding resistance of L_M is 0.4 Ω. The effective winding resistance of L_S is 0.01 Ω.
- The effective series resistance of the output filtering capacitor is 0.05 Ω.
- The switching operation of the converter has reached a steady state.

The resultant waveforms shown in Fig. 7.32 indicate that there are large voltage and current ringings in the circuit. These ringings are caused by the resonant circuits formed by the leakage inductance of the transformer and the parasitic capacitances of diodes and transistor.

A practical converter may therefore need snubber circuits to damp these ringings, as described below.

7.6.1.5 Circuit With Snubber Across The Transformer

In order to suppress the ringing voltage caused by the resonant circuit formed by transformer leakage inductance and the parasitic capacitance of the MOS switch, a snubber circuit, shown as R_1 and C_1 in Fig. 7.33, is now connected across the primary winding of transformer T_1. The new waveforms are shown in Fig. 7.34. Here, the drain-to-source voltage waveform of the MOS transistor, *V*(3), is found to be acceptable. However, there are still large ringing voltages across the output rectifiers (*V*(6,9) and *V*(9)).

In order to damp the ringing voltages across the output rectifiers, additional snubber circuits across the rectifiers may therefore also be required in a practical circuit, as described below.

7.6.1.6 Practical Circuit

Fig. 7.35 shows a practical forward converter with snubber circuits added also to rectifiers (R_2C_2 for D_R and R_3C_3 for D_F) to reduce the voltage ringing. Figs. 7.36 and 7.37 show the resultant voltage and current waveforms. Fig. 7.36 is for continuous-mode operation ($R_L = 0.35\Omega$), where *I(L1)* (current in L_1) is continuous. Fig. 7.37 is for discontinuous-mode operation ($R_L = 10\Omega$), where *I(L1)* becomes discontinuous due to an increased value of R_L. These waveforms are considered to be acceptable.

The design considerations of diode rectifier circuits in high-frequency converters will be discussed later in Section 7.6.3.

7.6.2 Flyback Rectifier Diode and Clamping Diode in a Flyback Converter

7.6.2.1 Ideal Circuit

Fig. 7.38 shows the basic circuit of a flyback converter. Due to its simple circuit, this type of converter is widely used in low-cost low-power applications. Discontinuous-mode operation (meaning that the magnetizing current in the transformer falls to zero before the end of each switching cycle) is often used because it offers the advantages of easy control and low diode reverse recovery loss. Fig. 7.39 shows the idealized steady-state waveforms for discontinuous-mode operation.

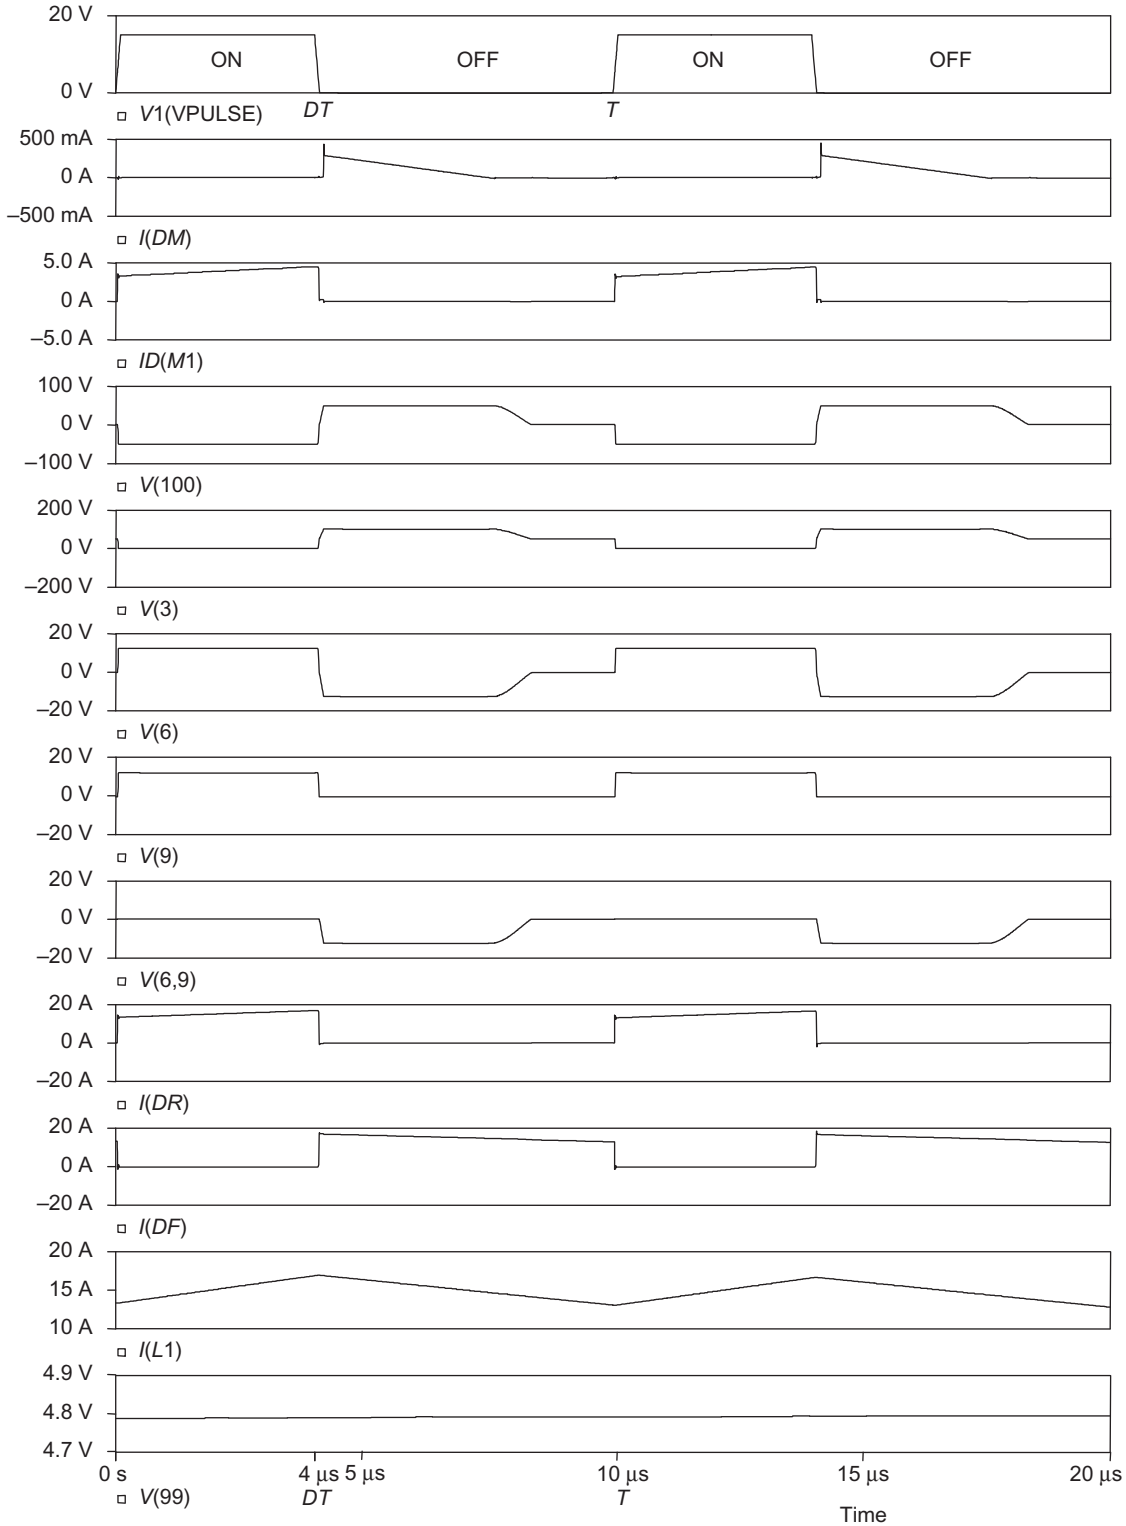

FIG. 7.31 Waveforms of forward converter using Schottky (fast-speed) diodes as output rectifiers.

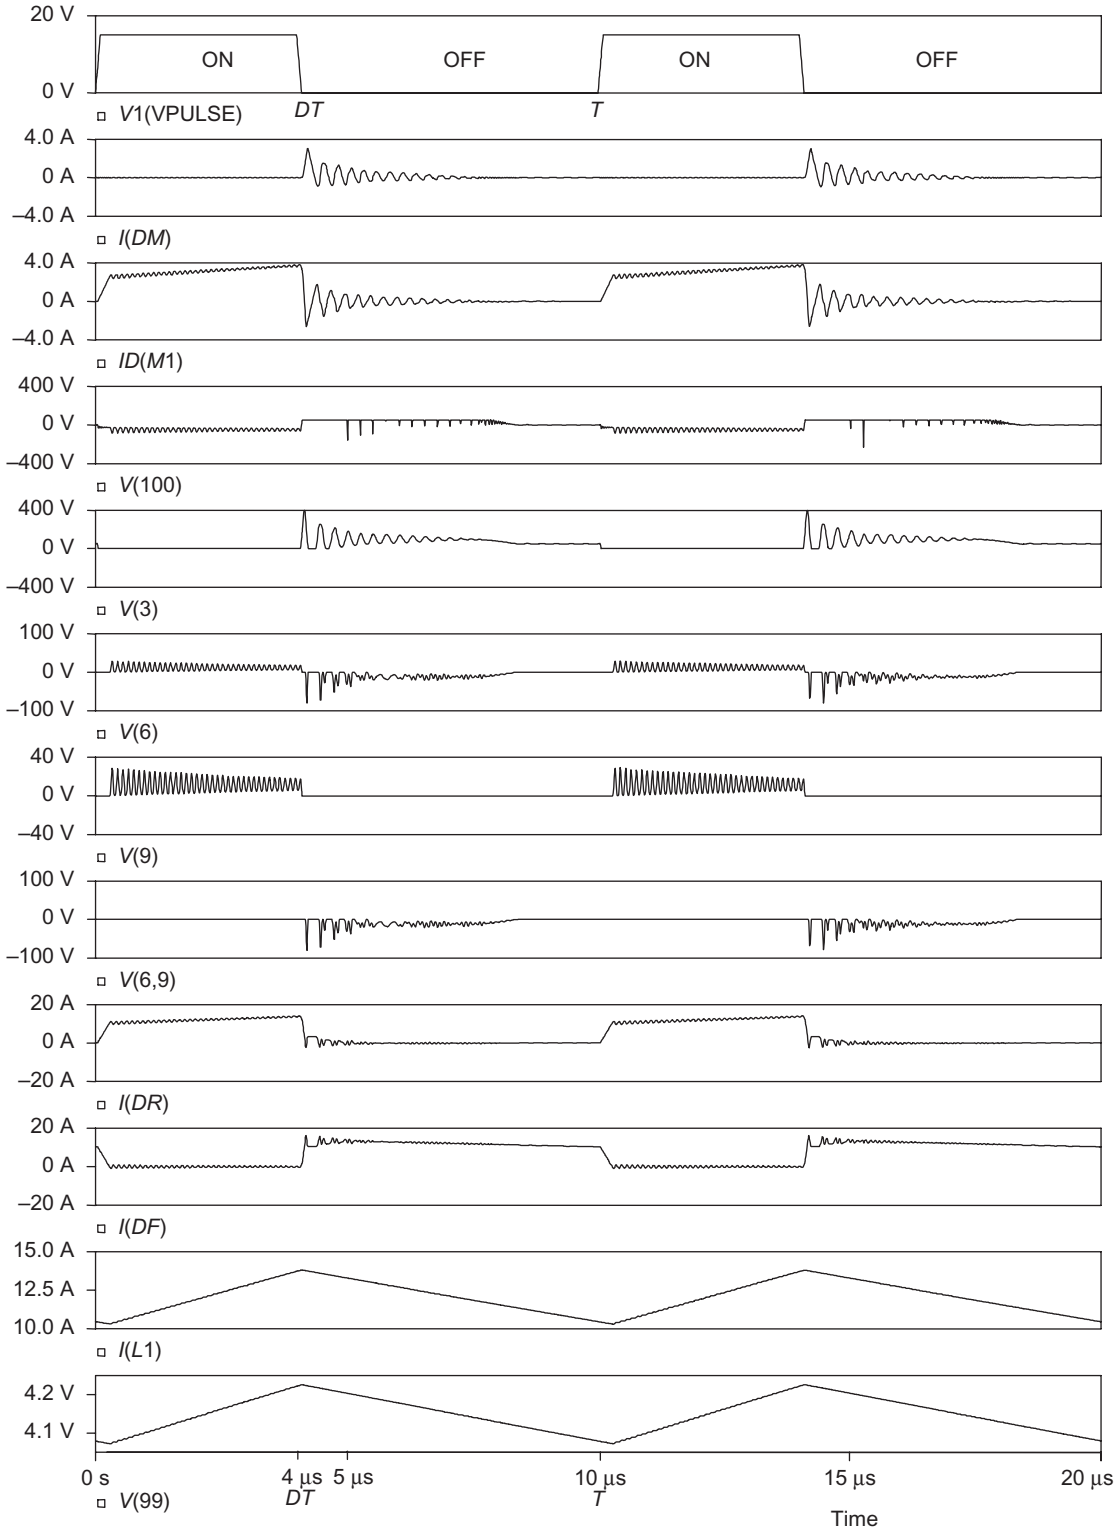

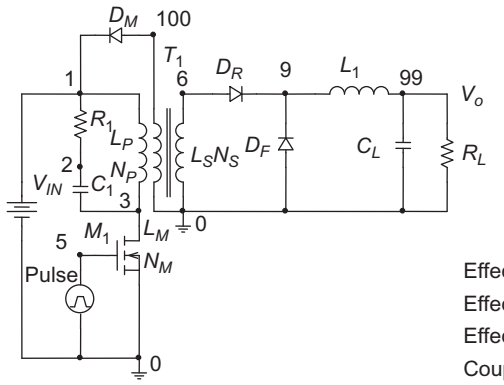

FIG. 7.32 Waveforms of forward converter with practical transformer and output filtering capacitor having nonzero series effective resistance.

V_{IN} = 50 V, D_M = MUR460
D_R = MBR2540, D_F = MBR2540
M_1 = IRF640, R_1 = 24 Ω
C_1 = 3000 pF, C_L = 3500 μF
ESR of C_L = 0.05 Ω, L_1 = 8 μH
L_P = 0.576 mH, L_M = 0.576 mH
L_S = 0.036 mH, $N_P : N_M : N_S$ = 4 : 4 : 1
R_L = 0.35 Ω
Effective winding resistance of L_P =0.1 Ω
Effective winding resistance of L_M =0.4 Ω
Effective winding resistance of L_S = 0.01 Ω
Coupling coefficient K = 0.996

FIG. 7.33 Forward converter with snubber circuit (R_1C_1) across transformer.

These waveforms are obtained from PSpice simulations, based on the following assumptions:

- D_R is an idealized rectifier diode with infinitely fast switching speed.
- M_1 is an idealized MOS switch with infinitely fast switching speed and

$$\text{On-stateresistance} = 0.067\ \Omega$$
$$\text{Off-stateresistance} = 1\ \text{M}\Omega$$

- Transformer T_1 has a coupling coefficient of 0.99999999.
- The switching operation of the converter has reached a steady state.

Referring to the circuit shown in Fig. 7.38 and the waveforms shown in Fig. 7.39, the operation of the converter can be explained as follows:

1. For $0 < t < DT$

   The switch M_1 is turned on at $t = 0$:

$$V(3) = 0 \quad \text{for } 0 < t < DT$$

   The current in M_1, denoted as $ID(M1)$, increases at the rate of

$$\frac{dID(M1)}{dt} = \frac{V_{IN}}{L_P} \tag{7.99}$$

   The output rectifier D_R is reversely biased.
2. For $DT < t < (D + D_2)T$

   The switching M_1 is turned off at $t = DT$.

   The collapse of magnetic flux induces a back emf in L_S to turn-on the output rectifier D_R. The initial amplitude of the rectifier current $I(DR)$, which is also denoted as $I(LS)$, can be found by equating the energy stored in the primary winding current $I(LP)$ just before $t = DT$ to the energy stored in the secondary winding current $I(LS)$ just after $t = DT$:

$$\frac{1}{2}L_P[I(LP)]^2 = \frac{1}{2}L_S[I(LS)]^2 \tag{7.100}$$

$$\frac{1}{2}L_P\left[\frac{V_{IN}}{L_P}DT\right]^2 = \frac{1}{2}L_S[I(LS)]^2 \tag{7.101}$$

$$I(LS) = \sqrt{\frac{L_P}{L_S}}\frac{V_{IN}}{L_P}DT \tag{7.102}$$

$$I(LS) = \frac{N_P}{N_S}\frac{V_{IN}}{L_P}DT \tag{7.103}$$

   The amplitude of $I(LS)$ falls at the rate of

$$\frac{dI(LS)}{dt} = \frac{-V_o}{L_S} \tag{7.104}$$

   and $I(LS)$ falls to zero at $t = (D + D_2)T$. Since $D_2V_o = V_{IN}(N_S/N_P)D$,

$$D_2 = \frac{V_{IN}}{V_o}\frac{N_S}{N_P}D \tag{7.105}$$

   D_2 is effectively the duty cycle of the output rectifier D_R.
3. For $(D + D_2)T < t < T$

   The output rectifier D_R is off.

   The output capacitor C_L provides the output current to the load R_L.

   The switching cycle restarts when the switch M_1 is turned on again at $t = T$.

From the waveforms shown in Fig. 7.39, the following information (for discontinuous-mode operation) can be obtained:

- The maximum value of the current in the switch M_1 is

$$ID(M1)_{max} = \frac{V_{IN}}{L_P}DT \tag{7.106}$$

- The maximum value of the current in the output rectifier D_R is

$$I(DR)_{max} = \frac{N_P}{N_S}\frac{V_{IN}}{L_P}DT \tag{7.107}$$

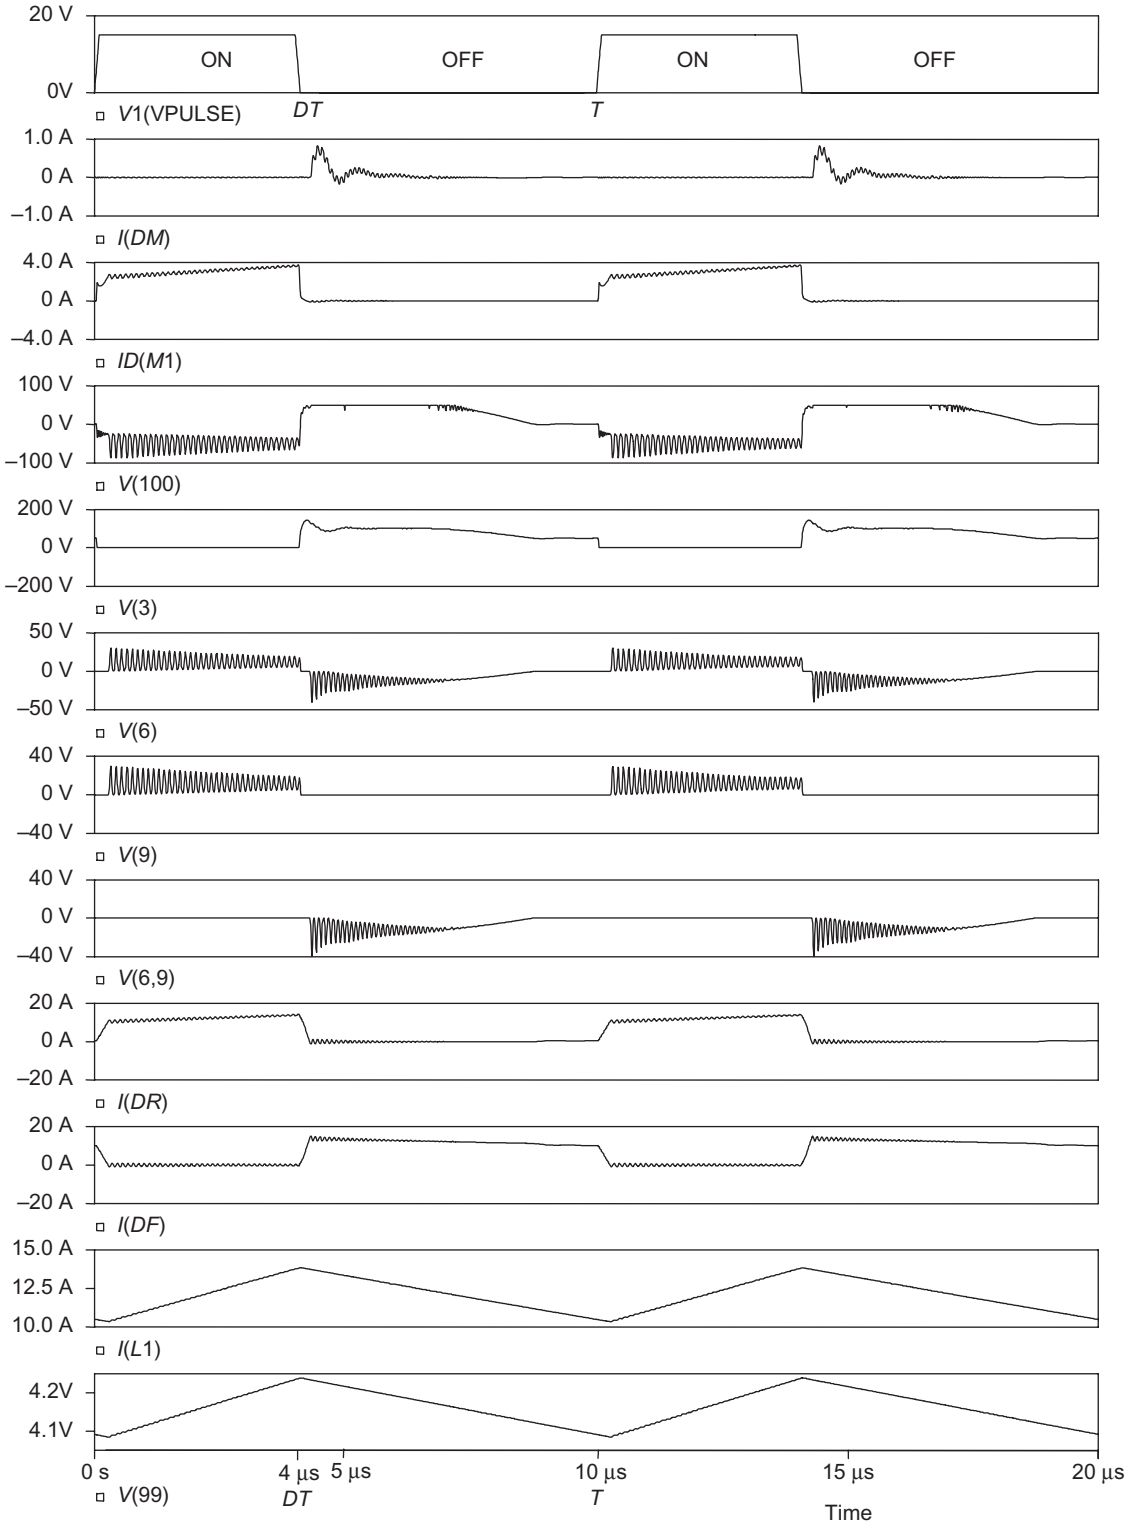

FIG. 7.34 Waveforms of forward converter with snubber circuit across the transformer.

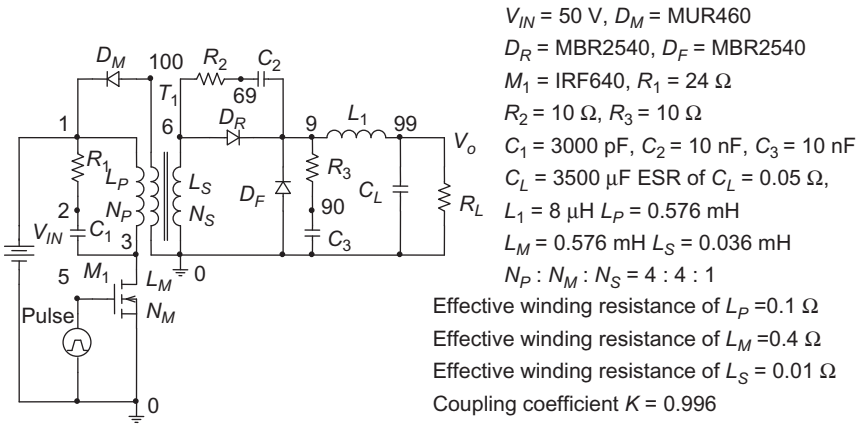

FIG. 7.35 Practical forward converter with snubber circuits across the transformer and rectifiers.

- The output voltage V_o can be found by equating the input energy to the output energy within a switching cycle.

$$V_{IN} \times [\text{Charge taken from } V_{IN} \text{ in a switching cycle}] = \frac{V_o^2}{R_L} T$$

$$V_{IN}\left[\frac{1}{2} DT \frac{DT}{L_P} V_{IN}\right] = \frac{V_o^2}{R_L} T \tag{7.108}$$

$$V_o = \sqrt{\frac{R_L T}{2L_P}} D V_{IN} \tag{7.109}$$

- The maximum reverse voltage of D_R, $V(6,9)$ (which is the voltage at node 6 with respect to node 9), is

$$V(DR)_{max} = V(6,9)_{max} = V_{IN} \frac{N_S}{N_P} + V_o \tag{7.110}$$

7.6.2.2 Practical Circuit

When a practical transformer (with leakage inductance) is used in the flyback converter circuit shown in Fig. 7.38, there will be large ringings. In order to reduce these ringings to practically acceptable levels, snubber and clamping circuits have to be added. Fig. 7.40 shows a practical flyback converter circuit where a resistor-capacitor snubber (R_2C_2) is used to damp the ringing voltage across the output rectifier D_R and a resistor-capacitor-diode clamping ($R_1C_1D_S$) is used to clamp the ringing voltage across the switch M_1. What the diode D_S does here is to allow the energy stored by the current in the leakage inductance to be converted to the form of a dc voltage across the clamping capacitor C_1. The energy transferred to C_1 is then dissipated slowly in the parallel resistor R_1, without ringing problems.

The simulated waveforms of the flyback converter (circuit given in Fig. 7.40) for discontinuous-mode operation are shown in Fig. 7.41, where the following assumptions are made:

- D_R and D_S are MUR460 ultrafast diodes.
- M_1 is an IRF640 MOS transistor.
- Transformer T_1 has a practical coupling coefficient of 0.992.
- The effective winding resistance of L_P is 0.025 Ω. The effective winding resistance of L_S is 0.1 Ω.
- The effective series resistance of the output filtering capacitor C_L is 0.05 Ω.
- The switching operation of the converter has reached a steady state.

The waveforms shown in Fig. 7.40 are considered to be acceptable.

7.6.3 Design Considerations

In the design of rectifier circuits, it is necessary for the designer to determine the voltage and current ratings of the diodes. The idealized waveforms and expressions for the maximum diode voltages and currents given under the heading of "Ideal Circuit" above (for both forward and flyback converters) are a good starting point. However, when parasitic/stray components are also considered, the simulation results given under "Practical Circuit" are much more useful for the determination of the voltage and current ratings of the high-frequency rectifier diodes.

Assuming that the voltage and current ratings have been determined, proper diodes can be selected to meet the requirements. The following are some general guidelines on the selection of diodes:

- For low-voltage applications, Schottky diodes should be used because they have very fast switching speed and low forward voltage drop. If Schottky diodes cannot be used, either because of their low reverse breakdown voltage or because of their large leakage current (when reversely biased), ultrafast diodes should be used.
- The reverse breakdown voltage rating of the diode should be reasonably higher (e.g., 10% or 20% higher) than the maximum reverse voltage, the diode is expected to encounter under the worst-case condition. However, an

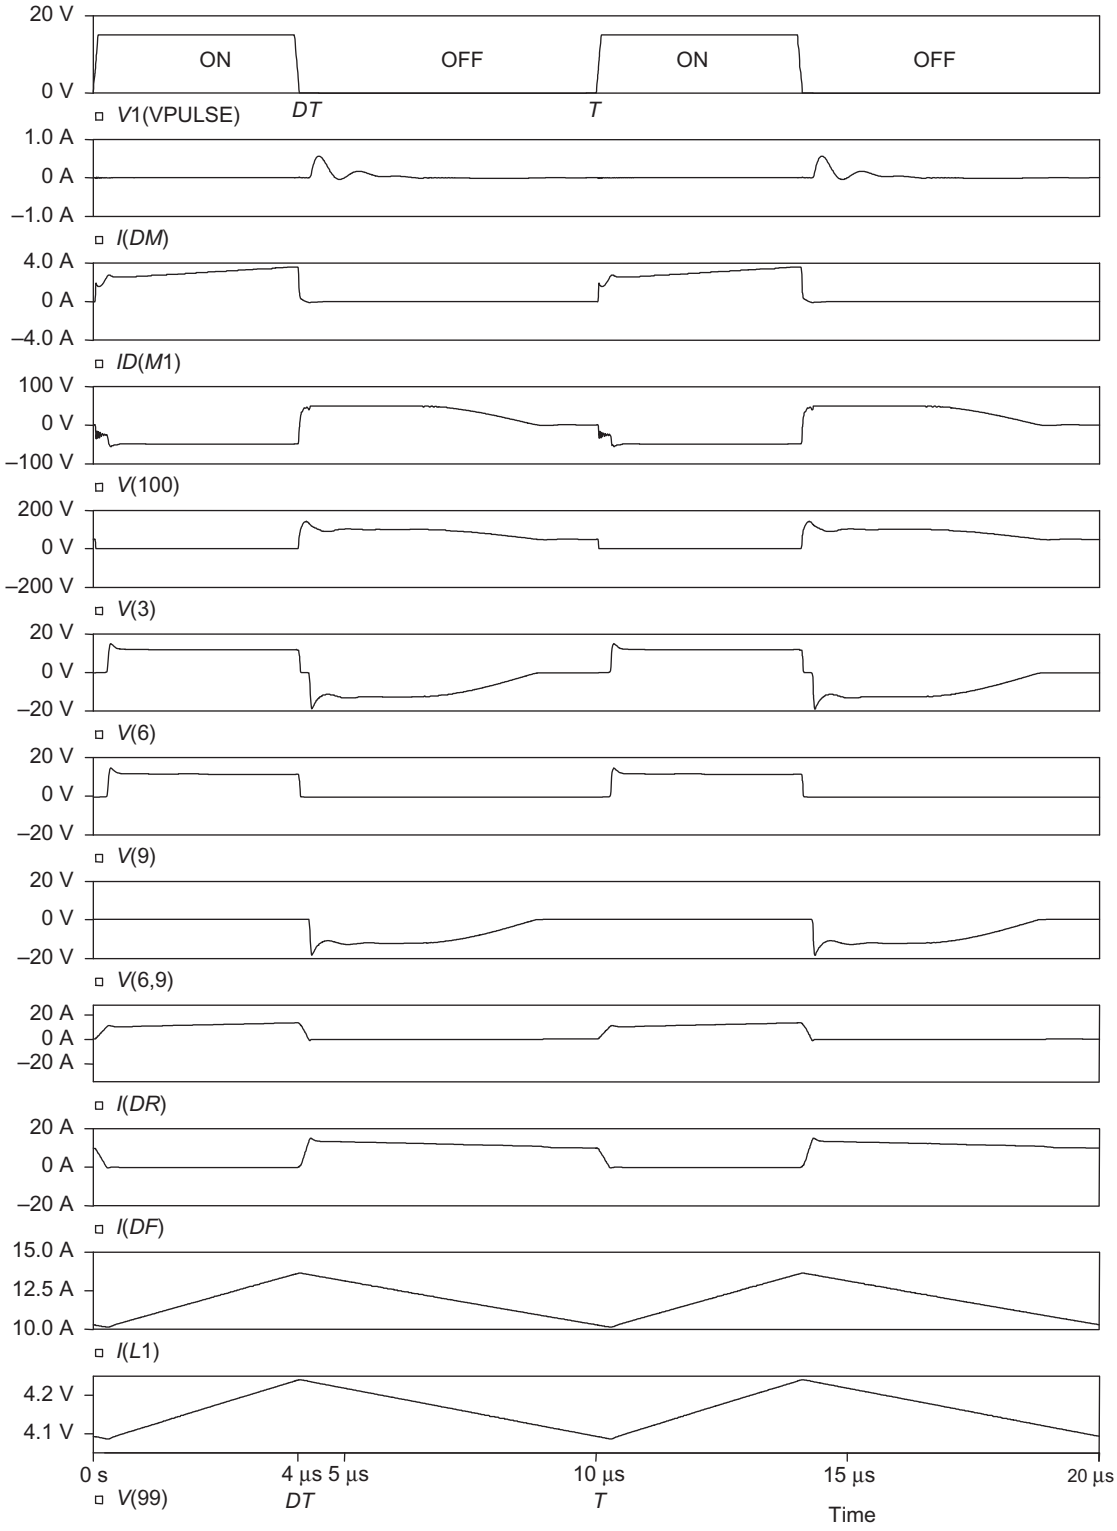

FIG. 7.36 Waveforms of practical forward converter for continuous-mode operation.

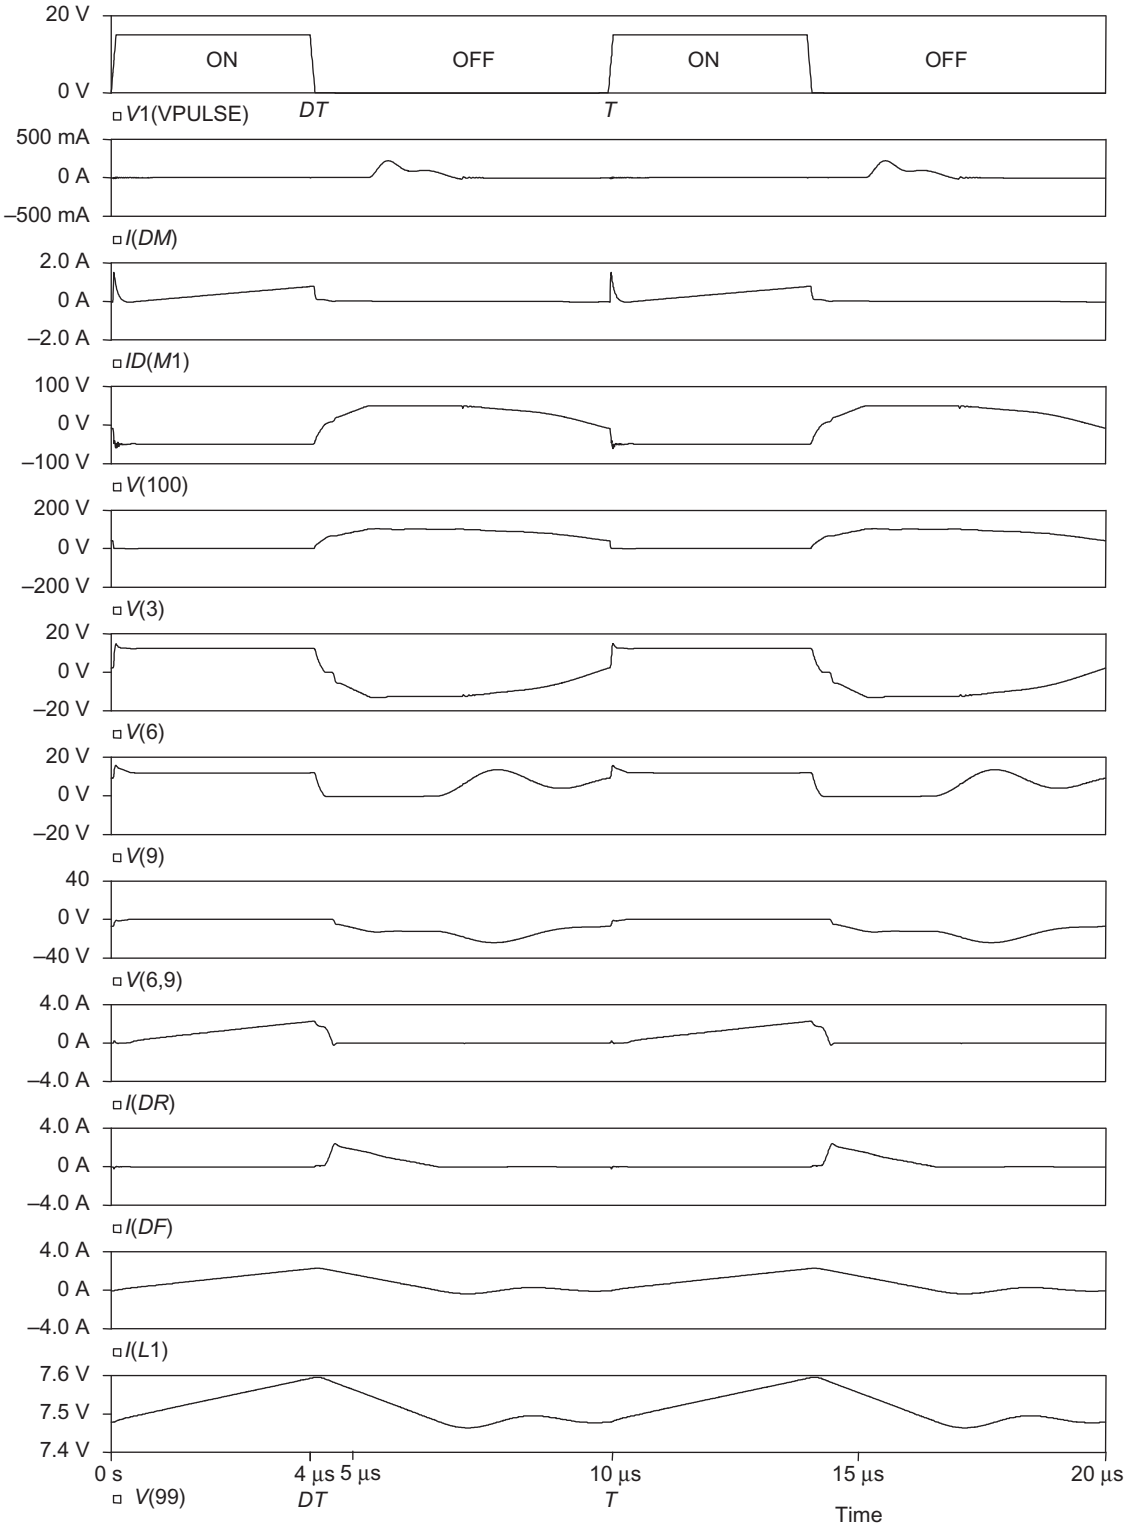

FIG. 7.37 Waveforms of practical forward converter for discontinuous-mode operation.

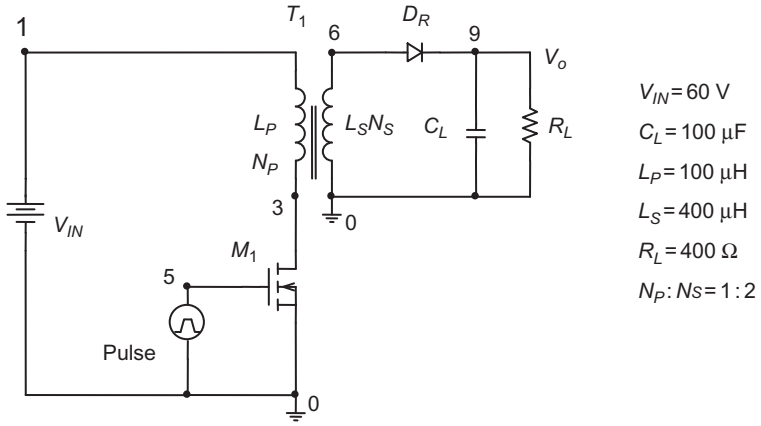

FIG. 7.38 Basic circuit of flyback converter.

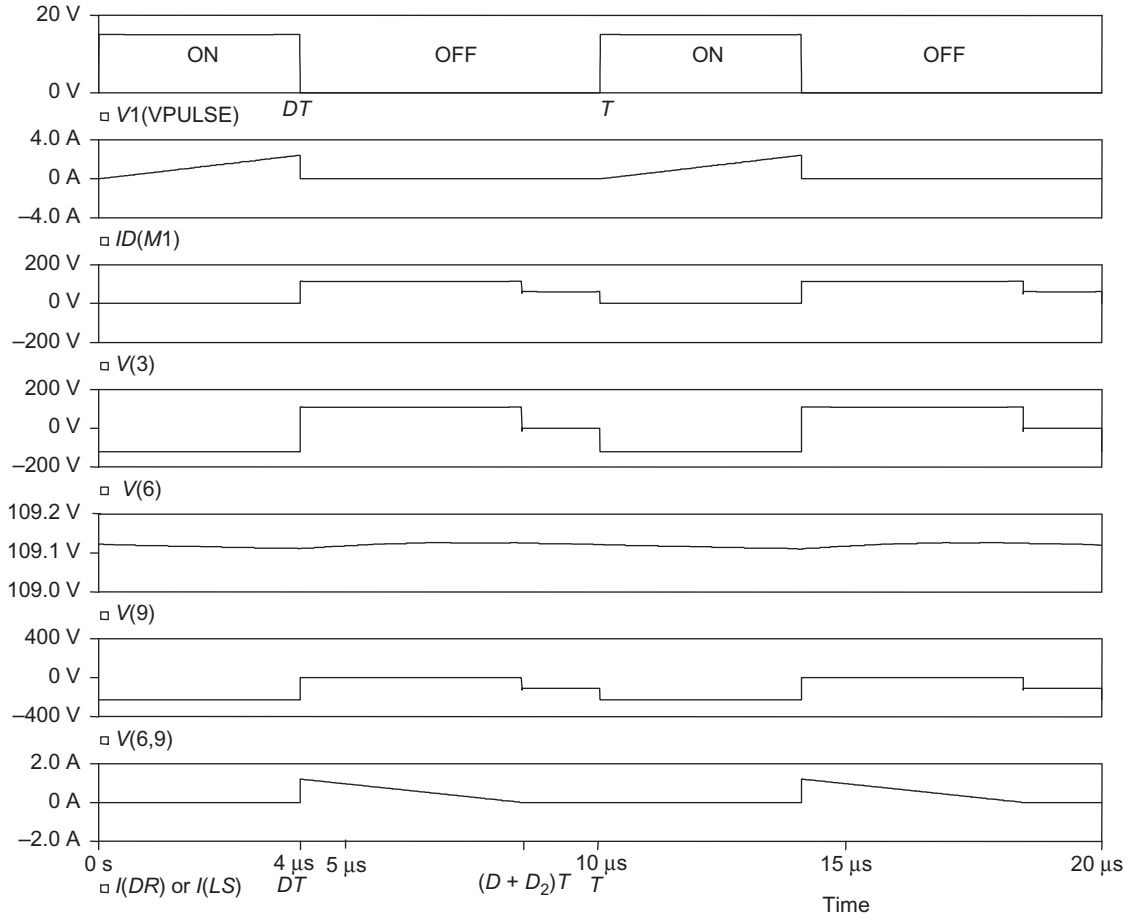

FIG. 7.39 Idealized steady-state waveforms of flyback converter for discontinuous-mode operation.

overly conservative design (using a diode with much higher breakdown voltage than necessary) would result in a lower rectifier efficiency, because a diode having a higher reverse voltage rating would normally have a larger voltage drop when it is conducting.

- The current rating of the diode should be substantially higher than the maximum current the diode is expected to carry during normal operation. Using a diode with a relatively large current rating has the following advantages:

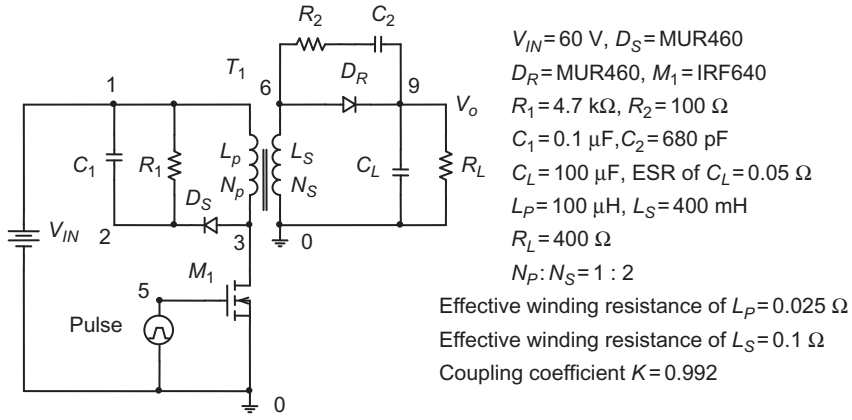

FIG. 7.40 Practical flyback converter circuit.

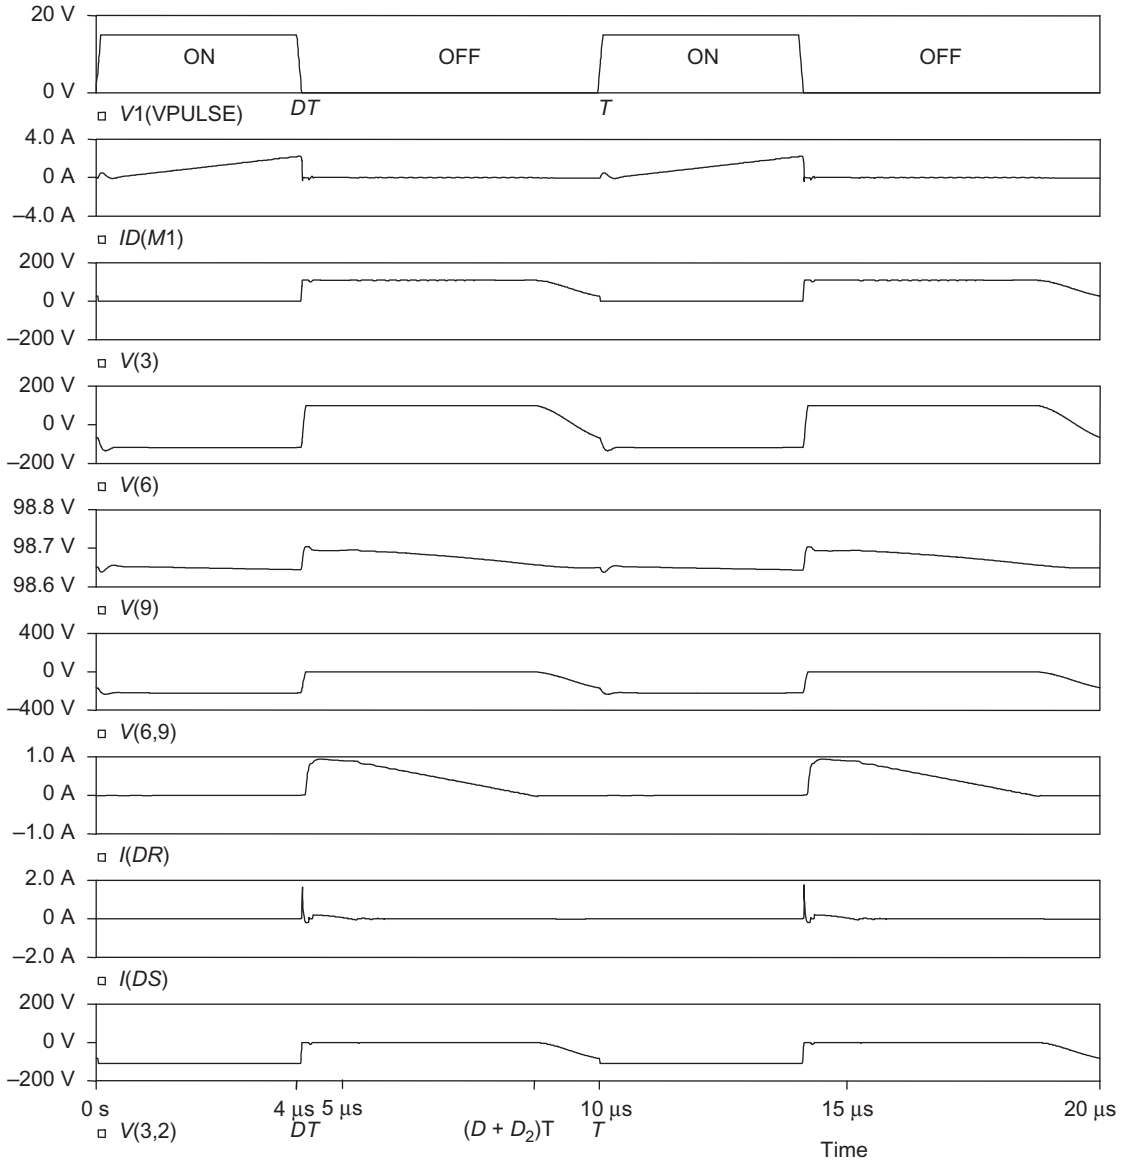

FIG. 7.41 Waveforms of practical flyback converter for discontinuous-mode operation.

- It reduces the possibility of damage due to transients caused by start-up, accidental short circuit, or random turning on and off of the converter.
- It reduces the forward voltage drop because the diode is operated in the lower current region of the *V-I* characteristic.

In some of the "high-efficiency" converter circuits, the current rating of the output rectifier can be many times larger than the actual current expected in the rectifier. In this way, a higher efficiency is achieved at the expense of a larger silicon area.

In the design of *R-C* snubber circuits for rectifiers, it should be understood that a larger *C* (and a smaller *R*) will give better damping. However, a large *C* (and a small *R*) will result in a large switching loss (which is equal to 0.5 CV^2f). As a guideline, a capacitor with five to ten times the junction capacitance of the rectifier may be used as a starting point for iterations. The value of the resistor should be chosen to provide a slightly underdamped operating condition.

7.6.4 Precautions in Interpreting Simulation Results

In using the simulated waveforms as references for design purposes, attention should be paid to the following:

- The voltage/current spikes that appear in the practically measured waveforms may not appear in the simulated waveforms. This is due to the lack of a model in the computer simulation to simulate unwanted coupling among the practical components.
- Most of the computer models of diodes, including those used in the simulations given above, do not take into account the effects of the forward recovery time. (The forward recovery time is not even mentioned in most manufacturers' data sheets.) However, it is also interesting to note that in most cases, the effect of the forward recovery time of a diode is masked by that of the effective inductance in series with the diode (e.g., the leakage inductance of a transformer).

8.1 Introduction

This chapter is dedicated to single-phase controlled rectifiers, which are used in a wide range of applications. As shown in Fig. 8.1, single-phase rectifiers can be classified into two big categories:

(i) Topologies working with low switching frequency, also known as line-commutated or phase controlled rectifiers
(ii) Circuits working with high switching frequency, also known as power factor correctors (PFCs), synchronous rectifiers

Line-commutated rectifiers with diodes, covered in a previous chapter of this handbook, do not allow the control of power being converted from ac to dc. This control can be achieved with the use of thyristors. These controlled rectifiers are addressed in the first part of this chapter.

In the last years, increasing attention has been paid to the control of current harmonics present at the input side of the rectifiers, originating from a very important development in the so-called PFCs and synchronous rectifiers. These circuits use power transistors working with high switching frequency to improve the waveform quality of the input current, increasing the power factor. High-power-factor rectifiers can be classified in regenerative and nonregenerative topologies. The synchronous rectification (SR) uses MOSFETs to achieve the rectification function typically performed by diodes. SR improves efficiency, thermal performance, power density, manufacturability, and reliability and decreases the overall system cost of power supply systems. New topology of control rectifier using the single-phase matrix converter is also covered in the second part of this chapter.

8.2 Line-Commutated Single-Phase Controlled Rectifiers

8.2.1 Single-Phase Half-Wave Rectifier

The single-phase half-wave rectifier uses a single thyristor to control the load voltage as shown in Fig. 8.2. The thyristor will conduct, on-state, when the voltage v_T is positive and a firing current pulse i_G is applied to the gate terminal. The control of the load voltage is performed by delaying the firing pulse by an angle α. The firing angle α is measured from the position where a diode would naturally conduct. In case of Fig. 8.2, the angle α is measured from the zero-crossing point of the supply voltage v_s. The load in Fig. 8.2 is resistive, and therefore, the current i_d has the same waveform of the load voltage. The thyristor goes to the nonconducting condition, off-state, when the load voltage and consequently the current reach a negative value.

The load average voltage is given by [1]

$$V_{d\alpha} = \frac{1}{2\pi}\int_{\alpha}^{\pi} V_{max}\sin(\omega t)d(\omega t) = \frac{V_{max}}{2\pi}(1+\cos\alpha) \qquad (8.1)$$

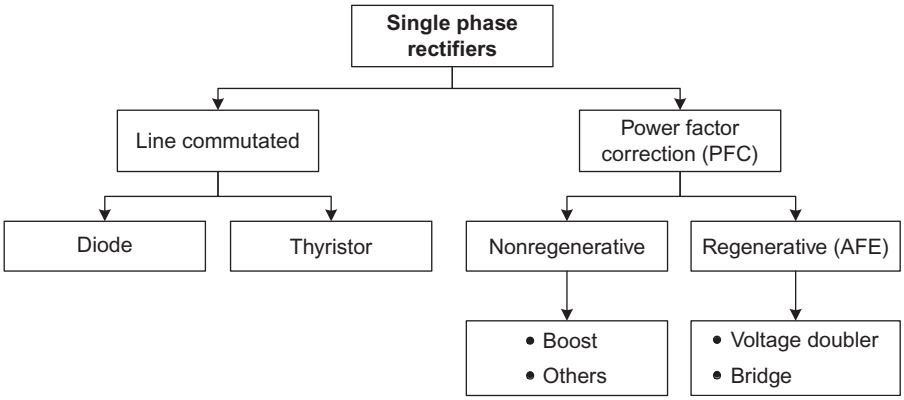

FIG. 8.1 Single-phase rectifier classification.

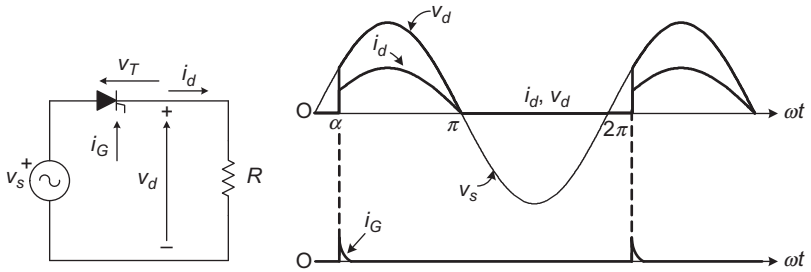

FIG. 8.2 Single-thyristor rectifier with resistive load.

where V_{max} is the supply peak voltage. Hence, it can be seen from Eq. (8.1) that changing the firing angle α controls both the load average voltage and the amount of transferred power.

Fig. 8.3A shows the rectifier waveforms for an *R-L* load. When the thyristor is turned on, the voltage across the inductance is

$$v_L = v_s - v_R = L\frac{di_d}{dt} \tag{8.2}$$

where v_R is the voltage in the resistance *R*, given by $v_R = R \cdot i_d$. If $v_s - v_R > 0$, from Eq. (8.2) holds that the load current increases its value. On the other hand, i_d decreases its value when $v_s - v_R < 0$. The load current is given by

$$i_d(\omega t) = \frac{1}{\omega L}\int_{\alpha}^{\omega t} v_L d\theta \tag{8.3}$$

Graphically, Eq. (8.3) means that the load current i_d is equal to zero when $A_1 = A_2$, maintaining the thyristor in conduction state even when $v_s < 0$.

When an inductive-active load is connected to the rectifier, as illustrated in Fig. 8.3B, the thyristor will be turned on if the firing pulse is applied to the gate when $v_s > E_d$. Again, the thyristor will remain in the on-state until $A_1 = A_2$. When the thyristor is turned off, the load voltage will be $v_d = E_d$.

8.2.2 Bi-Phase Half-Wave Rectifier

The biphase half-wave rectifier, shown in Fig. 8.4, uses a center-tapped transformer to provide two voltages v_1 and v_2. These two voltages are 180 degrees out of phase with respect to the midpoint neutral *N*. In this scheme, the load is fed via thyristors T_1 and T_2 during each positive cycle of voltages v_1 and v_2, respectively, while the load current returns via the neutral *N*.

As illustrated in Fig. 8.4, thyristor T_1 can be fired into the on-state at any time, while voltage $v_{T_1} > 0$. The firing pulses are delayed by an angle α with respect to the instant where diodes would conduct. Also the current paths for each conduction state are presented in Fig. 8.4. Thyristor T_1 remains in the on-state until the load current tends to a negative value. Thyristor T_2 is fired into the on-state when $v_{T_2} > 0$, which corresponds in Fig. 8.4 to the condition when $v_2 > 0$.

The mean value of the load voltage with resistive load is determined by

$$V_{di\alpha} = \frac{1}{\pi}\int_{\alpha}^{\pi} V_{max}\sin(\omega t)d(\omega t) = \frac{V_{max}}{\pi}(1+\cos\alpha) \tag{8.4}$$

The ac supply current is equal to $i_{T_1}\left(N^2/N^1\right)$ when T_1 is in the on-state and $-i_{T_2}\left(N^2/N^1\right)$ when T_2 is in the on-state, where N_2/N_1 is the transformer turns ratio.

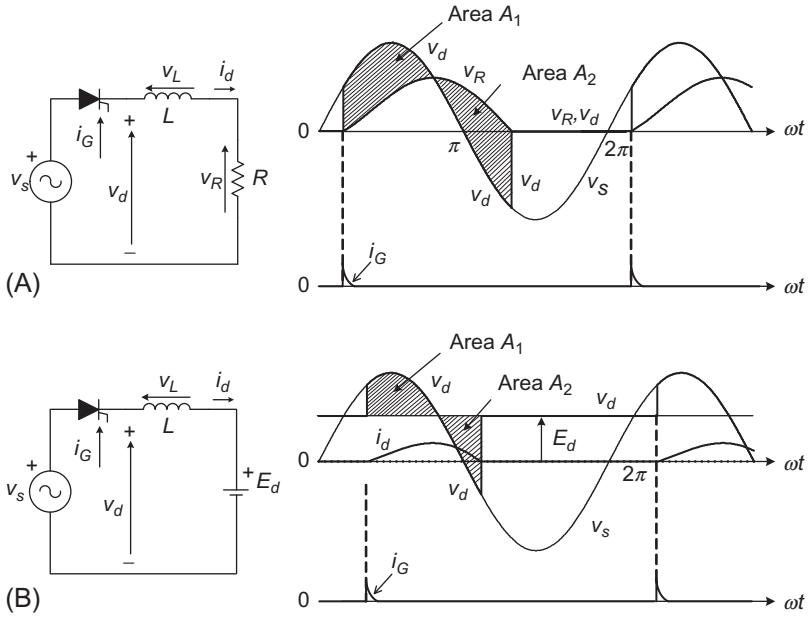

FIG. 8.3 Single-thyristor rectifier with (A) resistive-inductive load and (B) active load.

The effect of the load time constant $T_L = L/R$ on the normalized load current $i_d(t)/\hat{i}_R(t)$ for a firing angle $\alpha = 0$ degrees is shown in Fig. 8.5. The ripple in the load current reduces as the load inductance increases. If the load inductance $L \to \infty$, then the current is perfectly filtered.

8.2.3 Single-Phase Bridge Rectifier

Fig. 8.6A shows a fully controlled bridge rectifier, which uses four thyristors to control the average load voltage. In addition, Fig. 8.6B shows the half-controlled bridge rectifier that uses two thyristors and two diodes.

The voltage and current waveforms of the fully controlled bridge rectifier for a resistive load are illustrated in Fig. 8.7. Thyristors T_1 and T_2 must be fired on simultaneously during the positive half wave of the source voltage v_s, to allow the conduction of current. Alternatively, thyristors T_3 and T_4 must be fired simultaneously during the negative half wave of the source voltage. To ensure simultaneous firing, thyristors T_1 and T_2 use the same firing signal. The load voltage is similar to the voltage obtained with the biphase half-wave rectifier. The input current is given by

$$i_S = i_{T_1} - i_{T_4} \tag{8.5}$$

and its waveform is shown in Fig. 8.7.

Fig. 8.8 presents the behavior of the fully controlled rectifier with resistive-inductive load (with $L \to \infty$) [2] . The high load inductance generates a perfectly filtered current, and the rectifier behaves like a current source. With continuous load current, thyristors T_1 and T_2 remain in the on-state beyond the positive half wave of the source voltage v_s. For this reason, the load voltage v_d can have a negative instantaneous value. The firing of thyristors T_3 and T_4 has two effects:

(i) They turn off thyristors T_1 and T_2.
(ii) After the commutation, they conduct the load current.

This is the main reason why this type of converters is called "naturally commutated" or "line-commutated" rectifiers. The supply current i_S has the square waveform, as shown in Fig. 8.9, for continuous conduction. In this case, the average load voltage is given by

$$V_{di\alpha} = \frac{1}{\pi}\int_{\alpha}^{\pi+\alpha} V_{max}\sin(\omega t)d(\omega t) = \frac{2V_{max}}{\pi}\cos\alpha \tag{8.6}$$

8.2.4 Analysis of the Input Current

Considering a very high inductive load, the input current in a bridge-controlled rectifier is filtered and presents a square waveform. In addition, the input current i_s is shifted by the firing angle α with respect to the input voltage v_s, as shown in Fig. 8.9A. The input current can be expressed as a Fourier series, where the amplitude of the different harmonics is

$$I_{smax,\,n} = \frac{4I_d}{\pi n} \quad (n = 1,3,5,\ldots) \tag{8.7}$$

where n is the harmonic order. The root mean square (rms) value of each harmonic can be expressed as

$$I_{sn} = \frac{I_{smax,\,n}}{\sqrt{2}} = \frac{2\sqrt{2}I_d}{\pi\, n} \tag{8.8}$$

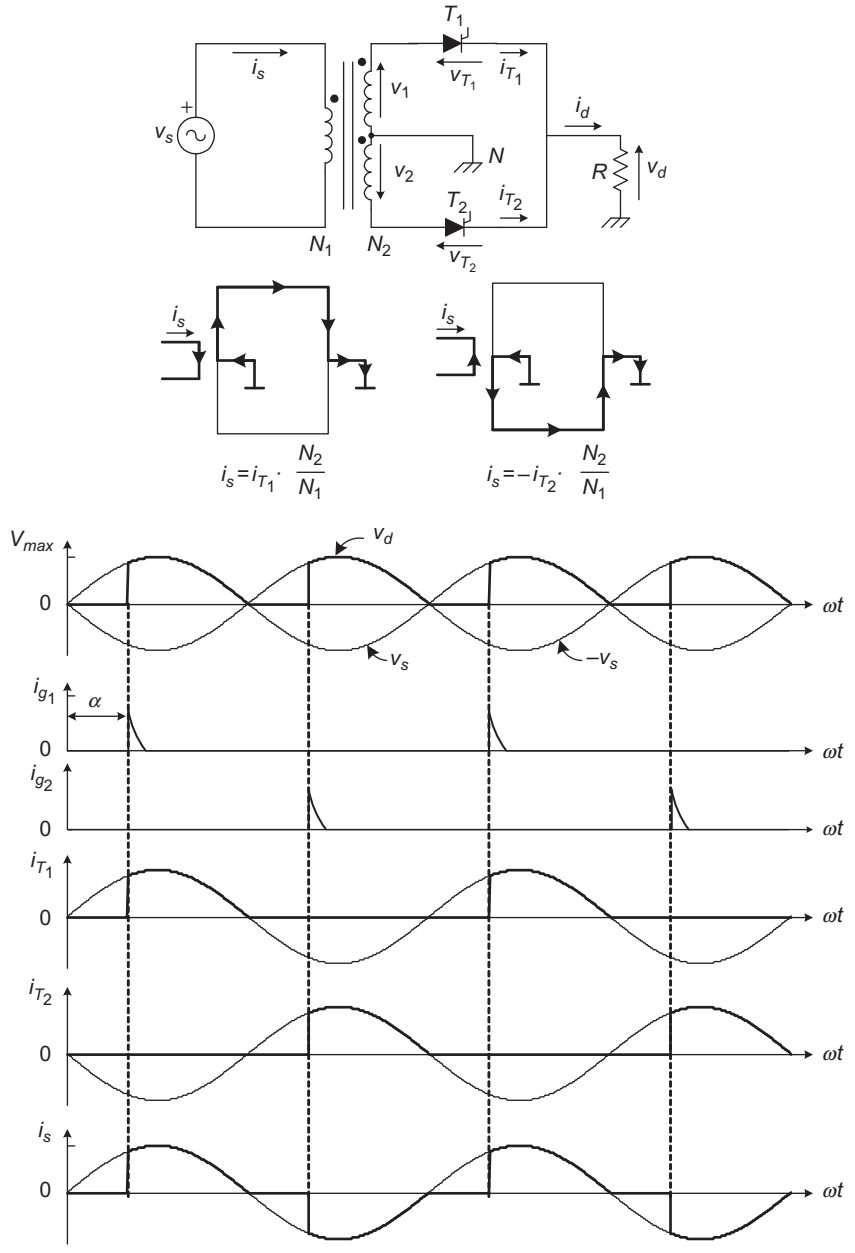

FIG. 8.4 Biphase half-wave rectifier.

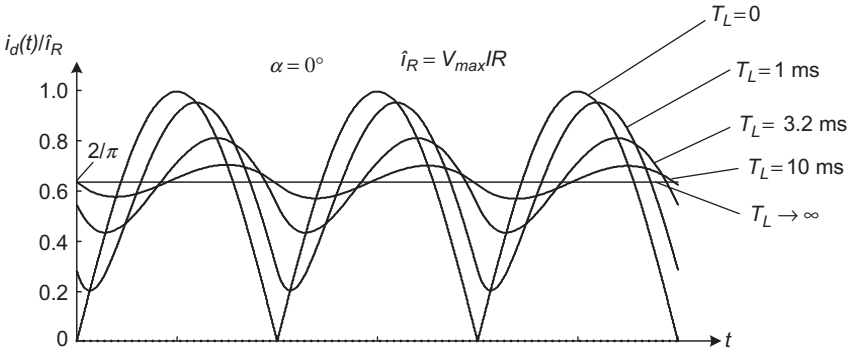

FIG. 8.5 Effect of the load time constant over the current ripple.

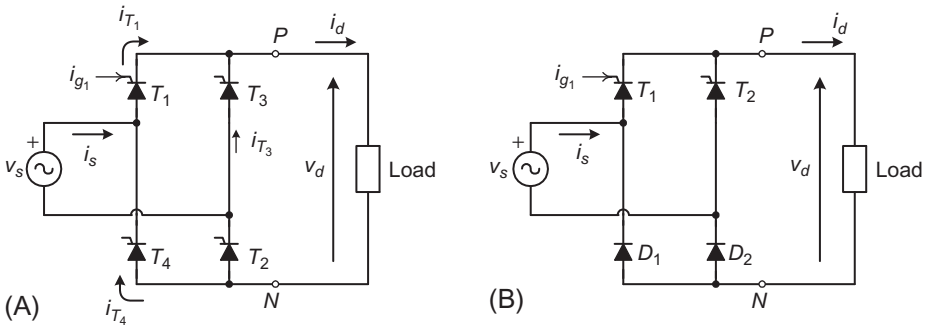

FIG. 8.6 Single-phase bridge rectifier, (A) fully controlled and (B) half-controlled.

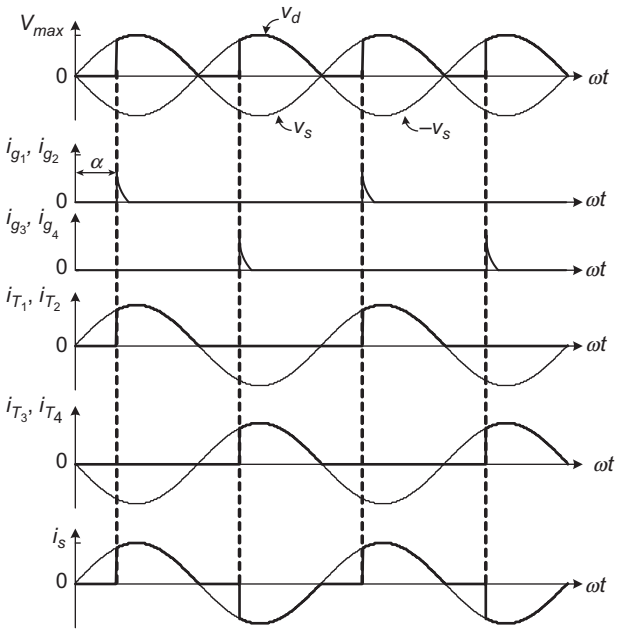

FIG. 8.7 Waveforms of a fully controlled bridge rectifier with resistive load.

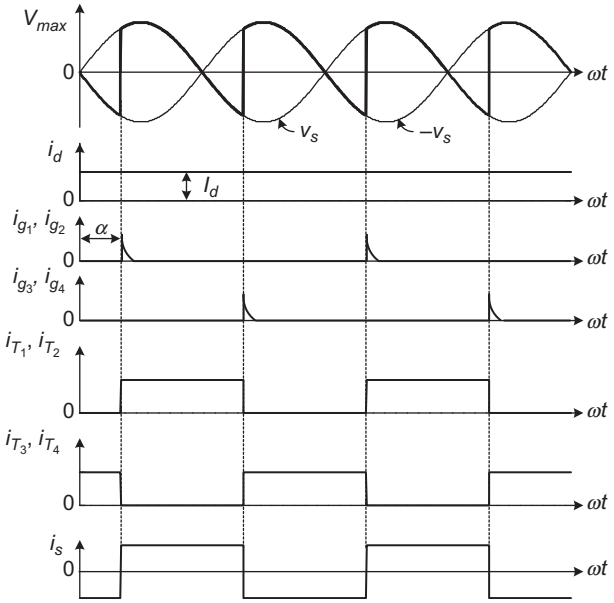

FIG. 8.8 Waveforms of a fully controlled bridge rectifier with resistive-inductive load ($L \rightarrow \infty$).

Thus, the rms value of the fundamental current i_{s1} is

$$I_{s1} = \frac{2\sqrt{2}}{\pi} I_d = 0.9 I_d \tag{8.9}$$

It can be observed from Fig. 8.9A that the displacement angle ϕ_1 of the fundamental current i_{s1} corresponds to the firing angle α. Fig. 8.9B shows that in the harmonic spectrum of the input current, only odd harmonics are present with decreasing amplitude while the frequency increases. Finally, the rms value of the input current i_s is

$$I_s = I_d \tag{8.10}$$

The total harmonic distortion (THD) of the input current can be determined by [3]

$$\text{THD} = \frac{\sqrt{I_s^2 - I_{s1}^2}}{I_{s1}} 100 = 48.4\% \tag{8.11}$$

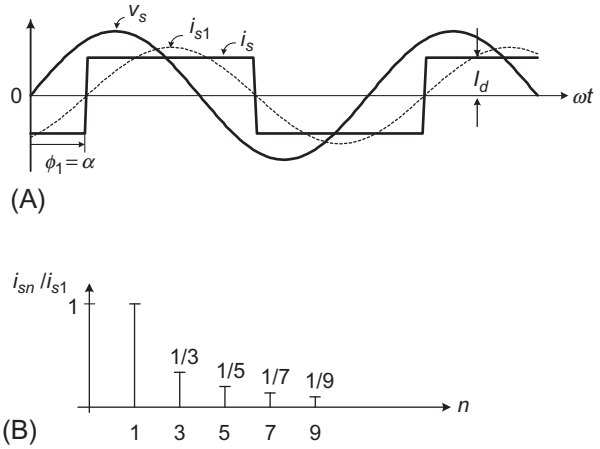

FIG. 8.9 Input current of the single-phase controlled rectifier in bridge connection, (A) waveforms and (B) harmonics spectrum.

8.2.5 Power Factor of the Rectifier

The displacement factor of the fundamental current, obtained from Fig. 8.9A, is

$$\cos\phi_1 = \cos\alpha \tag{8.12}$$

In the case of nonsinusoidal currents, the active power delivered by the sinusoidal single-phase supply is

$$P = \frac{1}{T}\int_0^T v_s(t) i_s(t) dt = V_s I_{s1} \cos\phi_1 \tag{8.13}$$

where V_s is the rms value of the single-phase voltage v_s.

The apparent power is given by

$$S = V_s I_s \tag{8.14}$$

The power factor (PF) is defined by

$$\text{PF} = \frac{P}{S} \tag{8.15}$$

Substitution from Eqs. (8.12), (8.13), and (8.14) in Eq. (8.15) yields

$$\text{PF} = \frac{I_{s1}}{I_s}\cos\alpha \tag{8.16}$$

This equation shows clearly that due to the nonsinusoidal waveform of the input current, the power factor of the rectifier is negatively affected both by the firing angle α and by the distortion of the input current. In effect, an increase in the distortion of the current produces an increase in the value of I_s in Eq. (8.16), which deteriorates the power factor.

8.2.6 The Commutation of the Thyristors

Until now, the current commutation between thyristors has been considered to be instantaneous. This condition is not valid in real cases due to the presence of the line inductance L, as shown in Fig. 8.10A. During the commutation, the current through the thyristors cannot change instantaneously, and for this reason, during the commutation angle μ, all four thyristors are conducting simultaneously. Therefore, during the commutation, the following relationship for the load voltage holds

$$v_d = 0 \quad \alpha \le \omega t \le \alpha + \mu \tag{8.17}$$

The effect of the commutation on the supply current, the voltage waveforms, and the thyristor current waveforms can be observed in Fig. 8.10B.

During the commutation, the following expression holds

$$L\frac{di_s}{dt} = v_s = V_{max}\sin(\omega t) \quad \alpha \le \omega t \le \alpha + \mu \tag{8.18}$$

Integrating Eq. (8.18) over the commutation interval yields

$$\int_{-I_d}^{I_d} di_s = \frac{V_{max}}{L}\int_{\alpha/\omega}^{\alpha+\mu/\omega} \sin(\omega t) dt \tag{8.19}$$

From Eq. (8.19), the following relationship for the commutation angle μ is obtained:

$$\cos(\alpha+\mu) = \cos\alpha - \frac{2\omega L}{V_{max}} I_d \tag{8.20}$$

Eq. (8.20) shows that an increase of the line inductance L or an increase of the load current I_d increases the commutation angle μ. In addition, the commutation angle is affected by the firing angle α. In effect, Eq. (8.18) shows that with different values of α, the supply voltage v_s has a different instantaneous value, which produces different di_s/dt, thereby affecting the duration of the commutation.

Eq. (8.17) and the waveform of Fig. 8.10B show that the commutation process reduces the average load voltage $V_{d\alpha}$. When the commutation is considered, the expression for the average load voltage is given by

$$V_{d\alpha} = \frac{1}{\pi}\int_{\alpha+\mu}^{\pi+\alpha} \sin(\omega t) d(\omega t) = \frac{V_{max}}{\pi}[\cos(\alpha+\mu) + \cos\alpha] \tag{8.21}$$

Substituting Eq. (8.20) into Eq. (8.21) yields

$$V_{d\alpha} = \frac{2}{\pi}V_{max}\cos\alpha - \frac{2\omega L}{\pi} I_d \tag{8.22}$$

8.2.7 Operation in the Inverting Mode

When the angle $\alpha > 90$ degrees, it is possible to obtain a negative average load voltage. In this condition, the power is fed back to the single-phase supply from the load. This operating mode is called inverter or inverting mode, because the energy is transferred from the dc to the ac side. In practical cases, this operating mode is obtained when the load configuration is as shown in Fig. 8.11A. It must be noticed that this rectifier allows unidirectional load current flow. Fig. 8.11B shows the waveform of the load voltage with the rectifier in the inverting mode, neglecting the source inductance L.

Section 8.2.6 described how supply inductance increases the conduction interval of the thyristors by the angle μ. As shown in Fig. 8.11C, the thyristor voltage v_{T_1} has a negative value during the extinction angle γ, defined by

$$\gamma = 180 - (\alpha + \mu) \tag{8.23}$$

To ensure that the outgoing thyristor will recover its blocking capability after the commutation, the extinction angle should satisfy the following restriction:

$$\gamma > \omega t_q \tag{8.24}$$

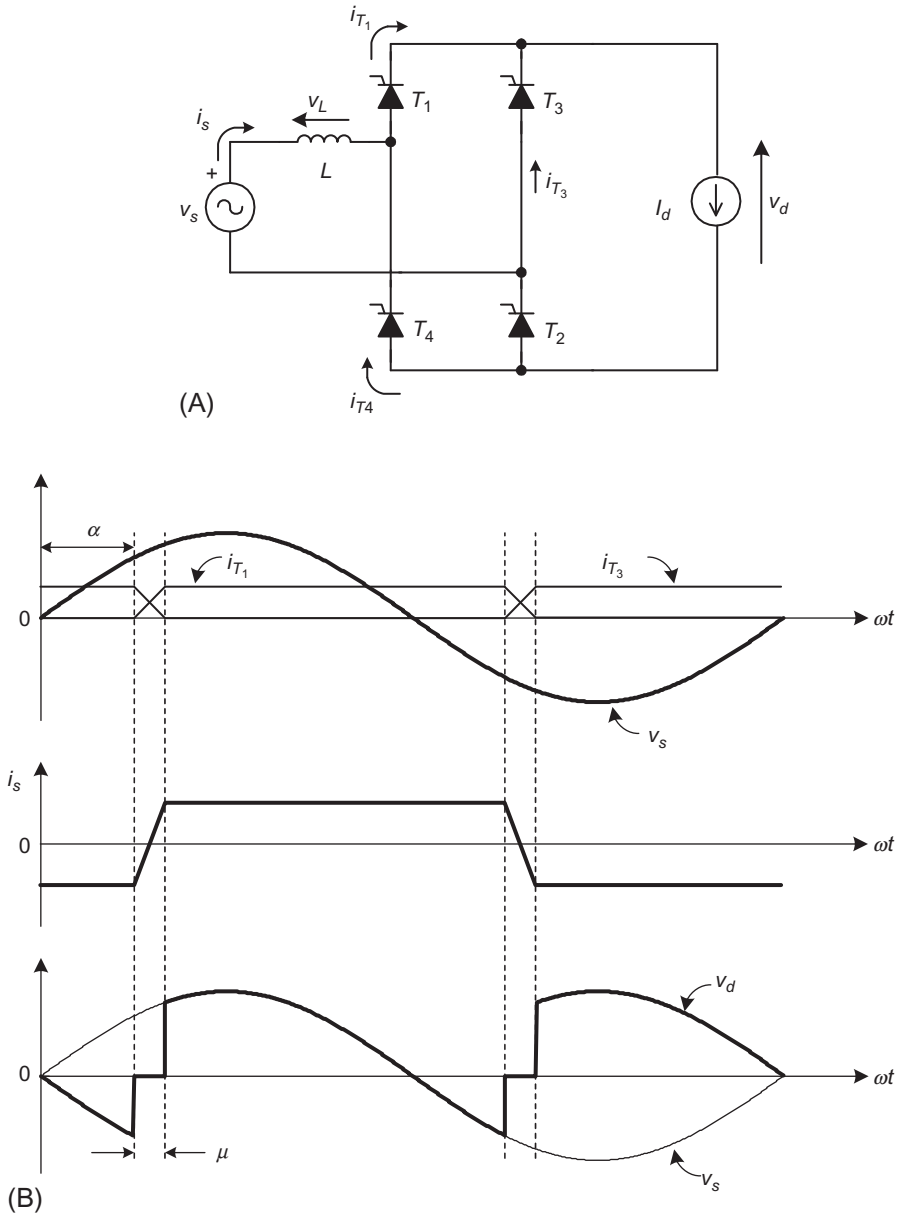

FIG. 8.10 The commutation process, (A) circuit and (B) waveforms.

where ω is the supply frequency and t_q is the thyristor turn-off time. Considering Eqs. (8.23) and (8.24), the maximum firing angle is, in practice,

$$\alpha_{max} = 180 - \mu - \gamma \tag{8.25}$$

If the condition of Eq. (8.25) is not satisfied, the commutation process will fail, originating destructive currents.

8.2.8 Applications

Important application areas of controlled rectifiers include uninterruptible power supplies (UPS), for feeding critical loads. Fig. 8.12 shows a simplified diagram of a single-phase UPS configuration, typically rated for <10 kVA. A fully controlled or half-controlled rectifier is used to generate the dc voltage for the inverter. In addition, the input rectifier acts as a battery charger. The output of the inverter is filtered before it is fed to the load. The operating modes of UPS are best explained in Ref. [4]. The control of low-power dc motors is another interesting application of controlled single-phase rectifiers. In the circuit of Fig. 8.13, the controlled rectifier regulates the armature voltage and consequently controls the motor current i_d in order to produce a required torque.

This configuration allows only positive current flow in the load. However, the load voltage can be both positive and

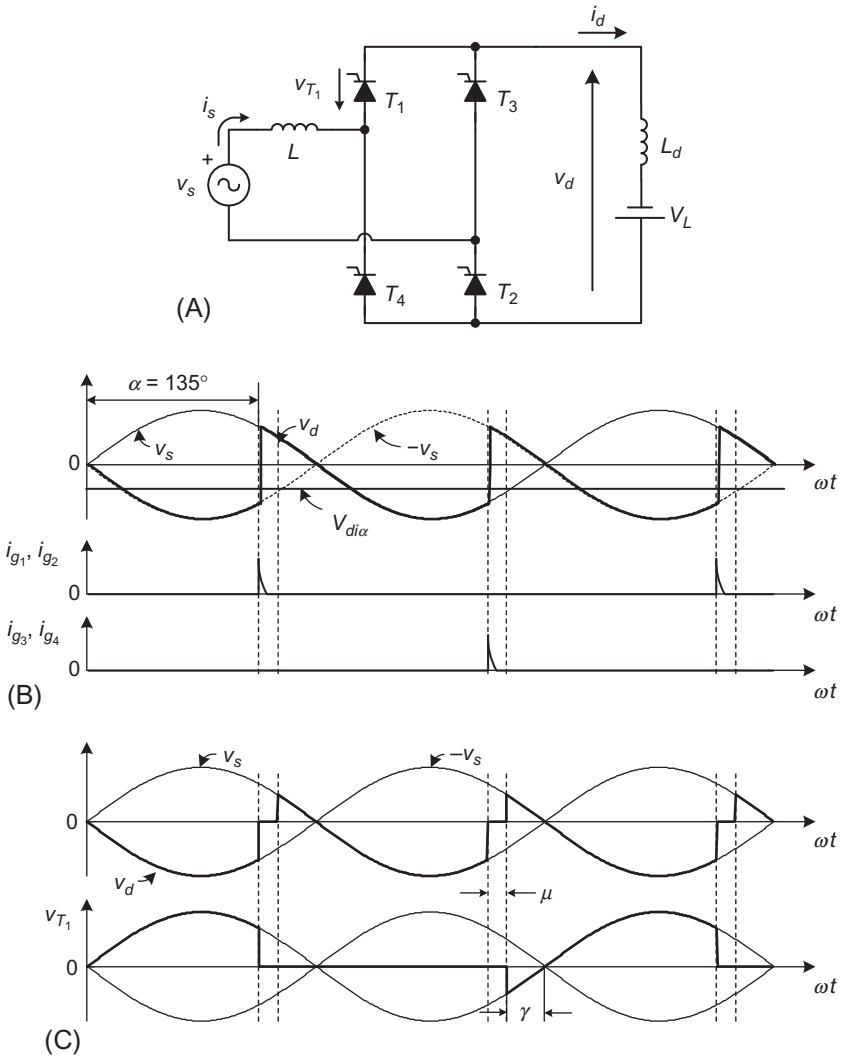

FIG. 8.11 Rectifier in the inverting mode: (A) circuit, (B) waveforms neglecting source inductance L, and (C) waveforms considering L.

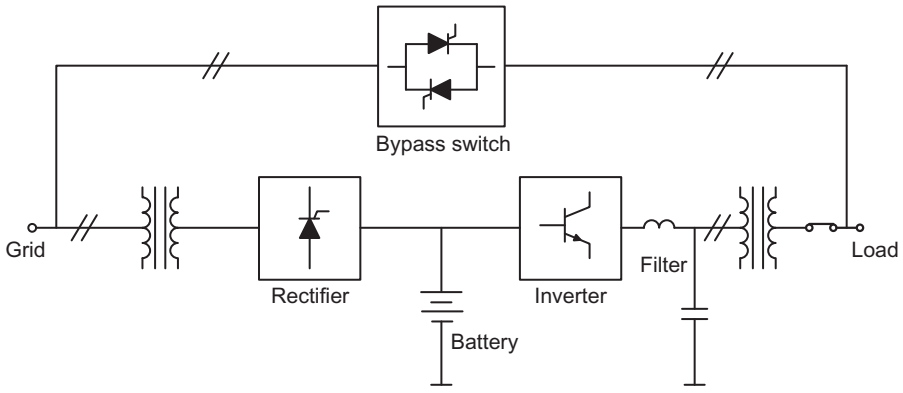

FIG. 8.12 Application of a rectifier in single-phase UPS.

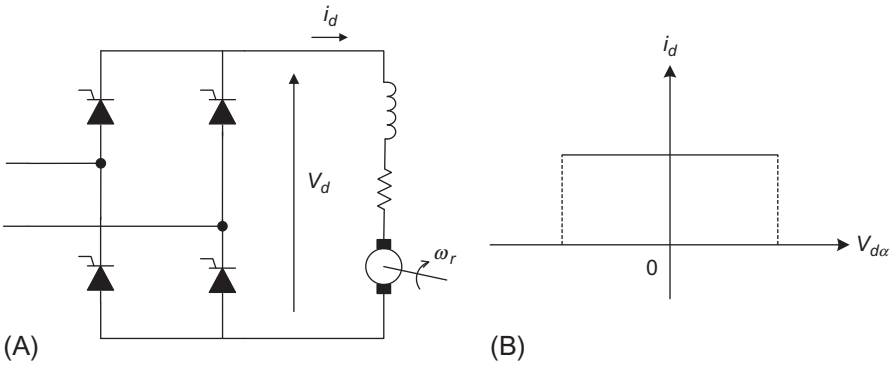

FIG. 8.13 Two-quadrant dc drive, (A) circuit and (B) quadrants of operation.

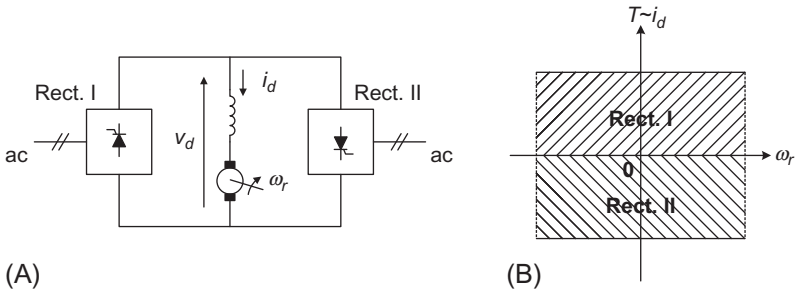

FIG. 8.14 Single-phase dual-converter drive, (A) connection and (B) four-quadrant operation.

negative. For this reason, this converter works in the two-quadrant mode of operation in the plane i_d vs $V_{d\alpha}$.

A better performance can be obtained with two rectifiers in back-to-back connection at the dc terminals, as shown in Fig. 8.14A. This arrangement, known as a dual-converter configuration, allows four-quadrant operation of the drive. Rectifier I provides positive load current i_d, while rectifier II provides negative load current. The motor can work in forward powering, forward braking (regenerating), reverse powering, and reverse braking (regenerating). These operating modes are shown in Fig. 8.14B, where the torque T vs the rotor speed ω_r is illustrated.

8.3 Unity Power Factor Single-Phase Rectifiers

8.3.1 The Problem of Power Factor in Single-Phase Line-Commutated Rectifiers

The main disadvantages of the classical line-commutated rectifiers are that (i) they produce a lagging displacement factor with respect to the voltage of the utility and (ii) they generate an important amount of input current harmonics. These aspects have a negative influence on both power factor and power quality. In the last several years, the massive use of single-phase power converters has increased the problems of power quality in electric systems. In effect, modern commercial buildings have 50% and even up to 90% of the demand, originated by nonlinear loads, which are composed mainly of rectifiers [5,6]. Today, it is not unusual to find rectifiers with total harmonic distortion of the current $\text{THD}_i > 40\%$, originating severe overloads in conductors and transformers.

Fig. 8.15A shows a single-phase rectifier with a capacitive filter, used in much of today's low-power equipment. The input current produced by this rectifier is illustrated in Fig. 8.15B; it appears highly distorted due to the presence of the filter capacitor. This current has a harmonic content shown in Fig. 8.16 and Table 8.1, with a $\text{THD}_i = 197\%$.

The rectifier in Fig. 8.15 has a very low power factor of $\text{PF} = 0.45$, due mainly to its large harmonic content.

8.3.2 Standards for Harmonics in Single-Phase Rectifiers

The relevance of the problems originated by harmonics in single-phase line-commutated rectifiers has motivated some agencies to introduce restrictions to these converters. The IEC 61000-3-2 [7], Class D International Standard, establishes limits to all low-power single-phase equipment having an input current with a "special wave shape" and an active input power $P \leq 600$ W. Class D equipment has an input current with a special wave shape contained within the envelope given in Fig. 8.15B. This class of equipment must satisfy certain

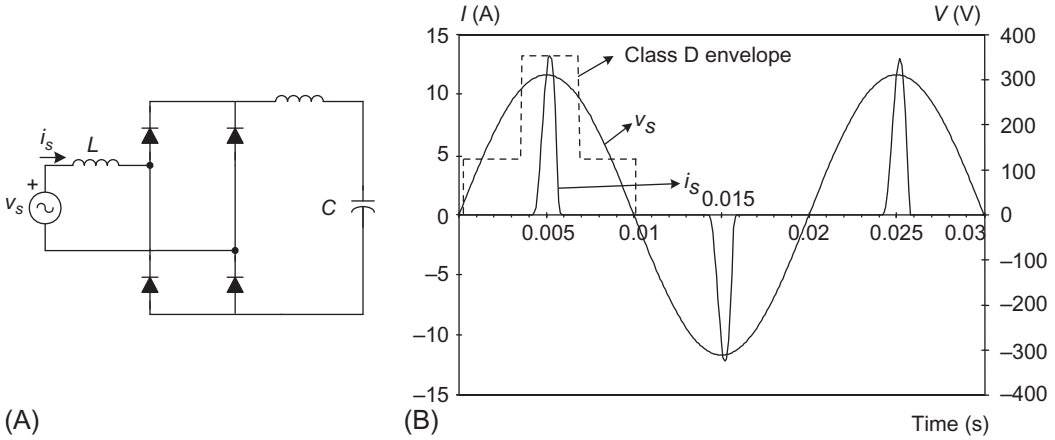

FIG. 8.15 Single-phase rectifier, (A) circuit and (B) waveforms of the input voltage and current.

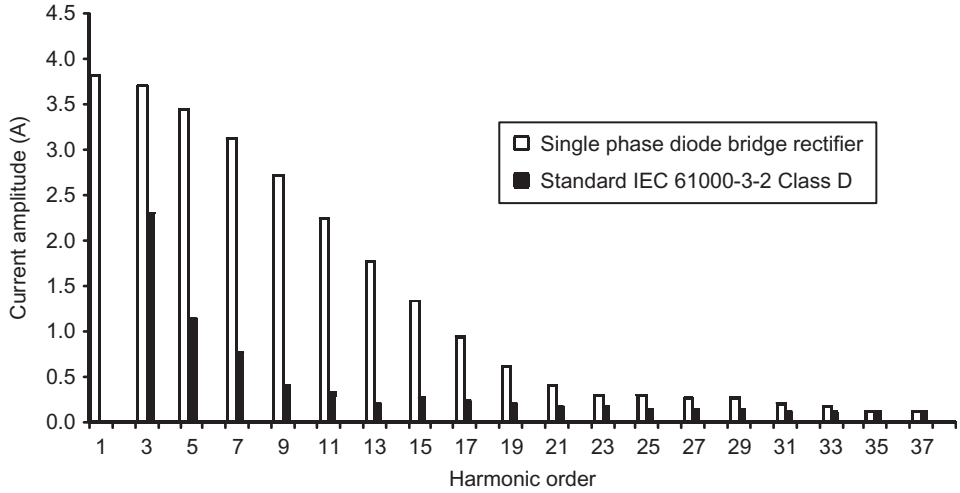

FIG. 8.16 Input current harmonics produced by a single-phase diode bridge rectifier.

TABLE 8.1 Harmonic Content of the Current of Fig. 8.15

n	3	5	7	9	11	13	15	17	19	21
I_n/I_1 (%)	96.8	90.5	81.7	71.0	59.3	47.3	35.7	25.4	16.8	10.6

harmonic limits, shown in Fig. 8.16. It is clear that a single-phase line-commutated rectifier with the parameters shown in Fig. 8.15A is not able to comply with the standard IEC 61000-3-2 Class D. The standard can be satisfied only by adding huge passive filters, which increases the size, weight, and cost of the rectifier. This standard has been the motivation for the development of active methods to improve the quality of the input current and, consequently, the power factor.

8.3.3 The Single-Phase Boost Rectifier

One of the most important high-power-factor rectifiers, from a theoretical and conceptual point of view, is the so-called single-phase boost rectifier, shown in Fig. 8.17A, which is obtained from a classical noncontrolled bridge rectifier, with the addition of transistor T, diode D, and inductor L.

8.3.3.1 Working Principle, Basic Concepts

In boost rectifiers, the input current $i_s(t)$ is controlled by changing the conduction state of transistor T. When transistor T is in the on-state, the single-phase power supply is short-circuited through the inductance L, as shown in Fig. 8.17B; the diode D avoids the discharge of the filter capacitor C through the transistor. The current of the inductance i_L is given by the following equation:

$$\frac{di_L}{dt} = \frac{v_L}{L} = \frac{|v_s|}{L} \tag{8.26}$$

Due to the fact that $|v_s| > 0$, the on-state of transistor T always produces an increase in the inductance current i_L and consequently an increase in the absolute value of the source current i_s.

When transistor T is turned off, the inductor current i_L cannot be interrupted abruptly and flows through diode D,

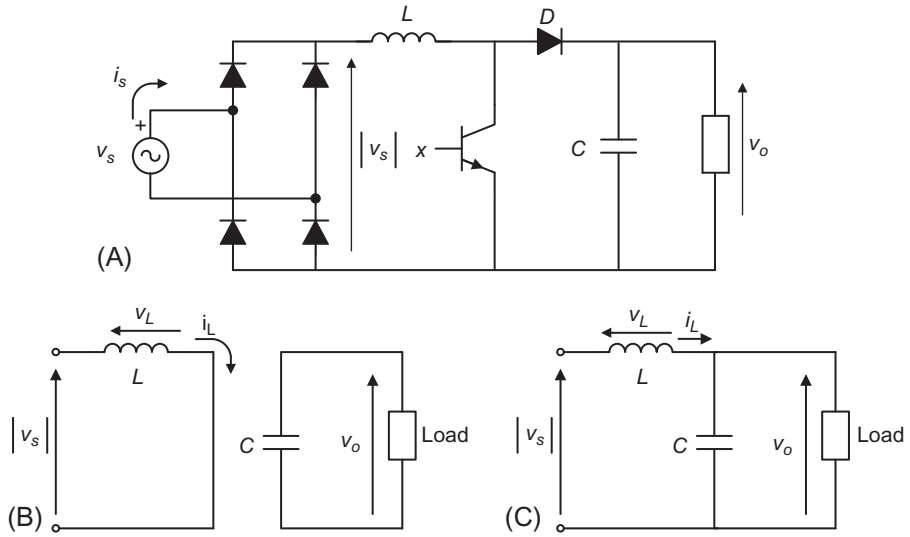

FIG. 8.17 Single-phase boost rectifier, (A) power circuit and equivalent circuit for transistor T in the (B) on-state and (C) off-state.

charging capacitor *C*. This is observed in the equivalent circuit of Fig. 8.17C. In this condition, the behavior of the inductor current is described by

$$\frac{di_L}{dt} = \frac{v_L}{L} = \frac{|v_s| - v_o}{L} \tag{8.27}$$

If $v_o > |v_s|$, which is an important condition for the correct behavior of the rectifier, then $|v_s| - v_o < 0$, and this means that in the off-state the inductor current decreases its instantaneous value.

8.3.3.2 Continuous Conduction Mode (CCM)

When an appropriate firing pulse sequence is applied to transistor T, the waveform of the input current i_s can be controlled to follow a sinusoidal reference, as can be observed in the positive half wave of i_s in Fig. 8.18. This figure shows the reference inductor current $i_{L_{ref}}$, the inductor current i_L, and the gate drive signal x for transistor T. Transistor T is on when $x = 1$, and it is off when $x = 0$.

Fig. 8.18 clearly shows that the on(off)-state of transistor T produces an increase (decrease) in the inductor current i_L. Note that for low values of v_s, the inductor does not have enough energy to increase the current value and, for this reason, it presents a distortion in their current waveform as shown in Fig. 8.18A.

Fig. 8.19 presents a block diagram of the control system for the boost rectifier, which includes a proportional-integral (PI) controller, to regulate the output voltage v_o. The reference value $i_{L_{ref}}$ for the inner current control loop is obtained from the multiplication between the output of the voltage controller and the absolute value $|v_s(t)|$. A hysteresis controller provides a fast control for the inductor current i_L, resulting in a practically sinusoidal input current i_s.

Typically, the output voltage v_o should be at least 10% higher than the peak value of the source voltage $v_s(t)$, in order to assure good dynamic control of the current. The control works with the following strategy: a step increase in the reference voltage $v_{o_{ref}}$ will produce an increase in the voltage error $v_{o_{ref}} - v_o$ and an increase of the output of the PI controller, which originates an increase in the amplitude of the reference current $i_{L_{ref}}$. The current controller will follow this new reference and will increase the amplitude of the sinusoidal input current i_s, which will increase the active power delivered by the single-phase power supply, producing finally an increase in the output voltage v_o.

Fig. 8.20A shows the waveform of the input current i_s and the source voltage v_s. The ripple of the input current can be reduced by shortening the hysteresis width δ. The trade-off for this improvement is an increase in the switching frequency, which is proportional to the commutation losses of the transistors. For a given hysteresis width δ, a reduction of inductance L also produces an increase in the switching frequency. As can be seen, the input current presents a third-harmonic component. This harmonic is generated by the second-harmonic component present in v_o, which is fed back through the voltage (PI) controller and multiplied by the sinusoidal waveform, generating a third-harmonic component on $i_{L_{ref}}$. This harmonic contamination can be avoided by filtering the v_o measurement with a low-pass filter or a band-stop filter around $2\omega_s$. The input current obtained using the measurement filter is shown in Fig. 8.20B. Fig. 8.20D confirms the reduction of the third-harmonic component.

However, in both cases, a drastic reduction in the harmonic content of the input current i_s can be observed in the frequency spectrum of Fig. 8.20C and D. This current fulfills the restrictions established by standard IEC 61000-3-2. The total harmonic

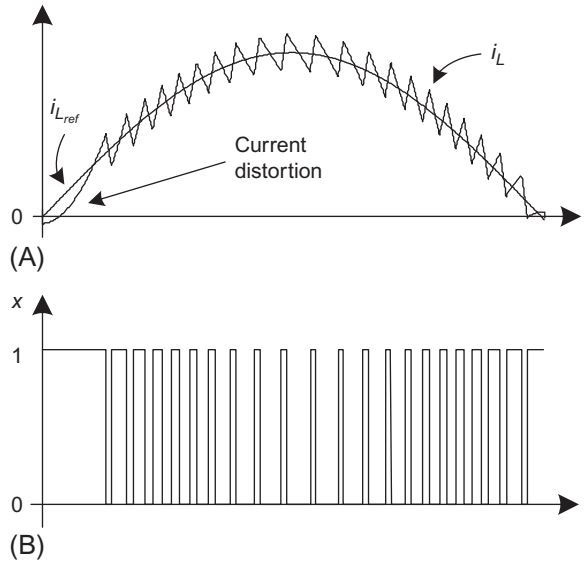

FIG. 8.18 Behavior of the inductor current i_L, (A) waveforms and (B) transistor T gate drive signal x.

distortion of the current in Fig. 8.20A is THD = 7.46%, while the THD of the current of Fig. 8.20B is 4.83%; in both cases, a very high power factor, over 0.99, is reached.

Fig. 8.21 shows the dc voltage control loop dynamic behavior for step changes in the load. An increase in the load, at $t = 0.3$ (s), produces an initial reduction of the output voltage v_o, which is compensated by an increase in the input current i_s. At $t = 0.6$ (s), a step decrease in the load is applied. The dc voltage controller again adjusts the supply current in order to balance the active power.

8.3.3.3 Discontinuous Conduction Mode (DCM)

This PFC method is based on an active current waveform-shaping principle. There are two different approaches considering fixed and variable switching frequency, both operating principles are illustrated in Fig. 8.22.

(a) DCM with fixed switching frequency

The current shaping strategy is achieved by combining three different conduction modes, performed over a

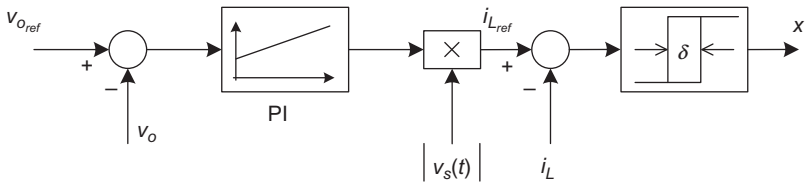

FIG. 8.19 Control system of the boost rectifier.

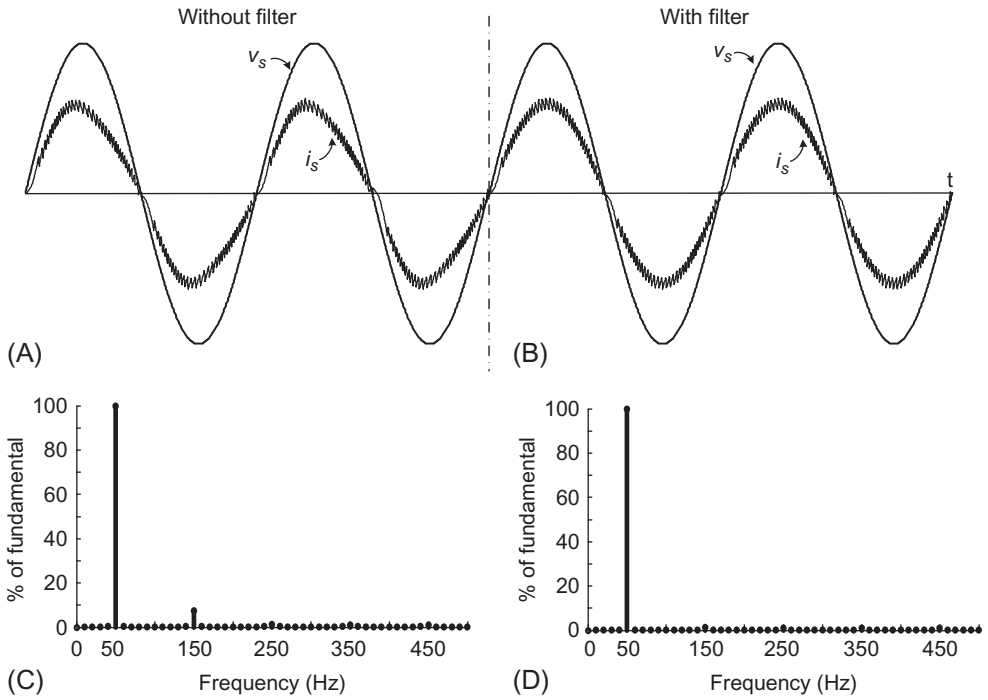

FIG. 8.20 Input current and voltage of the single-phase boost rectifier: (A) without a filter on v_o measurement; (B) with a filter on v_o measurement, frequency spectrum; (C) without filter; and (D) with filter.

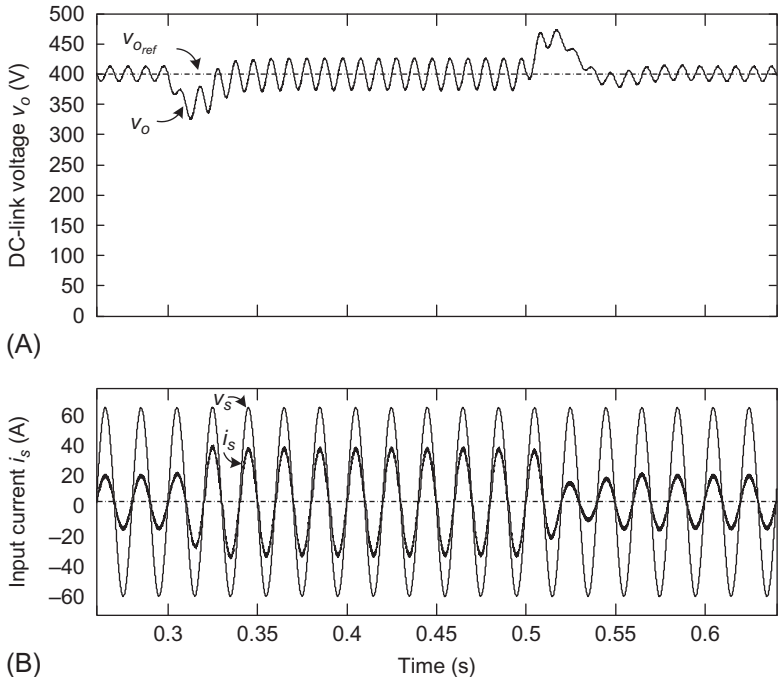

FIG. 8.21 Response to a change in the load, (A) output voltage v_o and (B) input current i_s.

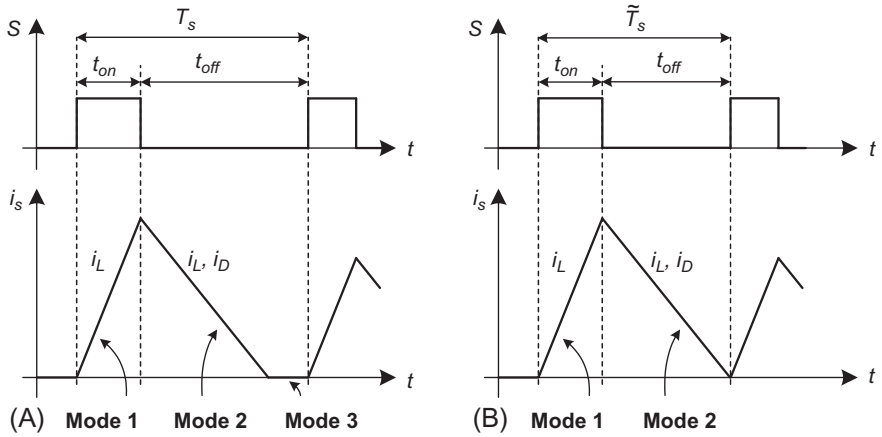

FIG. 8.22 Boost DCM operating principle, (A) with fixed switching frequency and (B) with variable switching frequency.

fixed switching period T_s. At the beginning of each period, the power semiconductor is turned on. During the on-state, shown in Fig. 8.23A, the power supply is short-circuited through the rectifier diodes, the inductor L, and the boost switch T. Hence, the inductor current i_L increases at a rate proportional to the instantaneous value of the supply voltage. As a result, during the on-state, the average supply current i_s is proportional to the supply voltage v_s, which yields to power factor correction.

When the switch is turned off, the current flows to the load trough diode D, as shown in Fig. 8.23B. The instantaneous current value decreases (since the load voltage v_o is higher than the supply peak voltage) at a rate proportional to the difference between the supply and load voltage. Finally, the last mode, illustrated in Fig. 8.23C, corresponds to the time in which the current reaches zero value, completing the switching period T_s. Therefore, the supply current is not proportional to the voltage source during the whole control period, introducing distortion and undesirable EMI in comparison with CCM.

The duty cycle $D = t_{on}/T_s$ is determined by the control loop, in order to obtain the desired output power and to ensure operation in DCM, that is, to reach zero current before the new switching cycle starts. The

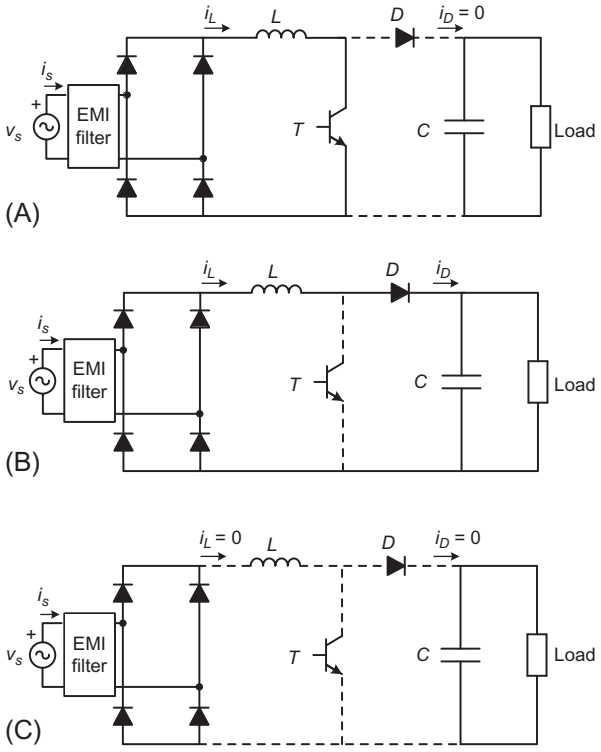

FIG. 8.23 Boost DCM equivalent circuits: (A) mode 1, transistor on, inductor current increasing; (B) mode 2, transistor off, inductor current decreasing; and (C) mode 3, transistor off, inductor current reaches zero. (Insert figure from the third edition).

control strategy can be implemented with analog circuitry as shown in Fig. 8.24, or digitally with modern computing devices. Generally, the duty cycle is controlled with a slow control loop, maintaining the output voltage and duty cycle constant over a half-source cycle.

A qualitative example of the supply voltage and current obtained using DCM is illustrated in Fig. 8.25.

(b) DCM with variable switching frequency

The operating principle is similar to the one used in the previous case, the main difference is that mode 3 is avoided by switching the transistor again to the on-state, immediately after the inductor current reaches zero value. This reduces the current distortion, with the trade-off of introducing variable switching frequency (T_s is variable) and consequently lower-order harmonic content.

Both CCM and DCM achieve an improvement in the power factor. The DCM is more efficient since reverse-recovery losses of the boost diode are eliminated; however, this mode introduces high-current ripple and considerable distortion, and usually, an important fifth-order harmonic is obtained. Therefore, boost DCM applications are limited to 300 W power levels, to meet standards and regulations. The DCM with variable switching frequency reduces this harmonic content, at expends of a wide distributed current spectrum and all related design problems.

8.3.3.4 Resonant Structures for the Boost Rectifiers

An important issue in power electronics is the power losses in power semiconductors. These losses can be classified in two groups: conduction losses and switching losses, as shown in Fig. 8.26.

The conduction losses are produced by the current through the semiconductor juncture, so these losses are unavoidable. However, the switching losses, which are produced while the power semiconductors work in linear state during the transition from on- to off-state or from off- to on-state, can be reduced or even eliminated, if the switch (transition) occurs when (a) the current across the power semiconductor is zero or (b) the voltage between the power terminals of the power semiconductor is zero.

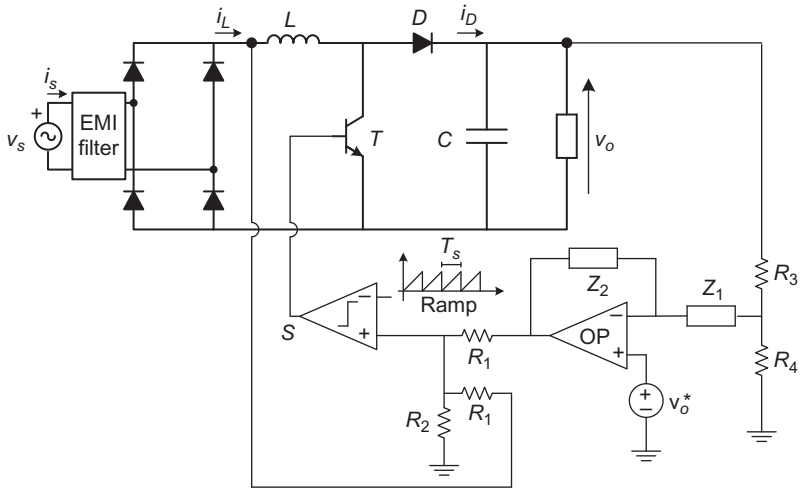

FIG. 8.24 Boost DCM control circuit with fixed switching frequency.

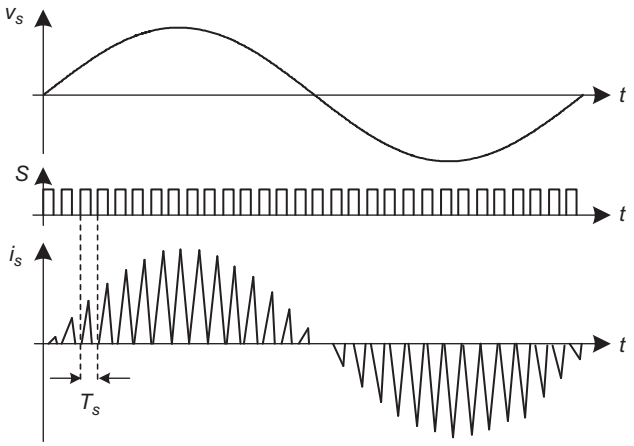

FIG. 8.25 Boost DCM waveforms: supply voltage, transistor control signal, and supply current.

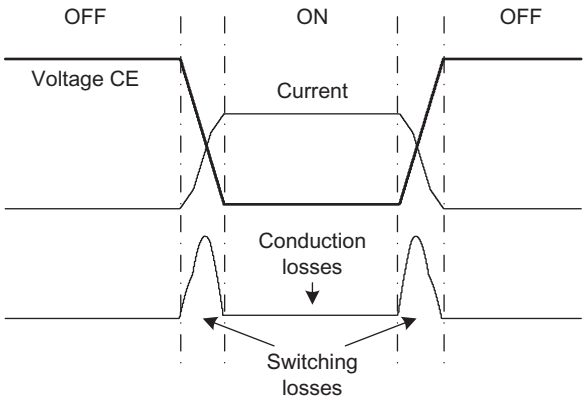

FIG. 8.26 Conduction and switching losses on a power switch.

This operation mode is used in the so-called *resonant* or *soft-switched* converters, which are discussed in detail in a different chapter of this handbook. Resonant operation can also be used with the boost converter topology. In order to produce this condition, topology of Fig. 8.17 needs to be modified, by including reactive components and additional semiconductors.

In Fig. 8.27, a resonant structure for zero-current switching (ZCS) [8] is shown. As can be seen, additional resonant inductors (L_{r_1} and L_{r_2}), capacitors (C_r), diodes (D_{r_1} and D_{r_2}), and power switch (S_r) have been included.

In a similar way, in Fig. 8.28, a resonant structure for zero-voltage switching (ZVS) [9] is shown. Once again, additional inductance (L_r), capacitor (C_r), and power switch (S_r) are added; note, however, that diode D has been replaced by two "resonant diodes," D_{r_1} and D_{r_2}. In both cases, the ZVS or ZCS condition is reached through a proper control of S_r. Other resonant topologies are described in the literature [10–12] with similar behavior.

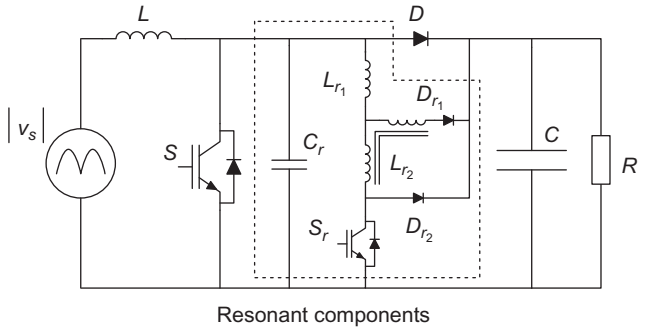

FIG. 8.27 Boost rectifier with ZCS.

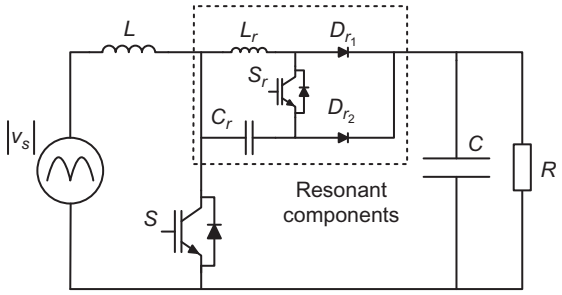

FIG. 8.28 Boost rectifier with ZVS.

8.3.3.5 Bridgeless Boost Rectifier

The bridgeless boost rectifier [13] is shown in Fig. 8.29A. This rectifier replaces the input diode rectifier by a combination of two boost rectifiers that work alternately: (a) When v_s is positive, T_1 and D_1 operate as boost rectifier 1 (Fig. 8.29B), and (b) when v_s is negative, T_2 and D_2 operate as boost rectifier 2 (Fig. 8.29C).

This topology reduces the conduction losses of the rectifier [14,15] but requires a slightly more complex control scheme; also EMI and EMC aspects must be considered.

8.3.4 Voltage Doubler PWM Rectifier

Fig. 8.30A shows the power circuit of the voltage-doubler pulse-width-modulated (PWM) rectifier, which uses two transistors T_1 and T_2 and two filter capacitors C_1 and C_2. The transistors are switched complementary to control the waveform of the input current i_s and the output dc voltage v_o. Capacitor voltages V_{C1} and V_{C2} must be higher than the peak value of the input voltage v_s to ensure the control of the input current.

The equivalent circuit of this rectifier with transistor T_1 in the on-state is shown in Fig. 8.30B. For this case, the inductor voltage dynamic equation is 10.5:

$$v_L = L\frac{di_s}{dt} = v_s(t) - V_{C1} < 0 \tag{8.28}$$

Eq. (8.28) means that under this conduction state, current $i_s(t)$ decreases its value.

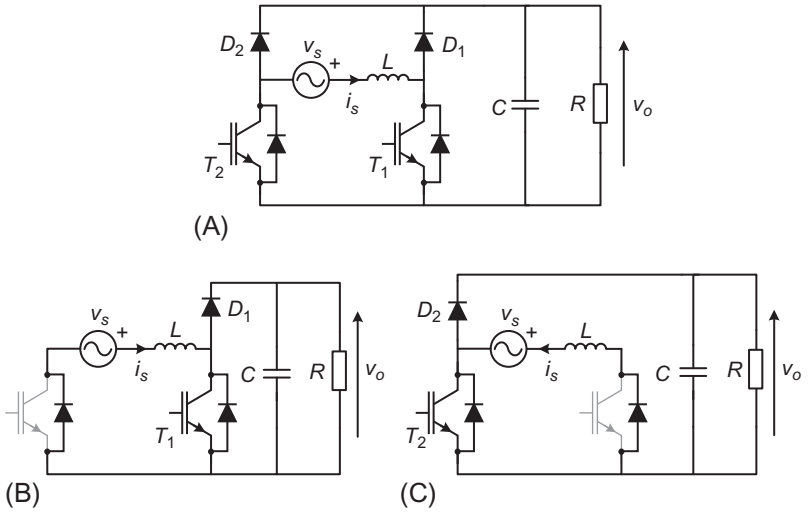

FIG. 8.29 (A) Power circuit of bridgeless boost rectifier; equivalent circuit when (B) $v_s > 0$ and (C) $v_s < 0$.

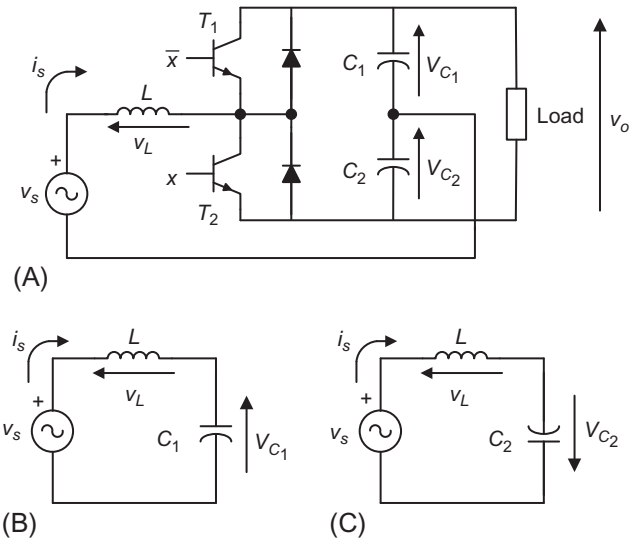

FIG. 8.30 Voltage-doubler rectifier: (A) power circuit, (B) equivalent circuit with T_1 on, and (C) equivalent circuit with T_2 on.

On the other hand, the equivalent circuit of Fig. 8.30C is valid when transistor T_2 is in the conduction state, resulting in the following expression for the inductor voltage

$$v_L = L\frac{di_s}{dt} = v_s(t) + V_{C2} > 0 \tag{8.29}$$

Hence, for this condition, the input current $i_s(t)$ increases.

Therefore, the waveform of the input current can be controlled by switching appropriately transistors T_1 and T_2 in a similar way as shown in Fig. 8.18A for the single-phase boost converter. Fig. 8.31 shows a block diagram of the control system for the voltage-doubler rectifier, which is very similar to the control scheme of the boost rectifier. This topology can present an unbalance in the capacitor voltages V_{C1} and V_{C2}, which will affect the quality of the control. This problem is solved by adding to the actual current value i_s an offset signal proportional to the capacitor's voltage difference.

Fig. 8.32 shows the waveform of the input current. The ripple amplitude of this current can be reduced by decreasing the hysteresis width of the controller.

8.3.5 The PWM Rectifier in Bridge Connection

Fig. 8.33A shows the power circuit of the fully controlled single-phase PWM rectifier in bridge connection, which uses four transistors with antiparallel diodes to produce a controlled dc voltage v_o. Using a bipolar PWM switching strategy, this converter may have two conduction states: (i) transistors T_1 and T_4 in the on-state and T_2 and T_3 in the off-state and (ii) transistors T_2 and T_3 in the on-state and T_1 and T_4 in the off-state.

In this topology, the output voltage v_o must be higher than the peak value of the ac source voltage v_s, to ensure a proper control of the input current.

Fig. 8.33B shows the equivalent circuit with transistors T_1 and T_4 on. In this case, the inductor voltage is given by

$$v_L = L\frac{di_s}{dt} = v_s(t) - V_0 < 0 \tag{8.30}$$

Therefore, in this condition, a reduction of the inductor current i_s is produced.

Fig. 8.33C shows the equivalent circuit with transistors T_2 and T_3 on. Here, the inductor voltage has the following expression:

$$v_L = L\frac{di_s}{dt} = v_s(t) + V_0 > 0 \tag{8.31}$$

which means an increase in the instantaneous value of the input current i_s.

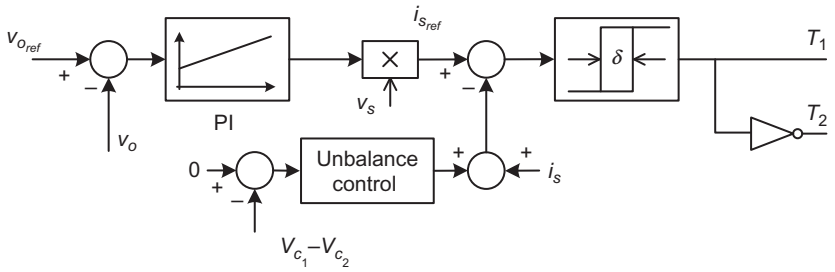

FIG. 8.31 Control system of the voltage-doubler rectifier.

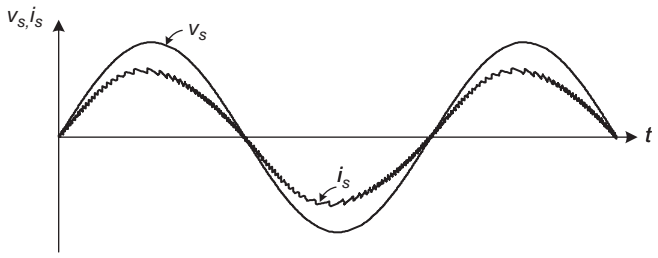

FIG. 8.32 Waveform of the input current in the voltage-doubler rectifier.

Finally, Fig. 8.33D shows the equivalent circuit with transistors T_1 and T_3 or T_2 and T_4 are in the on-state. In this case, the input voltage source is short-circuited through inductor L, which yields

$$v_L = L\frac{di_s}{dt} = v_s(t) + V_0 > 0 \tag{8.32}$$

Eq. (8.32) implies that the current value will depend on the sign of v_s.

The waveform of the input current i_s can be controlled by appropriately switching transistors T_1–T_4 or T_2–T_3, originating a similar shape to the one shown in Fig. 8.18A for the single-phase boost rectifier.

The control strategy for the rectifier is similar to the one illustrated in Fig. 8.31, for the voltage-doubler topology. The quality of the input current obtained with this rectifier is the same as presented in Fig. 8.32 for the voltage-doubler configuration.

The input current waveform can be slightly improved if the state of Fig. 8.33D is used. This can be done by replacing the hysteresis current control with a more complex linear control plus a three-level PWM modulator. This method reduces the semiconductor switching frequency and provides a more defined current spectrum.

Finally, it must be said that one of the most attractive characteristics of the fully controlled PWM converter in bridge connection and the voltage doubler is their regeneration capability. In effect, these rectifiers can deliver power from the load to the single-phase supply, operating with sinusoidal current and a high power factor of PF > 0.99. Fig. 8.33E shows that during regeneration, the input current i_s is 180 degrees out of phase with respect to the supply voltage v_s, which means operation with power factor PF ≈ −1 (PF is approximately 1 because of the small harmonic content in the input current).

8.3.6 Applications of Unity Power Factor Rectifiers

8.3.6.1 Boost Rectifier Applications

The single-phase boost rectifier has become the most popular topology for power factor correction (PFC) in general-purpose power supplies. To reduce the costs, the complete control system shown in Fig. 8.19 and the gate drive circuit of the power transistor have been included in a single integrated circuit (IC), like the UC3854 [16] or MC33262, shown in Fig. 8.34.

Today, there is increased interest in developing high-frequency electronic ballasts to replace the classical electromagnetic ballast present in fluorescent lamps. These electronic ballasts require an ac-dc converter. To satisfy the harmonic current injection from electronic equipment and to maintain a high power quality, a high-power-factor rectifier can be used, as shown in Fig. 8.35 [17].

8.3.6.2 Voltage Doubler PWM Rectifier

The development of low-cost compact motor drive systems is a very relevant topic, particularly in the low-power range. Fig. 8.36 shows a low-cost converter for low-power induction motor drives. In this configuration, a three-phase induction motor is fed through the converter from a single-phase power supply. Transistors T_1 and T_2 and capacitors C_1 and C_2 constitute the voltage-doubler single-phase rectifier, which controls the dc link voltage and generates sinusoidal input current, working with close-to-unity power factor [18]. On the other hand, transistors T_3, T_4, T_5, and T_6 and capacitors C_1 and C_2 constitute the power circuit of an asymmetrical inverter that supplies the motor. An important characteristic of the power circuit shown in Fig. 8.36 is the capability of regenerating power to the single-phase mains.

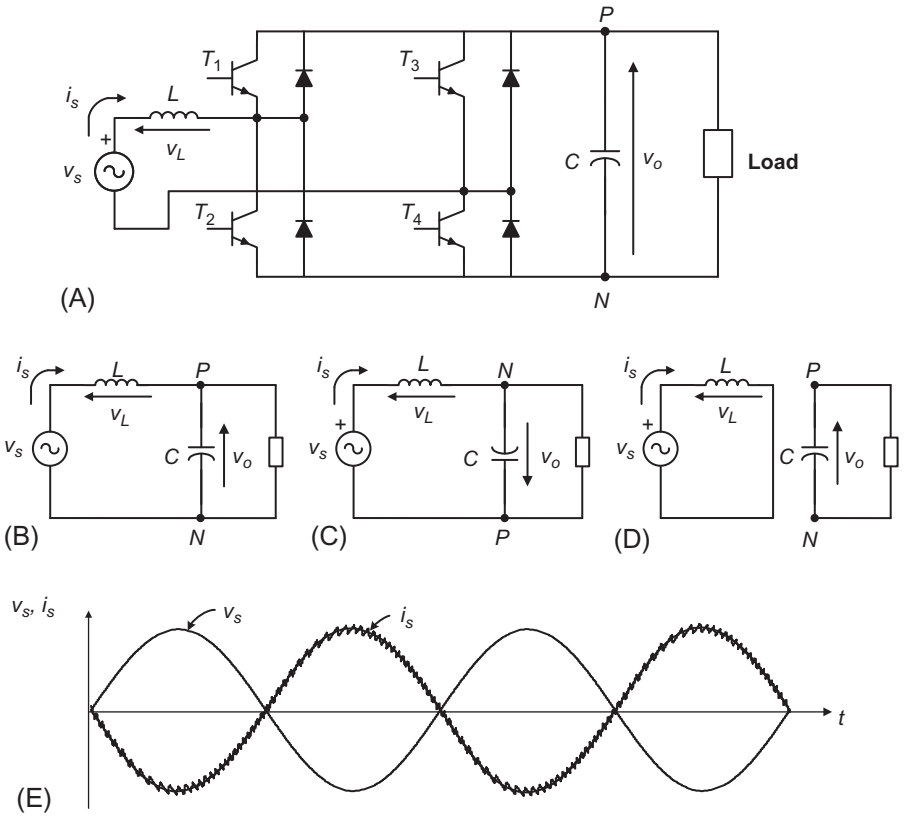

FIG. 8.33 Single-phase PWM rectifier in bridge connection: (A) power circuit, (B) equivalent circuit with T_1 and T_4 on, (C) equivalent circuit with T_2 and T_3 on, (D) equivalent circuit with T_1 and T_3 or T_2 and T_4 on, and (E) waveform of the input current during regeneration.

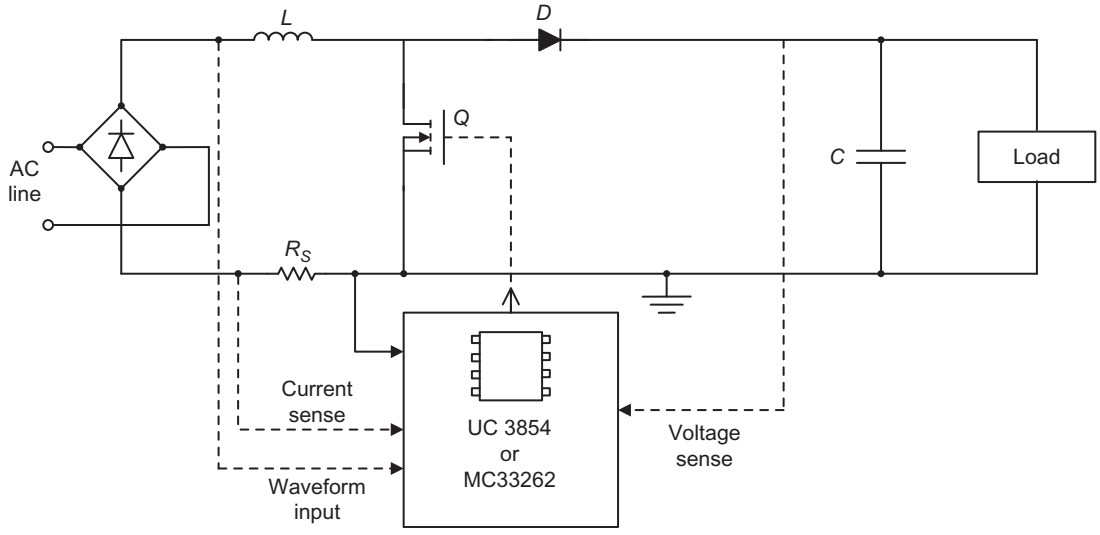

FIG. 8.34 Simplified circuit of a power factor corrector with control integrated circuit.

8.3.6.3 PWM Rectifier in Bridge Connection

Distortion of the input current in the line-commutated rectifiers with capacitive filtering is particularly critical in the UPS fed from motor-generator sets. In effect, due to the higher value of the generator impedance, the current distortion can originate an unacceptable distortion on the ac voltage, which affects the behavior of the whole system. For this reason, it is very attractive to use rectifiers with low distortion in the input current.

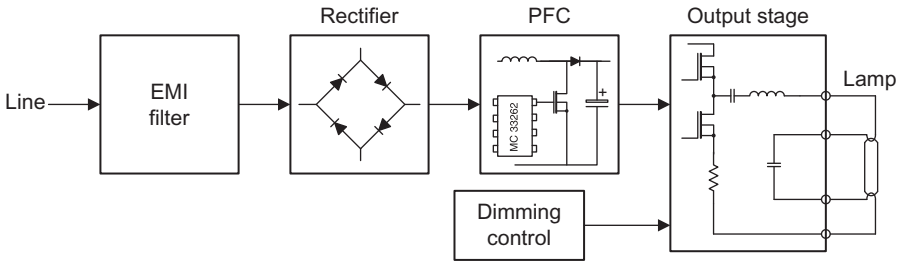

FIG. 8.35 Functional block diagram of electronic ballast with power factor correction.

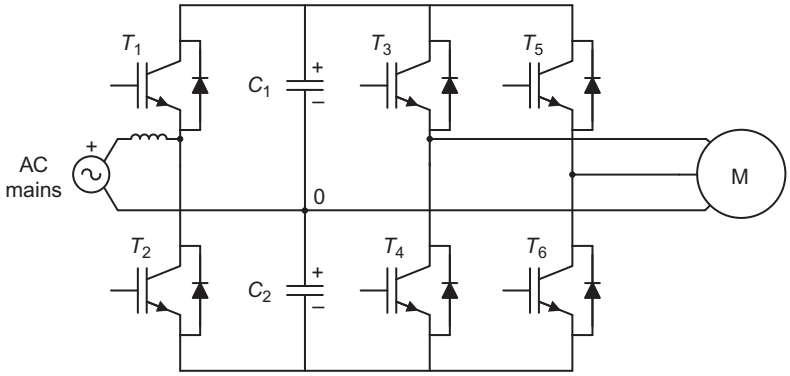

FIG. 8.36 Low-cost induction motor drive.

Fig. 8.37 shows the power circuit of a single-phase UPS, which has a PWM rectifier in bridge connection at the input side. This rectifier generates a sinusoidal input current and controls the charge of the battery [19].

Perhaps the most typical and widely accepted area of application of high-power-factor single-phase rectifiers is in locomotive drives [20]. An essential prerequisite for proper operation of voltage-source three-phase inverter drives in modern locomotives is the use of four-quadrant line-side converters, which ensure motoring and braking of the drive, with reduced harmonics in the input current. Fig. 8.38 shows a simplified power circuit of a typical drive for a locomotive connected to a single-phase power supply [20], which includes a high-power-factor rectifier at the input.

Finally, Fig. 8.39 shows the main circuit diagram of the 300 series Shinkansen train [21]. In this application, ac power from the overhead catenary is transmitted through a transformer to single-phase PWM rectifiers, which provide the dc voltage for the inverters. The rectifiers are capable of controlling the input ac current in an approximate sine waveform and in phase with the voltage, achieving power factor close to unity on powering and on regenerative braking. Regenerative braking produces energy savings and an important operational flexibility.

8.3.7 Synchronous Rectifier

The synchronous rectifier (SR) also known as active rectifier is able to reduce the losses, which lead to improvement in efficiency. The conduction loss contributes a significant role in the overall power loss of diode rectifier, especially in low-output-voltage applications. In the diode rectifier, conduction loss of diode

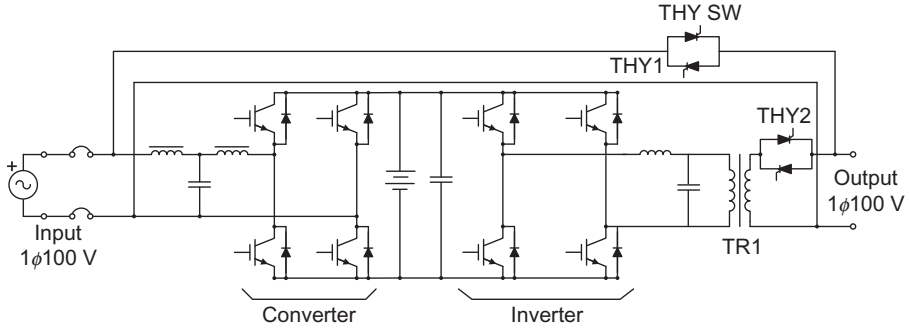

FIG. 8.37 Single-phase UPS with PWM rectifier.

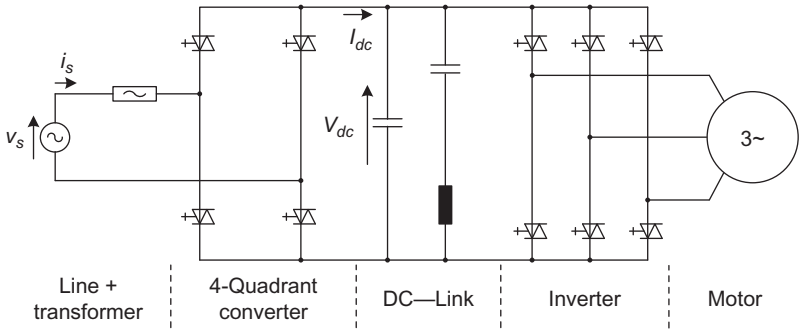

FIG. 8.38 Typical power circuit of an ac drive for locomotive.

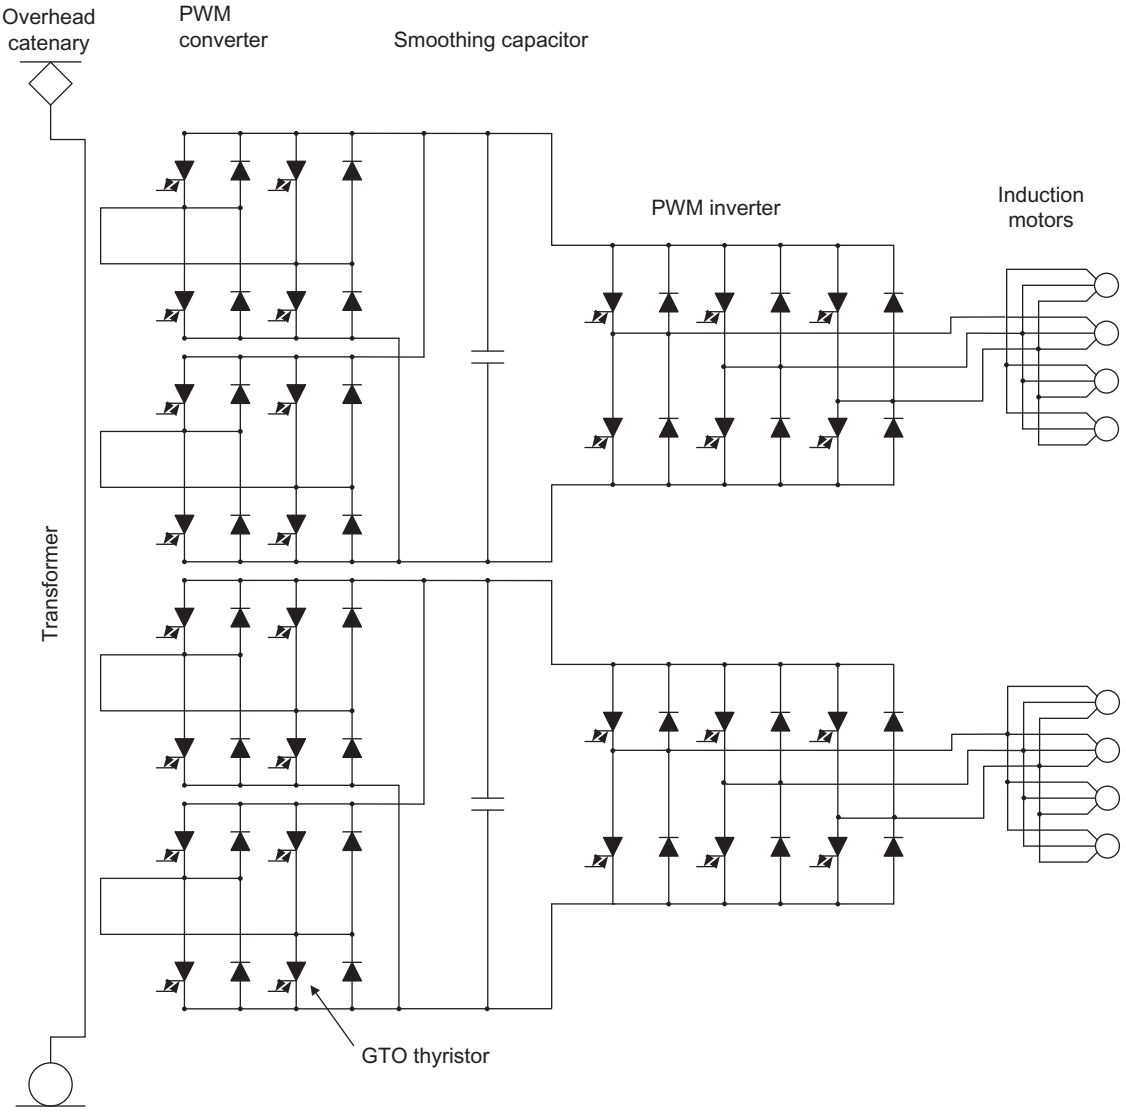

FIG. 8.39 Main circuit diagram of 300 series Shinkansen locomotives.

depends on the forward voltage drop, diode resistance, and the magnitude of current that passes through the devices, while in the SR, MOSFET conduction loss depends on the on resistance ($R_{DS,on}$) of the MOSFET and the current that passes through the devices. Moreover, driving loss is also a part of conduction losses in MOSFET, but it has a very less significant role as compared with total power loss. Therefore, the SR has been widely adopted in low-output-voltage applications with reducing the conduction loss of the output rectifier to improve the efficiency.

The advantages of using SR in high-performance, high-power converters include better efficiency, lower power dissipation, better thermal performance, and inherently optimal current sharing when synchronous MOSFETs are paralleled. The number of MOSFETs can be paralleled to handle higher output currents and results in less equivalent effective $R_{DS,on}$. Moreover, $R_{DS,on}$ has a positive temperature coefficient so the MOSFETs will automatically tend to share current equally, facilitating optimal thermal distribution among the SR devices. This improves the ability to remove heat from the components and the PCB, directly improving the thermal performance of the design. Other potential benefits from SR include smaller form factors, higher ambient operating temperatures, and higher power densities. As discussed above, the downside to SRs is that they require control circuitry to ensure the devices turn on or off synchronously, that is, at the right time. Circuitry required for the control of the SR normally includes voltage and current detectors and drive circuitry for the active devices.

8.3.7.1 Operating Principle

Fig. 8.40 shows the circuit diagram of SR that consists an inductor and four transistors with their body diodes. The transistor used in the circuit must be the MOSFET that can conduct in both the direction. The operating principle of SR is based on the modes of technique to generate the gate signal. The current-driven SR has been used to generate the gate signal for the devices as this method is suitable for all types of topologies and offered number of advantages over voltage-driven method. The current-driven method senses the current flowing through the SR to turn on and turn off the SR properly. The current sensor is used to sense the input current that must flow through the devices. However, for positive half cycle of supply voltage, the current will flow (source to rectifier direction) through the MOSFETs S_1 and S_2, and for negative cycle of supply voltage, current will flow (rectifier to source direction) through MOSFETs S_3 and S_4.

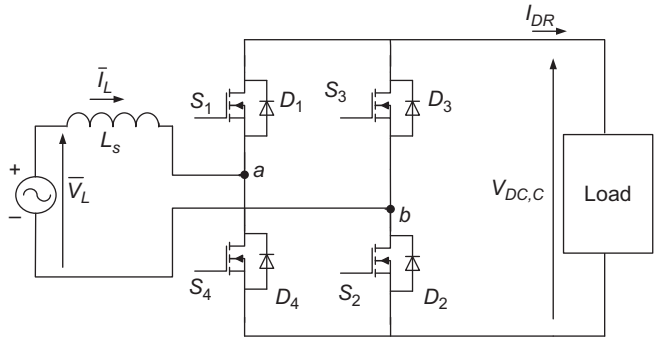

FIG. 8.40 Schematic of synchronous rectifier.

The waveforms of gate signal and dead time are shown in Fig. 8.41. At the beginning of the sinusoidal cycle, the current starts flowing in the body diode, generating a negative V_{DS} across the MOSFET; at that point, turn-on signal is provided to the MOSFET. The dropout voltage across the device falls to much lower voltage, and MOSFET turned on as soft switching that helps to reduce the power losses and results in increasing the system efficiency. Once the MOSFET is on, it must remain in this position until the rectified current will decrease to almost zero; closer is better for the losses point of view. Therefore, a zero-crossing comparator can be used to understand when the drain-source voltage reaches the zero-voltage condition. For this purposes, the value of threshold voltage to turn off the devices must be negative and close to zero, to avoid cross conduction and reduce the body-diode conduction interval at the tail of the semisinusoid.

Let us assume that there are two situations that occur: (a) Current has a spike, and (b) current has multiple zero crossing as shown in Figs. 8.42 and 8.43, respectively. When current has a spike, sensor detects zero current, and MOSFETs S_1 and S_2 are turned off, and negative current flows through the body diodes. Again, current crosses the zero crossing and becomes positive, and body diodes D_1 and D_2 start conducting for the dead-time C as shown in Fig. 8.43. After the dead-time C, again MOSFETs. Moreover, in the case of multiple zero crossing, when the current passes from positive to negative (i.e., at point z_1), sensor detects zero current, and MOSFETs S_1 and S_2 are

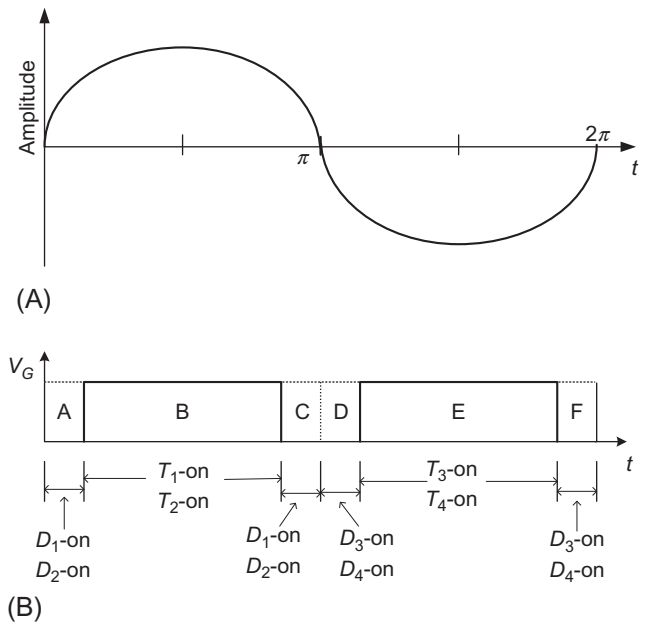

FIG. 8.41 Schematic diagram of (A) current signal and (B) turn-on and turn-off period [22].

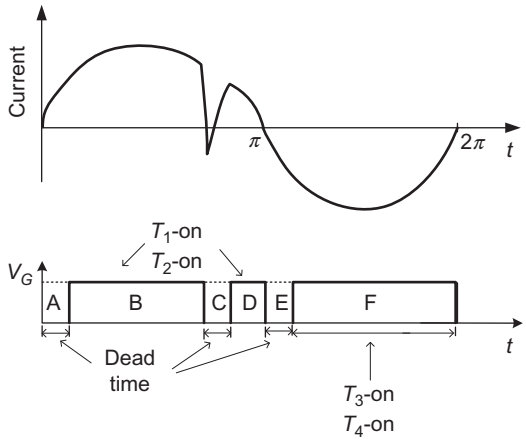

FIG. 8.42 Waveform of current spike.

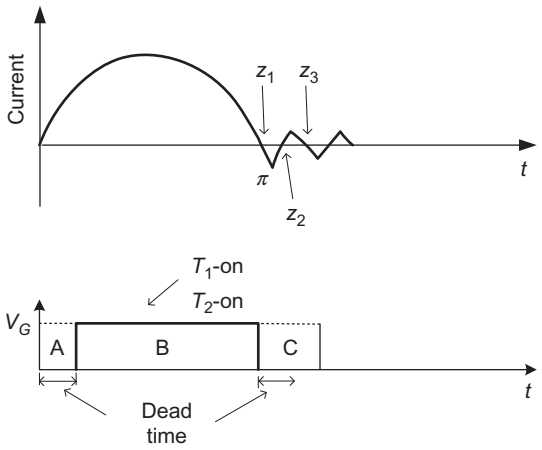

FIG. 8.43 Waveform of current with multiple zero crossing.

turned off. The negative current flows through the body diodes D_3 and D_4, and again, current changes the direction, crosses the zero crossing (i.e., at point z_2), and becomes positive. Then, body diodes D_1 and D_2 start conducting, and again, current changes the direction, crosses the zero crossing (i. e. at point z_3), becomes negative, and flows through the body diodes D_3 and D_4, and process will have continued. In multiple zero crossing, the conduction period of body diodes either D_1 and D_2 or D_3 and D_4 is larger than dead time; then, respective MOSFETs (for instance, for diodes D_1 and D_2, MOSFETs S_1 and S_2 will conduct) will turn on, and they will conduct till the next zero crossing.

8.3.8 Controlled Rectifier Using Single Phase Matrix Converter (SPMC)—Boost Rectifier Operation

The commutation problem is the use of inductive loads where the commutation occurs during the pair of switches turn "off" making the energy in the inductor, being converted into switching spikes. Theoretically, the switching in the SPMC must be instantaneous and simultaneous; unfortunately, it is impossible for realization in practical systems due to turn-on/turn-off IGBT characteristics; to solve these difficulties, safe commutation strategy was developed in Ref. [18] to suppress the spikes induced by manipulation of the switch according to the switching pattern as in Fig. 2.

The controlled rectifier using SPMC for boost operation is shown in Fig. 8.44. A boost inductor L is connected at the ac side to reduce electromagnetic interference. The circuit in Fig. 8.44 operates in two modes; in the mode 1, S1a and S3a are switched "on" at $t=0$. And the input current flows through inductor L. At $t=1$, switches S1a and S4a are switched "on" at $t=1$, while S3a is switched "off." Current would reverse and now flow through the load. The inductor current falls until switch S3a is turned "on" again in the next cycle. The energy stored in inductor L is then transferred to the load. The switching waveform is shown in the Fig. 8.45.

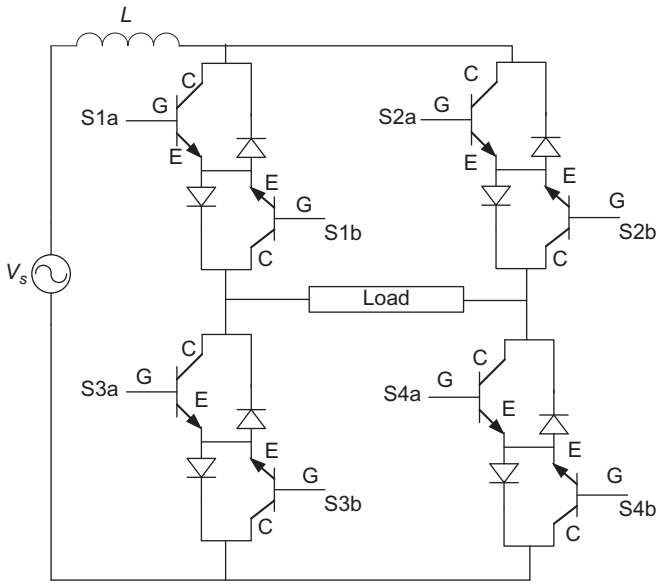

FIG. 8.44 Controlled rectifier using SPMC topology for boost rectifier operation [23].

9.1 Introduction

Three-phase controlled rectifiers have a wide range of applications, from small rectifiers to large high-voltage direct-current (HVDC) transmission systems. They are used for electrochemical processes, many kinds of motor drives, traction equipment, controlled power supplies, and many other applications. From the point of view of the commutation process, they can be classified into two important categories: *line-commutated controlled rectifiers (thyristor rectifiers) and force-commutated pulse-width modulated (PWM) rectifiers.*

9.2 Line-Commutated Controlled Rectifiers

9.2.1 Three-Phase Half-Wave Rectifier

Fig. 9.1 shows the three-phase half-wave rectifier topology. To control the load voltage, the half-wave rectifier uses three common cathode thyristor arrangements. In this figure, the power supply and the transformer are assumed ideal. The thyristor will conduct (*ON* state), when the anode-to-cathode voltage v_{AK} is positive and a firing current pulse i_G is applied to the gate terminal. Delaying the firing pulse by an angle α controls the load voltage. As shown in Fig. 9.2, the firing angle α is measured from the crossing point between the phase supply voltages. At that point, the anode-to-cathode thyristor voltage v_{AK} begins to be positive. Fig. 9.3 shows that the possible range for gating delay is between $\alpha = 0$ and 180 degrees, but because of commutation problems in actual situations, the maximum firing angle is limited to around 160 degrees. As shown in Fig. 9.4, when the load is resistive, current i_d has the same waveform of the load voltage. As the load becomes more and more inductive, the current flattens and finally becomes constant. The thyristor goes to the nonconducting condition (*OFF* state) when the following thyristor is switched *ON* or the current tries to reach a negative value.

With the help of Fig. 9.2, the load average voltage can be evaluated and is given by

$$\begin{aligned} V_D &= \frac{V_{MAX}}{\frac{2}{3}\pi} \int_{-\pi/3+\alpha}^{\pi/3+\alpha} \cos\omega t d(\omega t) \\ &= V_{MAX} \frac{\sin\frac{\pi}{3}}{\frac{\pi}{3}} \cos\alpha \asymp 1.17 V_{f-N}^{rms} \cos\alpha \end{aligned} \tag{9.1}$$

where V_{MAX} is the secondary phase-to-neutral peak voltage, V_{f-N}^{rms} is its root-mean-square (*rms)* value, and ω is the angular frequency of the main power supply. It can be seen from Eq. (9.1) that the load average voltage V_D is modified by changing

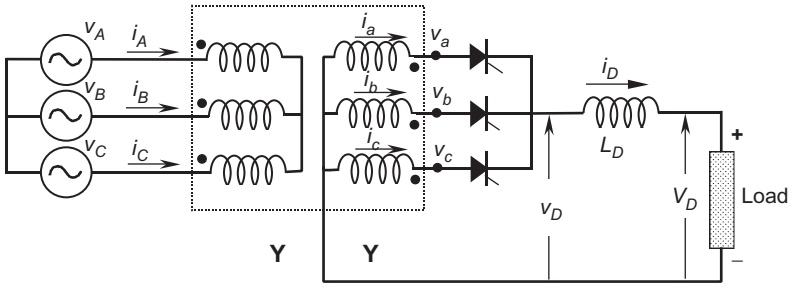

FIG. 9.1 Three-phase half-wave rectifier.

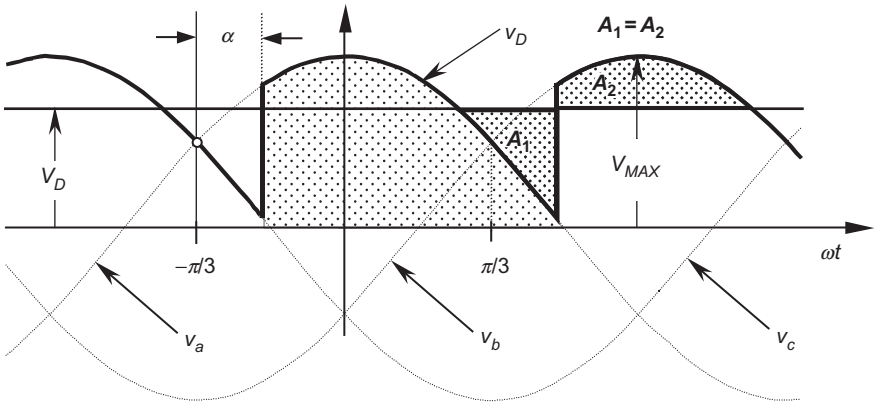

FIG. 9.2 Instantaneous *dc* voltage v_D, average *dc* voltage V_D, and firing angle α.

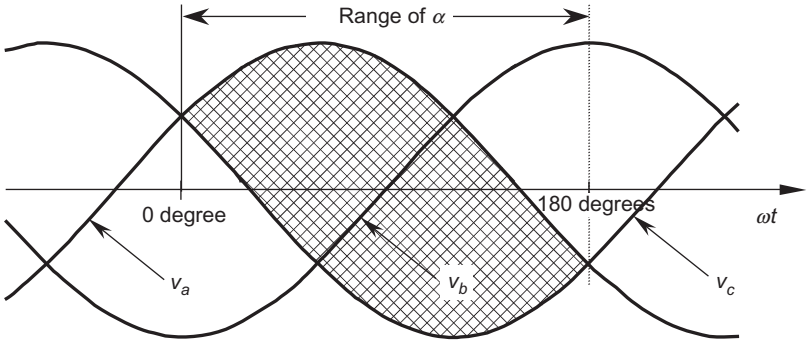

FIG. 9.3 Possible range for gating delay in angle α.

firing angle α. When $\alpha < 90$ degrees, V_D is positive, and when $\alpha > 90$ degrees, the average *dc* voltage becomes negative. In such a case, the rectifier begins to work as an inverter, and the load needs to be able to generate power reversal by reversing its *dc* voltage.

The *ac* currents of the half-wave rectifier are shown in Fig. 9.5. This drawing assumes that the *dc* current is constant (very large L_D). Disregarding commutation overlap, each valve conducts during 120 degrees per period. The secondary currents (and thyristor currents) present a *dc* component that is undesirable and makes this rectifier not useful for high-power applications. The primary currents show the same waveform but with the *dc* component removed. This very distorted waveform requires an input filter to reduce harmonic contamination.

The current waveforms shown in Fig. 9.5 are useful for designing the power transformer. Starting from

$$\begin{aligned} VA_{prim} &= 3V^{rms}_{(prim)f-N} I^{rms}_{prim} \\ VA_{sec} &= 3V^{rms}_{(sec)f-N} I^{rms}_{sec} \\ P_D &= V_D I_D \end{aligned} \tag{9.2}$$

where VA_{prim} and VA_{sec} are the ratings of the transformer for the primary and secondary side, respectively. Here, P_D is

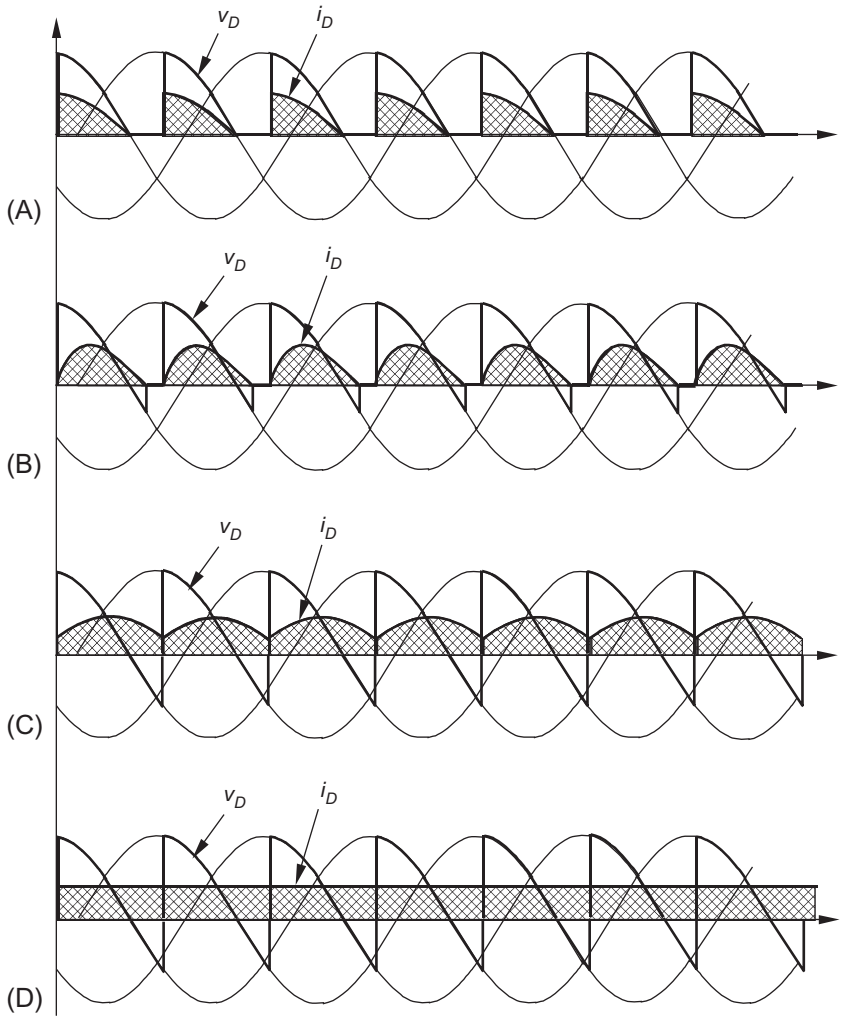

FIG. 9.4 *DC* current waveforms. (A) $R>0$, $L_D=0$, (B) $R>0$, $L_D>0$, (C) $R>0$, L_D large, and (D) R small, L_D very large.

the power transferred to the *dc* side. The maximum power transfer is with $\alpha=0$ degree (or $\alpha=180$ degrees). Then, to establish a relation between *ac* and *dc* voltages, Eq. (9.1) for $\alpha=0$ degree is required:

$$V_D = 1.17V^{rms}_{(sec)f-N} \tag{9.3}$$

and

$$V_D = 1.17aV^{rms}_{(prim)f-N} \tag{9.4}$$

where a is the secondary to primary turn relation of the transformer. On the other hand, a relation between the currents is also possible to obtain. With the help of Fig. 9.5,

$$I^{rms}_{sec} = \frac{I_D}{\sqrt{3}} \tag{9.5}$$

$$I^{rms}_{prim} = a\frac{I_D\sqrt{2}}{3} \tag{9.6}$$

Combining Eqs. (9.2)–(9.6), it yields

$$\begin{aligned} VA_{prim} &= 1.21P_D \\ VA_{sec} &= 1.48P_D \end{aligned} \tag{9.7}$$

Eq. (9.7) shows that the power transformer has to be oversized 21% at the primary side and 48% at the secondary side. Then, a special transformer has to be built for this rectifier. In terms of average *VA*, the transformer needs to be 35% larger than the rating of the *dc* load. The larger rating of the secondary with respect to primary is because the secondary carries a *dc* component inside the windings. Furthermore, the transformer is oversized because the circulation of current harmonics does not generate active power. Core saturation, due to the *dc* components inside the secondary windings, also needs to be taken in account for iron oversizing.

9.2.2 Six-Pulse or Double Star Rectifier

The thyristor side windings of the transformer shown in Fig. 9.6 form a six-phase system, resulting in a six-pulse starpoint (midpoint connection). Disregarding commutation overlap, each

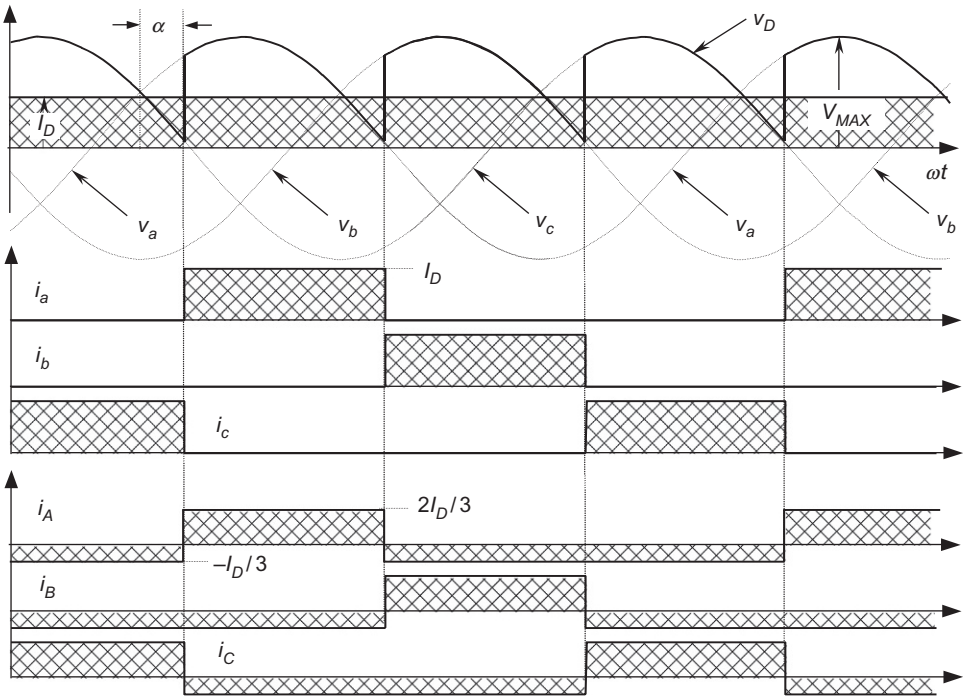

FIG. 9.5 *AC* current waveforms for the half-wave rectifier.

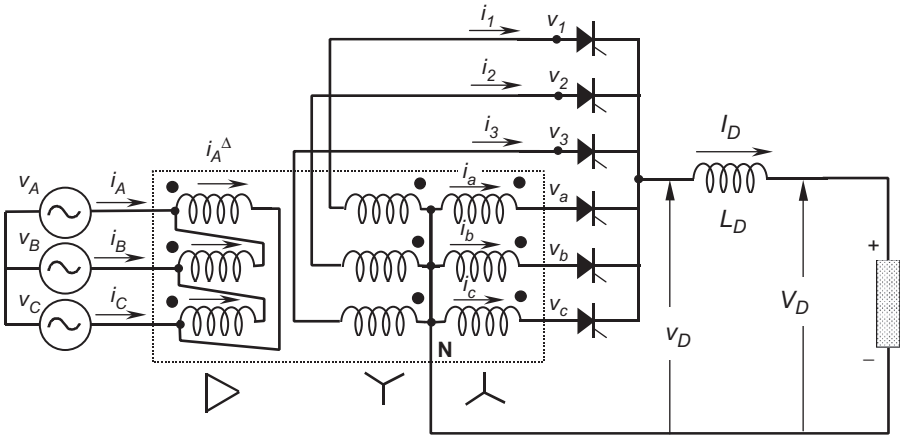

FIG. 9.6 Six-pulse rectifier.

valve conducts only during 60 degrees per period. The direct voltage is higher than that from the half-wave rectifier, and its average value is given by

$$V_D = \frac{V_{MAX}}{\frac{\pi}{3}} \int_{-\pi/6+\alpha}^{\pi/6+\alpha} \cos \omega t d(\omega t) = V_{MAX} \frac{\sin \frac{\pi}{6}}{\frac{\pi}{6}} \cos \alpha \approx 1.35 V_{f-N}^{rms} \cos \alpha \tag{9.8}$$

The *dc* voltage ripple is also smaller than the one generated by the half-wave rectifier, due to the absence of the third harmonic with its inherently high amplitude. The smoothing reactor L_D is also considerably smaller than the one needed for a three-pulse (half-wave) rectifier.

The *ac* currents of the six-pulse rectifier are shown in Fig. 9.7. The currents in the secondary windings present a *dc* component, but the magnetic flux is compensated by the double star. As can be observed, only one valve is fired at a time, and then this connection in no way corresponds to a parallel connection. The currents inside the delta show a symmetrical waveform with 60 degrees conduction. Finally, due to the particular transformer connection shown in Fig. 9.6, the source currents also show a symmetrical waveform but with 120 degrees conduction.

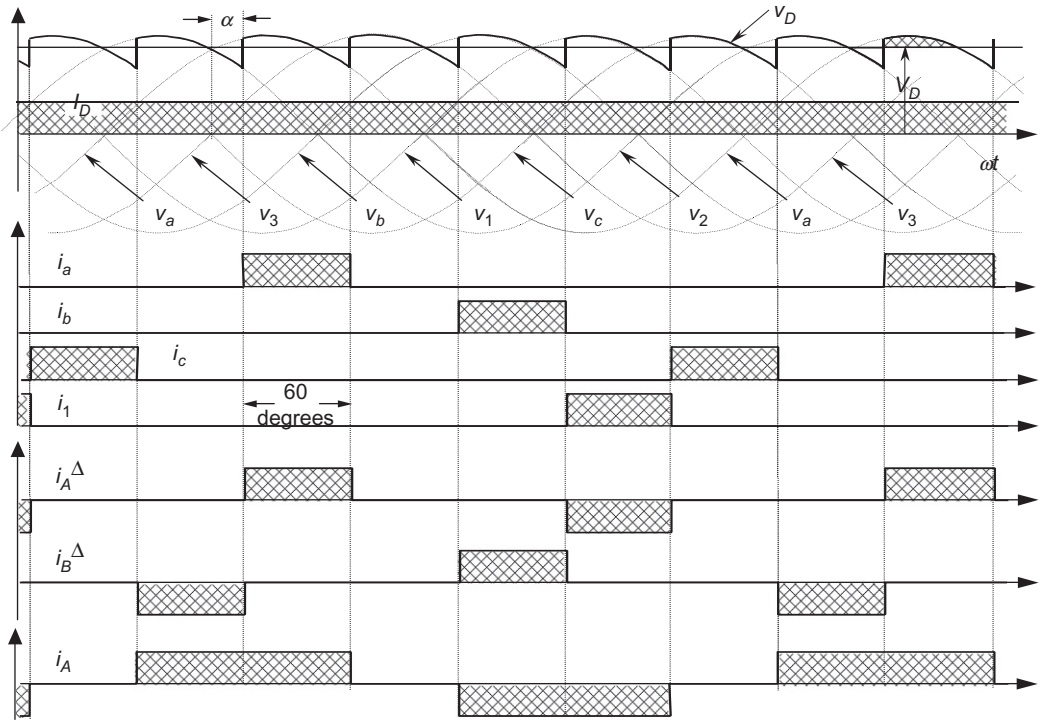

FIG. 9.7 *AC* current waveforms for the six-pulse rectifier.

Evaluation of the rating of the transformer is done in similar fashion to the way the half-wave rectifier is evaluated:

$$VA_{prim} = 1.28P_D$$
$$VA_{sec} = 1.81P_D \tag{9.9}$$

Thus, the transformer must be oversized 28% at the primary side and 81% at the secondary side. In terms of size, it has an average apparent power of 1.55 times the power P_D (55% oversized). Because of the short conducting period of the valves, the transformer is not particularly well utilized.

9.2.3 Double Star Rectifier With Interphase Connection

This topology works as two half-wave rectifiers in parallel and is very useful when high *dc* current is required. An optimal way to reach both good balance and elimination of harmonics is through the connection shown in Fig. 9.8. The two rectifiers are shifted by 180 degrees, and their secondary neutrals are connected through a middle-point autotransformer called "interphase transformer." The interphase transformer is connected between the two secondary neutrals and the middle

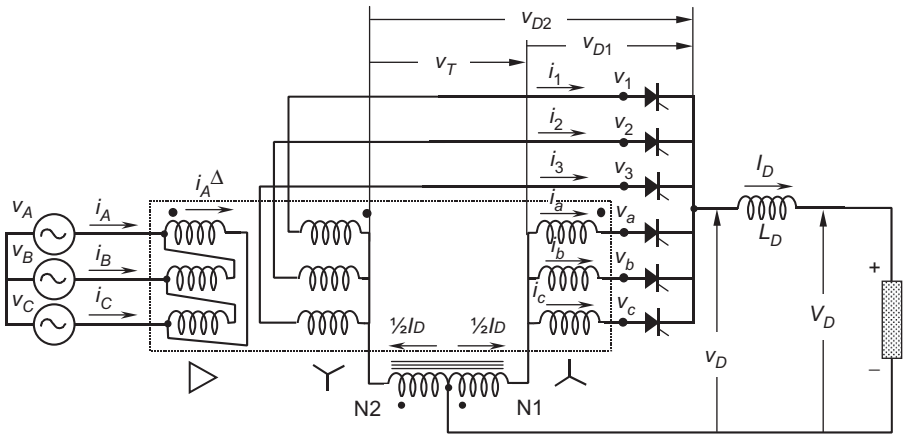

FIG. 9.8 Double-star rectifier with interphase transformer.

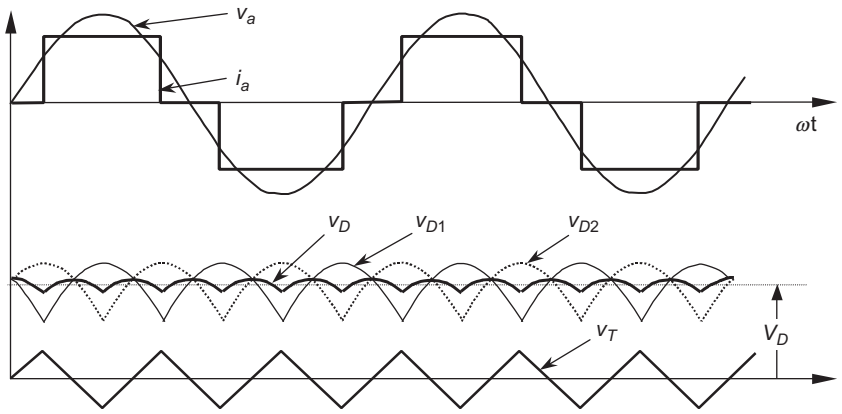

FIG. 9.9 Operation of the interphase connection for $\alpha = 0$ degree.

point at the load return. In this way, both groups operate in parallel. Half the direct current flows in each half of the interphase transformer, and then its iron core does not become saturated. The potential of each neutral can oscillate independently, generating an almost triangular voltage waveform (v_T) in the interphase transformer, as shown in Fig. 9.9. As this converter works like two half-wave rectifiers connected in parallel, the load average voltage is the same as in Eq. (9.1):

$$V_D \approx 1.17 V_{f-N}^{rms} \cos\alpha \tag{9.10}$$

where V_{f-N}^{rms} is the phase-to-neutral *rms* voltage at the valve side of the transformer (secondary).

Fig. 9.9 also shows the two half-wave rectifier voltages, related to their respective neutrals. Voltage v_{D1} represents the potential between the common cathode connection and the neutral N1. The voltage v_{D2} is between the common cathode connection and N2. It can be seen that the two instantaneous voltages are shifted, which gives as a result, a voltage v_D that is smoother than v_{D1} and v_{D2}.

Fig. 9.10 shows how v_D, v_{D1}, v_{D2}, and v_T change when the firing angle changes from $\alpha = 0$ to 180 degrees.The transformer rating in this case is

$$\begin{aligned} VA_{prim} &= 1.05 P_D \\ VA_{sec} &= 1.48 P_D \end{aligned} \tag{9.11}$$

And the average rating power will be $1.26 P_D$, which is better than the previous rectifiers (1.35 for the half-wave rectifier and 1.55 for the six-pulse rectifier). Thus, the transformer is well utilized. Fig. 9.11 shows *ac* current waveforms for a rectifier with interphase transformer.

9.2.4 Three-Phase Full-Wave Rectifier or Graetz Bridge

Parallel connection via interphase transformers permits the implementation of rectifiers for high current applications. Series connection for high voltage is also possible, as shown in the full-wave rectifier of Fig. 9.12. With this arrangement,

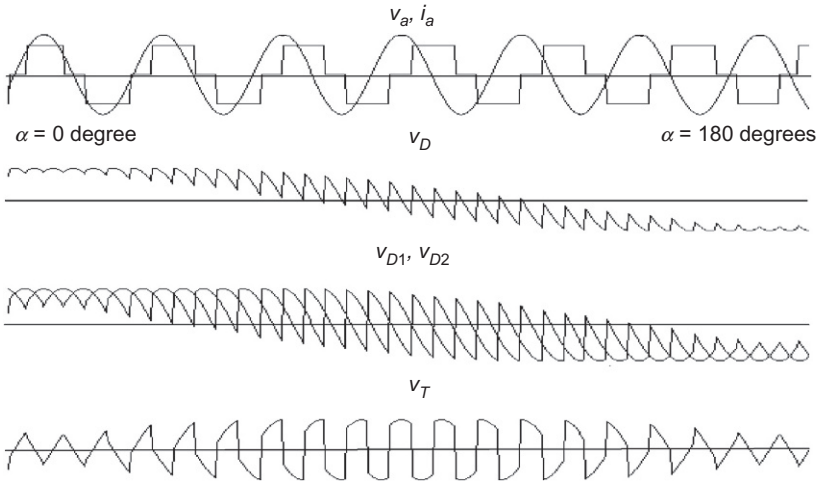

FIG. 9.10 Firing angle variation from $\alpha = 0$ to 180 degrees.

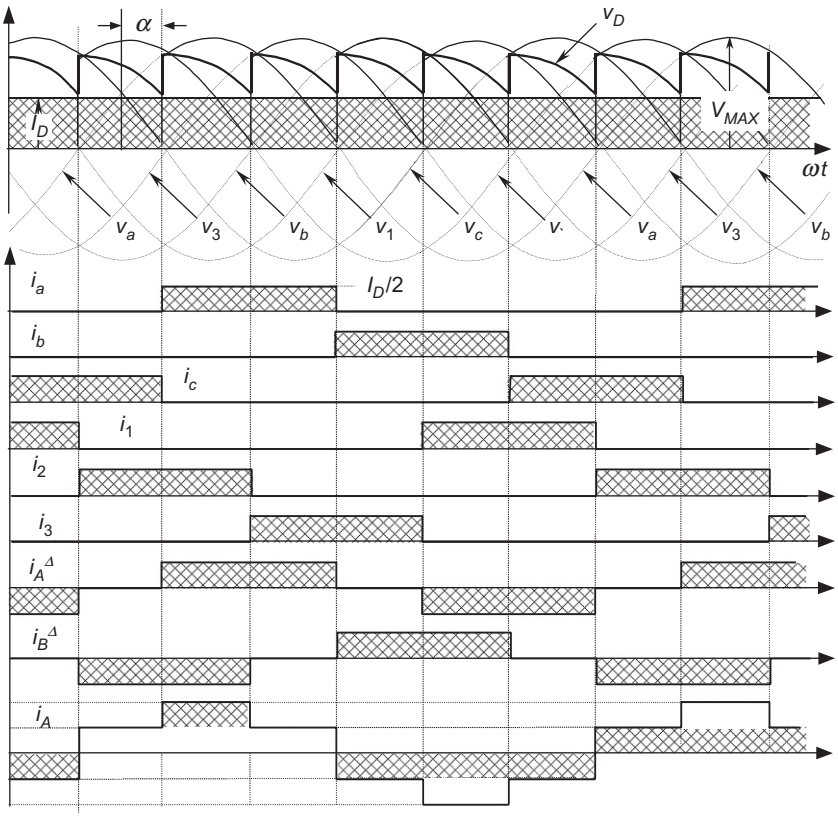

FIG. 9.11 *AC* current waveforms for the rectifier with interphase transformer.

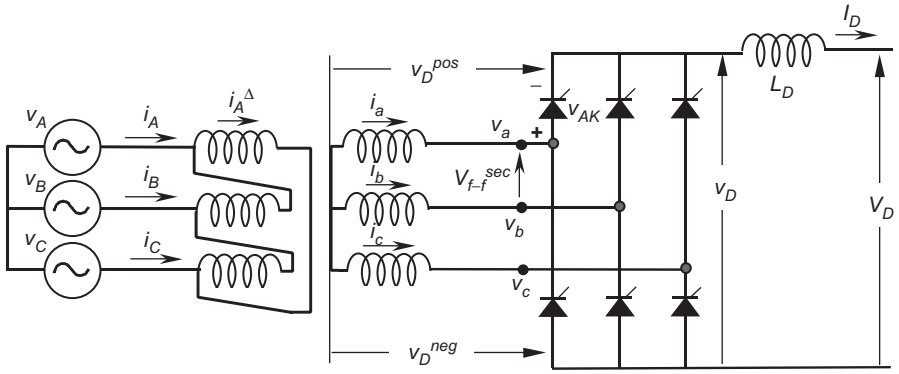

FIG. 9.12 Three-phase full-wave rectifier or Graetz bridge.

it can be seen that the three common cathode valves generate a positive voltage with respect to the neutral and the three common anode valves produce a negative voltage. The result is a *dc* voltage, twice the value of the half-wave rectifier. Each half of the bridge is a three-pulse converter group. This bridge connection is a two-way connection, and alternating currents flow in the valve-side transformer windings during both half periods, avoiding *dc* components into the windings and saturation in the transformer magnetic core. These characteristics make the so-called Graetz bridge the most widely used line-commutated thyristor rectifier. The configuration does not need any special transformer and works as a six-pulse rectifier. The series characteristic of this rectifier produces a *dc* voltage twice the value of the half-wave rectifier. The load average voltage is given by

$$V_D = \frac{2V_{MAX}}{\frac{2}{3}\pi} \int_{-\pi/3+\alpha}^{\pi/3+\alpha} \cos\omega t d(\omega t) = 2V_{MAX} \frac{\sin\frac{\pi}{3}}{\frac{\pi}{3}} \cos\alpha \approx 2.34 V_{f-N}^{rms} \cos\alpha \tag{9.12}$$

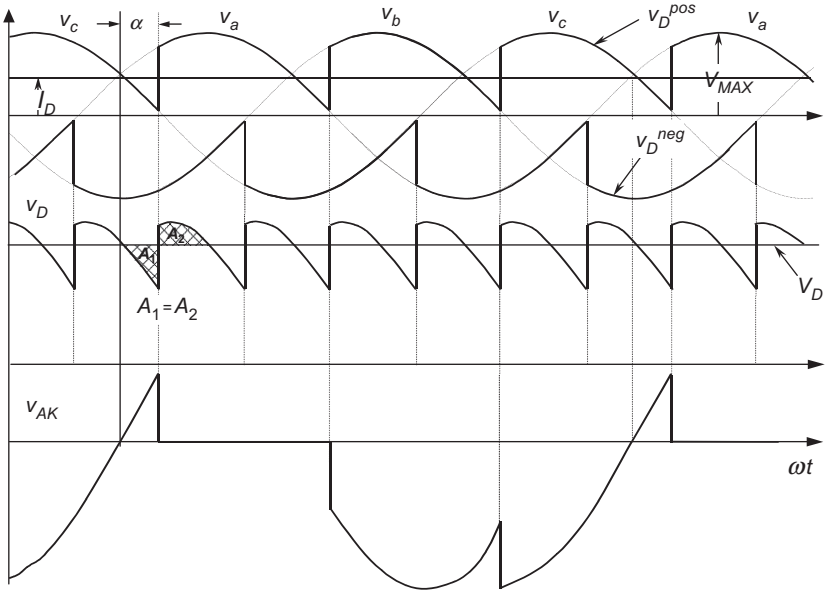

FIG. 9.13 Voltage waveforms for the Graetz bridge.

or

$$V_D = \frac{3\sqrt{2}V_{f-f}^{sec}}{\pi}\cos\alpha \approx 1.35V_{f-f}^{sec}\cos\alpha \qquad (9.13)$$

where V_{MAX} is the peak phase-to-neutral voltage at the secondary transformer terminals, V_{f-N}^{rms} its *rms* value, and V_{f-f}^{sec} the *rms* phase-to-phase secondary voltage at the valve terminals of the rectifier.

Fig. 9.13 shows the voltages of each half-wave bridge of this topology, v_D^{pos} and v_D^{neg}, the total instantaneous *dc* voltage v_D, and the anode-to-cathode voltage v_{AK} in one of the bridge thyristors. The maximum value of v_{AK} is $\sqrt{3}V_{MAX}$, which is the same as that of the half-wave converter and the interphase transformer rectifier. The double-star rectifier presents a maximum anode-to-cathode voltage of two times V_{MAX}. Fig. 9.14 shows the currents of the rectifier, which assumes that L_D is large enough to keep the *dc* current smooth. The example is for the same ΔY transformer connection shown in the topology of Fig. 9.9. It can be noted that the secondary currents do not carry any *dc* component, thereby avoiding overdesign of the windings and transformer saturation. These two figures have been drawn for a firing angle, α, of approximately 30 degrees. The perfect symmetry of the currents in all windings and lines is one of the reasons why this rectifier is the most popular of its type. The transformer rating in this case is

$$\begin{aligned} VA_{prim} &= 1.05P_D \\ VA_{sec} &= 1.05P_D \end{aligned} \qquad (9.14)$$

As can be noted, the transformer needs to be oversized only 5%, and both primary and secondary windings have the same rating. Again, this value can be compared with the previous rectifier transformers: $1.35P_D$ for the half-wave rectifier, $1.55P_D$ for the six-pulse rectifier, and $1.26P_D$ for the interphase transformer rectifier. The Graetz bridge makes excellent use of the power transformer.

9.2.5 Half Controlled Bridge Converter

The fully controlled three-phase bridge converter shown in Fig. 9.12 has six thyristors. As already explained here, this circuit operates as a rectifier when each thyristor has a firing angle $\alpha < 90$ degrees and functions as an inverter for $\alpha > 90$ degrees. If inverter operation is not required, the circuit may be simplified by replacing three controlled rectifiers with power diodes, as in Fig. 9.15A. This simplification is economically attractive because diodes are considerably less expensive than thyristors and they do not require firing angle control electronics.

The half-controlled bridge, or "semiconverter," is analyzed by considering it as a phase-controlled half-wave circuit in series with an uncontrolled half-wave rectifier. The average *dc* voltage is given by the following equation:

$$V_D = \frac{3\sqrt{2}V_{f-f}^{sec}}{2\pi}(1+\cos\alpha) \qquad (9.15)$$

Then, the average voltage V_D never reaches negative values. The output voltage waveforms of half-controlled bridge are similar to those of a fully controlled bridge with a freewheeling diode. The advantage of the freewheeling diode connection, shown in Fig. 9.15B, is that there is always a path for the *dc* current, independent of the status of the *ac* line and of the converter. This can be important if the load is inductive-resistive

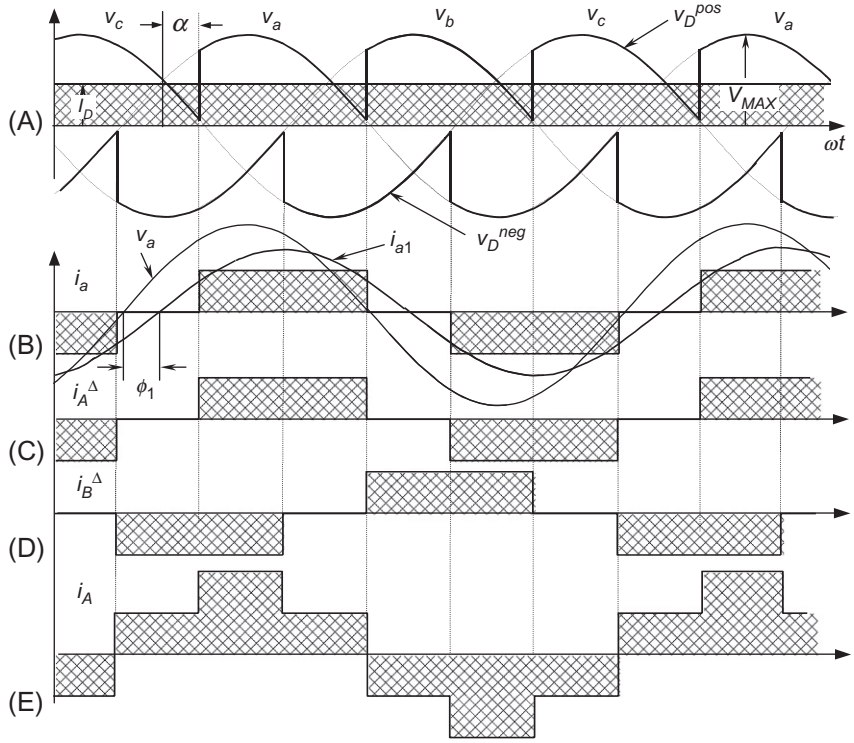

FIG. 9.14 Current waveforms for the Graetz bridge. (A) Output voltages for phases "*a*," "*b*," and "*c*"; (B) Phase "*a*" current, fundamental phase voltage, and current; (C) Phase "*b*" current; (D) Phase "*c*" current; (E) Line "*a*" current.

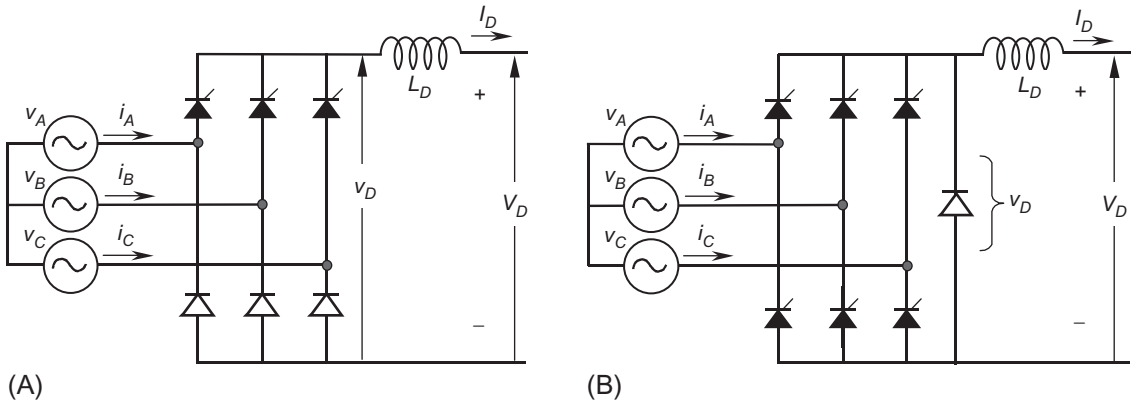

FIG. 9.15 One-quadrant bridge converter circuits: (A) half-controlled bridge and (B) freewheeling diode bridge.

with a large time constant and there is an interruption in one or more of the line phases. In such a case, the load current could commutate to the freewheeling diode.

9.2.6 Commutation

The description of the converters in the previous sections was based upon the assumption that the commutation was instantaneous. In practice, this is not possible, because the transfer of current between two consecutive valves in a commutation group takes a finite time. This time, called *overlap time*, depends on the phase-to-phase voltage between the valves participating in the commutation process and the line inductance L_S between the converter and power supply. During the overlap time, two valves conduct, and the phase-to-phase voltage drops entirely on the inductances L_S. Assuming the *dc* current I_D to be smooth and with the help of Fig. 9.16, the following relation is deduced:

$$2L_S\frac{di_{sc}}{dt} = \sqrt{2}V_{f-f}\sin\omega t = v_A - v_B \tag{9.16}$$

where i_{sc} is the current in the valve being fired during the commutation process (thyristor T2 in Fig. 9.16). This current can be evaluated, and it yields

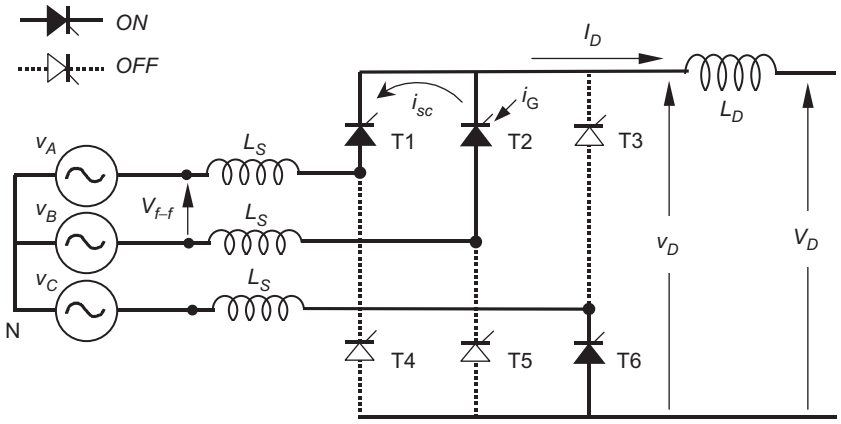

FIG. 9.16 Commutation process.

$$i_{sc} = -\frac{\sqrt{2}}{2L_S} V_{f-f} \frac{\cos \omega t}{\omega} + C \tag{9.17}$$

The constant "C" is evaluated through initial conditions at the instant when T2 is ignited. In terms of angle, when $\omega t = \alpha$,

$$\begin{aligned} &\text{when} \quad \omega t = \alpha, \quad i_{sc} = 0 \\ &\therefore C = \frac{V_{f-f}^{sec}}{\sqrt{2}\omega L_S} \cos \alpha \end{aligned} \tag{9.18}$$

Replacing Eq. (9.18) in (9.17),

$$i_{sc} = \frac{V_{f-f}}{\sqrt{2}\omega L_S} (\cos \alpha - \cos \omega t) \tag{9.19}$$

Before commutation, the current I_D was carried by thyristor T1 (see Fig. 9.16). During the commutation time, the load current I_D remains constant, i_{sc} returns through T1, and T1 is automatically switched off when the current i_{sc} reaches the value of I_D. This happens because thyristors cannot conduct in reverse direction. At this moment, the overlap time lasts, and the current I_D is then conducted by T2. In terms of angle, when $\omega t = \alpha + \mu$, $i_{sc} = I_D$, where μ is defined as the *overlap angle*. Replacing this final condition in Eq. (9.19) yields

$$I_D = \frac{V_{f-f}^{sec}}{\sqrt{2} \cdot \omega L_S} [\cos \alpha - \cos (\alpha + \mu)] \tag{9.20}$$

To avoid confusion in a real analysis, it has to be remembered that V_{f-f} corresponds to the secondary voltage in the case of transformer utilization. For this reason, the abbreviation "*sec*" has been added to the phase-to-phase voltage in Eq. (9.20).

During commutation, two valves conduct at a time, which means that there is an instantaneous short circuit between the two voltages participating in the process. As the inductances of each phase are the same, the current i_{sc} produces the same voltage drop in each L_S but with opposite sign because this current flows in reverse direction and with opposite slope in each inductance. The phase with the higher instantaneous voltage suffers a voltage drop $-\Delta v$, and the phase with the lower voltage suffers a voltage increase $+\Delta v$. This situation affects the *dc* voltage V_C, reducing its value an amount ΔV_{med}. Fig. 9.17 shows the meanings of Δv, ΔV_{med}, μ, and i_{sc}.

The area ΔV_{med} shown in Fig. 9.17 represents the loss of voltage that affects the average voltage V_C and can be evaluated through the integration of Δv during the overlap angle μ. The voltage drop Δv can be expressed as

$$\Delta v = \left(\frac{v_A - v_B}{2}\right) = \frac{\sqrt{2} V_{f-f}^{sec} \sin \omega t}{2} \tag{9.21}$$

Integrating Eq. (9.21) into the corresponding period (60 degrees) and interval (μ) and starting at the instant when the commutation begins (α),

$$\Delta V_{med} = \frac{3}{\pi} \frac{1}{2} \int_{\alpha}^{\alpha+\mu} \sqrt{2} V_{f-f}^{sec} \sin \omega t \, d\omega t \tag{9.22}$$

$$\Delta V_{med} = \frac{3}{\pi} \frac{V_{f-f}^{sec}}{\sqrt{2}} [\cos \alpha - \cos (\alpha + \mu)] \tag{9.23}$$

Subtracting ΔV_{med} in Eq. (9.13),

$$V_D = \frac{3\sqrt{2} V_{f-f}^{sec}}{\pi} \cos \alpha - \Delta V_{med} \tag{9.24}$$

$$V_D = \frac{3\sqrt{2} V_{f-f}^{sec}}{2\pi} [\cos \alpha + \cos (\alpha + \mu)] \tag{9.25}$$

or

$$V_D = \frac{3\sqrt{2} V_{f-f}^{sec}}{\pi} \left[\cos \left(\alpha + \frac{\mu}{2}\right) \cos \frac{\mu}{2}\right] \tag{9.26}$$

Eqs. (9.20), (9.25) can be written as a function of the primary winding of the transformer, if there is any transformer:

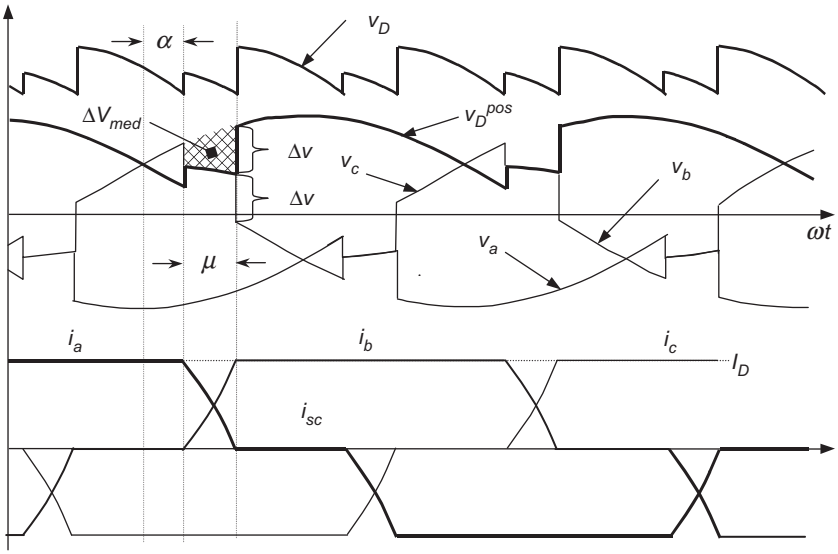

FIG. 9.17 Effect of the overlap angle on the voltages and currents.

$$I_D = \frac{aV_{f-f}^{prim}}{\sqrt{2}\omega L_S}[\cos\alpha - \cos(\alpha+\mu)] \tag{9.27}$$

$$V_D = \frac{3\sqrt{2}aV_{f-f}^{prim}}{2\pi}[\cos\alpha + \cos(\alpha+\mu)] \tag{9.28}$$

where $a = V_{f-f}^{sec}/V_{f-f}^{prim}$. With Eqs. (9.27), (9.28), one gets

$$V_D = \frac{3\sqrt{2}}{\pi}aV_{f-f}^{prim}\cos\alpha - \frac{3I_D\omega L_S}{\pi} \tag{9.29}$$

Eq. (9.29) allows a very simple equivalent circuit of the converter to be made, as shown in Fig. 9.18. It is important to note that the equivalent resistance of this circuit is not real, because it does not dissipate power.

From the equivalent circuit, regulation curves for the rectifier under different firing angles are shown in Fig. 9.19. It should be noted that these curves correspond only to an ideal situation but help in understanding the effect of voltage drop Δv on *dc* voltage. The commutation process and the overlap angle also affect the voltage v_a and anode-to-cathode thyristor voltage, as shown in Fig. 9.20.

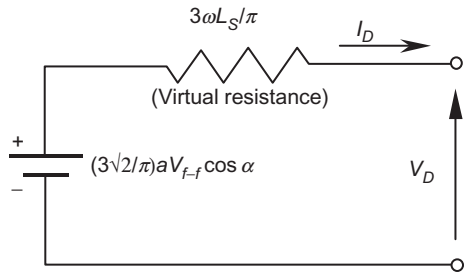

FIG. 9.18 Equivalent circuit for the converter.

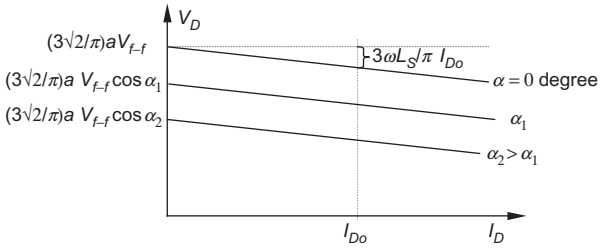

FIG. 9.19 *DC* voltage regulation curves for rectifier operation.

9.2.7 Power Factor

The displacement factor of the fundamental current, obtained from Fig. 9.14, is

$$\cos\phi_1 = \cos\alpha \tag{9.30}$$

In the case of nonsinusoidal current, the active power delivered per phase by the sinusoidal supply is

$$P = \frac{1}{T}\int_0^T v_a(t)i_a(t)dt = V_a^{rms}I_{a1}^{rms}\cos\phi_1 \tag{9.31}$$

where V_a^{rms} is the *rms* value of the voltage v_a and I_{a1}^{rms} the *rms* value of i_{a1} (fundamental component of i_a). Analog relations can be obtained for v_b and v_c.

The apparent power per phase is given by

$$S = V_a^{rms}I_a^{rms} \tag{9.32}$$

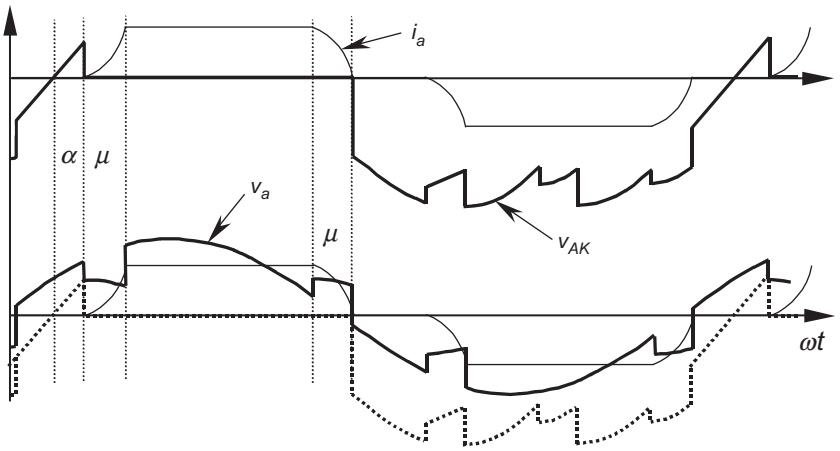

FIG. 9.20 Effect of the overlap angle on v_a and on thyristor voltage v_{AK}.

The power factor is defined by

$$PF = \frac{P}{S} \tag{9.33}$$

By substituting Eqs. (9.30)–(9.32) into Eq. (9.33), the power factor can be expressed as follows:

$$PF = \frac{I_{a1}^{rms}}{I_a^{rms}} \cos\alpha \tag{9.34}$$

This equation shows clearly that due to the nonsinusoidal waveform of the currents, the power factor of the rectifier is negatively affected by both the firing angle α and the distortion of the input current. In effect, an increase in the distortion of the current produces an increase in the value of I_a^{rms} in Eq. (9.34), which deteriorates the power factor.

9.2.8 Harmonic Distortion

The currents of the line-commutated rectifiers are far from being sinusoidal. For example, the currents generated from the Graetz rectifier (see Fig. 9.14B) have the following harmonic content:

$$i_A = \frac{2\sqrt{3}}{\pi} I_D \left(\cos\omega t - \frac{1}{5}\cos 5\omega t + \frac{1}{7}\cos 7\omega t - \frac{1}{11}\cos 11\omega t + \ldots \right) \tag{9.35}$$

Some of the characteristics of the currents, obtained from Eq. (9.35), include (i) the absence of triple harmonics, (ii) the presence of harmonics of order $6k \pm 1$ for integer values of k, (iii) those harmonics of orders $6k+1$ that are of positive sequence, (iv) those of orders $6k-1$ that are of negative sequence, (v) the *rms* magnitude of the fundamental frequency that is

$$I_1 = \frac{\sqrt{6}}{\pi} I_D \tag{9.36}$$

and (vi) the *rms* magnitude of the nth harmonic that is

$$I_n = \frac{I_1}{n} \tag{9.37}$$

If either the primary or the secondary three-phase windings of the rectifier transformer are connected in delta, the *ac* side current waveforms consist of the instantaneous differences between two rectangular secondary currents 120e apart as shown in Fig. 9.14E. The resulting Fourier series for the current in phase "a" on the primary side is

$$i_A = \frac{2\sqrt{3}}{\pi} I_D \left(\cos\omega t + \frac{1}{5}\cos 5\omega t - \frac{1}{7}\cos 7\omega t - \frac{1}{11}\cos 11\omega t + \ldots \right) \tag{9.38}$$

This series differs from that of a star-connected transformer only by the sequence of rotation of harmonic orders $6k \pm 1$ for odd values of k, that is, the 5th, 7th, 17th, and 19th.

9.2.9 Special Configurations for Harmonic Reduction

A common solution for harmonic reduction is through the connection of passive filters, which are tuned to trap a particular harmonic frequency. A typical configuration is shown in Fig. 9.21.

However, harmonics also can be eliminated using special configurations of converters. For example, 12-pulse configuration consists of 2 sets of converters connected as shown in Fig. 9.22. The resultant *ac* current is given by the sum of the two Fourier series of the star connection (Eq. 9.35) and delta connection transformers (Eq. 9.38):

$$i_A = 2\left(\frac{2\sqrt{3}}{\pi}\right) I_D\left(\cos\omega t - \frac{1}{11}\cos 11\omega t + \frac{1}{13}\cos 13\omega t - \frac{1}{23}\cos 23\omega t + \ldots\right) \tag{9.39}$$

The series only contains harmonics of order $12k \pm 1$. The harmonic currents of orders $6k \pm 1$ (with k odd), that is, 5th, 7th, 17th, and 19th, circulate between the two converter transformers but do not penetrate the *ac* network.

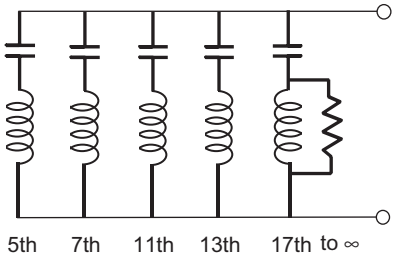

FIG. 9.21 Typical passive filter for one phase.

The resulting line current for the 12-pulse rectifier, shown in Fig. 9.23, is closer to a sinusoidal waveform than previous line currents. The instantaneous *dc* voltage is also smoother with this connection.

Higher-pulse configuration using the same principle is also possible. The 12-pulse rectifier was obtained with a 30 degrees phase shift between the two secondary transformers. The addition of further, appropriately shifted, transformers in parallel provides the basis for increasing pulse configurations. For instance, 24-pulse operation is achieved by means of 4 transformers with 15 degrees phase shift, and 48-pulse operation requires 8 transformers with 7.5 degrees phase shift (transformer connections in zigzag configuration).

Although theoretically possible, pulse numbers above 48 are rarely justified due to the practical levels of distortion found in the supply voltage waveforms. Further, the converter topology becomes more and more complicated.

An ingenious and very simple way to reach high-pulse operation is shown in Fig. 9.24. This configuration is called *dc* ripple reinjection. It consists of two parallel converters connected to the load through a multistep reactor. The reactor

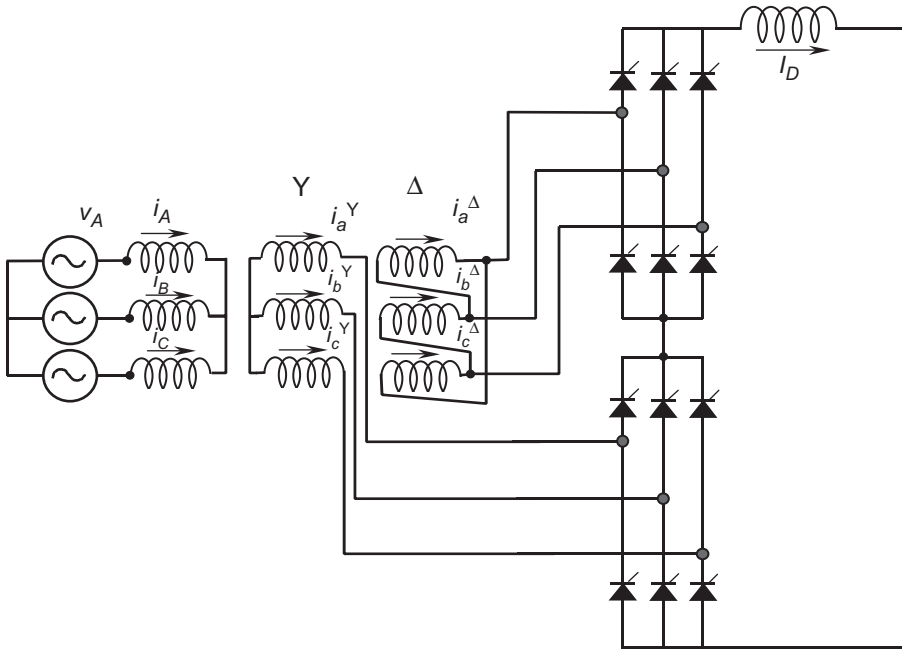

FIG. 9.22 Twelve-pulse rectifier configuration.

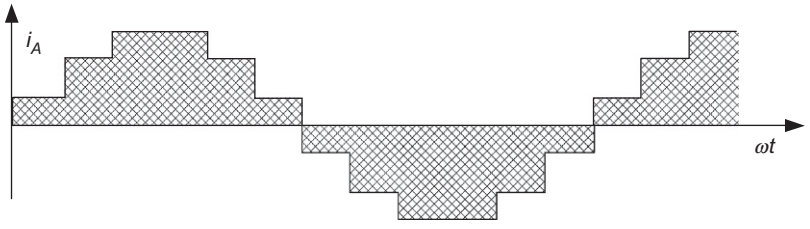

FIG. 9.23 Line current for the 12-pulse rectifier.

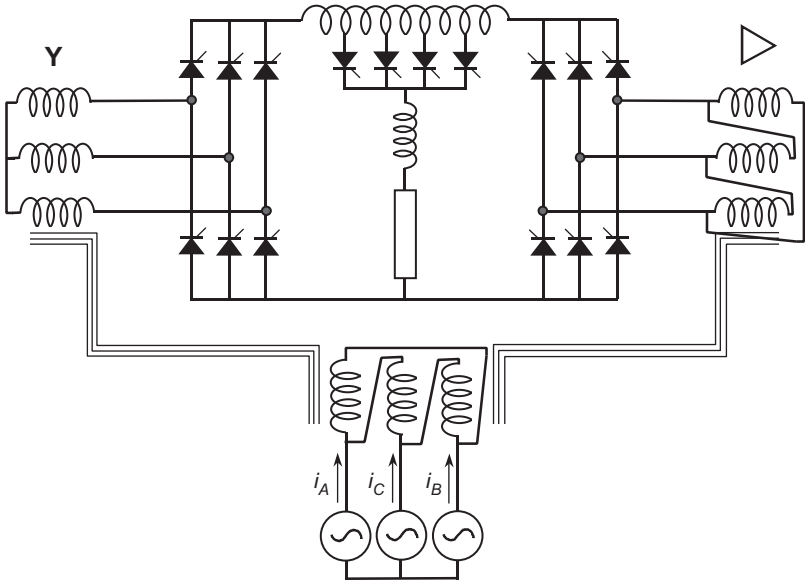

FIG. 9.24 *DC* ripple reinjection technique for 48-pulse operation.

uses a chain of thyristor-controlled taps, which are connected to symmetrical points of the reactor. By firing the thyristors located at the reactor at the right time, high-pulse operation is reached. The level of pulse operation depends on the number of thyristors connected to the reactor. They multiply the basic level of operation of the two converters. The example in Fig. 9.24 shows a 48-pulse configuration, obtained by the multiplication of basic 12-pulse operation by 4 reactor thyristors. This technique also can be applied to series-connected bridges.

Another solution for harmonic reduction is the utilization of active power filters. Active power filters are special pulse-width modulated (PWM) converters, able to generate the harmonics the converter requires. Fig. 9.25 shows a current-controlled shunt active power filter.

9.2.10 Applications of Line-Commutated Rectifiers in Machine Drives

Important applications for line-commutated three-phase controlled rectifiers are found in machine drives. Fig. 9.26 shows a *dc* machine control implemented with a six-pulse rectifier. Torque and speed are controlled through the armature current I_D and excitation current I_{exc}. Current I_D is adjusted with V_D, which is controlled by the firing angle α through Eq. (9.12). This *dc* drive can operate in two quadrants: positive and negative *dc* voltage. This two-quadrant operation allows regenerative braking when $\alpha > 90$ degrees and $I_{exc} < 0$.

The converter of Fig. 9.26 can also be used to control synchronous machines, as shown in Fig. 9.27. In this case, a second converter working in the inverting mode operates the machine as self-controlled synchronous motor. With this second converter, the synchronous motor behaves like a *dc* motor but has none of the disadvantages of mechanical commutation. This converter is not line commutated, but machine commutated.

The nominal synchronous speed of the motor on a 50 or 60 Hz *ac* supply is now meaningless, and the upper speed limit is determined by the mechanical limitations of the rotor construction. There is disadvantage that the rotational *emfs* required for load commutation of the machine side converter are not available at standstill and low speeds. In such a case, auxiliary force-commutated circuits must be used.

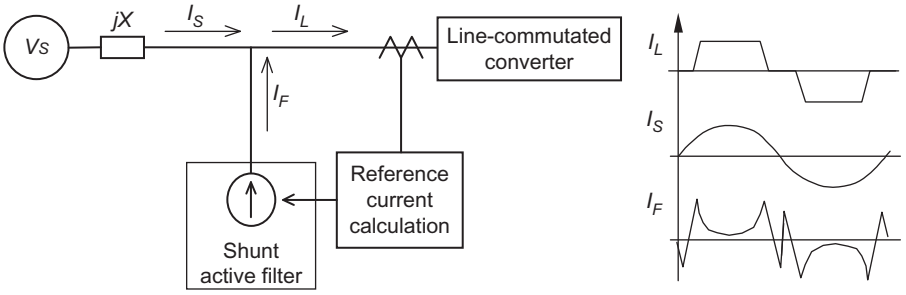

FIG. 9.25 Current-controlled shunt active power filter.

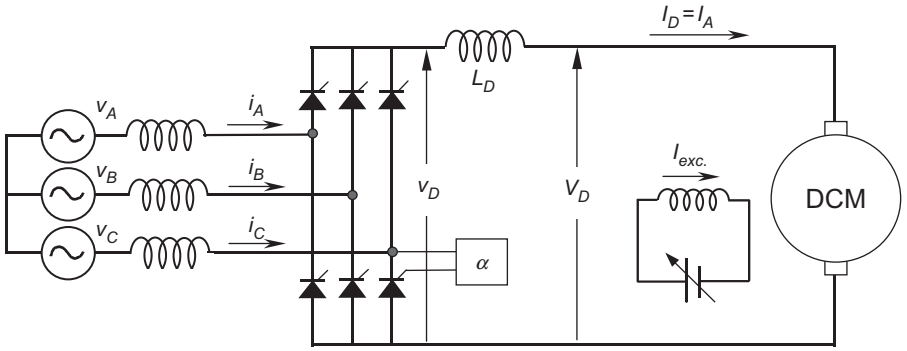

FIG. 9.26 *DC* machine drive with a six-pulse rectifier.

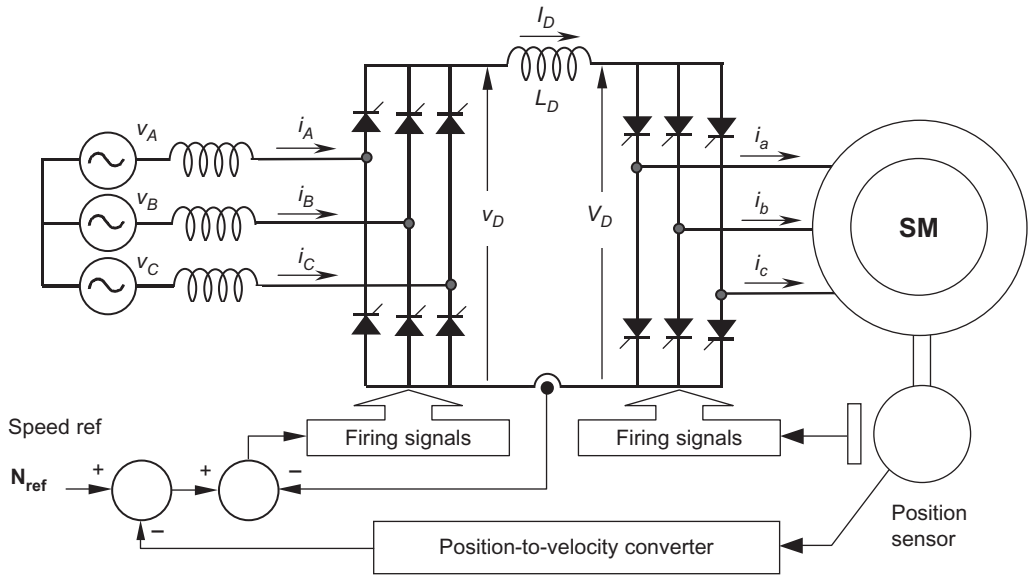

FIG. 9.27 Self-controlled synchronous motor drive.

The line-commutated rectifier controls the torque of the machine through firing angle a. This approach gives direct torque control of the commutatorless motor and is analogous to the use of armature current control shown in Fig. 9.26 for the converter-fed *dc* motor drive.

Line-commutated rectifiers are also used for speed control of wound rotor induction motors. Subsynchronous and supersynchronous static converter cascades using a naturally commutated *dc* link converter can be implemented. Fig. 9.28 shows a supersynchronous cascade for a wound rotor induction motor, using a naturally commutated *dc* link converter.

In the supersynchronous cascade shown in Fig. 9.28, the right-hand bridge operates at slip frequency as a rectifier or inverter, while the other operates at network frequency as an inverter or rectifier. Control is difficult near synchronism when slip frequency *emfs* are insufficient for natural commutation and special circuit configuration employing forced commutation or devices with a self-turn-off capability are necessary for the passage through synchronism. This kind of supersynchronous cascade works better with cycloconverters.

9.2.11 Applications in HVDC Power Transmission

High-voltage direct-current (HVDC) power transmission is the most powerful application for line-commutated converters that exist today. There are power converters with ratings in excess of 1000 MW. Series operation of hundreds of valves can be found in some HVDC systems. In high-power and long-distance applications, these systems become more economical than conventional *ac* systems. They also have some other advantages compared with *ac* systems:

1. They can link two *ac* systems operating unsynchronized or with different nominal frequencies, that is, $50 \leftrightarrow 60$ Hz.

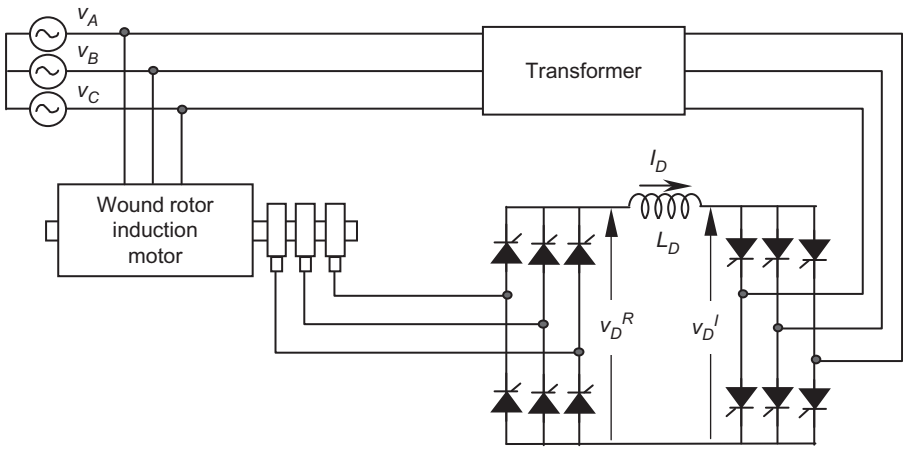

FIG. 9.28 Supersynchronous cascade for a wound rotor induction motor.

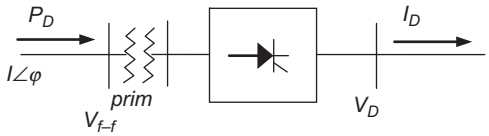
2. They can help in stability problems related with subsynchronous resonance in long *ac* lines.
3. They have very good dynamic behavior and can interrupt short-circuit problems very quickly.
4. If transmission is by submarine or underground cable, it is not practical to consider *ac* cable systems exceeding 50 km, but *dc* cable transmission systems are in service whose length is in hundreds of kilometers and even distances of 600 km or greater have been considered feasible.
5. Reversal of power can be controlled electronically by means of the delay firing angles a.
6. Some existing overhead *ac* transmission lines cannot be increased. If overbuilt with or upgraded to *dc* transmission, it can substantially increase the power transfer capability on the existing right-of-way.



The use of HVDC systems for interconnections of asynchronous systems is an interesting application. Some continental electric power systems consist of asynchronous networks such as those for the East, West, Texas, and Quebec networks in North America, and island loads such as that for the island of Gotland in the Baltic Sea make good use of the HVDC interconnections.

Nearly all HVDC power converters with thyristor valves are assembled in a converter bridge of 12-pulse configuration, as shown in Fig. 9.29. Consequently, the *ac* voltages applied to each 6-pulse valve group that makes up the 12-pulse valve group have a phase difference of 30 degrees that is utilized to cancel the *ac* side, 5th and 7th harmonic currents, and *dc* side, 6th harmonic voltage, thus resulting in a significant saving in harmonic filters.

Some useful relations for HVDC systems include the following:

(a) Rectifier side

$$P_D = V_D I_D = \sqrt{3} V_{f-f}^{prim} I_{line}^{rms} \cos\varphi \tag{9.40}$$

$$I_P = I\cos\varphi$$

$$I_Q = I\sin\varphi \tag{9.41}$$

$$\therefore P_D = V_D I_D = \sqrt{3} V_{f-f}^{prim} I_P$$

$$I_P = \frac{V_D I_D}{\sqrt{3} V_{f-f}^{prim}} \tag{9.42}$$

$$I_P = \frac{a^2\sqrt{3} V_{f-f}^{prim}}{4\pi\omega L_S}[\cos 2\alpha - \cos 2(\alpha+\mu)] \tag{9.43}$$

$$I_Q = \frac{a^2\sqrt{3} V_{f-f}^{prim}}{4\pi\omega L_S}[\sin 2(\alpha+\mu) - \sin 2\alpha - 2\mu] \tag{9.44}$$

$$I_P = I_D \frac{a\sqrt{6}}{\pi}\left[\frac{\cos\alpha + \cos(\alpha+\mu)}{2}\right] \tag{9.45}$$

Fundamental secondary component of I

$$I = \frac{a\sqrt{6}}{\pi} I_D \tag{9.46}$$

Replacing Eq. (9.46) in (9.45),

$$I_P = I\left[\frac{\cos\alpha + \cos(\alpha+\mu)}{2}\right] \tag{9.47}$$

As $I_p = I\cos\varphi$, it yields Fig. 9.30A:

$$\cos\varphi = \left[\frac{\cos\alpha + \cos(\alpha+\mu)}{2}\right] \tag{9.48}$$

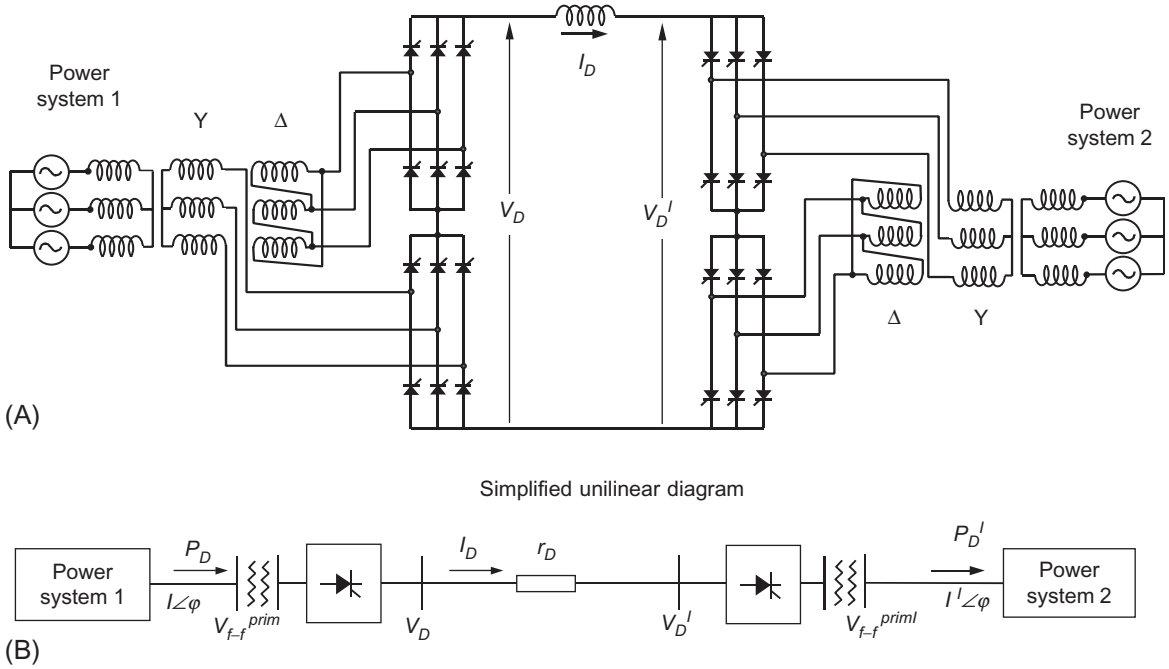


FIG. 9.29 Typical HVDC power system: (A) detailed circuit and (B) unilinear diagram.

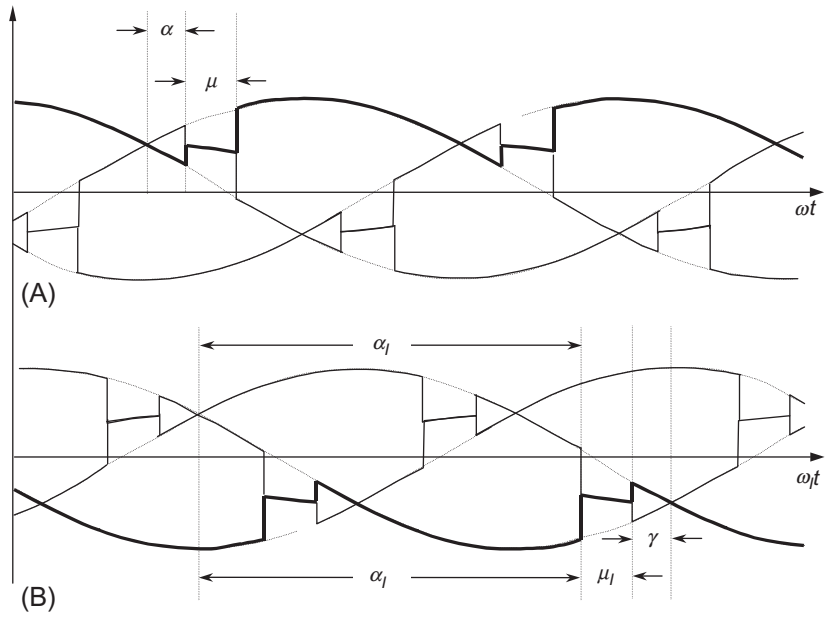

FIG. 9.30 Definition of angle γ for inverter side: (A) rectifier side and (B) inverter side.

(b) Inverter side

The same equations are applied for the inverter side, but the firing angle α is replaced by γ, where γ is

$$\gamma = 180 \text{ degrees} - (\alpha + \mu) \tag{9.49}$$

As reactive power always goes in the converter direction, Eq. (9.44) for inverter side becomes (Fig. 9.30B)

$$I_{QI} = -\frac{a_I^2\sqrt{3}V_{f-f_I}^{prim}}{4\pi\omega_I L_I}[\sin 2(\gamma + \mu_I) - \sin 2\gamma - 2\mu_I] \tag{9.50}$$

9.2.12 Dual Converters

In many variable-speed drives, four-quadrant operation is required, and three-phase dual converters are extensively used in applications up to 2 MW level. Fig. 9.31 shows a three-phase dual converter, where two converters are connected back-to-back.

In the dual converter, one rectifier provides the positive current to the load and the other the negative current. Due to the instantaneous voltage differences between the output voltages of the converters, a circulating current flows through the bridges. The circulating current is normally limited by circulating reactor, L_D, as shown in Fig. 9.31. The two converters are controlled in such a way that if α^+ is the delay angle of the positive current converter, the delay angle of the negative current converter is $\alpha^- = 180 \text{ degrees} - \alpha^+$.

Fig. 9.32 shows the instantaneous *dc* voltages of each converter, v_D^+ and v_D^-. Despite the average voltage V_D is the same in both the converters, their instantaneous voltage differences shown as voltage v_r are producing the circulating current i_r, which is superimposed with the load currents i_D^+ and i_D^-.

To avoid the circulating current i_r, it is possible to implement a "circulating current-free" converter if a dead time of a few milliseconds is acceptable. The converter section, not required to supply current, remains fully blocked. When a current reversal is required, a logic switchover system determines at first the instant at which the conducting converter's current becomes zero. This converter section is then blocked, and the further supply of gating pulses to it is prevented. After a short safety

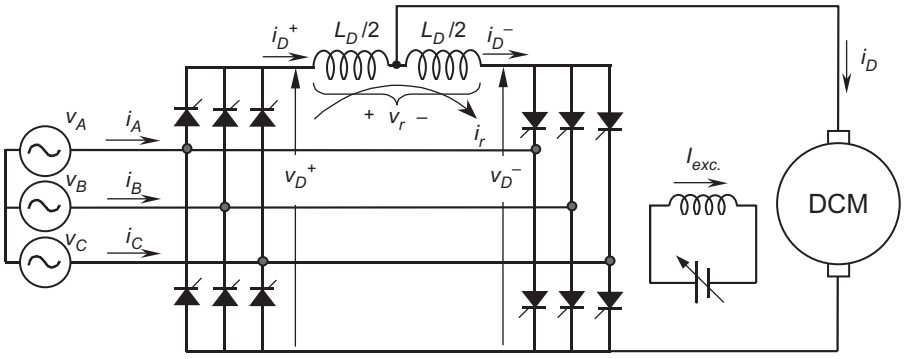

FIG. 9.31 Dual converter in a four-quadrant *dc* drive.

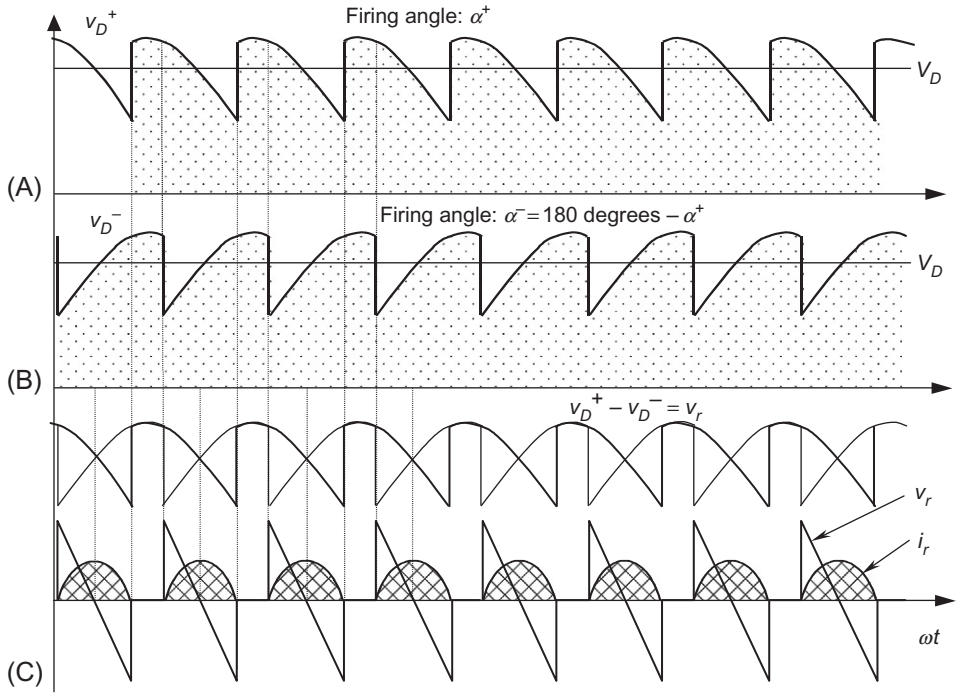

FIG. 9.32 Waveform of circulating current: (A) instantaneous *dc* voltage from positive converter; (C) instantaneous *dc* voltage from negative converter; and (C) voltage difference between v_D^+ and v_D^-, v_r, and circulating current i_r.

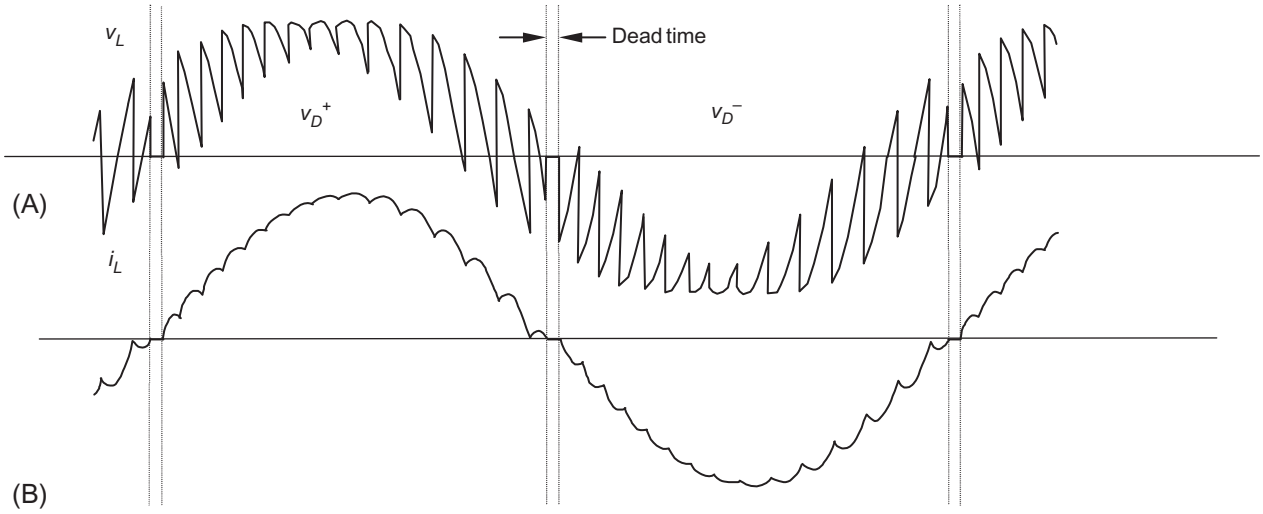

FIG. 9.33 Cycloconverter operation: (A) voltage waveform and (B) current waveform for inductive load.

interval (dead time), the gating pulses for the other converter section are released.

9.2.13 Cycloconverters

A different principle of frequency conversion is derived from the fact that a dual converter is able to supply an *ac* load with a lower frequency than the system frequency. If the control signal of the dual converter is a function of time, the output voltage will follow this signal. If this control signal value alters sinusoidally with the desired frequency, then the waveform depicted in Fig. 9.33A consists of a single-phase voltage with a large harmonic current. As shown in Fig. 9.33B, if the load is inductive, the current will present less distortion than voltage.

The cycloconverter operates in all four quadrants during a period. A pause (dead time) at least as small as the time required by the switchover logic occurs after the current reaches zero, that is, between the transfer to operation in the quadrant corresponding to the other direction of current flow.

Three single-phase cycloconverters may be combined to build a three-phase cycloconverter. The three-phase cycloconverters find an application in low-frequency, high-power requirements. Control speed of large synchronous motors in the low-speed range is one of the most common applications of three-phase cycloconverters. Fig. 9.34 is a diagram for this application. They are also used to control slip frequency in wound rotor induction machines, for supersynchronous cascade (Scherbius system).

9.2.14 Harmonic Standards and Recommended Practices

In view of the proliferation of the power converter equipment connected to the utility system, various national and international agencies have been considering limits on harmonic current injection to maintain good power quality. As a consequence, various standards and guidelines have been established that specify limits on the magnitudes of harmonic currents and harmonic voltages.

The Comité Européen de Normalisation Electrotechnique (CENELEC), International Electrotechnical Commission (IEC), and West German Standards (VDE) specify the limits on the voltages (as a percentage of the nominal voltage) at various harmonic frequencies of the utility frequency, when the equipment-generated harmonic currents are injected into a network whose impedances are specified.

According to the Institute of Electrical and Electronics Engineers-519 standards (IEEE), Table 9.1 lists the limits on the harmonic currents that a user of power electronics equipment and other nonlinear loads is allowed to inject into the utility system. Table 9.2 lists the quality of voltage that the utility can furnish the user.

In Table 9.1, the values are given at the point of connection of nonlinear loads. The *THD* is the total harmonic distortion given by Eq. (9.51), and h is the number of the harmonic:

$$THD = \frac{\sqrt{\sum_{h=2}^{\infty} I_h^2}}{I_1} \tag{9.51}$$

The total current harmonic distortion allowed in Table 9.1 increases with the value of short-circuit current.

The total harmonic distortion in the voltage can be calculated in a manner similar to that given by Eq. (9.51). Table 9.2 specifies the individual harmonics and the *THD* limits on the voltage that the utility supplies to the user at the connection point.

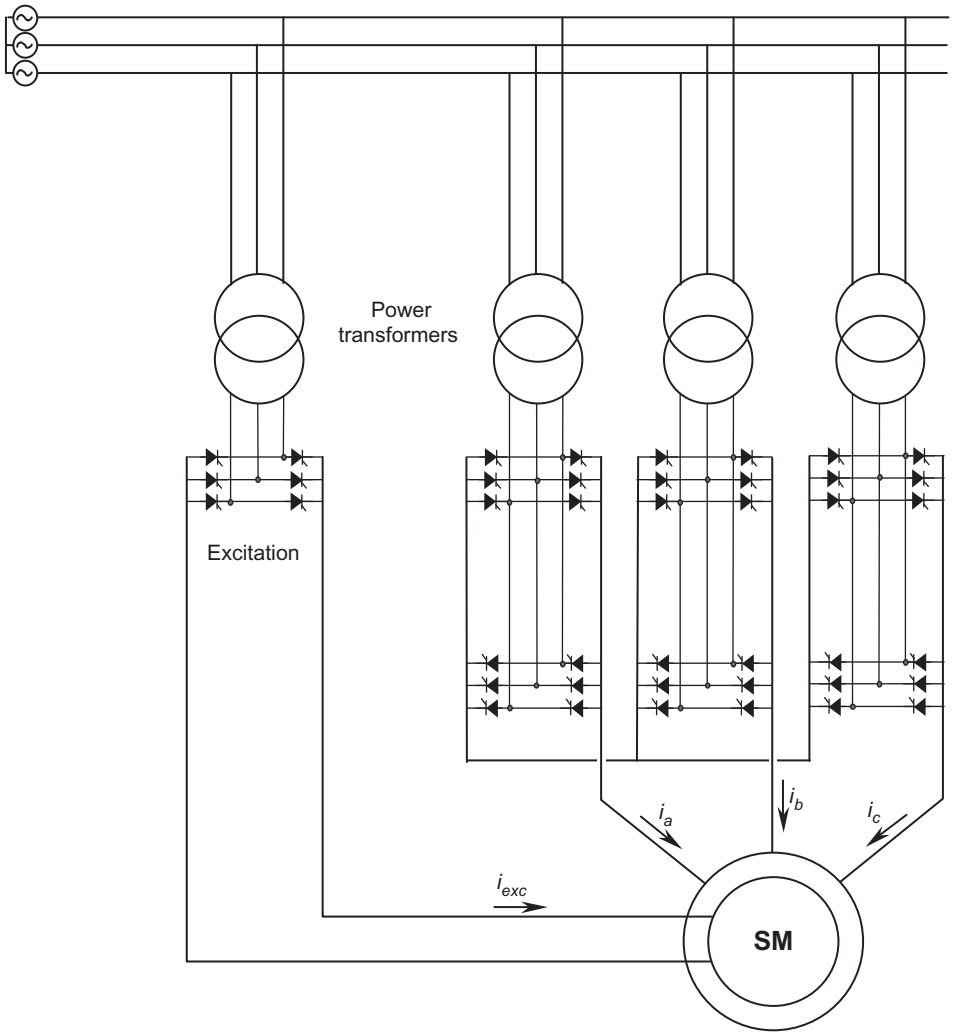

FIG. 9.34 Synchronous machine drive with a cycloconverter.

TABLE 9.1 Harmonic current limits in percent of fundamental

Short-circuit current (p.u.)	$h<11$	$11<h<17$	$17<h<23$	$23<h<35$	$35<h$	THD

9.3 Force-Commutated Three-Phase Controlled Rectifiers

9.3.1 Basic Topologies and Characteristics

Force-commutated rectifiers are built with semiconductors with gate-turn-off capability. The gate-turn-off capability allows full control of the converter, because valves can be

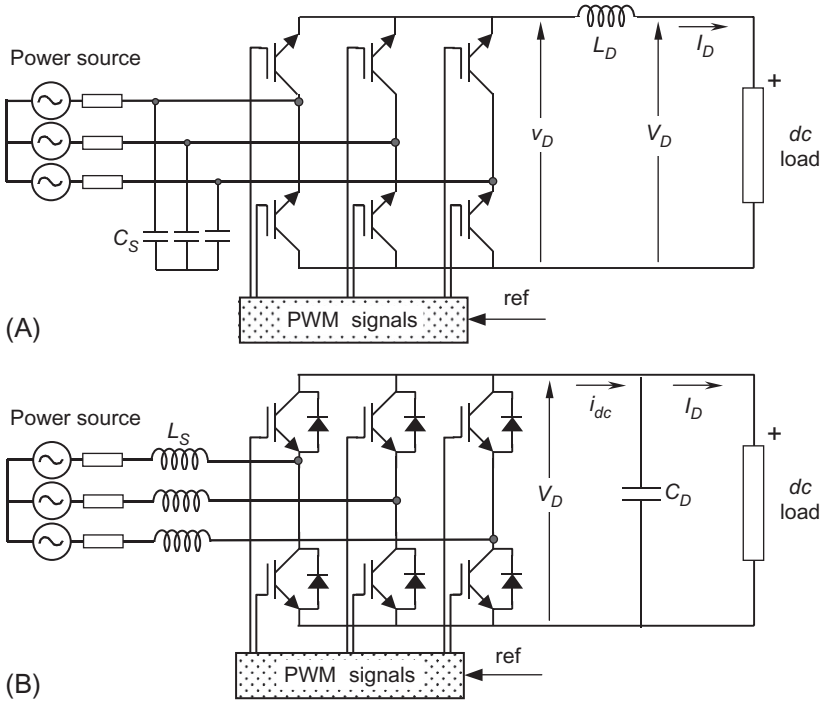

FIG. 9.35 Basic topologies for force-commutated PWM rectifiers: (A) current-source rectifier and (B) voltage-source rectifier.

switched *ON* and *OFF* whenever is required. This allows the commutation of the valves, hundreds of times in one period that is not possible with line-commutated rectifiers, where thyristors are switched *ON* and *OFF* only once a cycle. This feature has the following advantages: (a) The current or voltage can be modulated (PWM), generating less harmonic contamination; (b) power factor can be controlled and even it can be made leading; (c) they can be built as voltage-source or current-source rectifiers; and (d) the reversal of power in thyristor rectifiers is by reversal of voltage at the *dc* link. Instead, force-commutated rectifiers can be implemented for both, reversal of voltage or reversal of current.

There are two ways to implement force-commutated three-phase rectifiers: (A) as a current-source rectifier, where power reversal is by *dc* voltage reversal, and (B) as a voltage-source rectifier, where power reversal is by current reversal at the *dc* link. Fig. 9.35 shows the basic circuits for these two topologies.

9.3.2 Operation of the Voltage Source Rectifier

The voltage-source rectifier is by far the most widely used, and because of the duality of the two topologies shown in Fig. 9.35, only this type of force-commutated rectifier will be explained in detail.

The voltage-source rectifier operates by keeping the *dc* link voltage at a desired reference value, using a feedback control loop as shown in Fig. 9.36. To accomplish this task, the *dc* link voltage is measured and compared with a reference V_{REF}. The error signal generated from this comparison is used to switch the six valves of the rectifier *ON* and *OFF*. In this way, power can come or return to the *ac* source according to the *dc* link voltage requirements. The voltage V_D is measured at the capacitor C_D.

When the current I_D is positive (rectifier operation), the capacitor C_D is discharged, and the error signal asks the control block for more power from the *ac* supply. The control block takes the power from the supply by generating the appropriate PWM signals for the six valves. In this way, more current flows from the *ac* to the *dc* side, and the capacitor voltage is recovered. Inversely, when I_D becomes negative (inverter operation), the capacitor C_D is overcharged, and the error signal asks the control to discharge the capacitor and return power to the *ac* mains.

The PWM control can manage not only the active power but also the reactive power, allowing this type of rectifier to correct power factor. In addition, the *ac* current waveforms can be maintained as almost sinusoidal, which reduces harmonic contamination to the mains supply.

The PWM consists of switching the valves *ON* and *OFF*, following a preestablished template. This template could be a sinusoidal waveform of voltage or current. For example, the modulation of one phase could be as the one shown in Fig. 9.37. This PWM pattern is a periodical waveform whose fundamental is a voltage with the same frequency of the template. The amplitude of this fundamental, called V_{MOD} in Fig. 9.37, is also proportional to the amplitude of the template.

To make the rectifier work properly, the PWM pattern must generate a fundamental V_{MOD} with the same frequency as the

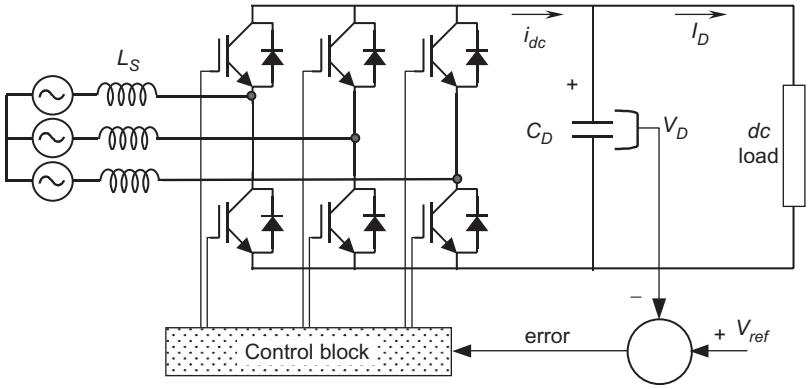

FIG. 9.36 Operation principle of the voltage-source rectifier.

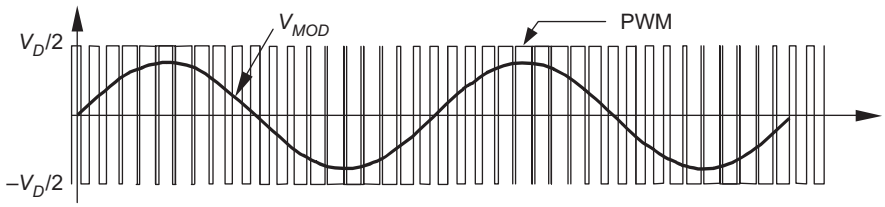

FIG. 9.37 A PWM pattern and its fundamental V_{MOD}.

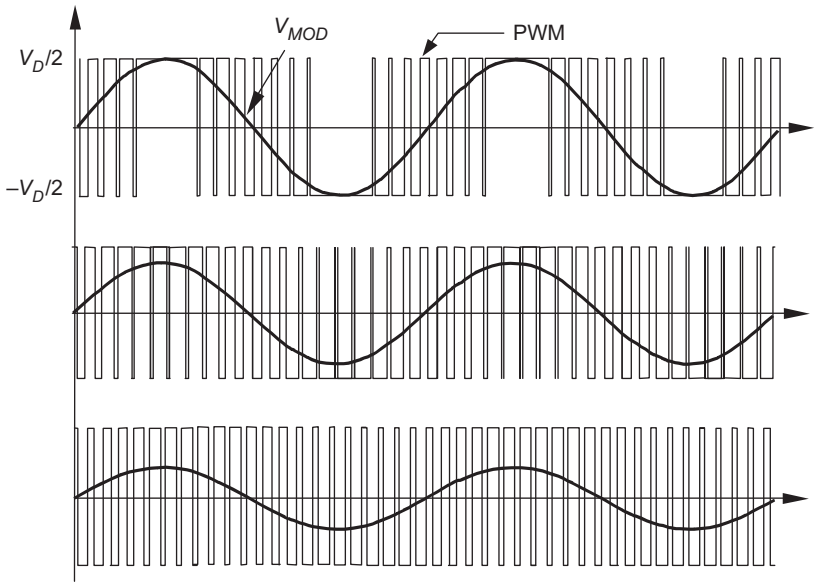

FIG. 9.38 Changing V_{MOD} through the PWM pattern.

power source. Changing the amplitude of this fundamental and its phase shift with respect to the mains, the rectifier can be controlled to operate in the four quadrants: leading power factor rectifier, lagging power factor rectifier, leading power factor inverter, and lagging power factor inverter. Changing the pattern of modulation, as shown in Fig. 9.38, modifies the magnitude of V_{MOD}. Displacing the PWM pattern changes the phase shift.

The interaction between V_{MOD} and V (source voltage) can be seen through a phasor diagram. This interaction permits understanding of the four-quadrant capability of this rectifier. In Fig. 9.39, the following operations are displayed: (A) rectifier at unity power factor, (B) inverter at unity power factor, (C) capacitor (zero power factor), and (D) inductor (zero power factor).

In Fig. 9.39, I_S is the *rms* value of the source current i_s. This current flows through the semiconductors in the way

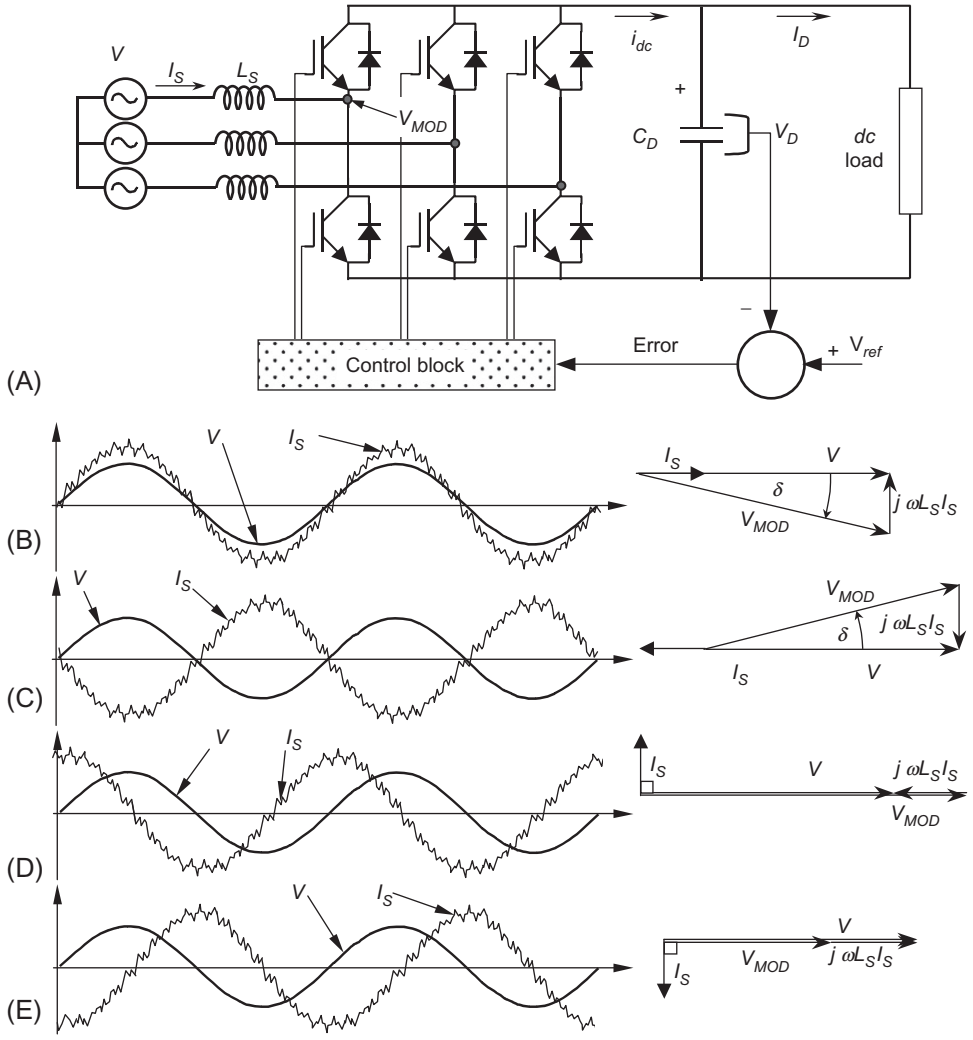

FIG. 9.39 Four-quadrant operation of the force-commutated rectifier: (A) the PWM force-commutated rectifier, (B) rectifier operation at unity power factor, (C) inverter operation at unity power factor, (D) capacitor operation at zero power factor, and (E) inductor operation at zero power factor.

shown in Fig. 9.40. During the positive half cycle, the transistor T_N, connected at the negative side of the *dc* link, is switched *ON*, and the current i_s begins to flow through T_N (i_{Tn}). The current returns to the mains and comes back to the valves, closing a loop with another phase and passing through a diode connected at the same negative terminal of the *dc* link. The current can also go to the *dc* load (inversion) and return through another transistor located at the positive terminal of the *dc* link. When the transistor T_N is switched *OFF,* the current path is interrupted, and the current begins to flow through the diode *Dp*, connected at the positive terminal of the *dc* link. This current, called i_{Dp} in Fig. 9.39, goes directly to the *dc* link, helping in the generation of the current i_{dc}. The current i_{dc} charges the capacitor C_D and permits the rectifier to produce *dc* power. The inductances L_S are very important in this process, because they generate an induced voltage that allows the conduction of the diode D_p. Similar operation occurs during the negative half cycle but with T_p and D_N (see Fig. 9.40).

Under inverter operation, the current paths are different because the currents flowing through the transistors come mainly from the *dc* capacitor, C_D. Under rectifier operation, the circuit works like a boost converter, and under inverter, it works as a buck converter.

To have full control of the operation of the rectifier, their six diodes must be polarized negatively at all values of instantaneous *ac* voltage supply. Otherwise, diodes will conduct, and the PWM rectifier will behave like a common diode rectifier bridge. The way to keep the diodes blocked is to ensure a *dc* link voltage higher than the peak *dc* voltage generated by the diodes alone, as shown in Fig. 9.41. In this way, the diodes remain polarized negatively, and they will conduct only when at least one transistor is switched *ON,* and favorable instantaneous *ac* voltage conditions are given. In Fig. 9.41, V_D represents the

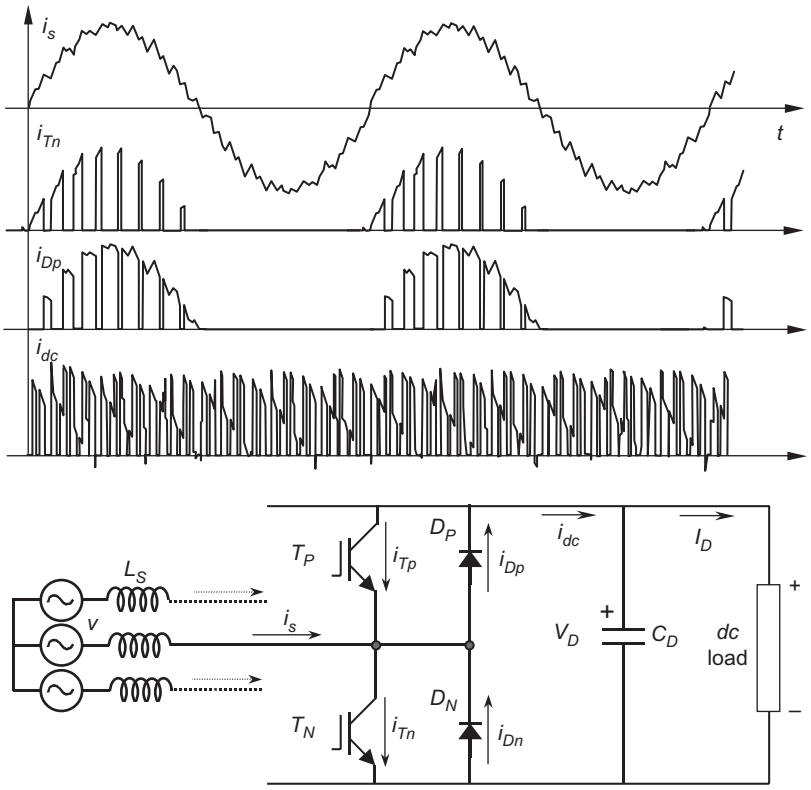

FIG. 9.40 Current waveforms through the mains, the valves, and the *dc* link.

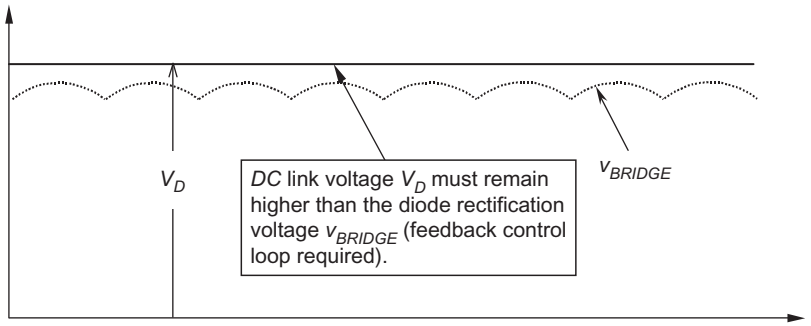

FIG. 9.41 The *DC* link voltage condition for the operation of the PWM rectifier.

capacitor *dc* voltage, which is kept higher than the normal diode-bridge rectification value v_{BRIDGE}. To maintain this condition, the rectifier must have a control loop like the one displayed in Fig. 9.36.

9.3.3 PWM Phase-to-Phase and Phase-to-Neutral Voltages

The PWM waveforms shown in the preceding figures are voltages measured between the middle point of the *dc* voltage and the corresponding phase. The phase-to-phase PWM voltages can be obtained with the help of Eq. (9.52), where the voltage V_{PWM}^{AB} is evaluated:

$$V_{PWM}^{AB} = V_{PWM}^{A} - V_{PWM}^{B} \tag{9.52}$$

where V_{PWM}^{A} and V_{PWM}^{B} are the voltages measured between the middle point of the *dc* voltage and the phases *a* and *b*, respectively. In a less straightforward fashion, the phase-to-neutral voltage can be evaluated with the help of Eq. (9.53):

$$V_{PWM}^{AN} = \frac{1}{3}\left(V_{PWM}^{AB} - V_{PWM}^{CA}\right) \tag{9.53}$$

where V_{PWM}^{AN} is the phase-to-neutral voltage for phase *a* and V_{PWM}^{jk} is the phase-to-phase voltage between phase *j* and phase *k*. Fig. 9.42 shows the PWM patterns for the phase-to-phase and phase-to-neutral voltages.

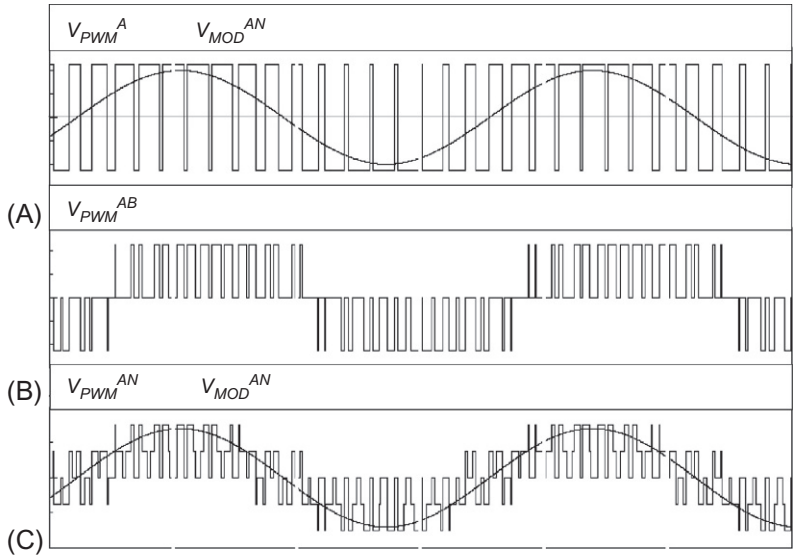

FIG. 9.42 PWM phase voltages: (A) PWM phase modulation, (B) PWM phase-to-phase voltage, and (C) PWM phase-to-neutral voltage.

9.3.4 Control of the *DC* Link Voltage

Control of the *dc* link voltage requires a feedback control loop. As already explained in Section 9.3.2, the *dc* voltage V_D is compared with a reference V_{REF}, and the error signal "e" obtained from this comparison is used to generate a template waveform. The template should be a sinusoidal waveform with the same frequency of the mains supply. This template is used to produce the PWM pattern and allows controlling the rectifier in two different ways: (1) as a voltage-source current-controlled PWM rectifier and (2) as a voltage-source voltage-controlled PWM rectifier. The first method controls the input current, and the second controls the magnitude and phase of the voltage V_{MOD}. The current-controlled method is simpler and more stable than the voltage-controlled method, and for these reasons, it will be explained first.

9.3.4.1 Voltage-Source Current-Controlled PWM Rectifier

This method of control is shown in the rectifier in Fig. 9.43. Control is achieved by measuring the instantaneous phase

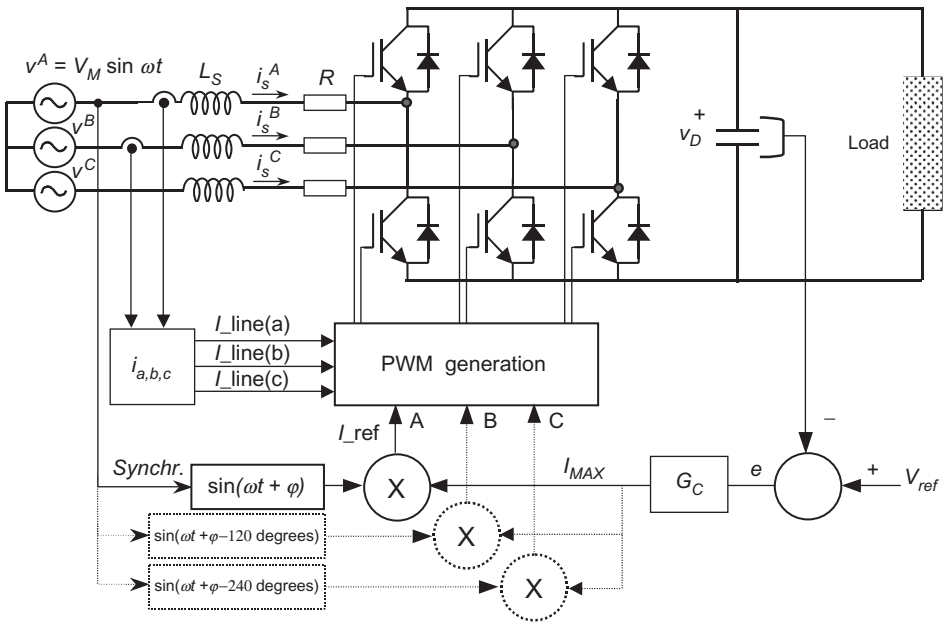

FIG. 9.43 Voltage-source current-controlled PWM rectifier.

currents and forcing them to follow a sinusoidal current reference template, *I*_ref. The amplitude of the current reference template, I_{MAX}, is evaluated using the following equation:

$$I_{MAX} = G_C e = G_C(V_{REF} - v_D) \tag{9.54}$$

where G_C is shown in Fig. 9.43 and represents a controller such as PI, P, Fuzzy, or other. The sinusoidal waveform of the template is obtained by multiplying I_{MAX} with a sine function, with the same frequency of the mains and with the desired phase-shift angle φ, as shown in Fig. 9.43. Further, the template must be synchronized with the power supply. After that, the template has been created and is ready to produce the PWM pattern.

However, one problem arises with the rectifier because the feedback control loop on the voltage V_C can produce instability. Then, it becomes necessary to analyze this problem during rectifier design. Upon introducing the voltage feedback and the G_C controller, the control of the rectifier can be represented in a block diagram in Laplace dominion, as shown in Fig. 9.44. This block diagram represents a linearization of the system around an operating point, given by the *rms* value of the input current, I_S.

The blocks $G_1(s)$ and $G_2(s)$ in Fig. 9.44 represent the transfer function of the rectifier (around the operating point) and the transfer function of the *dc* link capacitor C_D, respectively:

$$G_1(s) = \frac{\Delta P_1(s)}{\Delta I_S(s)} = 3(V\cos\varphi - 2RI_S - L_S I_S s) \tag{9.55}$$

$$G_2(s) = \frac{\Delta V_D(s)}{\Delta P_1(s) - \Delta P_2(s)} = \frac{1}{V_D C_D s} \tag{9.56}$$

where $\Delta P_1(s)$ and $\Delta P_2(s)$ represent the input and output power of the rectifier in Laplace dominion, V the *rms* value of the mains voltage supply (phase-to-neutral), I_S the input current being controlled by the template, L_S the input inductance, and R the resistance between the converter and power supply. According to stability criteria and assuming a *PI* controller, the following relations are obtained:

$$I_S \le \frac{C_D V_D}{3K_P L_S} \tag{9.57}$$

$$I_S \le \frac{K_P V\cos\varphi}{2RK_P + L_S K_I} \tag{9.58}$$

These two relations are useful for the design of the current-controlled rectifier. They relate the values of *dc* link capacitor, *dc* link voltage, *rms* voltage supply, input resistance and inductance, and input power factor with the *rms* value of the input current, I_S. With these relations, the proportional and integral gains K_P and K_I can be calculated to ensure the stability of the rectifier. These relations only establish limitations for rectifier operation, because negative currents always satisfy the inequalities.

With these two stability limits satisfied, the rectifier will keep the *dc* capacitor voltage at the value of V_{REF} (*PI* controller), for all load conditions, by moving power from the *ac* to the *dc* side. Under inverter operation, the power will move in the opposite direction.

Once the stability problems have been solved and the sinusoidal current template has been generated, a modulation method will be required to produce the PWM pattern for the power valves. The PWM pattern will switch the power valves to force the input currents *I*_line to follow the desired current template *I*_ref. There are many modulation methods in the literature, but three methods for voltage-source current-controlled rectifiers are the most widely used ones: *periodical sampling* (PS), *hysteresis band* (HB), and *triangular carrier* (TC).

The PS method switches the power transistors of the rectifier during the transitions of a square-wave clock of fixed frequency: the *periodical sampling* frequency. In each transition, a comparison between *I*_ref and *I*_line is made, and corrections take place. As shown in Fig. 9.45A, this type of control is very simple to implement: only a comparator and a D-type flip-flop are needed per phase. The main advantage of this method is that the minimum time between switching transitions is limited to the period of the sampling clock. This characteristic determines the maximum switching frequency of the converter. However, the average switching frequency is not clearly defined.

The HB method switches the transistors when the error between *I*_ref and *I*_line exceeds a fixed magnitude: the *hysteresis band*. As it can be seen in Fig. 9.45B, this type of control needs a single comparator with hysteresis per phase. In this case, the switching frequency is not determined, but its maximum value can be evaluated through the following equation:

$$f_S^{\max} = \frac{V_D}{4hL_S} \tag{9.59}$$

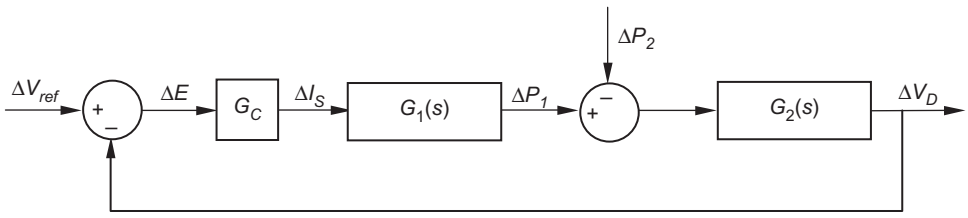

FIG. 9.44 Closed-loop rectifier transfer function.

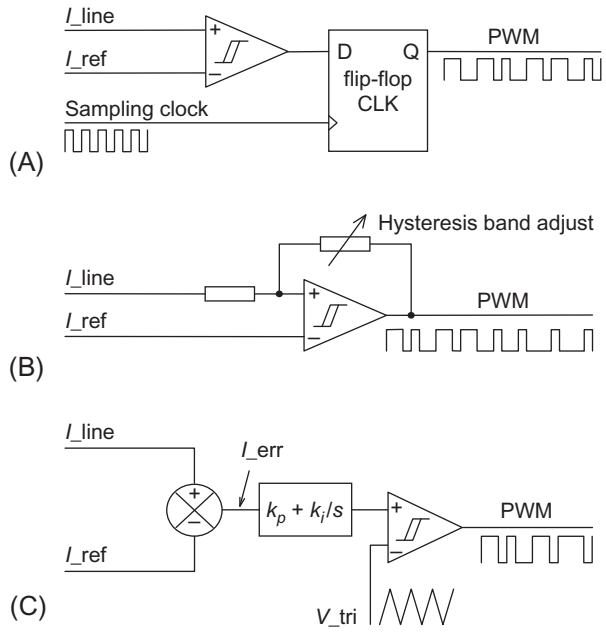

FIG. 9.45 Modulation control methods: (A) periodical sampling, (B) hysteresis band, and (C) triangular carrier.

where h is the magnitude of the hysteresis band.

The TC method, shown in Fig. 9.45C, compares the error between I_ref and I_line with a triangular wave. This triangular wave has fixed amplitude and frequency and is called the *triangular carrier*. The error is processed through a proportional-integral (PI) gain stage before comparison with the TC takes place. As can be seen, this control scheme is more complex than PS and HB. The values for k_p and k_i determine the transient response and steady-state error of the TC method. It has been found empirically that the values for k_p and k_i shown in Eqs. (9.60), (9.61) give a good dynamic performance under several operating conditions:

$$k_p = \frac{L_s \omega_c}{2V_D} \tag{9.60}$$

$$k_i = \omega_c K_P \tag{9.61}$$

where L_S is the total series inductance seen by the rectifier, ω_c is the TC frequency, and V_D is the *dc* link voltage of the rectifier.

In order to measure the level of distortion (or undesired harmonic generation) introduced by these three control methods, Eq. (9.62) is defined:

$$\%\text{Distortion} = \frac{100}{I_{rms}} \sqrt{\frac{1}{T}\int_T (I_\text{line} - I_\text{ref})^2 dt} \tag{9.62}$$

In Eq. (9.62), the term I_{rms} is the effective value of the desired current. The term inside the square root gives the *rms* value of the error current, which is undesired. This formula measures the percentage of error (or distortion) of the generated waveform. This definition considers the ripple, amplitude, and phase errors of the measured waveform, as opposed to the *THD*, which does not take into account offsets, scalings, and phase shifts.

Fig. 9.46 shows the current waveforms generated by the three aforementioned methods. The example uses an average switching frequency of 1.5 kHz. The PS is the worst, but its digital implementation is simpler. The HB method and TC with PI control are quite similar, and the TC with only proportional control gives a current with a small phase shift. However, Fig. 9.47 shows that the higher the switching frequency, the closer the results obtained with the different modulation methods. Over 6 kHz of switching frequency, the distortion is very small for all methods.

9.3.4.2 Voltage-Source Voltage-Controlled PWM Rectifier

Fig. 9.48 shows a one-phase diagram from which the control system for a voltage-source voltage-controlled rectifier is

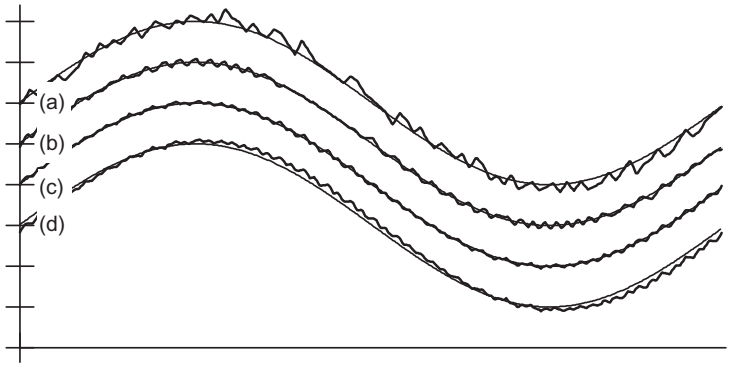

FIG. 9.46 Waveforms obtained using 1.5 kHz switching frequency and $L_S = 13$ mH: (a) PS method, (b) HB method, (c) TC method ($K_P + K_I$), and (d) TC method (K_P only).

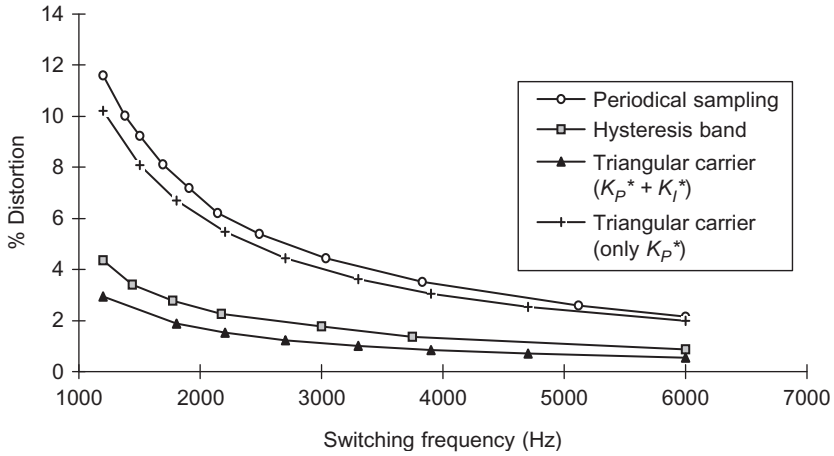

FIG. 9.47 Distortion comparison for a sinusoidal current reference.

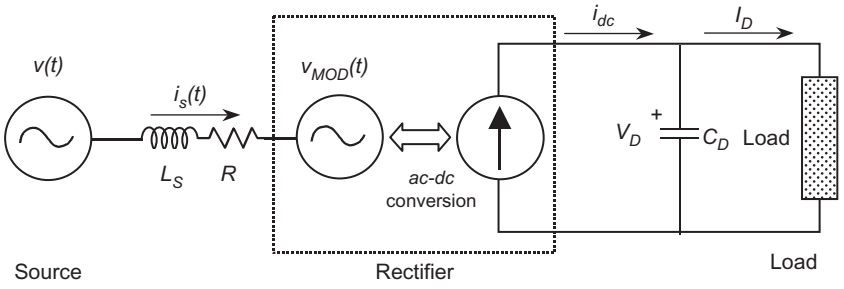

FIG. 9.48 One-phase fundamental diagram of the voltage-source rectifier.

derived. This diagram represents an equivalent circuit of the fundamentals, that is, pure sinusoidal at the mains side and pure *dc* at the *dc* link side. The control is achieved by creating a sinusoidal voltage template V_{MOD}, which is modified in amplitude and angle to interact with the mains voltage V. In this way, the input currents are controlled without measuring them. The template V_{MOD} is generated using the differential equations that govern the rectifier.

The following differential equation can be derived from Fig. 9.48:

$$v(t) = L_S \frac{di_s}{dt} + Ri_s + v_{MOD}(t) \tag{9.63}$$

Assuming that $v(t) = V\sqrt{2}\sin\omega t$, then the solution for $i_s(t)$, to acquire a template V_{MOD} able to make the rectifier work at constant power factor, should be of the form

$$i_s(t) = I_{max}(t)\sin(\omega t + \varphi) \tag{9.64}$$

Eqs. (9.63), (9.64), and $v(t)$ allow a function of time able to modify V_{MOD} in amplitude and phase that will make the rectifier work at a fixed power factor. Combining these equations with $v(t)$ yields

$$v_{MOD}(t) = \left[V\sqrt{2} + X_S I_{max}\sin\varphi - \left(RI_{max} + L_S\frac{dI_{max}}{dt}\right)\cos\varphi\right]\sin\omega t - \left[X_S I_{max}\cos\varphi - \left(RI_{max} + L_S\frac{dI_{max}}{dt}\right)\sin\varphi\right]\cos\omega t \tag{9.65}$$

Eq. (9.65) provides a template for V_{MOD}, which is controlled through variations of the input current amplitude I_{max}. Substituting the derivatives of I_{max} into Eq. (9.65) makes sense, because I_{max} changes every time the *dc* load is modified. The term X_S in Eq. (9.65) is ωL_S. This equation can also be written for unity power factor operation. In such a case, $\cos\varphi = 1$ and $\sin\varphi = 0$:

$$v_{MOD}(t) = \left(V\sqrt{2} - RI_{max} - L_S\frac{dI_{max}}{dt}\right)\sin\omega t - X_S I_{max}\cos\omega t \tag{9.66}$$

With this last equation, a unity power factor, voltage-source, voltage-controlled PWM rectifier can be implemented as shown in Fig. 9.49. It can be observed that Eqs. (9.65), (9.66) have an *in-phase* term with the mains supply ($\sin\omega t$) and an

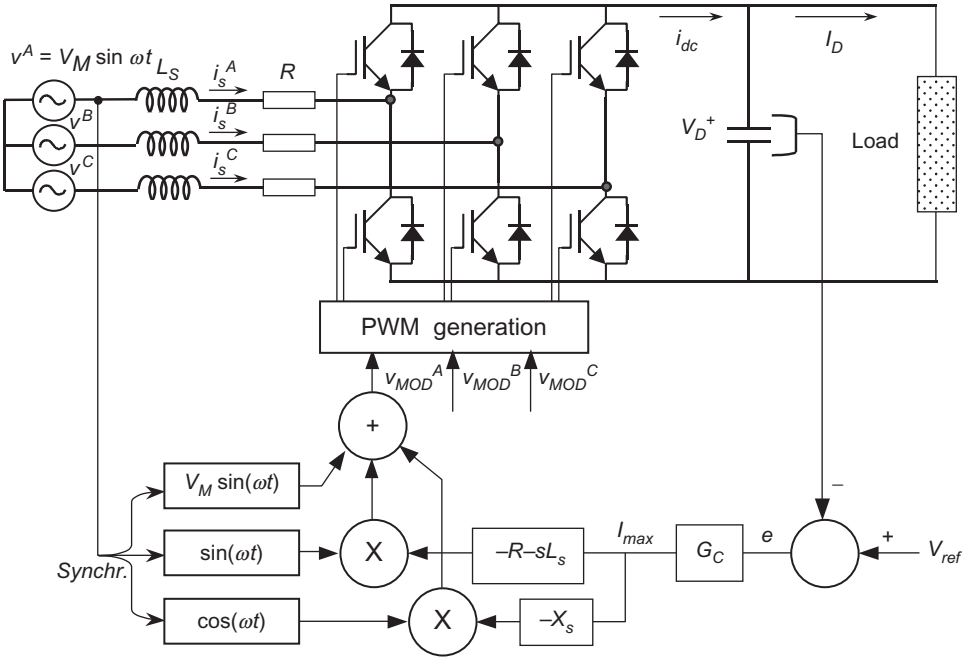

FIG. 9.49 Implementation of the voltage-controlled rectifier for unity power factor operation.

in-quadrature term (cos ωt). These two terms allow the template V_{MOD} to change in magnitude and phase so as to have full unity power factor control of the rectifier.

Compared with the control block of Fig. 9.43, in the voltage-source voltage-controlled rectifier of Fig. 9.49, there is no need to sense the input currents. However, to ensure stability limits as good as the limits of the current-controlled rectifier, the blocks "$-R-sL_S$" and "$-X_S$" in Fig. 9.49 have to emulate and reproduce exactly the real values of R, X_S, and L_S of the power circuit. However, these parameters do not remain constant, and this fact affects the stability of this system, making it less stable than the system shown in Fig. 9.43. In theory, if the impedance parameters are reproduced exactly, the stability limits of this rectifier are given by the same equations as used for the current-controlled rectifier seen in Fig. 9.43 (Eqs. 9.57, 9.58).

Under steady state, I_{max} is constant, and Eq. (9.66) can be written in terms of phasor diagram, resulting in Eq. (9.67). As shown in Fig. 9.50, different operating conditions for the unity power factor rectifier can be displayed with this equation:

$$\vec{V}_{MOD} = \vec{V} - R\vec{I}_S - jX_S\vec{I}_S \tag{9.67}$$

With the sinusoidal template V_{MOD} already created, a modulation method to commutate the transistors will be required. As in the case of current-controlled rectifier, there are many methods to modulate the template, with the most well-known the so-called sinusoidal pulse-width modulation (SPWM), which uses a TC to generate the PWM as shown in Fig. 9.51. Only this method will be described in this chapter.

In this method, there are two important parameters to define: the amplitude modulation ratio or modulation index m and the frequency modulation ratio p. Definitions are given by

$$m = \frac{V_{MOD}^{max}}{V_{TRIANG}^{max}} \tag{9.68}$$

$$p = \frac{f_T}{f_S} \tag{9.69}$$

where V_{MOD}^{max} and V_{TRIANG}^{max} are the amplitudes of V_{MOD} and V_{TRIANG}, respectively. On the other hand, f_S is the frequency of the mains supply and f_T the frequency of the TC. In Fig. 9.51, $m = 0.8$ and $p = 21$. When $m > 1$, overmodulation is defined.

The modulation method described in Fig. 9.51 has a harmonic content that changes with p and m. When $p < 21$, it is recommended that synchronous PWM be used, which means that the TC and the template should be synchronized. Furthermore, to avoid subharmonics, it is also desired that p be an integer. If p is an odd number, even harmonics will be eliminated. If p is a multiple of 3, then the PWM modulation of the three phases will be identical. When m increases, the amplitude of the fundamental voltage increases proportionally, but some harmonics decrease. Under overmodulation ($m > 1$), the fundamental voltage does not increase linearly, and more harmonics appear. Fig. 9.52 shows the harmonic spectrum of the three-phase PWM voltage waveforms for different values of m, and $p = 3k$ where k is an odd number.

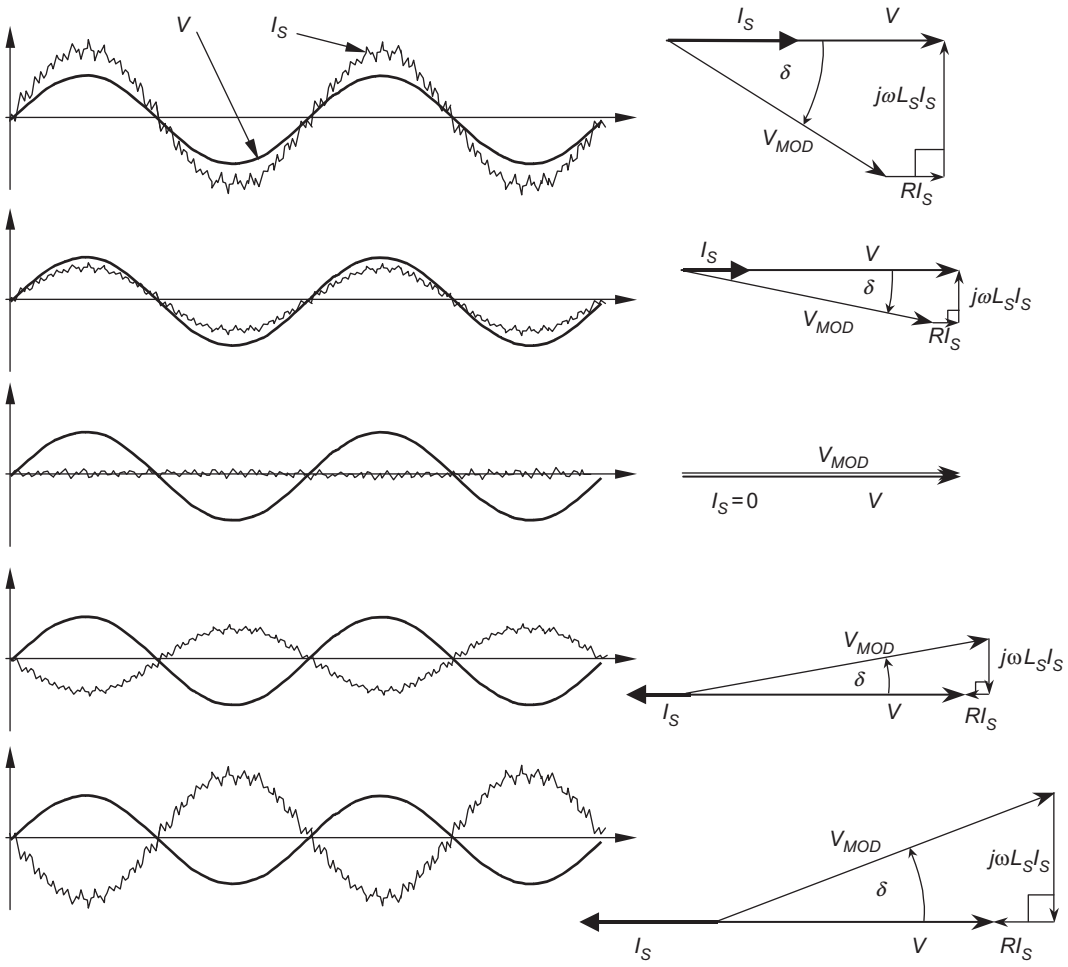

FIG. 9.50 Steady-state operation of the unity power factor rectifier under different load conditions.

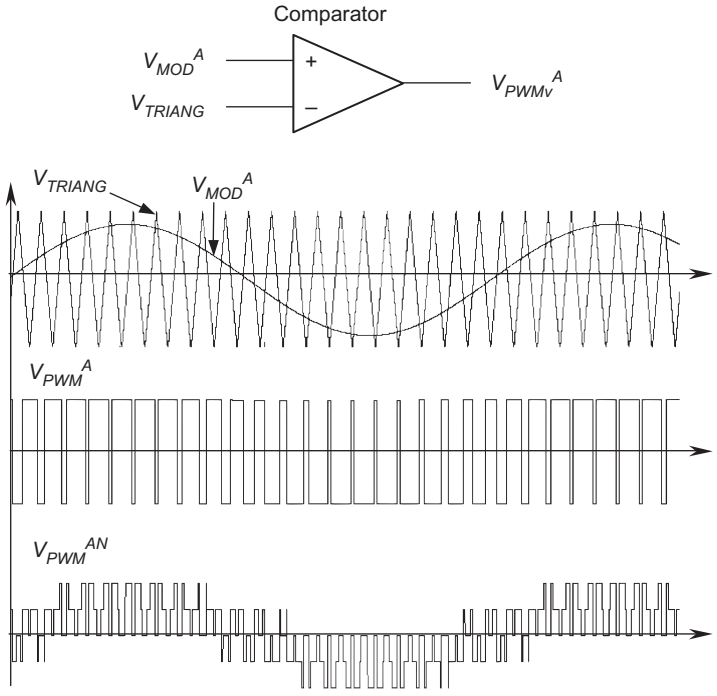

FIG. 9.51 Sinusoidal modulation method based on TC.

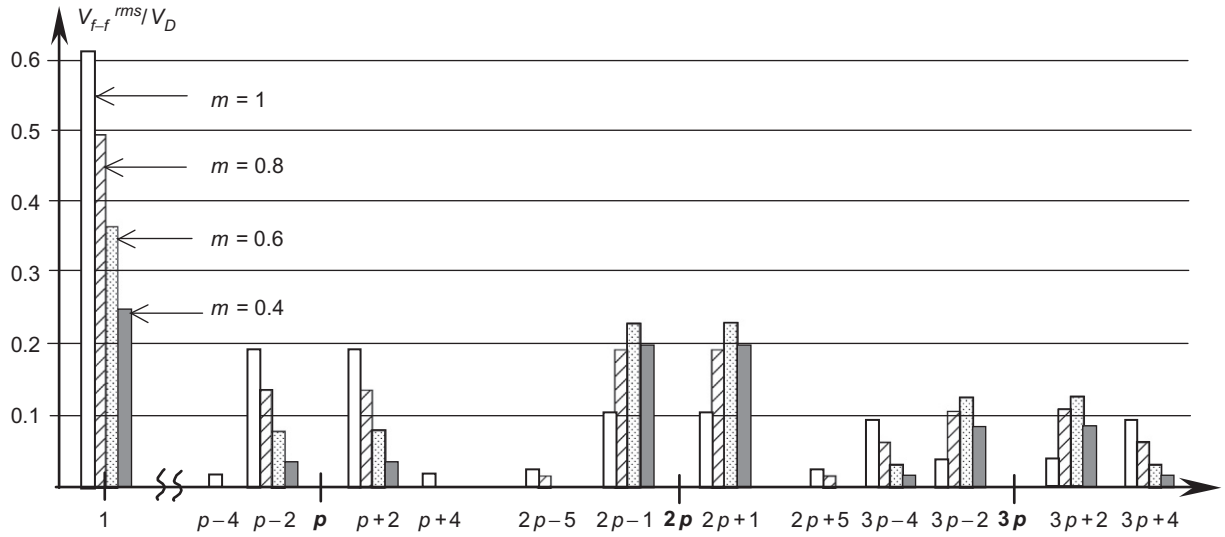

FIG. 9.52 Harmonic spectrum for SPWM modulation.

Due to the presence of the input inductance L_S, the harmonic currents that result are proportionally attenuated with the harmonic number. This characteristic is shown in the current waveforms of Fig. 9.53, where larger p numbers generate cleaner currents. The rectifier that originated the currents of Fig. 9.53 has the following characteristics: $V_D = 450 V_{dc}$, $V_{f-f}^{rms} = 220 V_{ac}$, $L_S = 2$ mH, and input current $I_S = 80$ A_{rms}. It can be observed that with $p > 21$, the current distortion is quite small. The value of $p = 81$ in Fig. 9.53 produces an almost pure sinusoidal waveform, and it means 4860 Hz of switching frequency at 60 Hz or only 4.050 Hz in a rectifier operating in a 50 Hz supply. This switching frequency can be managed by MOSFETs, IGBTs, and even Power Darlingtons. Then, a number $p = 81$ is feasible for today's low- and medium-power rectifiers.

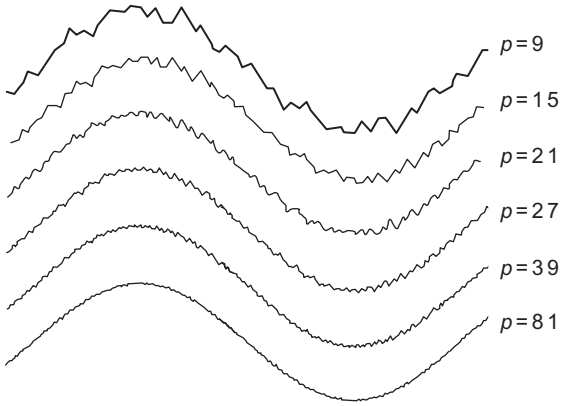

FIG. 9.53 Current waveforms for different values of p.

9.3.4.3 Voltage-Source Load-Controlled PWM Rectifier

A simple method of control for small PWM rectifiers (up to 10–20 kW) is based on direct control of the *dc* current. Fig. 9.54 shows the schematic of this control system. The fundamental voltage V_{MOD} modulated by the rectifier is produced by a fixed and unique PWM pattern, which can be carefully selected to eliminate most undesirable harmonics. As the PWM does not change, it can be stored in a permanent digital memory (ROM).

The control is based on changing the power angle δ between the mains voltage V and fundamental PWM voltage V_{MOD}. When δ changes, the amount of power flow transferred from the *ac* to the *dc* side also changes. When the power angle is negative (V_{MOD} lags V), the power flow goes from the *ac* to the *dc* side. When the power angle is positive, the power flows in the opposite direction. Then, the power angle can be controlled through the current I_D. The voltage V_D does not need to be sensed, because this control establishes a stable *dc* voltage operation for each *dc* current and power angle. With these characteristics, it is possible to find a relation between I_D and δ so as to obtain constant *dc* voltage for all load conditions. This relation is given by

$$I_D = f(\delta) = \frac{V\left(\cos\delta - \dfrac{\omega L_S}{R}\sin\delta - 1\right)}{R\left[1 + \left(\dfrac{\omega L_S}{R}\right)^2\right]} \tag{9.70}$$

From Eq. (9.70), a plot and a reciprocal function $\delta = f(I_D)$ is obtained to control the rectifier. The relation between I_D and δ allows for leading power factor operation and null regulation. The leading power factor operation is shown in the phasor diagram of Fig. 9.54.

The control scheme of the voltage-source load-controlled rectifier is characterized by the following: (i) There is neither

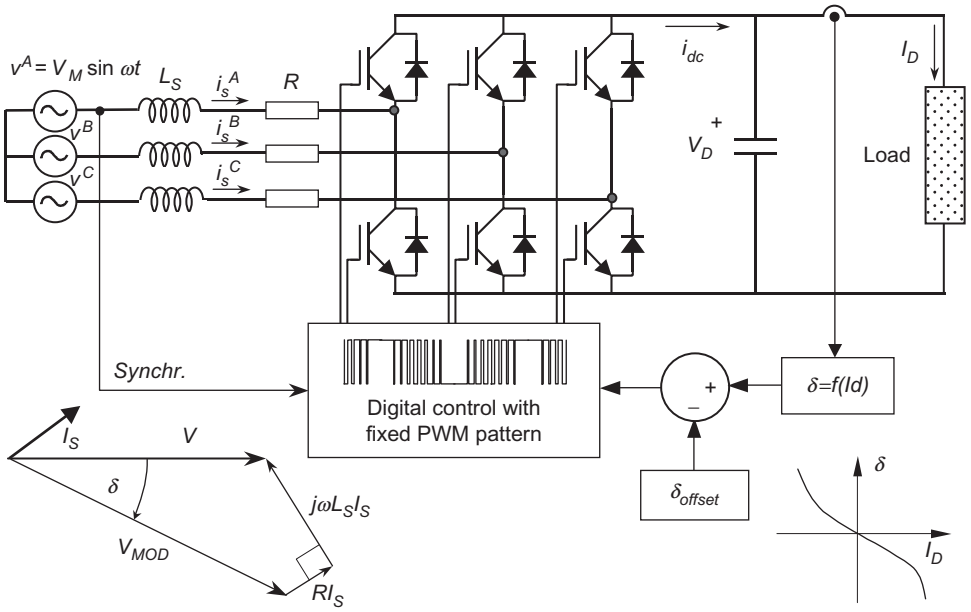

FIG. 9.54 Voltage-source load-controlled PWM rectifier.

input current sensors nor *dc* voltage sensor, (ii) it works with a fixed and predefined PWM pattern, (iii) it presents very good stability, (iv) its stability does not depend on the size of the *dc* capacitor, (v) it can work at leading power factor for all load conditions, and (vi) it can be adjusted with Eq. (9.70) to work at zero regulation. The drawback appears when R in Eq. (9.70) becomes negligible, because in such a case, the control system is unable to find an equilibrium point for the *dc* link voltage. That is why this control method is not applicable to large systems.

9.3.5 New Technologies and Applications of Force-Commutated Rectifiers

The additional advantages of force-commutated rectifiers with respect to line-commutated rectifiers make them better candidates for industrial requirements. They permit new applications such as rectifiers with harmonic elimination capability (active filters), power factor compensators, machine drives with four-quadrant operation, frequency links to connect 50 Hz with 60 Hz systems, and regenerative converters for traction power supplies. Modulation with very fast valves such as IGBTs permits almost sinusoidal currents to be obtained. The dynamics of these rectifiers is so fast that they can reverse power almost instantaneously. In machine drives, current-source PWM rectifiers, like the one shown in Fig. 9.35A, can be used to drive *dc* machines from the three-phase supply. Four-quadrant applications using voltage-source PWM rectifiers are extended for induction machines, synchronous machines with starting control, and special machines such as brushless dc motors. Back-to-back systems are being used in Japan to link power systems with different frequencies.

9.3.5.1 Active Power Filter

Force-commutated PWM rectifiers can work as active power filters. The voltage-source current-controlled rectifier has the capability to eliminate harmonics produced by other polluting loads. It only needs to be connected as shown in Fig. 9.55.

The current sensors are located at the input terminals of the power source, and these currents (instead of the rectifier currents) are forced to be sinusoidal. As there are polluting loads in the system, the rectifier is forced to deliver the harmonics that loads need, because the current sensors do not allow the harmonics going to the mains. As a result, the rectifier currents become distorted, but an adequate *dc* capacitor C_D can keep the *dc* link voltage in good shape. In this way, the rectifier can do its duty and also eliminate harmonics to the source. In addition, it also can compensate power factor and unbalanced load problems.

9.3.5.2 Frequency Link Systems

Frequency link systems permit power to be transferred form one frequency to another one. They are also useful for linking unsynchronized networks. Line-commutated converters are widely used for this application, but they have some drawbacks that force-commutated converters can eliminate. For example, the harmonic filter requirement, the poor power factor, and the necessity to count with a synchronous compensator when generating machines at the load side are absent. Fig. 9.56 shows a typical line-commutated system in which a 60 Hz load is fed by a 50 Hz supply. As the 60 Hz side needs excitation to commutate the valves, a synchronous compensator has been required.

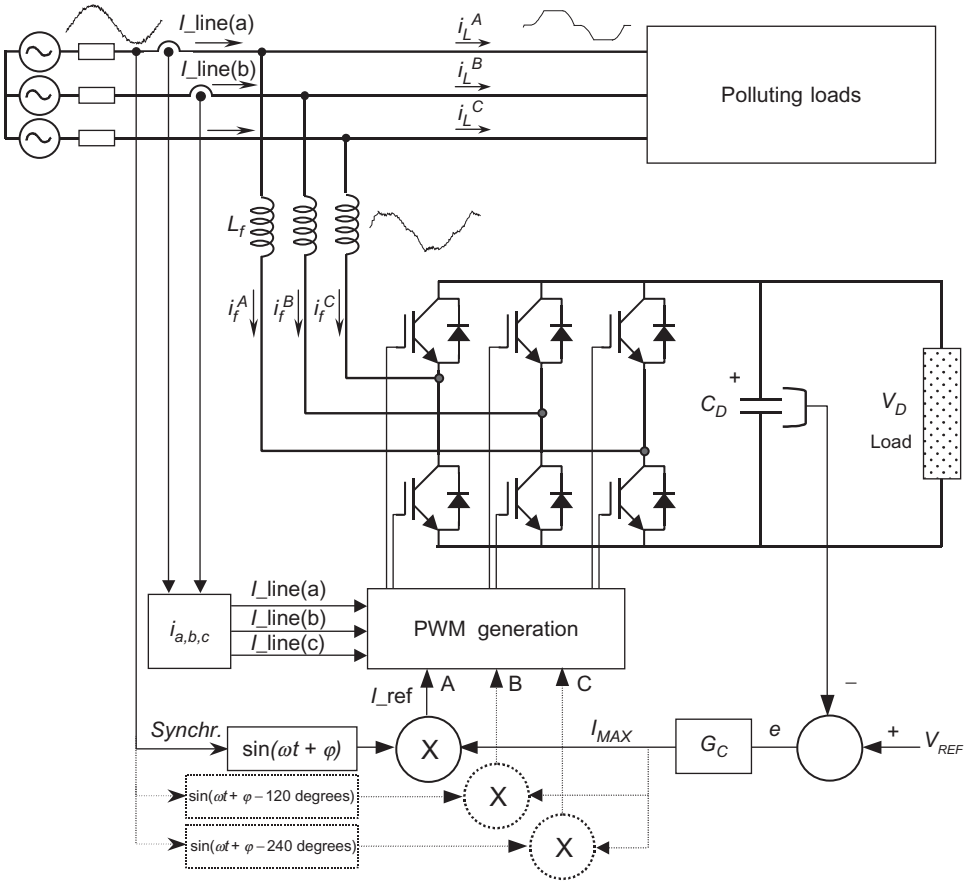

FIG. 9.55 Voltage-source rectifier with harmonic elimination capability.

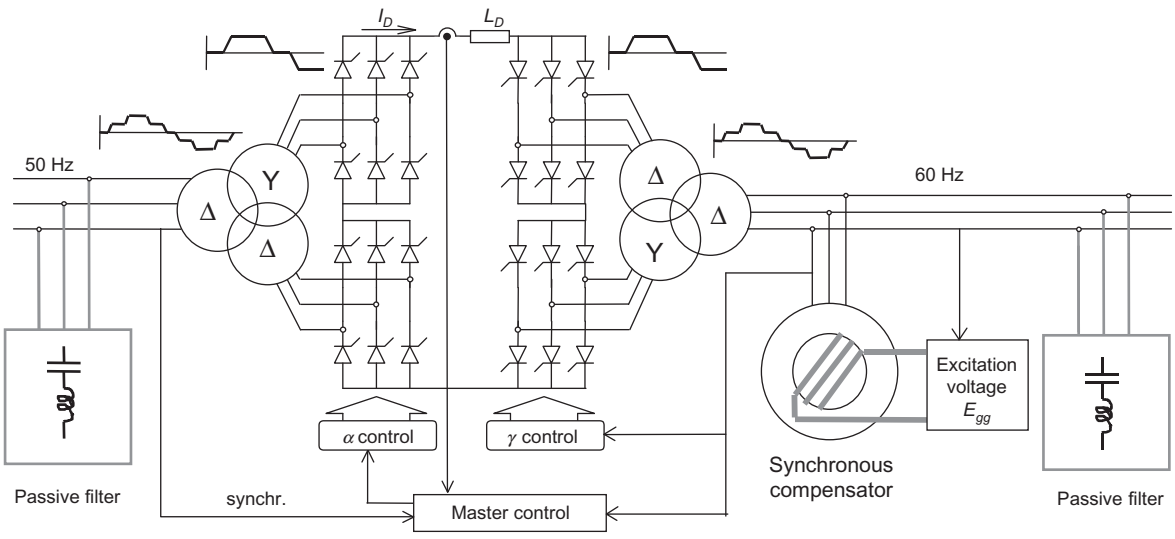

FIG. 9.56 Frequency link systems with line-commutated converters.

In contrast, an equivalent system with force-commutated converters is simpler, cleaner, and more reliable. It is implemented with a *dc* voltage-controlled rectifier and another identical converter working in the inversion mode. The power factor can be adjusted independently at the two *ac* terminals, and filters or synchronous compensators are not required. Fig. 9.57 shows a frequency-link system with force-commutated converters.

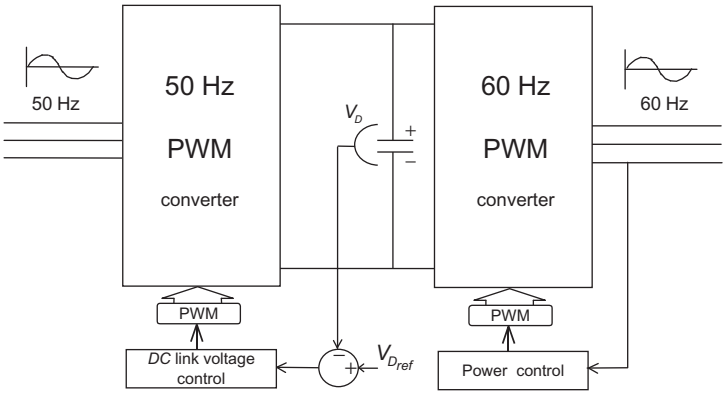

FIG. 9.57 Frequency link systems with force-commutated converters.

9.3.5.3 Special Topologies for High Power Applications

High-power applications require series- and/or parallel-connected rectifiers. Series and parallel operations with force-commutated rectifiers allow improving the power quality because harmonic cancelation can be applied to these topologies. Fig. 9.58 shows a series connection of force-commutated rectifiers, where the modulating carriers of the valves in each bridge are shifted to cancel harmonics. The example uses sinusoidal PWM that are with TC shifted.

The waveforms of the input currents for the series connection system are shown in Fig. 9.59. The frequency modulation ratio shown in this figure is for $p=9$. The carriers are shifted by 90 degrees each, to obtain harmonic cancelation. Shifting of the carriers δ_T depends on the number of converters in series (or in parallel) and is given by

$$\delta_T = \frac{2\pi}{n} \tag{9.71}$$

where n is the number of converters in series or in parallel. It can be observed that despite the low value of p, the total current becomes quite clean and clear, better than the current of one of the converters in the chain.

The harmonic cancelation with series- or parallel-connected rectifiers, using the same modulation but the carriers shifted, is quite effective. The resultant current is better with n converters and frequency modulation $p=p_1$ than with one converter and $p=np_1$. This attribute is verified in Fig. 9.60, where the total current of four converters in series with $p=9$ and carriers shifted is compared with the current of only one converter and $p=36$. This technique also allows for the use of valves with slow commutation times, such as high-power GTOs. Generally, high-power valves have low commutation times, and hence, the parallel and/or series options remain very attractive.

Another special topology for high power was implemented for Asea Brown Boveri (ABB) in Bremen. A 100 MW power converter supplies energy to the railways at $16^{2/3}$ Hz. It uses basic "H" bridges like the one shown in Fig. 9.61, connected to the load through power transformers. These transformers are connected in parallel at the converter side and in series at the load side.

The system uses SPWM with TCs shifted, and depending on the number of converters connected in the chain of bridges, the voltage waveform becomes more and more sinusoidal. Fig. 9.62 shows a back-to-back system using a chain of 12 "H" converters connected as shown in Fig. 9.61B.

The *ac* voltage waveform obtained with the topology of Fig. 9.62 is displayed in Fig. 9.63. It can be observed that the voltage is formed by small steps that depend on the number of converters in the chain (12 in this case). The current is almost perfectly sinusoidal.

Fig. 9.64 shows the voltage waveforms for different number of converters connected in the bridge. It is clear that the larger the number of converters, the better the voltage.

Another interesting result with this converter is that the *ac* voltages become modulated by both PWM and amplitude modulation (AM). This is because when the pulse modulation changes, the steps of the amplitude change. The maximum number of steps of the resultant voltage is equal to the number of converters. When the voltage decreases, some steps disappear, and then, the AM becomes a discrete function. Fig. 9.65 shows the AM of the voltage.

9.3.5.4 Machine Drives Applications

One of the most important applications of force-commutated rectifiers is in machine drives. Line-commutated thyristor converters have limited applications because they need excitation to extinguish the valves. This limitation does not allow the use of line-commutated converters in induction machine drives. On the other hand, with force-commutated converters, four-quadrant operation is achievable. Fig. 9.66 shows a typical frequency converter with a force-commutated rectifier-inverter link. The rectifier side controls the *dc* link, and the inverter side controls the machine. The machine can be a synchronous, brushless *dc*, or induction machine. The reversal of both speed and power is possible with this topology. At the rectifier side,

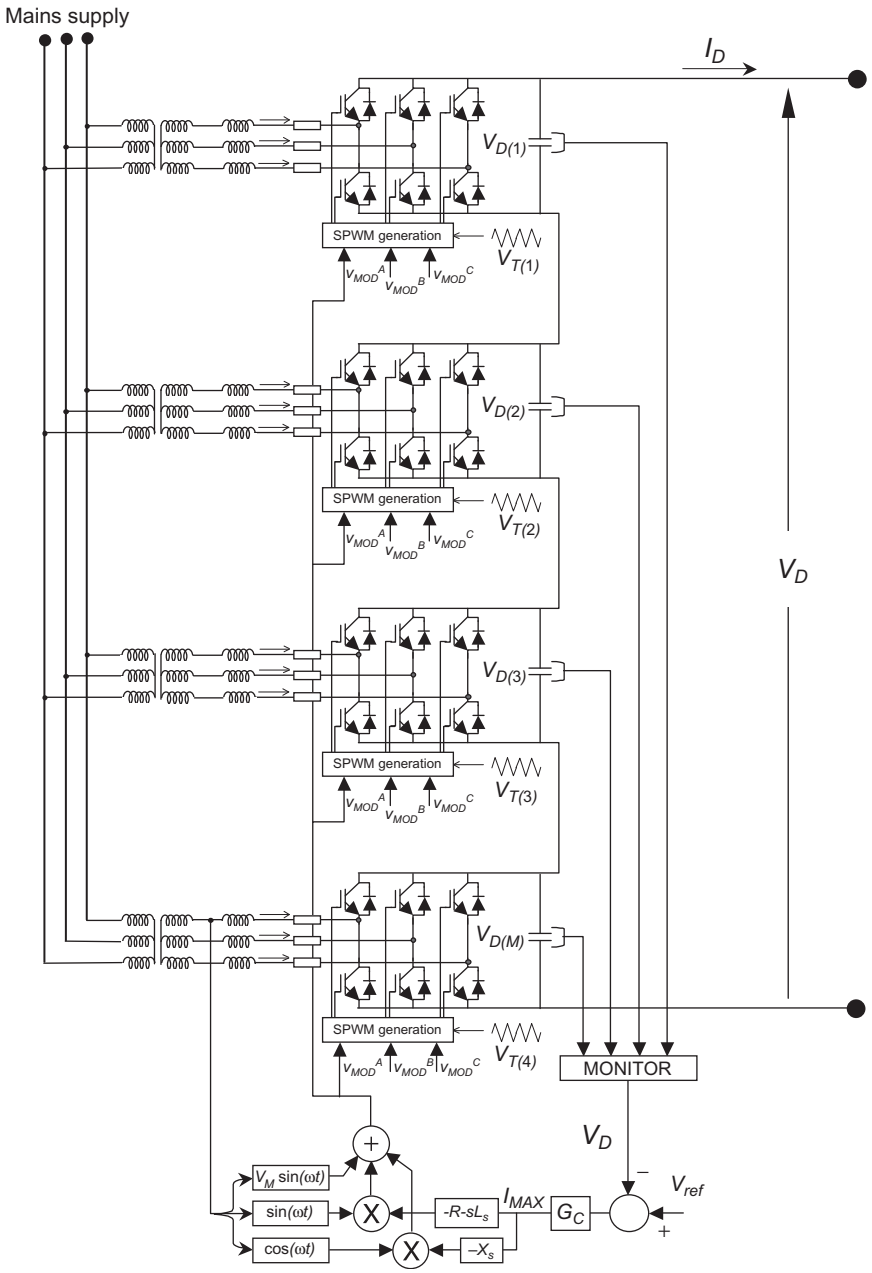

FIG. 9.58 Series connection system with force-commutated rectifiers.

the power factor can be controlled, and even with an inductive load such as an induction machine, the source can "see" the load as capacitive or resistive. Changing the frequency of the inverter controls the machine speed, and the torque is controlled through the stator currents and torque angle. The inverter will become a rectifier during regenerative braking, which is possible by making slip negative in an induction machine or by making the torque angle negative in synchronous and brushless *dc* machines.

A variation of the drive of Fig. 9.66 is found in electric traction applications. Battery-powered vehicles use the inverter as a rectifier during regenerative braking, and sometimes, the inverter is also used as a battery charger. In this case, the rectifier can be fed by a single-phase or three-phase system. Fig. 9.67 shows a battery-powered electric bus system. This system uses the power inverter of the traction motor as rectifier for two purposes: regenerative braking and as a battery charger fed by a three-phase power source.

9.3.5.5 Variable Speed Power Generation

Power generation at 50 or 60 Hz requires constant speed machines. In addition, induction machines are not currently

used in power plants because of magnetization problems. With the use of frequency-link force-commutated converters, variable-speed constant-frequency generation becomes possible even with induction generators. The power plant in Fig. 9.68 shows a wind generator implemented with an induction machine and a rectifier-inverter frequency link connected to the utility. The *dc* link voltage is kept constant with the converter located at the mains side. The converter connected at the machine side controls the slip of the generator and adjusts it according to the speed of wind or power requirements. The utility is not affected by the power factor of the generator, because the two converters keep the cos φ of the machine independent of the mains supply. The converter at the mains side can even be adjusted to operate at leading power factor.

Variable-speed constant-frequency generation also can be used in either hydraulic or thermal plants. This allows for optimal adjustment of the efficiency-speed characteristics of the machines. In many places, wound rotor induction generators working as variable-speed synchronous machines are being used as constant-frequency generators. They operate in hydraulic plants that are able to store water during low-demand periods. A power converter is connected at the slip rings of the generator. The rotor is then fed with variable-frequency excitation. This allows the generator to generate at different speeds around the synchronous rotating flux.

9.3.5.6 Power Rectifiers Using Multilevel Topologies

Almost all voltage-source rectifiers already described are two-level configurations. Today, multilevel topologies are becoming very popular, mainly three-level converters. The most popular three-level configuration is called diode-clamped converter, which is shown in Fig. 9.69. This topology is today the standard

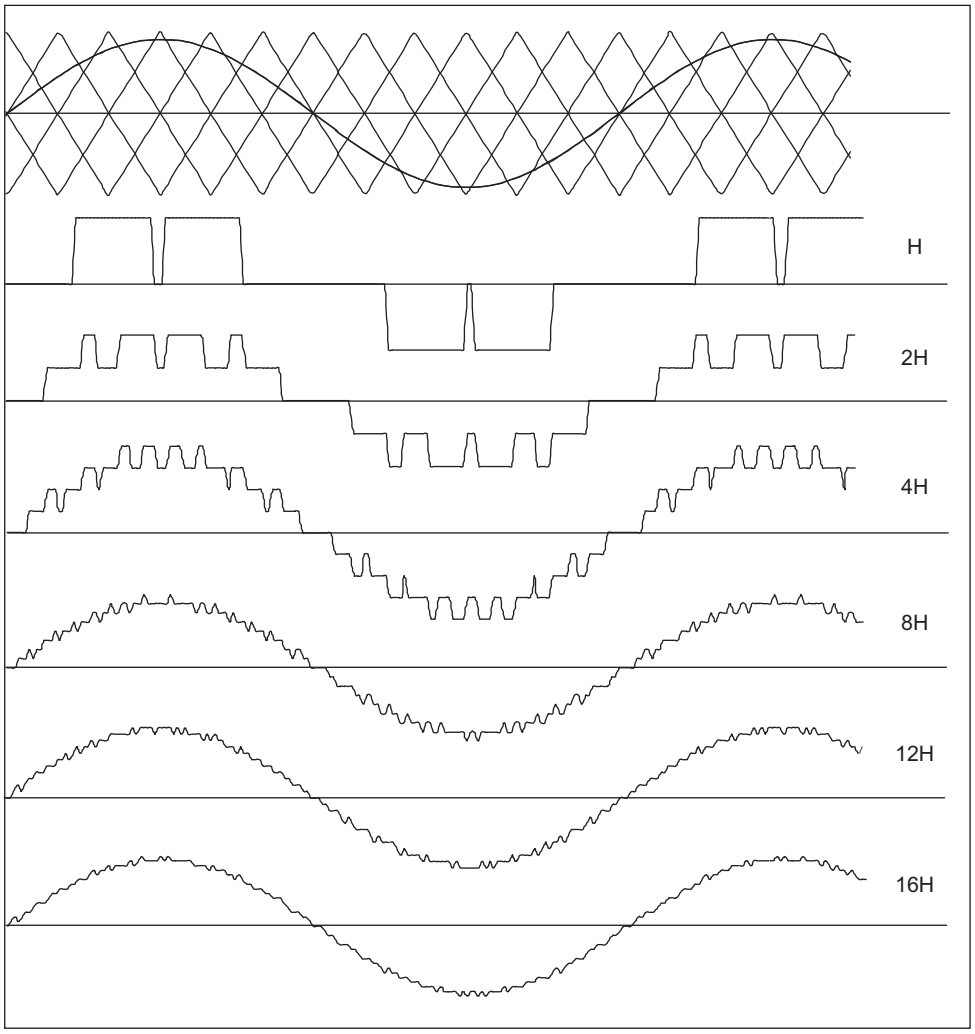

FIG. 9.64 Voltage waveforms with different numbers of "H" bridges in series.

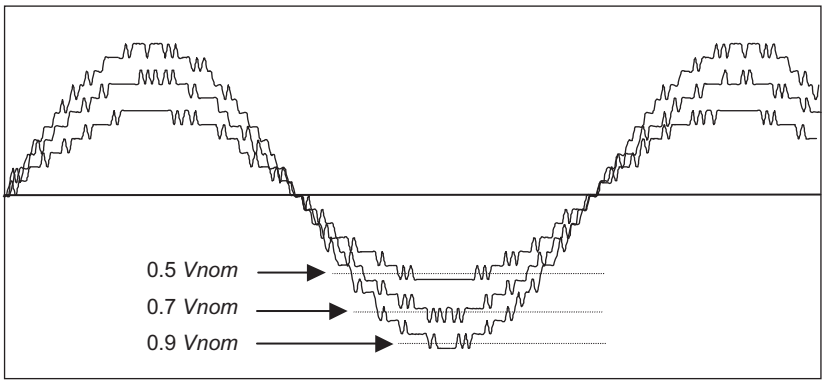

FIG. 9.65 Amplitude modulation of the "H" bridges of Fig. 9.62.

solution for high-power steel rolling mills, which uses back-to-back three-phase rectifier-inverter link configuration. In addition, this solution has been recently introduced in high-power downhill conveyor belts that operate almost permanently in the regeneration mode or rectifier operation. The more important advantage of three-level rectifiers is that voltage and current harmonics are reduced due to the increased number of levels.

Higher number of levels can be obtained using the same diode-clamped strategy, as shown in Fig. 9.70, where only

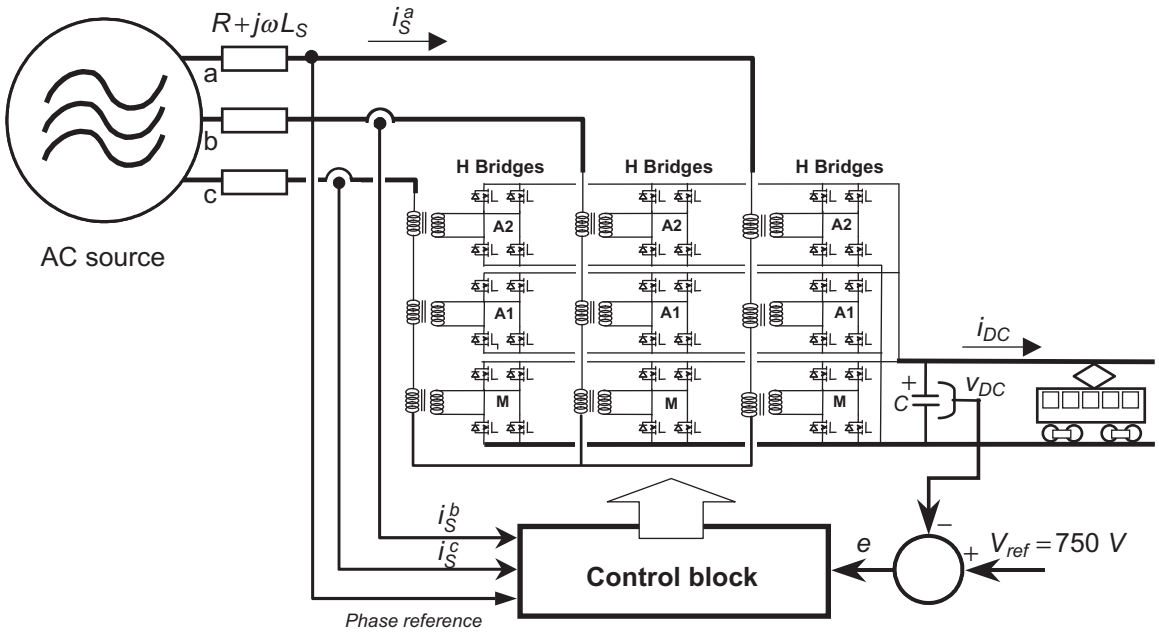

FIG. 9.71 Twenty-seven-level rectifier for railways, using H-bridges scaled in power of three.

one phase of a general approach is displayed. However, this topology becomes more and more complex with the increase of the number of levels. For this reason, new topologies are being studied to get a large number of levels with less power transistors. One example of such of these topologies is the multistage, 27-level converter shown in Fig. 9.71. This special 27-level, 4-quadrant rectifier uses only 3 H-bridges per phase with independent input transformers for each H-bridge. The transformers allow galvanic isolation and power escalation to get high-quality voltage waveforms, with *THD* of less than 1%. The power scalation consists on increasing the voltage rates of each transformer making use of the "three-level" characteristics of H-bridges. Then, the number of levels is optimized when transformers are scaled in power of three. Some advantages of this 27-level topology are the following: (a) Only one of the three H-bridges, called "main converter," manages more

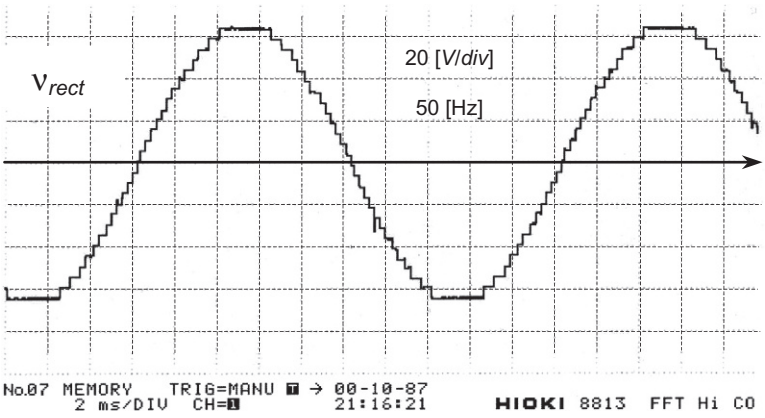

FIG. 9.72 *AC* voltage waveform generated by the 27-level rectifier.

than 80% of the total active power in each phase, and (b) this main converter switches at fundamental frequency reducing the switching losses at a minimum value. The rectifier of Fig. 9.71 is a current-controlled voltage-source type, with a conventional feedback control loop, which is being used as a rectifier in a subway substation. It includes fast reversal of power and the ability to produce clean *ac* and *dc* waveforms with negligible ripple. This rectifier can also compensate power factor and eliminate harmonics produced by other loads in the *ac* line. Fig. 9.72 shows the *ac* voltage waveform obtained with this rectifier from an experimental prototype. If one more H-bridge is added, 81 levels are obtained, because the number of levels increases according with $N=3^k$, where N is the number of levels or voltage steps and k the number of H-bridges used per phase.

Many other high-level topologies are under study, but this matter is beyond the main topic of this chapter.

10.1 Introduction

Modern electronic systems require high-quality, small, lightweight, reliable, and efficient power supplies. Linear power regulators, whose principle of operation is based on a voltage or current divider, are inefficient. They are limited to output voltages smaller than the input voltage. Also, their power density is low because they require low-frequency (50 or 60 Hz) line transformers and filters. Linear regulators can, however, provide a very high-quality output voltage. Their main area of application is at low power levels as low-dropout voltage (LDO) regulators. Electronic devices in linear regulators operate in their active (linear) modes. At higher power levels, switching regulators are used. Switching regulators use power electronic semiconductor switches in *on* and *off* states. Since there is a small power loss in those states (low voltage across a switch in the *on* state, zero current through a switch in the *off* state), switching regulators can achieve high energy conversion efficiencies. Modern power electronic switches can operate at high frequencies. The higher the operating frequency, the smaller and lighter the transformers, filter inductors, and capacitors. In addition, dynamic characteristics of converters improve with increasing operating frequencies. The bandwidth of a control loop is usually determined by the corner frequency of the output filter. Therefore, high operating frequencies allow for achieving a faster dynamic response to rapid changes in the load current and/or the input voltage.

High-frequency electronic power processors are used in dc-dc power conversion. The functions of dc-dc converters are

- to convert a dc input voltage V_S into a dc output voltage V_O,
- to regulate the dc output voltage against load and line variations,
- to reduce the ac voltage ripple on the dc output voltage below the required level,
- to provide isolation between the input source and the load (isolation is not always required),
- to protect the supplied system and the input source from electromagnetic interference (EMI),
- to satisfy various international and national safety standards.

The dc-dc converters can be divided into two main types: hard-switching pulse-width-modulated (PWM) converters and resonant and soft-switching converters. This chapter deals with the former type of dc-dc converters. The PWM converters have been very popular for the last three decades. They are widely used at all power levels. Topologies and properties of PWM converters are well understood and described in literature. Advantages of PWM converters include low component count, high efficiency, constant frequency operation, relatively

http://dx.doi.org/10.1016/B978-0-12-811407-0.00010-6

simple control and commercial availability of integrated circuit controllers, and ability to achieve high conversion ratios for both step-down and step-up application. A disadvantage of PWM dc-dc converters is that PWM rectangular voltage and current waveforms cause turn-on and turn-off losses in semiconductor devices that limit practical operating frequencies to a megahertz range. Rectangular waveforms also inherently generate EMI.

This chapter starts from a section on dc choppers that are used primarily in dc drives. The output voltage of dc choppers is controlled by adjusting the *on* time of a switch, which in turn adjusts the width of a voltage pulse at the output. This is the so-called pulse-width-modulation (PWM) control. The dc choppers with additional filtering components form PWM dc-dc converters. Four basic dc-dc converter topologies are presented in Sections 10.3–10.6: buck, boost, buck-boost, and Ćuk converters. Popular isolated versions of these converters are also discussed. Operation of converters is explained under ideal component and semiconductor device assumptions. Section 10.7 discusses effects of nonidealities in PWM converters. Section 10.8 presents topologies for increased efficiency at low output voltage and for bidirectional power flow. Section 10.9 reviews control principles of PWM dc-dc converters. Two main control schemes, voltage-mode control and current-mode control, are described. Summary of application areas of PWM dc-dc converters is given in Section 10.10. Finally, a list of modern textbooks on power electronics is provided. These books are excellent resources for deeper exploration of the area of dc-dc power conversion.

10.2 DC Choppers

A step-down dc chopper with a resistive load is shown in Fig. 10.1A. It is a series connection of a dc input voltage source V_S, controllable switch S, and load resistance R. In most cases, switch S has a unidirectional voltage blocking capabilities and unidirectional current conduction capabilities. Power electronic switches are usually implemented with power MOSFETs, IGBTs, MCTs, power BJTs, or GTOs. If an antiparallel diode is used or embedded in a switch, a switch exhibits a bidirectional current conduction property. Fig. 10.1B depicts waveforms in a step-down chopper. The switch is being operated with a duty ratio D defined as a ratio of the switch *on* time to the sum of the *on* and the *off* times. For a constant frequency operation,

$$D \equiv \frac{t_{on}}{t_{on} + t_{off}} = \frac{t_{on}}{T} \tag{10.1}$$

where $T = 1/f$ is the period of the switching frequency f. The average value of the output voltage is

$$V_O = DV_S \tag{10.2}$$

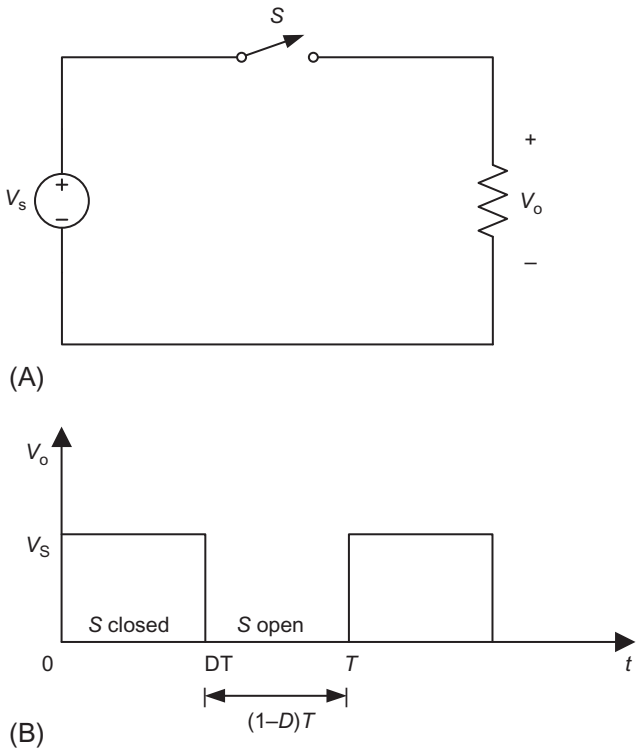

FIG. 10.1 DC chopper with resistive load, (A) circuit diagram and (B) output voltage waveform.

and can be regulated by adjusting duty ratio D. The average output voltage is always smaller than the input voltage, hence, the name of the converter.

The dc step-down choppers are commonly used in dc drives. In such a case, the load is presented as a series combination of inductance L, resistance R, and back emf E as shown in Fig. 10.2A. To provide a path for a continuous inductor current flow when the switch is in the *off* state, an antiparallel diode D must be connected across the load. Since the chopper of Fig. 10.2A provides a positive voltage and a positive current to the load, it is called a first-quadrant chopper. The load voltage and current are graphed in Fig. 10.2B under assumptions that the load current never reaches zero and the load time constant $\tau = L/R$ is much greater than the period T. Average values of the output voltage and current can be adjusted by changing the duty ratio D.

The dc choppers can also provide peak output voltages higher than the input voltage. Such a step-up configuration is presented in Fig. 10.3. It consists of dc input source V_S, inductor L connected in series with the source, switch S connecting the inductor to ground, and a series combination of diode D and load. If the switch operates with a duty ratio D, the output voltage is a series of pulses of duration $(1-D)T$ and amplitude $V_S/(1-D)$. Neglecting losses, the average value of the output voltage is V_S. To obtain an average value of the output voltage greater than V_S, a capacitor must be connected in parallel with

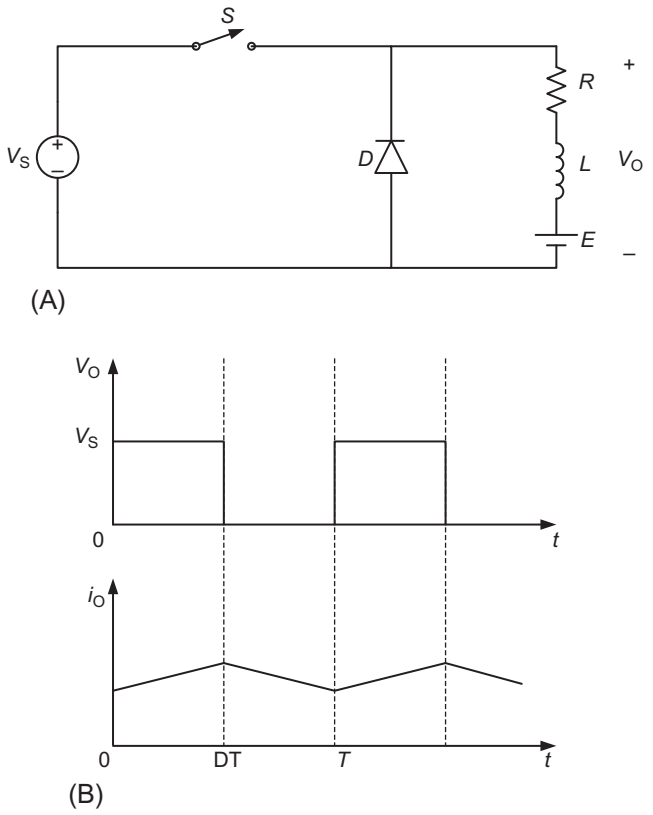

FIG. 10.2 DC chopper with RLE load, (A) circuit diagram and (B) waveforms.

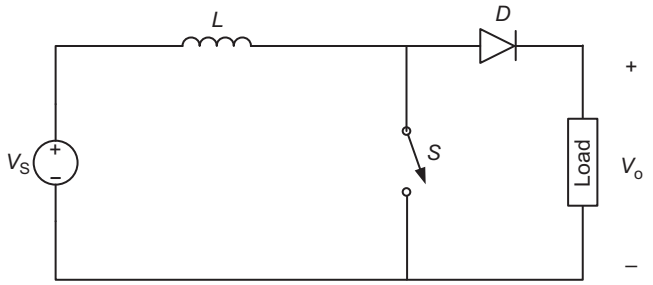

FIG. 10.3 The dc step-up chopper.

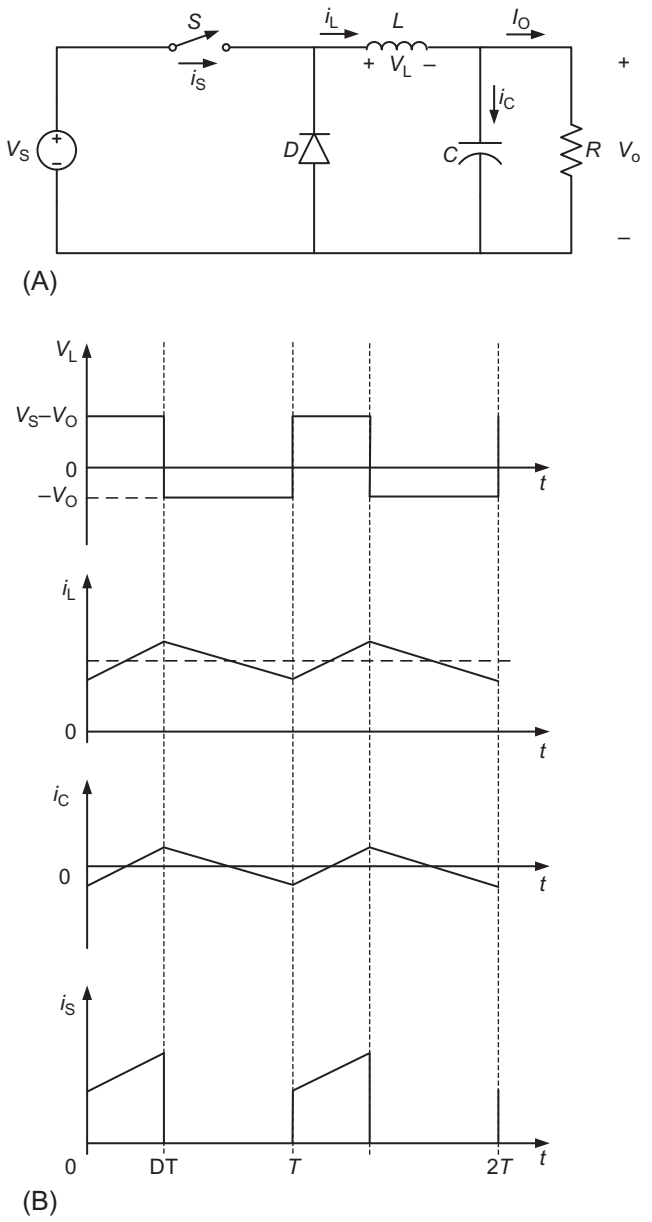

FIG. 10.4 Buck converter: (A) circuit diagram and (B) waveforms.

the load. This results in a topology of a boost dc-dc converter that is described in Section 10.4.

10.3 Step-Down (Buck) Converter

10.3.1 Basic Converter

The step-down dc-dc converter, commonly known as a buck converter, is shown in Fig. 10.4A. It consists of dc input voltage source V_S, controlled switch *S*, diode *D*, filter inductor *L*, filter capacitor *C*, and load resistance *R*. Typical waveforms in the converter are shown in Fig. 10.4B under assumption that the inductor current is always positive. The state of the converter in which the inductor current is never zero for any period of time is called the continuous conduction mode (CCM). It can be seen from the circuit that when the switch *S* is commanded to the *on* state, the diode *D* is reverse biased. When the switch *S* is off, the diode conducts to support an uninterrupted current in the inductor.

The relationship among the input voltage, output voltage, and the switch duty ratio *D* can be derived, for instance, from the inductor voltage v_L waveform (see Fig. 10.4B). According to Faraday's law, the inductor volt-second product over a period of steady-state operation is zero. For the buck converter,

$$(V_S - V_O)DT = -V_O(1-D)T \tag{10.3}$$

Hence, the dc voltage transfer function, defined as the ratio of the output voltage to the input voltage, is

$$M_V \equiv \frac{V_O}{V_S} = D \tag{10.4}$$

It can be seen from Eq. (10.4) that the output voltage is always smaller than the input voltage.

The dc-dc converters can operate in two distinct modes with respect to the inductor current i_L. Fig. 10.4B depicts the CCM in which the inductor current is always greater than zero. When the average value of the input current is low (high R) and/or the switching frequency f is low, the converter may enter the discontinuous conduction mode (DCM). In the DCM, the inductor current is zero during a portion of the switching period. The CCM is preferred for high efficiency and good utilization of semiconductor switches and passive components. The DCM may be used in applications with special control requirements, since the dynamic order of the converter is reduced (the energy stored in the inductor is zero at the beginning and at the end of each switching period). It is uncommon to mix these two operating modes because of different control algorithms. For the buck converter, the value of the filter inductance that determines the boundary between CCM and DCM is given by

$$L_b = \frac{(1-D)R}{2f} \tag{10.5}$$

For typical values of $D = 0.5$, $R = 10\,\Omega$, and $f = 100\,\text{kHz}$, the boundary is $L_b = 25\,\mu\text{H}$. For $L > L_b$, the converter operates in the CCM.

The filter inductor current i_L in the CCM consists of a dc component I_O with a superimposed triangular ac component. Almost all of this ac component flows through the filter capacitor as a current i_c. Current i_c causes a small voltage ripple across the dc output voltage V_O. To limit the peak-to-peak value of the ripple voltage below certain value V_r, the filter capacitance C must be greater than

$$C_{min} = \frac{(1-D)V_O}{8V_r L f^2} \tag{10.6}$$

At $D = 0.5$, $V_r/V_O = 1\%$, $L = 25\,\mu\text{H}$, and $f = 100\,\text{kHz}$, the minimum capacitance is $C_{min} = 25\,\mu\text{F}$.

Eqs. (10.5) and (10.6) are the key design equations for the buck converter. The input and output dc voltages (hence the duty ratio D) and the range of load resistance R are usually determined by preliminary specifications. The designer needs to determine values of passive components L and C and of the switching frequency f. The value of the filter inductor L is calculated from the CCM/DCM condition using Eq. (10.5). The value of the filter capacitor C is obtained from the voltage ripple condition Eq. (10.6). For the compactness and low conduction losses of a converter, it is desirable to use small passive components. Eqs. (10.5) and (10.6) show that it can be accomplished by using a high switching frequency f. The switching frequency is limited, however, by the type of semiconductor switches used and by switching losses. It should be also noted that values of L and C may be altered by effects of parasitic components in the converter, especially by the equivalent series resistance of the capacitor. The issue of parasitic components in dc-dc converters is discussed in Section 10.7.

10.3.2 Transformer Versions of Buck Converter

In many dc power supplies, a galvanic isolation between the dc or ac input and the dc output is required for safety and reliability. An economical mean of achieving such an isolation is to employ a transformer version of a dc-dc converter. High-frequency transformers are of a small size and weight and provide high efficiency. Their turns ratio can be used to additionally adjust the output voltage level. Among buck-derived dc-dc converters, the most popular are forward converter, push-pull converter, half-bridge converter, and full-bridge converter.

10.3.2.1 Forward Converter

The circuit diagram of a forward converter is depicted in Fig. 10.5. When the switch S is *on*, diode D_1 conducts, and diode D_2 is *off*. The energy is transferred from the input, through the transformer, to the output filter. When the switch is *off*, the state of diodes D_1 and D_2 is reversed. The dc voltage transfer function of the forward converter is

$$M_V = \frac{D}{n} \tag{10.7}$$

where $n = N_1/N_2$.

In the forward converter, the energy-transfer current flows through the transformer in one direction. Hence, an additional winding with diode D_3 is needed to bring the magnetizing current of the transformer to zero. This prevents transformer saturation. The turns ratio N_1/N_3 should be selected in such a way that the magnetizing current decreases to zero during a fraction of the time interval when the switch is *off*.

Eqs. (10.5) and (10.6) can be used to design the filter components. The forward converter is very popular for low-power applications. For medium power levels, converters with

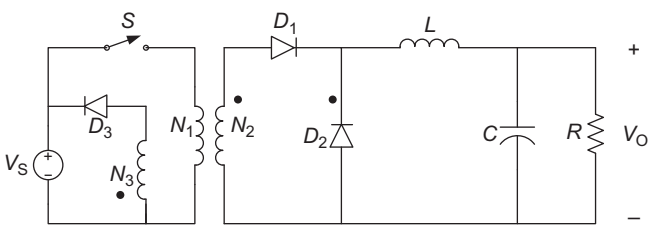

FIG. 10.5 Forward converter.

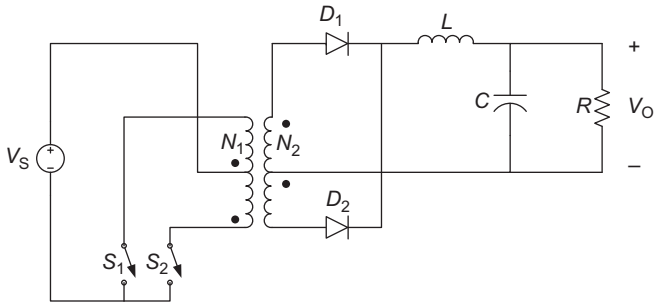

FIG. 10.6 Push-pull converter.

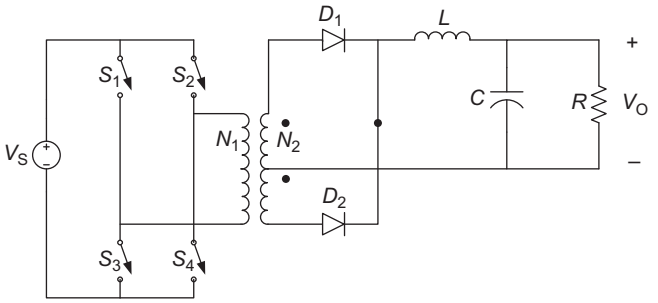

FIG. 10.8 Full-bridge converter.

bidirectional transformer excitation (push-pull, half bridge, and full bridge) are preferred due to better utilization of magnetic components.

10.3.2.2 Push-Pull Converter

The PWM dc-dc push-pull converter is shown in Fig. 10.6. The switches S_1 and S_2 operate shifted in phase by $T/2$ with the same duty ratio D. The duty ratio must be smaller than 0.5. When switch S_1 is *on*, diode D_1 conducts, and diode D_2 is *off*. Diode states are reversed when switch S_2 is *on*. When both controllable switches are *off*, the diodes are *on* and share equally the filter inductor current. The dc voltage transfer function of the push-pull converter is

$$M_V = \frac{2D}{n} \tag{10.8}$$

where $n = N_1/N_2$. The boundary value of the filter inductor is

$$L_b = \frac{(1-2D)R}{4f} \tag{10.9}$$

The filter capacitor can be obtained from

$$C_{min} = \frac{(1-2D)V_O}{32V_r L f^2} \tag{10.10}$$

10.3.2.3 Half-Bridge Converter

Fig. 10.7 shows the dc-dc half-bridge converter. The operation of the PWM half-bridge converter is similar to that of the push-pull converter. In comparison with the push-pull converter, the primary of the transformer is simplified at the expense of two voltage-sharing input capacitors. The half-bridge converter dc voltage transfer function is

$$M_V \equiv \frac{V_D}{V_S} = \frac{D}{n} \tag{10.11}$$

where $D \leq 0.5$. Eqs. (10.9) and (10.10) apply to the filter components of this converter.

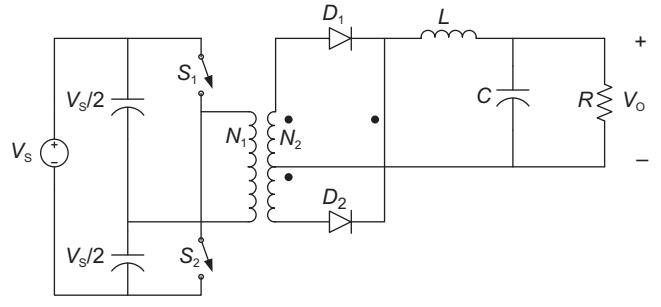

FIG. 10.7 Half-bridge converter.

10.3.2.4 Full-Bridge Converter

Comparing the PWM dc-dc full-bridge converter of Fig. 10.8 with the half-bridge converter, it can be seen that the input capacitors have been replaced by two controllable switches. The controllable switches are operated in pairs. When S_1 and S_4 are *on*, voltage V_S is applied to the primary of the transformer, and diode D_1 conducts. With S_2 and S_3 *on*, there is voltage $-V_S$ across the primary transformer, and diode D_2 is *on*. With all controllable switches *off*, both diodes conduct, similarly as in the push-pull and half-bridge converters. The dc voltage transfer function of the full-bridge converter is

$$M_V \equiv \frac{V_O}{V_S} = \frac{2D}{n} \tag{10.12}$$

where $D \leq 0.5$. Values of filter components can be obtained from Eqs. (10.9) and (10.10).

It should be stressed that the full-bridge topology is a very versatile one. With different control algorithms, it is very popular in dc-ac conversion (square-wave and PWM single-phase inverters). It is also used in four-quadrant dc drives.

10.4 Step-Up (Boost) Converter

Fig. 10.9A depicts a step-up or a PWM boost converter. It is composed of dc input voltage source V_S, boost inductor L, controlled switch S, diode D, filter capacitor C, and load resistance R. The converter waveforms in the CCM are presented in Fig. 10.9B. When the switch S is in the *on* state, the current in the boost inductor increases linearly. The diode D is *off* at

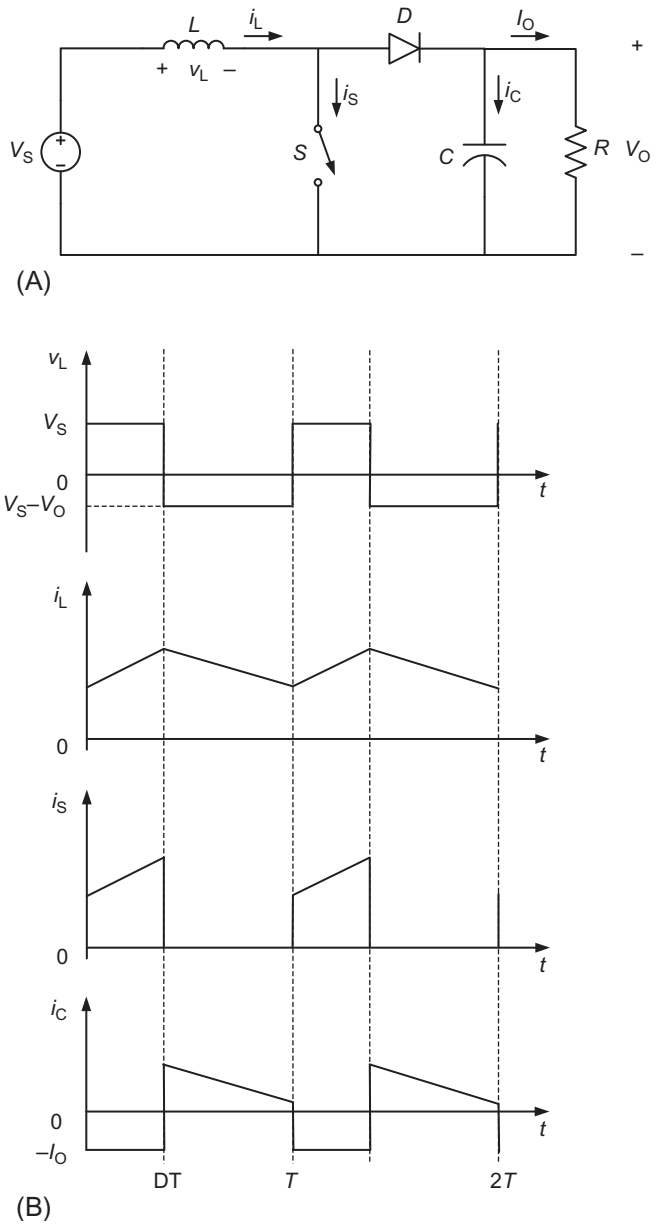

FIG. 10.9 Boost converter: (A) circuit diagram and (B) waveforms.

the time. When the switch S is turned *off*, the energy stored in the inductor is released through the diode to the input RC circuit.

Using the Faraday's law for the boost inductor,

$$V_S DT = (V_O - V_S)(1-D)T \tag{10.13}$$

from which the dc voltage transfer function turns out to be

$$M_V \equiv \frac{V_O}{V_S} = \frac{1}{1-D} \tag{10.14}$$

As the name of the converter suggests, the output voltage is always greater than the input voltage.

The boost converter operates in the CCM for $L > L_b$ where

$$L_b = \frac{(1-D)^2 DR}{2f} \tag{10.15}$$

For $D = 0.5$, $R = 10\,\Omega$, and $f = 100\,\text{kHz}$, the boundary value of the inductance is $L_b = 6.25\,\mu\text{H}$.

As shown in Fig. 10.9B, the current supplied to the output RC circuit is discontinuous. Thus, a larger filter capacitor is required in comparison with that in the buck-derived converters to limit the output voltage ripple. The filter capacitor must provide the output dc current to the load when the diode D is *off*. The minimum value of the filter capacitance that results in the voltage ripple V_r is given by

$$C_{min} = \frac{DV_O}{V_r Rf} \tag{10.16}$$

At $D = 0.5$, $V_r/V_O = 1\%$, $R = 10\,\Omega$, and $f = 100\,\text{kHz}$, the minimum capacitance for the boost converter is $C_{min} = 50\,\mu\text{F}$.

The boost converter does not have a popular transformer (isolated) version.

10.5 Buck-Boost Converter

10.5.1 Basic Converter

A nonisolated (transformerless) topology of the buck-boost converter is shown in Fig. 10.10A. The converter consists of dc input voltage source V_S, controlled switch S, inductor L, diode D, filter capacitor C, and load resistance R. With the switch *on*, the inductor current increases, while the diode is maintained *off*. When the switch is turned *off*, the diode provides a path for the inductor current. Note the polarity of the diode that results in its current being *drawn from* the output.

The buck-boost converter waveforms are depicted in Fig. 10.10B. The condition of a zero volt-second product for the inductor in steady state yields

$$V_S DT = -V_O(1-D)T \tag{10.17}$$

Hence, the dc voltage transfer function of the buck-boost converter is

$$M_V \equiv \frac{V_O}{V_S} = -\frac{D}{1-D} \tag{10.18}$$

The output voltage V_O is negative with respect to the ground. Its magnitude can be either greater or smaller (equal at $D = 0.5$) than the input voltage as the converter's name implies.

The value of the inductor that determines the boundary between the CCM and DCM is

$$L_b = \frac{(1-D)^2 R}{2f} \tag{10.19}$$

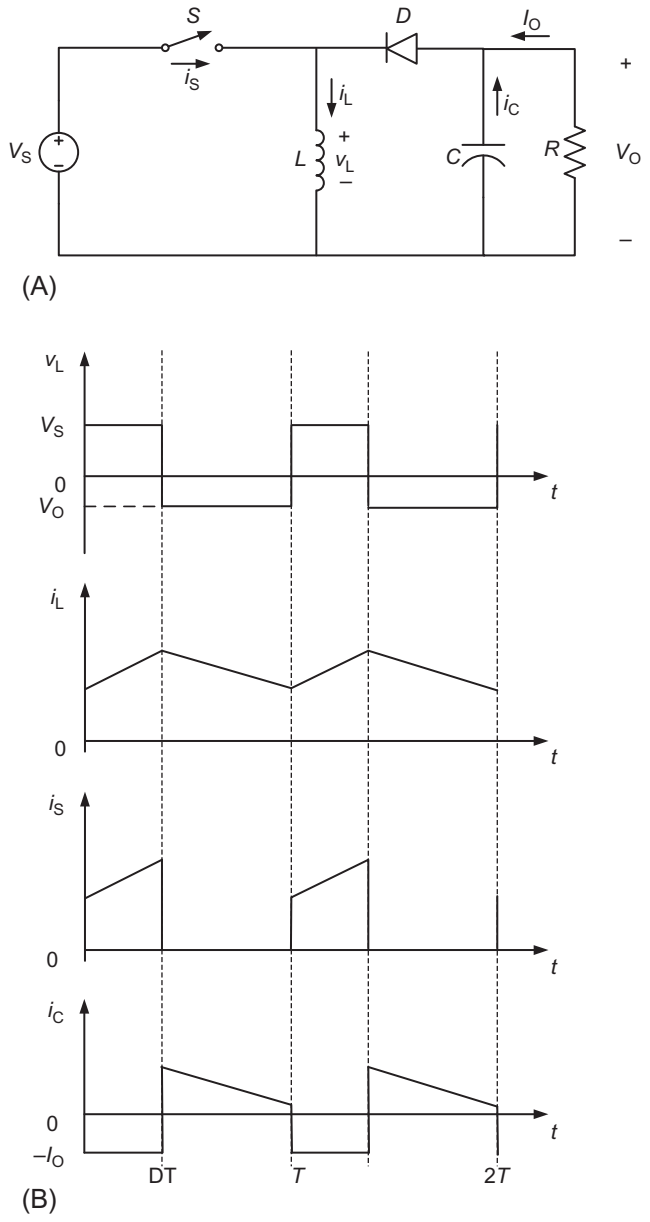

FIG. 10.10 Buck-boost converter: (A) circuit diagram and (B) waveforms.

The structure of the output part of the converter is similar to that of the boost converter (reversed polarities being the only difference). Thus, the value of the filter capacitor can be obtained from Eq. (10.16).

10.5.2 Flyback Converter

A PWM flyback converter is a very practical isolated version of the buck-boost converter. The circuit of the flyback converter is presented in Fig. 10.11A. The inductor of the buck-boost converter has been replaced by a flyback transformer. The input dc source V_S and switch S are connected in series with the primary

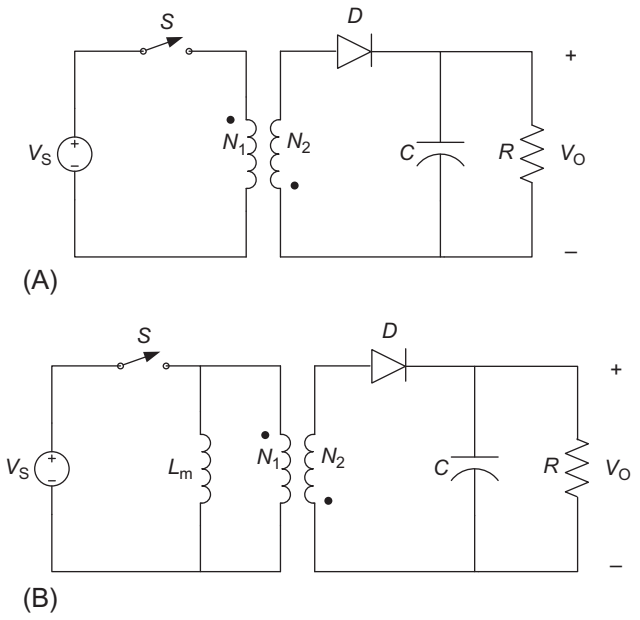

FIG. 10.11 Flyback converter: (A) circuit diagram and (B) circuit with a transformer model showing the magnetizing inductance L_m.

transformer. The diode D and the RC output circuit are connected in series with the secondary of the flyback transformer. Fig. 10.11B shows the converter with a simple flyback transformer model. The model includes a magnetizing inductance L_m and an ideal transformer with a turns ratio $n = N_1/N_2$. The flyback transformer leakage inductances and losses are neglected in the model. It should be noted that leakage inductances, although not important from the principle of operation point of view, affect adversely switch and diode transitions. Snubbers are usually required in flyback converters.

Refer to Fig. 10.11B for the converter operation. When the switch S is *on*, the current in the magnetizing inductance increases linearly. The diode D is *off*, and there is no current in the ideal transformer windings. When the switch is turned *off*, the magnetizing inductance current is diverted into the ideal transformer, the diode turns *on*, and the transformed magnetizing inductance current is supplied to the RC load. The dc voltage transfer function of the flyback converter is

$$M_V \equiv \frac{V_O}{V_S} = \frac{D}{n(1-D)} \tag{10.20}$$

It differs from the buck-boost converter voltage transfer function by the turns ratio factor n. A positive sign has been obtained by an appropriate coupling of the transformer windings.

Unlike in transformer buck-derived converters, the magnetizing inductance L_m of the flyback transformer is an important design parameter. The value of the magnetizing inductance that determines the boundary between the CCM and DCM is given by

$$L_{mb} = \frac{n^2(1-D)^2 R}{2f} \tag{10.21}$$

The value of the filter capacitance can be calculated using Eq. (10.16).

10.6 Ćuk Converter

The circuit of the Ćuk converter is shown in Fig. 10.12A. It consists of dc input voltage source V_S, input inductor L_1, controllable switch S, energy-transfer capacitor C_1, diode D, filter inductor L_2, filter capacitor C, and load resistance R. An important advantage of this topology is a continuous current at both the input and the output of the converter. Disadvantages of the Ćuk converter include a high number of reactive components and high current stresses on the switch, the diode, and the capacitor C_1. Main waveforms in the converter are presented in Fig. 10.12B. When the switch is *on*, the diode is *off*, and the capacitor C_1 is discharged by the inductor L_2 current. With the switch in the *off* state, the diode conducts currents of the inductors L_1 and L_2, whereas capacitor C_1 is charged by the inductor L_1 current.

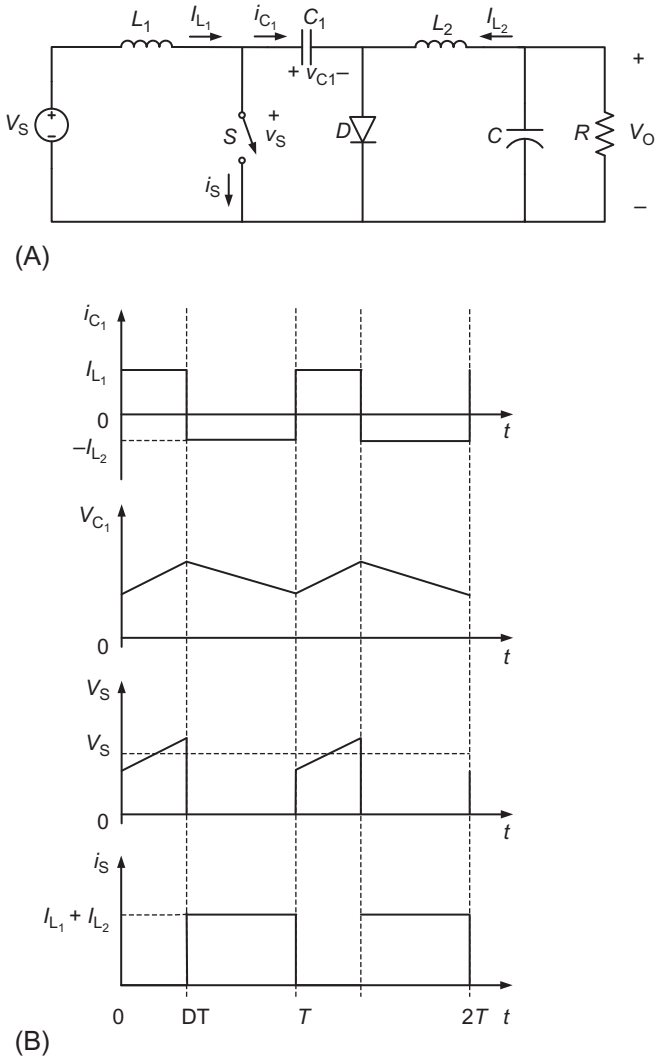

FIG. 10.12 Ćuk converter: (A) circuit diagram and (B) waveforms.

To obtain the dc voltage transfer function of the converter, we shall use the principle that the average current through a capacitor is zero for steady-state operation. Let us assume that inductors L_1 and L_2 are large enough that their ripple current can be neglected. Capacitor C_1 is in a steady state if

$$I_{L_2} DT = I_{L_1}(1-D)T \tag{10.22}$$

For a lossless converter,

$$P_S = V_S I_{L_1} = -V_O I_{L_2} = P_O \tag{10.23}$$

Combining these two equations, the dc voltage transfer function of the Ćuk converter is

$$M_V \equiv \frac{V_O}{V_S} = -\frac{D}{1-D} \tag{10.24}$$

This voltage transfer function is the same as that for the buck-boost converter.

The boundaries between the CCM and DCM are determined by

$$L_{b1} = \frac{(1-D)R}{2Df} \tag{10.25}$$

for L_1 and

$$L_{b2} = \frac{(1-D)R}{2f} \tag{10.26}$$

for L_2.

The output part of the Ćuk converter is similar to that of the buck converter. Hence, the expression for the filter capacitor C is

$$C_{min} = \frac{(1-D)V_O}{8V_r L_2 f^2} \tag{10.27}$$

The peak-to-peak ripple voltage in the capacitor C_1 can be estimated as

$$V_{r1} = \frac{DV_O}{C_1 Rf} \tag{10.28}$$

A transformer (isolated) version of the Ćuk converter can be obtained by splitting capacitor C_1 and inserting a high-frequency transformer between the split capacitors.

10.7 Effects of Parasitic Components

The analysis of converters in Sections 10.2–10.6 has been performed under ideal switch, diode, and passive component

assumptions. Nonidealities or parasitics of practical devices and components may, however, greatly affect some performance parameters of dc-dc converters. In this section, effects of parasitics on output voltage ripple, efficiency, and voltage transfer function of converters will be illustrated.

A more realistic model of a capacitor than just a capacitance C consists of a series connection of capacitance C and resistance r_C. The resistance r_C is called an equivalent series resistance (ESR) of the capacitor and is due to losses in the dielectric and physical resistance of leads and connections. Recall Eq. (10.6) that provided a value of the filter capacitance in a buck converter that limits the peak-to-peak output voltage ripple to V_r. The equation was derived under an assumption that the entire triangular ac component of the inductor current flows through a capacitance C. It is, however, closer to reality to maintain that this triangular component flows through a series connection of capacitance C and resistance r_C.

The peak-to-peak ripple voltage is independent of the voltage across the filter capacitor and is determined only by the ripple voltage of the ESR if the following condition is satisfied:

$$C \geq C_{\min} = \max\left\{\frac{1-D_{\min}}{2r_C f}, \frac{D_{\max}}{2r_C f}\right\} \tag{10.29}$$

If condition (10.29) is satisfied, the peak-to-peak ripple voltage of the buck and forward converters is

$$V_r = r_C \Delta i_{L\max} = \frac{r_C V_O (1-D_{\min})}{fL} \tag{10.30}$$

For push-pull, half-bridge, and full-bridge converters,

$$C \geq C_{\min} = \max\left\{\frac{0.5-D_{\min}}{2r_C f}, \frac{D_{\max}}{2r_C f}\right\} \tag{10.31}$$

where $D_{\max} \leq 0.5$. If condition (10.31) is met, the peak-to-peak ripple voltage V_r of these converters is given by

$$V_r = r_C \Delta i_{L\max} = \frac{r_C V_O (0.5-D_{\min})}{fL} \tag{10.32}$$

Waveforms of voltage across the ESR V_{rC}, voltage across the capacitance V_C, and total ripple voltage V_r are depicted in Fig. 10.13 for three values of the filter capacitances. For the case of the top graph in Fig. 10.13, the peak-to-peak value of V_r is higher than the peak-to-peak value of V_{rC} because $C < C_{\min}$. Middle and bottom graphs in Fig. 10.13 show the waveforms for $C = C_{\min}$ and $C > C_{\min}$, respectively. For both these cases, the peak-to-peak voltages of V_r and V_{rC} equal to each other.

Note that when the resistance r_C sets the ripple voltage V_r, the minimum value of inductance L is determined either by the boundary between the CCM and DCM according to Eq. (10.5) (buck and forward converters) or Eq. (10.9) (push-pull, half-bridge, and full-bridge converters) or by the voltage ripple condition (10.30) or (10.32).

In buck-boost and boost converters, the peak-to-peak capacitor current I_{Cpp} is equal to the peak-to-peak diode current and is given by

$$I_{Cpp} = \frac{I_O}{1-D} \tag{10.33}$$

under condition that the inductor current ripple is much lower than the average value of the inductor current. The peak-to-peak voltage across the ESR is

$$V_{rC} = r_C I_{Cpp} = \frac{r_C I_O}{1-D} \tag{10.34}$$

$L = 40\,\mu\text{H}$, $r_C = 0.05\,\Omega$, and various values of C: $C = 33\,\mu\text{F}$ (top graph), $C = C_{\min} = 65\,\mu\text{F}$ (middle graph), and $C = 100\,\mu\text{F}$ (bottom graph).

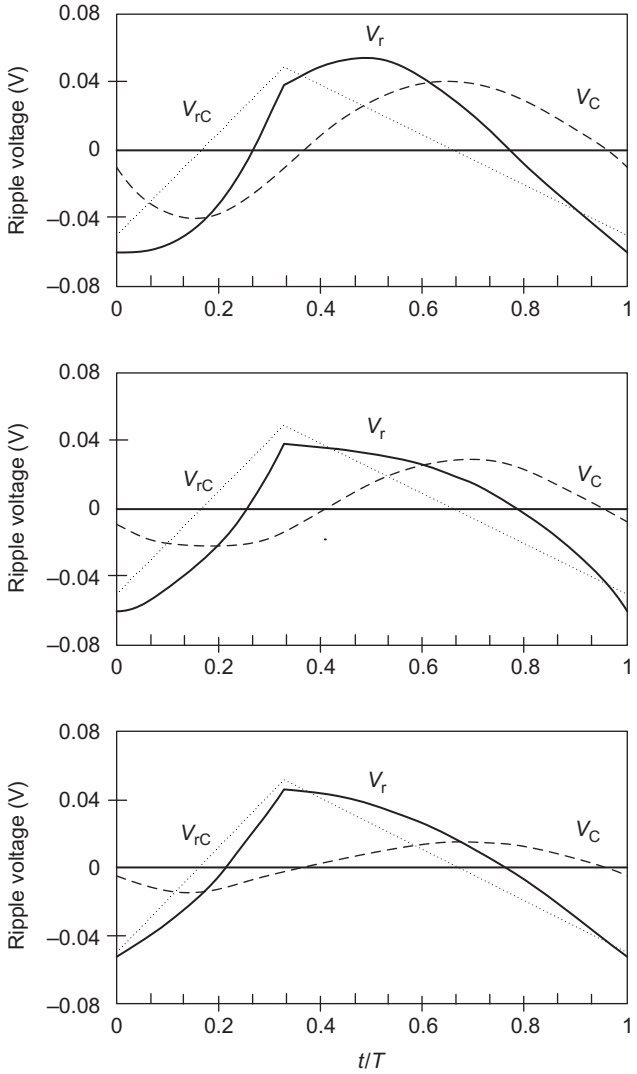

FIG. 10.13 Voltage ripple waveforms V_{rC}, V_C, and V_r for a buck converter at $V_O = 12\,\text{V}$, $f = 100\,\text{kHz}$.

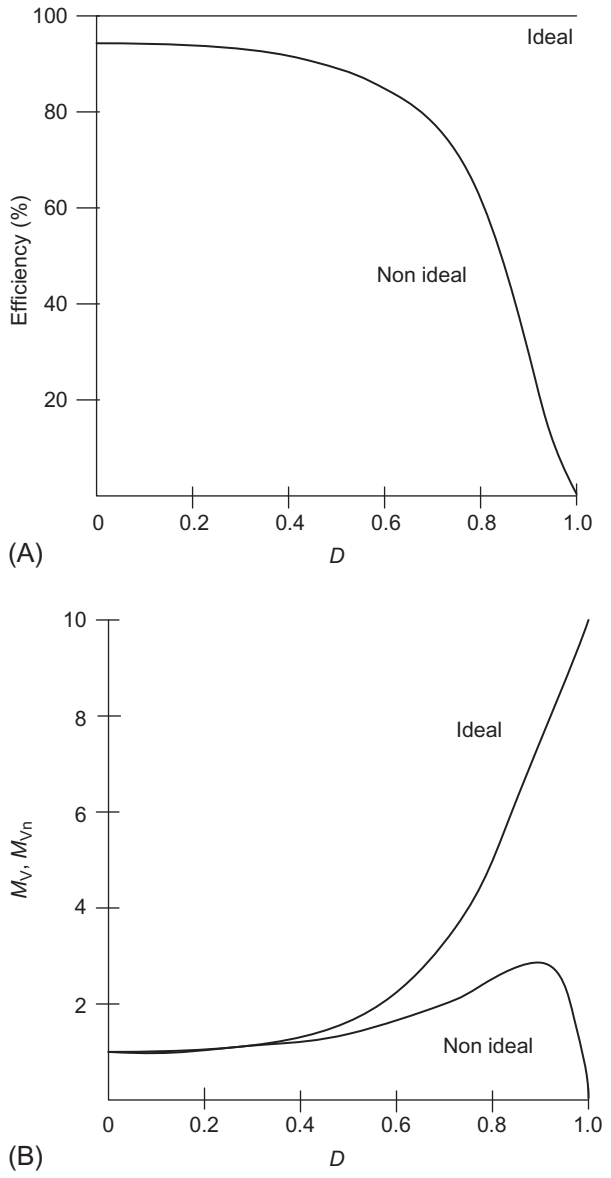

FIG. 10.14 Effects of parasitics on characteristics of a boost converter, (A) efficiency and (B) dc voltage transfer function.

Assuming that the total ripple voltage V_r is approximately equal to the sum of the ripple voltages across the ESR and the capacitance, the maximum value of the peak-to-peak ripple voltage across the capacitance is

$$V_{Cmax} \approx V_r - V_{rC} \tag{10.35}$$

Finally, by analogy to Eq. (10.16), when the ESR of the filter capacitor is taken into account in the boost-type output filter, the filter capacitance should be greater than

$$C_{min} = \frac{DV_O}{V_{Cmax} Rf} \tag{10.36}$$

Parasitic resistances, capacitances, and voltage sources affect also an energy conversion efficiency of dc-dc converters. The efficiency η is defined as a ratio of output power to the input power:

$$\eta \equiv \frac{P_O}{P_S} = \frac{V_O I_O}{V_S I_S} \tag{10.37}$$

Efficiencies are usually specified in percent. Let us consider the boot converter as an example. Under low ripple assumption, the boost converter efficiency can be estimated as

$$\eta = \frac{R(1-D)^2}{R(1-D)^2(1+(V_D/V_O)+fC_oR)+r_L+Dr_S+(1-D)r_D+D(1-D)r_C} \tag{10.38}$$

where V_D is the forward conduction voltage drop of the diode, C_o is the output capacitance of the switch, r_L is the ESR of the inductor, and r_D is the forward *on* resistance of the diode. The term fC_oR in Eq. (10.38) represents switching losses in the converter. Other terms account for conduction losses. Losses in a dc-dc converter also contribute to a decrease in the dc voltage transfer function. The nonideal dc voltage transfer function M_{Vn} is a product of the ideal one and the efficiency:

$$M_{Vn} = \eta M_V \tag{10.39}$$

Sample graphs for the boost converter that correspond to Eqs. (10.38) and (10.39) are presented in Fig. 10.14.

10.8 Synchronous and Bidirectional Converters

It can be observed in Eq. (10.38) that the forward voltage of a diode V_D contributes to a decrease in efficiency. This contribution is especially significant in low-output-voltage power supplies, for example, 3.3 V power supplies for microprocessors or power supplies for portable telecommunication equipment. Even with a Schottky diode, which has V_D in the range of 0.4 V, the power loss in the diode can easily exceed 10% of the total power delivered to the load. To reduce conduction losses in the diode, a low on-resistance switch can be added in parallel as shown in Fig. 10.15 for a buck converter. The input switch and the switch parallel to the diode must be turned on and off alternately. The arrangement of Fig. 10.15 is called a synchronous converter or a synchronous rectifier. Modern low-voltage MOSFETs have *on* resistances of only several milliohms. Hence, a synchronous converter may exhibit higher efficiency than a conventional one at output currents as large as tens of amperes. The efficiency is increased at an expense of more complicated driving circuitry for the switches. In particular, a special can must be exercised to avoid having both switches *on* at the same time as this would short the input voltage source. Since power semiconductor devices usually have

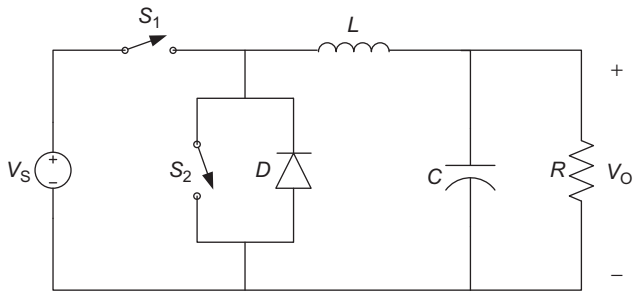

FIG. 10.15 Synchronous buck converter.

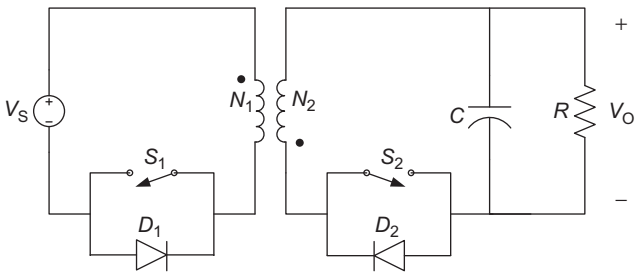

FIG. 10.16 Bidirectional flyback converter.

longer turn-off times than turn-on times, a dead time (sometimes called a blanking time) must be introduced in PWM driving signals.

The parallel combination of a controllable switch and a diode is also used in converters that allow for a current flow in both directions: from the input source to the load and from the load back to the input source. Such converters are called bidirectional power flow or simply bidirectional converters. As an example, a flyback bidirectional converter is shown in Fig. 10.16. It contains unipolar voltage and bidirectional current switch-diode combinations at both primary and secondary of the flyback transformer. When the primary switch and secondary diode operate, the current flows from the input source to the load. The converter current can also flow from the output to the input through the secondary switch and primary diode. Bidirectional arrangements can be made for buck and boost converters. A bidirectional buck converter operates as a boost converter when the current flow is from the output to the input. A bidirectional boost converter operates as a buck converter with a reversed current flow. If for any reason (for instance, to avoid the DCM) the controllable switches are driven at the same time, they must be driven alternately with a sufficient dead time to avoid a shot-through current.

10.9 Control Principles

A dc-dc converter must provide a regulated dc output voltage under varying load and input voltage conditions. The converter component values are also changing with time, temperature, pressure, etc. Hence, the control of the output voltage should be performed in a closed-loop manner using principles of negative feedback. Two most common closed-loop control methods for PWM dc-dc converters, namely, the voltage-mode control and the current-mode control, are presented schematically in Fig. 10.17.

In the voltage-mode control scheme shown in Fig. 10.17A, the converter output voltage is sensed and subtracted from an external reference voltage in an error amplifier. The error amplifier produces a control voltage that is compared to a constant-amplitude sawtooth waveform. The comparator produces a PWM signal that is fed to drivers of controllable switches in the dc-dc converter. The duty ratio of the PWM signal depends on the value of the control voltage. The frequency of the PWM signal is the same as the frequency of the sawtooth waveform. An important advantage of the voltage-mode control is its simple hardware implementation and flexibility.

The error amplifier in Fig. 10.17A reacts fast to changes in the converter output voltage. Thus, the voltage-mode control provides good load regulation, that is, regulation against variations in the load. Line regulation (regulation against variations in the input voltage) is, however, delayed because changes in the input voltage must first manifest themselves in the converter output before they can be corrected. To alleviate this problem, the voltage-mode control scheme is sometimes augmented by the so-called voltage feedforward path. The feedforward path affects directly the PWM duty ratio according to variations in the input voltage. As will be explained below, the input voltage feedforward is an inherent feature of current-mode control schemes.

The current-mode control scheme is presented in Fig. 10.17B. An additional inner control loop feeds back an inductor current signal. This current signal, converted into its voltage analog, is compared with the control voltage. This modification of replacing the sawtooth waveform of the voltage-mode control scheme by a converter current signal significantly alters the dynamic behavior of the converter. The converter takes on some characteristics of a current source. The output current in PWM dc-dc converters is either equal to the *average* value of the output inductor current (buck-derived and Ćuk converters) or a product of an *average* inductor current and a function of the duty ratio. In practical implementations of the current-mode control, it is feasible to sense the peak inductor current instead of the average value. Since the peak inductor current is equal to the peak switch current, the latter can be used in the inner loop, which often simplifies the current sensor. Note that the peak inductor (switch) current is proportional to the input voltage. Hence, the inner loop of the current-mode control naturally accomplishes the input voltage feedforward technique. Among several current-mode control versions, the most popular is the constant frequency one that requires a clock signal. Advantages of the current-mode control include input voltage feedforward, limit on the peak switch current, equal current sharing in modular converters, and reduction in the converter dynamic order.

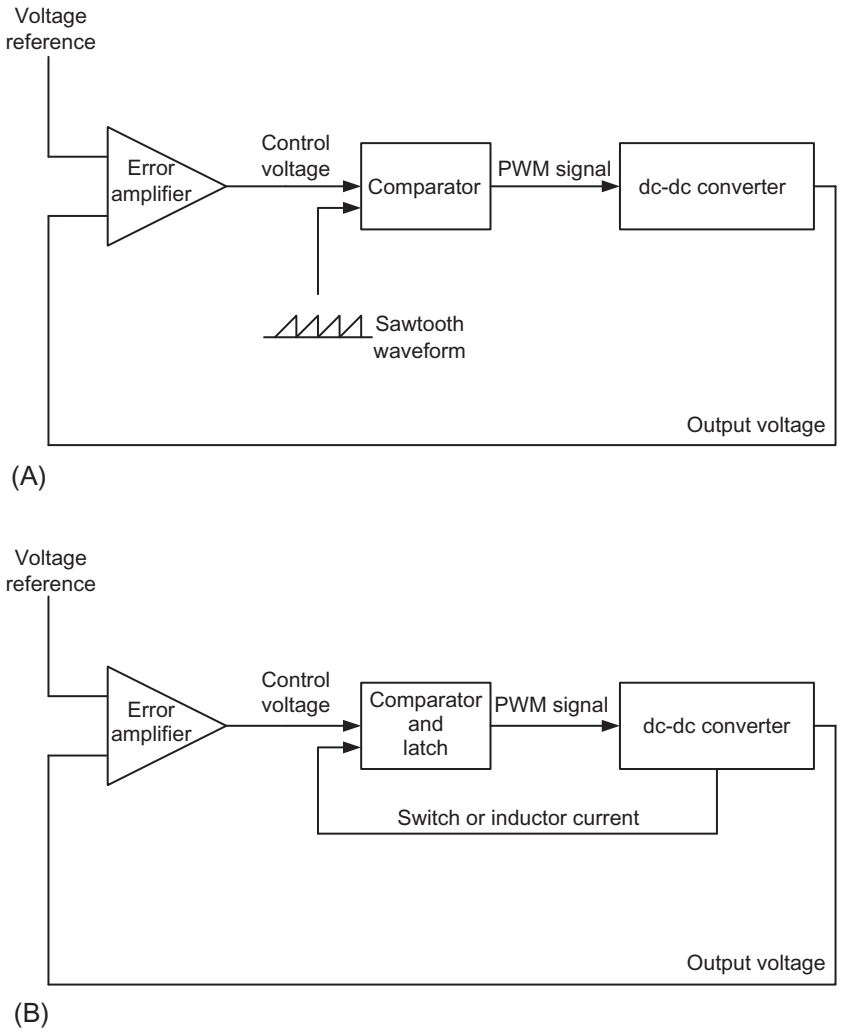

FIG. 10.17 Main control schemes for dc-dc converters, (A) voltage-mode control and (B) current-mode control.

The main disadvantage of the current-mode control is its complicated hardware that includes a need to compensate the control voltage by ramp signals (to avoid converter instability).

Among other control methods of dc-dc converters, a hysteretic (or bang-bang) control is very simple for hardware implementation. The hysteretic control results, however, in variable frequency operation of semiconductor switches. Generally, a constant switching frequency is preferred in power electronic circuits for easier elimination of electromagnetic interference and better utilization of magnetic components.

Application-specific integrated circuits (ASICs) are commercially available that contain main elements of voltage- or current-mode control schemes. On a single 14- or 16-pin chip, there is error amplifier, comparator, sawtooth generator, or sensed current input, latch, and PWM drivers. The switching frequency is usually set by an external *RC* network and can be varied from tens of kilohertz to a few megahertz. The controller has an oscillator output for synchronization with other converters in modular power supply systems. A constant voltage reference is generated on the chip as well. Additionally, the ASIC controller may be equipped in various diagnostic and protection features: current limiting, overvoltage and undervoltage protection, soft start, dead time in case of multiple PWM outputs, and duty ratio limiting. In several dc-dc converter topologies, for example, buck and buck-boost, neither control terminal of semiconductor switches is grounded (so-called high-side switches). The ASIC controllers are usually designed for a particular topology, and their PWM drivers may be able to drive high-side switches in low-voltage applications. In high-voltage applications, external PWM drivers must be used. External PWM drivers are also used for switches with high input capacitances. To take a full advantage of the input-output isolation in transformer versions of dc-dc converters, such an isolation must be also provided in the control loop. Signal transformers or optocouplers are used for isolating feedback signals.

Dynamic characteristic of closed-loop dc-dc converters must fulfill certain requirements. To simple analysis, these

requirements are usually translated into desired properties of the open loop. The open loop should provide a sufficient (typically, at least 45 degrees) phase margin for stability, high bandwidth (about one-tenth of the switching frequency) for good transient response, and high gain (several tens of decibels) at low frequencies for small steady-state error.

The open-loop dynamic characteristics are shaped by compensating networks of passive components around the error amplifier. Second- or third-order *RC* networks are commonly used. Since the converter itself is a part of the control loop, the design of compensating networks requires a knowledge of small-signal characteristics of the converter. There are several methods of small-signal characterization of PWM dc-dc converters. The most popular methods provide average models of converters under high-switching-frequency assumption. The averaged models are then linearized at an operating point to obtain small-signal transfer functions. Among analytic averaging methods, state-space averaging has been popular since the late 1970s. Circuit-based averaging is usually performed using PWM switch or direct replacement of semiconductor switches by controlled current and voltage sources. All these methods can take into account converter parasitics.

The most important small-signal characteristic is the *control-to-output* transfer function T_p. Other converter characteristics that are investigated include the *input-to-output* (or *line-to-output*) voltage transfer function, also called the *open-loop dynamic line regulation* or the *audio susceptibility*, which describes the input-output disturbance transmission; the *open-loop input impedance*; and the *open-loop dynamic load regulation*. Buck-derived, boost, and buck-boost converters are second-order dynamic systems; the Ćuk converter is a fourth-order system. Characteristics of buck and buck-derived converters are similar to each other. Another group of converters with similar small-signal characteristics is formed by boost, buck-boost, and flyback converters. Among parasitic components, the ESR of the filter capacitor r_C introduces additional dynamic terms into transfer functions. Other parasitic resistances usually modify slightly the effective value of the load resistance. Sample characteristics below are given for nonzero r_C, neglecting other parasitics.

The control-to-output transfer function of the forward converter is

$$T_p(s) \equiv \frac{v_o(s)}{d(s)}\Big|_{v_s(s)=0} = \frac{V_I R r_C}{nL(R+r_C)} \times \frac{s+(1/Cr_C)}{s^2+s(CRr_C+L/LC(R+r_C))+R/(LC(R+r_C))} \tag{10.40}$$

It can be seen that this transfer function has two poles and one zero. The zero is due to the filter capacitor ESR. Buck-derived converters can be easily compensated for stability with second-order controllers.

The control-to-output transfer function of the boost converter is given by

$$T_p(s) = -\frac{V_O r_C}{(1-D)(R+r_C)} \times \frac{[s+(1/Cr_C)]\left[s-\left((1-D)^2R\right)/L\right]}{s^2+s\left[\left((1-D)^2CRr_C+L\right)/(LC(R+r_C))\right]+\left[\left((1-D)^2R\right)/(LC(R+r_C))\right]} \tag{10.41}$$

The zero $-(1-D)^2R/L$ is located in the right half of the s-plane. Therefore, the boost converter (and buck-boost and flyback converters) is a nonminimum phase system. Nonminimum phase dc-dc converters are typically compensated with third-order controllers. Step-by-step procedures for a design of compensating networks are usually given by manufacturers of ASIC controllers in application notes.

The final word of this section is on the behavior of dc-dc converters in distributed power supply systems. An important feature of closed-loop regulated dc-dc converters is that they exhibit a negative input resistance. As the load voltage is kept constant by the controller, the output power changes with the load. With slow load changes, an increase (decrease) in the input voltage results in a decrease (increase) in the input power. This negative resistance property must be carefully examined during the system design to avoid resonances.

10.10 Applications of DC-DC Converters

Step-down choppers find most of their applications in high-performance dc drive systems, for example, electric traction, electric vehicles, and machine tools. The dc motors with their winding inductances and mechanical inertia act as filters resulting in high-quality armature currents. The average output voltage of step-down choppers is a linear function of the switch duty ratio. Step-up choppers are used primarily in radar and ignition systems. The dc choppers can be modified for two-quadrant and four-quadrant operation. Two-quadrant choppers may be a part of autonomous power supply system that contain battery packs and such renewable dc sources as photovoltaic arrays, fuel cells, or wind turbines. Four-quadrant choppers are applied in drives in which regenerative breaking of dc motors is desired, for example, transportation systems with frequent stops. The dc choppers with inductive outputs serve as inputs to current-driven inverters.

An addition of filtering reactive components to dc choppers results in PWM dc-dc converters. The dc-dc converters can be viewed as dc transformers that deliver to the load as dc voltage or current at a different level than the input source. This dc transformation is performed by electronic switching means, not by electromagnetic means like in conventional transformers. Output voltages of dc-dc converters range from a volt for special VLSI circuits to tens of kilovolts in x-ray lamps. The most common output voltages are 3.3 V for modern

microprocessors, 5 and 12 V for logic circuits, 48 V for telecommunication equipment, and 270 V for main dc bus on airplanes. Typical input voltages include 48, 170 (the peak value of a 120 V rms line), and 270 V.

Selection of a topology of dc-dc converters is determined not only by input/output voltages, which can be additionally adjusted with the turns ratio in isolated converters, but also by power levels, voltage and current stresses of semiconductor switches, and utilization of magnetic components. The low part-count flyback converter is popular in low-power applications (up to 200 W). Its main deficiencies are the large size of the flyback transformer core and high voltage stress on the semiconductor switch. The forward converter is also a single-switch converter. Since its core size requirements are smaller, it is popular in low-/medium (up to several hundreds of watts)-power applications. Disadvantages of the forward converter are in a need for demagnetizing winding and in a high voltage stress on the semiconductor switch. The push-pull converter is also used at medium power levels. Due to bidirectional excitation, the transformer size is small. An advantage of the push-pull converter is also a possibility to refer driving terminals of both switches to the ground, which greatly simplifies the control circuitry. A disadvantage of the push-pull converter is a potential core saturation in a case of asymmetry. The half-bridge converter has similar range of applications as the push-pull converter. There is no danger of transformer saturation in the half-bridge converter. It requires, however, two additional input capacitors to split in half the input dc source. The full-bridge converter is used at high (several kilowatts) power and voltage levels. The voltage stress on power switches is limited to the input voltage source value. A disadvantage of the full-bridge converter is a high number of semiconductor devices.

The dc-dc converters are building blocks of distributed power supply systems in which a common dc bus voltage is converted to various other voltages according to the requirements of particular loads. Such distributed dc systems are common in space stations, ships, and airplanes, as well as in computer and telecommunication equipment. It is expected that modern portable wireless communication and signal processing systems will use variable supply voltages to minimize power consumption and extend battery life. Low-output-voltage converters in these applications utilize the synchronous rectification arrangement.

Another big area of dc-dc converter applications is related to the utility ac grid. For critical loads, if the utility grid fails, there must be a backup source of energy, for example, a battery pack. This need for continuous power delivery gave rise to various types of uninterruptible power supplies (UPSs). The dc-dc converters are used in UPSs to adjust the level of a rectified grid voltage to that of the backup source. Since during normal operation the energy flows from the grid to the backup source and during emergency conditions the backup source must supply the load, bidirectional dc-dc converters are often used. The dc-dc converters are also used in dedicated battery chargers.

Power electronic loads, especially those with front-end rectifiers, pollute the ac grid with odd harmonics. The dc-dc converters are used as intermediate stages, just after a rectifier and before the load-supplying dc-dc converter, for shaping the input ac current to improve power factor and decrease the harmonic content. The boost converter is especially popular in such power-factor-correction (PFC) applications. Another utility grid-related application of dc-dc converters is in interfaces between ac networks and dc renewable energy sources such as fuel cells and photovoltaic arrays.

In isolated dc-dc converters, multiple outputs are possible with additional secondary windings of transformers. Only one output is regulated with a feedback loop. Other outputs depend on the duty ratio of the regulated one and on their loads. A multiple-output dc-dc converter is a convenient solution in application where there is a need for one closely regulated output voltage and for one or more noncritical other output voltage levels.

11.1 Introduction

To produce an ac output waveform from a dc power supply is the main objective of inverters. These types of converters are required in many applications, like adjustable speed drives (ASDs), uninterruptible power supplies, static var compensators, active power filters, flexible ac transmission systems, and grid-connected photovoltaic systems, which are only a few applications. For sinusoidal ac outputs, the magnitude, frequency, and phase of the waveform should be controllable. In the literature, different topologies have been reported; one of the most known converters is the voltage-source inverters (VSIs), but current-source inverters (CSIs) and impedance-source inverters (ISIs) can also be found; in Fig. 11.1, a classification of inverters is illustrated that considers the input source. The VSIs are the most widely used because they naturally behave as voltage sources as required by many industrial applications, such as ASDs, which are the most popular application of inverters. Similarly, the other topologies are widely used in medium-voltage industrial or low-power commercial applications.

The inverters are constructed from power switches and diodes. This leads to the generation of waveforms that feature fast transitions rather than smooth ones. These waveforms are made up of a fundamental component that behaves as a pure sinusoidal and an infinite number of harmonics. This behavior should be ensured by a modulating technique that controls the amount of time and the sequence used to switch the power semiconductors on and off. The modulating techniques mostly used are the carrier-based technique (e.g., sinusoidal pulse width modulation, SPWM), the space-vector (SV) technique, and the selective harmonic elimination (SHE) technique.

As an alternative not only to produce an inverter output with low harmonic content but also to avoid the negative side effects of high dv/dt (such as bearing and isolation problems), the multilevel topologies should be used. The basic principle is

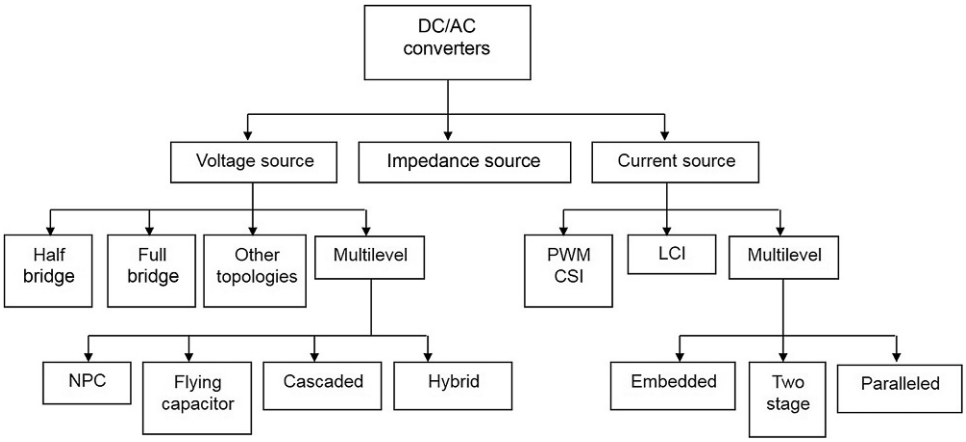

FIG. 11.1 Classification of the inverters.

to construct the required ac output waveform from various levels, which achieves waveforms at reduced dv/dt. Although these topologies are well developed in ASDs, they are also suitable for static var compensators, active power filters, and so on. Specialized modulating techniques have been developed to switch the higher number of power semiconductors involved in these topologies. Among others, the carrier-based (SPWM) and SV-based techniques have been naturally extended to these applications.

In many applications, it is required to take energy from the ac side of the inverter and send it back into the dc side. For instance, whenever ASDs need to either brake or slow down the motor speed, the kinetic energy is sent into the voltage dc link. This is known as the regenerative operating mode, and in contrast to the motoring mode, the dc link current direction is reversed due to the fact that the dc link voltage is fixed. If a capacitor is used to maintain the dc link voltage (as in standard ASDs), the energy must be either dissipated or fed back into the distribution system; otherwise, the dc link voltage gradually increases. The first approach requires the dc link capacitor be connected in parallel with a resistor, which must be properly switched only when the energy flows from the motor to the dc link. A better alternative is to feed back such energy into the distribution system. However, this alternative requires a reversible-current topology connected between the distribution system and the dc link capacitor. A modern approach to such a requirement is to use the active front-end rectifier technologies, where the regeneration mode is a natural operating mode of the system.

In this chapter, not only single-phase inverters in their voltage-, current-, and impedance-source alternatives but also the three-phase inverters in their voltage- and current-source configurations will be reviewed. Specifically, the topologies, the modulating techniques, and the control aspects oriented to standard applications are analyzed. In order to simplify the analysis, the inverters are considered lossless topologies, and the dc link will be assumed to be a perfect dc. Nevertheless, some practical nonideal conditions are also considered.

11.2 Single-Phase Inverters

Single-phase inverters can be classified by its input source; they are VSIs, CSIs, and ISIs. The operating principles are different in each converter. The main features of the different approaches are reviewed and presented in the following subsections. Although these converters cover the low-power range, they are widely used in power supplies or single-phase UPSs.

11.2.1 Voltage Source Inverter

The traditional topologies for single-phase VSIs are half bridge and full bridge (Fig. 11.2). The converter is composed of capacitors, switches, and diodes, where an array of two switches is called "inverter leg." For instance, the inverter leg of the half bridge is composed of S_+ and S_-. The capacitors required to provide a neutral point N are large, such that each capacitor maintains a constant voltage.

In order to operate properly the voltage-source inverter, the following rules are compulsory:

1. Switches of the same leg cannot be on simultaneously, because a short circuit across the dc link voltage source v_i would be produced.
2. Diode in antiparallel to each switch must be placed, in order to provide a current path for inductive loads. If the commercial switch includes this diode, then the circuit is already complete.
3. In practical implementation, a dead time, also known as blanking time, must be considered in the control signals of the leg switches, to avoid breaking rule 1.

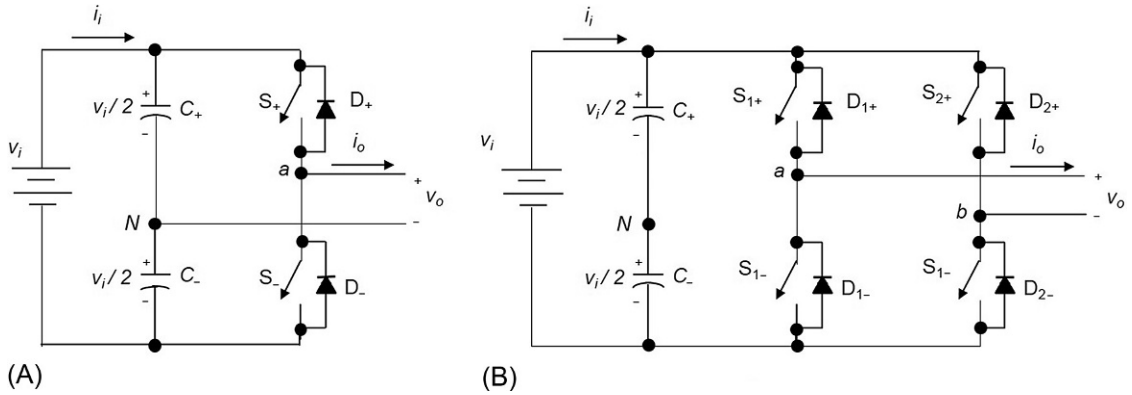

FIG. 11.2 Single-phase VSI: (A) half bridge and (B) full bridge.

TABLE 11.1 Switch states for a half-bridge single-phase VSI

State	State no.	v_o	Components conducting	
S_+ is on, and S_- is off	1	$v_i/2$	S_+	If $i_o > 0$
			D_+	If $i_o < 0$
S_- is on, and S_+ is off	2	$-v_i/2$	D_-	If $i_o > 0$
			S_-	If $i_o < 0$
S_+ and S_- are all off	3	$-v_i/2$	D_-	If $i_o > 0$
		$v_i/2$	D_+	If $i_o < 0$

For the half-bridge VSI (Fig. 11.2A), there are two defined (states 1 and 2) and one undefined (state 3) switching state as shown in Table 11.1. In order to avoid an undefined ac output voltage condition, state 3 should be used just for the dead time. Then, the modulating technique should always ensure that at any instant either the top or the bottom switch of the inverter leg is on.

Fig. 11.3 shows the ideal waveforms associated with the half-bridge inverter shown in Fig. 11.2A. The states for the switches S_+ and S_- are defined by the modulating technique, which in this case is a carrier-based PWM.

For the full-bridge VSI (Fig. 11.2B), there are four defined (states 1–4) and one undefined (state 5) switching state as shown in Table 11.2. Again, in order to avoid an undefined ac output voltage condition, state 5 should be used just for the dead time. Then, the modulating technique should always ensure that at any instant either the top or the bottom switch of an inverter leg is on.

Fig. 11.4 shows the ideal waveforms associated with the full-bridge inverter shown in Fig. 11.2B. The states for the switches are defined by the modulating technique, which in this case is a carrier-based PWM, but unipolar output is considered.

For the VSIs, different output filters may be employed, in order to provide the fundamental component of the output. Depending on the application, it would be desirable to provide a voltage or a current output. In Fig. 11.5, some output filters for this converter are shown; in all cases, an inductor is required immediately for the output of the converter. The first and the last one are used to provide a current output, such as in VSIs connected to the grid, where a current-like performance is required. The second-order filter is used for voltage output, such as stand-alone applications or ASDs.

11.2.2 Current Source Inverter

The topology for the single-phase CSIs is the shown in Fig. 11.6. The converter is composed of inductors, switches, and diodes. The inductors required are large, such that the inductors maintain a constant current i_i. Current-source topologies feature a low switching dv/dt and reliable overcurrent/short-circuit protection.

In order to operate properly the current-source inverter, the following rules are compulsory:

1. Top or bottom switches of the different legs cannot be off simultaneously, because no current path is provided to the input inductors.
2. Diode in series to each switch must be placed, because a short circuit across the output voltage v_o would be produced. If the commercial switch does not include anti-parallel diodes, then the circuit is already complete.
3. In practical implementation, an overlapping time must be considered in the control signals of the top or bottom switches of the different legs.

According to the previous rules, it should be noticed that both switches of the inverter leg can be turned on at the same time, and this is not possible in VSI.

For the CSI (Fig. 11.6), there are four defined (states 1–4) and one not permitted switching state (state 5) as shown in Table 11.3. The modulating technique should always ensure that at any instant, at least one of the top and bottom switch of the inverter legs is on; otherwise, the inverter will be damaged.

Fig. 11.7 shows the ideal waveforms associated with the CSI shown in Fig. 11.6. Notice that only the control signals of one inverter leg are graphed, since the other control signals are the

			$-v_i/2$		D_{2-}	If $i_o < 0$

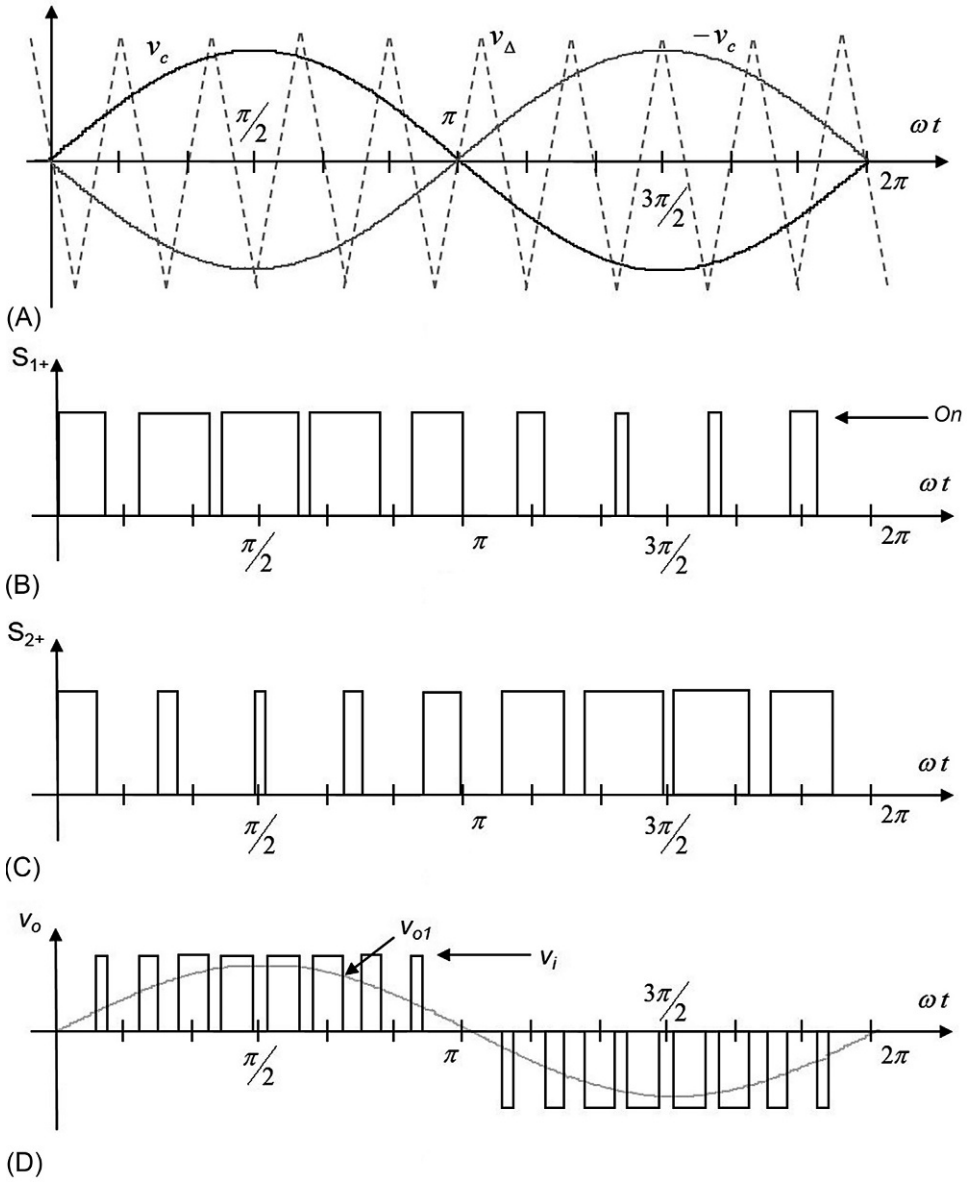

FIG. 11.4 The full-bridge VSI. Ideal waveforms for the unipolar SPWM: (A) carrier and modulating signals, (B) switch S_{1+} state, (C) switch S_{2+} state, and (D) ac output voltage.

opposite due to the rules (S_{1+} = not S_{2+} and S_{1-} = not S_{2-}), but the overlapping time should be considered for implementation. The states for the switches are defined by the modulating technique, which in this case is a carrier-based PWM, but unipolar output is considered.

For the CSIs, different output filters may be employed, in order to provide the fundamental component of the output waveform. Depending on the application, it would be desirable to provide a voltage or current output. In Fig. 11.8, some output filters for this converter are shown; in all cases, a capacitor is required immediately for the output of the converter.

11.2.3 Impedance Source Inverter

There are different topologies for single-phase ISIs, namely, "Z,"- "qZ,"- and "TZ"-source inverters; in Fig. 11.9, the Z-source inverter (ZSI) is shown. The converter is composed of capacitors and inductors, switches, and diodes. The capacitors and the inductors are arranged to form an input impedance for the inverter.

In order to operate properly the impedance-source inverter of Fig. 11.9, the following rules are compulsory:

1. No restrictions to the switches of the inverter leg apply.

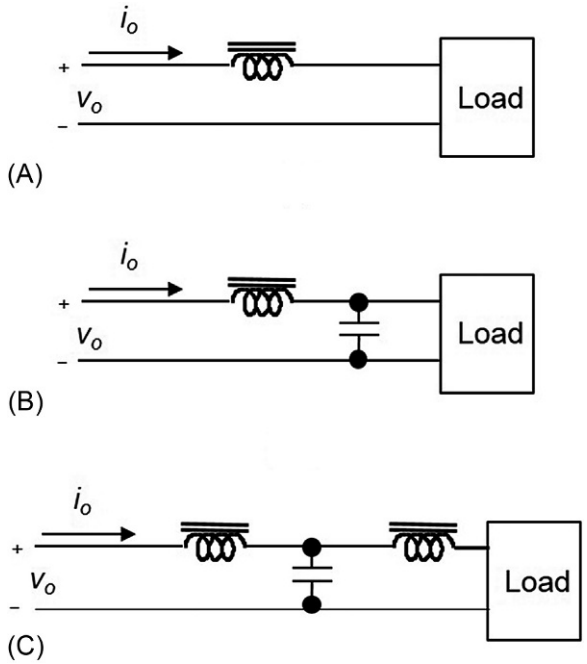

FIG. 11.5 Output filter for a VSI: (A) inductor, (B) second-order filter, and (C) LCL filter.

2. Diodes in antiparallel to each switch must be placed, in order to provide a current path for inductive loads. If the commercial switch includes these diodes, then the circuit is already complete.
3. In practical implementation, no dead or overlapping time must be considered in the control signals of the leg switches.

TABLE 11.3 Switch states for a single-phase CSI

State	State no.	i_o	Components conducting
S_{1+} and S_{2-} are on, and S_{1-} and S_{2+} are off	1	i_i	S_{1+}, S_{2-}, D_{1+}, and D_{2-}
S_{1-} and S_{2+} are on, and S_{1+} and S_{2-} are off	2	$-i_i$	S_{1-}, S_{2+}, D_{1-}, and D_{2+}
S_{1+} and S_{1-} are on, and S_{2+} and S_{2-} are off	3	0	S_{1+}, S_{1-}, D_{1+}, and D_{1-}
S_{2+} and S_{2-} are on, and S_{1+} and S_{1-} are off	4	0	S_{2+}, S_{2-}, D_{1-}, and D_{2-}
S_{1+} and S_{1-} are off, and S_{2+} and S_{2-} are off	5		This state must be avoided

According to the previous rules, it should be noticed that the switches of the inverter leg can be turned on and off at any time, and then, this converter has more switching states than the others, and this is used to boost the input voltage.

For the ISI shown in Fig. 11.9, there are five defined (states 1–5) and one undefined switching state as shown in Table 11.4. The modulating technique may permit to use the additional switching state (no. 5, known as shoot-through state), and then, another modulating signal should be employed for this purpose, but usually, it has a constant waveform.

Fig. 11.10 shows the ideal waveforms associated with the ZSI shown in Fig. 11.9. The states for the switches are defined by the modulating technique, which in this case is a carrier-based PWM, but unipolar output is considered; the shoot-through state is modulated by v_r.

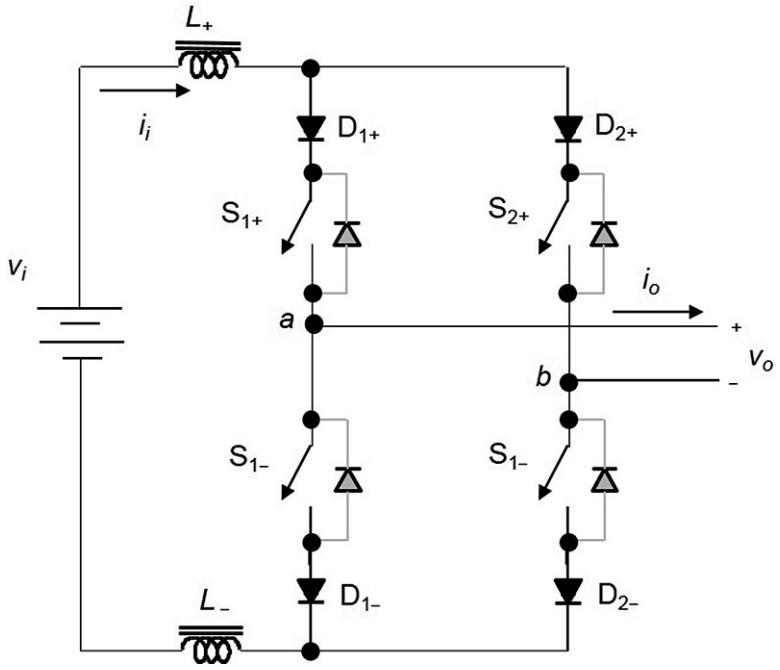

FIG. 11.6 Single-phase CSI.

For the converter ZSI, the output filter may be the same as for the VSI, and then, the filters are like the ones shown in Fig. 11.5.

11.2.4 Other Inverter Schemes

In the literature, other inverter topologies, with different operation from the previous discussed converters, have been proposed. However, the compulsory rules are valid, according to the input source. The entitled boost inverter is based on two bidirectional dc/dc boost converters and is able to produce an output voltage higher than the input voltage. This idea can be easily extrapolated to other dc/dc converter topologies. For more details, the appropriate references can be consulted.

11.2.5 Pulse Width Modulation

In order to produce a sinusoidal output, the pulse width modulation is employed. The modulating techniques mostly used are the carrier-based technique (e.g., sinusoidal pulse width modulation, SPWM), the space-vector (SV) technique, and the selective harmonic elimination (SHE) technique.

11.2.5.1 The Carrier-Based Pulse Width Modulation (PWM) Technique

As mentioned earlier, it is desired that the ac output voltage, v_o, follows a given waveform (e.g., sinusoidal) on a continuous basis by properly switching the semiconductors. The carrier-based PWM technique fulfills such a requirement as it defines

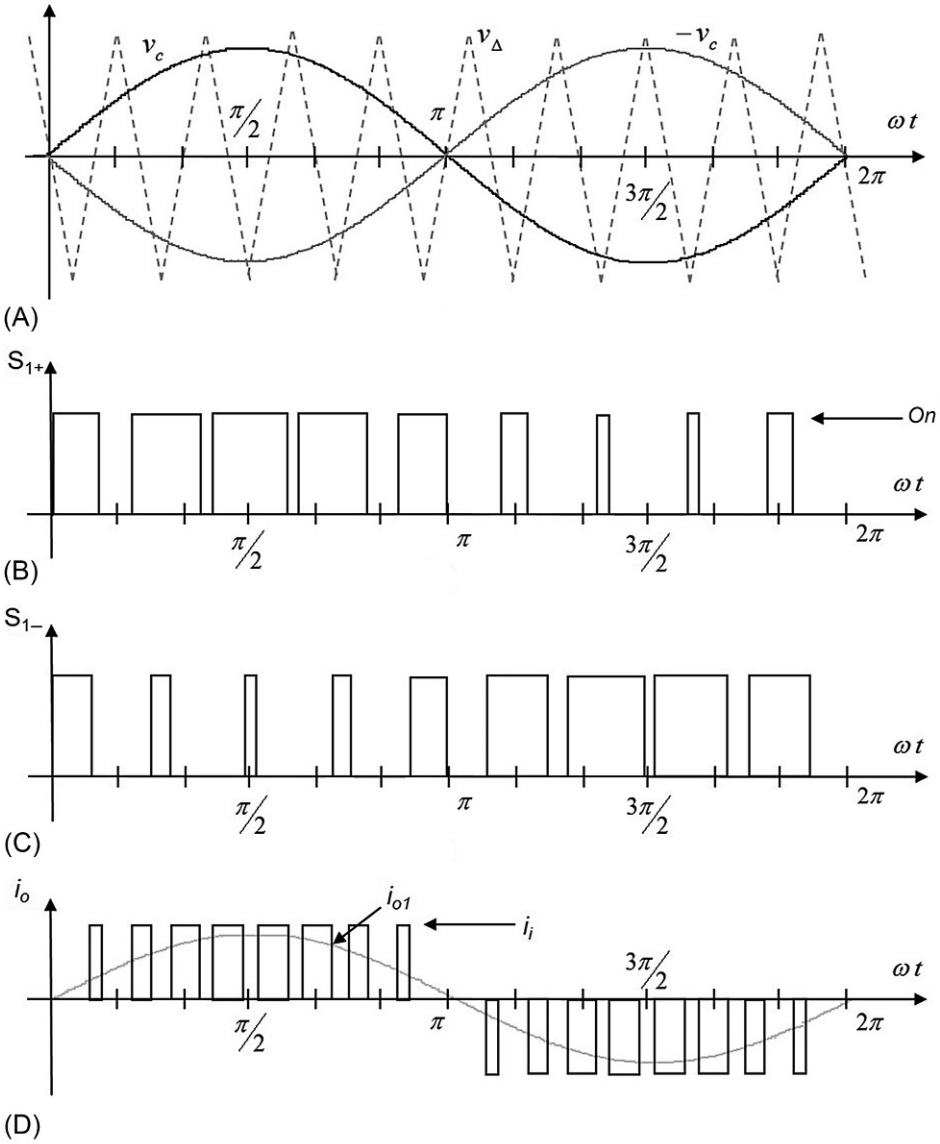

FIG. 11.7 The CSI, ideal waveforms for the unipolar SPWM: (A) carrier and modulating signals, (B) switch S_{1+} state, (C) switch S_{1-} state, and (D) ac output current.

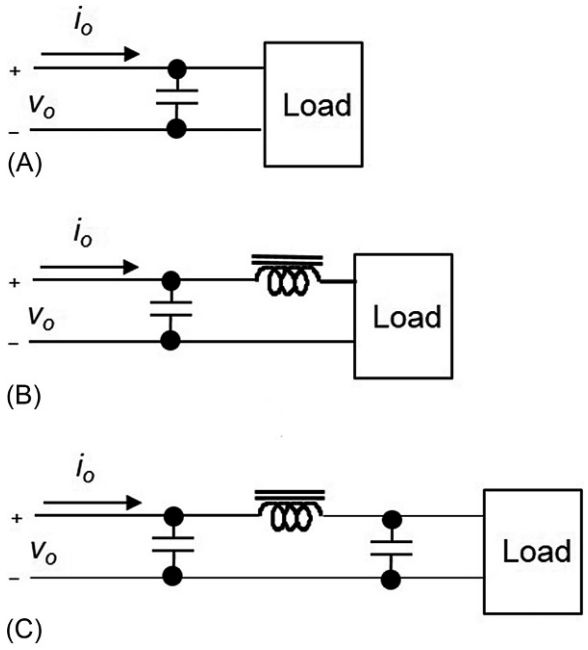

FIG. 11.8 Output filter for a CSI: (a) just capacitor, (b) second-order filter, and (c) CLC filter.

the on and off states of the switches of the inverter legs by comparing a modulating signal v_c (desired ac output voltage) and a triangular waveform v_Δ (carrier signal).

A special case is when the modulating signal v_c is a sinusoidal at frequency f_c and amplitude $\hat{v}_c$, and the triangular signal v_Δ is at frequency f_Δ and amplitude $\hat{v}_\Delta$. This is the sinusoidal PWM (SPWM) scheme. In this case, the modulation index m_a (also known as the amplitude modulation ratio) is defined as

$$m_a = \frac{\hat{v}_c}{\hat{v}_\Delta} \tag{11.1}$$

and the normalized carrier frequency m_f (also known as the frequency modulation ratio) is

$$m_f = \frac{f_\Delta}{f_c} \tag{11.2}$$

There are two known output waveforms entitled bipolar and unipolar output. Figs. 11.3D (bipolar) and 11.4d (unipolar) clearly show that the ac output voltage v_o is basically a sinusoidal waveform plus harmonics.

Bipolar PWM technique

To generate a bipolar output, a carrier-based technique can be used as shown in Fig. 11.3. In this technique, only one modulating signal v_c is used and also only one triangular signal v_Δ. The important features for the bipolar output are the following:

(a) The amplitude of the fundamental component of the ac output voltage $\hat{v}_{o1}$ satisfies the following expression:

$$\hat{v}_{o1} = \hat{v}_{aN1} = \frac{v_i}{2} m_a \tag{11.3}$$

for half-bridge VSI, Fig. 11.2A,

$$\hat{v}_{o1} = \hat{v}_{ab1} = v_i m_a \tag{11.4}$$

for the full-bridge VSI, Fig. 11.2B; these equations are valid for $m_a \leq 1$, which is called the linear region of the modulating technique (higher values of m_a lead to overmodulation that will be discussed later).

(b) For odd values of the normalized carrier frequency m_f, the harmonics in the ac output voltage appear at normalized frequencies f_h centered around m_f and its multiples, specifically,

$$h = l m_f \pm k \quad l = 1,2,3,\ldots \tag{11.5}$$

where $k = 2,4,6,\ldots$ for $l = 1,3,5,\ldots$ and $k = 1,3,5,\ldots$ for $l = 2,4,6,\ldots$.

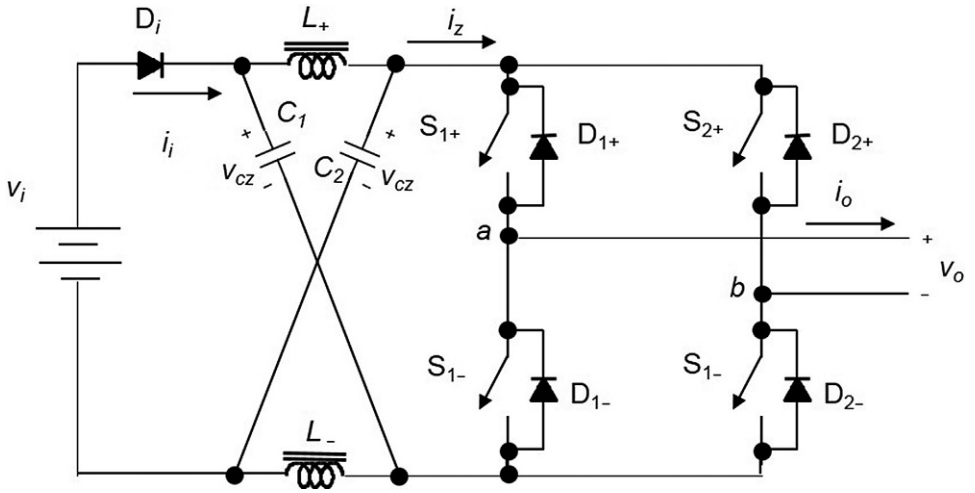

FIG. 11.9 Single-phase ZSI.

TABLE 11.4 Switch states for a single-phase ZSI

State	State no.	v_o
S_{1+} and S_{2-} are on, and S_{1-} and S_{2+} are off	1	$2v_{cz}-v_i$
S_{1-} and S_{2+} are on, and S_{1+} and S_{2-} are off	2	$-(2v_{cz}-v_i)$
S_{1+} and S_{2+} are on, and S_{1-} and S_{2-} are off	3	0
S_{1-} and S_{2-} are on, and S_{1+} and S_{2+} are off	4	0
S_{1+} and S_{2+} are on, and S_{1-} or S_{2-} is on S_{1-} and S_{2-} are on, and S_{1+} or S_{2+} is on	5	0
S_{1-} and S_{1+} are off	6	Depends on S_{2-} and S_{2+}
S_{2-} and S_{2+} are off		Depends on S_{1-} and S_{1+}

(c) The amplitude of the ac output voltage harmonics is a function of the modulation index m_a and is independent of the normalized carrier frequency m_f for $m_f > 9$.

(d) The harmonics in the dc link current (due to the modulation) appear at normalized frequencies f_p centered around the normalized carrier frequency m_f and its multiples, specifically,

$$p = lm_f \pm k \pm 1 \quad l = 1,2,\ldots \tag{11.6}$$

where $k = 2,4,6,\ldots$ for $l = 1,3,5,\ldots$ and $k = 1,3,5,\ldots$ for $l = 2,4,6,\ldots$.

Additional important issues are the following: (a) For small values of m_f ($m_f < 21$), the carrier signal v_Δ and the signal v_c should be synchronized to each other (m_f integer), which is required to hold the previous features; if this is not the case, subharmonics will be present in the ac output voltage; (b) for large values of m_f ($m_f > 21$), the subharmonics are negligible if an asynchronous PWM technique is used; however, due to potential very low-order subharmonics, its use should be avoided; finally, (c) in the overmodulation region ($m_a > 1$), some intersections between the carrier and the modulating signal are missed, which leads to the generation of low-order harmonics, but a higher fundamental ac output voltage is obtained; unfortunately, the linearity between m_a and $\hat{v}_{o1}$ achieved in the linear region does not hold in the overmodulation region; moreover, a saturation effect can be observed (Fig. 11.11).

As mentioned before, the PWM technique allows an ac output voltage to be generated that tracks a given modulating signal. In the SPWM technique, the modulating signal is a sinusoidal that provides, in the linear region, an ac output voltage that varies linearly as a function of the modulation index, and the harmonics are at well-defined frequencies and amplitudes. These features simplify the design of filtering components. Unfortunately, the maximum amplitude of the fundamental ac voltage is bounded in this operating mode. Higher voltages are obtained by using the overmodulation region ($m_a > 1$); however, low-order harmonics appear in the ac output voltage. Very large values of the modulation index ($m_a > 3.24$) lead to a totally square ac output voltage.

Unipolar PWM technique

To generate a unipolar output, also a carrier-based technique can be used as shown in Fig. 11.4, where two sinusoidal modulating signals (v_c and $-v_c$) are used. The signal v_c is used to generate S_{1+}, and $-v_c$ is used to generate S_{2+}. Notice that this output cannot be produced by a half-bridge inverter. Important features for the unipolar output are the following:

(a) The amplitude of the fundamental component of the ac output voltage $\hat{v}_{o1}$ satisfies the following expression:

$$\hat{v}_{o1} = 2 \cdot \hat{v}_{aN1} = m_a \cdot v_i \tag{11.7}$$

(b) Since the phase voltages (v_{aN} and v_{bN}) are identical but 180° out of phase, the output voltage ($v_o = v_{ab} = v_{aN} - v_{bN}$) will not contain even harmonics. Thus, if m_f is taken even, the harmonics in the ac output voltage appear at normalized odd frequencies f_h centered around twice the normalized carrier frequency m_f and its multiples. Specifically,

$$h = lm_f \pm k \quad l = 2,4,\ldots \tag{11.8}$$

where $k = 1,3,5,\ldots$; this feature is considered to be an advantage because it allows the use of smaller filtering components to obtain high-quality voltage and current waveforms while using the same switching frequency as in VSIs modulated by the bipolar approach.

(c) The amplitude of the ac output voltage harmonics is also a function of the modulation index m_a.

(d) The harmonics in the dc link current appear at normalized frequencies f_p centered around twice the normalized carrier frequency m_f and its multiples. Specifically,

$$p = lm_f \pm k \pm 1 \quad l = 2,4,\ldots \tag{11.9}$$

where $k = 1,3,5,\ldots$

11.2.5.2 Selective Harmonic Elimination

The main objective is to obtain a sinusoidal ac output voltage waveform where the fundamental component can be adjusted arbitrarily within a range and the intrinsic harmonics selectively eliminated. This is achieved by mathematically generating the exact instant of the turn-on and turnoff of the power semiconductors. The ac output voltage features odd half- and quarter-wave symmetry; therefore, even harmonics are not present ($v_{oh} = 0$, $h = 2,4,6,\ldots$). Moreover, the phase voltage waveform (v_o) should be chopped N times per half cycle in order to adjust the fundamental and eliminate $N-1$ harmonics in the ac output voltage waveform.

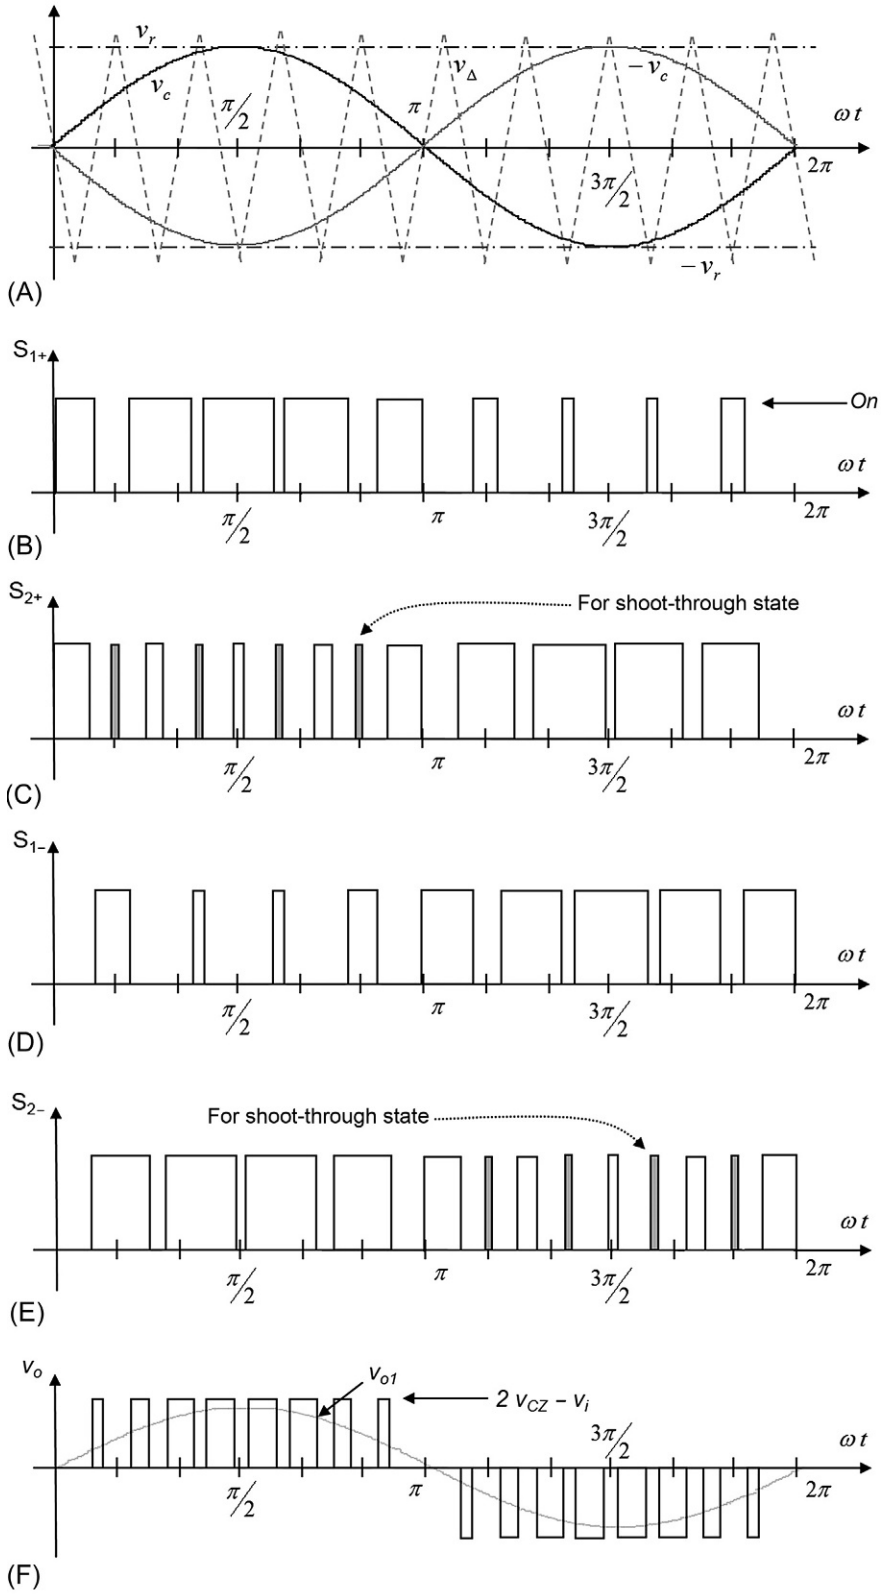

FIG. 11.10 The ZSI, ideal waveforms for the unipolar SPWM: (A) carrier and modulating signals, (B) switch S_{1+} state, (C) switch S_{2+} state, (D) switch S_{1-} state, (E) switch S_{2-} state, and (F) ac output voltage.

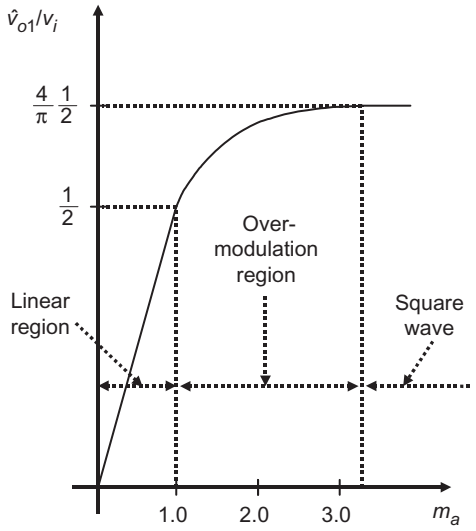

FIG. 11.11 Normalized fundamental ac component of the output voltage in a half-bridge VSI SPWM modulated.

For this modulation, also the output may be bipolar or unipolar.

Bipolar SHE technique

The general expressions to eliminate an even $N-1$ $(N-1=2,4,6,\ldots)$ number of harmonics are

$$\begin{aligned} -\sum_{k=1}^{N}(-1)^k\cos(\alpha_k) &= \frac{(2+\pi\hat{v}_{o1})/v_i}{4} \\ -\sum_{k=1}^{N}(-1)^k\cos(n\alpha_k) &= \frac{1}{2} \quad \text{for } n=3,5,\ldots,2N-1 \end{aligned} \tag{11.10}$$

where $\alpha_1, \alpha_2, \ldots, \alpha_N$ should satisfy $\alpha_1<\alpha_2<\cdots<\alpha_N<\pi/2$.

For instance, to eliminate the third and fifth harmonics and to perform fundamental magnitude control $(N=3)$, the equations to be solved are the following:

$$\begin{aligned} \cos(1\alpha_1)-\cos(1\alpha_2)+\cos(1\alpha_3) &= (2+\pi\hat{v}_{o1}/v_i)/4 \\ \cos(3\alpha_1)-\cos(3\alpha_2)+\cos(3\alpha_3) &= 1/2 \\ \cos(5\alpha_1)-\cos(5\alpha_2)+\cos(5\alpha_3) &= 1/2 \end{aligned} \tag{11.11}$$

where the angles α_1, α_2, and α_3 are defined as shown in Fig. 11.12A and the spectrum in Fig. 11.12B. The angles are found by means of iterative algorithms as no analytic solutions can be derived. The angles α_1, α_2, and α_3 are plotted for different values of $\hat{v}_{o1}/v_i$ in Fig. 11.13A.

Similarly, the general expressions to eliminate an odd $N-1$ $(N-1=3,5,7,\ldots)$ number of harmonics are given by

$$\begin{aligned} -\sum_{k=1}^{N}(-1)^k\cos(n\alpha_k) &= \frac{(2-\pi\hat{v}_{o1})/v_i}{4} \\ -\sum_{k=1}^{N}(-1)^k\cos(n\alpha_k) &= \frac{1}{2} \quad \text{for } n=3,5,\ldots,2N-1 \end{aligned} \tag{11.12}$$

where $\alpha_1, \alpha_2, \ldots, \alpha_N$ should satisfy $\alpha_1<\alpha_2<\cdots<\alpha_N<\pi/2$.

For instance, to eliminate the third, fifth, and seventh harmonics and to perform the fundamental magnitude control $(N-1=3)$, the equations to be solved are

$$\begin{aligned} &\cos(1\alpha_1)-\cos(1\alpha_2)+\cos(1\alpha_3)-\cos(1\alpha_4)=(2-\pi\hat{v}_{o1}/v_i)/4 \\ &\cos(3\alpha_1)-\cos(3\alpha_2)+\cos(3\alpha_3)-\cos(3\alpha_4)=1/2 \\ &\cos(5\alpha_1)-\cos(5\alpha_2)+\cos(5\alpha_3)-\cos(5\alpha_4)=1/2 \\ &\cos(7\alpha_1)-\cos(7\alpha_2)+\cos(7\alpha_3)-\cos(7\alpha_4)=1/2 \end{aligned} \tag{11.13}$$

where the angles α_1, α_2, α_3, and α_4 are defined as shown in Fig. 11.12C, and the spectrum in Fig. 11.12D. The angles α_1, α_2, and α_3 are plotted for different values of $\hat{v}_{o1}/v_i$ in Fig. 11.13B.

Unipolar SHE technique

The general expressions to eliminate an arbitrary $N-1$ $(N-1=3,5,7,\ldots)$ number of harmonics are given by

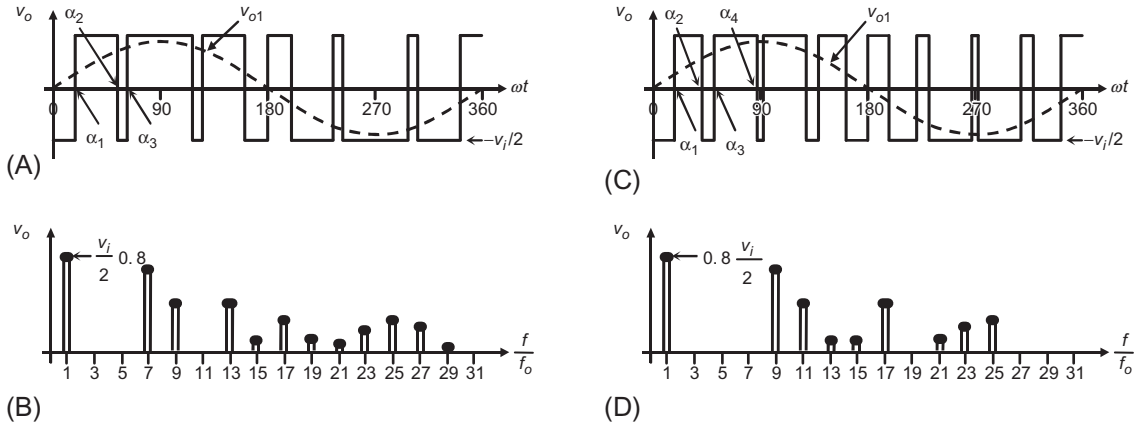

FIG. 11.12 The half-bridge VSI. Ideal waveforms for the SHE technique: (A) ac output voltage for third- and fifth-harmonic elimination, (B) spectrum of (A), (C) ac output voltage for third-, fifth-, and seventh-harmonic elimination, and (D) spectrum of (C).

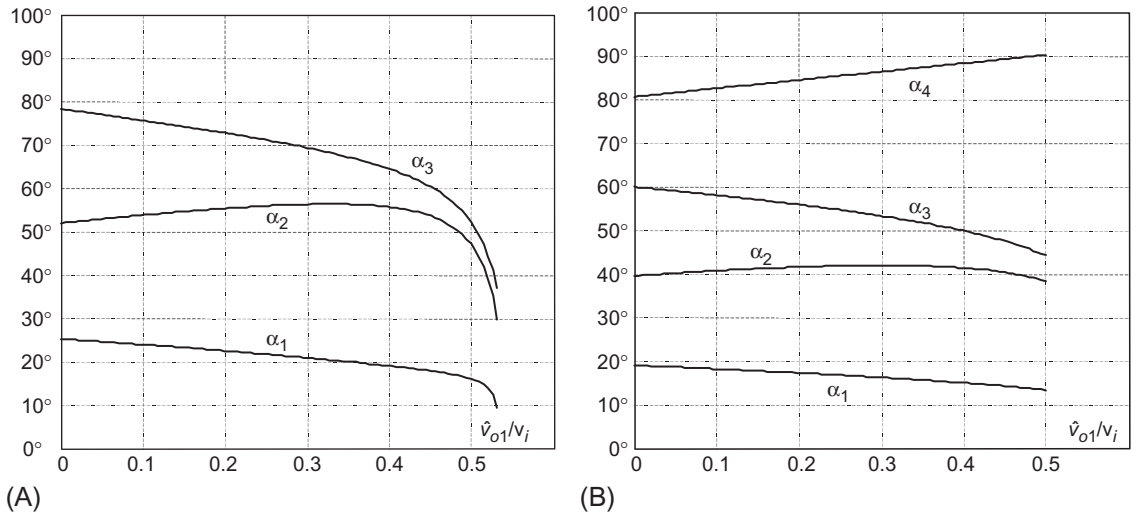

FIG. 11.13 Chopping angles for SHE and fundamental voltage control in half-bridge VSIs: (A) third- and fifth-harmonic elimination and (B) third-, fifth-, and seventh-harmonic elimination.

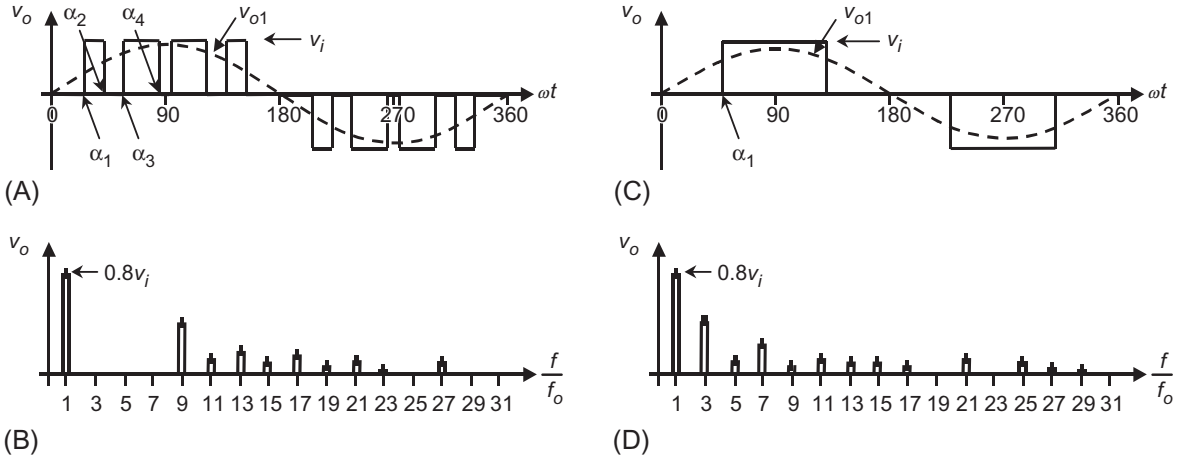

FIG. 11.14 The half-bridge VSI. Ideal waveforms for the SHE technique: (A) ac output voltage for third-, fifth-, and seventh-harmonic elimination; (B) spectrum of (A); (C) ac output voltage for fundamental control; and (D) spectrum of (C).

$$\begin{aligned} -\sum_{k=1}^{N}(-1)^k\cos(n\alpha_k) &= \frac{\pi}{4}\left(\frac{\hat{v}_{o1}}{v_i}\right) \\ -\sum_{k=1}^{N}(-1)^k\cos(n\alpha_k) &= 0 \quad \text{for } n=3,5,\ldots,2N-1 \end{aligned} \tag{11.14}$$

where $\alpha_1,\alpha_2,\ldots,\alpha_N$ should satisfy $\alpha_1<\alpha_2<\cdots<\alpha_N<\pi/2$.

For instance, to eliminate the third, the fifth, and the seventh harmonics and to perform fundamental component magnitude control ($N=4$), the equations to be solved are

$$\begin{aligned} &\cos(1\alpha_1)-\cos(1\alpha_2)+\cos(1\alpha_3)-\cos(1\alpha_4) = \pi\hat{v}_{o1}/(v_i4) \\ &\cos(3\alpha_1)-\cos(3\alpha_2)+\cos(3\alpha_3)-\cos(3\alpha_4) = 0 \\ &\cos(5\alpha_1)-\cos(5\alpha_2)+\cos(5\alpha_3)-\cos(5\alpha_4) = 0 \\ &\cos(7\alpha_1)-\cos(7\alpha_2)+\cos(7\alpha_3)-\cos(7\alpha_4) = 0 \end{aligned} \tag{11.15}$$

where the angles α_1, α_2, α_3, and α_4 are defined as shown in Fig. 11.14A and the spectrum in Fig. 11.14B. The angles α_1, α_2, α_3, and α_4 are plotted for different values of $\hat{v}_{o1}/v_i$ in Fig. 11.15A.

Fig. 11.14C shows a special case where only the fundamental ac output voltage is controlled. This is known as output control by voltage cancellation, which derives from the fact that its implementation is easily attainable by using two phase-shifted square-wave switching signals as shown in Fig. 11.16. The phase-shift angle becomes two · α_1 (Fig. 11.16B). Thus, the amplitude of the fundamental component and harmonics in the ac output voltage are given by

$$\hat{v}_{oh} = \frac{4}{\pi}v_i\frac{(-1)^{(h-1)/2}}{h}\cos(h\alpha_1) \quad h=1,3,5,\ldots \tag{11.16}$$

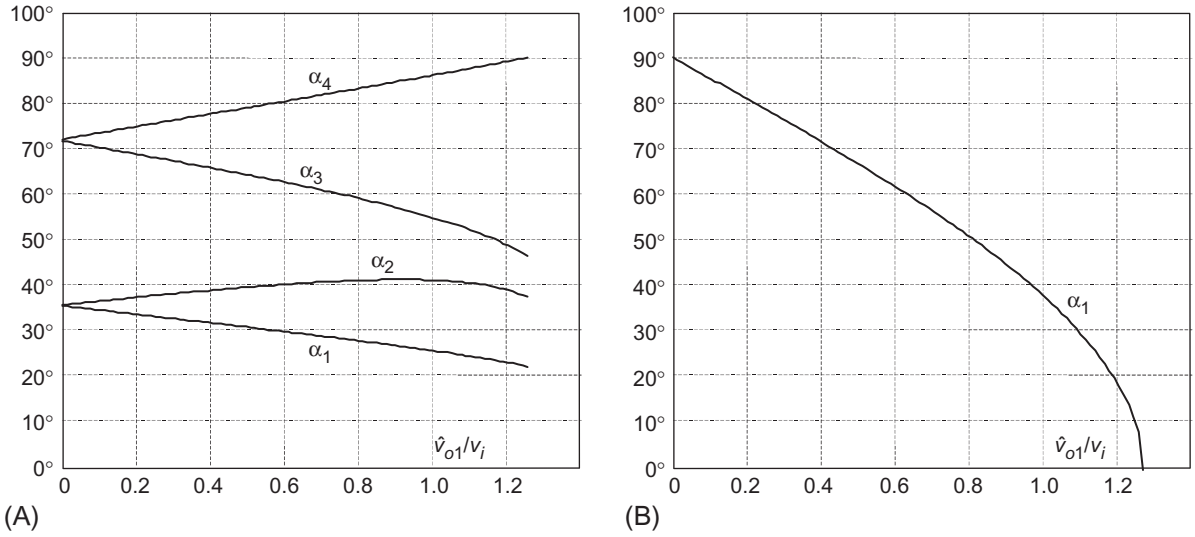

FIG. 11.15 Chopping angles for SHE and fundamental voltage control in half-bridge VSIs: (A) fundamental control and third-, fifth-, and seventh-harmonic elimination and (B) fundamental control.

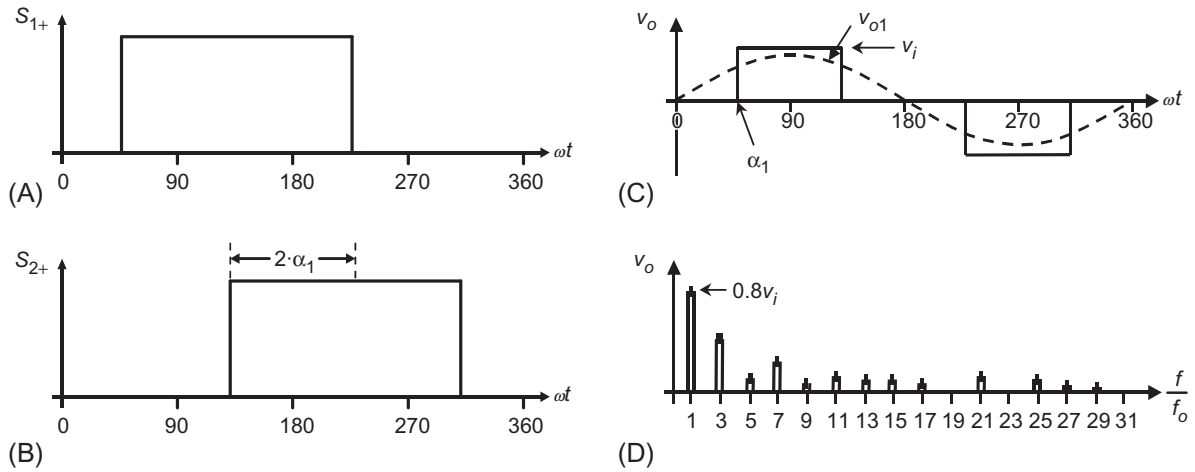

FIG. 11.16 The full-bridge VSI. Ideal waveforms for the output control by voltage cancellation: (A) switch S_{1+} state, (B) switch S_{2+} state, (C) ac output voltage, and (D) ac output voltage spectrum.

It can also be observed in Fig. 11.16C that for $\alpha_1 = 0$ square-wave operation is achieved. In this case, the fundamental ac output voltage is given by

$$\hat{v}_{o1} = \frac{4}{\pi} v_i \tag{11.17}$$

where the fundamental load voltage can be controlled by the manipulation of the dc link voltage v_i. Additional means to modify this voltage should be provided. Depending on the dc link source of power, this could be a controlled rectifier, for ac sources, or a dc/dc converter, for dc sources.

To implement the SHE modulating technique, the modulator should generate the gating pattern according to the angles as shown in Figs. 11.13 and 11.15. This task is usually performed by digital systems that normally store the angles in look-up tables.

11.2.5.3 DC Link Current

Due to the fact that the inverter is assumed lossless and constructed without storage energy components, the instantaneous power balance indicates that

$$v_i(t) \cdot i_i(t) = v_o(t) \cdot i_o(t) \tag{11.18}$$

For inductive load and relatively high switching frequencies, the load current *Io* is nearly sinusoidal. As a first approximation, the ac output voltage can also be considered sinusoidal. On the other hand, if the dc link voltage remains constant $v_i(t) = V_i$, Eq. (11.18) can be simplified to

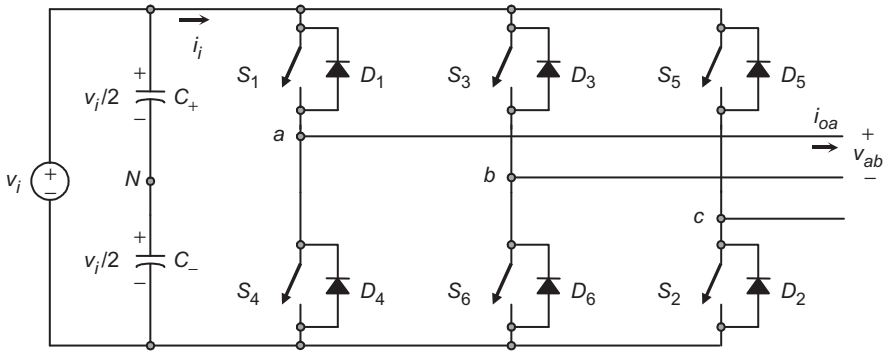

FIG. 11.17 Three-phase VSI topology.

$$i_i(t) = 1/\ V_i\sqrt{2}\ V_{o1}\sin(\omega t)\cdot\sqrt{2}\ I_o\sin(\omega t-\varphi) \qquad (11.19)$$

where V_{o1} is the fundamental rms ac output voltage, Io is the rms load current, and φ is an arbitrary inductive load power factor. Thus, the dc link current can be further simplified to

$$i_i(t) = V_{o1}/V_iI_o\cos(\varphi) - V_{o1}/Vi\ I_o\cos(2\omega t-\varphi) \qquad (11.20)$$

The preceding expression reveals an important issue, that is, the presence of a large second-order harmonic in the dc link current (its amplitude is similar to the dc link current). This second harmonic is injected back into the dc voltage source; thus, its design should be considered in order to guarantee a nearly constant dc link voltage. In practical terms, the dc voltage source is required to feature large amounts of capacitance, which is costly and demands space, both undesired features, especially in medium- to high-power supplies.

TABLE 11.5 Valid switch states for a three-phase VSI

State	State no.	v_{ab}	v_{bc}	v_{ca}	Space vector

S_1, S_3, and S_5 are on, and S_4, S_6, and S_2 are off	7	0	0	0	$\vec{\mathbf{v}}_7 = 0$
S_4, S_6, and S_2 are on, and S_1, S_3, and S_5 are off	8	0	0	0	$\vec{\mathbf{v}}_8 = 0$

11.3 Three-Phase Voltage Source Inverters

Single-phase VSIs cover low-range power applications, and three-phase VSIs cover medium- to high-power applications. The main purpose of these topologies is to provide a three-phase voltage source, where the amplitude, phase, and frequency of the voltages should always be controllable. Although most of the applications require sinusoidal voltage waveforms (e.g., ASDs, UPSs, FACTS, and var compensators), arbitrary voltages are also required in some other applications (e.g., active power filters and voltage compensators).

The standard three-phase VSI topology is shown in Fig. 11.17, and the eight valid switch states are given in Table 11.5. As in single-phase VSIs, the compulsory rules previously described in Section 11.2.1 also apply.

Of the eight valid states, two of them (7 and 8 in Table 11.5) produce zero ac line voltages. The remaining states (1–6 in Table 11.5) produce nonzero ac output voltages. In order to generate a given voltage waveform, the inverter moves from one state to another. Thus, the resulting ac output line voltages consist of discrete values of voltages that are v_i, 0, and $-v_i$ for the topology shown in Fig. 11.17. The selection of the states in order to generate the given waveform is done by the modulating technique that should ensure the use of only the valid states.

11.3.1 Sinusoidal PWM

This is an extension of the one introduced for single-phase VSIs. In this case and in order to produce 120° out-of-phase load voltages, three modulating signals that are 120° out of phase are used. Fig. 11.18 shows the ideal waveforms of three-phase VSI SPWM. In order to use a single-carrier signal and preserve the features of the PWM technique, the normalized carrier frequency m_f should be an odd multiple of 3. Thus, all phase voltages (v_{aN}, v_{bN}, and v_{cN}) are identical, but 120° out of phase without even harmonics; moreover, harmonics at frequencies, a multiple of 3, are identical in amplitude and phase in all phases. For instance, if the ninth harmonic in phase aN is

$$v_{aN9}(t) = \hat{v}_9\sin(9\omega t) \qquad (11.21)$$

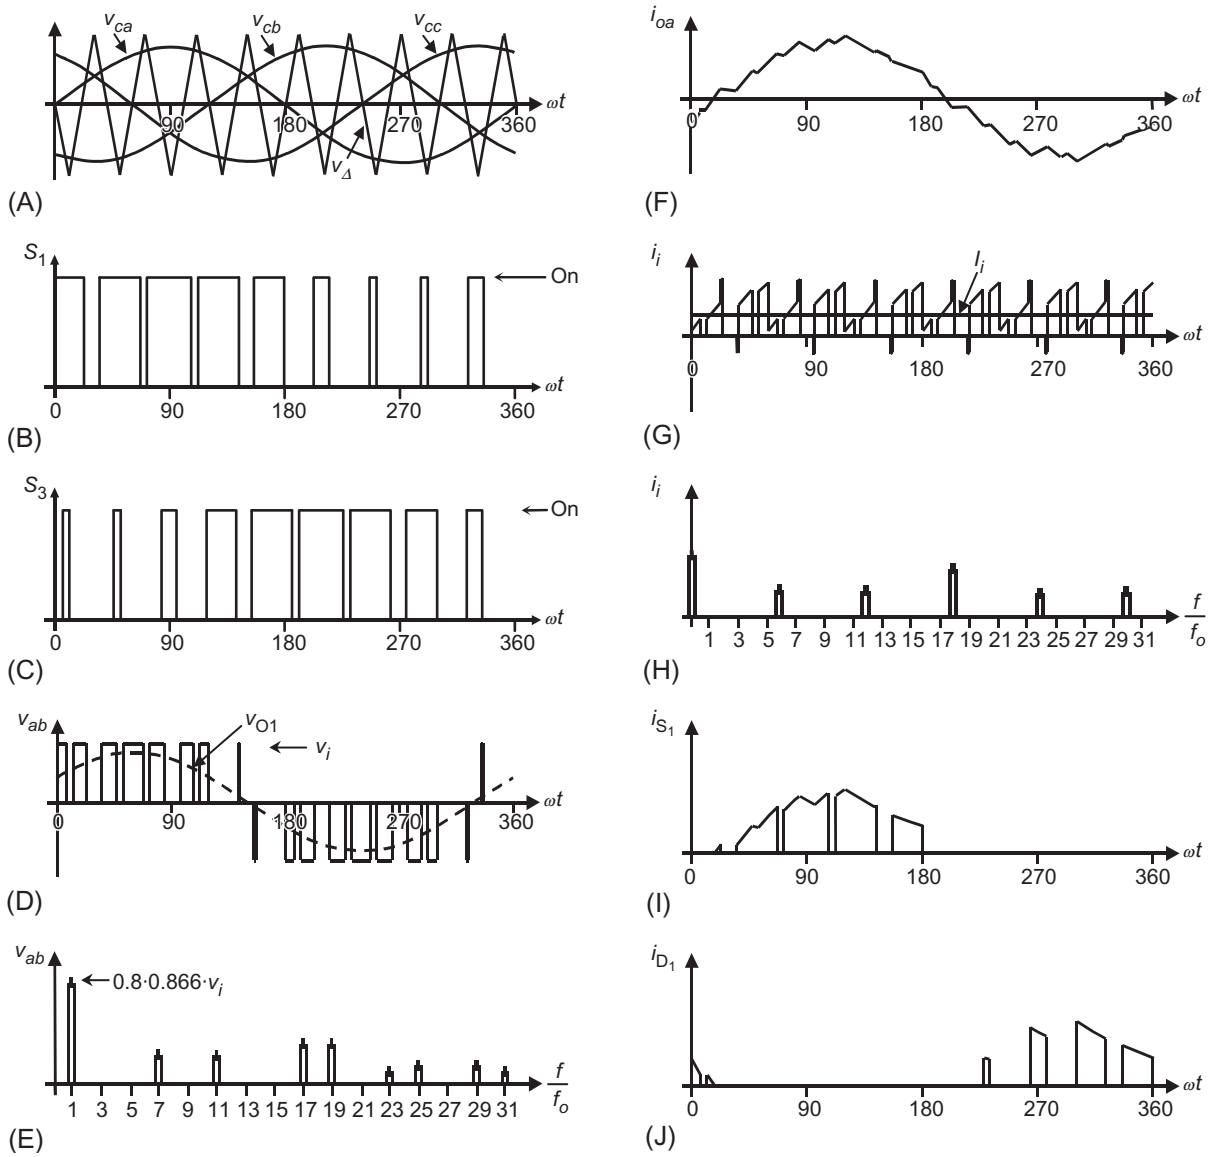

FIG. 11.18 The three-phase VSI. Ideal waveforms for the SPWM ($m_a = 0.8$, $m_f = 9$): (A) carrier and modulating signals, (B) switch S_1 state, (C) switch S_3 state, (D) ac output voltage, (E) ac output voltage spectrum, (F) ac output current, (G) dc current, (H) dc current spectrum, (I) switch S_1 current, and (J) diode D_1 current.

the ninth harmonic in phase bN will be

$$\begin{aligned} v_{bN9}(t) &= \hat{v}_9 \sin[9(\omega t - 120°)] \\ &= \hat{v}_9 \sin(9\omega t - 1080°) = \hat{v}_9 \sin(9\omega t) \end{aligned} \tag{11.22}$$

Thus, the ac output line voltage $v_{ab} = v_{aN} - v_{bN}$ will not contain the ninth harmonic. Therefore, for odd multiple of 3 values of the normalized carrier frequency m_f, the harmonics in the ac output voltage appear at normalized frequencies f_h centered around m_f and its multiples, specifically, at

$$h = lm_f \pm k \quad l = 1,2,\ldots \tag{11.23}$$

where $l = 1,3,5,\ldots$ for $k = 2,4,6,\ldots$ and $l = 2,4,\ldots$ for $k = 1,5,7,\ldots$ such that h is not a multiple of 3. Therefore, the harmonics will be at $m_f \pm 2$, $m_f \pm 4,\ldots$, $2m_f \pm 1$, $2m_f \pm 5,\ldots, 3m_f \pm 2$, $3m_f \pm 4,\ldots, 4m_f \pm 1$, $4m_f \pm 5,\ldots$. For nearly sinusoidal ac load current, the harmonics in the dc link current are at frequencies given by

$$h = lm_f \pm k \pm 1 \quad l = 1,2,\ldots \tag{11.24}$$

where $l = 0,2,4,\ldots$ for $k = 1,5,7,\ldots$ and $l = 1,3,5,\ldots$ for $k = 2,4,6,\ldots$ such that $h = l \cdot m_f \pm k$ is positive and not a multiple of 3.

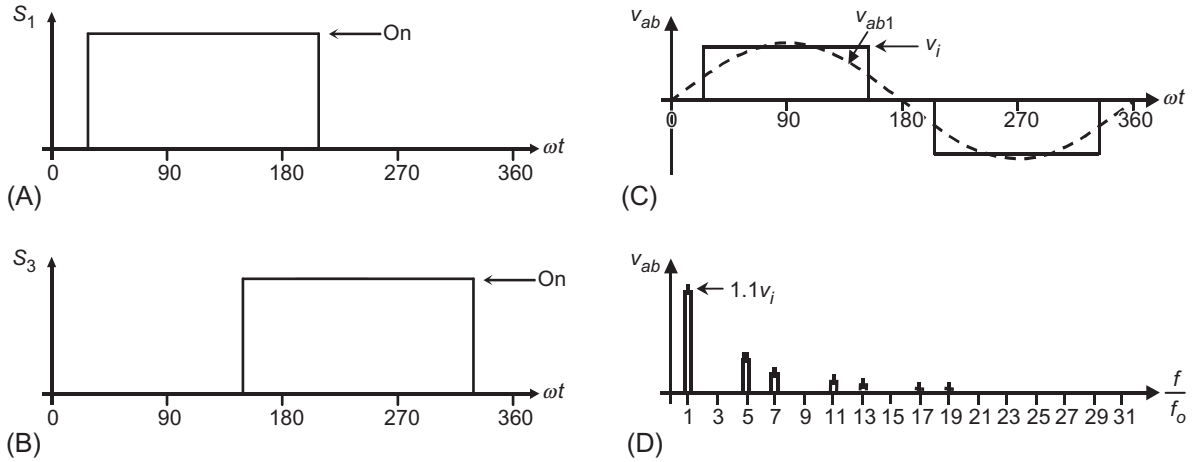

FIG. 11.19 The three-phase VSI. Square-wave operation: (A) switch S_1 state, (B) switch S_3 state, (C) ac output voltage, and (D) ac output voltage spectrum.

The identical conclusions can be drawn for the operation at small and large values of m_f as for the single-phase configurations. However, because the maximum amplitude of the fundamental phase voltage in the linear region ($m_a \leq 1$) is $v_i/2$, the maximum amplitude of the fundamental ac output line voltage is $\sqrt{3}v_i/2$. Therefore, one can write

$$\hat{v}_{ab1} = m_a \sqrt{3}\frac{v_i}{2} \quad 0 < m_a \leq 1 \tag{11.25}$$

To further increase the amplitude of the load voltage, the amplitude of the modulating signal $\hat{v}_c$ can be made higher than the amplitude of the carrier signal $\hat{v}_\Delta$, which leads to overmodulation. The relationship between the amplitude of the fundamental ac output line voltage and the dc link voltage becomes nonlinear as in single-phase VSIs. Thus, in the overmodulation region, the line voltages range is

$$\sqrt{3}\frac{v_i}{2} < \hat{v}_{ab1} = \hat{v}_{bc1} = \hat{v}_{ca1} < \frac{4}{\pi}\sqrt{3}\frac{v_i}{2} \tag{11.26}$$

11.3.2 Square-Wave Operation of Three-phase VSIs

Large values of m_a in the SPWM technique lead to full overmodulation. This is known as square-wave operation as illustrated in Fig. 11.19, where the power semiconductors are on for 180°. In this operation mode, the VSI cannot control the load voltage except by means of the dc link voltage v_i. This is based on the fundamental ac line-voltage expression

$$\hat{v}_{ab1} = \frac{4}{\pi}\sqrt{3}\frac{v_i}{2} \tag{11.27}$$

The ac line output voltage contains the harmonics f_h, where $h = 6 \cdot k \pm 1$ ($k = 1,2,3,\ldots$), and they feature amplitudes that are inversely proportional to their harmonic order (Fig. 11.18D). Their amplitudes are

$$\hat{v}_{abh} = \frac{1}{h}\frac{4}{\pi}\sqrt{3}\frac{v_i}{2} \tag{11.28}$$

11.3.3 Sinusoidal PWM with Zero Sequence Signal Injection

The restriction for m_a ($m_a \leq 1$) can be relaxed if a zero-sequence signal is added to the modulating signals before they are compared with the carrier signal. Fig. 11.20 shows the block diagram of the technique. Clearly, the addition of the zero sequence reduces the peak amplitude of the resulting modulating signals (u_{ca}, u_{cb}, u_{cc}), while the fundamental components remain unchanged. This approach expands the range of the linear region as it allows the use of modulation indexes m_a up to $2/\sqrt{3}$ without getting into the overmodulating region.

The maximum amplitude of the fundamental phase voltage in the linear region $\left(m_a \leq 2/\sqrt{3}\right)$ is $v_i/2$; thus, the maximum amplitude of the fundamental ac output line voltage is v_i. Therefore, one can write

$$\hat{v}_{ab1} = m_a \sqrt{3}\frac{v_i}{2} \quad \left(0 < m_a \leq 2/\sqrt{3}\right) \tag{11.29}$$

Fig. 11.21 shows the ideal waveforms of a three-phase VSI SPWM with zero injection for $m_a = 0.8$.

11.3.4 Selective Harmonic Elimination in Three-phase VSIs

As in single-phase VSIs, the SHE technique can be applied to three-phase VSIs. In this case, the power semiconductors of each leg of the inverter are switched so as to eliminate a given

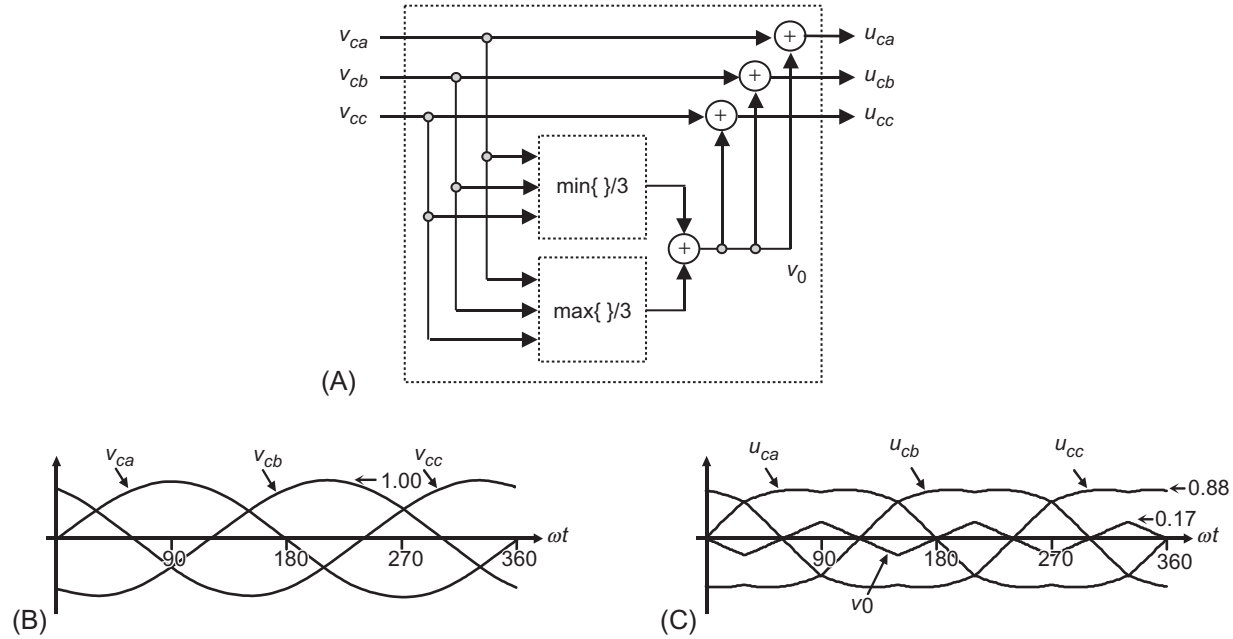

FIG. 11.20 Zero-sequence signal generator ($m_a = 1.0$, $m_f = 9$): (A) block diagram, (B) modulating signals, and (C) zero sequence and modulating signals with zero-sequence injection.

number of harmonics and to control the fundamental phase voltage amplitude. Considering that in many applications the required line output voltages should be balanced and 120° out of phase, the harmonic multiples of 3 ($h = 3,9,15,\ldots$), which could be present in the phase voltages (v_{aN}, v_{bN}, and v_{cN}), will not be present in the load voltages (v_{ab}, v_{bc}, and v_{ca}). Therefore, these harmonics are not required to be eliminated; thus, the chopping angles are used to eliminate only the harmonics at frequencies $h = 5,7,11,13,\ldots$ as required.

The expressions to eliminate a given number of harmonics are the same as those used in single-phase inverters. For instance, to eliminate the fifth and seventh harmonics and perform fundamental magnitude control ($N = 3$), the equations to be solved are

$$\begin{aligned} &\cos(1\alpha_1) - \cos(1\alpha_2) + \cos(1\alpha_3) = (2 + \pi\hat{v}_{aN1}/v_i)/4 \\ &\cos(5\alpha_1) - \cos(5\alpha_2) + \cos(5\alpha_3) = 1/2 \\ &\cos(7\alpha_1) - \cos(7\alpha_2) + \cos(7\alpha_3) = 1/2 \end{aligned} \tag{11.30}$$

where the angles α_1, α_2, and α_3 are defined as shown in Fig. 11.22A and plotted in Fig. 11.23. Fig. 11.22B shows that the third, ninth, fifteenth, … harmonics are all present in the phase voltages; however, they are not in the line voltages (Fig. 11.22D). If necessary, higher-order harmonics not eliminated with this technique can be filtered using small filters.

11.3.5 Space-Vector (SV)-Based Modulating Techniques

At present, the control strategies are implemented in digital systems, and therefore, digital modulating techniques are also available. The SV-based modulating technique is a digital technique in which the objective is to generate PWM load line voltages that are on average equal to given load line voltages. This is done in each sampling period by properly selecting the switch states from the valid ones of the VSI (Table 11.5) and by proper calculation of the period of times they are used. The selection and calculation times are based upon the SV transformation.

11.3.5.1 Space-Vector Transformation

Any three-phase set of variables that add up to zero in the stationary *abc* frame can be represented in a complex plane by a complex vector that contains a real (α) and an imaginary (β) component. For instance, the vector of three-phase line-modulating signals $\mathbf{v}_c^{abc} = [v_{ca} v_{cb} v_{cc}]^T$ can be represented by the complex vector $\vec{\mathbf{v}}_c = \mathbf{v}_c^{\alpha\beta} = [v_{c\alpha} v_{c\beta}]^T$ by means of the following transformation:

$$v_{c\alpha} = \frac{2}{3}[v_{ca} - 0.5(v_{cb} + v_{cc})] \tag{11.31}$$

$$v_{c\beta} = \frac{\sqrt{3}}{3}(v_{cb} - v_{cc}) \tag{11.32}$$

If the line-modulating signals $\mathbf{v}_c^{abc}$ are three balanced sinusoidal waveforms that feature an amplitude $\hat{v}_c$ and an angular frequency ω, the resulting modulating signals in the $\alpha\beta$ stationary frame become a vector $\vec{\mathbf{v}}_c = \mathbf{v}_c^{\alpha\beta}$ of fixed module $\hat{v}_c$, which rotates at frequency ω (Fig. 11.24). Similarly, the SV transformation is applied to the line voltages of the eight states of the VSI normalized with respect to v_i (Table 11.5), which generates

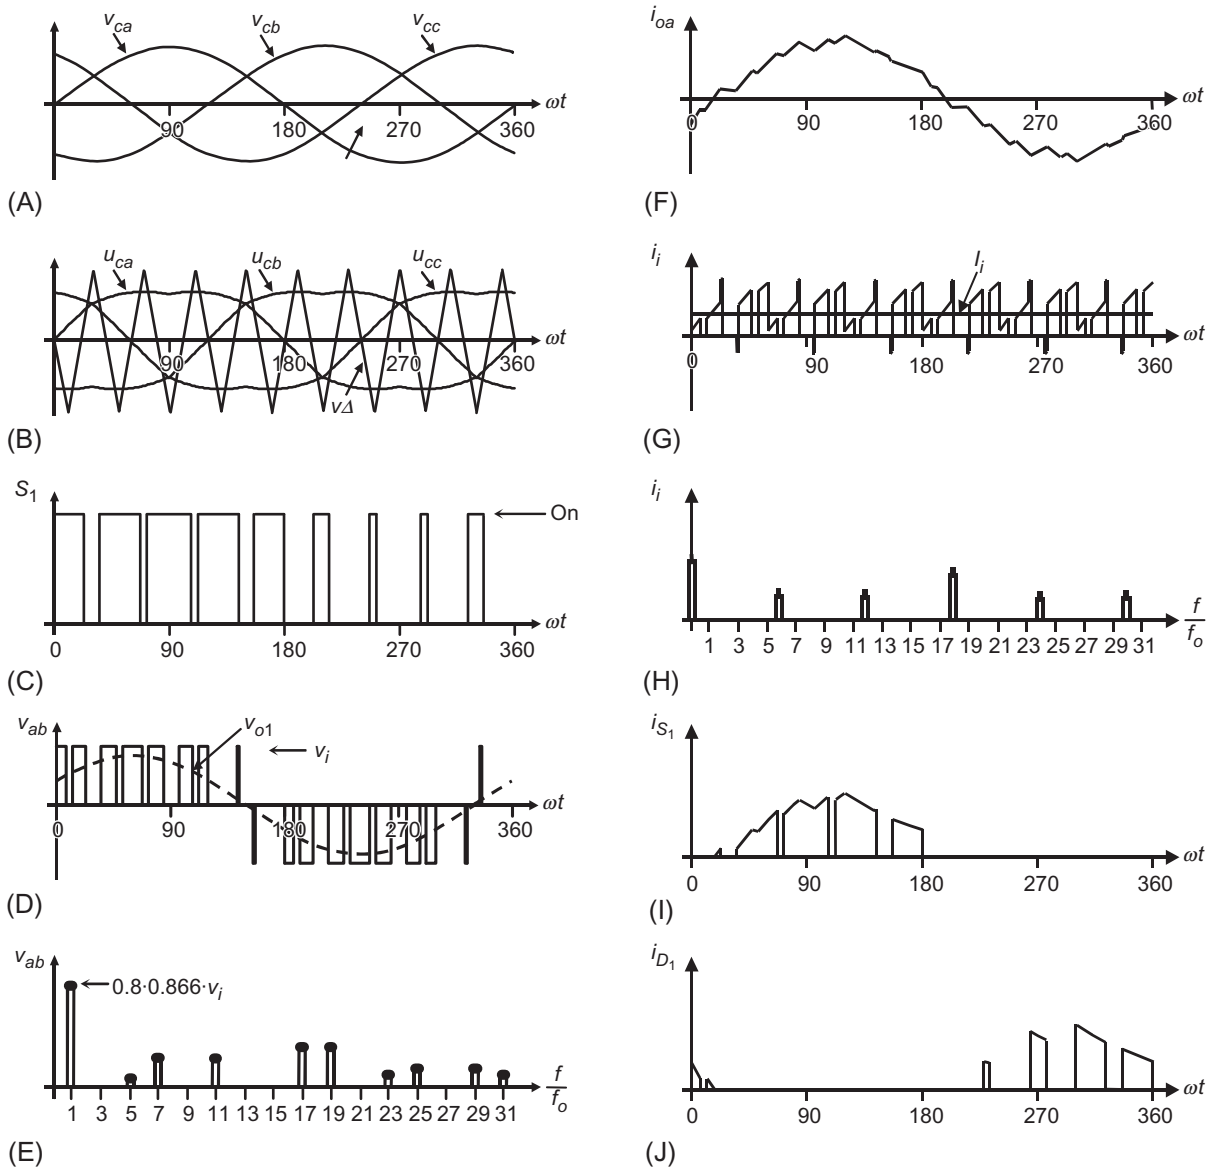

FIG. 11.21 The three-phase VSI. Ideal waveforms for the SPWM ($m_a = 0.8$, $m_f = 9$) with zero-sequence signal injection: (A) modulating signals, (B) carrier and modulating signals with zero-sequence signal injection, (C) switch S_1 state, (D) ac output voltage, (E) ac output voltage spectrum, (F) ac output current, (G) dc current, (H) dc current spectrum, (I) switch S_1 current, and (J) diode D_1 current.

the eight space vectors ($\vec{\mathbf{v}}_i$, $i = 1,2,\ldots,8$) in Fig. 11.24. As expected, $\vec{\mathbf{v}}_1$ to $\vec{\mathbf{v}}_6$ are nonnull line-voltage vectors, and $\vec{\mathbf{v}}_7$ and $\vec{\mathbf{v}}_8$ are null line-voltage vectors.

The objective of the SV technique is to approximate the line-modulating signal space vector $\vec{\mathbf{v}}_\mathbf{c}$ with the eight space vectors ($\vec{\mathbf{v}}_i$, $i = 1,2,\ldots,8$) available in VSIs. However, if the modulating signal $\vec{\mathbf{v}}_\mathbf{c}$ is laying between the arbitrary vectors $\vec{\mathbf{v}}_i$ and $\vec{\mathbf{v}}_{i+1}$, only the nearest two nonzero vectors ($\vec{\mathbf{v}}_i$ and $\vec{\mathbf{v}}_{i+1}$) and the zero SV ($\vec{\mathbf{v}}_z = \vec{\mathbf{v}}_7$ or $\vec{\mathbf{v}}_8$) should be used. Thus, the maximum load line voltage is maximized, and the switching frequency is minimized. To ensure that the generated voltage in one sampling period T_s (made up of the voltages provided by the vectors $\vec{\mathbf{v}}_i$, $\vec{\mathbf{v}}_{i+1}$, and $\vec{\mathbf{v}}_z$ used during times T_i, T_{i+1}, and T_z) is on average equal to the vector $\vec{\mathbf{v}}_\mathbf{c}$, the following expression should hold:

$$\vec{\mathbf{v}}_\mathbf{c} \cdot T_s = \vec{\mathbf{v}}_i \cdot T_s + \vec{\mathbf{v}}_{i+1} \cdot T_{i+1} + \vec{\mathbf{v}}_z \cdot T_z \tag{11.33}$$

The solution of the real and imaginary parts of Eq. (11.32) for a line-load voltage that features an amplitude restricted to $0 \le \hat{v}_c \le 1$ gives

$$T_i = T_s \cdot \hat{v}_c \cdot \sin(\pi/3 - \theta) \tag{11.34}$$

$$T_{i+1} = T_s \cdot \hat{v}_c \cdot \sin(\theta) \tag{11.35}$$

$$T_z = T_s - T_i - T_{i+1} \tag{11.36}$$

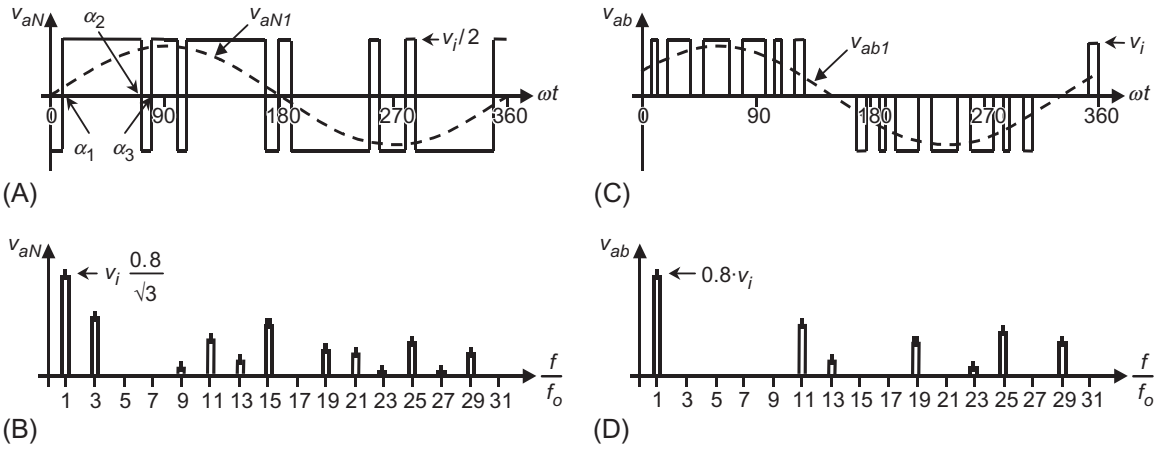

FIG. 11.22 The three-phase VSI. Ideal waveforms for the SHE technique: (A) phase voltage v_{aN} for fifth- and seventh-harmonic elimination, (B) spectrum of (A), (C) line voltage v_{ab} for fifth- and seventh-harmonic elimination, and (D) spectrum of (C).

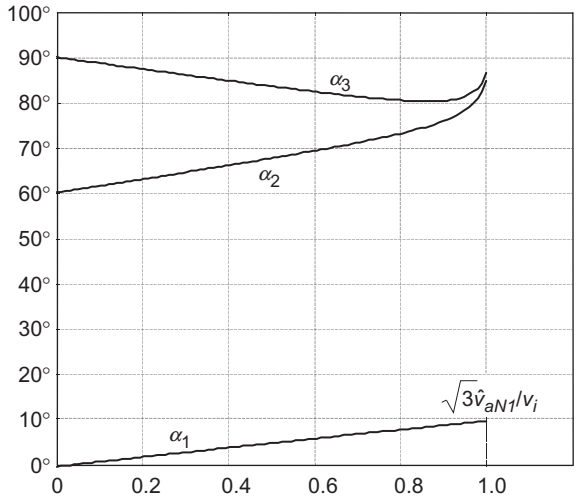

FIG. 11.23 Chopping angles for SHE and fundamental voltage control in three-phase VSIs: fifth- and seventh-harmonic elimination.

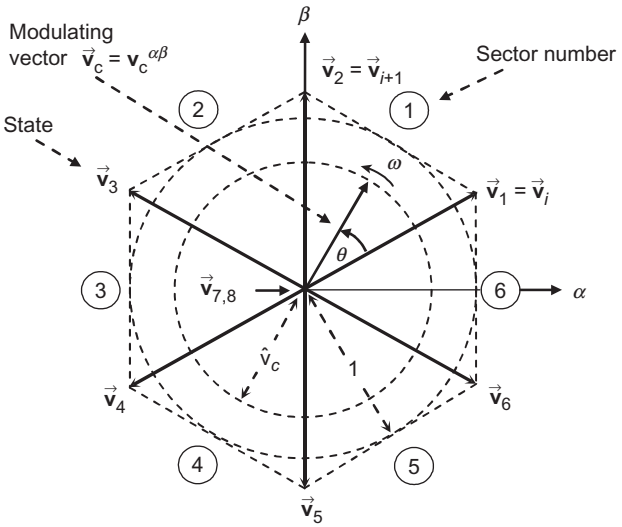

FIG. 11.24 The space-vector representation.

The preceding expressions indicate that the maximum fundamental line-voltage amplitude is unity as $0 \leq \theta \leq \pi/3$. This is an advantage over the SPWM technique that achieves a $\sqrt{3}/2$ maximum fundamental line-voltage amplitude in the linear operating region. Although the space-vector-modulation (SVM) technique selects the vectors to be used and their respective on-times, the sequence in which they are used, the selection of the zero space vector, and the normalized sampled frequency remain undetermined.

For instance, if the modulating line-voltage vector is in sector 1 (Fig. 11.24), the vectors $\vec{v}_1$, $\vec{v}_2$, and $\vec{v}_z$ should be used within a sampling period by intervals given by T_1, T_2, and T_z, respectively. However, the sequence should be different, for example, (i) $\vec{v}_1 - \vec{v}_2 - \vec{v}_z$, (ii) $\vec{v}_z - \vec{v}_1 - \vec{v}_2 - \vec{v}_z$, and (iii) $\vec{v}_z - \vec{v}_1 - \vec{v}_2 - \vec{v}_1 - \vec{v}_z$. Finally, the technique does not indicate whether $\vec{v}_z$ should be $\vec{v}_7$, $\vec{v}_8$, or a combination of both.

11.3.5.2 Space-Vector Sequences and Zero Space-Vector Selection

The sequence to be used should ensure load line voltages that feature quarter-wave symmetry in order to reduce unwanted harmonics in their spectra (even harmonics). Additionally, the zero SV selection should be done in order to reduce the switching frequency. Although there is not a systematic approach to generate a SV sequence, a graphic representation shows that the sequence $\vec{v}_i$, $\vec{v}_{i+1}$, $\vec{v}_z$ (where v_z is alternately chosen among $\vec{v}_7$ and $\vec{v}_8$) provides high performance in terms of minimizing unwanted harmonics and reducing the switching frequency.

11.3.5.3 The Normalized Sampling Frequency

The normalized carrier frequency m_f in three-phase carrier-based PWM techniques is chosen to be an odd integer number

multiple of 3 ($m_f = 3 \cdot n$, $n = 1,3,5,\ldots$). Thus, it is possible to minimize parasitic or nonintrinsic harmonics in the PWM waveforms. A similar approach can be used in the SVM technique to minimize uncharacteristic harmonics. Hence, it is found that the normalized sampling frequency f_{sn} should be an integer multiple of 6. This is due to the fact that in order to produce symmetrical line voltages, all the sectors (a total of six) should be used equally in one period. As an example, Fig. 11.25 shows the relevant waveforms of a VSI SVM for $f_{sn} = 18$ and $\hat{v}_c = 0.8$. Fig. 11.25 confirms that the first set of relevant harmonics in the load line voltage are at f_{sn}, which is also the switching frequency.

11.3.6 DC Link Current in Three-Phase VSIs

Due to the fact that the inverter is assumed to be lossless and constructed without storage energy components, the instantaneous power balance indicates that

$$v_i(t) \cdot i_i(t) = v_{ab}(t) \cdot i_a(t) + v_{bc}(t) \cdot i_b(t) + v_{ca}(t) \cdot i_c(t) \quad (11.37)$$

where $i_a(t)$, $i_b(t)$, and $i_c(t)$ are the phase-load currents as shown in Fig. 11.26. If the load is balanced and inductive and a relatively high switching frequency is used, the load currents become nearly sinusoidal balanced waveforms. On the other hand, if the ac output voltages are considered sinusoidal and

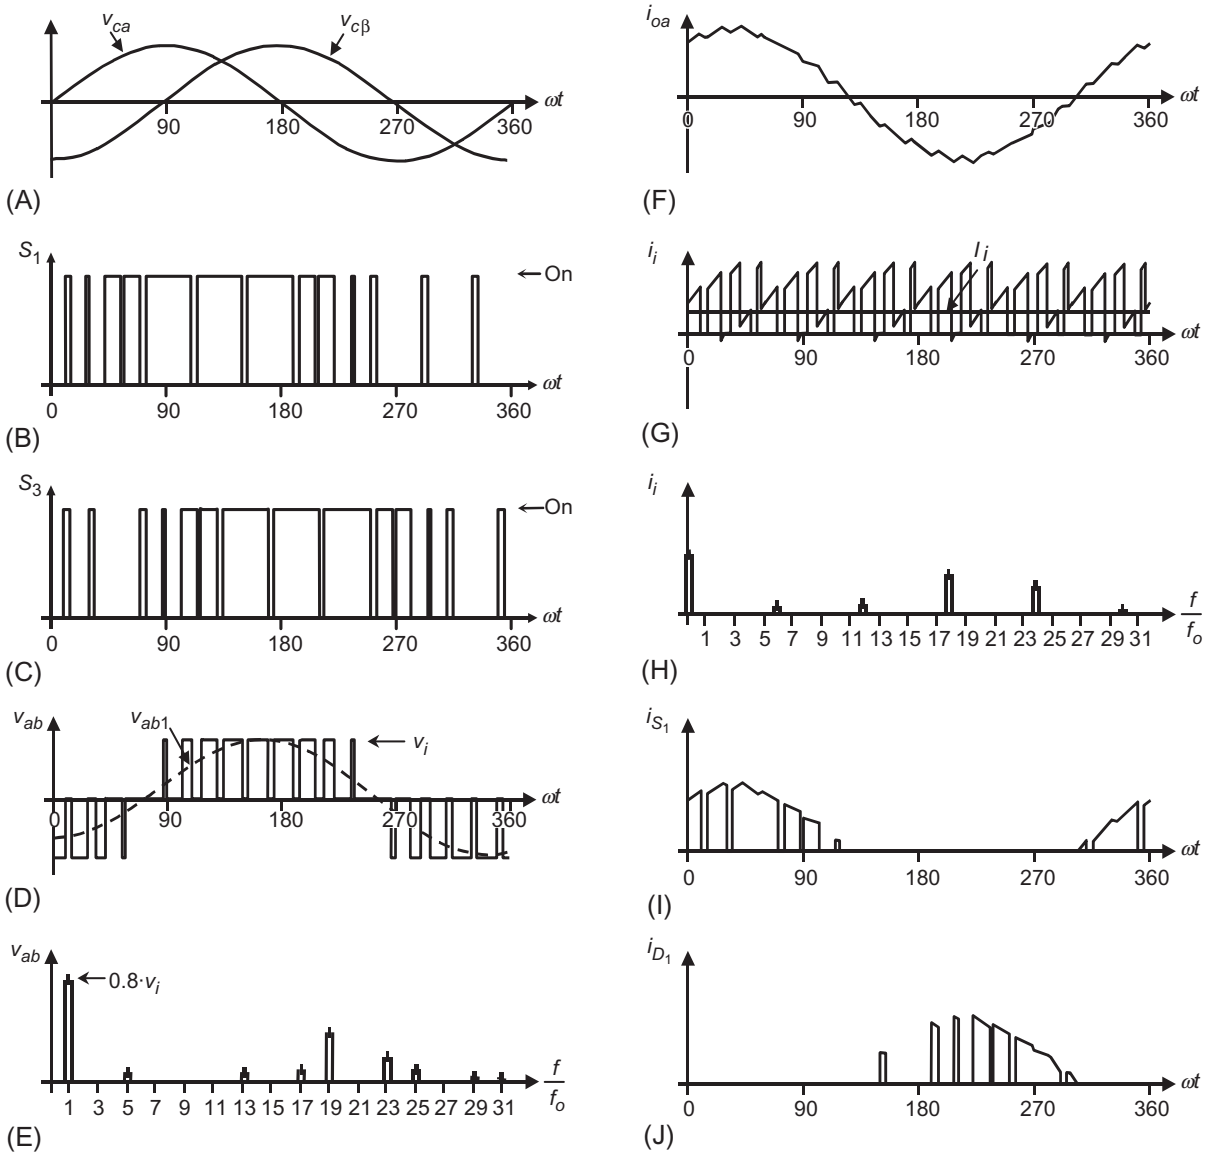

FIG. 11.25 The three-phase VSI. Ideal waveforms for space-vector modulation ($\hat{v}_c = 0.8$, $f_{sn} = 18$): (A) modulating signals, (B) switch S_1 state, (C) switch S_3 state, (D) ac output voltage, (E) ac output voltage spectrum, (F) ac output current, (G) dc current, (H) dc current spectrum, (I) switch S_1 current, and (J) diode D_1 current.

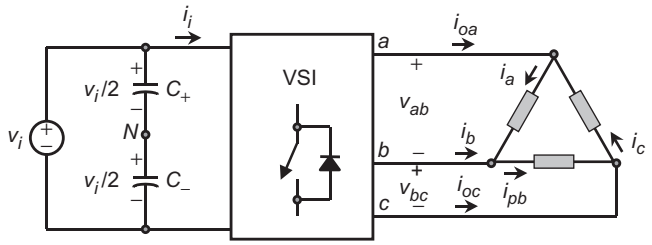

FIG. 11.26 Phase-load currents definition in a delta-connected load.

the dc link voltage is assumed constant $v_i(t) = V_i$, Eq. (11.37) can be simplified to

$$i_i(t) = \frac{1}{V_i}\left\{\begin{array}{l}\sqrt{2}V_{o1}\sin(\omega t)\cdot\sqrt{2}I_o\sin(\omega t-\phi)\\ +\sqrt{2}V_{o1}\sin(\omega t-120^\circ)\cdot\sqrt{2}I_o\sin(\omega t-120^\circ-\phi)\\ +\sqrt{2}V_{o1}\sin(\omega t-240^\circ)\cdot\sqrt{2}I_o\sin(\omega t-240^\circ-\phi)\end{array}\right\} \tag{11.38}$$

where V_{o1} is the fundamental rms ac output line voltage, I_o is the rms phase-load current, and ϕ is an arbitrary inductive load power factor. Hence, the dc link current expression can be further simplified to

$$i_i(t) = 3\frac{V_{o1}}{V_i}I_o\cos(\phi) = \sqrt{3}\frac{V_{o1}}{V_i}I_l\cos(\phi) \tag{11.39}$$

where $I_l = \sqrt{3}I_o$ is the rms load line current. The resulting dc link current expression indicates that under harmonic-free load voltages, only a clean dc current should be expected in the dc bus and, compared with single-phase VSIs, there is no presence of second harmonic. However, as the ac load line voltages contain harmonics around the normalized sampling frequency f_{sn}, the dc link current will contain harmonics but around f_{sn} as shown in Fig. 11.25H.

11.3.7 Phase-Load Voltage in Three-Phase VSIs

The load is sometimes wye-connected, and the phase-load voltages v_{an}, v_{bn}, and v_{cn} may be required (Fig. 11.27). To obtain them, it should be considered that the line-voltage vector is

$$\begin{bmatrix}v_{ab}\\ v_{bc}\\ v_{ca}\end{bmatrix} = \begin{bmatrix}v_{an}-v_{bn}\\ v_{bn}-v_{cn}\\ v_{cn}-v_{an}\end{bmatrix} \tag{11.40}$$

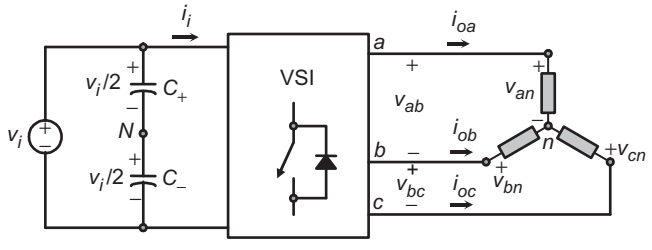

FIG. 11.27 Phase-load voltages definition in a wye-connected load.

which can be written as a function of the phase voltage vector $[v_{an}v_{bn}v_{cn}]^T$ as

$$\begin{bmatrix}v_{ab}\\ v_{bc}\\ v_{ca}\end{bmatrix} = \begin{bmatrix}1 & -1 & 0\\ 0 & 1 & -1\\ -1 & 0 & 1\end{bmatrix}\begin{bmatrix}v_{an}\\ v_{bn}\\ v_{cn}\end{bmatrix} \tag{11.41}$$

Expression (11.41) represents a linear system where the unknown quantity is the vector $[v_{an}v_{bn}v_{cn}]^T$. Unfortunately, the system is singular as the rows add up to zero (line voltages add up to zero); therefore, the phase-load voltages cannot be obtained by matrix inversion. However, if the phase-load voltages add up to zero, Eq. (11.41) can be rewritten as

$$\begin{bmatrix}v_{ab}\\ v_{bc}\\ 0\end{bmatrix} = \begin{bmatrix}1 & -1 & 0\\ 0 & 1 & -1\\ 1 & 1 & 1\end{bmatrix}\begin{bmatrix}v_{an}\\ v_{bn}\\ v_{cn}\end{bmatrix} \tag{11.42}$$

which is not singular, and hence,

$$\begin{bmatrix}v_{an}\\ v_{bn}\\ v_{cn}\end{bmatrix} = \begin{bmatrix}1 & -1 & 0\\ 0 & 1 & -1\\ 1 & 1 & 1\end{bmatrix}^{-1}\begin{bmatrix}v_{ab}\\ v_{bc}\\ 0\end{bmatrix} = \frac{1}{3}\begin{bmatrix}2 & 1 & 1\\ -1 & 1 & 1\\ -1 & -2 & 1\end{bmatrix}\begin{bmatrix}v_{ab}\\ v_{bc}\\ 0\end{bmatrix} \tag{11.43}$$

that can be further simplified to

$$\begin{bmatrix}v_{an}\\ v_{bn}\\ v_{cn}\end{bmatrix} = \frac{1}{3}\begin{bmatrix}2 & 1\\ -1 & 1\\ -1 & -2\end{bmatrix}\begin{bmatrix}v_{ab}\\ v_{bc}\end{bmatrix} \tag{11.44}$$

The final expression for the phase-load voltages is only a function of v_{ab} and v_{bc}, which is due to the fact that the last row in Eq. (11.42) is chosen to be only ones. Fig. 11.28 shows the line and phase voltages obtained using Eq. (11.44).

In the particular case of a square-wave three-phase VSI, this is known as a six-step inverter because of the six voltage changes per output voltage cycle.

11.4 Three-Phase Current Source Inverters

The main objective of these static power converters is to produce an ac output current waveforms from a dc current power supply. For sinusoidal ac outputs, its magnitude, frequency, and phase should be controllable. Due to the fact that the ac line currents i_{oa}, i_{ob}, and i_{oc} (Fig. 11.29) feature high di/dt, a capacitive filter should be connected at the ac output. These topologies are mainly used in medium-voltage industrial applications, where high-quality voltage waveforms are required.

In order to properly gate the power switches of a three-phase CSI, the compulsory rules of Section 11.2.2 are valid. The main constraints are that one top switch (1, 3, or 5 (Fig. 11.29)) and

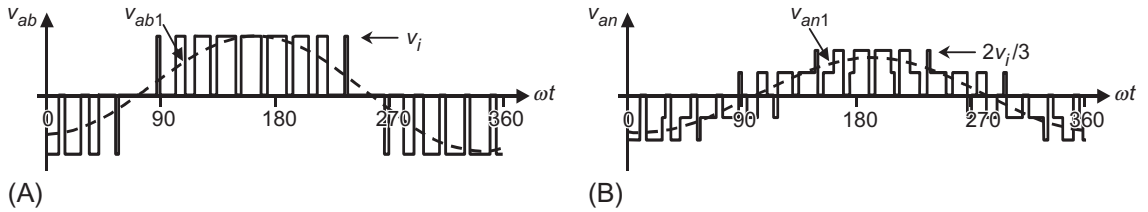

FIG. 11.28 The three-phase VSI and line- and phase-load voltages: (A) line-load voltage v_{ab} and (B) phase-load voltage v_{an}.

one bottom switch (4, 6, or 2 (Fig. 11.29)) should be closed at any time.

There are nine valid states in three-phase CSIs. The states 7, 8, and 9 (Table 11.6) produce zero ac line currents. The remaining states (1–6 in Table 11.6) produce nonzero ac output line currents. In order to generate a given set of ac line current waveforms, the inverter must move from one state to another. Thus, the resulting line currents consist of discrete values of current, which are i_i, 0, and $-i_i$. The selection of the states in order to generate the given waveforms is done by the modulating technique that should ensure the use of only the valid states.

There are several modulating techniques that deal with the special requirements of CSIs and can be implemented. These techniques are classified into three categories: (a) the carrier-based, (b) the SHE-based, and (c) the SV-based techniques. Although they are different, they generate gating signals that satisfy the special requirements of CSIs. To simplify the analysis, a constant dc link current source is considered ($i_i = I_i$).

11.4.1 Carrier-Based PWM Techniques in CSIs

It has been mentioned that the carrier-based PWM techniques that were initially developed for three-phase VSIs can be extended to three-phase CSIs. The circuit shown in Fig. 11.30 obtains the gating pattern for a CSI from the gating pattern developed for a VSI. As a result, the line current appears to be identical to the line voltage in a VSI for similar carrier and modulating signals.

It is composed of a switching pulse generator, a shorting pulse generator, a shorting pulse distributor, and a switching and shorting pulse combinator. The circuit basically produces the gating signals ($\mathbf{s} = [s_1 \ldots s_6]^T$) according to a carrier i_Δ and three modulating signals $\mathbf{i}_\mathbf{c}^{abc} = [i_{ca} i_{cb} i_{ca}]^T$.

The first component of this stage (Fig. 11.30) is the switching pulse generator, where the signals $\mathbf{s}_\mathbf{a}^{123}$ are generated according to

$$\mathbf{s}_\mathbf{a}^{123} = \begin{cases} \text{HIGH} = 1 \; if & \mathbf{i}_\mathbf{c}^{abc} > v_c \\ \text{LOW} = 0 & otherwise \end{cases} \tag{11.45}$$

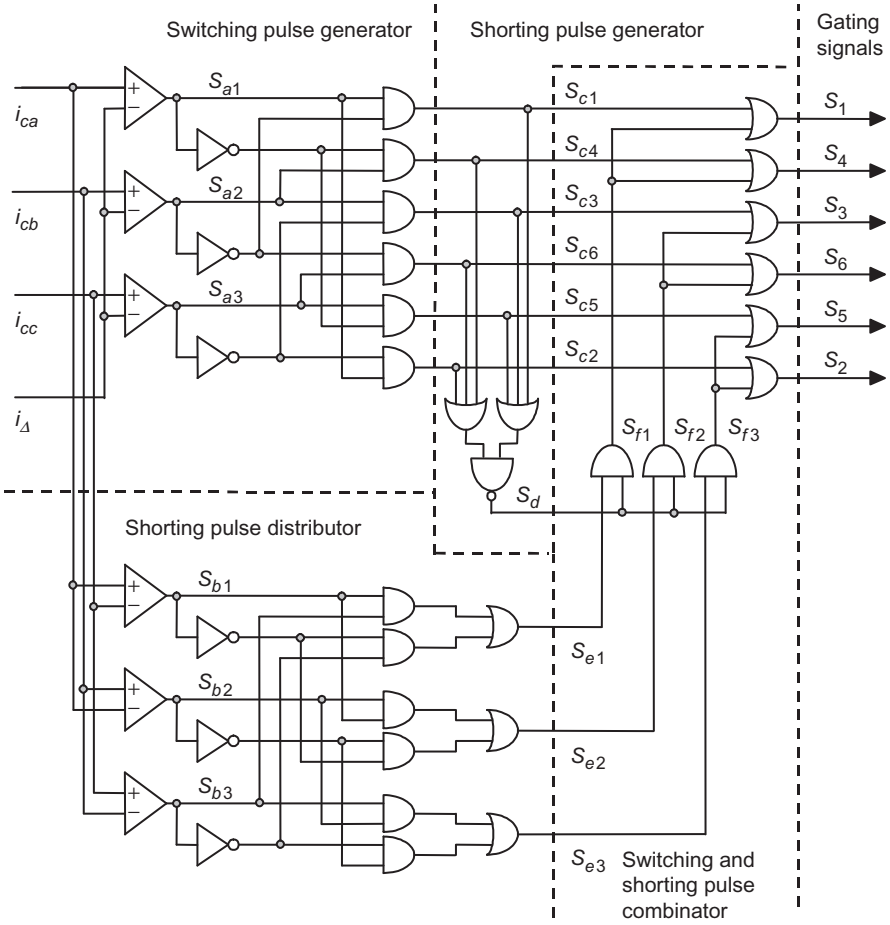

FIG. 11.30 The three-phase CSI. Gating pattern generator for analog online carrier-based PWM.

The outputs of the *switching pulse generator* are the signals $\mathbf{s_c}$, which are basically the gating signals of the CSI without the shorting pulses. These are necessary to inject the dc link current i_i when no zero ac output currents are required.

In order to satisfy the first compulsory rule for CSI, the shorting pulse ($s_d = 1$) is generated by the *shorting pulse generator* (Fig. 11.30); this are used to produce zero ac output currents. Then, this pulse is added (using OR gates) to only one leg of the CSI (either to the switches 1 and 4, 3 and 6, or 5 and 2) by means of the *switching and shorting pulse combinator* (Fig. 11.30). The signals generated by the *shorting pulse generator* $\mathbf{s_e}^{123}$ not only ensure that only one leg of the CSI is shorted at any time but also give an even distribution of the shorting pulse, as $\mathbf{s_e}^{123}$ is high for 120° in each period. This ensures that the rms currents are equal in all legs.

Fig. 11.31 shows the relevant waveforms if a triangular carrier i_{Δ} and sinusoidal modulating signals $\mathbf{i_c}^{abc}$ are used in combination with the gating pattern generator circuit (Fig. 11.30); this is SPWM in CSIs. It can be observed that some of the waveforms (Fig. 11.31) are identical to those obtained in three-phase VSIs, where an SPWM technique is used (Fig. 11.18). Specifically, (i) the load line voltage (Fig. 11.18D) in the VSI is identical to the load line current (Fig. 11.31D) in the CSI and (ii) the dc link current (Fig. 11.18G) in the VSI is identical to the dc link voltage (Fig. 11.31G) in the CSI.

This brings up the duality issue between both the topologies when similar modulation approaches are used. Therefore, for odd multiples of 3 values of the normalized carrier frequency m_f, the harmonics in the ac output current appear at normalized frequencies f_h centered around m_f and its multiples, specifically, at

$$h = l m_f \pm k \quad l = 1, 2, \ldots \tag{11.46}$$

where $l = 1, 3, 5, \ldots$ for $k = 2, 4, 6, \ldots$ and $l = 2, 4, \ldots$ for $k = 1, 5, 7, \ldots$ such that h is not a multiple of 3. Therefore, the harmonics will be at $m_f \pm 2$, $m_f \pm 4, \ldots$, $2m_f \pm 1$, $2m_f \pm 5, \ldots$, $3m_f \pm 2$, $3m_f \pm 4, \ldots$, $4m_f \pm 1$, $4m_f \pm 5, \ldots$. For nearly sinusoidal ac load voltages, the harmonics in the dc link voltage are at frequencies given by

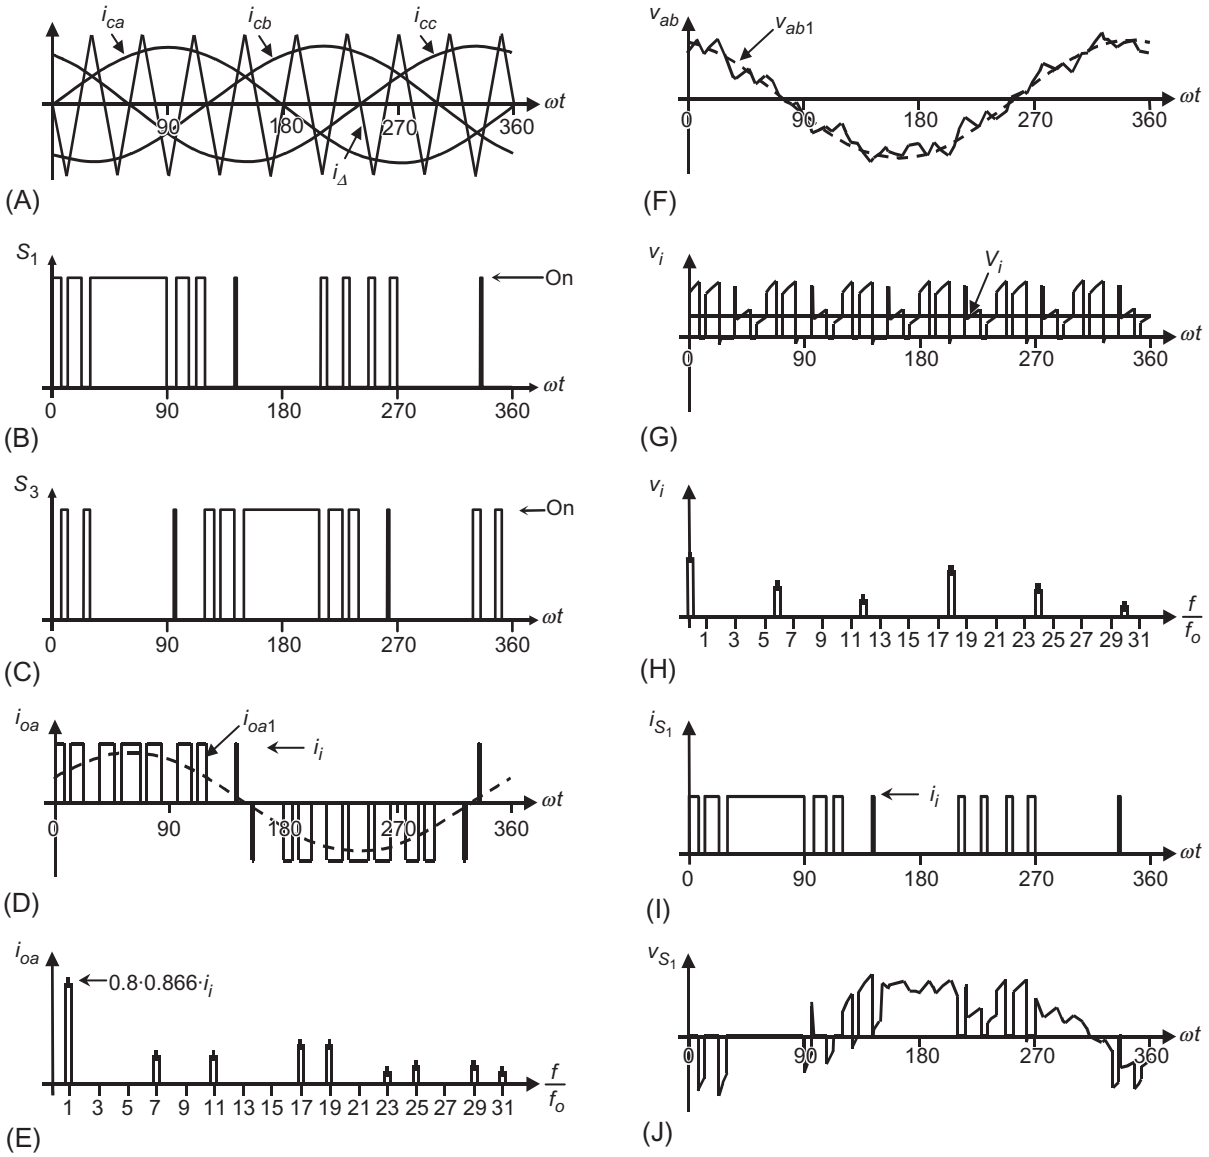

FIG. 11.31 The three-phase CSI. Ideal waveforms for the SPWM ($m_a = 0.8$, $m_f = 9$): (A) carrier and modulating signals, (B) switch S_1 state, (C) switch S_3 state, (D) ac output current, (E) ac output current spectrum, (F) ac output voltage, (G) dc voltage, (H) dc voltage spectrum, (I) switch S_1 current, and (J) switch S_1 voltage.

$$h = lm_f \pm k \pm 1 \quad l = 1,2,\ldots \tag{11.47}$$

where $l = 0,2,4,\ldots$ for $k = 1,5,7,\ldots$ and $l = 1,3,5,\ldots$ for $k = 2,4,6,\ldots$ such that $h = l \cdot m_f \pm k$ is positive and not a multiple of 3. For instance, Fig. 11.31H shows the sixth harmonic ($h = 6$), which is due to $h = 1 \cdot 9 - 2 - 1 = 6$. Identical conclusions can be drawn for the small and large values of m_f in the same way as for three-phase VSI configurations. Thus, the maximum amplitude of the fundamental ac output line current is $\hat{i}_{oa1} = \sqrt{3}i_i/2$, and therefore, one can write

$$\hat{i}_{oa1} = m_a \frac{\sqrt{3}}{2} i_i \quad 0 < m_a \leq 1 \tag{11.48}$$

To further increase the amplitude of the load current, the overmodulation approach can be used. In this region, the fundamental line currents range in

$$\frac{\sqrt{3}}{2} i_i < \hat{i}_{oa1} = \hat{i}_{ob1} = \hat{i}_{oc1} < \frac{4}{\pi}\frac{\sqrt{3}}{2} i_i \tag{11.49}$$

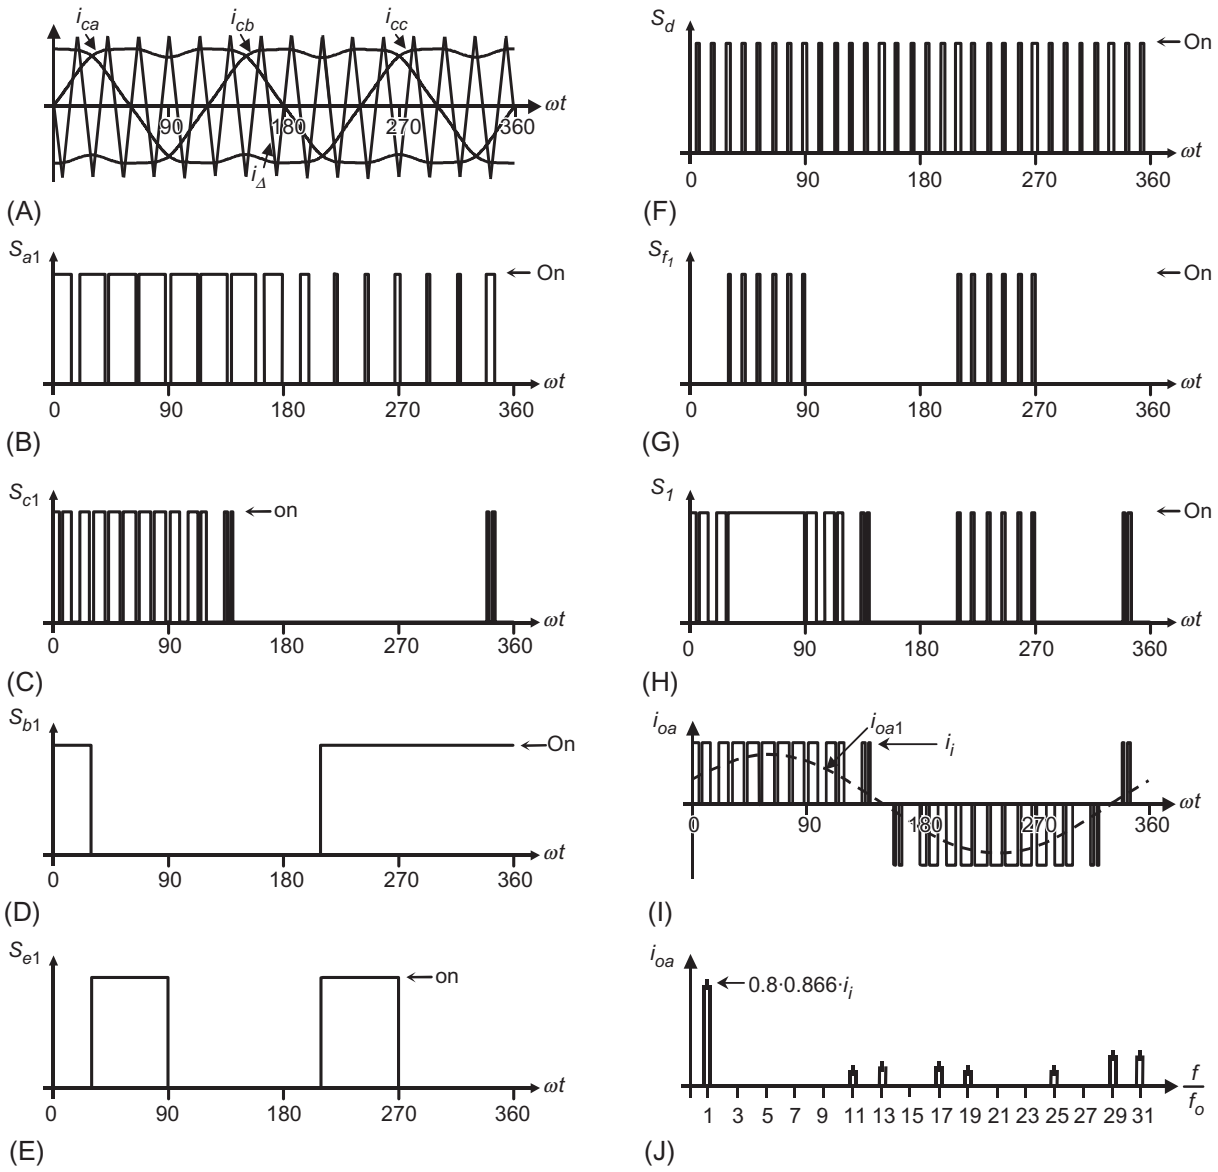

FIG. 11.32 Gating pattern generator. Waveforms for third- and ninth-harmonic injection PWM ($m_a = 0.8$, $m_f = 15$): signals as described in Fig. 11.30.

To further test the gating signal generator circuit (Fig. 11.30), a sinusoidal set with third- and ninth-harmonic injection modulating signals are used. Fig. 11.32 shows the relevant waveforms.

11.4.2 Square-Wave Operation of Three-phase CSIs

As in VSIs, large values of m_a in the SPWM technique lead to full overmodulation. This is known as square-wave operation. Fig. 11.33 depicts this operating mode in a three-phase CSI, where the power semiconductors are on for 120°. As presumed, the CSI cannot control the load current except by means of the dc link current i_i. This is due to the fact that the fundamental ac line current expression is

$$\hat{i}_{oa1} = \frac{4}{\pi}\frac{\sqrt{3}}{2} i_i \tag{11.50}$$

The ac line current contains the harmonics f_h, where $h = 6 \cdot k \pm 1$ ($k = 1, 2, 3, \ldots$), and they feature amplitudes that are inversely proportional to their harmonic order (Fig. 11.33D). Thus,

$$\hat{i}_{oah} = \frac{1}{h}\frac{4}{\pi}\frac{\sqrt{3}}{2} i_i \tag{11.51}$$

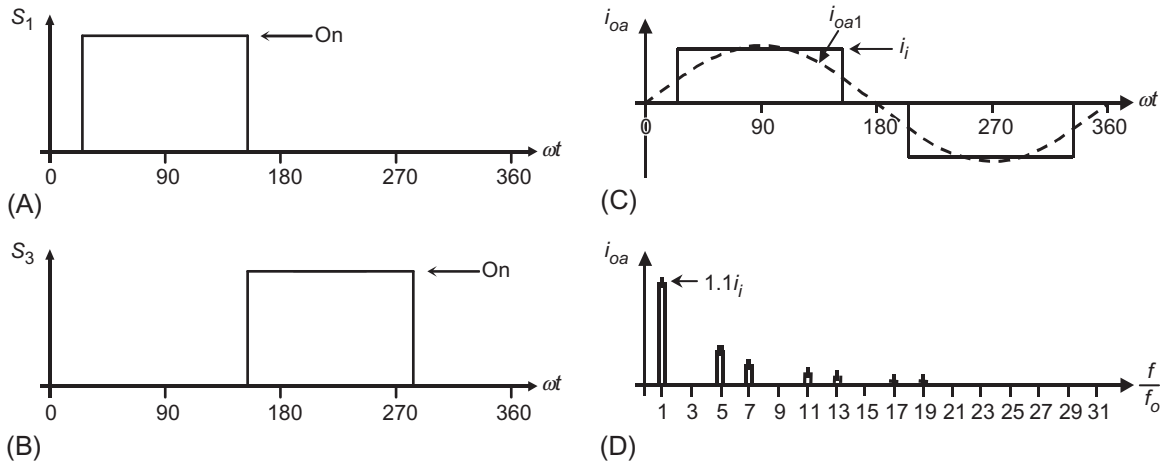

FIG. 11.33 The three-phase CSI. Square-wave operation: (A) switch S_1 state, (B) switch S_3 state, (C) ac output current, and (D) ac output current spectrum.

The duality issue among both the three-phase VSI and CSI should be noted especially in terms of the line-load waveforms. The line-load voltage produced by a VSI is identical to the load line current produced by the CSI when both are modulated using identical techniques. The next section will show that this also holds for SHE-based techniques.

11.4.3 Selective Harmonic Elimination in Three-phase CSIs

The SHE-based modulating techniques in VSIs define the gating signals such that a given number of harmonics are eliminated and the fundamental phase voltage amplitude is controlled. If the required line output voltages are balanced and 120° out of phase, the chopping angles are used to eliminate only the harmonics at frequencies $h = 5,7,11,13,\ldots$ as required.

The circuit shown in Fig. 11.34 uses the gating signals $\mathbf{s}_\mathbf{a}^{123}$ developed for a VSI and a set of synchronizing signals $\mathbf{i}_\mathbf{c}^{abc}$ to obtain the gating signals $\mathbf{s}$ for a CSI. The synchronizing signals $\mathbf{i}_\mathbf{c}^{abc}$ are sinusoidal balanced waveforms that are synchronized with the signals $\mathbf{s}_\mathbf{a}^{123}$ in order to symmetrically distribute the shorting pulse and thus generate symmetrical gating patterns. The circuit ensures line current waveforms as the line-voltage ones in a VSI. Therefore, any arbitrary number of harmonics can be eliminated, and the fundamental line current can be controlled in CSIs. Moreover, the same chopping angles obtained for VSIs can be used in CSIs.

For instance, to eliminate the fifth and seventh harmonics, the chopping angles are shown in Fig. 11.35, which are identical to that obtained for a VSI using Eq. (11.10). Fig. 11.36 shows that the line current does not contain the fifth and the seventh harmonics as expected. Hence, any number of harmonics can be eliminated in three-phase CSIs by means of the circuit (Fig. 11.34) without the hassle of how to satisfy the gating signal constrains.

11.4.4 Space-Vector-Based Modulating Techniques in CSIs

The objective of the SV-based modulating technique is to generate PWM load line currents that are on average equal to given load line currents. This is done digitally in each sampling period by properly selecting the switch states from the valid ones of the CSI (Table 11.6) and the proper calculation of the period of times they are used. As in VSIs, the selection and time calculations are based upon the space-vector transformation.

11.4.4.1 Space-Vector Transformation in CSIs

Similarly to VSIs, the vector of three-phase line-modulating signals $\mathbf{i}_\mathbf{c}^{abc} = [i_{ca}\, i_{cb}\, i_{cc}]^T$ can be represented by the complex vector $\vec{\mathbf{i}}_\mathbf{c} = \mathbf{i}_\mathbf{c}^{\alpha\beta} = [i_{c\alpha}\, i_{c\beta}]^T$ by means of Eqs. (11.31) and (11.32). For three-phase balanced sinusoidal modulating waveforms, which feature an amplitude $\hat{\imath}_c$ and an angular frequency ω, the resulting modulating signal complex vector $\vec{\mathbf{i}}_\mathbf{c} = \mathbf{i}_\mathbf{c}^{\alpha\beta}$ becomes a vector of fixed module $\hat{\imath}_c$, which rotates at frequency ω (Fig. 11.37). Similarly, the SV transformation is applied to the line currents of the nine states of the CSI normalized with respect to i_i, which generates nine space vectors ($\vec{\mathbf{i}}_i$, $i = 1,2,\ldots,9$ in Fig. 11.37). As expected, $\vec{\mathbf{i}}_1$ to $\vec{\mathbf{i}}_6$ are nonnull line current vectors, and $\vec{\mathbf{i}}_7$, $\vec{\mathbf{i}}_8$, and $\vec{\mathbf{i}}_9$ are null line current vectors.

The SV technique approximates the line-modulating signal space vector $\vec{\mathbf{i}}_\mathbf{c}$ by using the nine space vectors ($\vec{\mathbf{i}}_i$, $i = 1,2,\ldots,9$) available in CSIs. If the modulating signal vector $\vec{\mathbf{i}}_\mathbf{c}$ is between the arbitrary vectors $\vec{\mathbf{i}}_i$ and $\vec{\mathbf{i}}_{i+1}$, then $\vec{\mathbf{i}}_i$ and $\vec{\mathbf{i}}_{i+1}$ combined with one zero SV ($\vec{\mathbf{i}}_z = \vec{\mathbf{i}}_7$ or $\vec{\mathbf{i}}_8$ or $\vec{\mathbf{i}}_9$) should be used to generate $\vec{\mathbf{i}}_\mathbf{c}$. To ensure that the generated current in one sampling period T_s (made up of the currents provided by the vectors $\vec{\mathbf{i}}_i$, $\vec{\mathbf{i}}_{i+1}$, and $\vec{\mathbf{i}}_z$ used during times T_i, T_{i+1}, and T_z) is on average equal to the vector $\vec{\mathbf{i}}_\mathbf{c}$, the following expressions should hold:

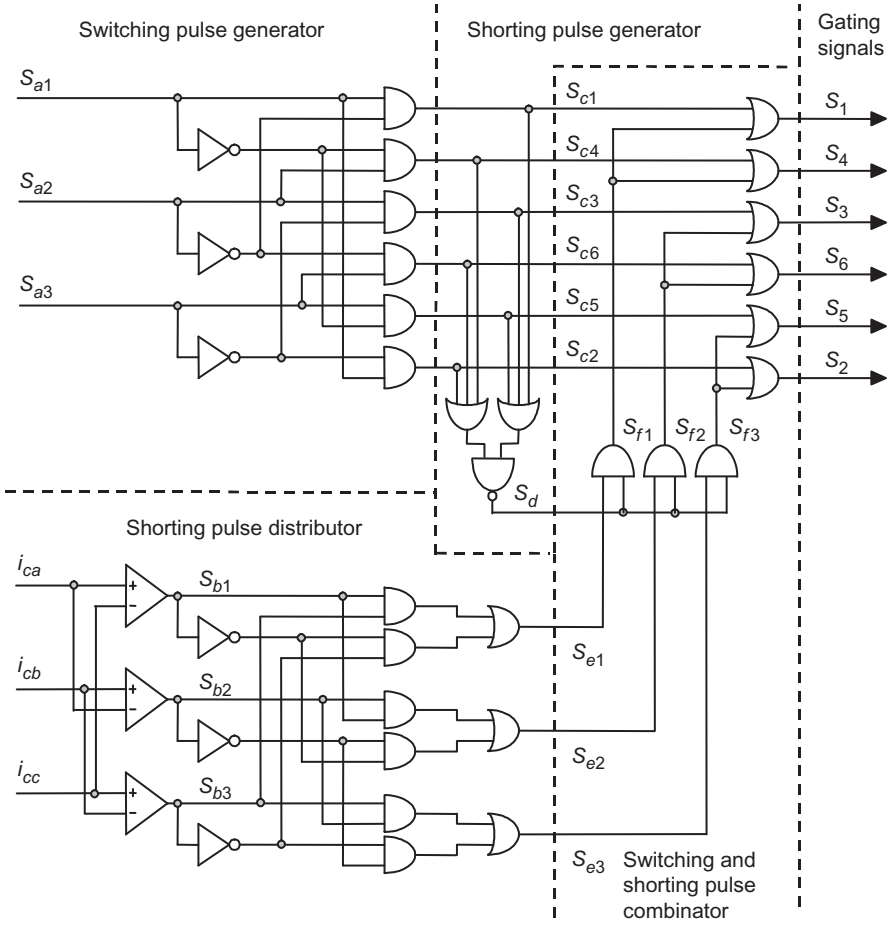

FIG. 11.34 The three-phase CSI. Gating pattern generator for SHE PWM techniques.

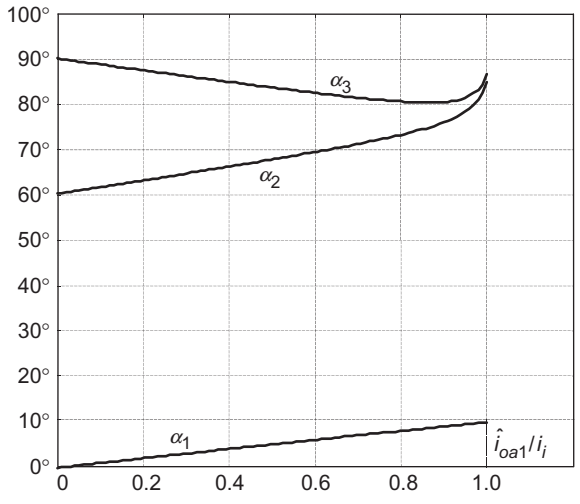

FIG. 11.35 Chopping angles for SHE and fundamental current control in three-phase CSIs, fifth- and seventh-harmonic elimination.

$$T_i = T_s \cdot \hat{i}_c \cdot \sin(\pi/3 - \theta) \tag{11.52}$$

$$T_{i+1} = T_s \cdot \hat{i}_c \cdot \sin(\theta) \tag{11.53}$$

$$T_z = T_s - T_i - T_{i+1} \tag{11.54}$$

where $0 \leq \hat{i}_c \leq 1$. Although the SVM technique selects the vectors to be used and their respective on-times, the sequence in which they are used, the selection of the zero space vector, and the normalized sampled frequency remain undetermined.

11.4.4.2 Space-Vector Sequences and Zero Space-Vector Selection

Although there is no systematic approach to generate a SV sequence, a graphic representation shows that the sequence $\vec{\mathbf{i}}_i$, $\vec{\mathbf{i}}_z$, $\vec{\mathbf{i}}_{i+1}$ (where the chosen $\vec{\mathbf{i}}_z$ depends upon the sector) provides high performance in terms of minimizing unwanted harmonics and reducing the switching frequency. To obtain

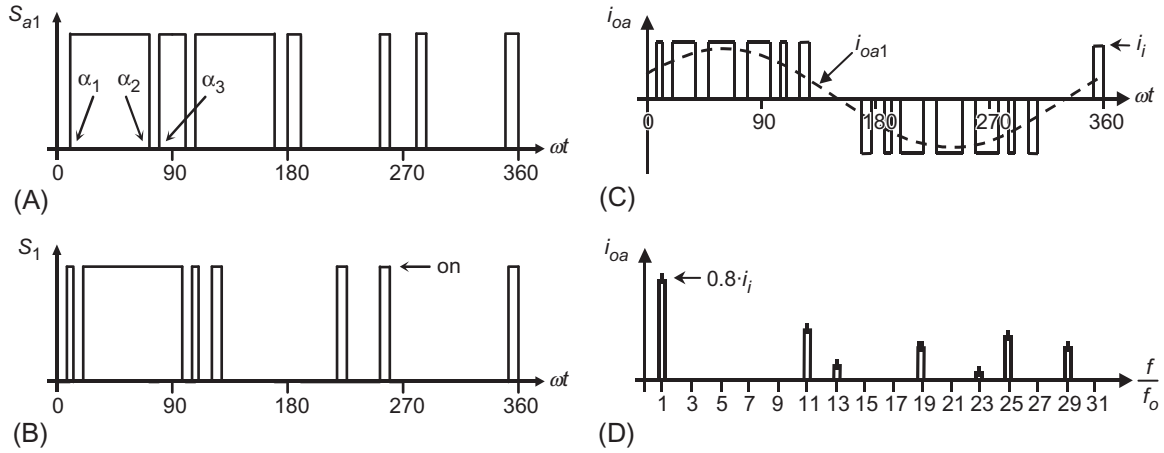

FIG. 11.36 The three-phase CSI. Ideal waveforms for the SHE technique: (A) VSI gating pattern for fifth- and seventh-harmonic elimination, (B) CSI gating pattern for fifth- and seventh-harmonic elimination, (C) line current i_{oa} for fifth- and seventh-harmonic elimination, and (D) spectrum of (C).

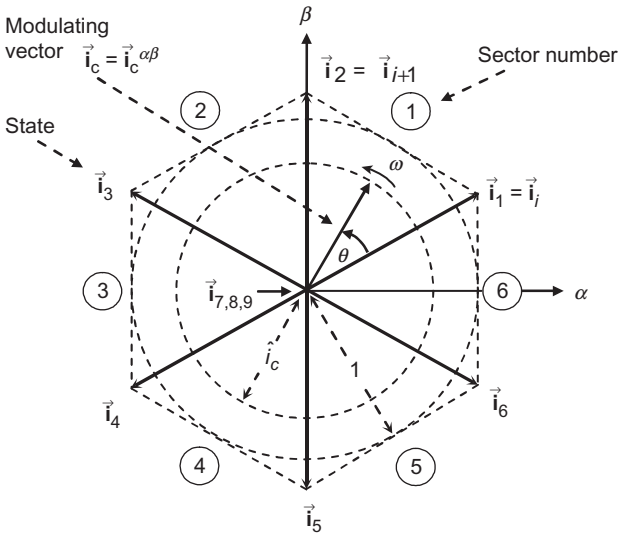

FIG. 11.37 The space-vector representation in CSIs.

the zero SV that minimizes the switching frequency, it is assumed that $\mathbf{I_c}$ is in sector ②. Then, Fig. 11.38 shows all the possible transitions that could be found in sector ②. It can be seen that the zero vector $\vec{\mathbf{i}}_9$ should be chosen to minimize the switching frequency in all cases. Table 11.7 gives a summary of the zero space vector to be used in each sector in order to minimize the switching frequency. However, it should be noted that Table 11.7 is valid only for the sequence $\vec{\mathbf{i}}_i$, $\vec{\mathbf{i}}_{i+1}$, $\vec{\mathbf{i}}_z$. Another sequence will require reformulating the zero space-vector selection algorithm.

11.4.4.3 The Normalized Sampling Frequency

As in VSIs modulated by an SV approach, the normalized sampling frequency f_{sn} should be an integer multiple of 6 to minimize uncharacteristic harmonics. As an example, Fig. 11.39 shows the relevant waveforms of a CSI SVM for $f_{sn} = 18$ and $\hat{i}_c = 0.8$. Fig. 11.39 also shows that the first set of relevant harmonics load line current are at f_{sn}.

11.4.5 DC Link Voltage in Three-phase CSIs

An instantaneous power balance indicates that

$$v_i(t) \cdot i_i(t) = v_{an}(t) \cdot i_{oa}(t) + v_{bn}(t) \cdot i_{ob}(t) + v_{cn}(t) \cdot i_{oc}(t) \tag{11.55}$$

where $v_{an}(t)$, $v_{bn}(t)$, and $v_{cn}(t)$ are the phase filter voltages as shown in Fig. 11.40. If the filter is large enough and a relatively high switching frequency is used, the phase voltages become nearly sinusoidal balanced waveforms. On the other hand, if the ac output currents are considered sinusoidal and the dc link current is assumed constant $i_i(t) = I_i$, Eq. (11.55) can be simplified to

$$v_i(t) = \frac{1}{I_i}\left\{\begin{array}{l}\sqrt{2}V_{on}\sin(\omega t)\cdot\sqrt{2}I_{o1}\sin(\omega t - \phi) \\ +\sqrt{2}V_{on}\sin(\omega t - 120^\circ)\cdot\sqrt{2}I_{o1}\sin(\omega t - 120^\circ - \phi) \\ +\sqrt{2}V_{on}\sin(\omega t - 240^\circ)\cdot\sqrt{2}I_{o1}\sin(\omega t - 240^\circ - \phi)\end{array}\right\} \tag{11.56}$$

where V_{on} is the rms ac output phase voltage, I_{o1} is the rms fundamental line current, and ϕ is an arbitrary filter-load angle. Hence, the dc link voltage expression can be further simplified to the following:

$$v_i(t) = 3\frac{I_{o1}}{I_i}V_{on}\cos(\phi) = \sqrt{3}\frac{I_{o1}}{I_i}V_o\cos(\phi) \tag{11.57}$$

where $V_o = \sqrt{3}V_{on}$ is the rms load line voltage. The resulting dc link voltage expression indicates that the first line current harmonic I_{o1} generates a clean dc current. However, as the load line currents contain harmonics around the normalized

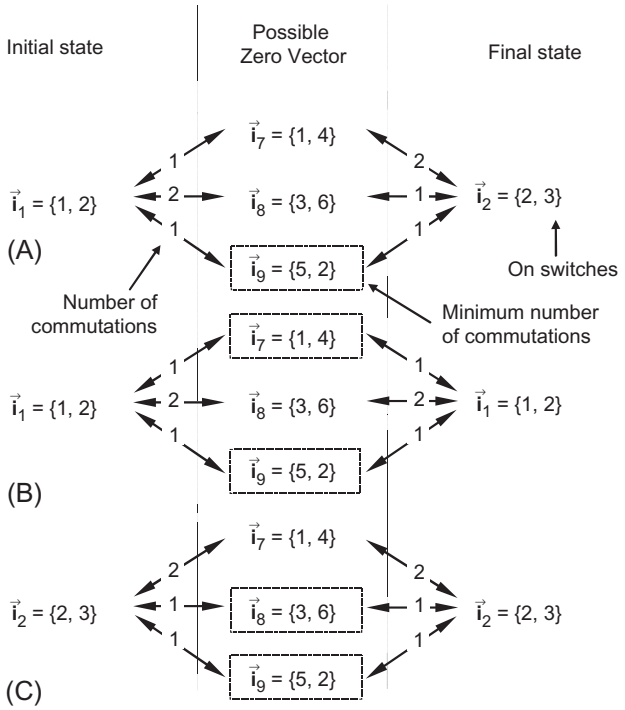

FIG. 11.38 Possible state transitions in sector ② involving a zero SV: (A) transition, $\vec{i}_1 \Leftrightarrow \vec{i}_z \Leftrightarrow \vec{i}_2$ or $\vec{i}_2 \Leftrightarrow \vec{i}_z \Leftrightarrow \vec{i}_1$; (B) transition, $\vec{i}_1 \Leftrightarrow \vec{i}_z \Leftrightarrow \vec{i}_1$; and (C) transition, $\vec{i}_2 \Leftrightarrow \vec{i}_z \Leftrightarrow \vec{i}_2$.

TABLE 11.7 Zero SV for minimum switching frequency in CSI and sequence $\vec{i}_i$, $\vec{i}_{i+1}$, $\vec{i}_z$

Sector	$\vec{i}_i$	$\vec{i}_{i+1}$	$\vec{i}_z$
①	$\vec{i}_6$	$\vec{i}_1$	$\vec{i}_7$
②	$\vec{i}_1$	$\vec{i}_2$	$\vec{i}_9$
③	$\vec{i}_2$	$\vec{i}_3$	$\vec{i}_8$
④	$\vec{i}_3$	$\vec{i}_4$	$\vec{i}_7$
⑤	$\vec{i}_4$	$\vec{i}_5$	$\vec{i}_9$
⑥	$\vec{i}_5$	$\vec{i}_6$	$\vec{i}_8$

sampling frequency f_{sn}, the dc link current will contain harmonics but around f_{sn} as shown in Fig. 11.39H. Similarly, in carrier-based PWM techniques, the dc link current will contain harmonics around the carrier frequency m_f (Fig. 11.31).

In practical implementations, a CSI requires a dc current source that should behave as a constant (as required by PWM CSIs) or variable (as square-wave CSIs) current source. Such current sources should be implemented as separate units.

11.5 Multilevel Inverters

The traditional inverters can generate an output in two or three different levels. For instance, a single-phase full-bridge inverter can produce v_i, $-v_i$, and zero; this type of output is unacceptable in the medium- to high-voltage ranges due to the high dv/dt present in the PWM ac line voltages. In order to solve this, the multilevel inverters were initially proposed. However, now, their use has been more extended not only due to the low harmonic content obtained at low switching frequencies but also for the good efficiency obtained.

Different multilevel topologies have been proposed. The goal is to produce an output defined by different levels that can be voltage or current levels. The basic principle is to connect the output to multiple points, one at a time. Fig. 11.41A shows the idea for a voltage-source configuration. Usually, the number M of possible level defines the name of the inverter; for instance, if five points are available as in Fig. 11.41A ($M = 5$), the inverter is usually named a five-level inverter.

For a five-level inverter, the output voltage shown in Fig. 11.41B would be produced. By simple inspection, this output voltage looks more similar to a sinusoidal waveform; then, the harmonic content is expected to be lower than traditional inverters, and the power semiconductors are operating at low switching frequency.

11.5.1 Voltage Source-Based Multilevel Topologies

The three-phase VSI can be called also two-level VSI due to the fact that the inverter phase voltages v_{aN}, v_{bN}, and v_{cN}

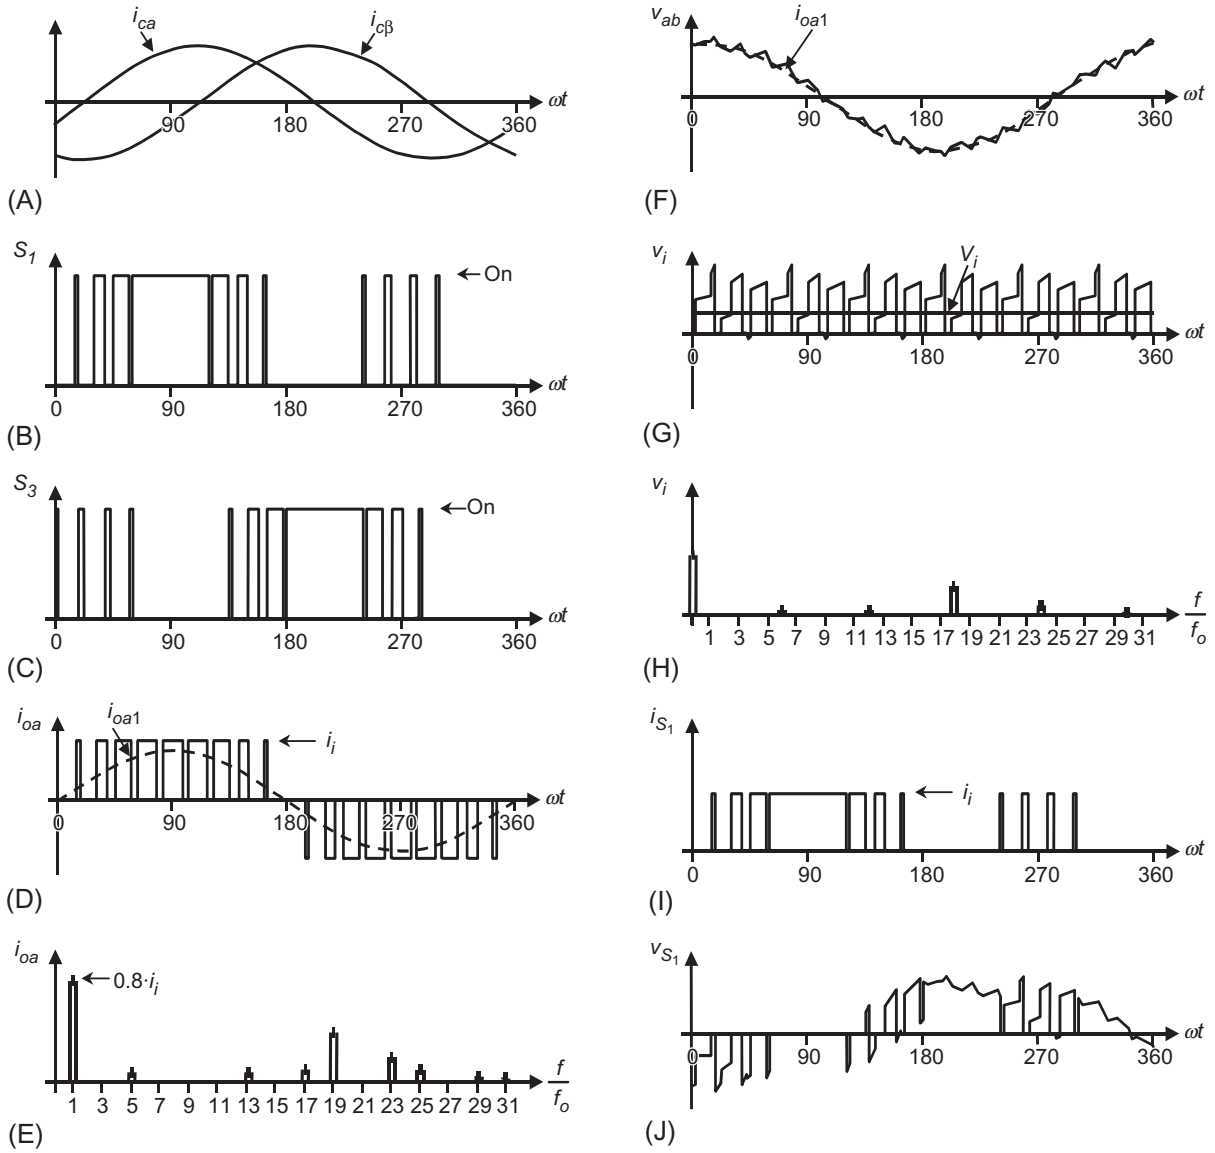

FIG. 11.39 The three-phase CSI. Ideal waveforms for space-vector modulation ($\hat{i}_c = 0.8$, $f_{sn} = 18$): (A) modulating signals, (B) switch S_1 state, (C) switch S_3 state, (D) ac output current, (E) ac output current spectrum, (F) ac output voltage, (G) dc voltage, (H) dc voltage spectrum, (I) switch S_1 current, and (J) switch S_1 voltage.

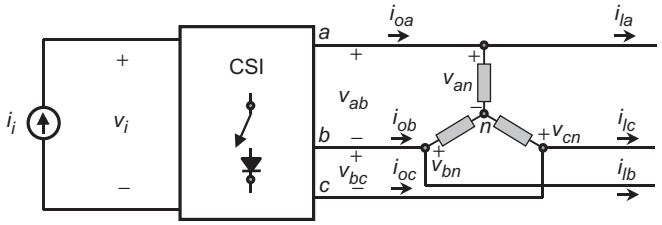

FIG. 11.40 Phase voltage definition in a wye-connected filter.

(Fig. 11.17) are instantaneously either $v_i/2$ or $-v_i/2$. In other words, the phase voltages can take one of the two voltage levels. However, regarding to multilevel inverters, the topologies usually have more than two levels.

The typical multilevel voltage-source topologies are the neutral-point-clamped (also called diode-clamped) inverters, the flying capacitors, and the cascaded configuration. Since they are voltage-source converters, the compulsory rules described in Section 11.2.1 also apply, but certainly, some remarks are made for each converter.

11.5.1.1 Neutral Point Clamped Inverter

In Fig. 11.42, the neutral-point-clamped inverter is shown (three levels). For this topology, not only an M-level inverter requires $(M-1)$ capacitors and $2(M-1)$ switching semiconductors per leg, but also $2(M-2)$ additional diodes must be

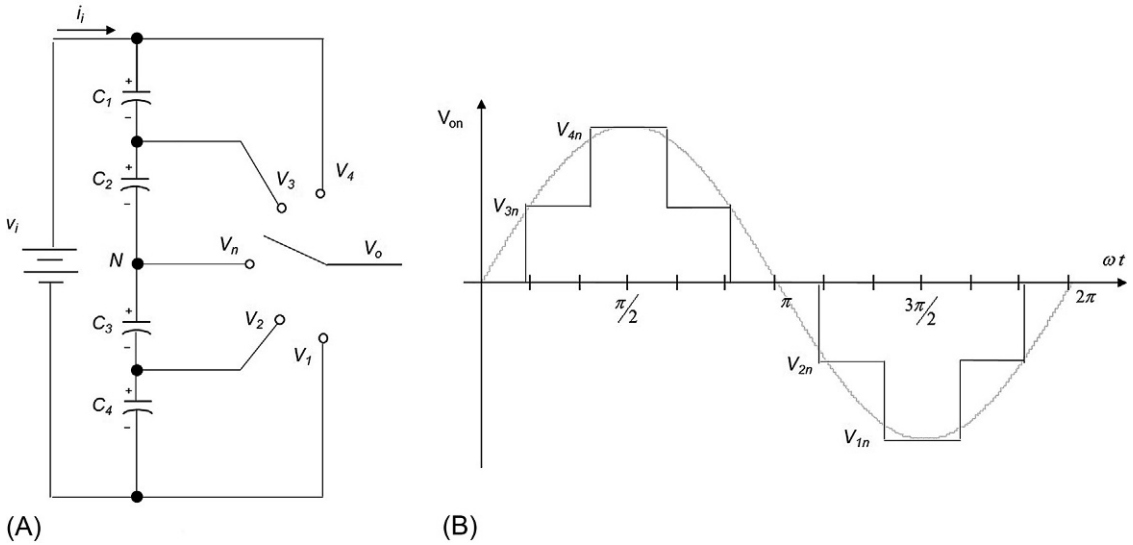

FIG. 11.41 Basic principle of multilevel output: (A) voltage source and (B) typical output.

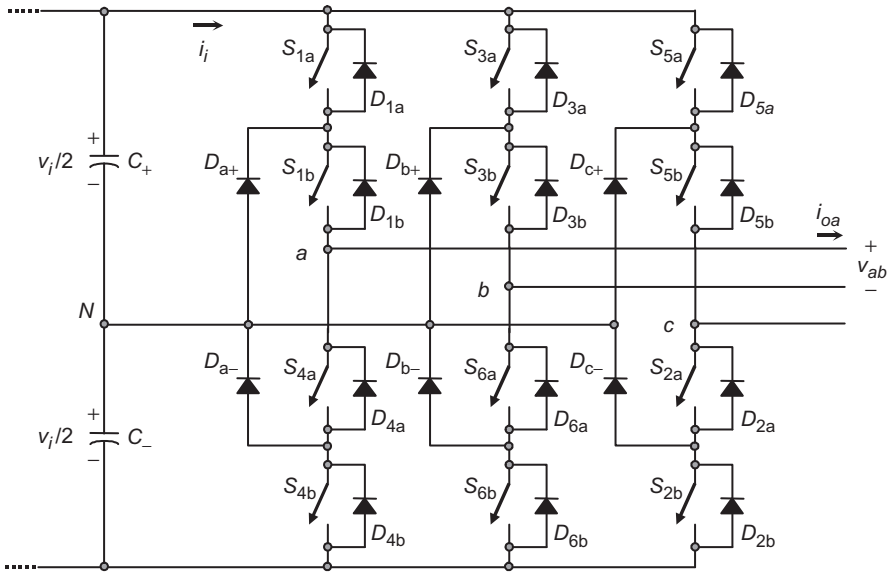

FIG. 11.42 Three-phase three-level VSI topology, neutral-point-clamped inverter.

included per leg; for instance, D_{a+} and D_{a-} are added for the left leg. $M-1$ devices per leg must be on to select the desired level.

Table 11.8 gives the switch states of the three-level inverter, just left leg. As it can be observed, not only always two switches are on, but also the signal S_{1a} is the opposite of S_{4a}, and S_{1b} is the opposite of S_{4b}. These conditions must be always satisfied. The switch states for phases *b* and c are identical to those of phase *a*.

TABLE 11.8 Valid switch states for the three-level neutral-point-clamped inverter, the left leg

s_{1a}	s_{1b}	s_{4a}	s_{4b}	v_{an}	Components conducting	
1	1	0	0	$v_i/2$	S_{1a}, S_{1b}	If $i_{oa}>0$
					D_{1a}, D_{1b}	If $i_{oa}<0$
0	1	1	0	0	S_{1b}, D_{a+}	If $i_{oa}>0$
					S_{4a}, D_{a-}	If $i_{oa}<0$
0	0	1	1	$-v_i/2$	D_{4a}, D_{4b}	If $i_{oa}>0$
					S_{4a}, S_{4b}	If $i_{oa}<0$

11.5.1.2 Flying Capacitors Inverter

In Fig. 11.43, the flying capacitor inverter is shown (three levels). For this topology, an *M*-level inverter requires

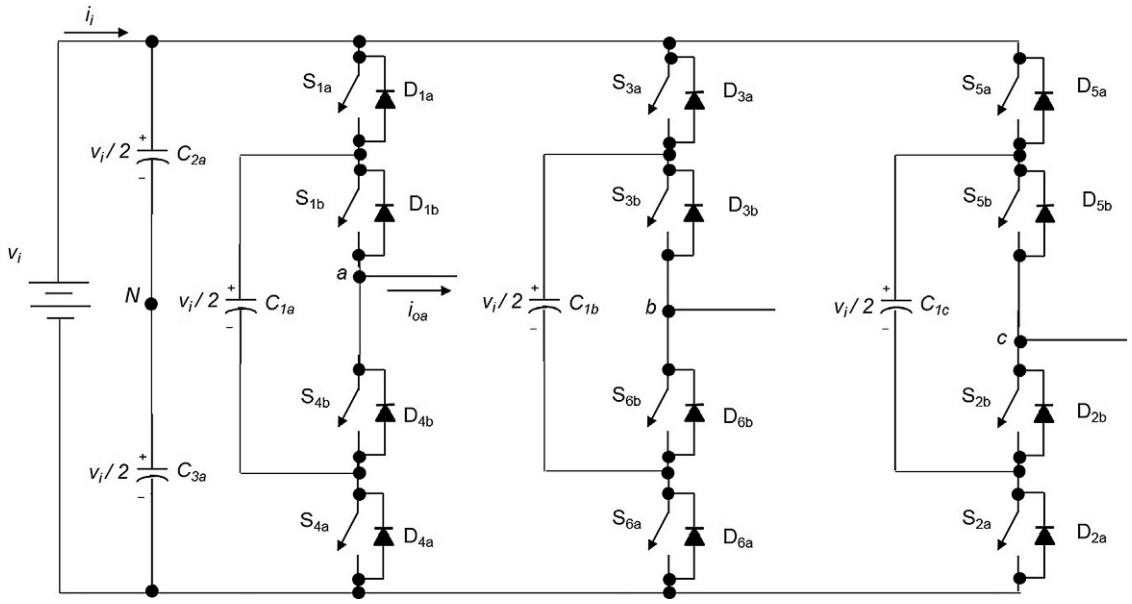

FIG. 11.43 Three-phase three-level VSI topology, flying capacitors.

$\sum_{j=1}^{M-1}(M-j)$ capacitors per leg (considering that the capacitors have the same voltage rating) and $2(M-1)$ switching semiconductors per leg, but no additional diodes are required. Also $M-1$ switches per leg must be on to select the desired level.

Table 11.9 is the switch state of the three-level inverter, just left leg. As it can be observed, not only always two switches are on, but also the signal S_{1a} is the opposite of S_{4a}, and S_{1b} is the opposite of S_{4b}. These conditions must be always satisfied. Table 11.9 shows that there is more than one switching state to produce the zero output level; this redundancy should be employed to distribute the losses or to regulate the capacitor voltages. Moreover, as the number of levels increase, more redundancy exists at different levels.

11.5.1.3 Casacade Inverter

In Fig. 11.44, the cascade inverter is shown (five levels). This topology is based on several full-bridge single-phase voltage-source inverters with their output connected in series. An M-level inverter requires $(M-1)/2$ single-phase full-bridge VSI per leg and $2(M-1)$ switching semiconductors per leg, but no additional diodes are required. Also $M-1$ switches per leg must be on to select the desired level.

Table 11.10 gives the switch states of the five-level inverter. Notice that only the top switch control signals of each single-phase full-bridge VSI are shown. Their respective bottom switch control signals are complementary, in order to accomplish with the first compulsory rule for VSIs. As it can be observed, always four devices are on; notice that since a single-phase full-bridge inverter is used, the same rules apply for the control signals of the semiconductors. As it can be observed in Table 11.10, there are more than one switching state to produce some output levels; this redundancy should be employed to distribute the losses. Moreover, as the number of levels increases, more redundancy exists at different levels.

TABLE 11.9 Valid switch states for the three-level flying capacitors inverter, left leg

					S_{4a}, S_{4b}	If $i_{oa}<0$

11.5.2 Current Source-Based Multilevel Topologies

Duality is found in many aspects related to voltage- and current-source inverters. Perhaps, the most evident is the duality in terms of modulating techniques. Thus, current-source-based multilevel topologies are available as well. There are different topologies reported: paralleled, two-stage, and embedded configurations.

Fig. 11.45 shows a three-level $M=3$ current-source topology, which is formed by paralleling two three-phase CSI topologies, the named paralleled CSI (Table 11.11). The main goal is to share evenly the ac current $\mathbf{i}_{\mathbf{o}}^{\mathbf{abc}}$ among the two topologies ($\mathbf{i}_{\mathbf{o}}^{\mathbf{abc}}/2=\mathbf{i}_{\mathbf{o1}}^{\mathbf{abc}}=\mathbf{i}_{02}^{\mathbf{abc}}$). This should be ensured by having equal

dc link currents ($i_{i1} = i_{i2}$). Similarly to voltage-source-based multilevel topologies, this could be achieved either by using two independent dc link currents or by properly gating the power semiconductors.

11.5.3 Modulation Techniques in Multilevel Inverters

As in traditional inverters, the sinusoidal pulse width and space-vector modulation can be employed in multilevel inverters, for both CSI and VSI.

11.5.3.1 The SPWM Technique

The main objective is to generate the appropriate gating signals so as to obtain fundamental inverter phase voltages or currents equal to a given set of modulating signals. Specifically, the SPWM in three-level VSIs uses a sinusoidal set of modulating signals (v_{ca}, v_{cb}, and v_{cc} for phases a, b, and c, respectively) and

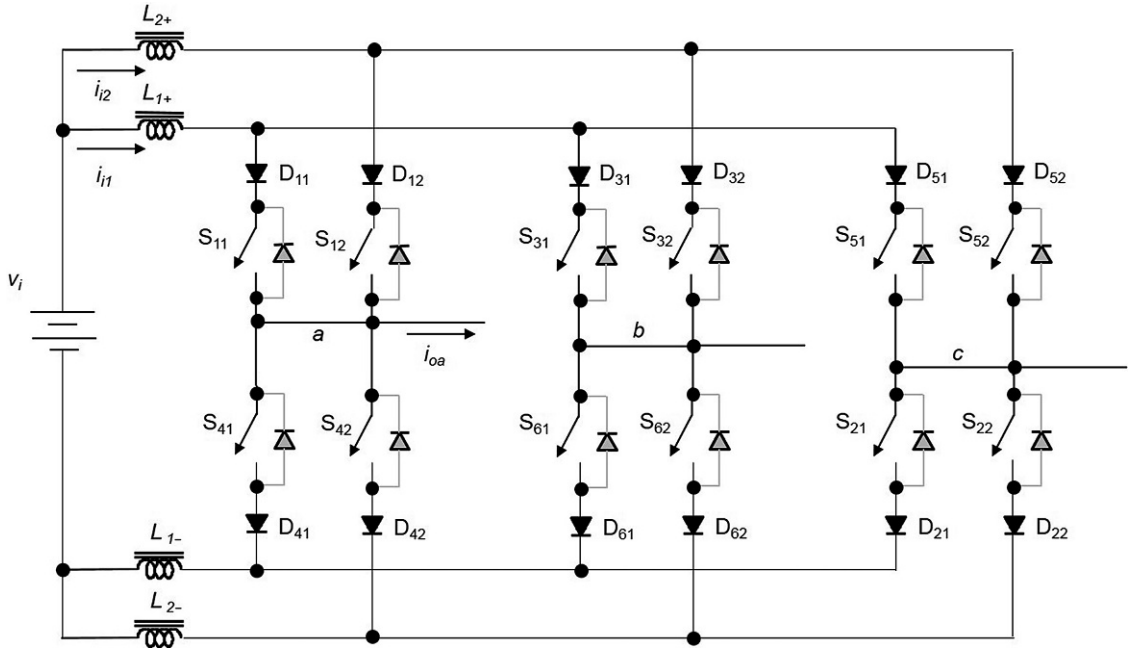

FIG. 11.45 Three-phase three-level paralleled CSI topology.

$M-1=2$ triangular type of carrier signals ($v_{\Delta 1}$ and $v_{\Delta 2}$) as illustrated in Fig. 11.46A. The best results are obtained if the carrier signals are in-phase (synchronized with the modulating signal) and feature an odd normalized frequency (e.g., $m_f=15$). According to Fig. 11.46A and considering a neutral-point-clamped inverter (Fig. 11.42), the switch S_{1a} is turned either on if $v_{ca}>v_{\Delta 1}$ or off if $v_{ca}<v_{\Delta 1}$, and switch S_{1b} is turned either on if $v_{ca}>v_{\Delta 2}$ or off if $v_{ca}<v_{\Delta 2}$. Additionally, the switch S_{4a} status is obtained as the opposite to switch S_{1a}, and the switch S_{4b} status is obtained as the opposite to switch S_{1b}. In order to use the same set of carrier signals to generate the gating signals for phases b and c, the normalized frequency of the carrier signal m_f should be a multiple of 3. Thus, the possible values are $m_f=3,9,15,21,\ldots$.

Fig. 11.46 shows the relevant waveforms for a three-level neutral-point-clamped inverter modulated by means of an SPWM technique ($m_f=15$, $m_a=0.8$). Specifically, Fig. 11.46D shows the inverter phase voltage, which is clearly a three-level type of voltage, and Fig. 11.46F shows the load line voltage, which shows that the step voltages are at most $v_i/2$. More importantly, the inverter phase voltage (Fig. 11.46E) contains harmonics at $l\cdot m_f\pm k$ with $l=1,3,\ldots$ and $k=0,2,4,\ldots$ and at $l\cdot m_f\pm k$ with $l=2,4,\ldots$ and $k=1,3,\ldots$. For instance, the first set of harmonics ($l=1$, $m_f=15$) are at 15, 15 ± 2, $15\pm 4,\ldots$. The inverter line voltage (Fig. 11.46G) contains harmonics at $l\cdot m_f\pm k$ with $l=1,3,\ldots$ and $k=2,4,\ldots$ and at $l\cdot m_f\pm k$ with $l=2,4,\ldots$ and $k=1,3,\ldots$. For instance, the first set of harmonics in the line voltages ($l=1$, $m_f=15$) are at 15 ± 2, $15\pm 4,\ldots$.

All the other features of carrier-based PWM techniques also apply in multilevel inverters. Firstly, the fundamental component of the inverter phase voltages satisfies

$$\hat{v}_{aN1}=\hat{v}_{bN1}=\hat{v}_{cN1}=m_a\frac{v_i}{2}\quad 0<m_a\leq 1 \tag{11.58}$$

and thus, the line voltages satisfy

$$\hat{v}_{ab1}=\hat{v}_{bc1}=\hat{v}_{ca1}=m_a\sqrt{3}\frac{v_i}{2}\quad 0<m_a\leq 1 \tag{11.59}$$

where $0<m_a\leq 1$ is the linear operating region. To further increase the amplitude of the load voltages, the overmodulation operating region can be used by further increasing the modulating signal amplitudes ($m_a>1$), where the line voltages range in

$$\sqrt{3}\frac{v_i}{2}<\hat{v}_{ab1}=\hat{v}_{bc1}=\hat{v}_{ca1}<\frac{4}{\pi}\sqrt{3}\frac{v_i}{2} \tag{11.60}$$

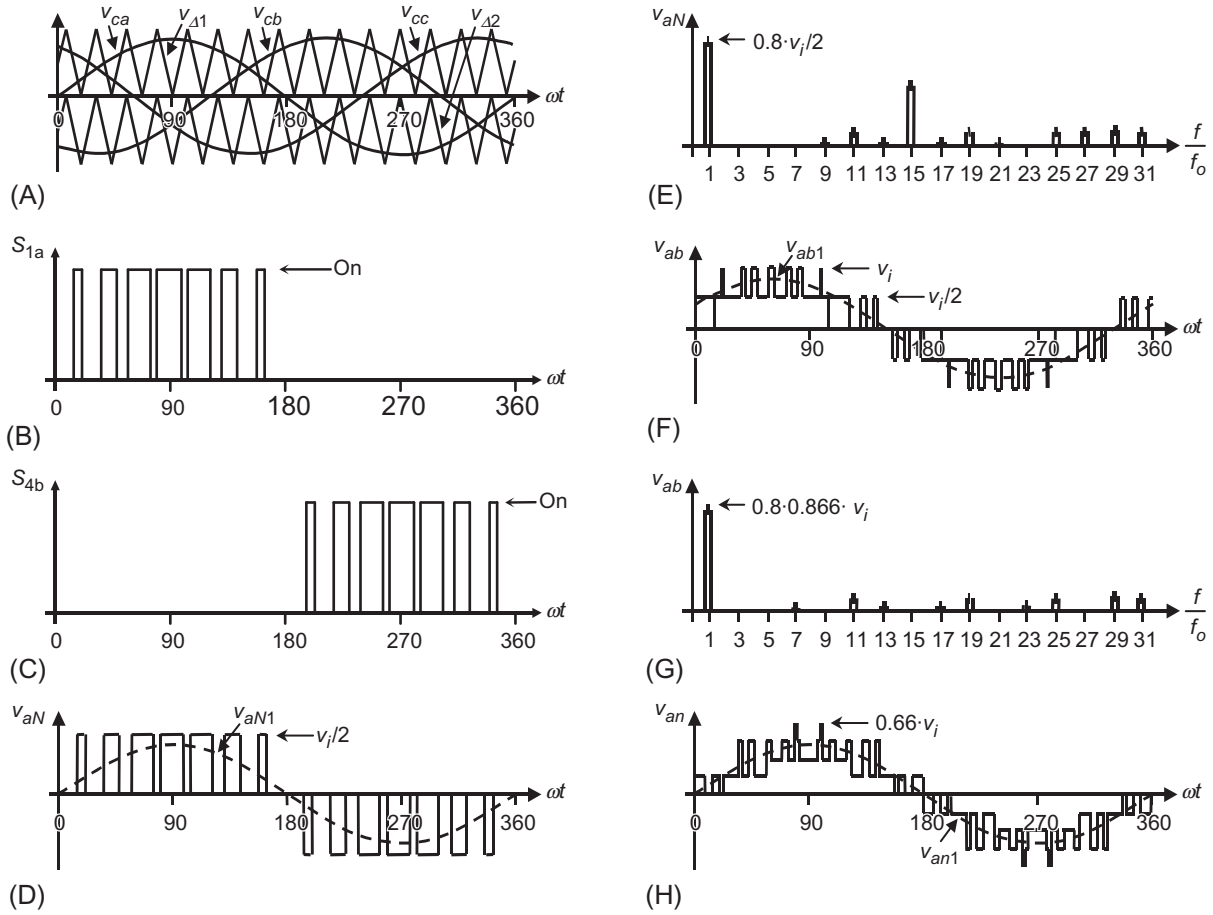

FIG. 11.46 Three-level VSI topology. Relevant waveforms using an SPWM ($m_f = 15$, $m_a = 0.8$): (A) modulating and carrier signals, (B) switch S_{1a} status, (C) switch S_{4b} status, (D) inverter phase *a* voltage, (E) inverter phase *a* voltage spectrum, (F) load line voltage, (G) load line voltage spectrum, and (H) phase-load *a* voltage.

Second, the modulating signals could be improved by adding a third harmonic (zero sequence), which will increase the linear region up to $m_a = 1.15$. This results in a maximum fundamental line-voltage component equal to v_i; as a third point, a nonsinusoidal set of modulating signals could also be used by the modulating technique. This is the case where nonsinusoidal line voltages are required as in active filter applications, and finally, because of the two quadrants operation of VSIs, the multilevel inverter could equally be used in applications where the active power flow goes from the dc to the ac side or from the ac to the dc side.

In general, for an *M*-level inverter modulated by means of a carrier-based technique, three modulating signals 120° out of phase and $M-1$ carrier signals are required. Key waveforms are shown in Fig. 11.47.

One of the drawbacks of the multilevel inverter is that the dc link capacitor voltages or inductor currents, depending on the type of inverter, should be regulated. Unfortunately, this is not a natural operating condition mainly due to the fact that the storage elements are operated in a not symmetrical manner, and therefore, they will not equally share energy.

11.5.3.2 The SPWM Technique in Three-level CSIs

As in three-level VSIs, the main objective is to generate the appropriate 12 gating signals so as to obtain fundamental inverter line currents equal to a given set of modulating signals. Specifically, the SPWM in three-level inverters uses a sinusoidal set of modulating signals (i_{ca}, i_{cb}, and i_{cc} for phases *a*, *b*, and *c*, respectively) and $N-1=2$ triangular type of carrier signals ($i_{\Delta 1}$ and $i_{\Delta 2}$) as illustrated in Fig. 11.48A and E. The best results are obtained if the carrier signals are 180° out of phase and feature an odd normalized frequency (e.g., $m_f = 15$). In order to use the same set of carrier signals to generate the gating signals for phases *b* and *c*, the normalized frequency of the carrier signal m_f should be a multiple of 3. Thus, the possible values are $m_f = 3, 9, 15, 21, \ldots$.

Fig. 11.48 shows the relevant waveforms for a three-level inverter modulated by means of an SPWM technique

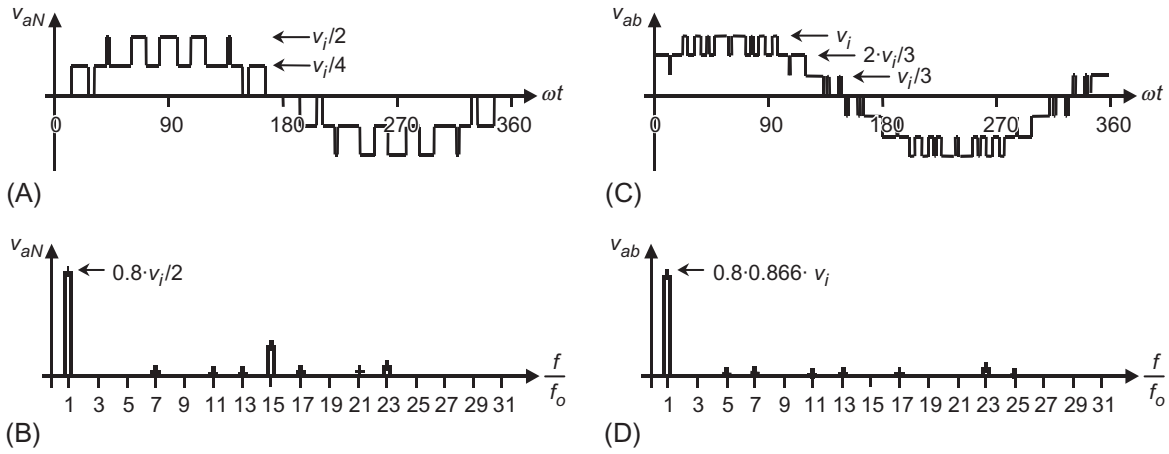

FIG. 11.47 Five-level VSI topology. Relevant waveforms using a SPWM ($m_f = 15$, $m_a = 0.8$): (A) inverter phase *a* voltage, (B) inverter phase *a* voltage spectrum, (C) load line voltage, and (D) load line voltage spectrum.

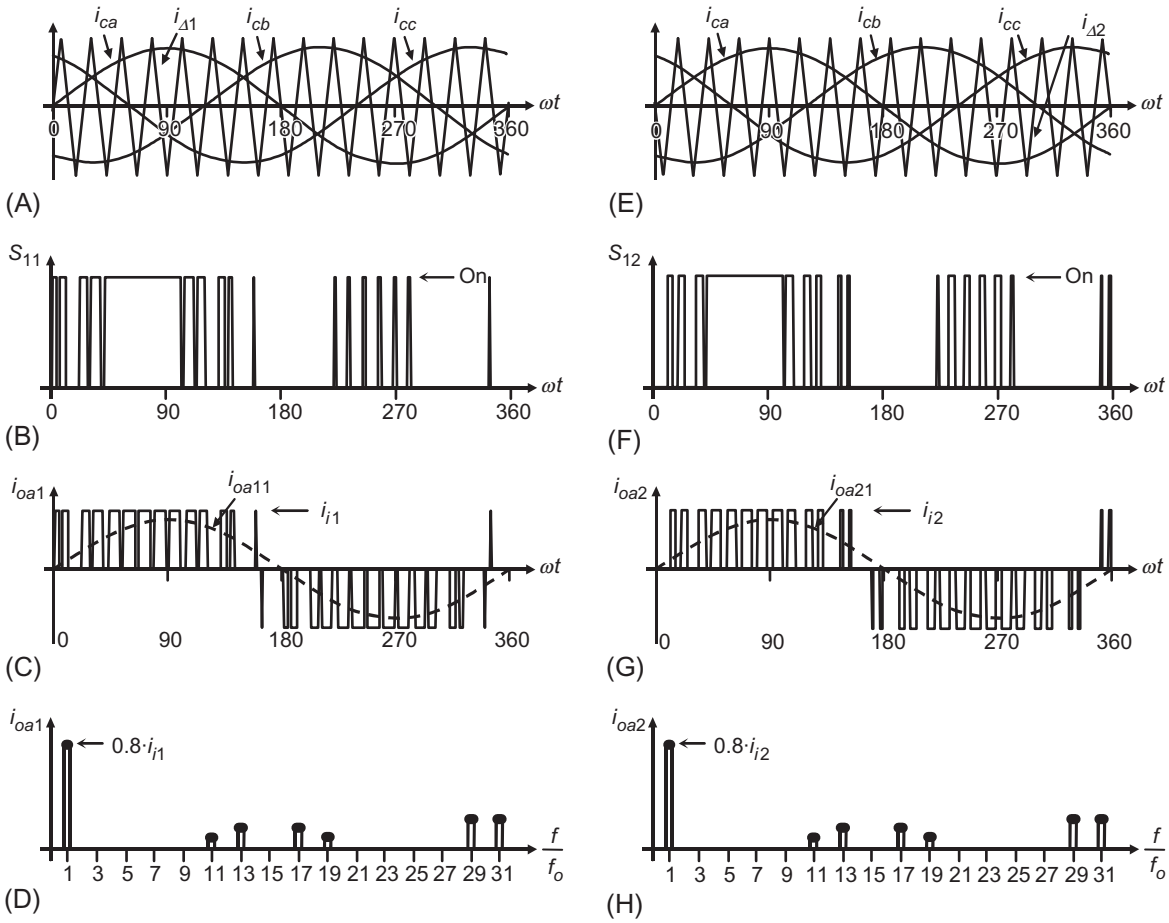

FIG. 11.48 Three-level CSI topology. Relevant waveforms using an SPWM ($m_f = 15$, $m_a = 0.8$): (A) modulating signals and carrier signal 1, (B) switch S_{11} status, (C) inverter 1 linear current, (D) inverter 1 linear current spectrum, (E) modulating signals and carrier signal 2, (F) switch S_{12} status, (G) inverter 2 linear current, and (H) inverter 2 linear current spectrum.

($m_f = 15$, $m_a = 0.8$). Specifically, Fig. 11.48B and F show the gating signals obtained as described earlier in this chapter. The inverter line currents shown in Fig. 11.48C and G feature spectra shown in Fig. 11.48D and H, respectively. As expected, the inverter line currents contain harmonics at $l \cdot m_f \pm k$ with $l = 1,3,\ldots$ and $k = 2,4,\ldots$ and at $l \cdot m_f \pm k$ with $l = 2,4,\ldots$ and $k = 1,3,\ldots$. For instance, the first set of harmonics in the line currents ($l = 1$, $m_f = 15$) are at 15 ± 2, $15 \pm 4, \ldots$.

The total inverter line current is shown in Fig. 11.49A and features the first set of unwanted harmonics around $2m_f$(Fig. 11.49B). This becomes the first advantage of using a multilevel topology as the filtering component requirements become more relaxed. All the other features of carrier-based PWM techniques also apply in current-source multilevel inverters. For instance, (I) the fundamental component of the line currents satisfies

$$\hat{i}_{oa1} = \hat{i}_{ob1} = \hat{i}_{oc1} = m_a \frac{\sqrt{3}}{2}(i_{i1} + i_{i2}) \quad 0 < m_a \leq 1 \qquad (11.61)$$

where $0 < m_a \leq 1$ is the linear operating region. Also, (II) to further increase the amplitude of the load currents, a zero-sequence signal could be injected to the modulating signals, in this case,

$$\hat{i}_{oa1} = \hat{i}_{ob1} = \hat{i}_{oc1} = m_a \frac{\sqrt{3}}{2}(i_{i1} + i_{i2}) \quad 0 < m_a \leq 2/\sqrt{3} \qquad (11.62)$$

the overmodulation operating region can be used by further increasing the modulating signal amplitudes ($m_a > 2/\sqrt{3}$), where the line currents range in

$$(i_{i1} + i_{i2}) < \hat{i}_{oa1} = \hat{i}_{ob1} = \hat{i}_{oc1} < \frac{4}{\pi}(i_{i1} + i_{i2}) \qquad (11.63)$$

Also, (III) a nonsinusoidal set of modulating signals could also be used by the modulating technique. This is the case where nonsinusoidal line currents are required as in active filter applications, and (IV) because of the two quadrants operation of CSIs, the multilevel inverter could equally be used in applications where the active power flow goes from the dc to the ac side or from the ac to the dc side. In general, for an N-level inverter modulated by means of a carrier-based technique, three modulating signals 120° out of phase and $N-1$ carrier signals are required, and the line currents in the inverters have a peak value of $i_i/(N-1)$.

One of the drawbacks of the multilevel inverter is that the dc link capacitors cannot be supplied by a single dc voltage source. This is due to the fact that the currents required by the inverter in the dc bus are not symmetrical, and therefore, the capacitors will not equally share the dc supply voltage v_i. To overcome this problem, two alternatives are developed later on.

11.5.3.3 The Space-Vector Modulation

The SV modulating technique can be applied using the same principles used in two-level inverters. However, the higher number of voltage levels increases the complexity of the practical implementation of the technique. For instance, in $M = 3$-level inverters, each leg allows $M = 3$ different switch combinations as indicated in the previous sections. Therefore, in a three-phase system, there are $M^3 = 27$ total valid switch combinations, which generate $M^3 = 27$ load line voltages that are represented by $M^3 = 27$ space vectors ($\vec{\mathbf{v}}_1, \vec{\mathbf{v}}_2, \ldots, \vec{\mathbf{v}}_{27}$) in Fig. 11.50. For instance, $\vec{\mathbf{v}}_2 = 0.5 + j0.866$ is due to the line voltages $v_{ab} = 0.5$, $v_{bc} = 0.5$, $v_{ca} = -1.0$ in per unit. Thus, although the principle of operation is the same, the SV digital algorithm will have to deal with a higher number of states M^3. Moreover, because some space vectors (e.g., $\vec{\mathbf{v}}_{13}$ and $\vec{\mathbf{v}}_{14}$ in Fig. 11.50) produce the same load voltage terminals, the algorithm will have to decide between the two based on additional criteria and that of

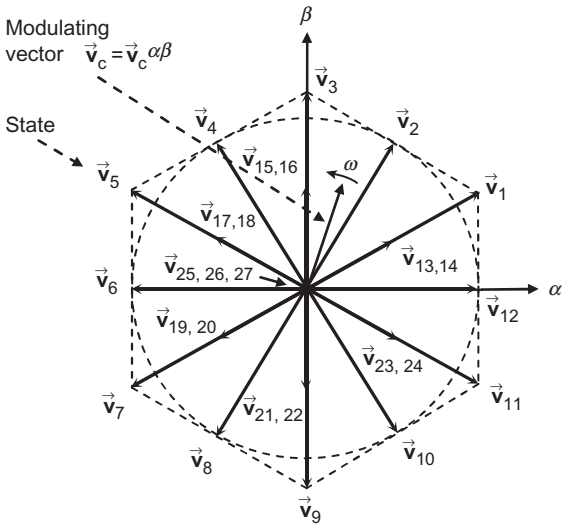

FIG. 11.50 The space-vector representation in a three-level VSI.

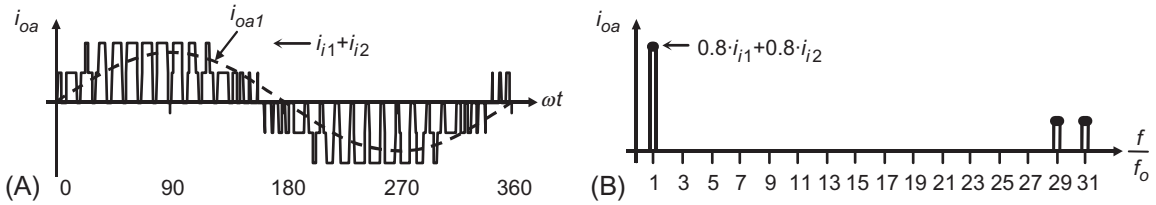

FIG. 11.49 Three-level CSI topology. Relevant waveforms using an SPWM ($m_f = 15$, $m_a = 0.8$): (A) total inverter line current and (B) total inverter line current spectrum.

the basic SV approach. Clearly, as the number of level increases, the algorithm becomes more and more elaborate. However, the benefits are not evident as the number of level increases. The maximum number of levels used in practical applications is five. This is based on a compromise between the complexity of the implementation and the benefits of the resulting waveforms.

11.5.3.4 Balancing Issues

The operation for the multilevel converter was made considering an even distribution of the voltage across the dc link capacitors or current of the inductors, depending of the type of inverter. This even distribution is not naturally achieved and could be overcome by supplying the storage elements from independent supplies or properly gating the power semiconductors of the inverter in order to minimize the unbalance.

Fig. 11.51 shows an ASD based on a three-level VSI, where the dc link capacitors are feed from two different sources. This approach is being commercially used as it ensures a robust balanced dc link voltage distribution and operates with a high-performance type of ac main current. Indeed, for an M-level inverter, $M-1$-independent dc voltage supplies are required that could be provided by $M-1$ six-pulse rectifiers feed from an $M-1$ pulse transformer. Therefore, the ac main currents are an $M-1$-level type of waveform.

This approach cannot be used when the inverter does not feature dc link voltage supplies. This is the case of static power reactive power compensators and static power active filters. In this case, the proper gating of the power semiconductors becomes the only choice to keep and balance the dc link voltages. Fig. 11.52A shows this case where the current added by the inverter i_o^{abc} provides the reactive power and current harmonics such that the ac main current i_s^{abc} features a given power factor.

The SPWM modulating technique could be used as in Fig. 11.46; however, the zero level of the carrier δ is left as a manipulable variable in Fig. 11.52B. In fact, it is used to control the difference of the upper and lower capacitor voltages $\Delta v_i = v_{i1} - v_{i2}$. A closed-loop alternative is depicted in Fig. 11.52C to manipulate δ. The modulating signals $\mathbf{v_c^{abc}}$ are left to control the reactive power and current harmonics injected into the ac mains by regulating the currents $\mathbf{i_o^{abc}}$ and

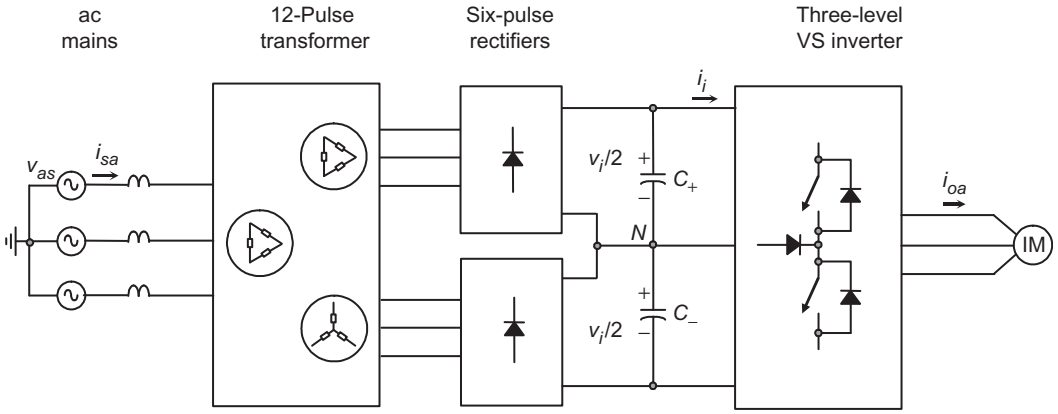

FIG. 11.51 ASD based on a three-phase three-level VSI topology.

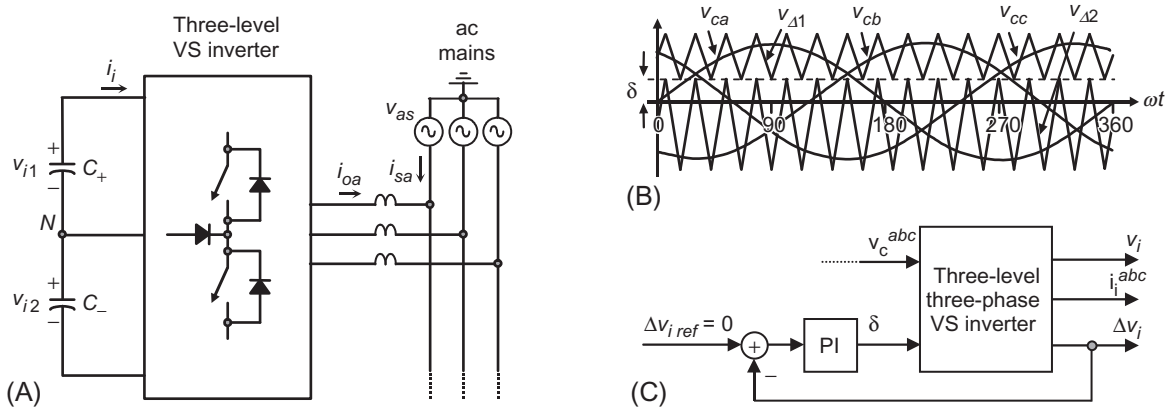

FIG. 11.52 Reactive power and current harmonics compensator based on a three-phase three-level VSI topology: (A) power topology, (B) carrier and modulating signals, and (C) δ closed-loop scheme.

keep the total dc link voltage $v_i = v_{i1} + v_{i2}$ equal to a reference. Both loops are not included in Fig. 11.52C.

11.6 Closed-Loop Operation of Inverters

In the inverter, as a classic power converter, the output depends on different conditions. For instance, in ASDs, the load usually changes, so the ac waveforms should be adjusted to these new conditions. Also, as the dc power supplies are not ideal and the dc quantities are not fixed, the inverter should compensate for such variations. Such adjustments can be done automatically by means of a closed-loop approach. Inverters also provide an alternative to changing the load operating conditions.

There are two alternatives for closed-loop operation, the feedback and the feedforward approaches. It is known that the feedback approach can compensate for both the perturbations (dc power variations) and the load variations (load torque changes). However, the feedforward strategy is more effective in mitigating perturbations as it prevents its negative effects at the load side. These cause-effect issues are analyzed in three-phase inverters in the following, although similar results are obtained for single-phase VSIs.

11.6.1 Feedforward Techniques in Voltage Source Inverters

The dc link bus voltage in VSIs is usually considered a constant-voltage source v_i. Unfortunately and due to the fact that most practical applications generate the dc bus voltage by means of a diode rectifier (Fig. 11.53), the dc bus voltage contains low-order harmonics such as the sixth, twelfth, … (due to six-pulse diode rectifiers) and the second harmonic if the ac voltage supply features an unbalance, which is usually the case. Additionally, if the three-phase load is unbalanced, as in UPS applications, the dc input current in the inverter i_i also contains the second harmonic, which in turn contributes to the generation of a second voltage harmonic in the dc bus.

The basic principle of feedforward approaches is to sense the perturbation and then modify the input in order to compensate for its effect. In this case, the dc link voltage should be sensed, and the modulating technique should accordingly be modified. The fundamental *ab* line voltage in a VSI SPWM can be written as

$$v_{ab1}(t) = \left\{ \frac{v_{ca1}(t)}{\hat{v}_\Delta} - \frac{v_{cb1}(t)}{\hat{v}_\Delta} \right\} \frac{\sqrt{3}}{2} v_i(t) \quad \hat{v}_\Delta > \hat{v}_{ca1}, \hat{v}_{cb1} \tag{11.64}$$

where $\hat{v}_\Delta$ is the carrier signal peak, $\hat{v}_{ca1}$ and $\hat{v}_{cb1}$ are the modulating signal peaks, and $v_{ca}(t)$ and $v_{cb}(t)$ are the modulating signals. If the dc bus voltage v_i varies around a nominal V_i value, then the fundamental line voltage varies proportionally; however, if the carrier signal peak $\hat{v}_\Delta$ is redefined as

$$\hat{v}_\Delta = \hat{v}_{\Delta m} \frac{v_i(t)}{V_i} \tag{11.65}$$

where $\hat{v}_{\Delta m}$ is the carrier signal peak (Fig. 11.54), then the resulting fundamental *ab* line voltage in a VSI SPWM is

$$v_{ab1}(t) = \left\{ \frac{v_{ca1}(t)}{\hat{v}_{\Delta m}} - \frac{v_{cb1}(t)}{\hat{v}_{\Delta m}} \right\} \frac{\sqrt{3}}{2} V_i \tag{11.66}$$

where, clearly, the result does not depend upon the variations of the dc bus voltage.

Fig. 11.55 shows the waveforms generated by the SPWM under a severe dc bus voltage variation (a second harmonic has been added manually to a constant V_i). As a consequence, the ac line voltage generated by the VSI is distorted as it contains low-order harmonics (Fig. 11.55E). These operating conditions may not be acceptable in standard applications such as

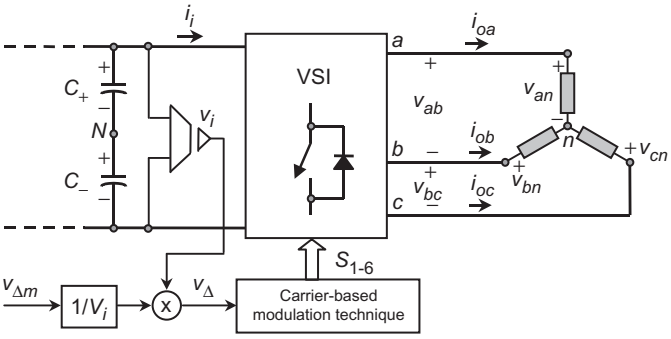

FIG. 11.54 The three-phase VSI. Feedforward control technique to reject dc bus voltage variations.

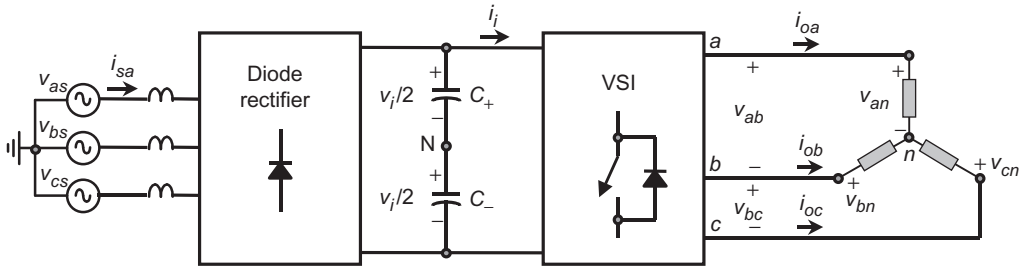

FIG. 11.53 Three-phase VSI topology with a diode-based front-end rectifier.

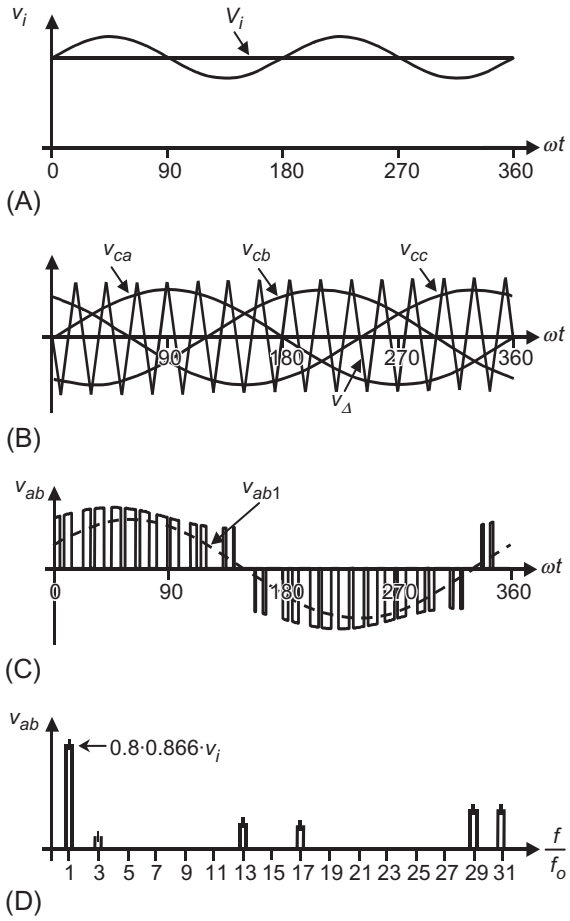

FIG. 11.55 The three-phase VSI. Waveforms for regular SPWM ($m_a = 0.8$, $m_f = 9$): (A) dc bus voltage, (B) carrier and modulating signals, (C) ac output voltage, and (D) ac output voltage spectrum.

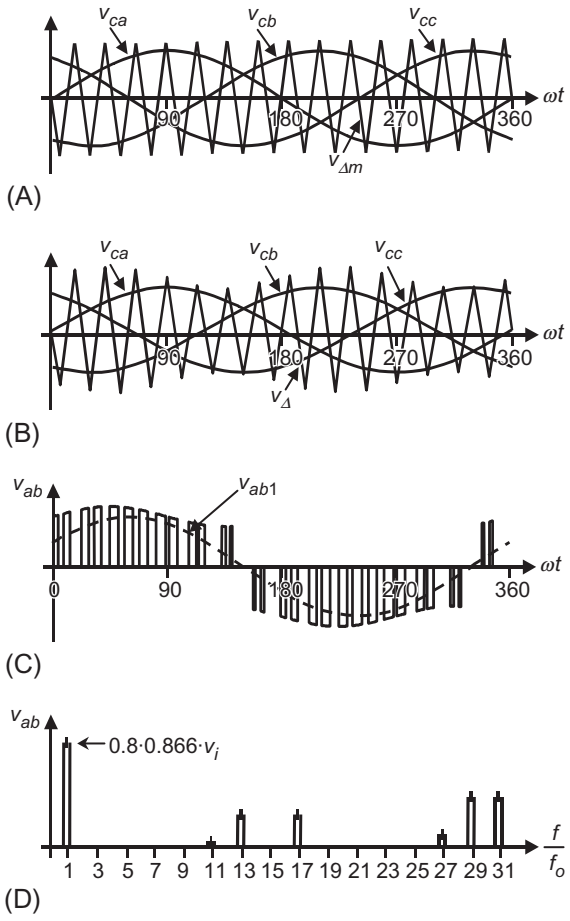

FIG. 11.56 The three-phase VSI. Waveforms for SPWM including a feedforward loop ($m_a = 0.8$, $m_f = 9$): (A) carrier and modulating signals, (B) modified carrier and modulating signals, (C) ac output voltage, and (D) ac output voltage spectrum.

ASDs because the load will draw distorted three-phase currents as well. The feedforward loop performance is illustrated in Fig. 11.56. As expected, the carrier signal is modified so as to compensate for the dc bus voltage variation (Fig. 11.56B). This is probed by the spectrum of the ac line voltage that does not contain low-order harmonics (Fig. 11.56E). It should be noted that $\hat{v}_\Delta > \hat{v}_{ca1}, \hat{v}_{cb1}$; therefore, the compensation capabilities are limited by the required ac line voltage.

The performance of the feedforward approach depends upon the frequency of the harmonics present in the dc bus voltage and the carrier signal frequency. Fortunately, the relevant unwanted harmonics to be found in the dc bus voltage are the second, due to unbalanced supply voltages, and/or the sixth as the dc bus voltage is generated by means of a six-pulse diode rectifier. Therefore, a carrier signal featuring a 15-pu frequency is found to be sufficient to properly compensate for dc bus voltage variations.

Unbalanced loads generate a dc input current i_i that contains a second harmonic, which contributes to the dc bus voltage variation. The previous feedforward approach can compensate for such perturbation and maintain balanced ac load voltages.

Digital techniques can also be modified in order to compensate for dc bus voltage variations by means of a feedforward approach.

The duality principle between the voltage- and the current-source inverters indicates that, as described previously, the feedforward approach can be also used for CSIs and for VSIs. Therefore, low-order harmonics present in the dc bus current can be compensated for before they appear at the load side. This can be done for both analog-based (e.g., carrier-based) and digital-based (e.g., space-vector) modulating techniques.

11.6.2 Feedback Techniques in Voltage Source Inverters

Unlike the feedforward advantages, the feedback techniques are more effective to regulate than the system output by gating signals of the inverters properly. Another important difference is

that feedback techniques need to sense the controlled variables. In general, the controlled variables (output to the system) are chosen according to the control objectives. For instance, in ASDs, it is usually necessary to keep the motor line currents equal to a given set of sinusoidal references. Therefore, the controlled variables become the ac line currents. There are several alternatives to implement feedback techniques in VSIs, and three of them are discussed next.

11.6.2.1 Hysteresis Current Control

The main purpose here is to force the ac line current to follow a given reference. The status of the power semiconductors are changed whenever the actual i_{oa} current goes beyond a given reference $i_{oa,ref} \pm \Delta i/2$. Fig. 11.57 shows the hysteresis current controller for one phase. Identical controllers are used in the other phases. The implementation of this controller is simple as it requires a simple comparator operating in the hysteresis mode; thus, the controller and modulator are combined in one unit.

Unfortunately, there are several drawbacks associated with the technique itself. First, the switching frequency cannot be predicted as in carrier-based modulators, and therefore, the harmonic content of the ac line voltages and currents becomes random (Fig. 11.58D). This could be a disadvantage when designing the filtering components. Second, as three-phase loads do not have the neutral connected as in ASDs, the load currents add up to zero. This means that only two ac line currents can be controlled independently at any given instant. Therefore, one of the hysteresis controllers is redundant at a given time. This explains why the load current goes beyond the limits and introduces limit cycles (Fig. 11.58A). Finally, although the ac load currents add up to zero, the controllers cannot ensure that all load line currents feature a zero dc component in one load cycle.

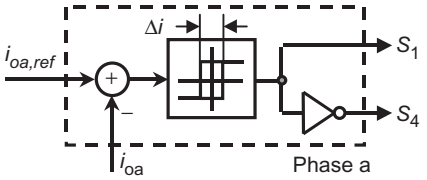

FIG. 11.57 Hysteresis current control, one phase.

11.6.2.2 Linear Control of VSIs

Proportional and proportional-integrative controllers can also be used in VSIs by employing a transformation. The main purpose is to generate the modulating signals v_{ca}, v_{cb}, and v_{cc} in a closed-loop fashion as depicted in Fig. 11.59. The modulating signals can be used by a carrier-based technique such as the

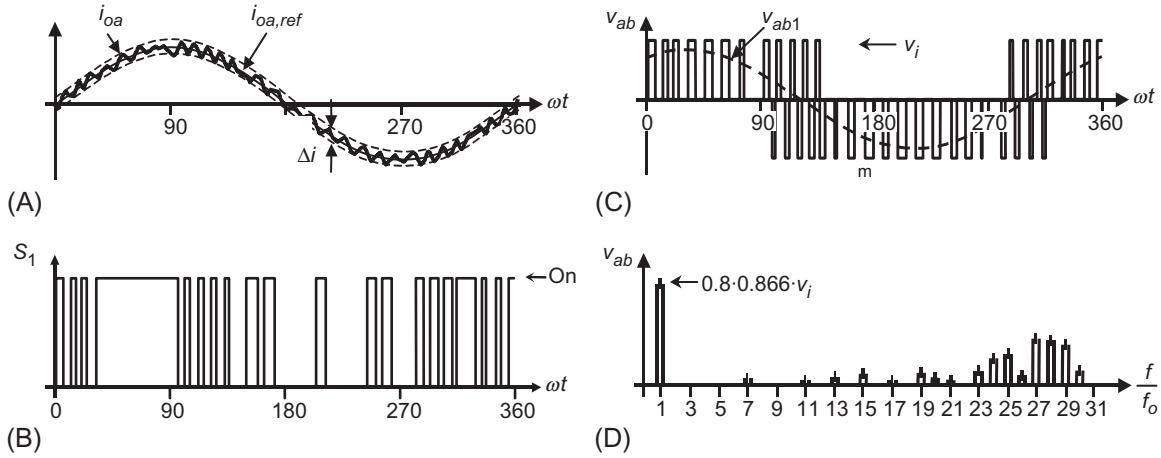

FIG. 11.58 The three-phase VSI. Ideal waveforms for hysteresis current control: (A) actual ac load current and reference, (B) switch S_1 state, (C) ac output voltage, and (D) ac output voltage spectrum.

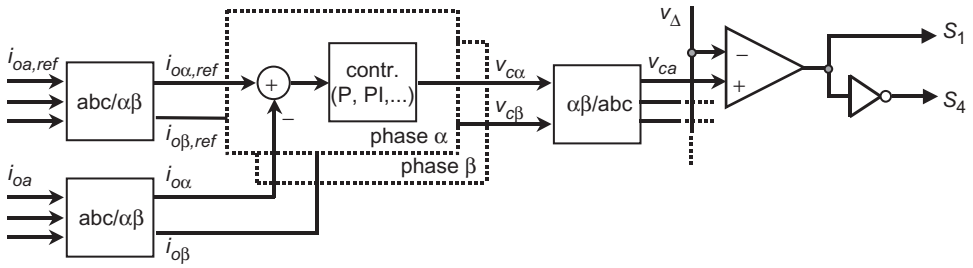

FIG. 11.59 The three-phase VSI. Feedback control based on linear controllers.

SPWM (as depicted in Fig. 11.59) or by space-vector modulation. Because the load line currents add up to zero, the load line current references must add up to zero. Thus, the abc/ αβγ transformation can be used to reduce to two controllers the overall implementation scheme as the γ component is always zero. This avoids limit cycles in the ac load currents.

The transformation of a set of variables in the stationary abc frame $\mathbf{x}^{abc}$ into a set of variables in the stationary αβ frame $\mathbf{x}^{\alpha\beta}$ is given by

$$\mathbf{x}^{\alpha\beta} = \frac{2}{3}\begin{bmatrix} 1 & -1/2 & -1/2 \\ 0 & \sqrt{3}/2 & -\sqrt{3}/2 \end{bmatrix}\mathbf{x}^{abc} \tag{11.67}$$

The selection of the controller (P, PI, …) is done according to the control procedures such as steady-state error, settling time, and overshoot. Fig. 11.60 shows the relevant waveforms of a VSI SPWM controlled by means of a PI controller as shown in Fig. 11.59.

Although it is difficult to prove that no limit cycles are generated, the ac line current appears very much sinusoidal. Moreover, the ac line voltage generated by the VSI preserves the characteristics of such waveforms generated by SPWM modulators.

However, an error between the actual i_{oa} and the ac line current reference $i_{oa,ref}$ can be observed (Fig. 11.60A). This error is inherent to linear controllers and cannot be totally eliminated, but it can be minimized by increasing the gain of the controller. However, the noise in the circuit is also increased, which could deteriorate the overall performance of the control scheme. The inherent presence of the error in this type of controllers is due to the fact that the controller needs a sinusoidal error to generate sinusoidal modulating signals v_{ca}, v_{cb}, and v_{cc}, as required by the modulator. Therefore, an error must exist between the actual and the ac line current references.

Nevertheless, as current-controlled VSIs are actually the inner loops in many control strategies, their inherent errors are compensated by the outer loop. This is the case of ASDs, where the outer speed loop compensates the inner current loops. In general, if the outer loop is implemented with dc quantities (such as speed), it can compensate the ac inner loops (such as ac line currents). If it is mandatory that a zero steady-state error be achieved with the ac quantities, then a stationary (abc frame) to rotating (dq frame) transformation is a valid alternative to use.

11.6.2.3 Linear Control of VSIs in a Rotating Frame

The rotating dq transformation allows ac three-phase circuits to be operated as if they were dc circuits. This is based upon a mathematical operation, that is, the transformation of a set of variables in the stationary abc frame $\mathbf{x}^{abc}$ into a set of variables in the rotating dq0 frame $\mathbf{x}^{dq0}$. The transformation is given by

$$\mathbf{x}^{dq} = \frac{2}{3}\begin{bmatrix} \sin(\omega t) & \sin(\omega t - 2\pi/3) & \sin(\omega t - 4\pi/3) \\ \cos(\omega t) & \cos(\omega t - 2\pi/3) & \cos(\omega t - 4\pi/3) \\ 1/\sqrt{2} & 1/\sqrt{2} & 1/\sqrt{2} \end{bmatrix}\mathbf{x}^{abc} \tag{11.68}$$

where ω is the angular frequency of the ac quantities. For instance, the current vector given by

$$\mathbf{i}^{abc} = \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} = \begin{bmatrix} I\sin(\omega t - \varphi) \\ I\sin(\omega t - 2\pi/3 - \varphi) \\ I\sin(\omega t - 4\pi/3 - \varphi) \end{bmatrix} \tag{11.69}$$

becomes the vector

$$\mathbf{i}^{dq0} = \begin{bmatrix} i_d \\ i_q \\ i_0 \end{bmatrix} = \begin{bmatrix} I\cos(\varphi) \\ -I\sin(\varphi) \\ 0 \end{bmatrix} \tag{11.70}$$

where I and φ are the amplitude and phase of the line currents, respectively. It can be observed that (a) the zero-component i_0 is always zero as the three-phase quantities add up to zero and

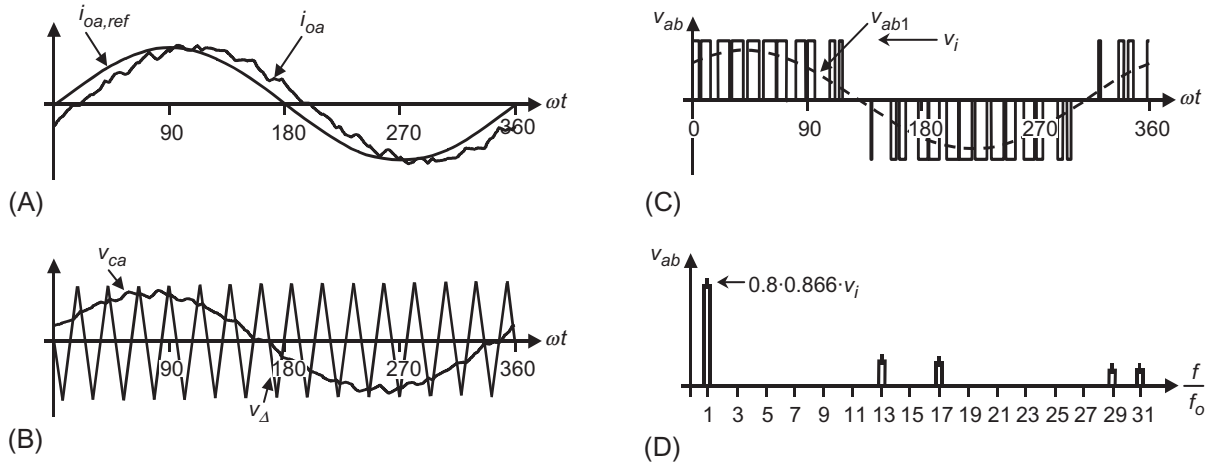

FIG. 11.60 The three-phase VSI. Ideal waveforms for a PI controller in a feedback loop ($m_a = 0.8$, $m_f = 15$): (A) actual ac load current and reference, (B) carrier and modulating signals, (C) ac output voltage, and (D) ac output voltage spectrum.

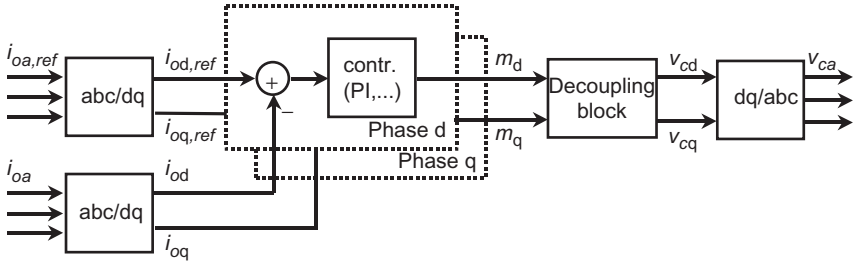

FIG. 11.61 The three-phase VSI. Feedback control based on dq0 transformation.

(b) the d and q components i_d, i_q are dc quantities. Thus, linear controllers should help to achieve zero steady-state error. The control strategy shown in Fig. 11.61 is an alternative where the zero-component controller has been eliminated due to the fact that the line currents at the load side add up to zero.

The controllers in Fig. 11.61 include an integrator that generates the appropriate dc outputs m_d and m_q even if the actual and the line current references are identical. This ensures that the zero steady-state error is achieved. The decoupling block in Fig. 11.61 is used to eliminate the cross coupling effect generated by the dq0 transformation and to allow an easier design of the parameters of the controllers.

The dq0 transformation requires the intensive use of multiplications and trigonometric functions. These operations can readily be done by means of digital microprocessors. Also, analog implementations would indeed be involved.

11.6.3 Feedback Techniques in Current Source Inverters

Duality indicates that CSIs should be controlled as equally as VSIs except that the voltages become currents and the currents become voltages. Thus, hysteresis, linear, and dq linear-based control strategies are also applicable to CSIs; however, the controlled variables are the load voltages instead of the load line currents.

For instance, the linear control of a CSI based on a dq transformation is depicted in Fig. 11.62. In this case, a passive balanced load is considered. In order to show that zero steady-state error is achieved, the per phase equations of the converter are written as

$$C\frac{d}{dt}\mathbf{v}_\mathbf{p}^{\mathbf{abc}} = \mathbf{i}_\mathbf{o}^{\mathbf{abc}} - \mathbf{i}_\mathbf{l}^{\mathbf{abc}} \tag{11.71}$$

$$L\frac{d}{dt}\mathbf{i}_\mathbf{l}^{\mathbf{abc}} = \mathbf{v}_\mathbf{p}^{\mathbf{abc}} - R\mathbf{i}_\mathbf{l}^{\mathbf{abc}} \tag{11.72}$$

The ac line currents are in fact imposed by the modulator, and they satisfy

$$\mathbf{i}_\mathbf{o}^{\mathbf{abc}} = i_i\mathbf{i}_\mathbf{c}^{\mathbf{abc}} \tag{11.73}$$

Replacing Eq. (11.73) into the model of the converter Eqs. (11.71) and (11.72), using the dq0 transformation and assuming null zero component, the model of the converter becomes

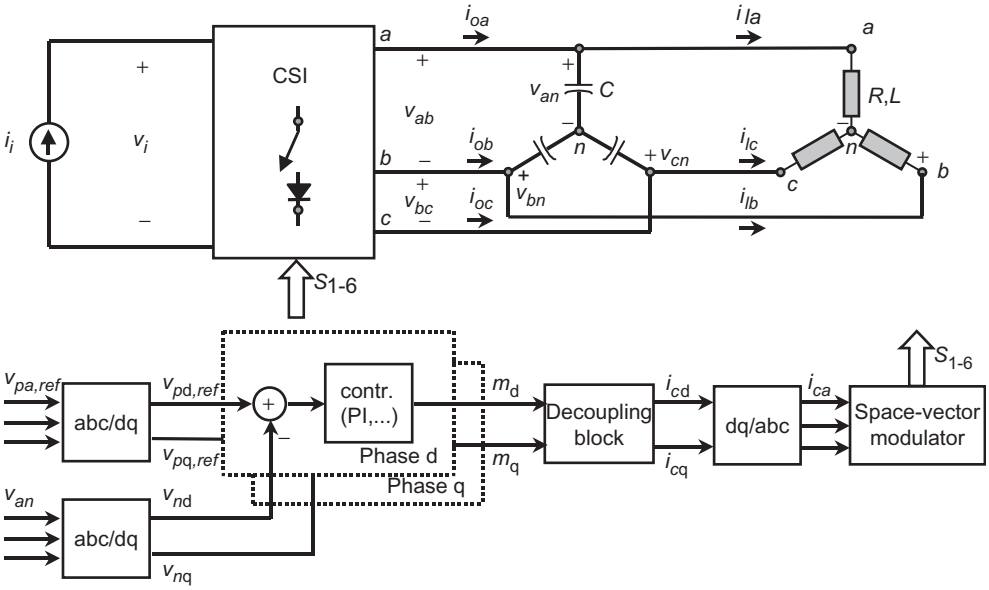

FIG. 11.62 The three-phase CSI. Feedback control based on dq0 transformation.

$$\frac{d}{dt}\mathbf{v}_{\mathbf{p}}^{\mathrm{dq}} = -\mathbf{W}\mathbf{v}_{\mathbf{p}}^{\mathrm{dq}} + \frac{i_i}{C}\mathbf{i}_{\mathbf{c}}^{\mathrm{dq}} - \frac{1}{C}\mathbf{i}_{\mathrm{l}}^{\mathrm{dq}} \tag{11.74}$$

$$\frac{d}{dt}\mathbf{i}_{\mathrm{l}}^{\mathrm{dq}} = -\mathbf{W}\mathbf{i}_{\mathrm{l}}^{\mathrm{dq}} + \frac{1}{L}\mathbf{v}_{\mathbf{p}}^{\mathrm{dq}} - \frac{R}{L}\mathbf{i}_{\mathrm{l}}^{\mathrm{dq}} \tag{11.75}$$

where $\mathbf{W}$ is given by

$$\mathbf{W} = \begin{bmatrix} 0 & -\omega \\ \omega & 0 \end{bmatrix} \tag{11.76}$$

A first approximation is to assume that the decoupling block is not there; in other words, $\mathbf{i}_{\mathbf{c}}^{\mathrm{dq}} = \mathbf{m}^{\mathrm{dq}}$. On the other hand, the model of the controllers can be written as

$$\mathbf{m}^{\mathrm{dq}} = k\left\{\mathbf{v}_{\mathbf{p,ref}}^{\mathrm{dq}} - \mathbf{v}_{\mathbf{p}}^{\mathrm{dq}}\right\} + \frac{1}{T}\int_{-\infty}^{t}\left(\mathbf{v}_{\mathbf{p,ref}}^{\mathrm{dq}} - \mathbf{v}_{\mathbf{p}}^{\mathrm{dq}}\right)dt \tag{11.77}$$

where k and T are the proportional and integrative gains of the PI controller that are chosen to achieve a desired dynamic response. Combining the model of the controllers and the model of the converter in dq coordinates and using the Laplace transform, the following relationship between the reference and actual phase-load voltages is found:

$$\begin{aligned}\mathbf{v}_{\mathbf{p}}^{\mathrm{dq}} = {} & \frac{i_i}{C}\left\{sk + \frac{1}{T}\right\}\left\{s\mathbf{I} + \mathbf{W} + \frac{R}{L}\mathbf{I}\right\}\times \\ & \left[\left\{s\mathbf{I} + \mathbf{W} + \frac{R}{L}\mathbf{I}\right\}\left\{s^2\mathbf{I} + s\left(\mathbf{W} + \frac{i_i}{C}k\mathbf{I}\right) + \frac{i_i}{CT}\mathbf{I}\right\}\right. \\ & \left. + \frac{s}{LC}\mathbf{I}\right]^{-1}\mathbf{v}_{\mathbf{p,ref}}^{\mathrm{dq}}\end{aligned} \tag{11.78}$$

Finally, in order to prove that the zero steady-state error is achieved for step inputs in either the d or q component of the phase-load voltage reference, the previous expression is evaluated in $s = 0$. This results in the following:

$$\begin{aligned}\mathbf{v}_{\mathbf{p}}^{\mathrm{dq}} = {} & \frac{i_i}{C}\left\{\frac{1}{T}\right\}\left\{\mathbf{W} + \frac{R}{L}\mathbf{I}\right\}\left[\left\{W + \frac{R}{L}\mathbf{I}\right\}\left\{\frac{i_i}{CT}\mathbf{I}\right\}\right]^{-1}\mathbf{v}_{\mathbf{p,ref}}^{\mathrm{dq}} \\ = {} & \mathbf{v}_{\mathbf{p,ref}}^{\mathrm{dq}}\end{aligned} \tag{11.79}$$

As expected, the actual and reference values are identical. Finally, the relationship in Eq. (11.78) is a matrix that is not diagonal. This means that both the actual and the reference phase-load voltages are coupled. In order to obtain a decoupled control, the decoupling block in Fig. 11.62 should be properly chosen.

11.7 Regeneration in Inverters

Industrial applications are usually characterized by a power flow that goes from the ac distribution system to the load. This is, for example, the case of an ASD operating in the motoring mode. In this instance, the active power flows from the dc side to the ac side of the inverter. However, there are an important number of applications in which the load may supply power to the system. Moreover, this could be an occasional condition and a normal operating condition. This is known as the regenerative operating mode. For example, when an ASD reduces the speed of an electric machine, this can be considered a transient condition. Downhill belt conveyors in mining applications can be considered as a normal operating condition. In order to simplify the notation, it could be said that an inverter operates in the motoring mode when the power flows from the dc to the ac side and in the regenerative mode when the power flows from the ac to the dc side.

11.7.1 Motoring Operating Mode in Three-phase VSIs

This is the case where the power flows from the dc side to the ac side of the inverter. Fig. 11.63 shows a simplified scheme of an ASD where the motor has been modeled by three *RLe* branches, where the sources $\mathbf{e}^{\mathrm{abc}}$ are the back emf. Because the ac line voltages applied by the inverter are imposed by the pulse width modulation technique being used, they can be adjusted according to specific requirements. In particular, Fig. 11.64 shows the relevant waveforms in a steady state for the motoring operating mode of the ASD. To simplify the analysis, a constant dc bus voltage $v_i = V_i$ has been considered.

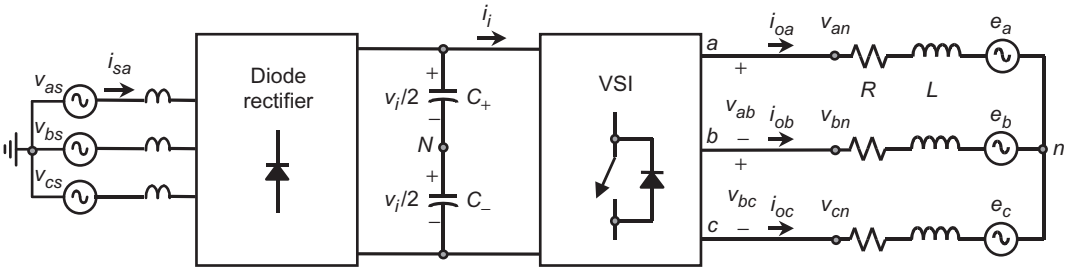

FIG. 11.63 Three-phase VSI topology with a diode-based front-end rectifier.

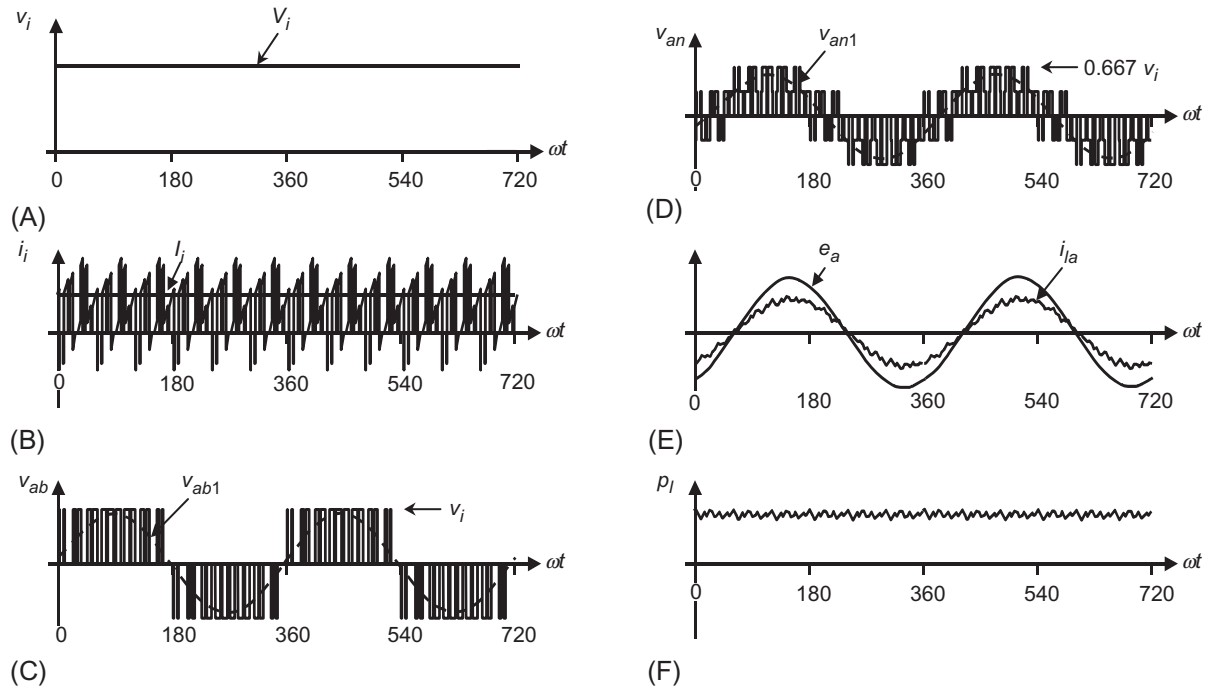

FIG. 11.64 The ASD based on a VSI. Motoring mode: (A) dc bus voltage, (B) dc bus current, (C) ac line-load voltage, (D) ac phase-load voltage, (E) motor line current and back emf, and (F) shaft power.

It can be observed that (i) the dc bus current i_i features a dc value I_i that is positive and (ii) the motor line current is in phase with the back emf. Both features confirm that the active power flows from the dc source to the motor. This is also confirmed by the shaft power plot (Fig. 11.64F), which is obtained as

$$p_l(t) = e_a(t)i_{la}(t) + e_b(t)i_{lb}(t) + e_c(t)i_{lc}(t) \tag{11.80}$$

11.7.2 Regenerative Operating Mode in Three-phase VSIs

The back emf sources $\mathbf{e}^{abc}$ are functions of the machine speed, and as such, they ideally change just as the speed changes. The regeneration operating mode can be achieved by properly modifying the ac line voltages applied to the machine. This is done by the speed outer loop that could be based on a scalar (e.g., V/f) or vectorial (e.g., field-oriented) control strategy. As indicated earlier, there are two cases of regenerative operating modes.

11.7.2.1 Occasional Regenerative Operating Mode

This mode is required during transient conditions such as in occasional braking of electric machines (ASDs). Specifically, the speed needs to be reduced, and the kinetic energy is taken into the dc bus. Because the motor line voltage is imposed by the VSI, the speed reduction should be done in such a way that the motor line currents do not exceed the maximum values. This boundary condition will limit the ramp-down speed to a minimum, but shorter braking times will require a mechanical braking system.

Fig. 11.65 shows a transition from the motoring to regenerative operating mode for an ASD as shown in Fig. 11.63. Here, a stiff dc bus voltage has been used. Zone I in Fig. 11.65 is the motoring mode, zone II is a transition condition, and zone III is the regeneration mode. The line voltage is adjusted dynamically to obtain nominal motor line currents during regeneration (Fig. 11.65D). Zone III clearly shows that the shaft power gets reversed.

Occasional regeneration means that the drive rarely goes into this operating mode. Therefore, such energy can be (a) left uncontrolled or (b) burned in resistors that are paralleled to the dc bus. The first option is used in low- to medium-power applications that use diode-based front-end rectifiers. Therefore, the dc bus current flows into the dc bus capacitor, and the dc bus voltage rises accordingly to

$$\Delta v_i = \frac{1}{C} I_i \Delta t \tag{11.81}$$

where Δv_i is the dc bus voltage variation, C is the dc bus voltage capacitor, I_i is the average dc bus current during regeneration, and Δt is the duration of the regeneration operating mode. Usually, the drives have the capacitor C designed to allow a 10% overvoltage in the dc bus.

The second option uses burning resistors R_R that are paralleled in the dc bus as shown in Fig. 11.66 by means of the switch

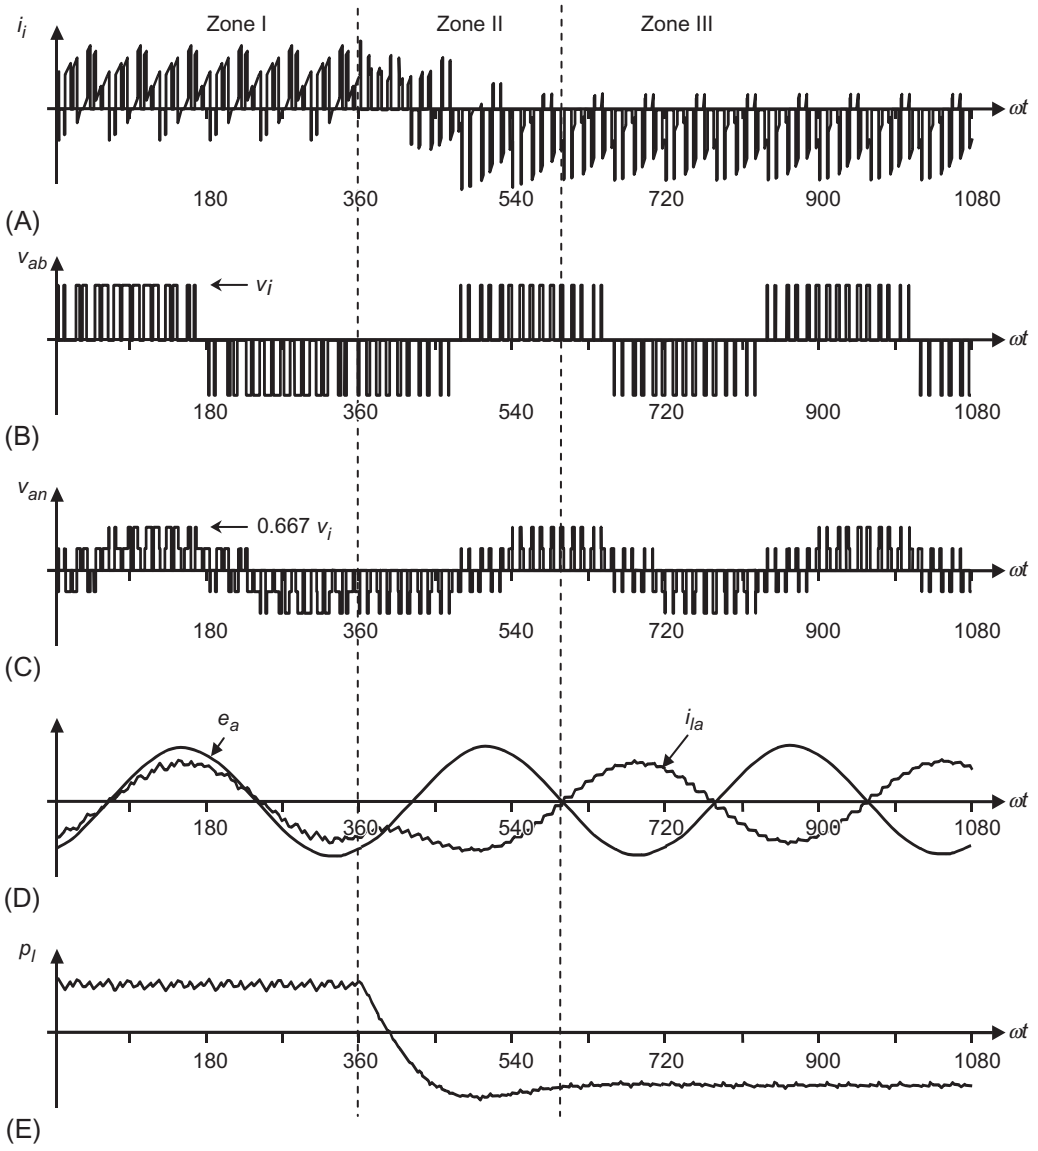

FIG. 11.65 The ASD based on a VSI. Motoring to regenerative operating mode transition: (A) dc bus current, (B) ac line motor voltage, (C) ac phase motor voltage, (D) motor line current and back emf, and (E) shaft power.

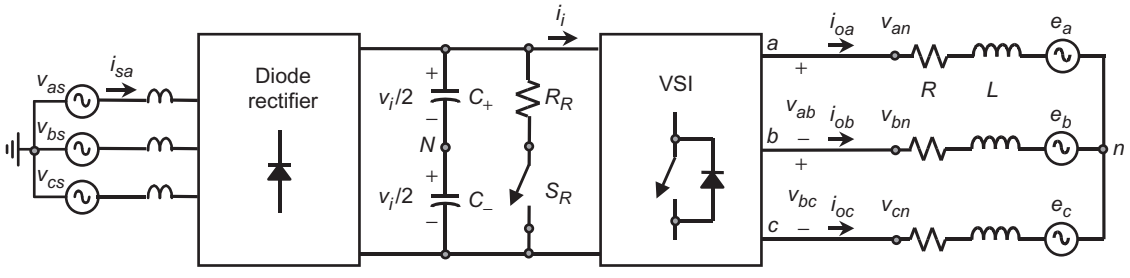

FIG. 11.66 The ASD based on a VSI. Burning resistor strategy.

S_R. A closed-loop strategy based on the actual dc bus voltage modifies the duty cycle of the turn-on/turnoff of the switch S_R in order to keep such voltage under a given reference. This alternative is used when the energy recovered by the VSI would result in an acceptable dc bus voltage variation if an uncontrolled alternative is used.

There are some special cases where the regeneration operating mode is frequently used. For instance, electric shovels in mining companies have repetitive working cycles, and $\asymp 15\%$ of the energy is sent back into the dc bus. In this case, a valid alternative is to send back the energy into the ac distribution system.

The schematic shown in Fig. 11.67 is capable of taking the kinetic energy and sending it into the ac grid. As reviewed earlier, the regeneration operating mode reverses the polarity of the dc current i_i, and because the diode-based front-end converter cannot take negative currents, a thyristor-based front-end converter is added. Similarly to the burning resistor approach, a closed-loop strategy based on the actual dc bus voltage v_i modifies the commutation angle α of the thyristor rectifier in order to keep such voltage under a given reference.

11.7.2.2 Regenerative Operating Mode as Normal operating Mode

Fewer industrial applications are capable of returning energy into the ac distribution system on a continuous basis. For instance, mining companies usually transport their product downhill for a few kilometers before processing it. In such cases, the drive maintains the transportation belt conveyor at constant speed and takes the kinetic energy. Due to the large amount of energy and the continuous operating mode, the drive should be capable of taking the kinetic energy, transforming it into electric energy, and sending it into the ac distribution system. This would make the drive a generator that would compensate for the active power required by other loads connected to the electric grid.

The schematic shown in Fig. 11.68 is a modern alternative for adding regeneration capabilities to the VSI-based drive on a continuous basis. In contrast to the previous alternatives, this scheme uses a VSI topology as an active front-end converter, which is generally called voltage-source rectifier (VSR). The VSR operates in two quadrants, that is, positive dc voltages and positive/negative dc currents as reviewed earlier. This feature makes it a perfect match for ASDs based on a

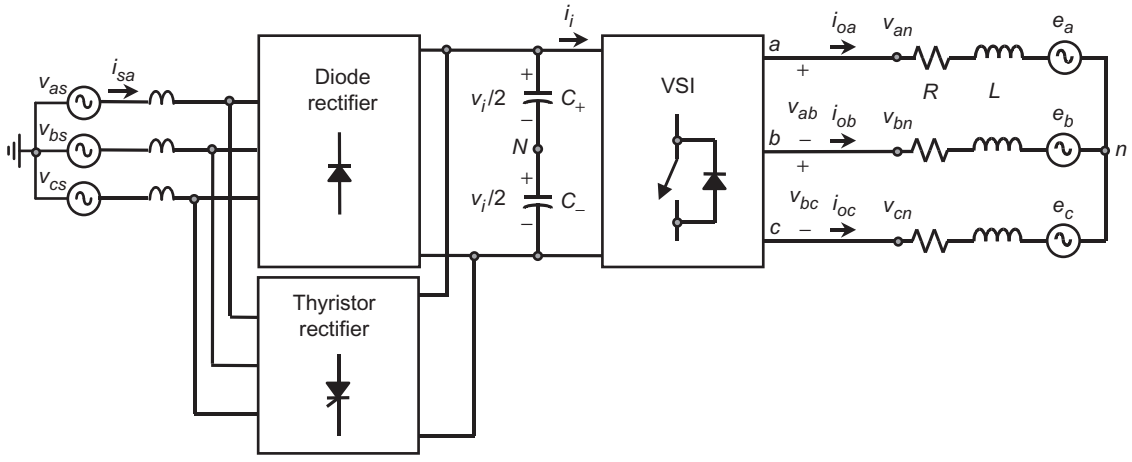

FIG. 11.67 The ASD based on a VSI. Diode-thyristor-based front-end rectifier with regeneration capabilities.

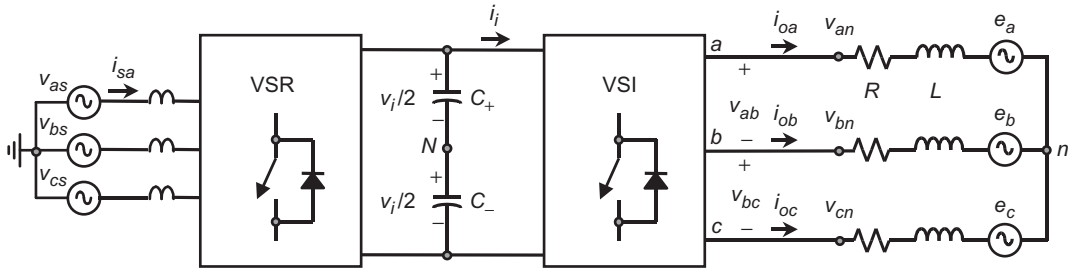

FIG. 11.68 The ASD based on a VSI. Active front-end rectifier with regeneration capabilities.

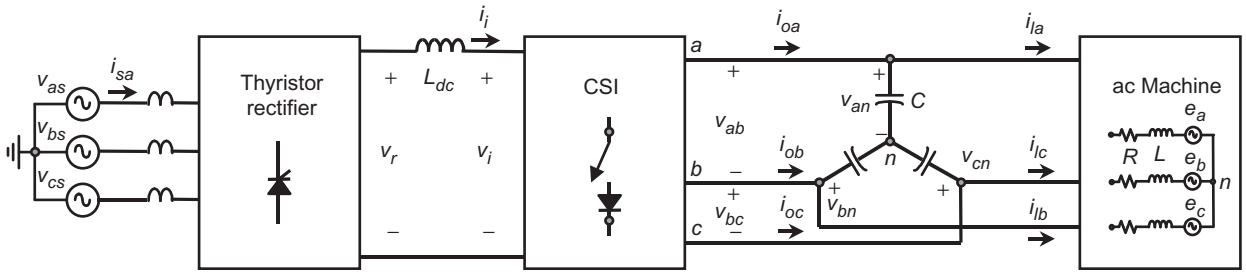

FIG. 11.69 The ASD based on a CSI. Thyristor-based rectifier.

VSI. Some of the advantages of using a VSR topology are the following: (i) The ac supply current can be as sinusoidal as required (by increasing the switching frequency of the VSR or the ac line inductance), (ii) the operation can be done at a unity displacement power factor in both motoring and regenerative operating modes, and (iii) the control of the VSR is done in both motoring and regenerative operating modes by a single dc bus voltage loop.

11.7.3 Regenerative Operating Mode in Three-phase CSIs

There are drives where the motor side converter is a CSI. This is usually the case where near sinusoidal motor voltages are needed instead of the PWM type of waveform generated by VSIs. This is normally the case for medium-voltage applications. Such inverters require a dc current source that is constructed by means of a controlled rectifier.

Fig. 11.69 shows a CSI-based ASD where the dc current source is generated by means of a thyristor-based rectifier in combination with a dc link inductor L_{dc}. In order to maintain a constant dc link current $i_i = I_i$, the thyristor-based rectifier adjusts the commutation angle α by means of a closed-loop control strategy. Assuming a constant dc link current, the regenerating operating mode is achieved when the dc link voltage v_i reverses its polarity. This can be done by modifying the PWM pattern applied to the CSI as in the VSI-based drive. To maintain the dc link current constant, the thyristor-based rectifier also reverses its dc link voltage v_r. Fortunately, the thyristor rectifier operates in two quadrants, that is, positive dc link currents and positive/negative dc link voltages. Thus, no additional equipment is required to include regeneration capabilities in CSI-based drives.

Similarly, an active front-end rectifier could be used to improve the overall performance of the thyristor-based rectifier. A PWM current-source rectifier (CSR) could replace the thyristor-based rectifier with the following added advantages: (i) The ac supply current can be as sinusoidal as required (e.g., by increasing the switching frequency of the CSR), (ii) the operation can be done at a unity displacement power factor in both motoring and regenerative operating modes, and (iii) the control of the CSR is done in both motoring and regenerative operating modes by a single dc bus current loop.

12.1 Introduction

Advances in power electronics in the last few decades have led to not only improvements in power devices but also new concepts in converter topologies and control. In the 1970s, conventional pulse-width modulation (PWM) power converters were operated in a switched-mode operation. Power switches have to cut off the load current within the turn-on and turn-off times under the hard-switching conditions. Hard switching refers to the stressful switching behavior of the power electronic devices. The switching trajectory of a hard-switched power device is shown in Fig. 12.1. During the turn-on and turn-off processes, the power device has to withstand high voltage and current simultaneously, resulting in high switching losses and stress.

Dissipative passive snubbers are usually added to the power circuits so that the *dv/dt* and *di/dt* of the power devices could be reduced and the switching loss and stress be diverted to the

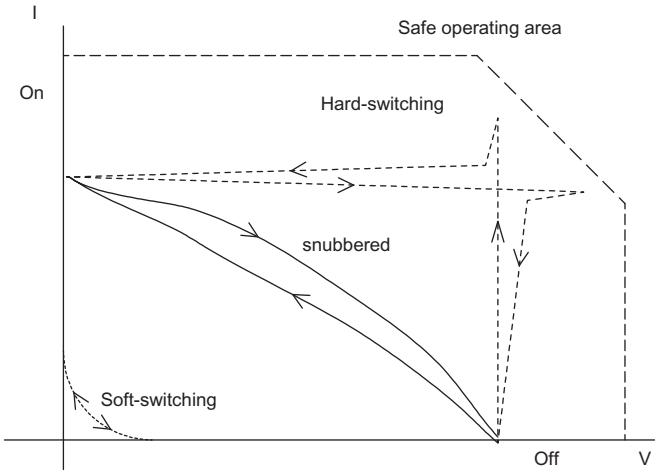

FIG. 12.1 Typical switching trajectories of power switches.

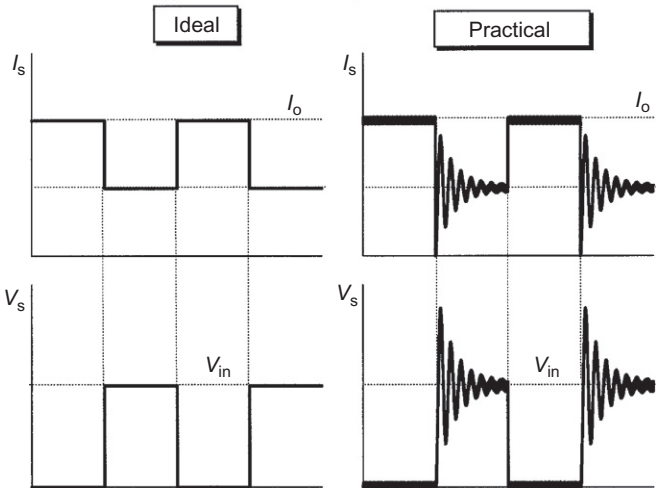
passive snubber circuits. However, the switching loss is proportional to the switching frequency, thus limiting the maximum switching frequency of the power converters. Typical converter switching frequency was limited to a few tens of kilohertz (typically 20–50 kHz) in the early 1980s. The stray inductive and capacitive components in the power circuits and power devices still cause considerable transient effects, which in turn give rise to electromagnetic interference (EMI) problems. Fig. 12.2 shows ideal switching waveforms and typical practical waveforms of the switch voltage. The transient ringing effects are major causes of EMI.



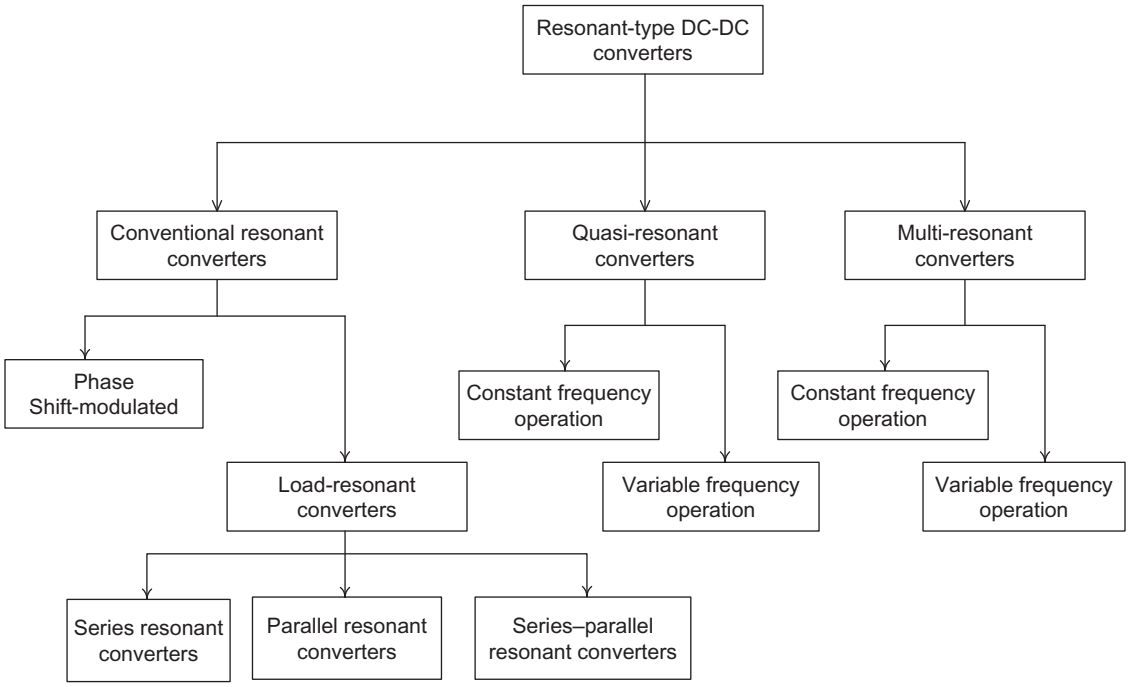


FIG. 12.2 Typical: (A) ideal and (B) practical switching waveforms.

In the 1980s, lots of research efforts were diverted toward the use of resonant converters. The concept was to incorporate resonant tanks in the converters to create oscillatory (usually sinusoidal) voltage and/or current waveforms so that zero-voltage switching (ZVS) or zero-current switching (ZCS) conditions can be created for the power switches. The reduction of switching loss and the continual improvement of power switches allow the switching frequency of the resonant converters to reach hundreds of kilohertz (typically 100–500 kHz). Consequently, the size of magnetic components can be reduced, and the power density of the converters increased. Various forms of resonant converters have been proposed and developed. However, most of the resonant converters suffer several problems. When compared with the conventional PWM converters, the resonant current and the voltage of resonant converters have high peak values, leading to higher conduction loss and higher V and I rating requirements for the power devices. Also, many resonant converters require frequency modulation (FM) for output regulation. Variable switching frequency operation makes the filter design and control more complicated.

In the late 1980s and throughout the 1990s, further improvements have been made in converter technology. New generations of soft-switched converters that combine the advantages of conventional PWM converters and resonant converters have been developed. These soft-switched converters have switching waveforms similar to those of conventional PWM converters except that the rising and falling edges of the waveforms are "smoothed" with no transient spikes. Unlike the resonant converters, new soft-switched converters usually utilize the resonance in a controlled manner. Resonance is allowed to occur just before and during the turn-on and turn-off processes so as to create ZVS and ZCS conditions. Other than that, they behave just like conventional PWM converters. With simple modifications, many customized control integrated circuits (ICs) designed for conventional converters can be employed for soft-switched converters. Because the switching loss and stress have been reduced, soft-switched converter can be operated at the very high frequency (typically 500 kHz to a few megahertz). Soft-switching converters also provide an effective solution to suppress EMI and have been applied to DC-DC, AC-DC, and DC-AC converters. This chapter covers the basic technology of resonant and soft-switching converters. Various forms of soft-switching techniques such as ZVS, ZCS, voltage clamping, and zero-voltage transition methods are addressed. The emphasis is placed on the basic operating principle and practicality of the converters without using much mathematical analysis.

12.2 Classification

12.3 Resonant Switch

Prior to the availability of fully controllable power switches, thyristors were the major power devices used in power electronic circuits. Each thyristor requires a commutation circuit, which usually consists of an *LC* resonant circuit, for forcing the current to zero in the turn-off process [1]. This mechanism is in fact a type of zero-current turn-off process. With the recent advancement in semiconductor technology, the voltage and current handling capability and the switching speed of fully controllable switches have significantly been improved. In many high-power applications, controllable switches such as gate turn-offs (GTOs) and insulated-gate bipolar transistors (IGBTs) have replaced thyristors [2,3]. However, the use of resonant circuit for achieving ZCS and/or ZVS [4–8] has also emerged as a new technology for power converters. The concept of resonant switch that replaces conventional power switch is introduced in this section.

A resonant switch is a subcircuit comprising a semiconductor switch S and resonant elements, L_r and C_r [9–11]. The switch S can be implemented by a unidirectional or bidirectional switch, which determines the operation mode of the resonant switch. Two types of resonant switches [12], including zero-current (ZC) resonant switch and zero-voltage (ZV) resonant switches, are shown in Figs. 12.3 and 12.4, respectively.

12.3.1 ZC Resonant Switch

In a ZC resonant switch, an inductor L_r is connected in series with a power switch S in order to achieve zero-current switching (ZCS). If the switch S is a unidirectional switch, the switch current is allowed to resonate in the positive half cycle only. The resonant switch is said to operate in *half-wave* mode. If a diode is connected in antiparallel with the unidirectional switch, the switch current can flow in both directions. In this case, the resonant switch can operate in *full-wave* mode. At turn-on, the switch current will rise slowly from zero. It will then oscillate, because of the resonance between L_r and C_r. Finally, the switch can be commutated at the next zero-current duration. The objective of this type of switch is to shape the switch current waveform during conduction time in order to create a zero-current condition for the switch to turn off [13].

12.3.2 ZV Resonant Switch

In a ZV resonant switch, a capacitor C_r is connected in parallel with the switch S for achieving zero-voltage switching (ZVS). If

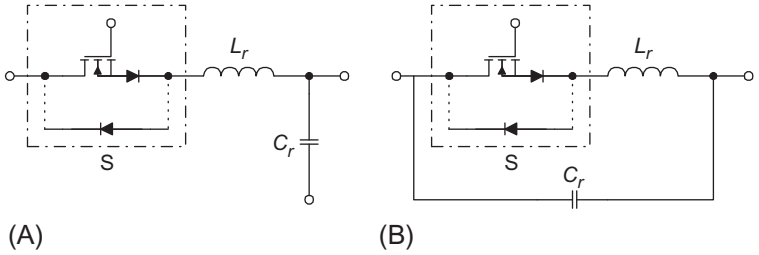

FIG. 12.3 Zero-current (ZC) resonant switch. (A) Option 1. (B) Option 2.

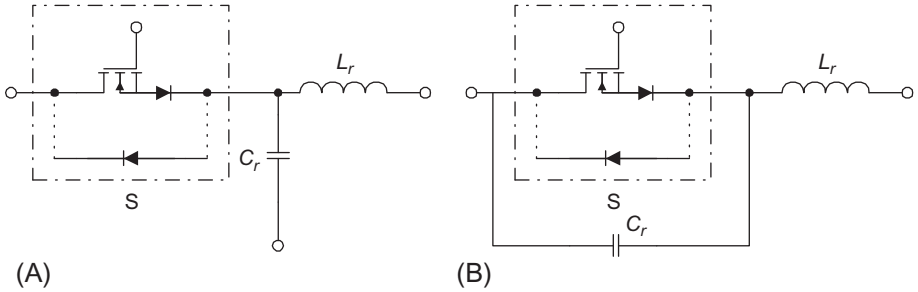

FIG. 12.4 Zero-voltage (ZV) resonant switch. (A) Option 1. (B) Option 2.

the switch S is a unidirectional switch, the voltage across the capacitor C_r can oscillate freely in both positive and negative half cycle. Thus, the resonant switch can operate in *full-wave* mode. If a diode is connected in antiparallel with the unidirectional switch, the resonant capacitor voltage is clamped by the diode to zero during the negative half cycle. The resonant switch will then operate in *half-wave* mode. The objective of a ZV switch is to use the resonant circuit to shape the switch voltage waveform during the off time in order to create a zero-voltage condition for the switch to turn on [13].

12.4 Quasi-Resonant Converters

Quasi-resonant converters (QRCs) can be considered as a hybrid of resonant and PWM converters. The underlying principle is to replace the power switch in PWM converters with the resonant switch. A large family of conventional converter circuits can be transformed into their resonant converter counterparts. The switch current and/or voltage waveforms are forced to oscillate in a quasi-sinusoidal manner, so that ZCS and/or ZVS can be achieved. Both ZCS-QRCs and ZVS-QRCs have *half-wave* and *full-wave* mode of operations [8–10,12].

12.4.1 ZCS-QRCs

A ZCS-QRC designed for *half-wave* operation is illustrated with a buck-type DC-DC converter. The schematic is shown in Fig. 12.5A. It is formed by replacing the power switch in conventional PWM buck converter with the ZC resonant switch in Fig. 12.3A. The circuit waveforms in steady state are shown in Fig. 12.5B. The output filter inductor L_f is sufficiently large so that its current is approximately constant. Prior to turning the switch on, the output current I_o freewheels through the output diode D_f. The resonant capacitor voltage V_{Cr} equals zero. At t_0, the switch is turned on with ZCS. A quasi-sinusoidal current I_S flows through L_r and C_r, the output filter, and the load. S is then softly commutated at t_1 with ZCS again. During and after the gate pulse, the resonant capacitor voltage V_{Cr} rises and then decays at a rate depending on the output current. Output voltage regulation is achieved by controlling the switching frequency. Operation and characteristics of the converter depend mainly on the design of the resonant circuit L_r C_r. The following parameters are defined: voltage conversion ratio M, characteristic impedance Z_r, resonant frequency f_r, normalized load resistance r, and normalized switching frequency γ:

$$M = \frac{V_o}{V_i} \tag{12.1A}$$

$$Z_r = \sqrt{\frac{L_r}{C_r}} \tag{12.1B}$$

$$f_r = \frac{1}{2\pi\sqrt{L_r C_r}} \tag{12.1C}$$

$$r = \frac{R_L}{z_r} \tag{12.1D}$$

$$\gamma = \frac{f_s}{f_r} \tag{12.1E}$$

It can be seen from the waveforms that if $I_o > V_i/Z_r$, I_S will not come back to zero naturally and the switch will have to be forced off, thus resulting in turn-off losses.

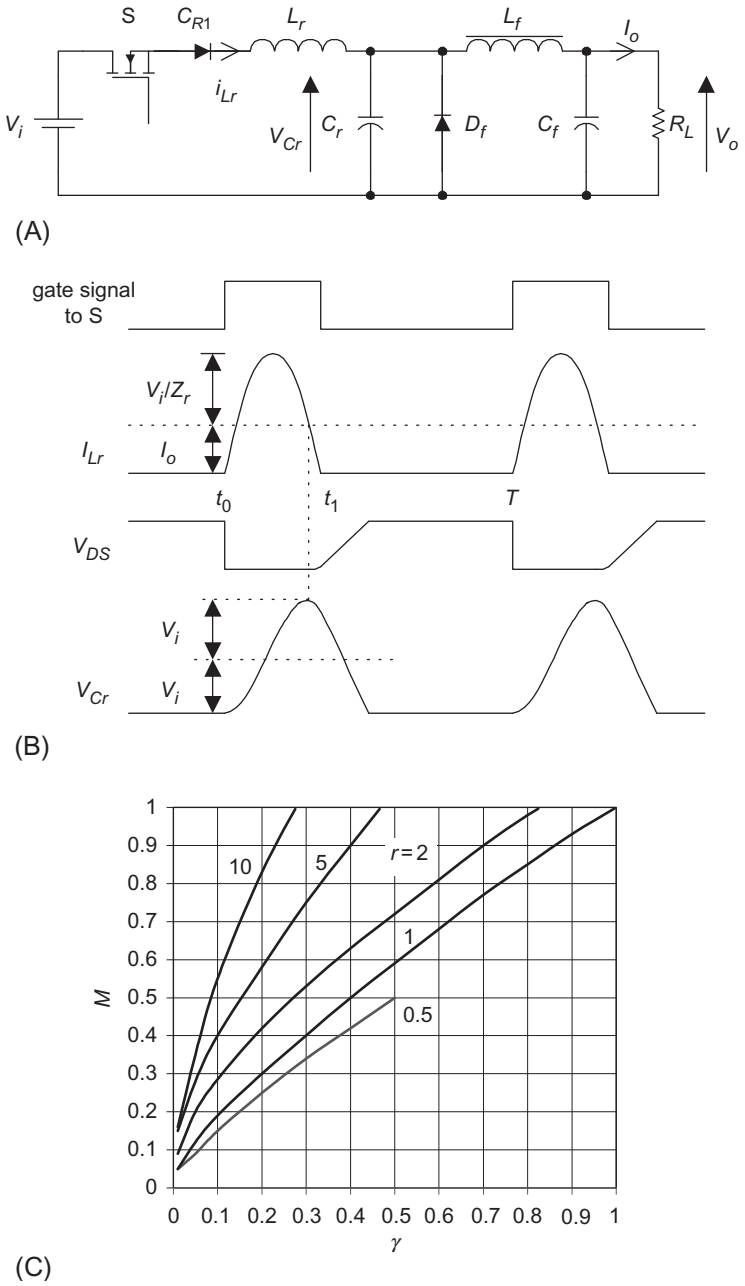

FIG. 12.5 Half-wave, quasi-resonant buck converter with ZCS: (A) schematic diagram, (B) circuit waveforms, and (C) relationship between M and γ.

The relationships between M and γ at different r are shown in Fig. 12.5C. It can be seen that M is sensitive to the load variation. At light-load conditions, the unused energy is stored in C_r, leading to an increase in the output voltage. Thus, the switching frequency has to be controlled, in order to regulate the output voltage.

If an antiparallel diode is connected across the switch, the converter will be operating in *full-wave* mode. The circuit schematic is shown in Fig. 12.6A. The circuit waveforms in steady state are shown in Fig. 12.6B. The operation is similar to the one in *half-wave* mode. However, the inductor current is allowed to reverse through the antiparallel diode, and the duration for the resonant stage is lengthened. This permits excess energy in the resonant circuit at light loads to be transferred back to the voltage source V_i. This significantly reduces the dependence of V_o on the output load. The relationships between M and γ at different r are shown in Fig. 12.6C. It can be seen that M is insensitive to load variation.

By replacing the switch in the conventional converters, a family of QRC [9] with ZCS is shown in Fig. 12.7.

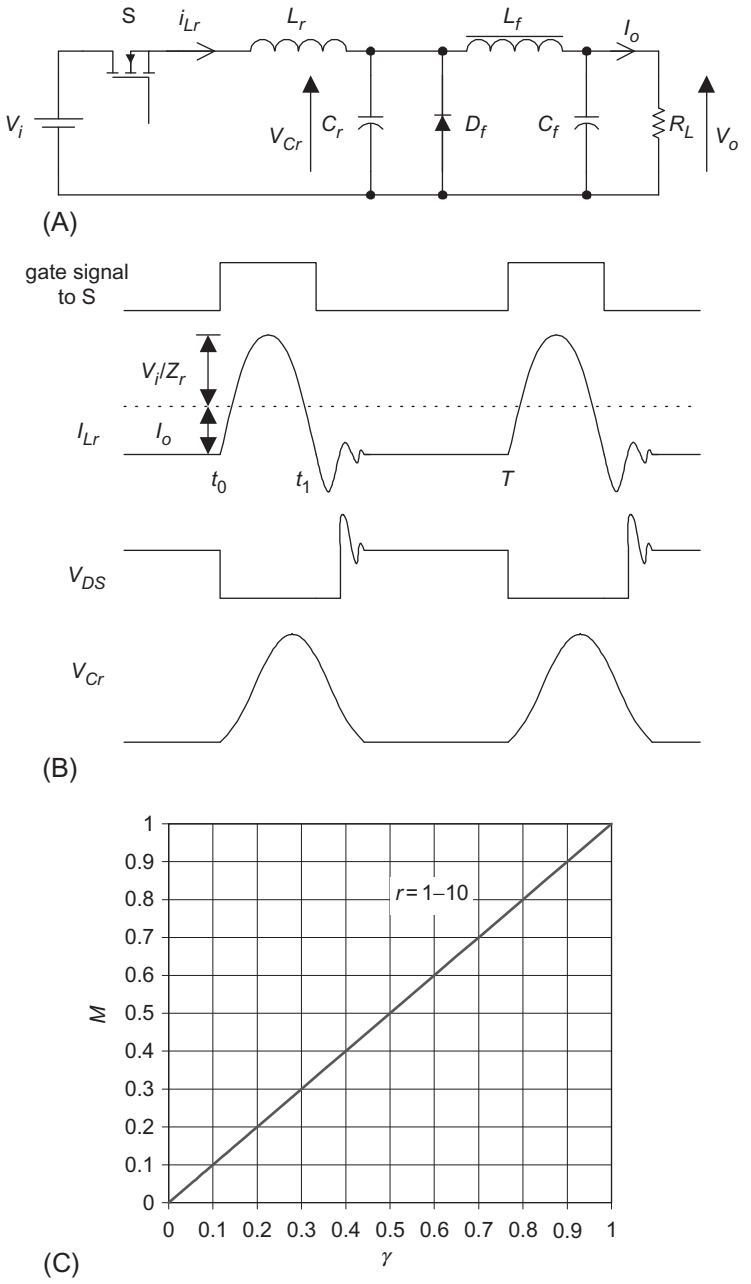

FIG. 12.6 Full-wave, quasi-resonant buck converter with ZCS: (A) schematic diagram, (B) circuit waveforms, and (C) relationship between M and γ.

12.4.2 ZVS-QRC

In these converters, the resonant capacitor provides a zero-voltage condition for the switch to turn on and off. A quasi-resonant buck converter designed for *half-wave* operation is shown in Fig. 12.8A—using a ZV resonant switch in Fig. 12.4B. The steady-state circuit waveforms are shown in Fig. 12.8B. Basic relations of ZVS-QRCs are given in Eqs. (12.1A)–(12.1E). When the switch S is turned on, it carries the output current I_o. The supply voltage V_i reverse biases the diode D_f. When the switch is zero-voltage (ZV) turned off, the output current starts to flow through the resonant capacitor C_r. When the resonant capacitor voltage V_{Cr} is equal to V_i, D_f turns on. This starts the resonant stage. When V_{Cr} equals zero, the antiparallel diode turns on. The resonant capacitor is shorted, and the source voltage is applied to the resonant inductor L_r. The resonant inductor current I_{Lr} increases linearly until it reaches I_o. Then, D_f turns off. In order to achieve ZVS, S should be triggered during the time when the antiparallel diode conducts. It can be seen from the waveforms that the

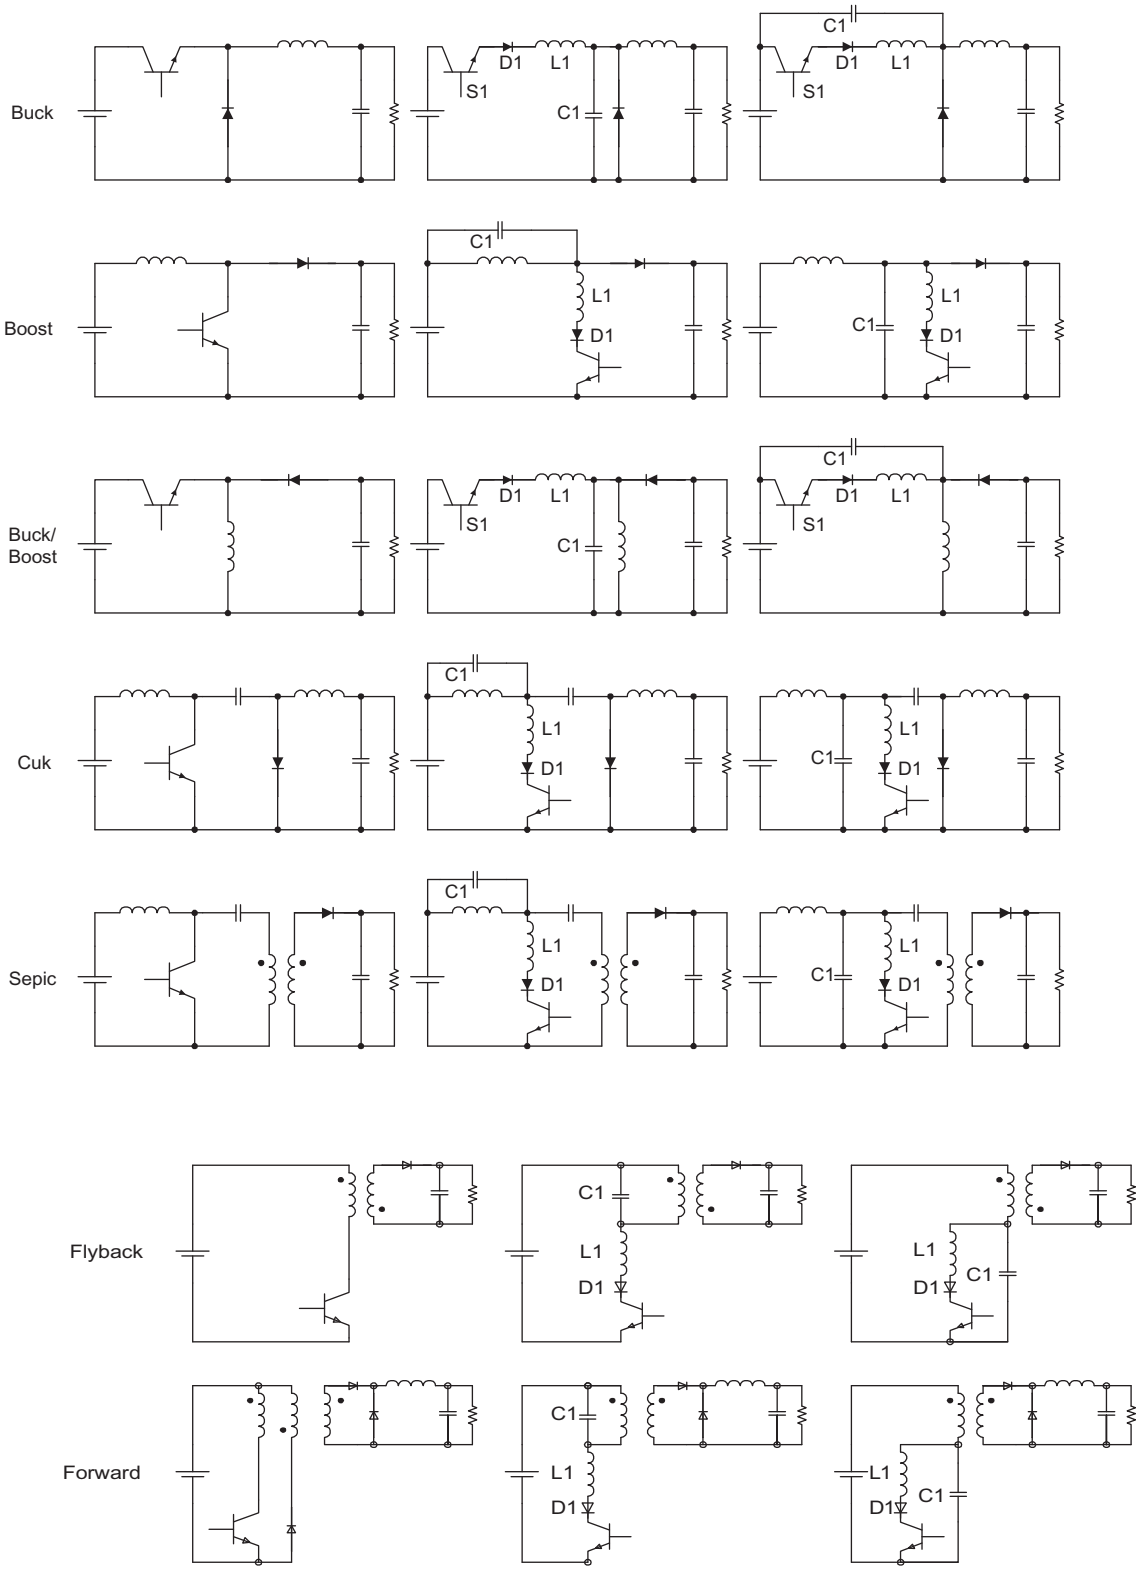

FIG. 12.7 A family of quasi-resonant converter with ZCS.

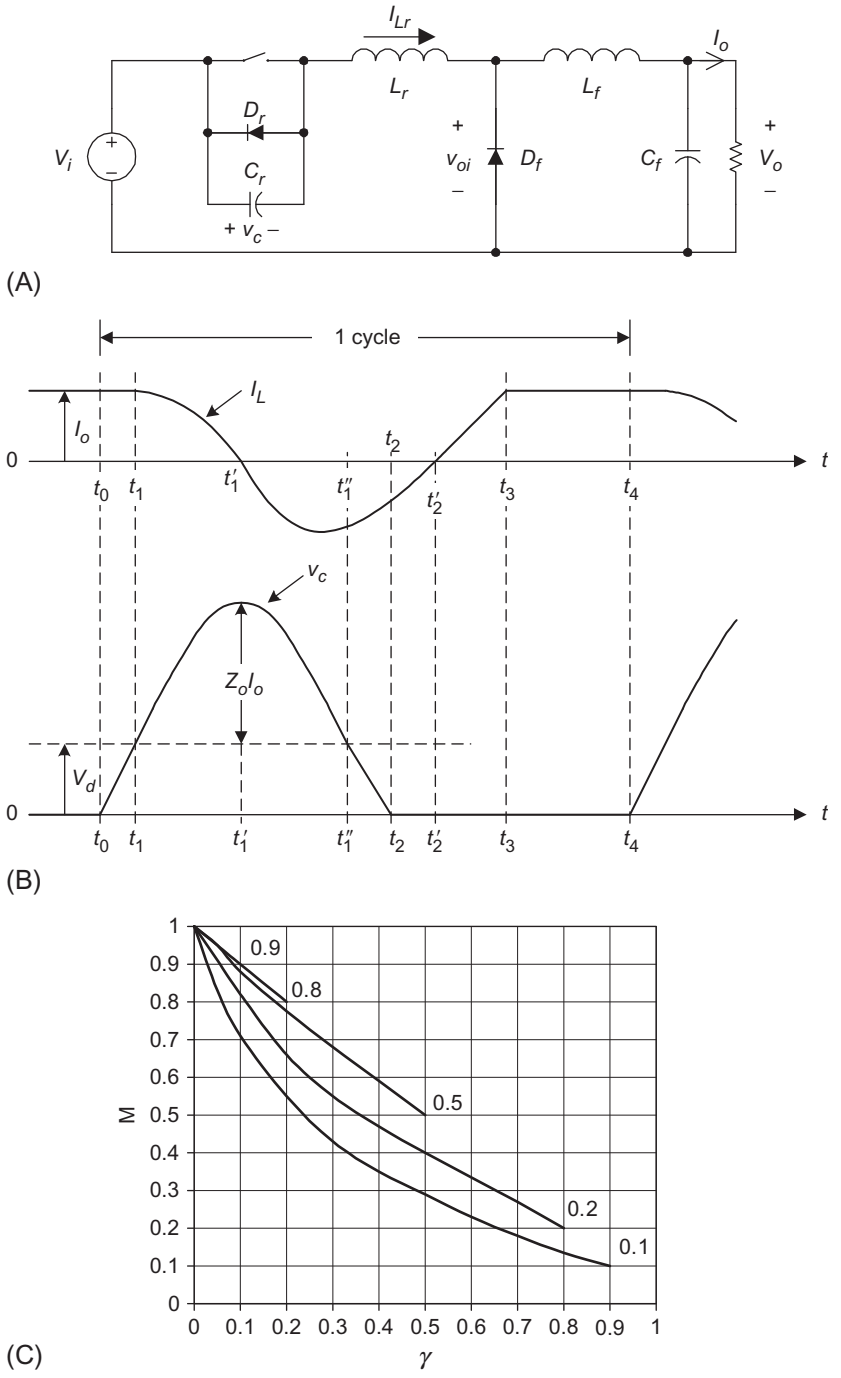

FIG. 12.8 Half-wave, quasi-resonant buck converter with ZVS: (A) schematic diagram, (B) circuit waveforms, and (C) relationship between M and γ.

peak amplitude of the resonant capacitor voltage should be greater or equal to the input voltage (i.e., $I_o Z_r > V_{in}$). From Fig. 12.8C, it can be seen that the voltage conversion ratio is load-sensitive. In order to regulate the output voltage for different loads r, the switching frequency should also be changed accordingly.

ZVS converters can be operated in *full-wave* mode. The circuit schematic is shown in Fig. 12.9A. The circuit waveforms in steady state are shown in Fig. 12.9B. The operation is similar to *half-wave* mode of operation, except that V_{Cr} can swing between positive and negative voltages. The relationships between M and γ at different r are shown in Fig. 12.9C.

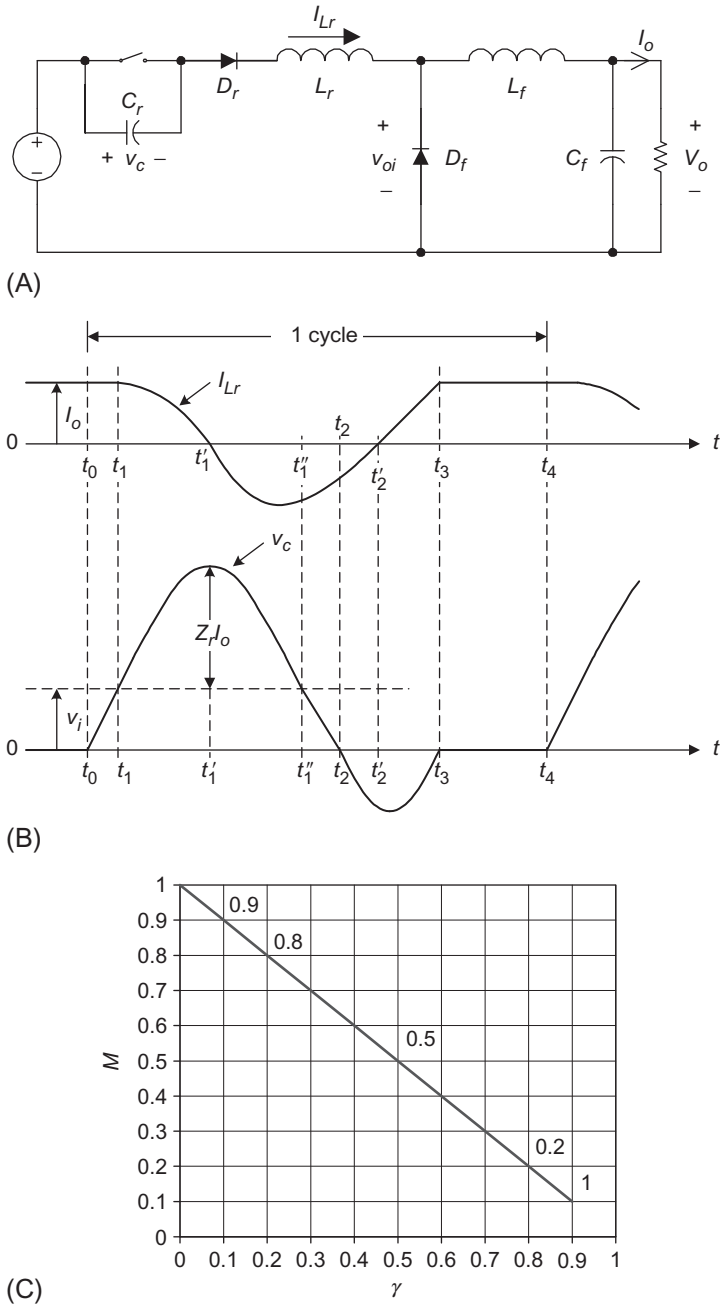

FIG. 12.9 Full-wave, quasi-resonant buck converter with ZVS: (A) schematic diagram, (B) circuit waveforms, and (C) relationship between M and γ.

Comparing Fig. 12.8C with Fig. 12.9C, it can be seen that M is load-insensitive in *full-wave* mode. This is a desirable feature. However, as the series diode limits the direction of the switch current, energy will be stored in the output capacitance of the switch and will dissipate in the switch during turn-on. Hence, the *full-wave* mode has the problem of capacitive turn-on loss and is less practical in high-frequency operation. In practice, ZVS-QRCs are usually operated in *half-wave* mode rather than *full-wave* mode.

By replacing the ZV resonant switch in the conventional converters, various ZVS-QRCs can be derived. They are shown in Fig. 12.10.

12.4.3 Comparisons Between ZCS and ZVS

ZCS can eliminate the switching losses at turnoff and reduce the switching losses at turn-on. As a relatively large capacitor is connected across the output diode during resonance,

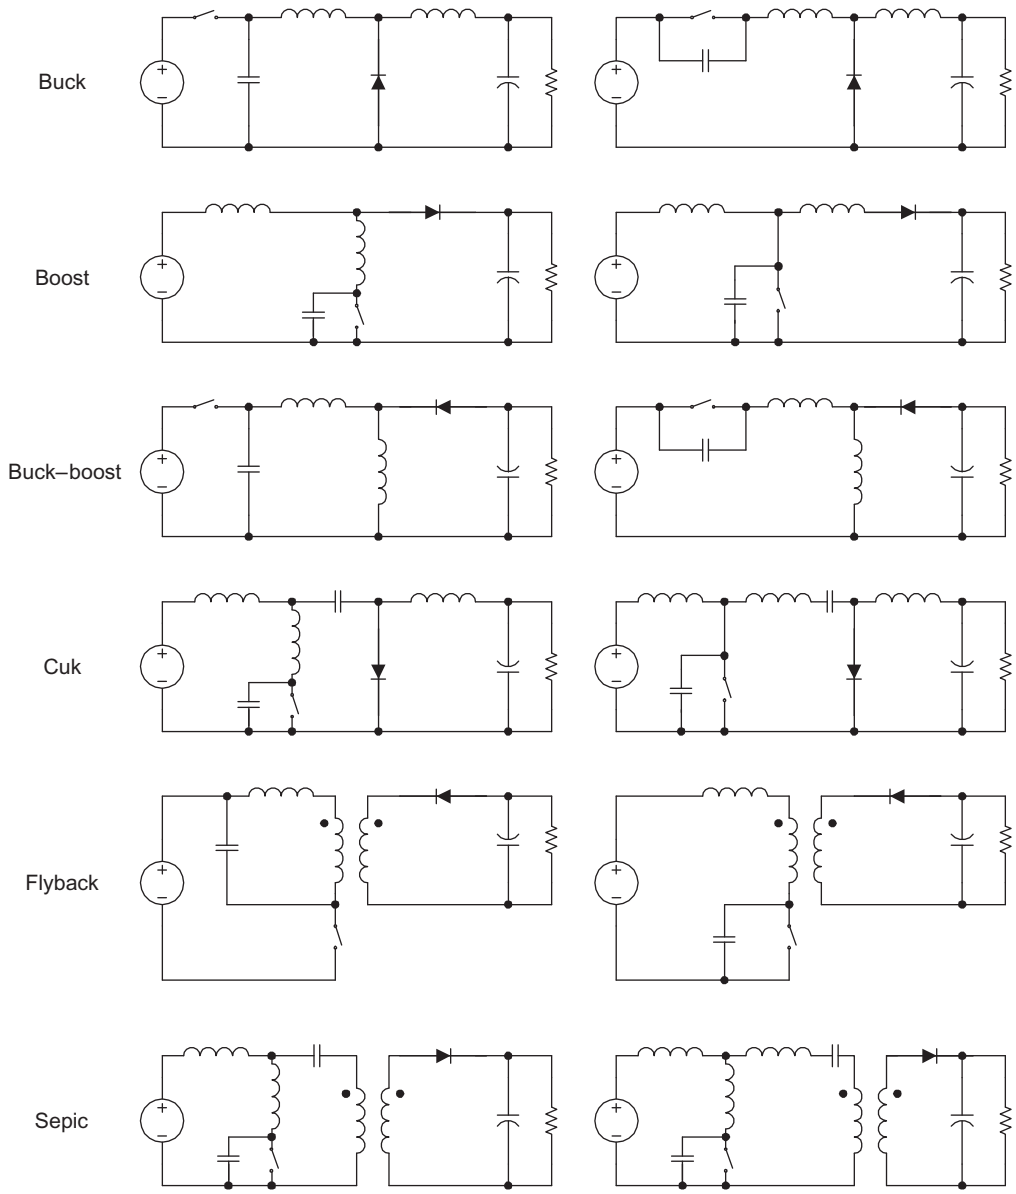

FIG. 12.10 A family of quasi-resonant converter with ZVS.

the converter operation becomes insensitive to the diode's junction capacitance. When power MOSFETs are zero-current switched on, the energy stored in the device's capacitance will be dissipated. This capacitive turn-on loss is proportional to the switching frequency. During turn-on, considerable rate of change of voltage can be coupled to the gate drive circuit through the Miller capacitor, thus increasing switching loss and noise. Another limitation is that the switches are under high current stress, resulting in higher conduction loss. However, it should be noted that ZCS is particularly effective in reducing switching loss for power devices (such as IGBT) with large tail current in the turn-off process.

ZVS eliminates the capacitive turn-on loss. It is suitable for high-frequency operation. For single-ended configuration, the switches could suffer from excessive voltage stress, which is proportional to the load. It will be shown in Section 12.5 that the maximum voltage across switches in half-bridge and full-bridge configurations is clamped to the input voltage.

For both ZCS and ZVS, the output regulation of the resonant converters can be achieved by variable frequency control. ZCS operates with constant on-time control, while ZVS operates with constant off-time control. With a wide input and load range, both techniques have to operate with a wide switching frequency range, making it not easy to design resonant converters optimally.

12.5 ZVS in High Frequency Applications

By the nature of the resonant tank and ZCS, the peak switch current in resonant converters is much higher than that in the square-wave counterparts. In addition, a high voltage will be established across the switch in the off state after the resonant stage. When the switch is switched on again, the energy stored in the output capacitor will be discharged through the switch, causing a significant power loss at high frequencies and high voltages. This switching loss can be reduced by using ZVS.

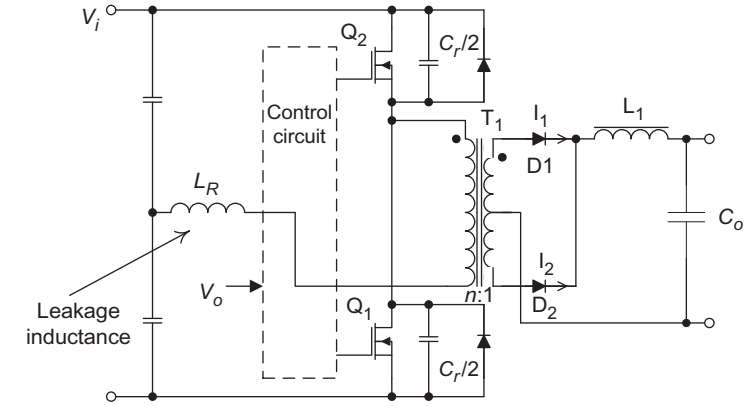
ZVS can be viewed as square-wave power utilizing a constant off-time control. Output regulation is achieved by controlling the on-time or switching frequency. During the off time, the resonant tank circuit traverses the voltage across the switch from zero to its peak value and then back to zero again. At that ZV instant, the switch can be reactivated. Apart from the conventional single-ended converters, some other examples of converters with ZVS are illustrated in the following section.

12.5.1 ZVS With Clamped Voltage

The high voltage stress problem in the single-switch configuration with ZVS can be avoided in half-bridge (HB) and full-bridge (FB) configurations [14–17]. The peak switch voltage can be clamped to the DC supply rail, thus reducing the switch voltage stress. In addition, the series transformer leakage and circuit inductance can form parts of the resonant path. Therefore, these parasitic components, which are undesirable in hard-switched converter, become useful components in ZVS ones. Figs. 12.11 and 12.12 show the ZVS HB and FB circuits, respectively, together with the circuit waveforms. The resonant capacitor is equivalent to the parallel connection of the two capacitors ($C_r/2$) across the switches. The off-state voltage of the switches will not exceed the input voltage during resonance because they will be clamped to the supply rail by the antiparallel diode of the switches.

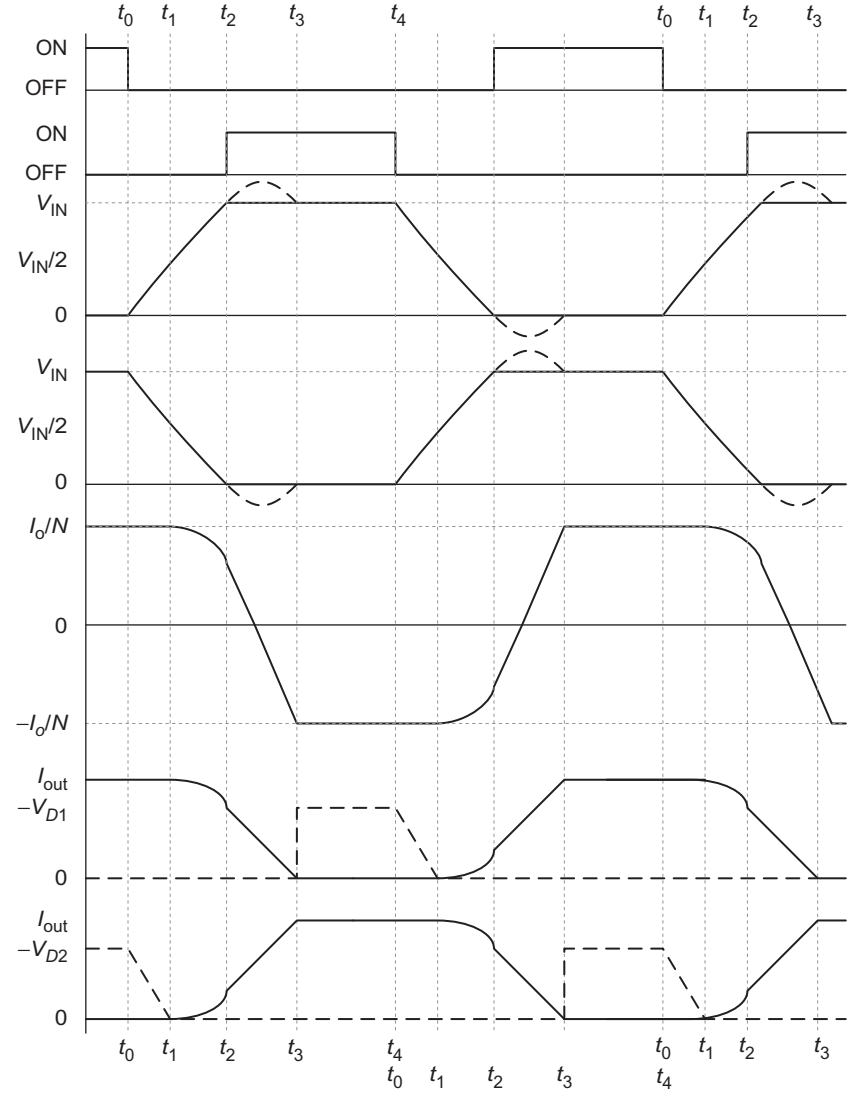
12.5.2 Phase-shifted Converter With Zero Voltage Transition

In a conventional FB converter, the two diagonal switch pairs are driven alternatively. The output transformer is fed with an AC rectangular voltage. By applying a phase-shifting approach, a deliberate delay can be introduced between the gate signals and the switches [18]. The circuit waveforms are shown in Fig. 12.13. Two upper or lower switches can be conducting (either through the switch or the antiparallel diode), yet the applied voltage to the transformer is zero. This zero-voltage condition appears in the interval $[t_1, t_2]$ of V_{pri} in Fig. 12.13. This operating stage corresponds to the required off time for that particular switching cycle. When the desired switch is turned off, the primary transformer current flows into the switch output capacitance causing the switch voltage to resonate to the opposite input rail. Effects of the parasitic circuit components are used advantageously to facilitate the resonant transitions. This enables a ZVS condition for turning on the opposite switch. Thus, varying the phase shift controls the effective duty cycle and hence the output power. The resonant circuit is necessary to meet the requirement of providing sufficient inductive energy to drive the capacitors to the opposite bus rail. The resonant transition must be achieved within the designed transition time.



12.6 Multi-resonant Converters

The ZCS-QRCs and ZVS-QRCs optimize the switching condition for either the active switch or the output diode only, but not for both of them simultaneously. Multiresonant switch concept, which is an extension of the concept of the resonant switch, has been developed to overcome such limitation. The zero-current multiresonant (ZC-MR) and zero-voltage multiresonant (ZV-MR) switches [12,17] are shown in Fig. 12.14.



The multiresonant circuits incorporate all major parasitic components, including switch output capacitance, diode junction capacitance, and transformer leakage inductance into the resonant circuit. In general, ZVS (*half-wave* mode) is more favorable than ZCS in DC-DC converters for high-frequency operation because the parasitic capacitance of the active switch and the diode will form a part of the resonant circuit.

An example of a buck ZVS-MRC is shown in Fig. 12.15. Depending on the ratio of the resonant capacitance C_D/C_S, two possible topological modes, namely, mode I and mode II, can be operated [19]. The ratio affects the time at which the voltages across the switch S and the output diode D_f become zero. Their waveforms are shown in Fig. 12.16A and B, respectively. If diode voltage V_D falls to zero earlier than the switch voltage V_S, the converter will follow mode I. Otherwise, the converter will follow mode II.

Instead of having one resonant stage, there are three in this converter. The mode I operation in Fig. 12.16A is described first. Before the switch S is turned on, the output diode D_f is conducting, and the resonant inductor current I_{Lr} is negative (flowing through the antiparallel diode of S). S is then turned on with ZVS. The resonant inductor current I_{Lr} increases linearly and D_f is still conducting. When I_{Lr} reaches the output current I_o, the first resonant stage starts. The resonant circuit is formed by the resonant inductor L_r and the capacitor C_D across the output diode. This stage ends when S is turned off with ZVS. Then, a second resonant stage starts. The resonant circuit consists of L_r, C_D, and the capacitor across the switch C_s. This stage ends when the output diode becomes forward-biased. A third resonant stage will then start. L_r and C_s form the resonant circuit. This stage ends and completes one operation cycle when the diode C_s becomes forward-biased.

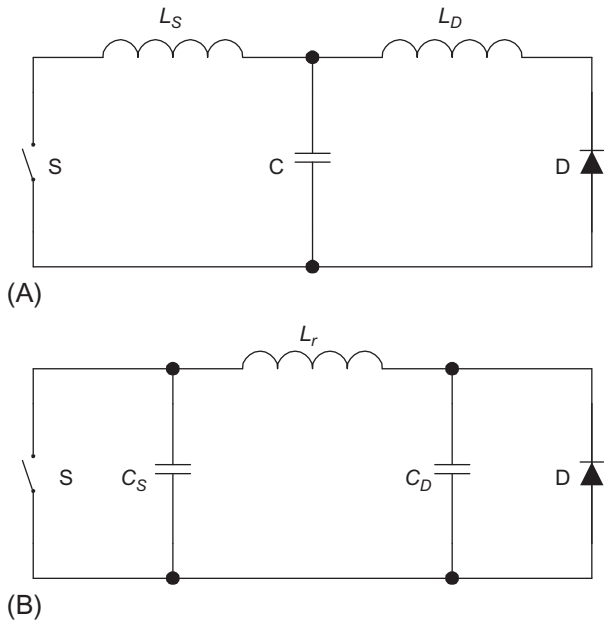

FIG. 12.14 Multiresonant switches: (A) ZC-MR switch and (B) ZV-MR switch.

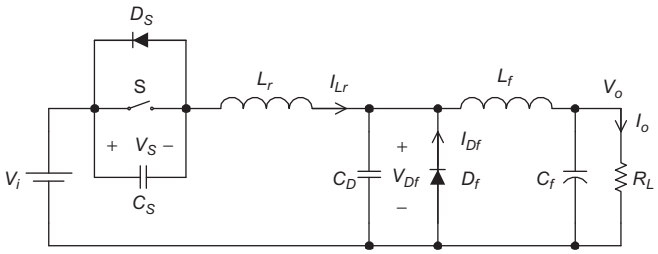

FIG. 12.15 Buck ZVS-MRC.

The only difference between mode I and mode II in Fig. 12.16B is in the third resonant stage, in which the resonant circuit is formed by L_r and C_D. This stage ends when D_f becomes forward-biased. The concept of the multiresonant switch can be applied to conventional converters [19–21]. A family of multi-resonant converters (MRCs) are shown in Fig. 12.17.

Although the variation of the switching frequency for regulation in MRCs is smaller than that of QRCs, a wideband frequency modulation is still required. Hence, the optimal design of magnetic components and the EMI filters in MRCs is not easy.

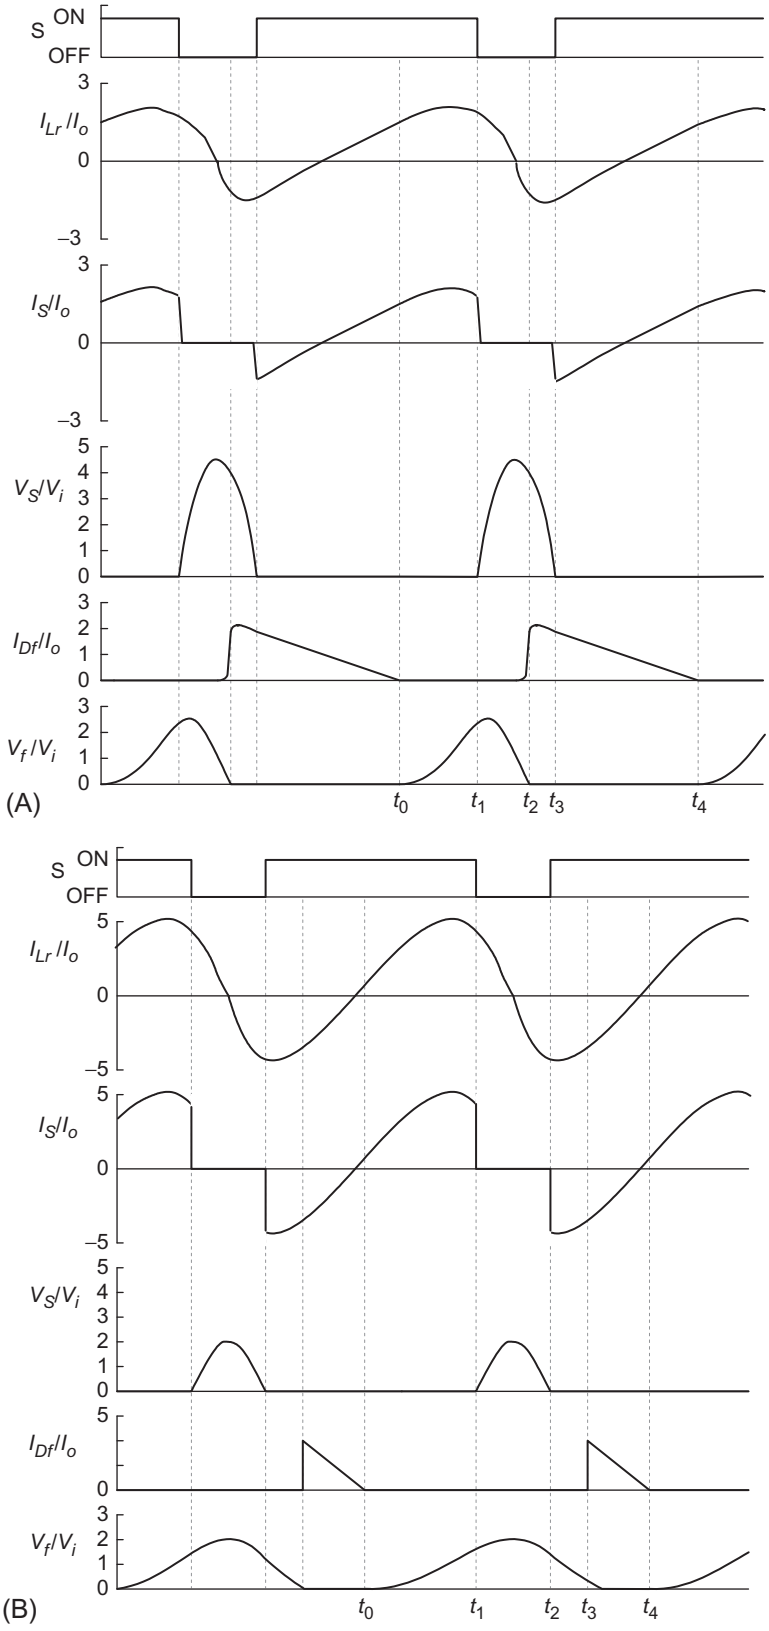

FIG. 12.16 Possible modes of the buck ZVS-MRC: (A) mode I and (B) mode II.

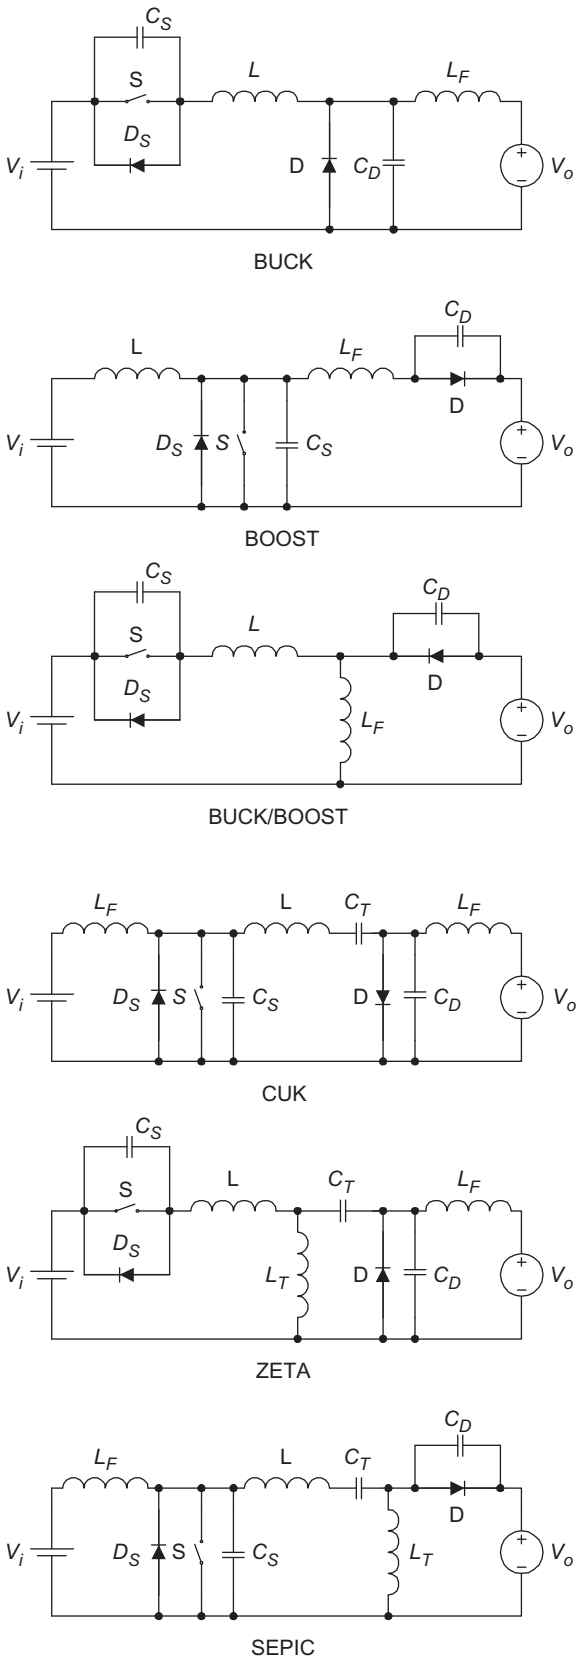

FIG. 12.17 Use of the multiresonant switch in conventional PWM converters.

It would be desirable to have a constant switching frequency operation. In order to operate the MRCs with constant switching frequency, the diode in Fig. 12.14 can be replaced with an active switch S_2 [22]. A constant-frequency multiresonant (CF-MR) switch is shown in Fig. 12.18. The output voltage is regulated by controlling the on-time of the two switches. This concept can be illustrated with the buck converter as shown in Fig. 12.19, together with the gate drive waveforms and operating

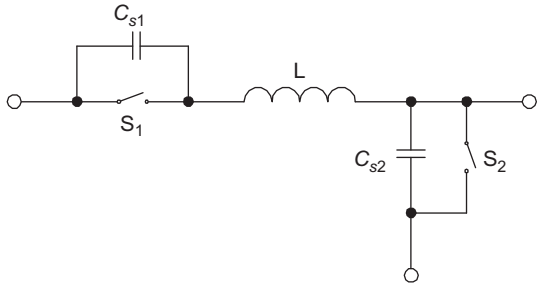

FIG. 12.18 Constant frequency multiresonant switch.

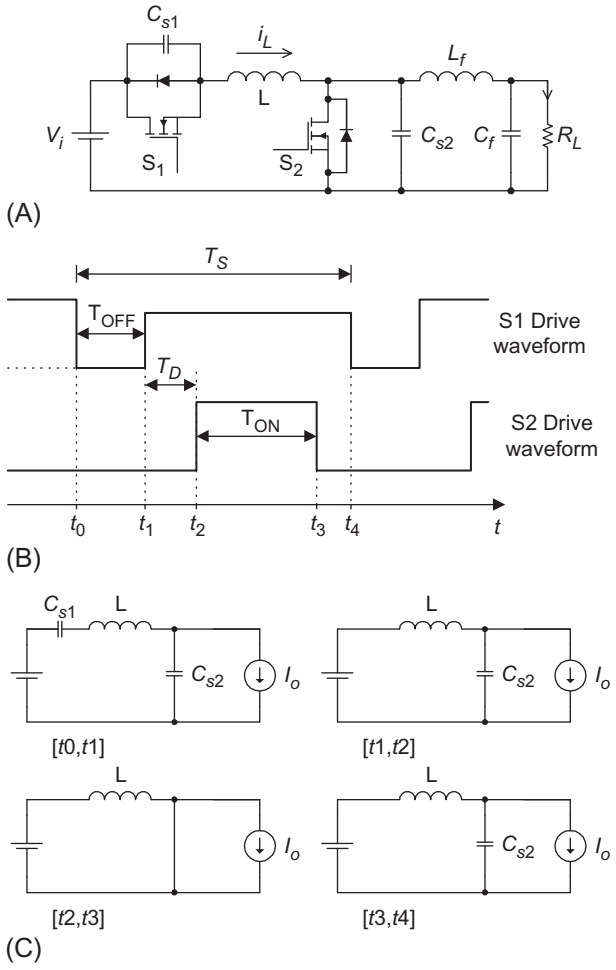

FIG. 12.19 Constant frequency buck MRC: (A) circuit schematics, (B) gate drive waveforms, and (C) operating stages.

stages. S_1 and S_2 are turned on during the time when currents flow through the anti-parallel diodes of S_1 and S_2. This stage ends when S_2 is turned off with ZVS. The first resonant stage is then started. L_r and C_{S2} form the resonant circuit. A second resonant stage begins. L_r resonates with C_{S1} and C_{S2}. The voltage across S_1 oscillates to zero. When I_{Lr} becomes negative, S_1 will be turned on with ZVS. Then, L_r resonates with C_{S2}. S_2 will be turned on when current flows through D_{S2}. As the output voltage is the average voltage across S_2, output voltage regulation is achieved by controlling the conduction time of S_2.

All switches in MRCs operate with ZVS, which reduces the switching losses and switching noise and eliminates the oscillation due to the parasitic effects of the components (such as the junction capacitance of the diodes). However, all switches are under high current and voltage stresses, resulting in an increase in the conduction loss.

12.7 Zero-voltage-transition Converters

By introducing a resonant circuit in parallel with the switches, the converter can achieve ZVS for both power switch and diode without significantly increasing their voltage and current stresses [23]. Fig. 12.20A shows a buck-type ZVT-PWM converter, and Fig. 12.20B shows the associated waveforms. The converter consists of a main switch S and an auxiliary switch S_1. It can be seen that the voltage and current waveforms of the switches are square-wave-like except during turn-on and turn-off switching intervals, where zero-voltage-transition (ZVT) takes place. The main switch and the output diode are under ZVS and are subjected to low voltage and current stresses. The auxiliary switch is under ZCS, resulting in low switching loss.

The concept of ZVT can be extended to other PWM circuits by adding the resonant circuit. Some basic ZVT-PWM converters are shown in Fig. 12.21.

12.8 Non-dissipative Active Clamp Network

The active-clamp circuit can utilize the transformer leakage inductance energy and can minimize the turn-off voltage stress in the isolated converters. The active-clamp circuit provides a means of achieving ZVS for the power switch and reducing the rate of change of the diode's reverse-recovery current. An example of a flyback converter with active clamp is shown in Fig. 12.22A, and the circuit waveforms are shown in Fig. 12.22B. Clamping action is obtained by using a series combination of an active switch (i.e., S_2) and a large capacitor so that the voltage across the main switch (i.e., S_1) is clamped to a minimum value. S_2 is turned on with ZVS. However, S_2 is turned off with finite voltage and current and has turn-off switching loss. The clamp-mode ZVS-MRCs is discussed in [24–26].

12.9 Load Resonant Converters

Load resonant converters (LRCs) have many distinct features over conventional power converters. Due to the soft commutation of the switches, no turn-off loss or stress is present. LRCs are especially suitable for high-power applications because they allow high-frequency operation for equipment size/weight reduction, without sacrificing the conversion efficiency and imposing extra stress on the switches. Basically, LRCs can be divided into three different configurations, namely, series resonant converters, parallel resonant converters, and series-parallel resonant converters.

12.9.1 Series Resonant Converters

Series resonant converters (SRCs) have their load connected in series with the resonant tank circuit, which is formed by L_r and C_r [15,27–29]. The half-bridge configuration is shown in Fig. 12.23. When the resonant inductor current i_{Lr} is positive, it flows through T_1 if T_1 is on; otherwise, it flows through the diode D_2. When i_{Lr} is negative, it flows through T_2 if T_2 is on; otherwise, it flows through the diode D_1. In the steady-state symmetrical operation, both the active switches are operated in a complementary manner. Depending on the ratio between the switching frequency ω_S and the converter resonant frequency ω_r, the converter has several possible operating modes.

12.9.1.1 Discontinuous Conduction Mode With $\omega_S < 0.5\omega_r$

Fig. 12.24A shows the waveforms of i_{Lr} and the resonant capacitor voltage v_{Cr} in this mode of operation. From 0 to t_1, T_1 conducts. From t_1 to t_2, the current in T_1 reverses its direction. The current flows through D_1 and back to the supply source. From t_2 to t_3, all switches are in the off state. From t_3 to t_4, T_2 conducts. From t_4 to t_5, the current in T_2 reverses its direction. The current flows through D_2 and back to the supply source. T_1 and T_2 are switched on under ZCS condition, and they are switched off under zero-current and zero-voltage conditions. However, the switches are under high current stress in this mode of operation and thus have higher conduction loss.

12.9.1.2 Continuous Conduction Mode With $0.5\omega_r < \omega_S < \omega_r$

Fig. 12.24B shows the circuit waveforms. From 0 to t_1, i_{Lr} transfers from D_2 to T_1. T_1 is switched on with finite switch current and voltage, resulting in turn-on switching loss. Moreover, the diodes must have good reverse-recovery characteristics in order to reduce the reverse-recovery current. From t_1 to t_2, D_1 conducts and T_1 is turned off softly with zero voltage and zero current. From t_2 to t_3, T_2 is switched on with finite switch current and voltage. At t_3, T_2 is turned off softly and D_2 conducts until t_4.

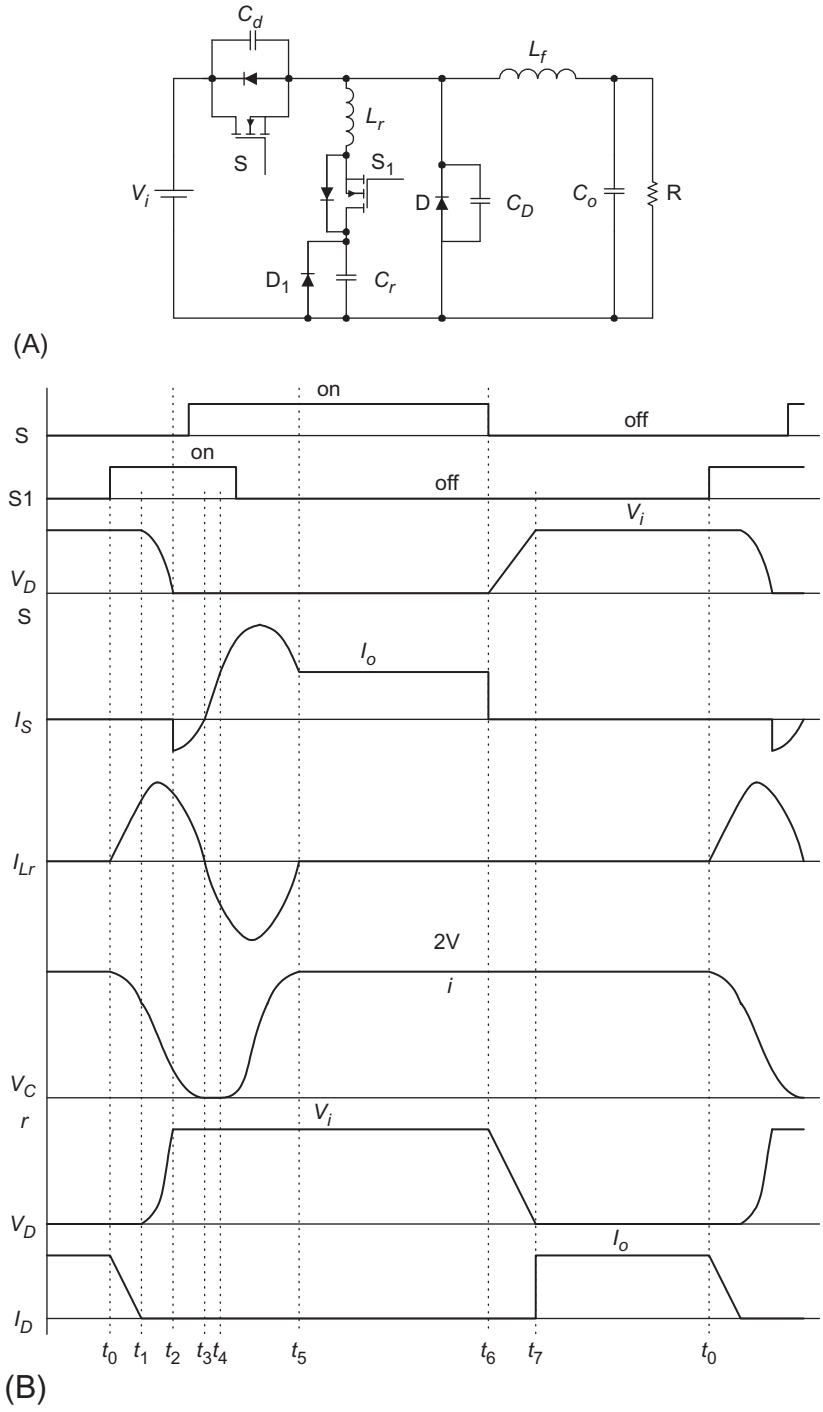

FIG. 12.20 Buck ZVT-PWM converter: (A) circuit schematics and (B) waveforms.

12.9.1.3 Continuous Conduction Mode With $\omega_r < \omega_S$

Fig. 12.24C shows the circuit waveforms. From 0 to t_1, i_{Lr} transfers from D_1 to T_1. Thus, T_1 is switched on with zero current and zero voltage. At t_1, T_1 is switched off with finite voltage and current, resulting in turn-off switching loss. From t_1 to t_2, D_2 conducts. From t_2 to t_3, T_2 is switched on with zero current and zero voltage. At t_3, T_2 is switched off. i_{Lr} transfers from T_2 to D_1. As the switches are turned on with ZVS, lossless snubber capacitors can be added across the switches.

The following parameters are defined: voltage conversion ratio M, characteristic impedance Z_r, resonant frequency f_r, normalized load resistance r, normalized switching frequency γ.

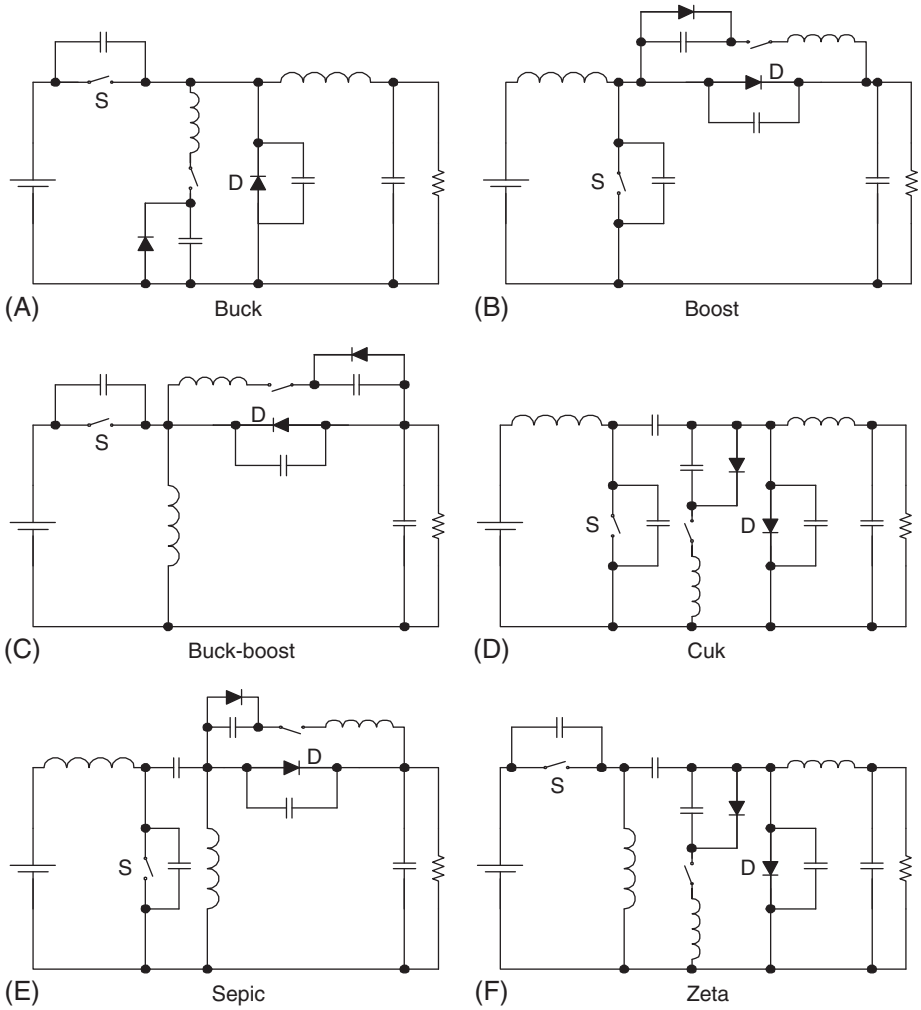

FIG. 12.21 Conventional ZVT-PWM converters. (A) Buck converter. (B) Boost converter. (C) Buck-boost converter. (D) Cuk converter. (E) SEPIC. (F) ZETA converter.

$$M = nV_o/V_{in} \tag{12.2A}$$

$$Z_r = \sqrt{L_r/C_r} \tag{12.2B}$$

$$f_r = 1/\left(2\pi\sqrt{L_rC_r}\right) \tag{12.2C}$$

$$r = n^2R_L/Z_r \tag{12.2D}$$

$$\gamma = f_s/f_r \tag{12.2E}$$

$$M = 1/\sqrt{(\gamma - 1/\gamma)^2/\left(r^2+1\right)} \tag{12.2F}$$

The relationships between M and γ for different value of r are shown in Fig. 12.25. The boundary between continuous conduction mode (CCM) and discontinuous conduction mode (DCM) is at $r = 1.27\gamma$. When the converter is operating in DCM and $0.2 < \gamma < 0.5$, $M = 1.27r\gamma$.

The SRC has the following advantages. Transformer saturation can be avoided since the series capacitor can block the DC component. The light-load efficiency is high because the device current and conduction loss are low. However, the major disadvantages are that there is difficulty in regulating the output voltage under light-load and no-load conditions. Moreover, the output DC filter capacitor has to carry high ripple current, which could be a major problem in low-output-voltage and high-output-current applications [29].

12.9.2 Parallel Resonant Converters

Parallel resonant converters (PRCs) have their load connected in parallel with the resonant tank capacitor C_r [27–30]. The half-bridge configuration is shown in Fig. 12.26. SRC behaves as a current source, whereas the PRC acts as a voltage source. For voltage regulation, PRC requires a smaller operating frequency range than the SRC to compensate for load variation.

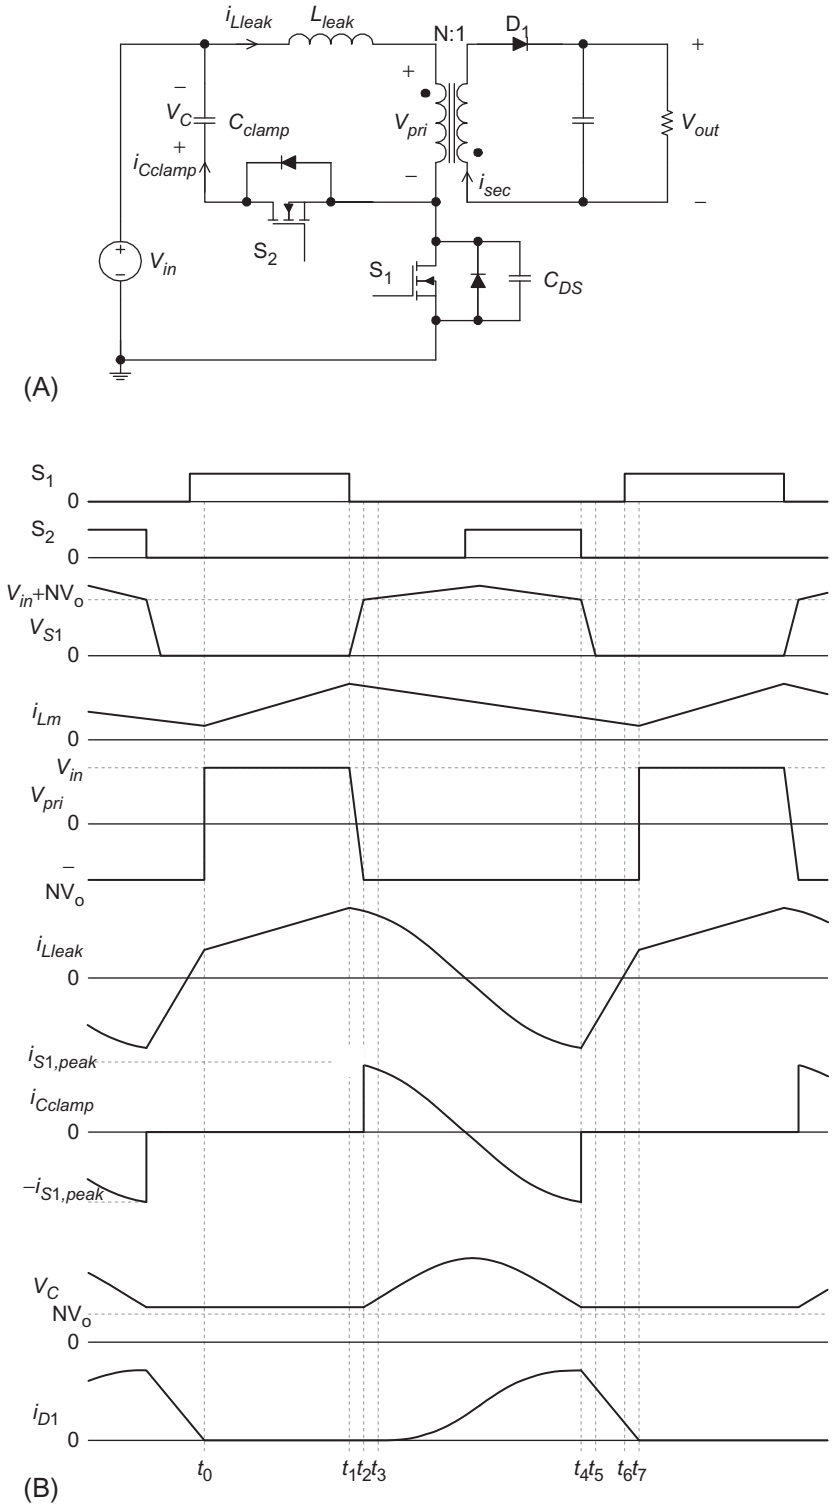

FIG. 12.22 Active-clamp flyback converter: (A) circuit schematics and (B) circuit waveforms.

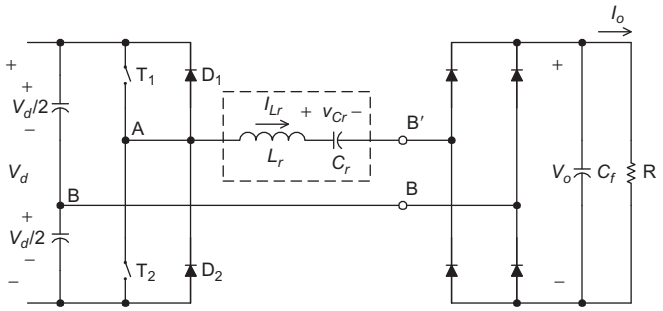

FIG. 12.23 SRC half-bridge configuration.

12.9.2.1 Discontinuous Conduction Mode

The steady-state waveforms of the resonant inductor current i_{Lr} and the resonant capacitor voltage v_{Cr} are shown in Fig. 12.27A. Initially, both i_{Lr} and v_{Cr} are zero. From 0 to t_2, T_1 conducts and is turned on with zero current. When i_{Lr} is less than the output current I_o, i_{Lr} increases linearly from 0 to t_1 and the output current circulates through the diode bridge. From t_1 to t_3, L_r resonates with C_r. Starting from t_2, i_{Lr} reverses its direction and flows through D_1. T_1 is then turned off with zero current and zero voltage. From t_3 to t_4, v_{Cr} decreases linearly due to the relatively constant value of I_o. At t_4, when v_{Cr} equals zero, the output current circulates through the diode bridge again. Both i_{Lr} and v_{Cr} will stay at zero for an interval. From t_5 to t_9, the above operations will be repeated for T_2 and D_2. The output voltage is controlled by adjusting the time interval of $[t_4, t_5]$.

12.9.2.2 Continuous Conduction Mode $\omega_S < \omega_r$

This mode is similar to the operation in the DCM but with a higher switching frequency. Both i_{Lr} and v_{Cr} become continuous. The waveforms are shown in Fig. 12.27B. The switches T_1 and T_2 are hard turned on with finite voltage and current and are soft turned off with ZVS.

12.9.2.3 Continuous Conduction Mode $\omega_S > \omega_r$

If the switching frequency is higher than ω_r (Fig. 12.27C), the antiparallel diode of the switch will be turned on before the switch is triggered. Thus, the switches are turned on with ZVS. However, the switches are hard turned off with finite current and voltage.

The parameters defined in Eq. (12.2) are applicable. The relationships between M and γ for various values of r are shown in Fig. 12.28. During the DCM (i.e., $\gamma < 0.5$), M is in linear relationship with γ. Output voltage regulation can be achieved easily. The output voltage is independent on the output current. The converter shows good voltage-source characteristics. It is also possible to step up and step down the input voltage.

The PRC has the advantages that the load can be short-circuited and the circuit is suitable for low-output-voltage, high-output-current applications. However, the major disadvantage of the PRC is the high device current. Moreover, since the device current does not decrease with the load, the efficiency drops with a decrease in the load [29].

12.9.3 Series-Parallel Resonant Converter

Series-parallel resonant converter (SPRC) combines the advantages of the SRC and PRC. The SPRC has an additional capacitor or inductor connected in the resonant tank circuit [29–31]. Fig. 12.29A shows an LCC-type SPRC, in which an additional capacitor is placed in series with the resonant inductor. Fig. 12.29B shows an LLC-type SPRC, in which an additional inductor is connected in parallel with the resonant capacitor in the SRC. However, there are many possible combinations of the resonant tank circuit. Detailed analysis can be found in [31].

12.10 Control Circuits for Resonant Converters

Since the 1985s, various control integrated circuits (ICs) for resonant converters have been developed. Some common ICs for different converters are described in this section.

12.10.1 QRCs and MRCs

Output regulations in many resonant-type converters, such as QRCs and MRCs, are achieved by controlling the switching frequency. ZCS applications require controlled switch-on times, while ZVS applications require controlled switch-off times. The fundamental control blocks in the IC include an error amplifier, voltage-controlled oscillator (VCO), one-shot generator with a zero wave-crossing detection comparator, and an output stage to drive the active switch. Typical ICs include UC1861-UC1864 for ZVS applications and UC 1865-UC 1868 for ZCS applications [32]. Fig. 12.30 shows the controller block diagram of UC 1864.

The maximum and minimum switching frequencies (i.e., f_{max} and f_{min}) are controlled by the resistors R_{ange} and R_{min} and the capacitor C_{vco}. f_{max} and f_{min} can be expressed as

$$f_{\max} = \frac{3.6}{(R_{ange} // R_{\min}) C_{VCO}} \quad \text{and} \quad f_{\min} = \frac{3.6}{R_{\min} C_{VCO}} \tag{12.3}$$

The frequency range Δf is then equal to

$$\Delta f = f_{\max} - f_{\min} = \frac{3.6}{R_{ange} C_{VCO}} \tag{12.4}$$

The frequency range of the ICs is from 10 kHz to 1 MHz. The output frequency of the oscillator is controlled by the error amplifier (E/A) output. An example of a ZVS-MR forward converter is shown in Fig. 12.31.

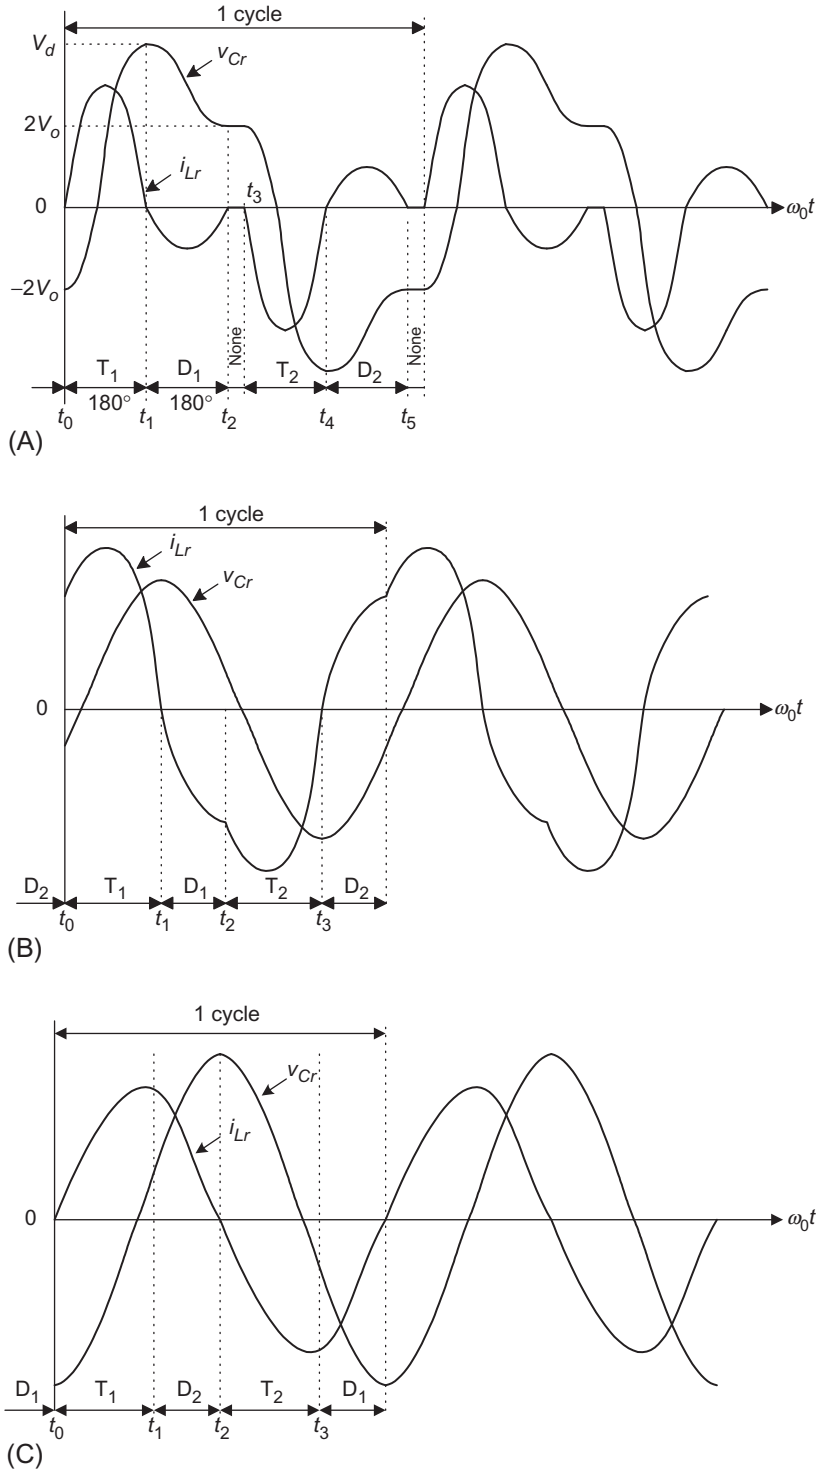

FIG. 12.24 Circuit waveforms under different operating conditions: (A) $\omega_S < 0.5\omega_r$, (B) $0.5\ \omega_r < \omega_S < \omega$, and (C) $\omega_r < \omega_S$.

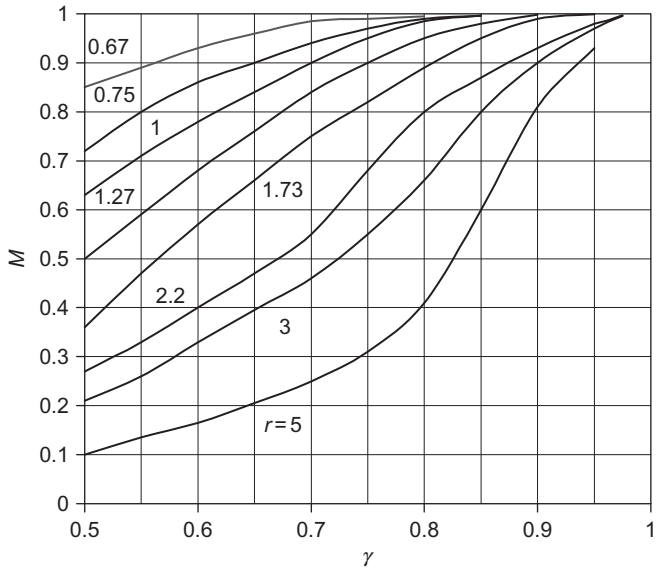

FIG. 12.25 M vs γ in SRC.

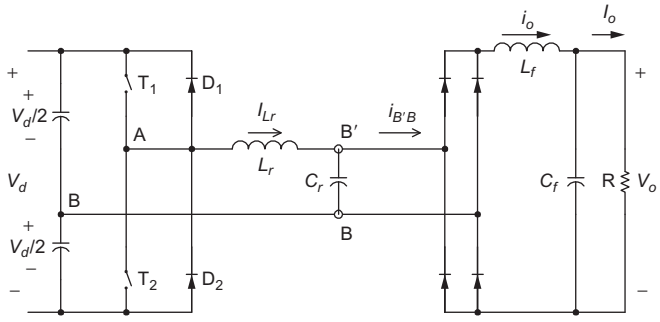

FIG. 12.26 PRC half-bridge configuration.

12.10.2 Phase-shifted, ZVT FB Circuit

The UCC3895 is a phase-shift PWM controller that can generate a phase-shifting pattern of one half-bridge with respect to the other. The application diagram is shown in Fig. 12.32.

The four outputs "OUTA," "OUTB," "OUTC," and "OUTD" are used to drive the MOSFETs in the full-bridge. The dead time between "OUTA" and "OUTB" is controlled by "DELAB," and the dead time between "OUTC" and "OUTD" is controlled by "DELCD." Separate delays are provided for the two half-bridges to accommodate differences in resonant capacitor charging currents. The delay in each set is approximated by

$$t_{DELAY} = \frac{25 \times 10^{-12} R_{DEL}}{0.75(V_{CS} - V_{ADS}) + 0.5} + 25\,ns \qquad (12.5)$$

where R_{DEL} is the resistor value connected between "DELAB" and "DELCD" to ground.

The oscillator period is determined by R_T and C_T. It is defined as

$$t_{OSC} = \frac{5R_TC_T}{48} + 120\,ns \qquad (12.6)$$

The maximum operating frequency is 1 MHz. The phase shift between the two sets of signals is controlled by the ramp voltage and the error amplifier output having a 7-MHz bandwidth.

12.11 Extended-Period Quasi-Resonant Converters

Generally, resonant and quasi-resonant converters operate with frequency control. The extended-period quasi-resonant (EP-QR) converters proposed by Barbi [33] offer a simple solution to modify existing hard-switched converters into soft-switched ones with constant frequency operation. This makes both output filter design and control simple. Fig. 12.33 shows a standard hard-switched boost-type PFC converter. In this hard-switched circuit, the main switch SW1 could be subject to significant switching stress because the reverse-recovery current of the diode D_F could be excessive when SW1 is turned on. In practice, a small saturable inductor may be added in series with the power diode D_F in order to reduce the di/dt of the reverse-recovery current. In addition, an optional R-C snubber may be added across SW1 to reduce the dv/dt of SW1. These extra reactance components can in fact be used in the EP-QR circuit to achieve soft switching, as shown in Fig. 12.34. The resonant components L_r and C_r are of small values and can come from the snubber circuits of a standard hard-switched converter. Thus, the only additional component is the auxiliary switch Q2. The small resonant inductor is put in series with the main switch SW1 so that SW1 can be switched on under ZC condition and the di/dt problem of the reverse-recovery current be eliminated. The resonant capacitor C_r is used to store energy for creating condition for soft switching. Q2 is used to control the resonance during the main switch transition. It should be noted that all power devices including SW1, Q1, and main power diode D_F are turned on and off under ZV and/or ZC conditions. Therefore, the large di/dt problem due to the reverse recovery of the power diode can be eliminated. The soft-switching method is an effective technique for EMI suppression.

Together with power factor correction technique, soft-switching converters offer a complete solution to meet EMI regulations for both conducted and radiated EMI. The operation of the EP-QR boost PFC circuit [34,35] can be described in six modes as shown in Fig. 12.35. The corresponding idealized waveforms are included in Fig. 12.36.

12.11.0.1 Circuit Operation

Interval I: ($t_0 - t_1$). Due to the resonant inductor L_r limits the di/dt of the switch current, switch SW1 is turned on at zero-current condition with a positive gating signal V_{GS1} to start a switching cycle at $t = t_0$. Current in D_F is diverted to

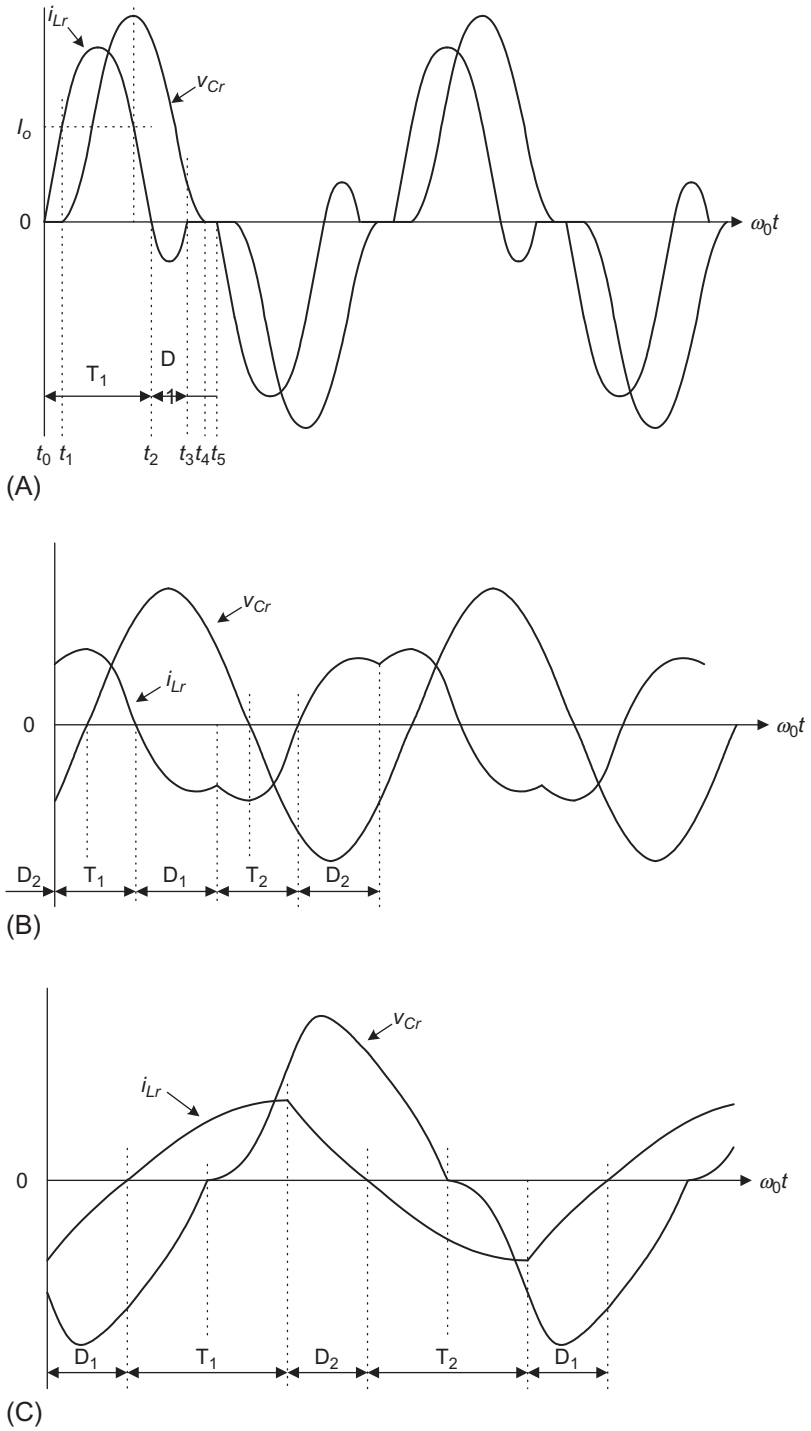

FIG. 12.27 Circuit waveforms under different operating conditions: (A) discontinuous conduction mode, (B) continuous conduction mode $\omega_S < \omega_r$, and (C) continuous conduction mode $\omega_S > \omega_r$.

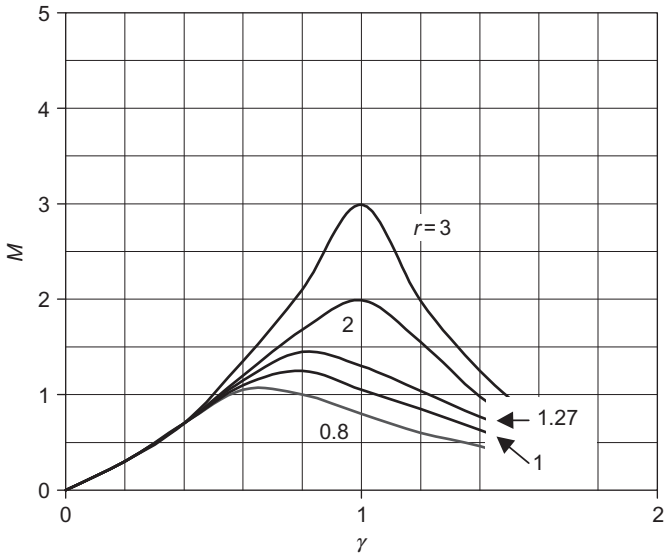

FIG. 12.28 M versus γ in PRC.

inductor L_r. Because D_F is still conducting during this short period, D_{S2} is still reverse-biased and is thus not conducting. The equivalent circuit topology for the conducting paths is shown in Fig. 12.35A. Resonant switch Q_2 remains off in this interval.

Interval II: $(t_1 - t_a)$. When D_F regains its blocking state, D_{S2} becomes forward-biased. The first half of the resonance cycle occurs and resonant capacitor C_r starts to discharge, and current flows in the loop C_r-Q_2-L_r-SW_1. The resonance half cycle stops at time $t = t_a$ because D_{S2} prevents the loop current i_{Cr} from flowing in the opposition direction. The voltage across C_r is reversed at the end of this interval. The equivalent circuit is shown in Fig. 12.35B.

Interval III: $(t_a - t_b)$. Between t_a and t_b, current in L_F and L_r continues to build up. This interval is the extended period for the resonance during which energy is pumped into L_r. The corresponding equivalent circuit is shown in Fig. 12.35C.

Interval IV: $(t_b - t_2)$. Fig. 12.35D shows the equivalent circuit for this operating mode. Before SW_1 is turned off, the second half of the resonant cycle needs to take place in order that a zero-voltage condition can be created for the turn-off process of SW_1. The second half of the resonant cycle starts

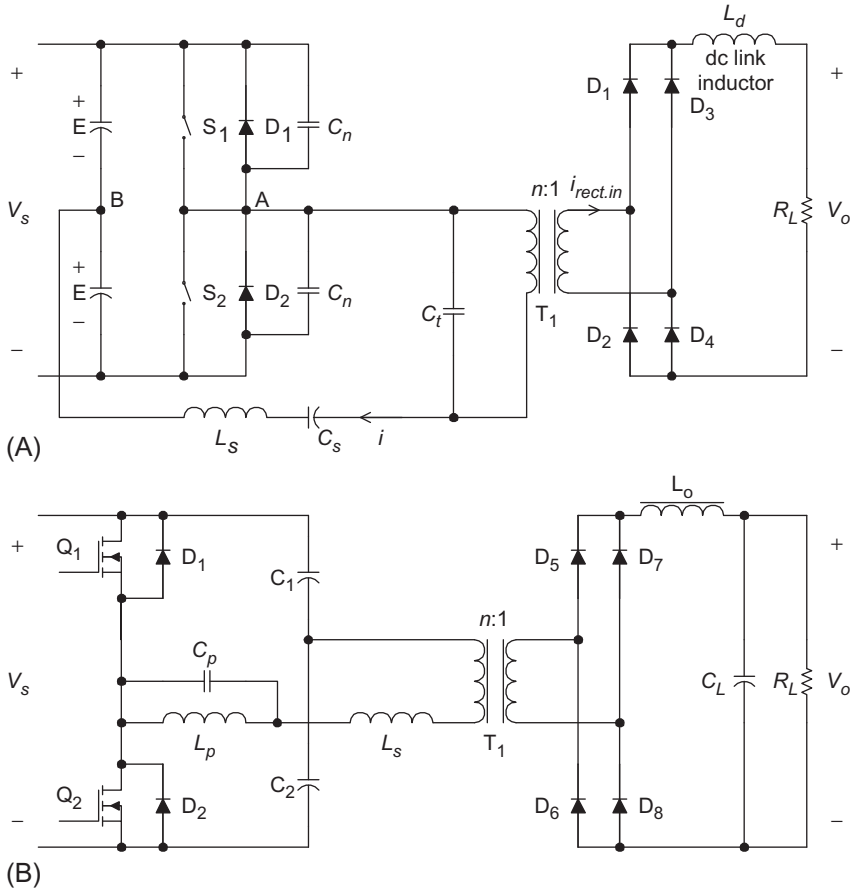

FIG. 12.29 Different types of SPRC: (A) LCC-type and (B) LLC-type.

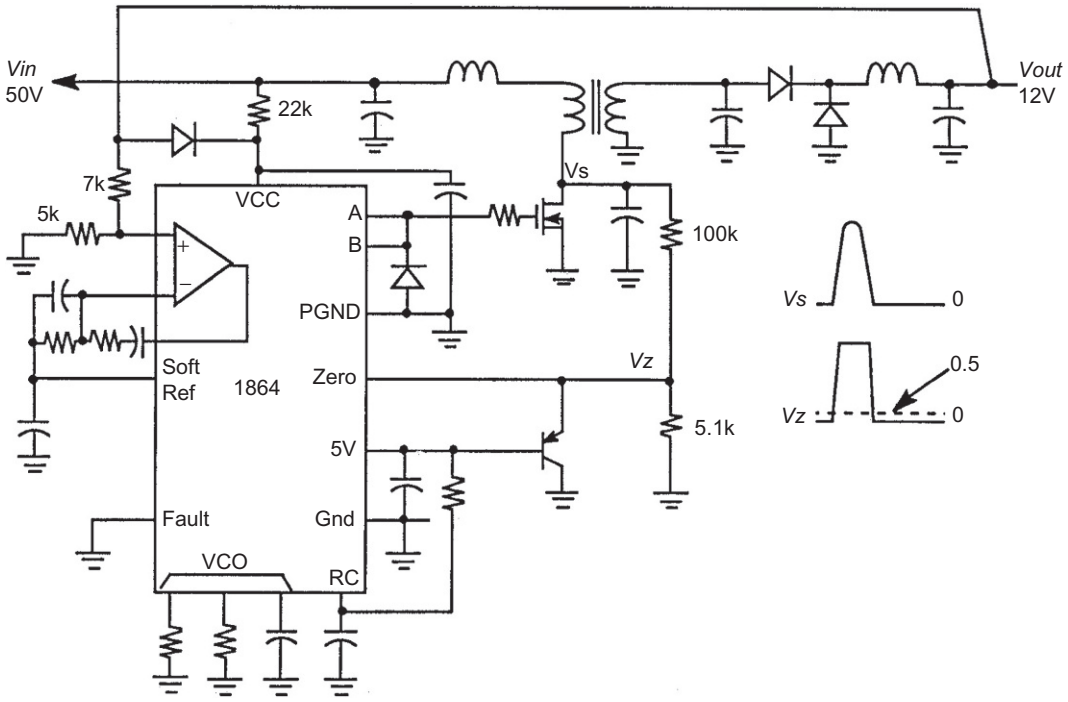

FIG. 12.31 ZV-MR forward converter. Courtesy of Unitrode Corp. and Texas Instruments.

when auxiliary switch Q_2 is turned on at $t = t_b$. Resonant current then flows through the loop L_r-Q_2-C_r-antiparallel diode of SW_1. This current is limited by L_r, and thus, Q_2 is turned on under zero-current condition. Since the antiparallel diode of SW_1 is conducting, the voltage across SW_1 is clamped to the on-state voltage of the antiparallel diode. SW_1 can therefore be turned off at (near) zero-voltage condition before $t = t_2$ at which the second half of the resonant cycle ends.

Interval V: ($t_2 - t_3$). During this interval, the voltage across C_r is less than the output voltage V_o. Therefore, D_F is still reverse-biased. Inductor current I_s flows into C_r until V_{Cr} reaches V_o at $t = t_3$. The equivalent circuit is represented in Fig. 12.35E.

Interval VI: ($t_3 - t_4$). During this period, the resonant circuit is not in action, and the inductor current I_s charges the output capacitor C_F via D_F, as in the case of a classical boost-type PFC circuit. C_r is charged to V_o; therefore, Q_2 can be turned

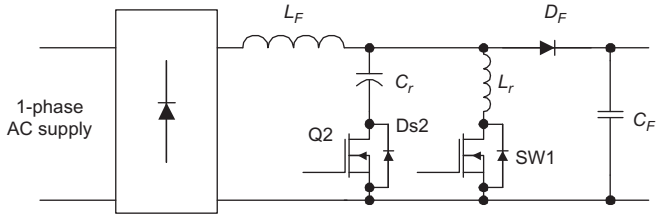

FIG. 12.34 EP-QR boost-type AC-DC power factor correction circuit.

off at zero-voltage and zero-current conditions. Fig. 12.35F shows the equivalent topology of this operating mode.

In summary, SW1, Q2, and D_F are fully soft-switched. Since the two resonance half cycles take place within a closed loop outside the main inductor, the high resonant pulse will not occur in the inductor current, thus making a well-established averaged current mode control technique applicable for such QR circuit. For full soft switching in the turn-off process, the resonant components need to be designed so that the peak resonant current exceeds the maximum value of the inductor current. Typical measured switching waveforms and trajectories of SW1, Q2, and D_F are shown in Figs. 12.37, 12.38, and 12.39, respectively.

12.11.0.2 Design Procedure

Given: Input AC voltage = V_s (V)
Peak AC voltage = $V_s(max)$ (V)
Nominal output DC voltage = V_o (V)
Switching frequency = f_{sw} (Hz)
Output power = P_o (W)

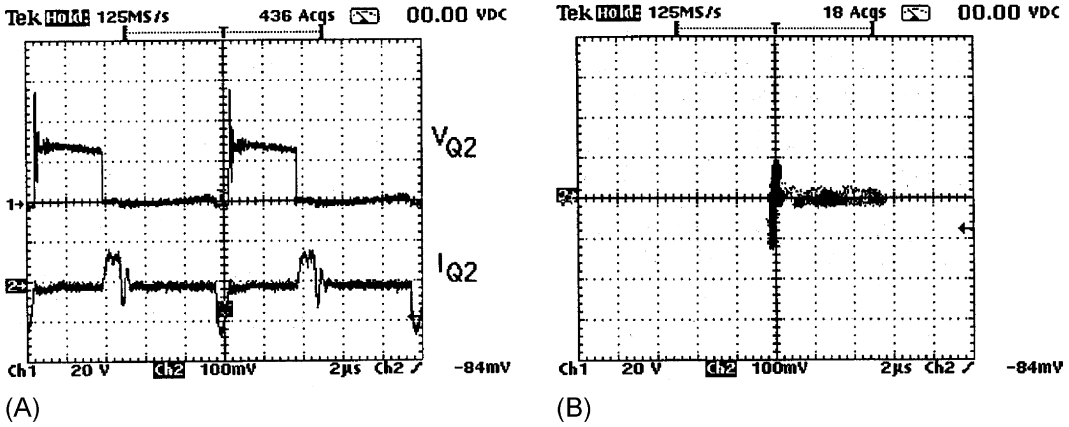

FIG. 12.38 (A) Drain-source voltage and current of Q2 and (B) switching locus of Q2.

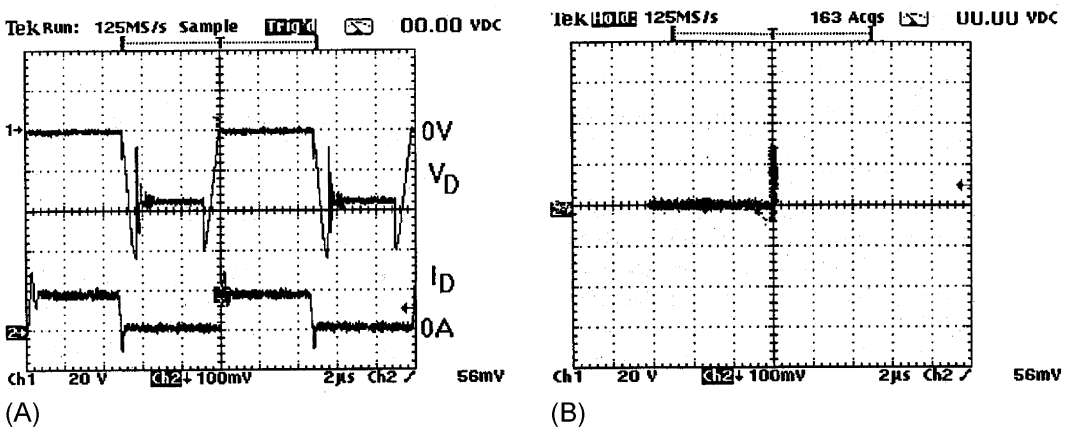

FIG. 12.39 (A) Diode voltage and current and (B) switching locus of diode.

Input current ripple = ΔI (A)
Output voltage ripple = ΔV (V)

(I) Resonant tank design:

Step 1. Because the peak resonant current must be greater than the peak inductor current (same as peak input line current) in order to achieve soft turnoff, it is necessary to determine the peak input current $I_s(max)$. Assuming lossless AC-DC power conversion, $I_s(max)$ can be estimated from the following equation:

$$I_{s(\max)} \approx \frac{2V_oI_o}{V_{s(\max)}} \tag{12.7}$$

where $I_o = P_o/V_o$ is the maximum output current.

Step 2. Soft-switching criterion is

$$Z_r \le \frac{V_o}{I_{s(\max)}} \tag{12.8}$$

where $Z_r = \sqrt{\frac{L_r}{C_r}}$ is the impedance of the resonant tank.

For a chosen resonant, frequency f_r, L_r, and C_r can be obtained from

$$2\pi f_r = \frac{1}{\sqrt{L_rC_r}} \tag{12.9}$$

(II) Filter component design:

The minimum conversion ratio is

$$M_{(\max)} = \frac{V_o}{V_{s(\max)}} = \frac{1}{1-\left(\frac{f_{sw}}{f_r}+\frac{t_e}{T_{sw}}\right)} \tag{12.10}$$

where $T_{sw} = 1/f_{sw}$ and t_e is the extended period. From Eq. (12.10), minimum t_e can be estimated.

The turn-on period of the SW1 is

$$T_{on}(sw1) = t_e + 1/f_r \tag{12.11}$$

Inductor value L is obtained from

$$L \ge \left(\frac{T_{on(sw1)}}{\Delta I}\right)V_{s(\max)} \tag{12.12}$$

The filter capacitor value C can be determined from

$$C\left(\frac{\Delta V}{\frac{T_s}{\pi}\sin^{-1}\left(\frac{I_o}{I_{s(\max)}}\right)}\right) = I_o \tag{12.13}$$

where $T_s = 1/f_s$ is the period of the AC voltage supply frequency.

12.11.1 Soft-Switched DC-DC Flyback Converter

A simple approach that can turn an existing hard-switched converter design into a soft-switched one is shown in Fig. 12.40. The key advantage of the proposal is that many well proved and reliable hard-switched converter designs can be kept. The modification required is the addition of a simple circuit (consisting an auxiliary winding, a switch, and a small capacitor) to an existing isolated converter [36]. This principle, which is the modified version of the EPQR technique for isolated converter, is demonstrated in an isolated soft-switched flyback converter with multiple outputs. Other advantageous features of the proposal are as follows:

- All switches and diodes of the converter are "fully" soft-switched, that is, soft-switched at both turn-on and turn-off transitions under zero-voltage and/or zero-current conditions.
- The leakage inductance of each winding in the flyback transformer forms part of the resonant circuit for achieving ZVS and ZCS of all switches and diodes.
- The control technique is simply PWM-based as in standard hard-switched converters.
- The soft-switched technique is a proved method for EMI reduction [37].

12.11.2 A ZCS Bidirectional Flyback DC-DC Converter

A bidirectional flyback DC-DC converter that uses one auxiliary circuit for both power flow directions is proposed in Fig. 12.41 [38]. The methodology is based on extending the unidirectional soft-switched flyback converter in Ref. [36] and replacing the output diode with a controlled switch, which acts as either a rectifier [39] or a power control switch in the corresponding power flow direction. An auxiliary circuit that consists of a winding in the coupled inductor, a switch, and a capacitor converts the hard-switched design into a soft-switched one. The operation is the same as [36] in the forward mode. An extended-period resonant stage [34] is introduced when the power control switch is on. Conversely, in the reverse mode, a complete resonant stage is initiated before the main switch is off. In both the power flow operations, the leakage inductance of the coupled inductor is used to create zero-current switching conditions for all switches.

12.12 Soft-Switching and EMI Suppression

A family of EP-QR converters are displayed in Fig. 12.42. Their radiated EMI emissions have been compared with that from their hard-switched counterparts [37]. Fig. 12.43A and B shows the conducted EMI emission from a hard-switched flyback

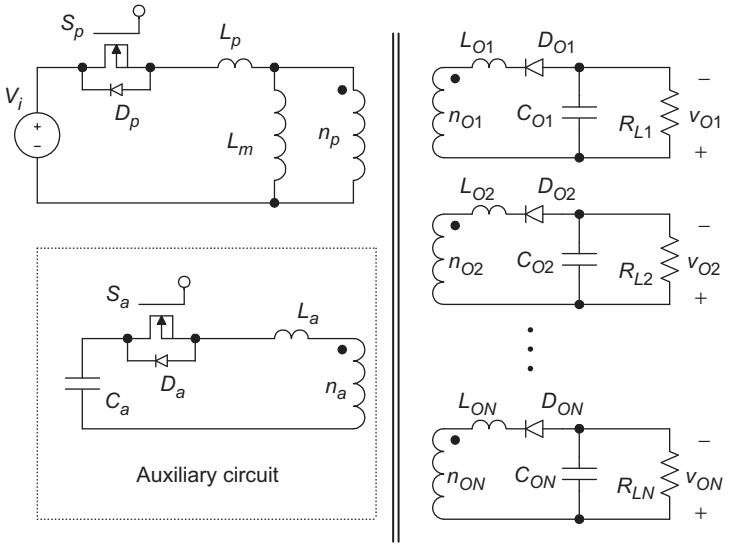

FIG. 12.40 Fully soft-switched isolated flyback converter.

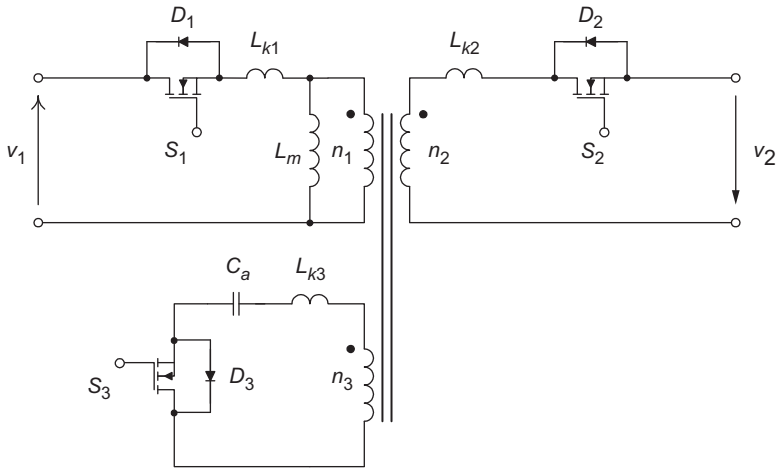

FIG. 12.41 Bidirectional soft-switched isolated flyback converter.

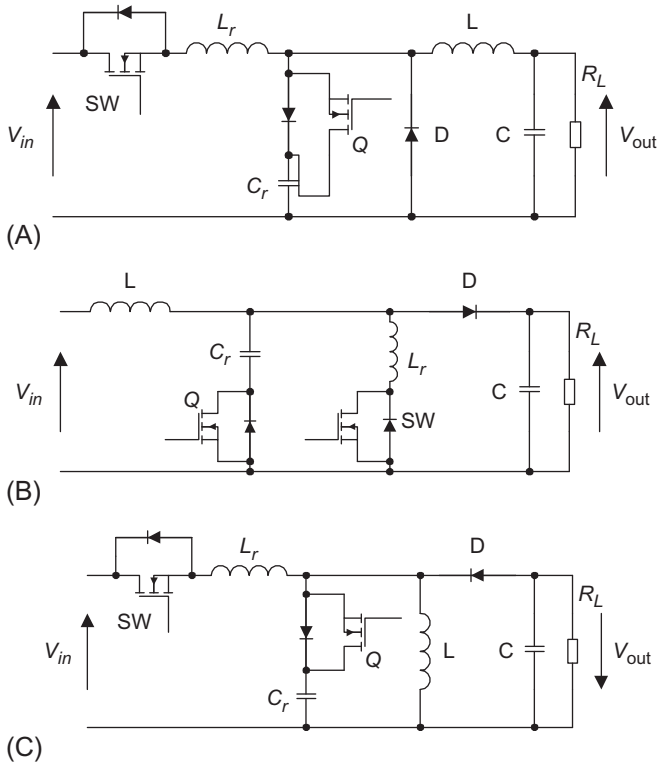
converter and a soft-switched one, respectively. Their radiated EMI emissions are included in Fig. 12.44. Both converters are tested at an output power of 50 W. No special filtering or shielding measures have been taken during the measurement. It is clear from the measurements that soft switching is an effective means to EMI suppression.

12.13 Snubbers and Soft-Switching for High Power Devices

Today, most of the medium power (up to 200 kVA) and medium voltage (up to 800 V) inverter are hard-switched. Compared with low-power switched-mode power supplies, the high voltage involved in the power inverters makes the *dv/dt*, *di/dt*, and the switching stress problems more serious. In addition, the reverse recovery of power diodes in the inverter leg may cause very sharp current spike, leading to severe EMI problem. It should be noted that some high-power devices such as GTO thyristors do not have a square safe operating area (SOA). It is therefore essential that the switching stress they undergone must be within their limits. Commonly used protective measures are to use snubber circuits for protecting high-power devices.

Among various snubbers, two snubber circuits are most well-known for applications in power inverters. They are the Undeland snubber [40] (Fig. 12.45) and McMurray snubber circuits [41] (Fig. 12.46). The Undeland snubber is an asymmetrical snubber circuit with one turn-on inductor and one



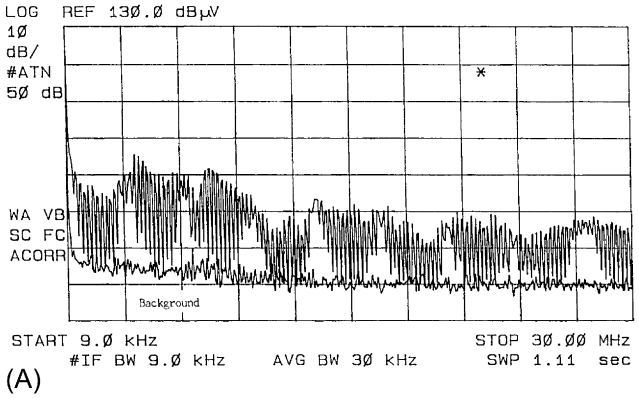


FIG. 12.42 A family of EP-QR converters: (A) buck converter, (B) boost converter, and (C) flyback converter.

turn-off capacitor. The turn-off snubber capacitor C_s is clamped by another capacitor C_c. At the end of each switching cycle, the snubber energy is dumped into C_c and then discharged into the DC bus via a discharge resistor. In order to reduce the snubber loss, the discharge resistor can be replaced by a switched-mode circuit. In this way, the Undeland snubber can become a snubber with energy recovery. The McMurray snubber is symmetrical. Both the turn-off snubber capacitors share current in parallel during turnoff. The voltage transient is limited by the capacitor closest to the turn-off device because the stray inductance to the other capacitor will prevent instantaneous current sharing. The turn-on inductors require midpoint connection. Snubber energy is dissipated into the snubber resistor. Like the Undeland snubber, the McMurray snubber can be modified into an energy recovery snubber. By using an energy recovery transformer as shown in Fig. 12.47, this snubber becomes a regenerative one. Although other regenerative circuits have been proposed, their complexity makes them unattractive in industrial applications. Also, they do not necessarily solve the power diode reverse-recovery problems.

Although the use of snubber circuits can reduce the switching stress in the power devices, the switching loss is actually damped into the snubber resistors unless regenerative snubbers are used. The switching loss is still a limiting factor to the high-frequency operation of power inverters. However, the advent of soft-switching techniques opens a new way to high-frequency inverter operation. Because the switching trajectory of a soft-switched switch is close to the voltage and current axis, faster power electronic devices with smaller SOAs can in principle be used. In general, both ZVS and ZCS can reduce switching loss in high-power power switches. However, for power switches with tail currents, such as IGBT, ZCS is more effective than ZVS.

12.14 Soft-Switching DC-AC Power Inverters

Soft-switching technique not only offers a reduction in switching loss and thermal requirement but also allows the possibility

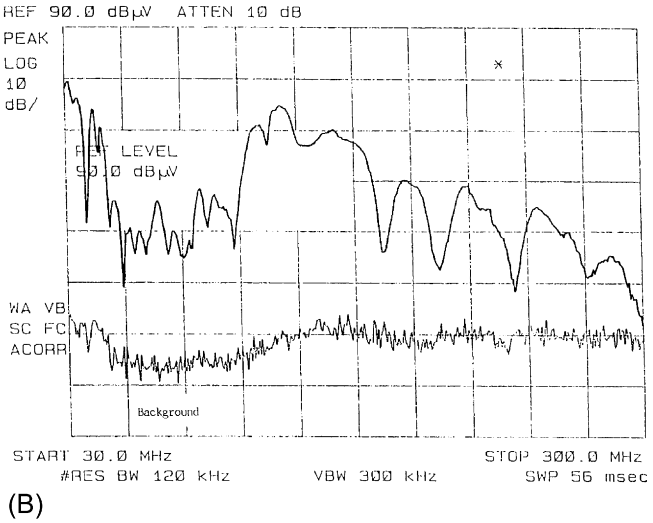

FIG. 12.43 (A) Conducted EMI from hard-switched flyback converter and (B) radiated EMI from hard-switched flyback converter.

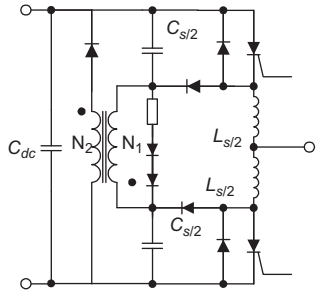

FIG. 12.47 McMurray snubber with energy recovery.

of high-frequency and snubberless operation. Improved circuit performance and efficiency and reduction of EMI emission can be achieved. For zero-voltage switching (ZVS) inverter applications, two major approaches that enable inverters to be soft-switched have been proposed. The first approach pulls the DC link voltage to zero momentarily so that the inverter's switches can be turned on and off with ZVS. Resonant DC link and quasi-resonant inverters belong to this category. The second approach uses the resonant pole idea. By incorporating the filter components into the inverter operation, resonance condition and thus zero-voltage/current conditions can be created for the inverter switches.

In this section, the following soft-switched inverters are described:

Approach 1: Resonant DC link inverters are as follows:

1. Resonant (pulsating) DC link inverters
2. Actively clamped resonant DC link inverters
3. Resonant inverters with minimum voltage stress
4. Quasi-resonant soft-switched inverter
5. Parallel resonant DC link inverter

Approach 2: Resonant pole inverters (RPIs) are as follows:

1. Resonant pole inverters
2. Auxiliary RPIs
3. Auxiliary resonant commutated pole inverters (ARCPIs)

Type 1 is the resonant DC link inverter [42–44] that sets the DC link voltage into oscillation so that the zero-voltage instants are created periodically for ZVS. Despite the potential advantages that this soft-switching approach can offer, a recent review on existing resonant-link topologies for inverters [45] concludes that the resonant DC link system results in an increase in circuit complexity and the frequency spectrum is restricted by the need of using integral pulse-density modulation (IPDM) when compared with a standard hard-switched

inverter. In addition, the peak pulsating link voltage of resonant-link inverters is twice the DC link voltage in a standard hard-switched inverter. Although clamp circuits (type 2) can be used to limit the peak voltage to 1.3–1.5 per unit [44], power devices with higher than normal voltage ratings have to be used.

Circuits of types 3–5 employ a switched-mode front-stage circuit that pulls the DC link voltage to zero momentarily whenever inverter switching is required. This soft-switching approach does not cause extra voltage stress to the inverter, and hence, the voltage rating of the power devices is only 1 per unit. As ZVS conditions can be created at any time, there is virtually no restriction in the PWM strategies. Therefore, well-established PWM schemes developed in the last 2 decades can be employed. In some ways, this approach is similar to some DC-side commutation techniques proposed in the past for thyristor inverters [46,47], although these DC-side commutation techniques were used for turning off thyristors in the inverter bridge and were not primarily developed for soft switching.

Circuits of type 6–8 retain the use of a constant DC link voltage. They incorporate the use of the resonant components and/or filter components into the inverter circuit operation. This approach is particularly useful for inverter applications in which output filters are required. Examples include uninterruptible power supplies (UPS) and inverters with output filters for motor drives. The LC filter components can form the auxiliary resonant circuits that create the soft-switching conditions. However, these tend to have high-power device count and require complex control strategy.

12.14.1 Resonant (Pulsating) DC Link Inverter

Resonant DC link converter for DC-AC power conversion was proposed in 1986 [42]. Instead of using a nominally constant DC link voltage, a resonant circuit is added to cause the DC link voltage to be pulsating at a high frequency. This resonant circuit theoretically creates periodic zero-voltage duration at which the inverter switches can be turned on or off. Fig. 12.48 shows the schematics of the pulsating link inverter. Typical DC link voltage, inverter's phase voltage, and the line voltages are shown in Fig. 12.49. Because the inverter switching can only occur at zero-voltage duration, integral pulse-density modulation (IPDM) has to be adopted in the switching strategy.

Analysis of the resonant DC link converter can be simplified by considering that the inverter system is highly inductive. The equivalent circuit is shown in Fig. 12.50.

The link current I_x may vary with the changing load condition but can be considered constant during the short resonant cycle. If switch S is turned on when the inductor current is I_{Lo}, the resonant DC link voltage can be expressed as

$$V_c(t) = V_s + e^{-\alpha t}[-V_s cos(\omega t) + \omega L I_M sin(\omega t)] \qquad (12.14)$$

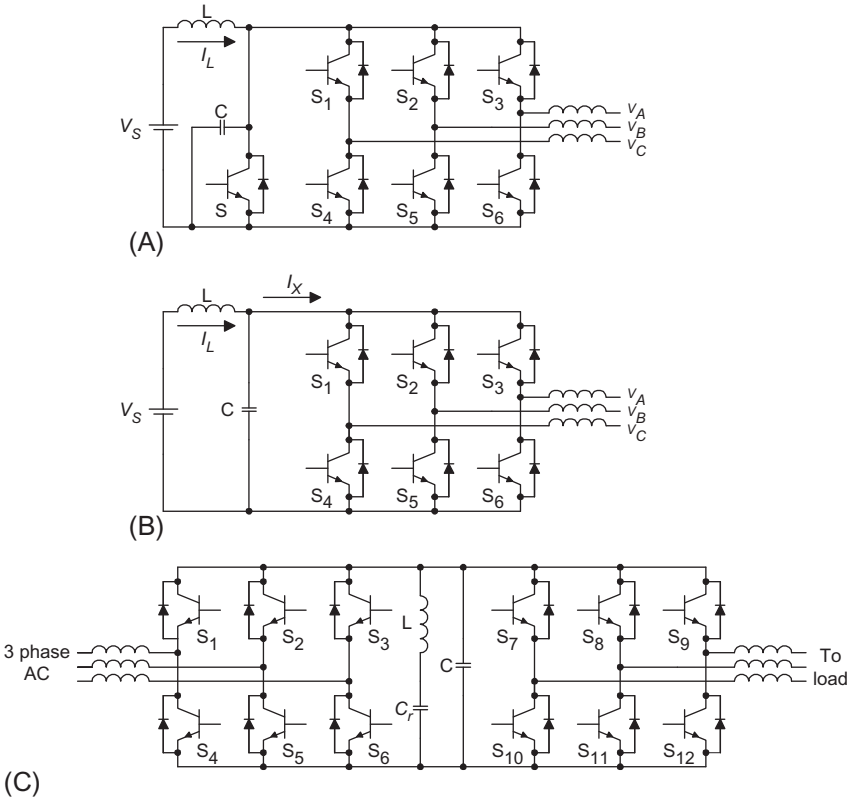

FIG. 12.48 Resonant-link inverters. (A) With resonant switch in the DC link. (B) With resonant tank in the DC link. (C) With resonant tank in the tank for AC-DC-AC system.

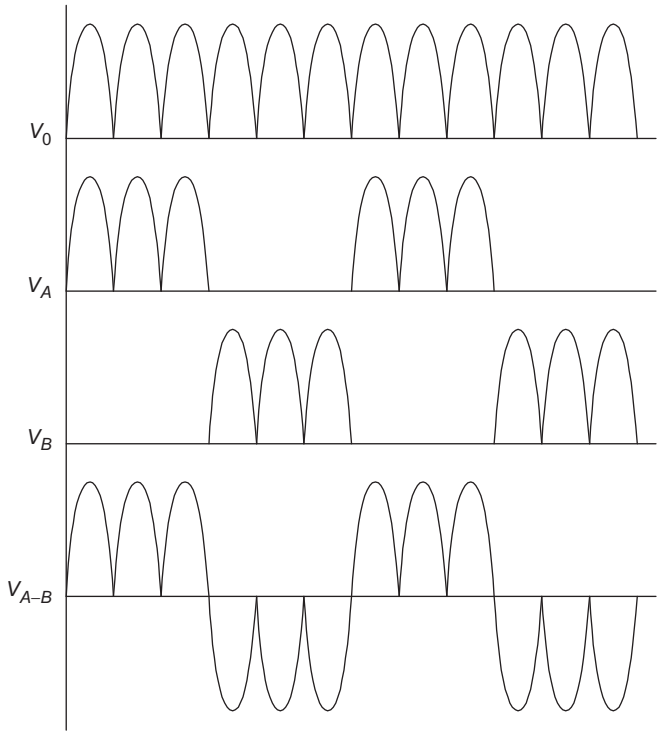

FIG. 12.49 Typical DC link voltage (V_0), phase voltages (V_A,V_B), and line voltage (V_{AB}) of resonant-link inverters.

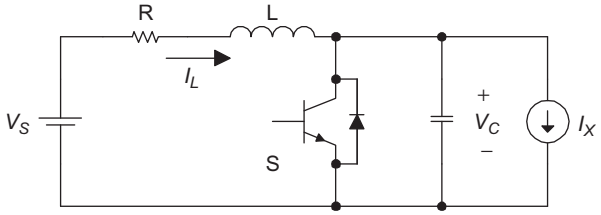

FIG. 12.50 Equivalent circuit of resonant-link inverter.

and inductor current i_L is

$$i_L(t) \approx I_x + e^{-\alpha t}\left[I_M \cos(\omega t) + \frac{V_s}{\omega L}\sin(\omega t)\right] \tag{12.15}$$

where

$$\alpha = \frac{R}{2L} \tag{12.16}$$

$$\omega_o = (LC)^{-0.5} \tag{12.17}$$

$$\omega = \left(\omega_0{}^2 - \alpha^2\right)^{0.5} \tag{12.18}$$

and

$$I_M = I_{Lo} - I_x \tag{12.19}$$

The resistance in the inductor could affect the resonant behavior because it dissipates some energy. In practice, $(i_L - I_x)$ has to be monitored when S is conducting. S can be turned on when $(i_L - I_x)$ is equal to a desired value. The objective is to ensure that the DC link voltage can be resonated to zero-voltage level in the next cycle.

The pulsating DC link inverter has the following advantages:

- Reduction of switching loss.
- Snubberless operation.
- High switching frequency (> 18 kHz) operation becomes possible, leading to the reduction of acoustic noise in inverter equipment.
- Reduction of heat sink requirements and thus improvement of power density.

This approach has the following limitations:

- The peak DC pulsating link voltage (2.0 per unit) is higher than the nominal DC voltage value of a conventional inverter. This implies that power devices and circuit components of higher voltage ratings must be used. This could be a serious drawback because power components of higher voltage ratings not only are more expensive but also usually have inferior switching performance than their low-voltage counterparts.
- Although voltage clamp can be used to reduce the peak DC link voltage, the peak voltage value is still higher than normal, and the additional clamping circuit makes the control more complicated.
- Integral pulse-density modulation has to be used. Many well-established PWM techniques cannot be employed.

Despite these advantages, this resonant converter concept has paved the way for other soft-switched converters to develop.

12.14.2 Active-Clamp Resonant DC Link Inverter

In order to solve the high voltage requirement in the basic pulsating DC link inverters, active-clamping techniques (Fig. 12.51)

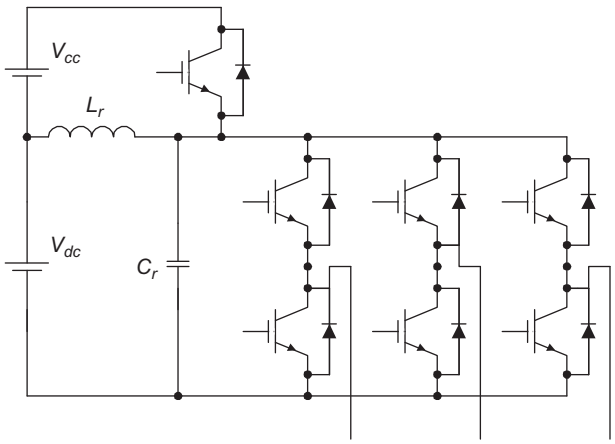

FIG. 12.51 Active-clamp resonant-link inverter.

have been proposed. The active clamp can reduce the per unit peak voltage from 2.0 to about 1.3–1.5 [44]. It has been reported that operating frequency in the range of 60–100 kHz has been achieved [48] with an energy efficiency of 97% for a 50 kVA drive system.

The design equations for active-clamp resonant-link inverter are

$$T_L = \frac{1}{f_L} = 2\sqrt{L_r C_r}\left(\cos^{-1}(1-k) + \frac{\sqrt{k(2-k)}}{k-1}\right) \tag{12.20}$$

where T_L is the minimum link period, f_L is the maximum link frequency, and k is the clamping ratio. For the active-clamp resonant inverter, k is typically 1.3–1.4 per unit.

The rate of rise of the current in the clamping device is

$$\frac{di}{dt} = \frac{(k-1)V_s}{L_r} \tag{12.21}$$

The peak clamping current required to ensure that the DC bus return to 0 V is

$$I_{sp} = V_s\sqrt{\frac{k(2-k)C_r}{L_r}} \tag{12.22}$$

In summary, resonant (pulsating) DC link inverters offer significant advantages such as the following:

- High switching frequency operation
- Low dv/dt for power devices
- ZVS with reduced switching loss
- Suitable for 1–250 kW
- Rugged operation with few failure mode

12.14.3 Resonant DC Link Inverter With Low Voltage Stress [49]

A resonant DC link inverter with low voltage stress is shown in Fig. 12.52. It consists of a front-end resonant converter that can pull the DC link voltage down just before any inverter switching. This resonant DC circuit serves as an interface between the DC power supply and the inverter. It essentially retains all the advantages of the resonant (pulsating) DC link inverters. But it offers extra advantages such as the following:

- No increase in the DC link voltage when compared with conventional hard-switched inverter. That is, the DC link voltage is 1.0 per unit.
- The zero-voltage condition can be created at any time. The ZVS is not restricted to the periodic zero-voltage instants as in resonant DC link inverter.
- Well-established PWM techniques can be employed.
- Power devices of standard voltage ratings can be used.

The timing program and the six operating modes of this resonant circuit are as shown in Figs. 12.53 and 12.54, respectively.

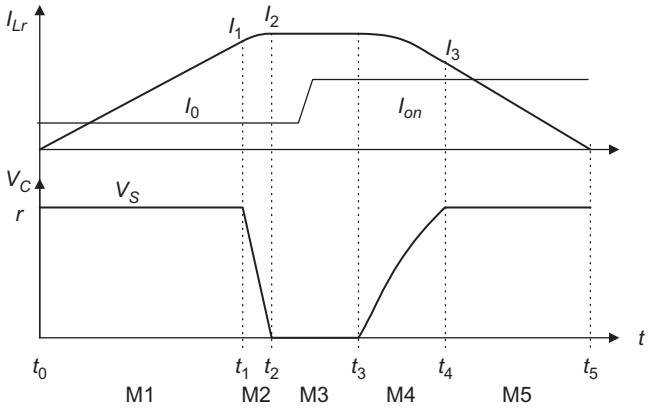

FIG. 12.53 Timing diagram of resonant-link inverter with minimum voltage stress.

(1) *Normal mode*

This is the standard PWM inverter mode. The resonant inductor current $i_{Lr}(t)$ and the resonant voltage $V_{cr}(t)$ are given by

$$i_{Lr}(t) = 0$$

$$v_{Cr}(t) = V_s$$

where V_s is the nominal DC link voltage.

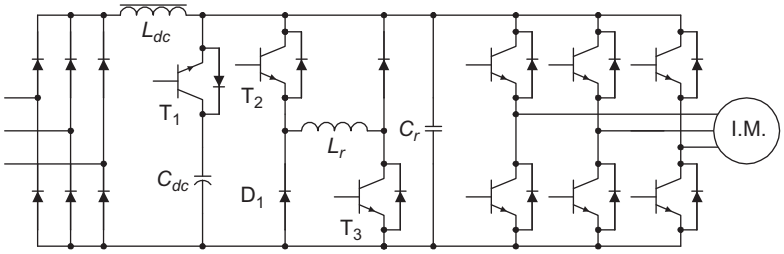

FIG. 12.52 Resonant DC link inverter with low voltage stress.

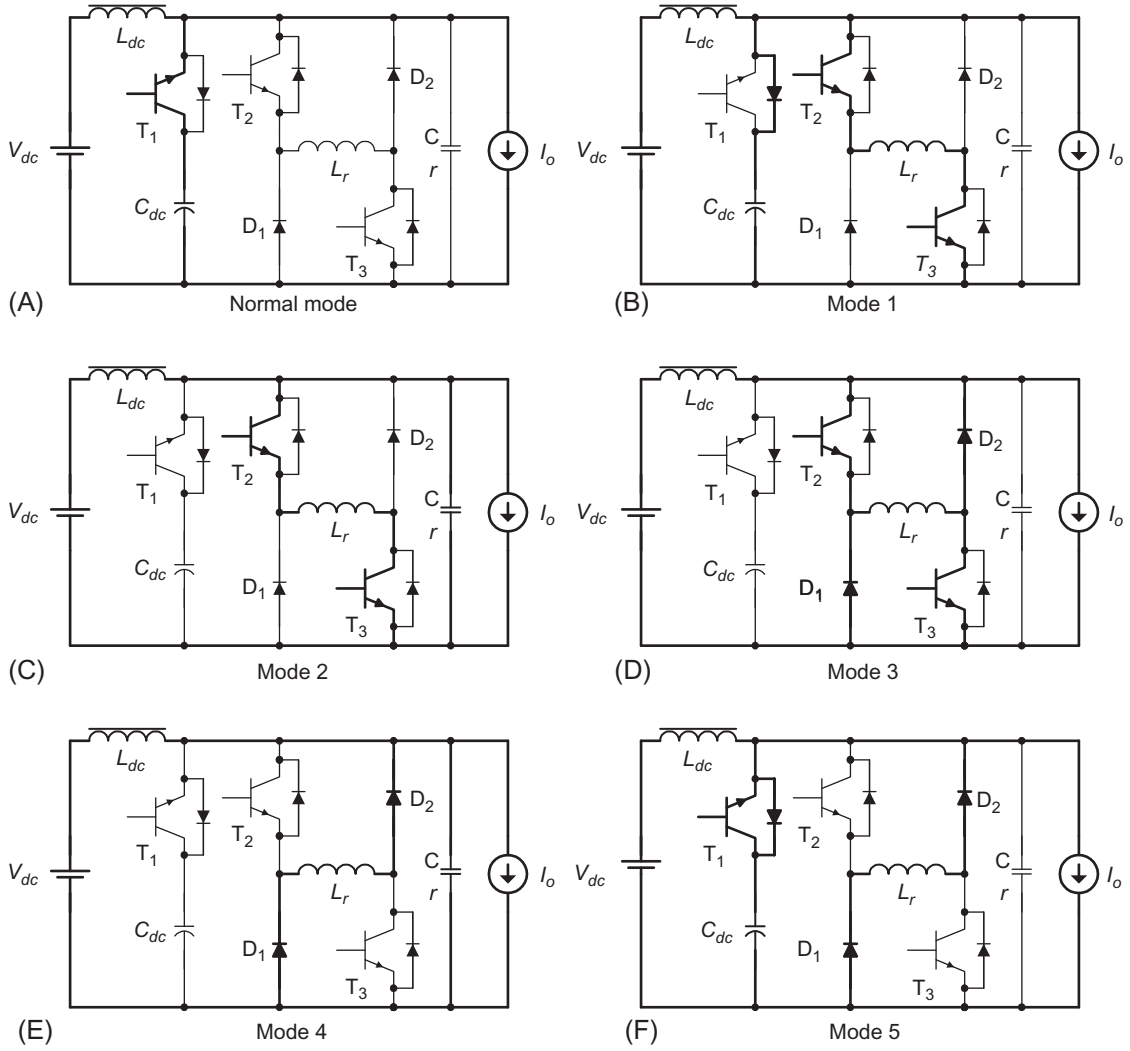

FIG. 12.54 Operating modes of resonant-link inverter with minimum voltage stress. (A) Normal mode. (B) Mode 1. (C) Mode 2. (D) Mode 3. (E) Mode 4. (F) Mode 5.

(2) *Mode 1 (Initiating mode): $(t_0 - t_1)$*

At t_0, mode 1 begins by switching on T_2 and T_3 on with zero current. $i_{Lr}(t)$ increases linearly with a di/dt of V_s/L_r. If $i_{Lr}(t)$ is equal to the initialized current I_i, T_1 is zero-voltage turned off. If $(I_s - I_o) < I_i$, then the initialization is ended when i_{Lr} (t) is equal to I_i, where I_s is the current flowing into the DC inductor L_{dc}. If $(I_s - I_o) > I_i$, then this mode continues until i_{Lr} (t) is equal to $(I_s - I_o)$. The equations in this interval are

$$i_{Lr}(t) = \frac{V_s}{L_r} t$$

$$v_{Cr}(t) = V_s$$

$$i_{Lr\,(t_1)} = \frac{V_s}{L_r} t_1 = I_i$$

(3) *Mode 2 (Resonant mode): $(t_1 - t_2)$*

After T_1 is turned off under ZVS condition, resonance between L_r and C_r occurs. V_{cr} (t) decreases from V_s to 0. At t_2, i_{Lr} (t) reaches the peak value in this interval. The equations are

$$i_{Lr}(t) = \frac{V_s}{Z_r} \sin(\omega_r t) + [I_1 + (I_o - I_s)] \cos(\omega_r t) - (I_o - I_s)$$

$$V_{Cr}(t) = -V_s \cos(\omega_r t) - [I_1 + (I_o - I_s)] Z_r \sin(\omega_r t)$$

$$i_{Lr}(t_2) = I_2 = I_{Lr,peak}$$

$$V_{Cr}(t_2) = 0$$

where

$$Z_r = \sqrt{\frac{L_r}{C_r}} \quad \text{and} \quad \omega_r = \frac{1}{\sqrt{L_r C_r}}$$

(4) *Mode 3 (Freewheeling mode): ($t_2 - t_3$)*

The resonant inductor current flows through two freewheeling paths (T_2-L_r-D_2 and T_3-D_1-L_r). This duration is the zero-voltage period created for ZVS of the inverter and should be longer than the minimum on and off times of the inverter's power switches:

$$i_{Lr}(t) = I_2$$

$$v_{Cr}(t) = 0$$

(5) *Mode 4 (Resonant mode): ($t_3 - t_4$)*

This mode begins when T_2 and T_3 are switched off under ZVS. The second half of the resonance between L_r and C_r starts again. The capacitor voltage V_{cr} (t) increases back from 0 to V_s and is clamped to V_s. The relevant equations in this mode are

$$i_{Lr}(t) = [I_2 - (I_{on} - I_s)]\cos(\omega_r t) - (I_{on} - I_s)$$
$$V_{Cr}(t) = [I_2 - (I_{on} - I_s)]Z_r \sin(\omega_r t)$$
$$i_{Lr}(t_4) = I_3$$
$$V_{Cr}(t_4) = V_s$$

where I_{on} is the load current after the switching state.

(6) *Mode 5 (Discharging mode): ($t_4 - t_5$)*

In this period, T_1 is switched on under ZV condition because V_{cr} (t) = V_s. The inductor current decreases linearly. This mode finishes when i_{Lr} (t) becomes zero:

$$i_{Lr}(t) = -\frac{V_s}{L_r}t + I_3$$
$$v_{Cr}(t) = V_s$$
$$i_{Lr}(t_5) = 0$$

12.14.4 Quasi-Resonant Soft-Switched Inverter [50]

12.14.4.1 Circuit Operation

Consider an inverter fed by a DC voltage source versus a front-stage interface circuit shown in Fig. 12.55 can be added between the DC voltage source and the inverter. The front-stage circuit consists of a quasi-resonant circuit in which the first half of the resonance cycle is set to occur to create the zero-voltage condition whenever inverter switching is needed. After inverter switching has been completed, the second half of the resonance cycle takes place so that the DC link voltage is set back to its normal level. To avoid excessive losses in the resonant circuit, a small capacitor C_{r1} is normally used to provide the DC link voltage, while the large smoothing DC link capacitor C_1 is isolated from the resonant circuit just before the zero-voltage duration. This method avoids the requirement for pulling the DC voltage of the bulk capacitor to zero.

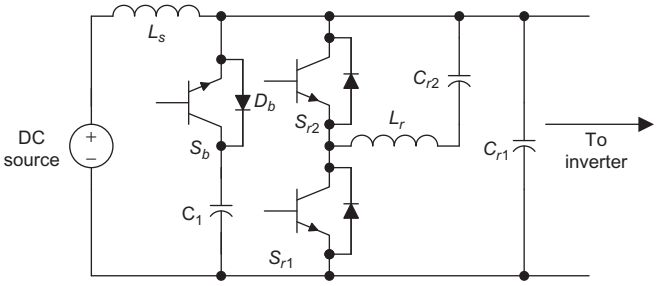

FIG. 12.55 Quasi-resonant circuit for soft-switched inverter.

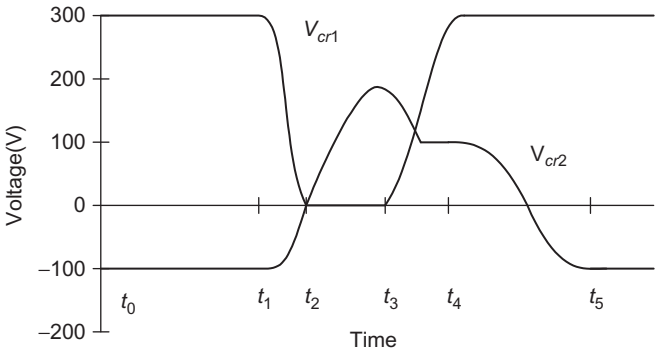

FIG. 12.56 Typical waveforms for V_{cr1} and V_{cr2}.

The period for this mode is from t_0 to t_1 in Fig. 12.56. In this mode, switch S_b is turned on, and switches S_{r1} and S_{r2} are turned off. The inverter in Fig. 12.55 works like a conventional DC link inverter. In this mode, $V_{cr1} = V_{c1}$. The voltage across switch S_b is zero. Before an inverter switching takes place, switch S_{r1} is triggered at t_1 to discharge C_{r1}. This operating mode ends at t_2 when V_{cr1} approaches zero. The equivalent circuit in this mode is shown in Fig. 12.57A. The switch S_b must be turned off at zero voltage when switch S_{r1} is triggered. After S_{r1} is triggered, C_{r1} will be discharged via the loop C_{r1}, C_{r2}, L_r, and S_{r1}. Under conditions of $V_{cr2} \leq 0$ and $C_{r1} \leq C_{r2}$, the energy stored in C_{r1} will be transferred to C_{r2}, and V_{cr1} falls to zero in the first half of the resonant cycle in the equivalent circuit of Fig. 12.57A. V_{cr1} will be clamped to zero by the freewheel diodes in the inverter bridge and will not become negative. Thus, V_{cr1} can be pulled down to zero for zero-voltage switching. When the current in inductor L_r becomes zero, switch S_{r1} can be turned off at zero current.

Inverter switching can take place in the period from t_2 to t_3 in which V_{cr1} remains zero. This period must be longer than the turn-on and turn-off times of the switches. When inverter switching has been completed, it is necessary to reset the voltage of capacitor C_{r1}. The equivalent circuit in this mode is shown in Fig. 12.57B. The current in inductor L_r reaches zero at t_3. Due to the voltage in V_{cr2} and the

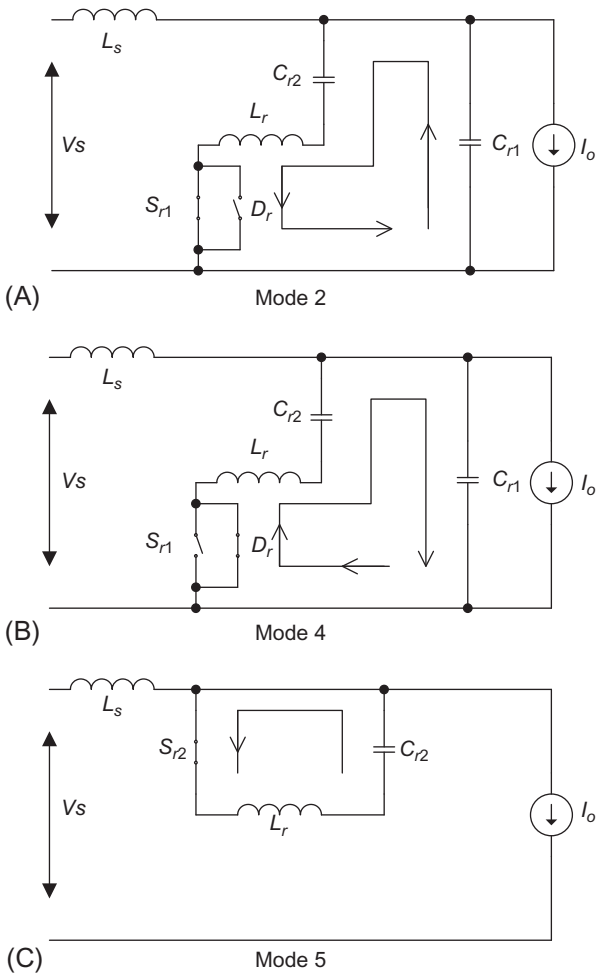

FIG. 12.57 Equivalent circuits of the quasi-resonant circuit for different modes. (A) Mode 2. (B) Mode 4. (C) Mode 5.

presence of diode D_r, this current then flows in the opposite direction. C_{r1} will be recharged via L_r, C_{r2}, C_{r1}, and D_r. The diode D_r turns off when the current in L_r becomes zero. V_{cr1} will not go beyond 1 per unit because C_{r1} is clamped to supply voltage by diode D_b. The switch S_b can be turned on again at zero-voltage condition when V_{cr1} returns to normal DC supply voltage. After D_r turns off, V_{cr2} may not be zero. Some positive residual capacitor voltage remains in C_2 at t_4, as shown in Fig. 12.56. In case V_{cr2} is positive, V_{cr1} cannot be pulled down to zero again in the next switching cycle. Therefore, S_{r2} should be triggered after t_4 to reverse the residual voltage in C_{r2}. At time t_5, Sr_2 turns off at zero-current condition, and V_{cr2} is now reversed to negative. The equivalent circuit in this mode is shown in Fig. 12.57C. When $V_{cr2} \leq 0$ and $C_{r1} \leq C_{r2}$, V_{cr1} can be pulled down to zero again before the next inverter switching. The operation can then be repeated in next switching cycle.

12.14.4.2 Design Considerations

(1) C_{r1} and C_{r2}

The criterion for getting zero capacitor voltages V_{cr1} is

$$(C_{r1} - C_{r2})V_s + 2C_{r2}V_{o2} - \Delta I\pi\sqrt{L_r C_e} \leq 0 \tag{12.23}$$

where

- V_{o1} is the initial voltage of C_{r1},
- V_{o2} is the initial voltage of C_{r2},
- i_{L0} is the initial current of inductor L_r,
- $\Delta I = I_o - I_s$ is the difference between load current and supply current. It is assumed to be a constant within a resonant cycle,
- R_r is the equivalent resistance in the resonant circuit,
- $C_e = \dfrac{C_{r1}C_{r2}}{C_{r1} + C_{r2}}$

When $\Delta I \geq 0$, the above criterion is always true under conditions of

$$C_{r1} \leq C_{r2}, V_{o2} \leq 0$$

The criterion for recharging voltage V_{cr1} to 1 per unit DC link voltage is

$$\frac{2C_{r2}}{C_{r1} + C_{r2}}V_{02} - \frac{\Delta I}{C_{r1} + C_{r2}}\pi\sqrt{L_r C_e} \geq V_s \tag{12.24}$$

(2) Inductor L_r

The inductor L_r should be small so that the DC link voltage can be decreased to zero quickly. However, a small L_r could result in large peak resonant current and therefore requirement of power devices with large current pulse ratings. An increase in the inductance of L_r can limit the peak current in the quasi-resonant circuit. Because the resonant frequency depends on both the inductor and the capacitor, therefore, the selection of L_r can be considered together with the capacitors C_{r1} and C_{r2} and with other factors such as the current ratings of power devices, the zero-voltage duration, and the switching frequency required in the soft-switching circuit.

(3) Triggering instants of the switches

The correct triggering instants for the switches are essential for the successful operation of this soft-switched inverter. For the inverter switches, the triggering instants are determined from a PWM modulation. Let T_s be the time at which the inverter switches change states. To get the zero-voltage inverter switching, switch S_{r1} should be turned on half resonant cycle before the inverter switching instant. The turn-on instant of S_{r1}, which is t_1 in Fig. 12.56, can be written as

$$t_1 = T_s - \frac{\pi}{\omega} \tag{12.25}$$

where $\omega = \sqrt{\omega_0^2 - \alpha^2}, \alpha = \frac{R_r}{2L_r}, \omega_0 = \sqrt{\frac{1}{L_r C_e}}$. The switch S_b is turned off at t_1.

S_{r1} may be turned off during its zero-current period when diode D_r is conducting. For easy implementation, its turn-off time can be selected as $T_s + \pi/\omega$. Because the DC link voltage can be pulled down to zero in less than half resonant cycle, T_s should occur between t_2 and t_3.

At time t_3 (the exact instant depends on the ΔI), the diode D_r turns on in the second half of the resonant cycle to recharge C_{r1}. At t_4, V_{cr1} reaches 1 per unit and diode D_b clamps V_{cr1} to 1 per unit. The switch S_b can be turned on again at t_4, which is half resonant cycle after the start of t_3:

$$t_4 \approx t_3 + \frac{\pi}{\omega} \tag{12.26}$$

As t_3 cannot be determined accurately, a voltage sensor in principle can be used to provide information for t_4 so that S_b can be turned on to reconnect C_1 to the inverter. In practice, however, S_b can be turned on a few microseconds (longer than $T_s + \pi/\omega$) after t_2 without using a voltage sensor (because it is not critical for S_b to be on exactly at the moment V_{cr} reaches the nominal voltage). As for switch S_{r2}, it can be turned on a few microseconds after t_4. It will be turned off half of resonant cycle $\left(\pi\sqrt{L_r C_{r2}}\right)$ in the $L_r - C_{r2}$ circuit later. In practice, the timing of S_{r1}, S_{r2}, and S_b can be adjusted in a simple tuning procedure for a given set of parameters. Fig. 12.58 shows the measured gating signals of S_{r1}, S_{r2}, and S_b with the DC link voltage V_{cr1} in a 20-kHz switching inverter. Figs. 12.59 and 12.60 show the measured waveforms of I_s, I_o, and V_{cr1} under no-load condition and loaded condition, respectively.

12.14.4.3 Control of Quasi-Resonant Soft-Switched Inverter Using Digital Time Control [51]

Based on the zero-average-current error (ZACE) control concept, a digital time control (DTC) method has been developed for a current-controlled quasi-resonant soft-switched inverter. The basic ZACE concept is shown in Fig. 12.61. The current error is obtained from the difference of a reference current

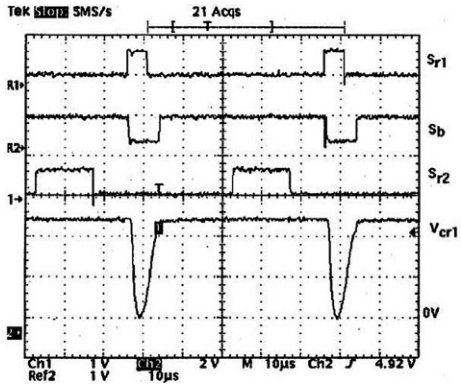

FIG. 12.58 Gating signals for S_{r1}, S_{r2}, and S_b with V_{cr1}.

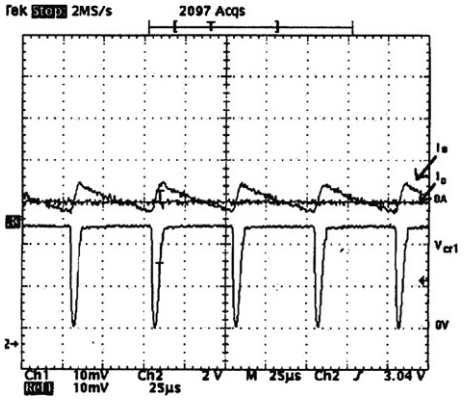

FIG. 12.59 Typical I_s, I_o, and V_{cr1} under no-load condition.

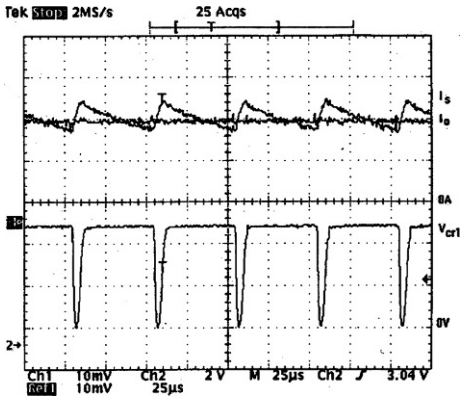

FIG. 12.60 Typical I_s, I_o, and V_{cr1} under loaded condition.

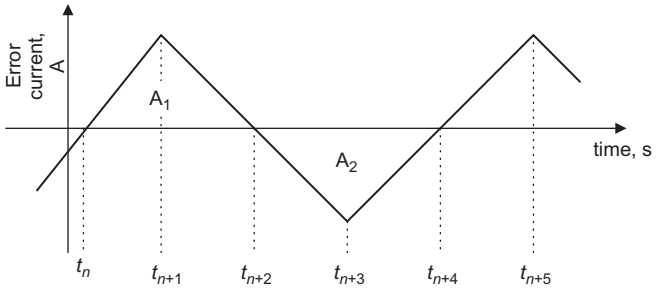

FIG. 12.61 Zero-average-current error (ZACE) control concept.

and the sensed current. The idea is to make the areas of each transition (A1 and A2) equal. If the switching frequency is significantly greater than the fundamental frequency of the reference signal, the rising and falling current segments can be assumed to be linear. The following simplified equation can be established:

$$\Delta t_{n+1} = t_{n+1} - t_n \tag{12.27}$$

The control algorithm for the inverter is

$$\Delta t_{n+3} = \Delta t_{n+2} + D\left[\frac{T_{sw}}{2} - (t_{n+2} - t_n)\right] \tag{12.28}$$

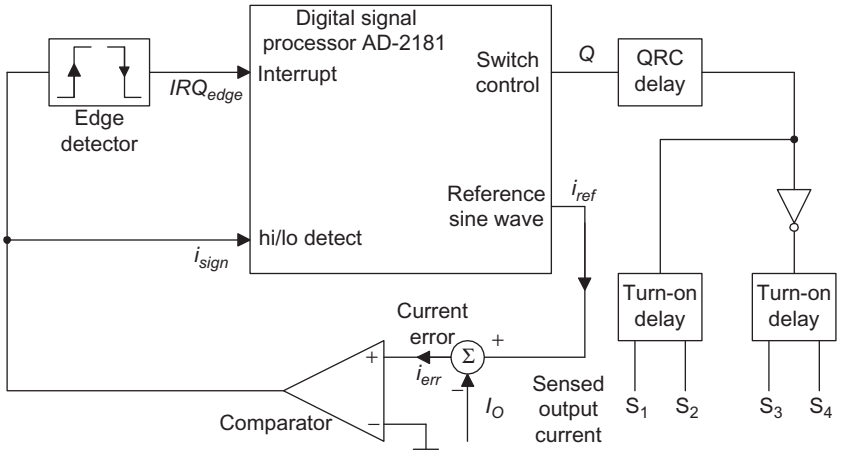

FIG. 12.62 Implementation of DTC.

where $D = \dfrac{\Delta t_{n+2}}{t_{n+2} - t_n}$ and $T_{sw} = t_{n+4} - t_n$.

The schematic of a digital signal processor (DSP)-based controller for the DTC method is shown in Fig. 12.62. The duty cycle can be approximated from the reference sine wave by level shifting and scaling it between 0 and 1. The time $t_{n+2} - t_n$ is the sum of Δt_{n+1} and Δt_{n+2}. These data provide information for the calculation of the next switching time Δt_{n+1}.

The switches are triggered by the changing edge of the switch control Q. Approximate delays are added to the individual switching signals for both the inverter switches and the quasi-resonant switches. Typical gating waveforms are shown in Fig. 12.63. The use of the quasi-resonant soft-switched inverter is a very effective way in suppressing switching transient and EMI emission. Fig. 12.64A and B shows the inverter switch voltage waveforms of a standard hard-switched inverter and a quasi-resonant soft-switched inverter, respectively. It is clear that the soft-switched waveform has much less transient than the hard-switched waveform.

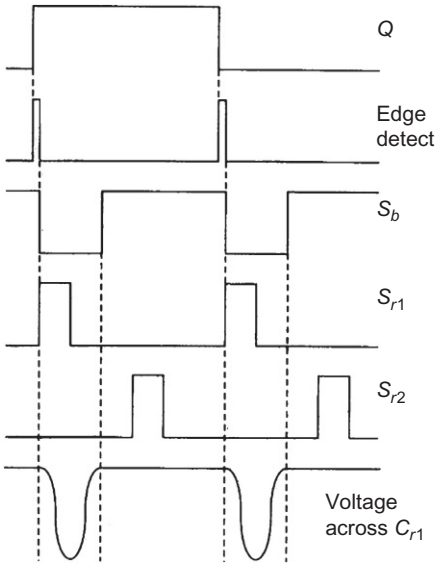

FIG. 12.63 Timing diagrams for the gating signals.

12.14.5 RPI and ARCPI

The RPI integrates the resonant components with the output filter components L_f and C_f. The load is connected to the

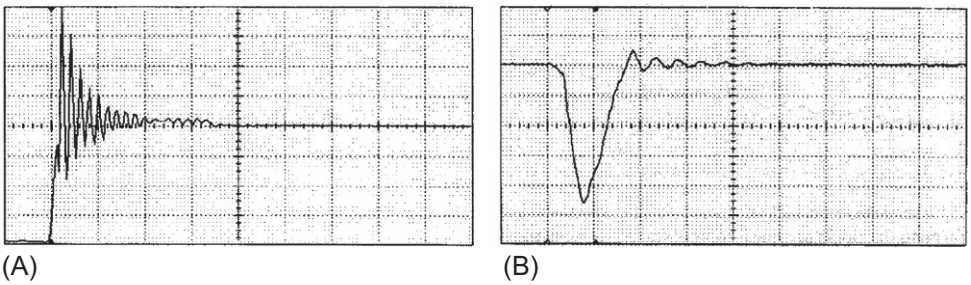

FIG. 12.64 (A) Typical switch voltage under hard turnoff and (B) typical switch voltage under soft turnoff.

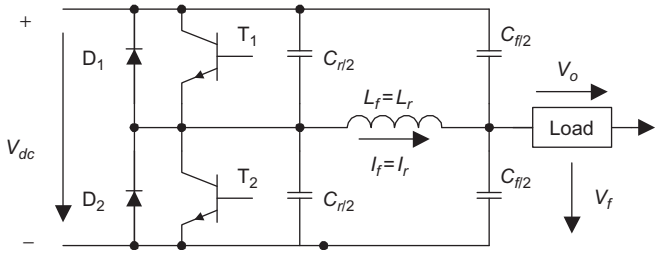

FIG. 12.65 One leg of a resonant pole inverter.

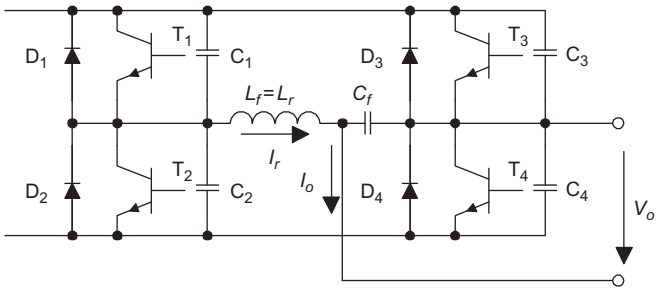

FIG. 12.66 Single-phase resonant pole inverter.

midpoint of the DC bus capacitors as shown in Fig. 12.65. It should however be noted that the RPI can be described as a resonant inverter. Fig. 12.66 shows a single-phase RPI. Its operation can be described with the timing diagram in Fig. 12.67. The operating modes are included in Fig. 12.68. The RPI provides soft switching for all power switches. But it has two disadvantages. First, the power devices have to be switched continuously at the resonant frequency determined by the resonant components. Second, the power devices in the RPI circuit require a 2.2–2.5 p.u. current turn-off capability.

An improved version of the RPI is the ARCPI. The ARCPI for one inverter leg is shown in Fig. 12.69. Unlike the basic RPI, the ARCPI allows the switching frequency to be controlled. Each of the primary switches is closely paralleled with a snubber capacitor to ensure ZV turnoff. Auxiliary switches are connected in series with an inductor, ensuring that they operate under ZC conditions. For each leg, an auxiliary circuit comprising two extra switches A1 and A2, two freewheeling diodes, and a resonant inductor L_r is required. This doubles the number of power switches when compared with hard-switched inverters. Fig. 12.70 shows the three-phase ARCPI system. Depending on the load conditions, three commutation modes are generally needed. The commutation methods at low and high current are different. This makes the control of the ARCPI very complex. The increase in control and circuit complexity represents a considerable cost penalty [52,53].

13.1 Introduction

Numerous industrial applications require higher power apparatus in recent years. Some medium-voltage motor drives and utility applications require medium-voltage and megawatt power level converters. For a medium-voltage grid, it is troublesome to connect only one power semiconductor switch directly. Hence, a multilevel power converter structure has been introduced as an alternative in high-power and medium-voltage situations. A multilevel converter not only achieves high-power ratings but also enables the use of renewable energy sources. Renewable energy sources such as photovoltaics or wind turbines can be easily interfaced to a multilevel converter system for a high-power utility application [1–3].

The concept of multilevel converters has been introduced since 1975 [4]. The term *multilevel* began with the three-level converter [5]. Subsequently, several multilevel converter topologies have been developed [6–13]. However, the basic concept of a multilevel converter to achieve higher power is to use a series of power semiconductor switches with several lower voltage dc sources to perform the power conversion by synthesizing a staircase voltage waveform. Capacitors, batteries, and renewable energy voltage sources can be used as the multiple dc voltage sources. The commutation of the power switches aggregate these multiple dc sources to achieve high voltage at the output; however, the rated voltage of the power semiconductor switches depends only on the rating of the dc voltage sources to which they are connected.

A multilevel converter has several advantages over a conventional two-level converter that uses high switching frequency pulse-width modulation (PWM). The attractive features of a multilevel converter are summarized as follows:

- *Staircase waveform quality*: Multilevel converters not only can generate the output voltages with very low distortion but also can reduce the dv/dt stresses; therefore, electromagnetic compatibility (EMC) problems can be reduced.
- *Common-mode (CM) voltage*: Multilevel converters produce smaller CM voltage; therefore, the stress in the bearings of a motor connected to a multilevel motor drive can be reduced. Furthermore, CM voltage can be eliminated by using advanced modulation strategies such as that proposed in [14].
- *Input current*: Multilevel converters can draw input current with low distortion.
- *Switching frequency*: Multilevel converters can operate at both fundamental switching frequency and high switching frequency PWM. It should be noted that lower switching frequency usually means lower switching loss and higher efficiency.

Unfortunately, multilevel converters do have some disadvantages. One particular disadvantage is the requirement of greater number of power semiconductor switches. Although lower voltage rated switches can be utilized in a multilevel converter, each switch requires a related gate-drive circuit. This may cause the overall system to be more expensive and complex.

Many multilevel converter topologies have been proposed during the last two decades. Contemporary research has engaged novel converter topologies and unique modulation schemes. Moreover, four different major multilevel converter structures have been reported in the literature: cascaded H-bridge converter with separate dc sources, diode clamp (neutral-clamped), flying capacitors (capacitor-clamped), and modular multilevel converter. Moreover, abundant modulation techniques and control paradigms have been developed for multilevel converters, such as sinusoidal pulse-width modulation (SPWM), selective harmonic elimination (SHE PWM), and space vector modulation (SVM). In addition, many multilevel converter applications focus on industrial medium-voltage motor drives [11,15], utility interface for renewable energy systems [16], flexible ac transmission system (FACTS) [17], and traction drive systems [18].

This chapter reviews the state of the art of multilevel power converter technology. Fundamental multilevel converter structures and modulation paradigms are discussed including the pros and cons of each. The main focus is on modern and more practical industrial applications of multilevel converters. Finally, the possible future developments of multilevel converter technology are noted.

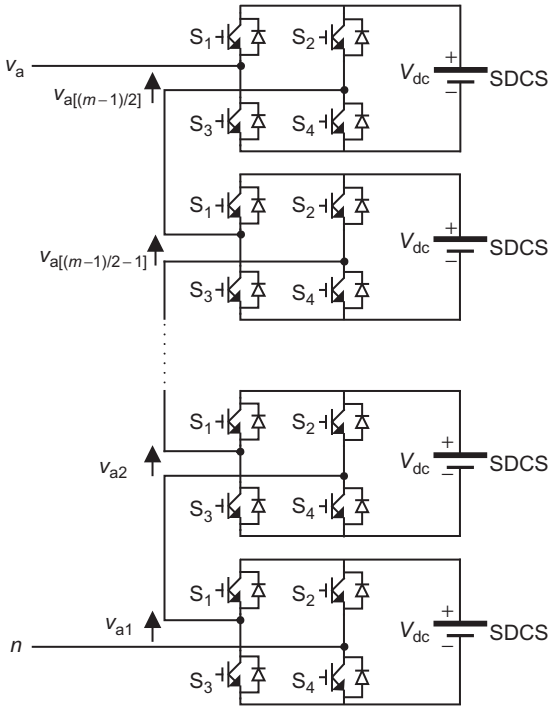

FIG. 13.1 Single-phase structure of a multilevel cascaded H-bridge inverter.

13.2 Multilevel Power Converter Structures

As mentioned earlier, four different major multilevel converter structures have been used in industrial applications: cascaded H-bridge converter with separate dc sources, diode clamped, flying capacitors, and modular multilevel converter. It should be noted that the term *multilevel converter* refers to a power electronic circuit that could operate in an inverter or rectifier mode. The multilevel inverter structures are the focus of this chapter; however, the illustrated structures can be implemented for rectifying operation as well.

13.2.1 Cascaded H-Bridges

A single-phase structure of an m-level cascaded inverter is illustrated in Fig. 13.1. Each separate dc source (SDCS) is connected to a single-phase full-bridge or H-bridge inverter.

Each inverter level can generate three different voltage outputs, $+V_{dc}$, 0, and $-V_{dc}$, by connecting the dc source to the ac output by different combinations of the four switches: S_1, S_2, S_3, and S_4. To obtain $+V_{dc}$, switches S_1 and S_4 are turned on, whereas to obtain $-V_{dc}$, switches S_2 and S_3 are turned on. By turning on either S_1 and S_2 or S_3 and S_4, the output voltage will be zero. The ac outputs of each of the different full-bridge inverter levels are connected in series such that the synthesized voltage waveform is the sum of the inverter outputs. The number of output phase voltage levels, m, in a cascade inverter is defined by $m = 2s + 1$, where s is the number of separate dc sources. An example of phase voltage waveform for an 11-level cascaded H-bridge inverter with five SDCSs and five full bridges is shown in Fig. 13.2. The phase voltage $v_{an} = v_{a1} + v_{a2} + v_{a3} + v_{a4} + v_{a5}$.

For a stepped waveform such as the one depicted in Fig. 13.2 with s steps, the Fourier transform for this waveform follows [14,18]:

$$V(\omega t) = \frac{4V_{dc}}{\pi}\sum_n [\cos(n\theta_1) + \cos(n\theta_2) + \cdots + \cos(n\theta_s)] \times \frac{\sin(n\omega t)}{n}, \quad \text{where } n = 1,3,5,7,\ldots \tag{13.1}$$

From Eq. (13.1), the magnitudes of the Fourier coefficients when normalized with respect to V_{dc} are as follows:

$$H(n) = \frac{4}{\pi n}[\cos(n\theta_1) + \cos(n\theta_2) + \cdots + \cos(n\theta_s)], \quad \text{where } n = 1,3,5,7,\ldots \tag{13.2}$$

The conducting angles, $\theta_1, \theta_2, \ldots, \theta_s$, can be chosen such that the voltage total harmonic distortion is minimum. Generally, these angles are chosen so that predominant lower frequency harmonics, 5, 7, 11, and 13 are eliminated [19]. More details on harmonic elimination techniques will be discussed in the following section.

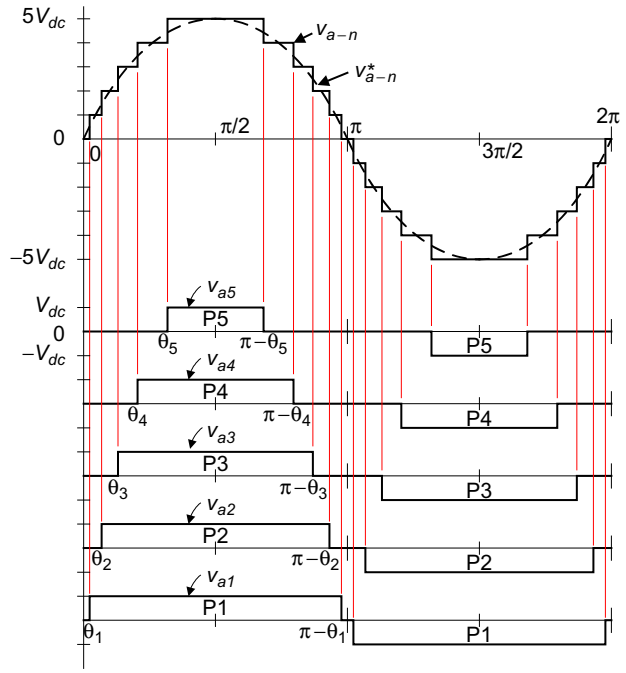

FIG. 13.2 Output phase voltage waveform of an 11-level cascade inverter with five separate dc sources.

Multilevel cascaded inverters have been proposed for such applications as static var generation, an interface with renewable energy sources, and for battery-based applications.

Three-phase cascaded inverters can be connected in wye, as shown in Fig. 13.3, or in delta. Peng et al. have demonstrated a prototype multilevel cascaded static var generator connected in parallel with an electric system that could supply or draw reactive current from an electric system [20–23]. The inverter could be controlled to regulate either the power factor of the current drawn from the source or the bus voltage of the electric system where the inverter was connected. Peng et al. [20] and Joos et al. [24] have also shown that a cascade inverter can be directly connected in series with the electric system for static var compensation. Cascaded inverters are ideal for connecting renewable energy sources with an ac grid because of the need for separate dc sources in applications such as photovoltaics or fuel cells.

Cascaded inverters have also been proposed for use as the main traction drive in electric vehicles where several batteries or ultracapacitors are well suited to serve as SDCSs [18,25]. The cascaded inverter could also serve as a rectifier or charger for the batteries of an electric vehicle while the vehicle was connected to an ac supply as shown in Fig. 13.3. In addition, the cascade inverter can act as a rectifier in a vehicle that uses regenerative braking.

Manjrekar and Lipo have proposed a cascade topology that uses multiple dc levels, which instead of being identical in value are multiples of each other [26,27]. They also used a combination of fundamental frequency switching for some of the levels and PWM switching for part of the levels to achieve the output voltage waveform. This approach enables a wider diversity of output voltage magnitudes; however, it also results in unequal voltage and current ratings for each of the levels and loses the advantage of being able to use identical modular units for each level.

The main advantages and disadvantages of multilevel cascaded H-bridge converters are as follows [28,29]:

13.2.1.1 Advantages

- The number of possible output voltage levels is more than twice the number of dc sources ($m = 2s + 1$).
- The series of H-bridges makes for modularized layout and packaging. This will enable the manufacturing process to be done more quickly and cheaply.

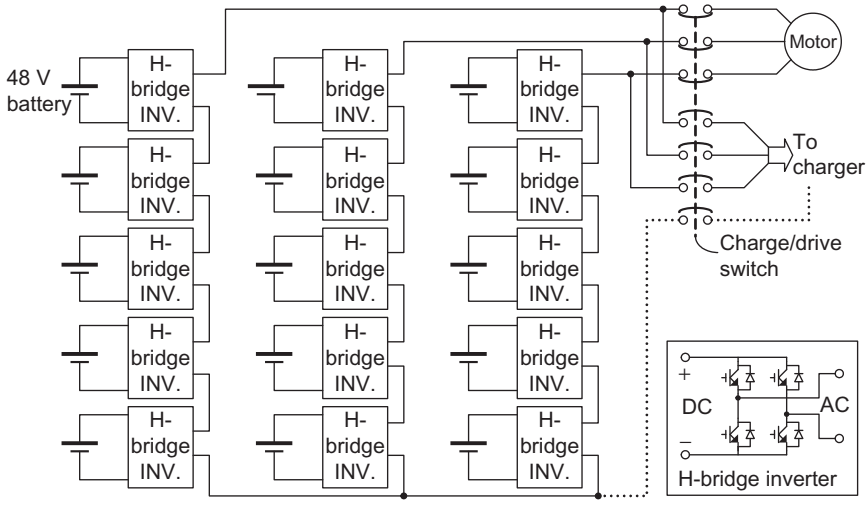

FIG. 13.3 Three-phase wye-connection structure for electric vehicle motor drive and battery charging.

13.2.1.2 Disadvantages

- Separate dc sources are required for each of the H-bridges. This will limit its application to products that already have multiple SDCSs readily available.

Another kind of cascaded multilevel converter with transformers using standard three-phase bilevel converters has been proposed [14]. The circuit is shown in Fig. 13.4. The converter uses output transformers to add different voltages. In order to add up the converter output voltages, the outputs of the three converters need to be synchronized with a separation of 120° between each phase. For example, for obtaining a three-level voltage between outputs *a* and *b*, the output voltage can be synthesized by $V_{ab} = V_{a1-b1} + V_{b1-a2} + V_{a2-b2}$. An isolated transformer is used to provide voltage boost. With three converters synchronized, the voltages, $V_{a1-b1}, V_{b1-a2}, V_{a2-b2}$, are all in phase, and thus, the output level can be tripled [1].

The advantage of the cascaded multilevel converters with transformers using standard three-phase bilevel converters is that the three converters are identical, and thus, control is more simple. However, the three converters need separate dc sources, and a transformer is needed to add up the output voltages.

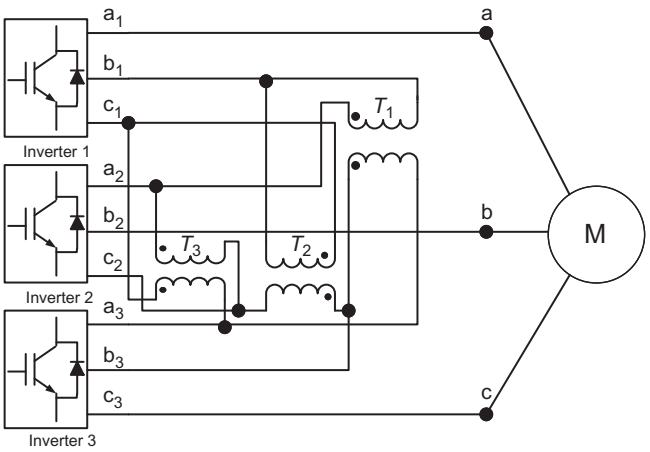

FIG. 13.4 Cascaded multilevel converter with transformers using standard three-phase bilevel converters.

13.2.2 Diode-Clamped Multilevel Inverter

The neutral point converter proposed by Nabae, Takahashi, and Akagi in 1981 was essentially a three-level diode-clamped inverter [5]. Several researchers published articles that have reported experimental results for four-, five-, and six-level diode-clamped converters for uses such as static var compensation, variable speed motor drives, and high-voltage system interconnections [17–30]. A three-phase six-level diode-clamped inverter is shown in Fig. 13.5. Each of the three phases of the inverter shares a common dc bus, which has been subdivided by five capacitors into six levels. The voltage across each capacitor is V_{dc}, and the voltage stress across each switching device is limited to V_{dc} through the clamping diodes. Table 13.1 lists the output voltage levels possible for one phase of the inverter with the negative dc rail voltage V_0 as a reference. State condition 1 means the switch is on, and 0 means the switch is off. Each phase has five complementary switch pairs such that turning on one of the switches of the pair requires the

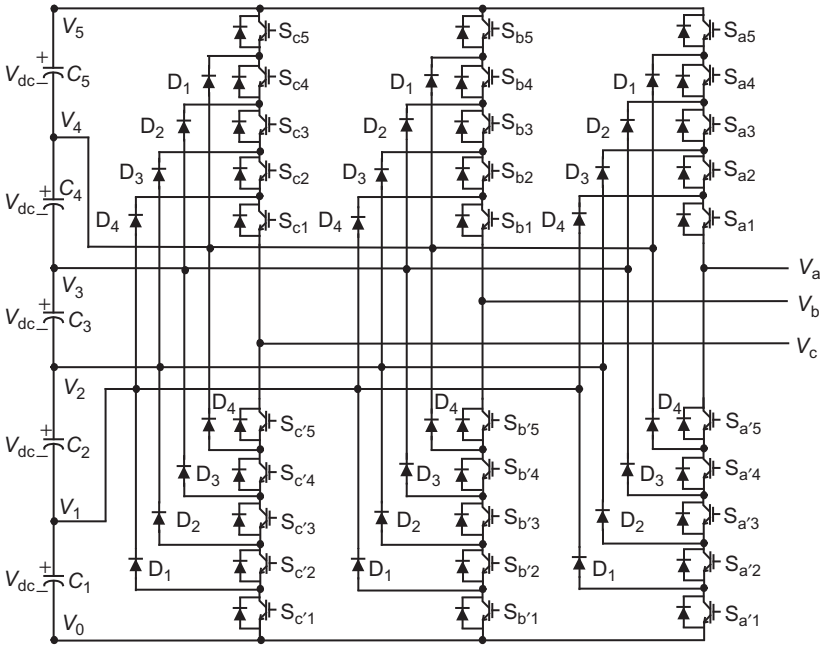

FIG. 13.5 Three-phase six-level structure of a diode-clamped inverter.

TABLE 13.1 Diode-clamped six-level inverter voltage levels and corresponding switch states

	Switch state									
Voltage V_{a0}	S_{a5}	S_{a4}	S_{a3}	S_{a2}	S_{a1}	$S_{a'5}$	$S_{a'4}$	$S_{a'3}$	$S_{a'2}$	$S_{a'1}$
$V_5 = 5V_{dc}$	1	1	1	1	1	0	0	0	0	0
$V_4 = 4V_{dc}$	0	1	1	1	1	1	0	0	0	0
$V_3 = 3V_{dc}$	0	0	1	1	1	1	1	0	0	0
$V_2 = 2V_{dc}$	0	0	0	1	1	1	1	1	0	0
$V_1 = 1V_{dc}$	0	0	0	0	1	1	1	1	1	0
$V_0 = 0$	0	0	0	0	0	1	1	1	1	1

other complementary switch to be turned off. The complementary switch pairs for phase-leg a are $(S_{a1}, S_{a'1})$, $(S_{a2}, S_{a'2})$, $(S_{a3}, S_{a'3})$, $(S_{a4}, S_{a'4})$, and $(S_{a5}, S_{a'5})$. Table 13.1 also shows that in a diode-clamped inverter, the switches that are on for a particular phase leg are always adjacent and in series. For a six-level inverter, a set of five switches should be on at any given time.

Fig. 13.6 shows one of the three line-line voltage waveforms for a six-level inverter. The line voltage V_{ab} consists of a phase-leg "a" voltage and a phase-leg "b" voltage. The resulting line voltage is an 11-level staircase waveform. This means that an m-level diode-clamped inverter has an m-level output phase voltage and a $(2m-1)$-level output line voltage.

Although each active switching device is required to block only a voltage level of V_{dc}, the clamping diodes require different ratings for reverse voltage blocking. Using phase a of Fig. 13.5 as an example, when all the lower switches $S_{a'1}$ through $S_{a'5}$ are turned on, D_4 must block four voltage levels or $4V_{dc}$. Similarly, D_3 must block $3V_{dc}$, D_2 must block $2V_{dc}$, and D_1 must block V_{dc}. If the inverter is designed such that each blocking diode has the same voltage rating as the active switches, D_n will require n diodes in series; consequently, the number of diodes required for each phase would be $(m-1)\times(m-2)$. Thus, the number of blocking diodes is quadratically related to the number of levels in a diode-clamped converter [28].

One application of the multilevel diode-clamped inverter is an interface between a high-voltage dc transmission line and an ac transmission line [29]. Another application would be a variable speed drive for high-power medium-voltage (2.4–13.8 kV) motors as proposed in [3,6,19,28–30]. Several authors have proposed for the diode-clamped converter that static var compensation is an additional function. The main advantages and disadvantages of multilevel diode-clamped converters are as follows [1–3].

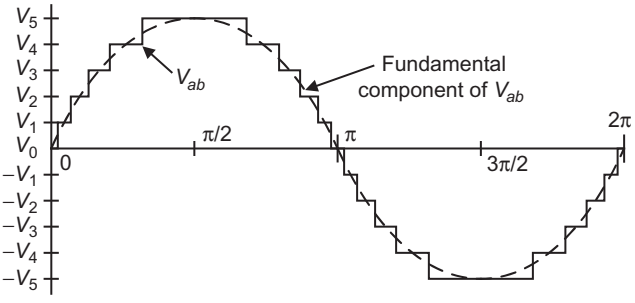

FIG. 13.6 Line voltage waveform for a six-level diode-clamped inverter.

13.2.2.1 Advantages

- All the phases share a common dc bus, which minimizes the capacitance requirements of the converter. For this reason, a back-to-back topology is not only possible but also practical for uses such as a high-voltage back-to-back interconnection or an adjustable speed drive.
- The capacitors can be precharged as a group.
- Efficiency is high for fundamental frequency switching.

13.2.2.2 Disadvantages

- Real power flow is difficult for a single inverter because the intermediate dc levels will tend to overcharge or discharge without precise monitoring and control.
- The number of clamping diodes required is quadratically related to the number of levels, which can be cumbersome for units with a high number of levels.

13.2.3 Flying-Capacitor Multilevel Inverter

Meynard and Foch introduced a flying-capacitor-based inverter in 1992 [31]. The structure of this inverter is similar to that of the diode-clamped inverter except that instead of using clamping diodes, the inverter uses capacitors. The circuit topology of the flying-capacitor multilevel inverter is shown in Fig. 13.7. This topology has a ladder structure of dc side capacitors, where the voltage on each capacitor differs from that of the next capacitor. The voltage increment between two adjacent capacitor legs gives the size of the voltage steps in the output waveform.

One advantage of the flying-capacitor-based inverter is that it has redundancies for inner voltage levels, that is, two or more valid switch combinations can synthesize an output voltage. Table 13.2 shows a list of all the combinations of phase voltage levels that are possible for the six-level circuit shown in Fig. 13.7. Unlike the diode-clamped inverter, the flying-capacitor inverter does not require all of the switches that are "on" (conducting) be in a consecutive series. Moreover, the flying-capacitor inverter has "phase" redundancies, whereas the diode-clamped inverter has only "line-line" redundancies [2,3,32]. These redundancies allow a choice of charging or discharging specific capacitors and can be incorporated in the control system for balancing the voltages across the various levels.

In addition to the $(m-1)$ dc link capacitors, the m-level flying-capacitor multilevel inverter will require $(m-1)\times(m-2)/2$ auxiliary capacitors per phase if the voltage rating of the capacitors is identical to that of the main switches. One application proposed

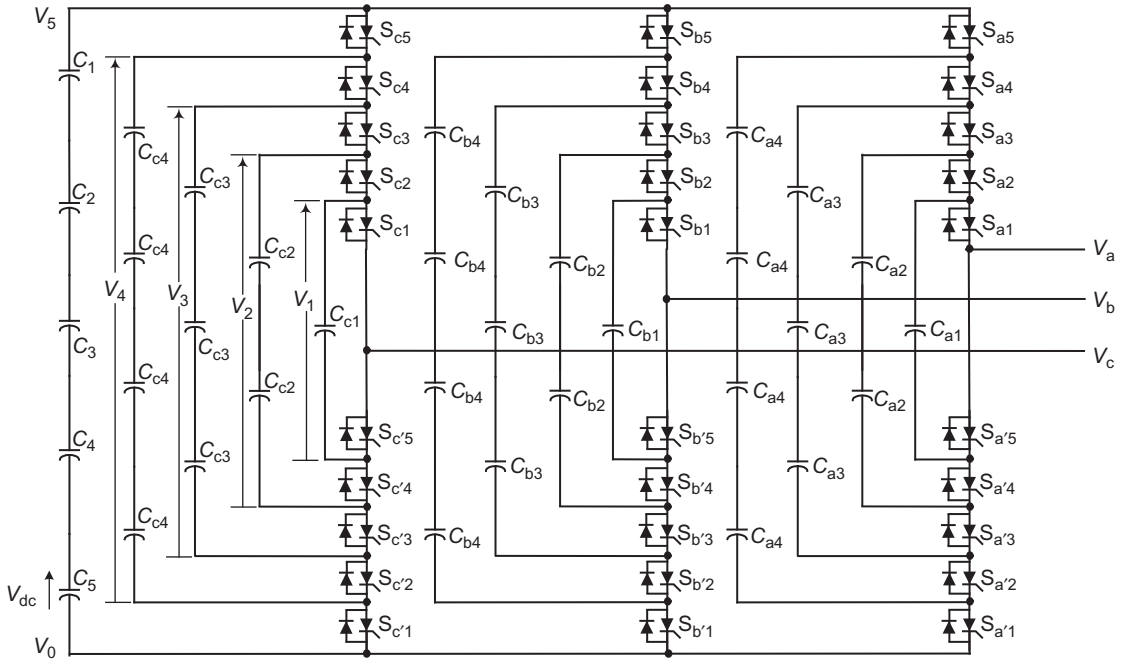

FIG. 13.7 Three-phase six-level structure of a flying-capacitor inverter.

in the literature for the multilevel flying capacitor is static var generation [2,3]. The main advantages and disadvantages of multilevel flying-capacitor converters are as follows [2,3]:

13.2.3.1 Advantages

- Phase redundancies are available for balancing the voltage levels of the capacitors.
- Real and reactive power flow can be controlled.
- The large number of capacitors enables the inverter to ride through short duration outages and deep voltage sags.

13.2.3.2 Disadvantages

- Control is complicated to track the voltage levels for all of the capacitors. Also, precharging all of the capacitors to the same voltage level and start-up is complex.
- Switching utilization and efficiency is poor for real power transmission.
- The large number of capacitors is both more expensive and bulky than clamping diodes in multilevel diode-clamped converters. Packaging is also more difficult in inverters with a high number of levels.

13.2.4 Modular Mutilevel Inverter Structures

The modular multilevel converter (MMC) was first introduced by Marquardt in 2001 [33]. The configuration of a MMC is shown in Fig. 13.8A. Each phase leg of the MMC consists of one upper and one lower arm connected in series between the dc terminals. N series-connected SMs and one arm inductor L_{arm} form an arm. Each SM can be realized by a half-bridge [34] [35], H-bridge [36] [37], or clamp-double [38] circuit, as illustrated in Fig. 13.8B–D.

Among these, the MMC with half-bridge SM does not have any intrinsic fault current-limiting or current-blocking capability. Under a dc short-circuit fault, the fault current can flow from the ac side to the faulted dc side through the antiparalleled diodes of the controllable power switches, even though these switches are turned off. Therefore, fast-acting dc breakers are necessary to protect the system from damage. On the other hand, the H-bridge SM is capable of generating negative capacitor voltage, which can be used to block the fault current. However, compared with the half-bridge SM, the H-bridge one has twice the number of semiconductor devices, leading to higher cost and operating losses. For the "clamp-double" SM in Fig. 13.8D, power device T_5 always conducts under normal operation conditions, making the clamp-double SM equivalent to two series-connected half-bridge SMs. Under a dc side fault, T_5 is turned off, and dc voltage is inserted by both capacitors to minimize the dc fault current. Compared with the H-bridge SM, the output voltage of clamp-double SM can be doubled, with additional conduction loss of T_5.

Due to the lower cost and higher efficiency, the MMC with half-bridge SMs is used for most of the commercial HVDC projects [39]. Therefore, the basic operation principle of an MMC with half bridge will be introduced in this section. As illustrated in Fig. 13.9B, each half-bridge SM contains two IGBTs as switching elements and a DC storage capacitor C_{sub}. A SM is considered to be bypassed if the lower switch is closed and the upper switch is open, while if the lower switch is open

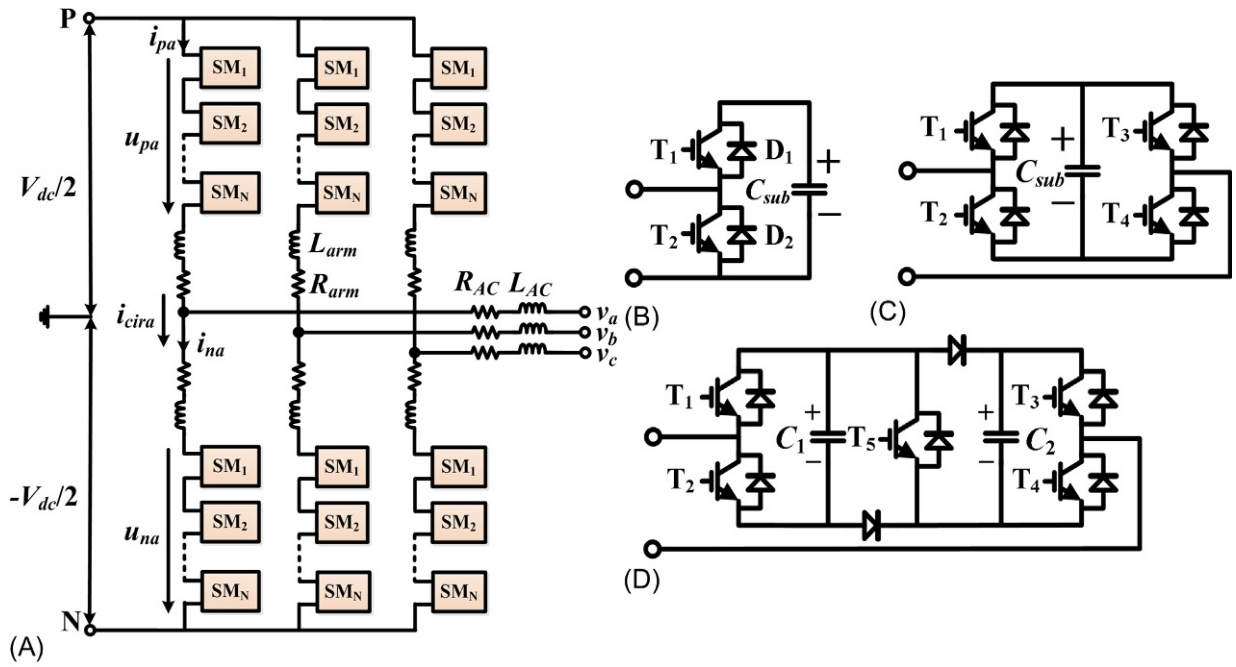

FIG. 13.8 (A) Circuit configuration of a MMC with (B) half-bridge cell, (C) full-bridge cell, and (D) clamp-double cell.

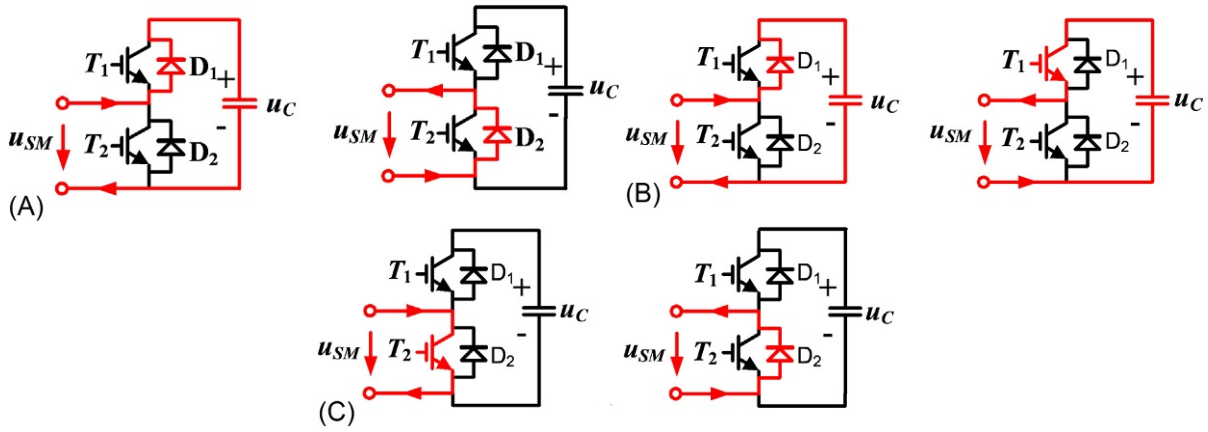

FIG. 13.9 States and current paths of an SM in the MMC converter, (A) both IGBTs are switched off, (B) IGBT1 is switched on, IGBT2 is switched off, (C) IGBT1 is switched off, and IGBT2 is switched on.

and the upper switch is closed, the SM is inserted. Three different states are relevant for the proper operation of an SM, as illustrated in Fig. 13.9:

1. Both IGBTs are switched off.
   This case does not occur during normal operation with power transfer. Upon charging, that is, after closing the AC power switch, all SMs of the converter are under this condition. In the event of a serious failure, all SMs of the converter should return to this state. If the current flows from the AC terminal to the dc side during this state, the flow passes through diode D_1 and charges the capacitor. When it flows in the opposite direction, the freewheeling diode D_2 conducts and bypasses the capacitor.
2. IGBT1 (T_1) is switched on, and IGBT2 (T_2) is switched off.
   Irrespective of the current flow direction, the voltage of the storage capacitor is applied to the terminals of the SM. Depending on the current direction, the current either flows through D_1 and charges the SM capacitor or flows through T_1 and discharges the SM capacitor.
3. IGBT1 is switched off, and IGBT2 is switched on.
   In this case, the current flows through either T_2 or D_2 depending on its direction, which ensures that zero voltage is applied to the terminals of the SM. The voltage in the capacitor remains unchanged.

It is thereby possible to separately and selectively control each of the individual SMs in a converter leg. In principle, the two converter arms of each phase represent a controllable voltage source. In this arrangement, the total voltage generated by the upper and lower arm SMs in one phase unit should equal to the dc link voltage. By adjusting the output voltage of SMs in both arms, that is, inserting and bypassing of SM capacitors according to a switching pattern created by a modulator, the desired sinusoidal voltage at the AC terminal can easily be achieved.

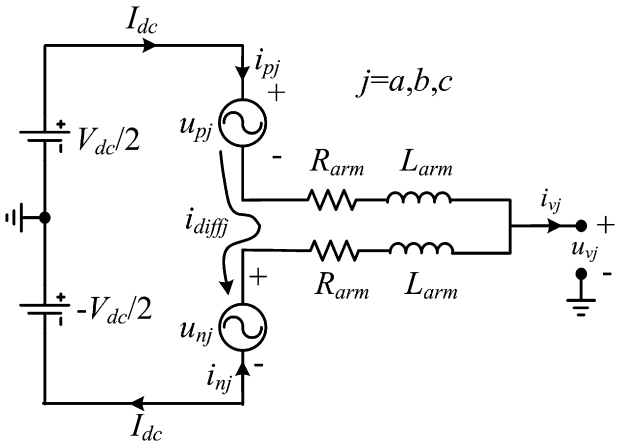

FIG. 13.10 Single-phase equivalent circuit of the MMC.

Fig. 13.10 illustrates the equivalent circuit of the MMC. L_{arm} and R_{arm} are the arm inductance and equivalent arm resistance, respectively. V_{dc} and I_{dc} are the total dc bus voltage and dc current individually. u_{vj} is the converter output voltage of j phase at point v, whereas i_{vj} is the corresponding line current. The arm voltages generated by the cascaded SMs are expressed as u_{pj} and u_{nj}, where the subscripts p and n denote the upper (positive) and lower (negative) arms, respectively. i_{pj} and i_{nj} are the corresponding arm currents, which can be expressed as

$$\begin{aligned} i_{pj} &= \frac{i_{vj}}{2} + i_{diffj} \\ i_{nj} &= \frac{i_{vj}}{2} - i_{diffj} \end{aligned} \tag{13.3}$$

where i_{diffj} denotes the inner circulating current of phase j, which flows through both the upper and lower arms and is given as

$$i_{diffj} = \frac{i_{pj} - i_{nj}}{2}. \tag{13.4}$$

According to [40], the MMC can be characterized by the following equations:

$$u_{vj} = e_j - \frac{R_{arm}}{2} \cdot i_{vj} - \frac{L_{arm}}{2} \cdot \frac{di_{vj}}{dt} \quad (j = a,b,c) \tag{13.5}$$

$$R_{arm} \cdot i_{diffj} + L_{arm} \cdot \frac{di_{diffj}}{dt} = \frac{V_{dc}}{2} - \frac{u_{nj} + u_{pj}}{2} \quad (j = a,b,c) \tag{13.6}$$

where e_j in (13.5) is the inner emf generated in a phase and

$$e_j = \frac{u_{nj} - u_{pj}}{2} \tag{13.7}$$

According to (13.5), when u_{vj} is regarded as the ac network voltage, the current i_{vj} can be controlled directly by regulating the control variable e_j. The inner dynamic performance of the MMC is characterized by (13.6) and can be redefined as

$$u_{diffj} = R_{arm} \cdot i_{diffj} + L_{arm} \cdot \frac{di_{diffj}}{dt} = \frac{V_{dc}}{2} - \frac{u_{nj} + u_{pj}}{2} \quad (j = a,b,c) \tag{13.8}$$

where u_{diffj} is the inner unbalance voltage of phase j.

According to (13.8), the circulating current i_{diffj} can be controlled by regulating the unbalance voltage u_{diffj}. Combining (13.7) and (13.8), the arm voltage references are

$$\begin{aligned} u_{pj_ref} &= \frac{V_{dc}}{2} - e_j - u_{diffj} \\ u_{nj_ref} &= \frac{V_{dc}}{2} + e_j - u_{diffj} \end{aligned} \tag{13.9}$$

Because the same voltage u_{diffj} is subtracted from u_{pj_ref} and u_{nj_ref}, according to (13.5) and (13.7), the resulting e_j will not change, and thus, the ac side dynamics are not affected. As previously described, the reference of e_j is generated from the traditional system control loops, whereas the inner unbalance voltage u_{diffj} is used to control the MMC inner dynamic performance including the three-phase inner circulating currents.

Due to its unique structure, MMC has two typical issues, which will be discussed in the following sections.

(1) *SM capacitor voltage balancing*

According to the operating principle described above, the arm current in an MMC will only flow through the SM capacitor when the upper switch turns on and the SM is inserted. However, determined by various modulation schemes, the switching state for SMs is different from each other, leading to different charging/discharging times of the SM capacitors and thus voltage deviations. These unbalanced SM capacitor voltages generate the output voltage distortion and bring high-voltage stress to SM capacitors, as illustrated in

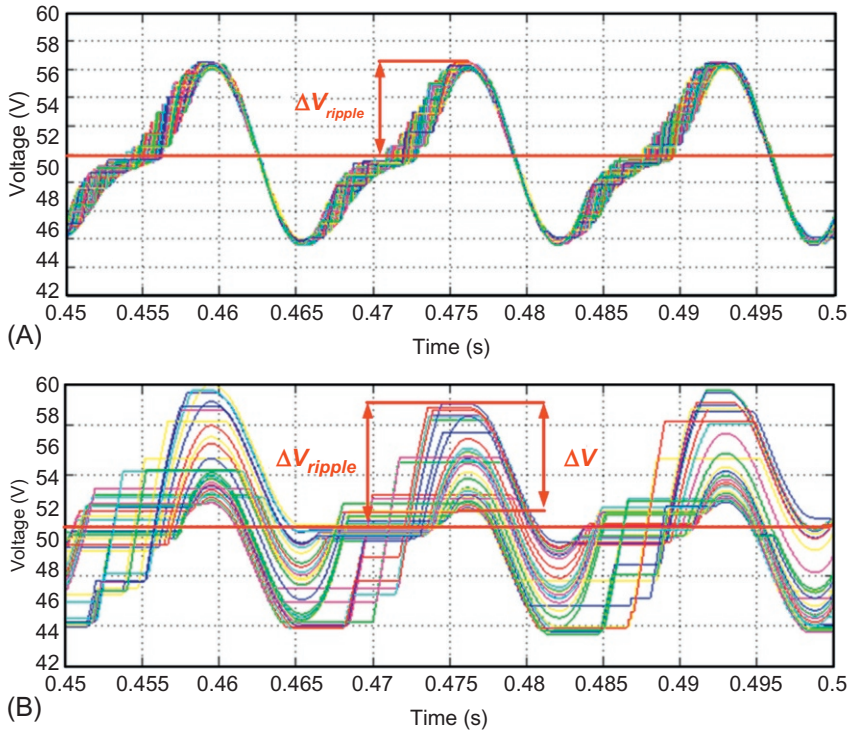

FIG. 13.11 SM capacitor voltages in well-balanced and poorly balanced conditions, (A) well-balanced capacitor voltage and (B) unbalanced capacitor voltage.

Fig. 13.11. To address this issue, several voltage-balancing control schemes have been proposed over the last decade.

In [41], a voltage-balancing control consisting of an averaging control, individual-balancing control, and arm-balancing control was proposed for phase-shifted modulation schemes. The most widely accepted voltage-balancing control is based on a sorting method [42] [43]. The selection criteria are based on (1) SM capacitor voltages and (2) the direction of the arm currents. If the arm current is charging the capacitors, the SMs with the lowest capacitor voltages will be inserted. On the other hand, if the arm current is discharging the capacitors, the SMs with the highest capacitor voltages will be inserted. With this algorithm, the SM capacitor voltages can be well balanced. Here, the total SMs that need to be inserted can be calculated based on different modulation schemes introduced earlier.

The main disadvantage of the above algorithms is the unnecessary switching actions of the SMs. Even if the capacitor voltage deviation is quite low and/or the number of required on-state SMs keep the same within two consecutive control periods, the SM insertion and bypassing may still occur, leading to increased switching frequency and loss. A modified sorting method has been proposed in [44] to avoid the high switching frequency, as shown in Fig. 13.12. In this method, a voltage deviation threshold is set, and the SM switching states only vary under the following two cases:

Case 1: The voltage deviation is larger than the predefined threshold (V_{th}).

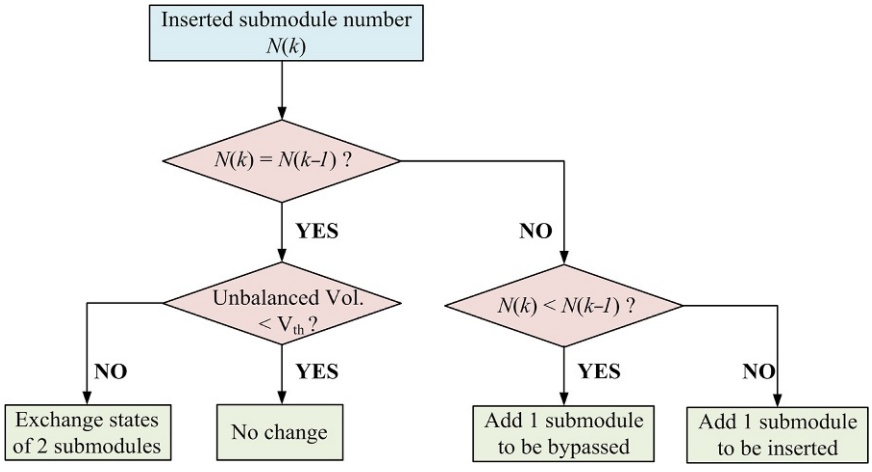
Case 2: Different number of SMs need to be inserted.

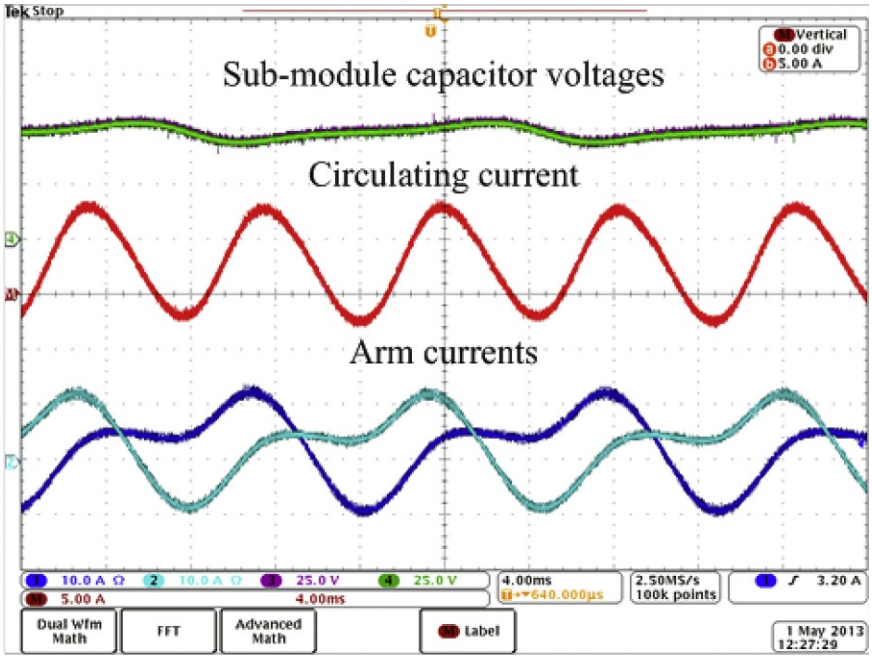
In Case 1, two SM operation status will be changed based on the arm current direction. If the arm current is charging the capacitors, the SM with the highest capacitor voltage will be bypassed, and the SM with the lowest capacitor voltage will be inserted. If the current is discharging the capacitors in that arm, the SM with the lowest capacitor voltage is bypassed, and the SM with the highest capacitor voltage is inserted. For Case 2, an additional SM will be inserted or bypassed, and the same SM selection scheme in Case 1 is utilized. Due to its easy implementation and reduced switching losses, this modified sorting method with a capacitor voltage deviation threshold is widely used for MMC control.

(2) *Circulating current control*

According to (13.6), if the SM capacitor voltage in Fig. 13.8 equals to V_{dc}/N (V_{dc} is dc link voltage, and N is SM number per arm) all the time, no circulating current will be generated. However, in a real MMC converter, low-frequency voltage ripples exist due to alternating arm current. For modulation schemes assuming constant SM capacitor voltages, for example, the direct modulation in [43], the inserted SM voltages in different half bridges could be different, inducing circulating current among the three phases. The circulating current will not affect the ac output voltage and currents. However, if it is not effectively suppressed, it increases the peak and RMS values of the arm currents, leading to high power losses and large SM capacitor voltage ripples. Under normal operation conditions, the dominant circulating current is negative sequence with second-order harmonic frequency [45,46]. Although the circulating current can be effectively mitigated by increasing the arm inductance, active suppression control schemes are preferred for lower converter volume and cost. A comparative experimental result with and without circulating current suppression control is given in Fig. 13.13 as an example.

Several circulating current suppressing control schemes have been proposed to reduce the circulating current in an MMC [47,48]. The basic idea of these control schemes is injecting a common mode arm





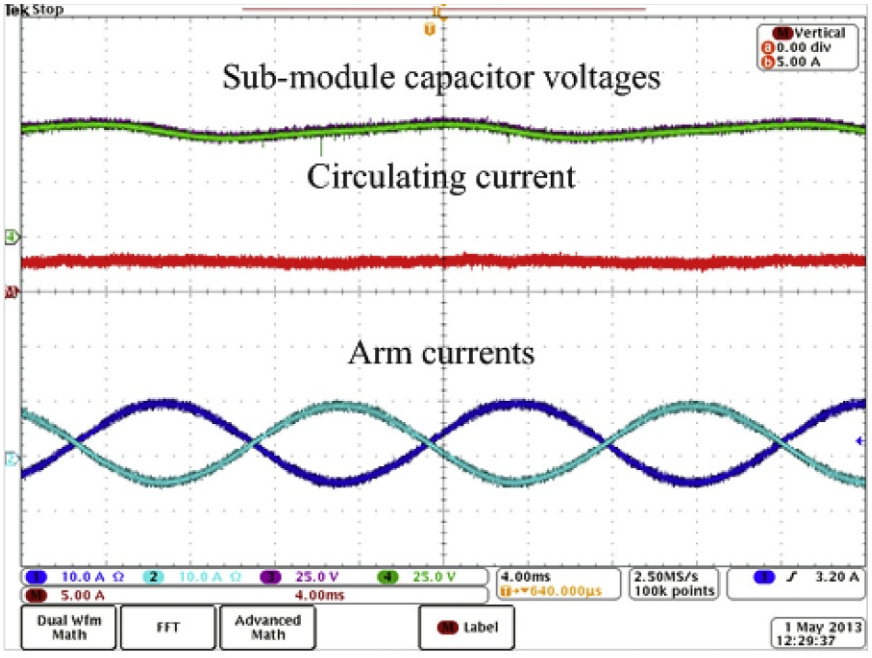


FIG. 13.12 Modified sorting algorithm in Ref. [44].

(A)

(B)

FIG. 13.13 Experimental results with $L_{arm} = 1$ mH and (A) circulating current suppressing control disabled and (B) circulating current suppressing control enabled.

voltage to counteract the submodule capacitor voltage variation. In the indirect modulation schemes proposed in [49,50], the sum of instantaneous capacitor voltages instead of the constant dc link voltage is used for insertion index calculation. In addition, the calculated or estimated total capacitor energy and the unbalanced arm energy are regulated, which inherently limit the circulating current. The second-order circulating current was transformed to d-q coordinates and controlled by a pair of PI controllers in [47]. During normal conditions, the dominant negative sequence second-order circulating current becomes dc components under d-q coordinates

and can be eliminated without steady-state error. However, under ac grid unbalanced conditions, positive and/or zero-sequence circulating current will also be generated, which are ac components under the previous d-q coordinates and cannot be completely removed [51]. As a solution, proportional-resonant (PR)-based controllers were developed in [52,53], targeting elimination of all second-order components in circulating current under abc or αβ coordinates.

13.2.4.1 Advantages

- The number of SMs in each arm depends on the HVDC voltage level and individual IGBT device voltage. For example, with N series-connected SMs per arm, voltage rating of devices is reduced to V_{dc}/N (V_{dc} is dc link voltage), which eliminates the direct series connection of devices in two- and three-level converters. Given that the IGBT ratings are in kV level and HVDC rating is typically in hundreds of kV, often several hundred SMs are used for one MMC [54].
- Higher quality output voltage. With higher number of SMs in each arm (N), the output phase voltage of MMC becomes much more sinusoidal, which enables smaller ac filters, lower cost and compact converter footprint, as illustrated in Fig. 13.14.
- Lower switching frequency and higher efficiency. The series connection of N SMs per arm can achieve an equivalent switching frequency of Nf_c (f_c represents carrier frequency of each device) in the output voltage. In practical applications, the device average switching frequency is generally below 200 Hz. Consequently, state-of-the-art MMC-HVDC has loss level about 1%, close to that of LCC.
- Lower high-frequency noise due to reduced dv/dt and di/dt.
- Modular design and inherent redundancy. The modular design of MMC contributes to lower cost, shorter manufacturing as well as maintenance period, and high extensibility for higher voltage and power applications. Furthermore, the system becomes more reliable since failed SMs can be easily replaced by redundant ones [55].

The comparison of site footprint, building area, and building volumes for LCC-HVDC (Grita project, 500 MW and 400 kV), two-level VSC-HVDC, and half-bridge MMC-HVDC (EWIC project, 500 MW and ±200 kV) is presented in Table 13.3, using the Grita project as the 100% reference [56]. Different from LCC-HVDC, the converter reactors and dc yard equipment in VSC-HVDC are mounted in converter buildings, which provide more convenient maintenance, improved personal safety, lower high-frequency emissions and acoustic noise, and protection for equipment from adverse weather.

Without the requirement for reactive power compensation, the overall site area for two-level VSC-HVDC is 77% of that for LCC-HVDC, in spite of its higher converter building footprint, height, and volume. By adopting MMC, the site area is further reduced to only 58% of the reference value, and lower building height is achieved because of a decreased internal suspension height of converter valves. The overall site area reduction of MMC-HVDC supplies a significant benefit, especially for locations with restricted available area and/or high land price.

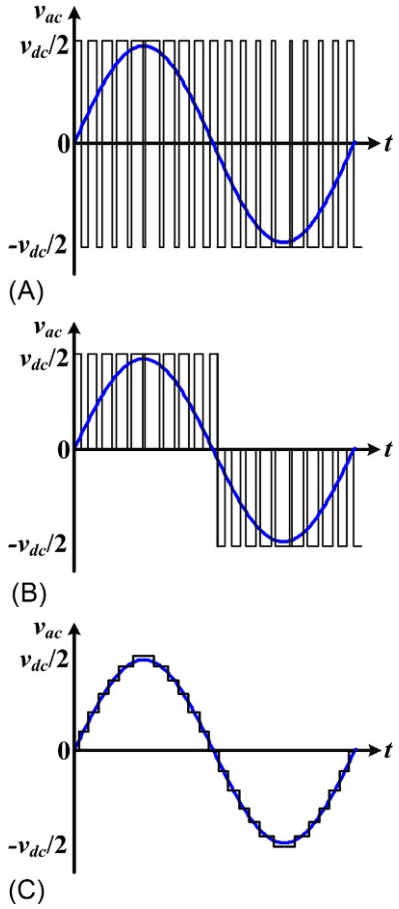

FIG. 13.14 Output ac voltage of a (A) two-level converter, (B) three-level converter, and (C) MMC.

13.2.4.2 Disadvantages

- To meet the requirement for capacitor voltage ripple, C_{sub}/N should be constant, which makes the power stage dimensioning quite difficult, especially for a MMC with numerous SMs per arm. Each SM requires a gate drive, protection, capacitor voltage monitoring, and associated communication resources, which greatly increase the cost of the system.
- The control scheme becomes much more complicated than that in a two-level converter. In addition to the generic upper level control to meet the overall system behavior requirements (V_{dc}-Q, P-Q, etc.), the capacitor voltage-balancing control and circulating current suppression control are indispensable in a MMC for desirable

TABLE 13.3 Comparison of site areas among LCC and two-level VSC- and MMC-based HVDC systems [56]

	Site footprint	Site area (%)	Max building height (%)	Converter building footprint	Converter building area (%)	Converter building volume (%)
LCC-HVDC (reference)	225 m × 120 m	27,000 m^2 (100%)	20 m (100%)	35 m × 20 m	700 m^2 (100%)	14,000 m^2 (100%)
Two-level VSC	180 m × 115 m	20,700 m^2 (77%)	24 m (120%)	38 m × 35 m	1330 m^2 (190%)	25,000 m^2 (179%)
Half-bridge MMC-HVDC	165 m × 95 m	15,675 m^2 (58%)	15 m (75%)	70 m × 45 m	2730 m^2 (390%)	29,500 m^2 (211%)

operation performance, and to lower the voltage and current stress applied on semiconductor devices and passive components. Because of the demand for accurate capacitor voltage and arm current detection and/or high-speed communication, these control schemes will introduce considerable expense and computing burden to the control unit.

13.2.5 Other Multilevel Inverter Structures

Besides the four basic multilevel inverter topologies discussed earlier, other multilevel converter topologies have been proposed; however, most of these are "hybrid" circuits that are combinations of two of the basic multilevel topologies or slight variations to them. In addition, the combination of multilevel power converters can be designed to match with a specific application based on the basic topologies. In the interest of completeness, some of these will be identified and briefly described.

13.2.4.1 Generalized Multilevel Topology

Existing multilevel converters such as diode-clamped and capacitor-clamped multilevel converters can be derived from the generalized converter topology called P2 topology proposed by Peng [57] as shown in Fig. 13.15. The generalized multilevel converter topology can balance each voltage level by itself regardless of load characteristics, active or reactive power conversion, and without any assistance from other circuits at any number of levels automatically. Thus, the topology provides a complete multilevel topology that embraces the existing multilevel converters in principle.

Fig. 13.15 shows the P2 multilevel converter structure per phase leg. Each switching device, diode, or capacitor's voltage is $1V_{dc}$, for instance, $1/(m-1)$ of the dc link voltage. Any converter with any number of levels, including the conventional bilevel converter, can be obtained using this generalized topology [1,57].

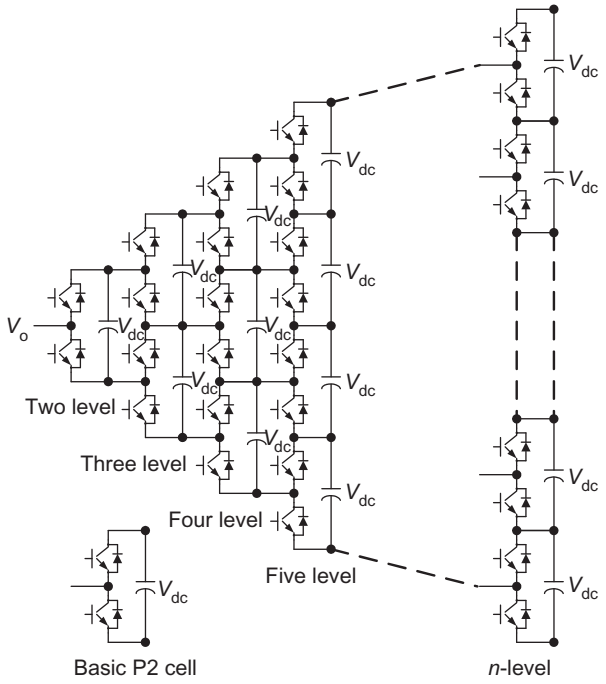

FIG. 13.15 Generalized P2 multilevel converter topology for one phase leg.

13.2.4.2 Mixed-Level Hybrid Multilevel Converter

To reduce the number of separate dc sources for high-voltage,-high-power applications with multilevel converters, diode-clamped or capacitor-clamped converters can be used to replace the full-bridge cell in a cascaded converter [58]. An example is shown in Fig. 13.16. The nine-level cascade converter incorporates a three-level diode-clamped converter as the cell. The original cascaded H-bridge multilevel converter requires four separate dc sources for one phase leg and 12 for a three-phase converter. If a five-level converter replaces the full-bridge cell, the voltage level is effectively doubled for each cell. Thus, to achieve the same nine voltage levels for each phase, only two separate dc sources are needed for one phase leg and six for a three-phase converter. The configuration has mixed-level hybrid multilevel units because it embeds multilevel cells as the building block of the cascade converter. The advantage of the topology is it needs less separate dc sources. The disadvantage for the topology is its control will be complicated due to its hybrid structure.

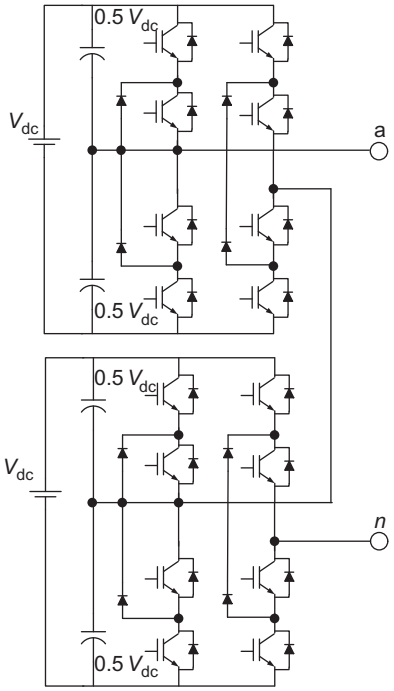

FIG. 13.16 Mixed-level hybrid unit configuration using the three-level diode-clamped converter as the cascaded converter cell to increase the voltage levels.

13.2.4.3 Soft-Switched Multilevel Converter

Some soft-switching methods can be implemented for different multilevel converters to reduce the switching loss and to increase efficiency. For the cascaded converter, because each converter cell is a bilevel circuit, the implementation of soft switching is not at all different from that of conventional bilevel converters. For capacitor-clamped or diode-clamped converters, soft-switching circuits have been proposed with different circuit combinations. One of the soft-switching circuits is a zero-voltage-switching type that includes auxiliary resonant commutated pole (ARCP), coupled inductor with zero-voltage transition (ZVT), and their combinations [1,59] as shown in Fig. 13.17.

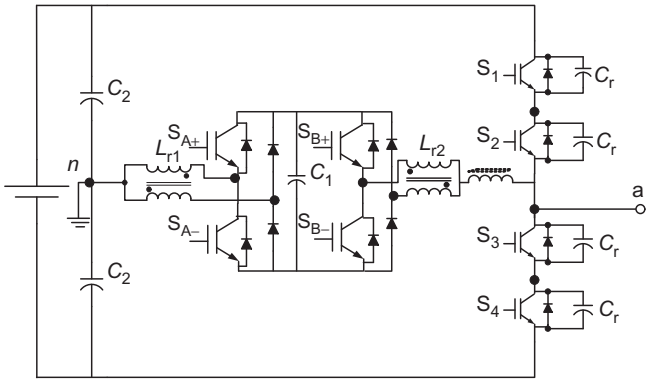

FIG. 13.17 Zero-voltage-switching capacitor-clamped inverter circuit.

13.2.4.4 Back-to-Back Diode-Clamped Converter

Two multilevel converters can be connected in a back-to-back arrangement, and then, the combination can be connected to the electric system in a series-parallel arrangement as shown in Fig. 13.18. Both the current demanded from the utility and the voltage delivered to the load can be controlled at the same time. This series-parallel active power filter has been referred to as a universal power conditioner [60–66] when used on electric distribution systems and as a universal power flow controller [67–71] when applied at the transmission level. Earlier, Lai and Peng [29] proposed the back-to-back diode-clamped topology shown in Fig. 13.19 for use as a high-voltage dc interconnection between two asynchronous ac systems or as a rectifier or inverter for an adjustable speed drive for high-voltage motors. The diode-clamped inverter has been chosen over the other two basic multilevel circuit topologies for use in a universal power conditioner for the following reasons:

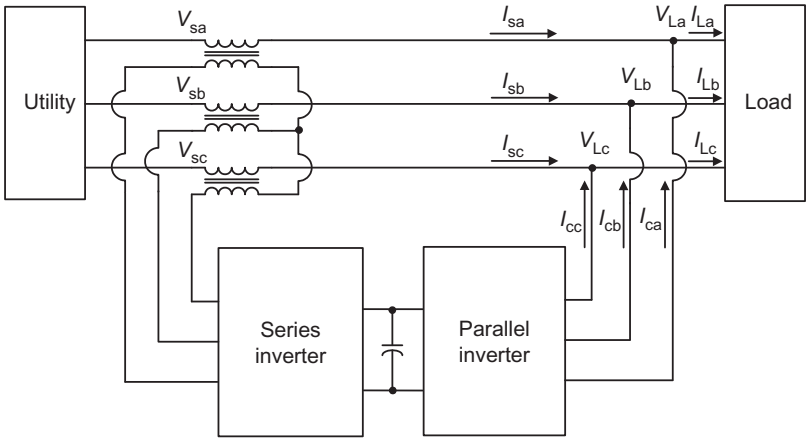

FIG. 13.18 Series-parallel connection to electric system of two back-to-back inverters.

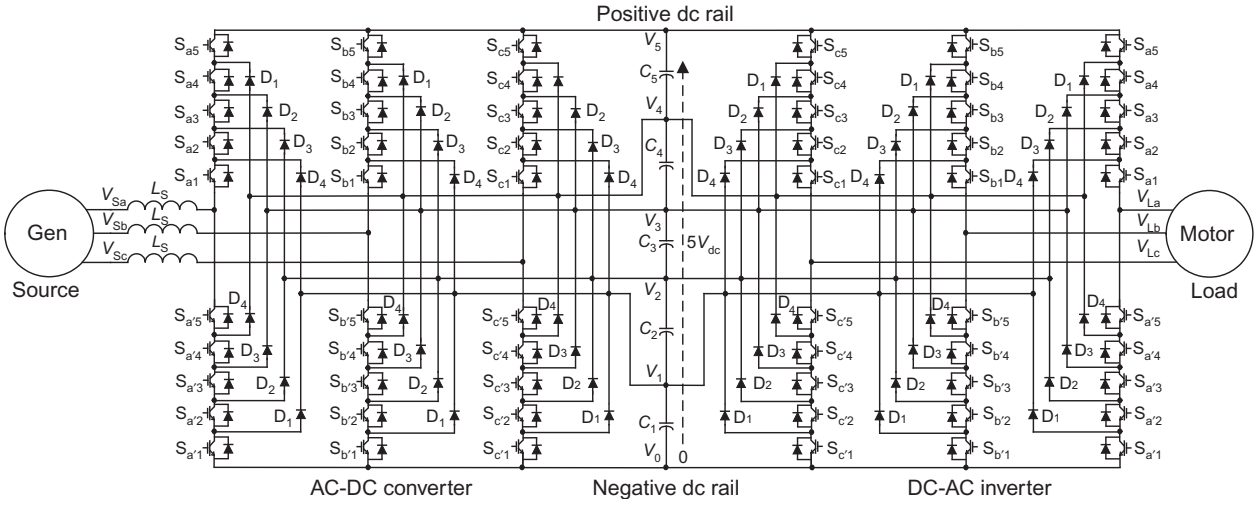

FIG. 13.19 Six-level diode-clamped back-to-back converter structure.

- All six phases (three on each inverter) can share a common dc link. Conversely, the cascade inverter requires that each dc level to be separate, and this is not conducive to a back-to-back arrangement.
- The multilevel flying-capacitor converter also shares a common dc link; however, each phase leg requires several additional auxiliary capacitors. These extra capacitors would add substantially to the cost and the size of the conditioner.

Because a diode-clamped converter acting as a universal power conditioner will be expected to compensate for harmonics and/or operate in low-amplitude modulation index regions, a more sophisticated higher frequency switch control than the fundamental frequency switching method will be needed. For this reason, multilevel space vector and carrier-based PWM approaches are compared in the next section and novel carrier-based PWM methodologies are given.

13.3 Multilevel Converter PWM Modulation Strategies

Pulse-width modulation strategies used in a conventional inverter can be modified to use in multilevel converters. The advent of the multilevel converter PWM modulation methodologies can be classified according to switching frequency as shown in Fig. 13.20. The three multilevel PWM methods most discussed in the literature have been multilevel carrier-based

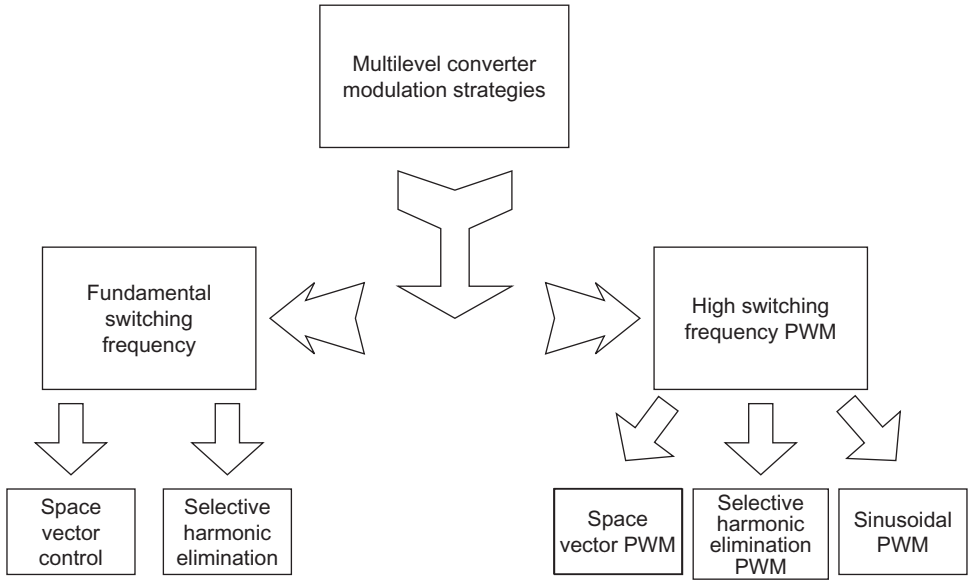

FIG. 13.20 Classification of PWM multilevel converter modulation strategies.

PWM, selective harmonic elimination, and multilevel space vector PWM, which are all extensions of traditional two-level PWM strategies to several levels. Other multilevel PWM methods have been used to a much lesser extent by researchers; therefore, only the three major techniques will be discussed in detail in this chapter.

On the other hand, for MMC with tens to hundreds of SMs, new modulation schemes, for example, nearest level control (NLC), have been proposed for lower switching frequency and easy implementation, which will also be introduced in this chapter.

13.3.1 Multilevel Carrier-Based PWM

Several different two-level, carrier-based PWM techniques have been extended to multiple levels as a means for controlling the active devices in a multilevel converter. The most popular and easiest technique to implement uses several triangle carrier signals and one reference, or modulation, signal per phase. Fig. 13.21 illustrates three major techniques used in a conventional inverter that can be applied in a multilevel inverter: sinusoidal PWM (SPWM), third-harmonic injection PWM (THPWM), and space vector PWM (SVM). SPWM is a very popular method in industrial applications.

In order to achieve better dc link utilization at high modulation indexes, the sinusoidal reference signal can be injected by a third harmonic with a magnitude equal to 15% of the fundamental; its line-line output voltage is shown in Fig. 13.21B. As can be seen in Fig. 13.21B and C, the reference signals have some margin at unity amplitude modulation index. Obviously, the dc utilization of THPWM and SVM are better than SPWM in the linear modulation region. The dc utilization means the ratio of the output fundamental voltage to the dc link voltage. Other interesting carrier-based multilevel PWM are subharmonic PWM (SH-PWM) and switching frequency optimal PWM (SFO-PWM). Some particular aspects of these carrier-based methods are discussed as follows.

13.3.1.1 Subharmonic PWM

Carrara et al. [72] extended SH-PWM to multiple levels as follows: for an m-level inverter, $m-1$ carriers with the same frequency f_c and the same amplitude A_c are disposed such that the bands they occupy are contiguous. The reference waveform has peak-to-peak amplitude A_m, a frequency f_m, and its zero centered in the middle of the carrier set. The reference signal is continuously compared with each of the carrier signals. If the reference signal is greater than a carrier signal, then the active device corresponding to that carrier is switched on, and if the reference signal is lesser than a carrier signal, then the active device corresponding to that carrier is switched off.

In multilevel inverters, the amplitude modulation index, m_a, and the frequency ratio, m_f, are defined as

$$m_a = \frac{A_m}{(m-1)\cdot A_c} \tag{13.10}$$

$$m_f = \frac{f_c}{f_m} \tag{13.11}$$

Fig. 13.22 shows a set of carriers $(m_f = 21)$ for a six-level diode-clamped inverter and a sinusoidal reference or modulation waveform, with an amplitude modulation index of 0.8. Fig. 13.22 also shows the resulting output voltage of the inverter.

13.3.1.2 Switching Frequency Optimal PWM

Another carrier-based method that was extended to multilevel applications by Menzies et al. is termed *SFO-PWM*, and it is similar to SH-PWM except that a zero-sequence (triplen harmonic) voltage is added to each of the carrier waveforms [73]. This method takes the instantaneous average of the maximum and minimum of the three reference voltages $\left(V_a^*, V_b^*, V_c^*\right)$ and subtracts this value from each of the individual reference voltages, that is,

$$V_{offset} = \frac{\max\left(V_a^*, V_b^*, V_c^*\right) + \min\left(V_a^*, V_b^*, V_c^*\right)}{2} \tag{13.12}$$

$$V_{aSFO}^* = V_a^* - V_{offset} \tag{13.13}$$

$$V_{bSFO}^* = V_b^* - V_{offset} \tag{13.14}$$

$$V_{cSFO}^* = V_c^* - V_{offset} \tag{13.15}$$

The addition of this triplen-offset voltage centers all of the three reference waveforms in the carrier band, which is equivalent to using space vector PWM [74,75]. The analog equivalent of Eqs. (13.12)–(13.15) is shown in Fig. 13.23 [76]. The SFO-PWM is shown in Fig. 13.24 for the same reference voltage waveform that was used in Fig. 13.22. The resulting output voltage of the inverter is also shown in Fig. 13.24. The SFO-PWM technique enables the modulation index to be increased by 15% before the overmodulation region is reached.

For the SH-PWM and SFO-PWM techniques shown in Figs. 13.22 and 13.24, the top and bottom switches are switched much more often than the intermediate devices. Methods to balance or reduce the device switchings without an adverse effect on a multilevel inverter's output voltage total harmonic distortion would be beneficial. The development of such methods is discussed in [77]. A novel method to balance device switchings for all of the levels in a diode-clamped inverter has been demonstrated for SH-PWM and SFO-PWM by varying the frequency for the different triangle wave carrier bands as shown in Fig. 13.25 [77].

13.3.1.3 Modulation Index Effect on Level Utilization

For low-amplitude modulation indexes, a multilevel inverter will not make use of all of its levels, and at very low modulation indexes, it operates as if it is a traditional two-level inverter.

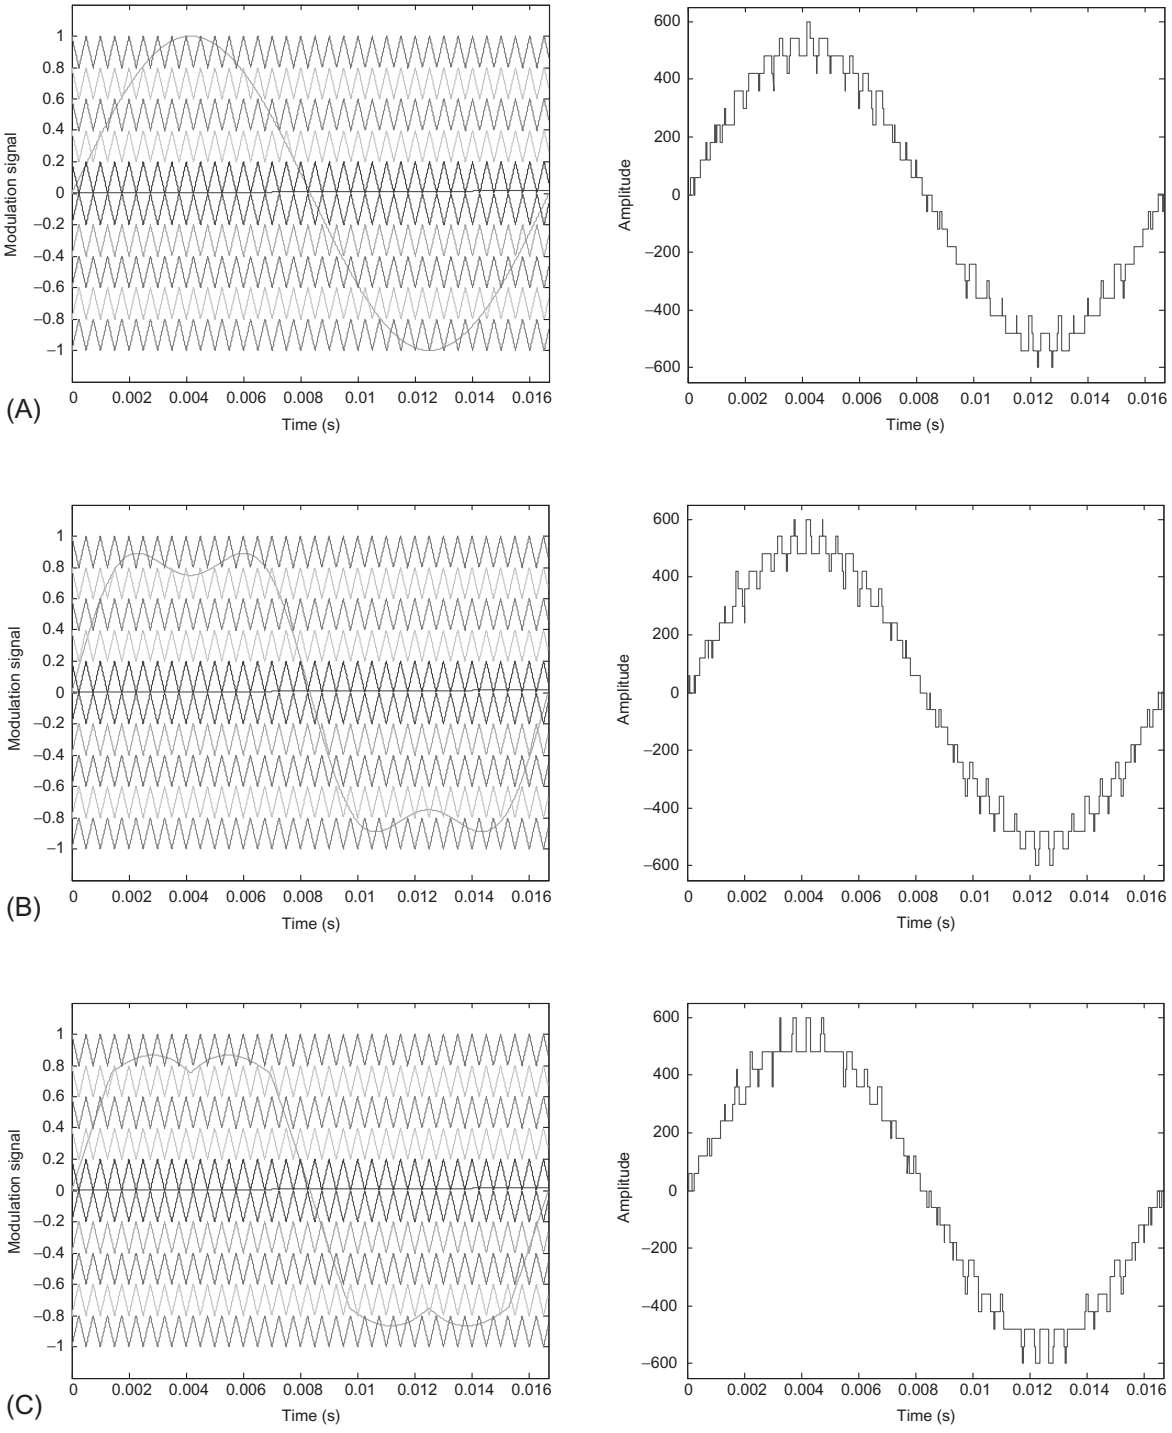

FIG. 13.21 Simulation of modulation signals and their line-line output voltage using five separate dc source (60 V for each dc source) cascaded multilevel inverter with three major conventional carrier-based PWM techniques at unity modulation index and 2 kHz switching frequency: (A) SPWM, (B) THPWM, and (C) SVM.

Fig. 13.26 shows two simulation results of what the output voltage waveform looks like at amplitude modulation indexes of 0.5 and 0.15. Fig. 13.26A shows how the bottom and top switches ($S_{a1} - S_{a'1}$, $S_{a5} - S_{a'5}$ in Fig. 13.5) are unused for amplitude modulation indexes less than 0.6 in a six-level inverter. Fig. 13.26B shows how only the middle switches ($S_{a3} - S_{a'3}$ in Fig. 13.5) change states when a six-level inverter is operated at an amplitude modulation index less than 0.2. The output waveform in Fig. 13.26B appears to be that of a traditional two-level inverter rather than a multilevel inverter.

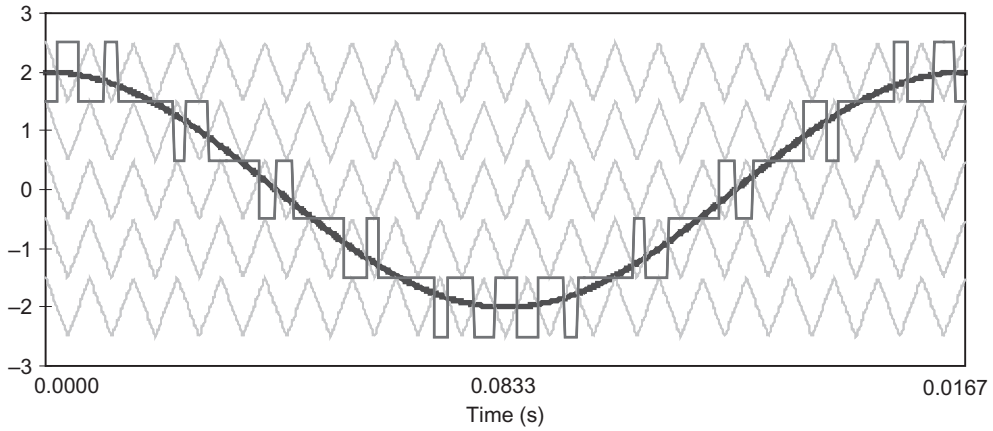

FIG. 13.22 Multilevel carrier-based SH-PWM showing carrier bands, modulation waveform, and inverter output waveform ($m = 6, m_f = 21, m_a = 0.8$).

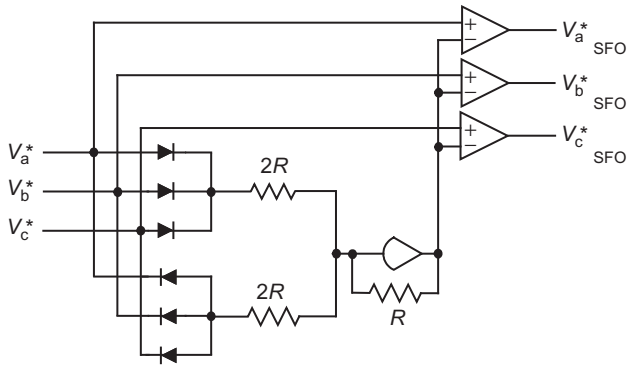

FIG. 13.23 Analog circuit for zero-sequence addition in SFO-PWM.

The minimum modulation index m_{amin}, for which a multilevel inverter controlled with SH-PWM makes use of all of its levels, m, is

$$m_{amin} = \frac{m-3}{m-1} \tag{13.16}$$

Table 13.4 lists the minimum modulation index in which a multilevel inverter uses all its constituent levels for both SH-PWM and SFO-PWM techniques. Table 13.4 also shows that the maximum modulation index before pulse dropping (overmodulation) occurs is 1.000 for SH-PWM and 1.155 for SFO-PWM. As shown in Table 13.4, when a multilevel inverter operates at modulation indexes much less than 1.000, not all of its levels are involved in the generation of the output voltage and simply remain in an unused state until the modulation index increases sufficiently. The table also shows that level usage is more likely to suffer to a greater extent as the number of levels in the inverter increases.

One way to make use of the multiple levels, even during low modulation periods, is to take advantage of the redundant output voltage states by rotating level usage in the inverter after each modulation cycle. This will reduce the switching stresses on some of the inner levels by making use of those outer voltage levels that otherwise would go unused.

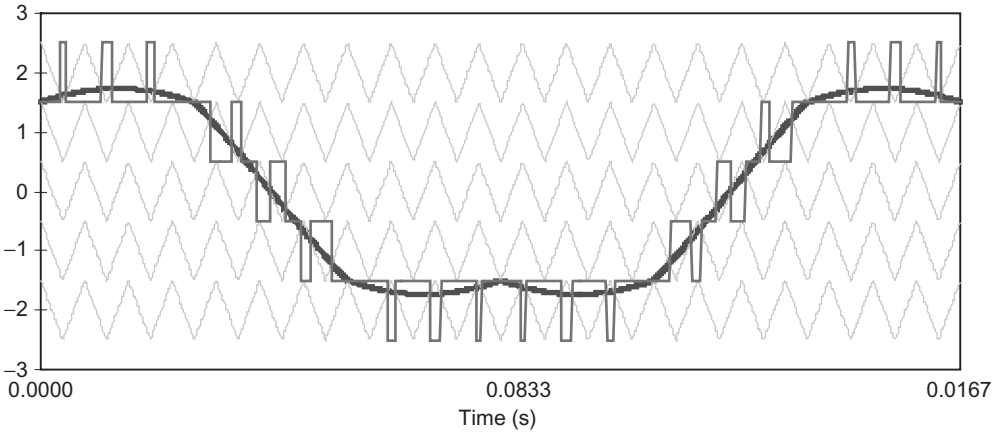

FIG. 13.24 Multilevel carrier-based SFO-PWM showing carrier bands, modulation waveform, and inverter output waveform ($m = 6, m_f = 21, m_a = 0.8$).

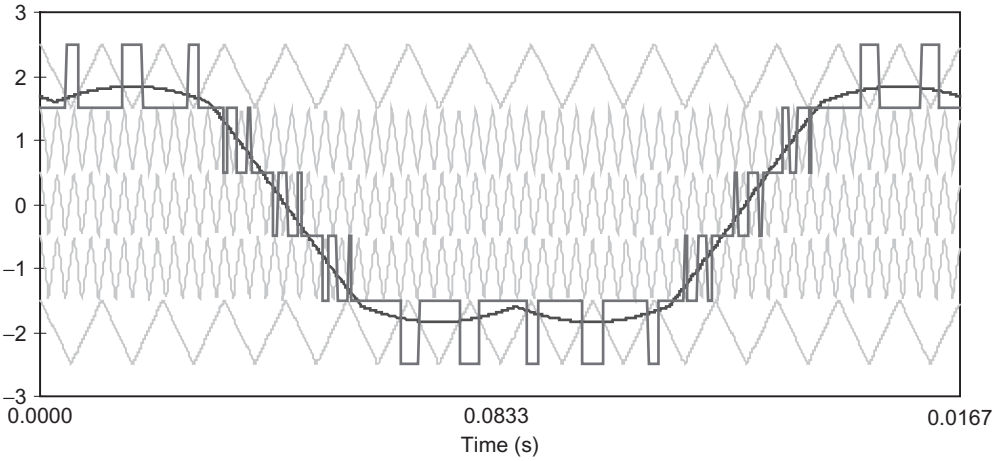

FIG. 13.25 SFO-PWM where carriers have different frequencies ($m_a = 0.85, m_f = 15$ for $Band_2$, $Band_{-2}$; $m_f = 55$ for $Band_1$, $Band_{-1}$; $Band_0$, $\phi = 0.10$ rad).

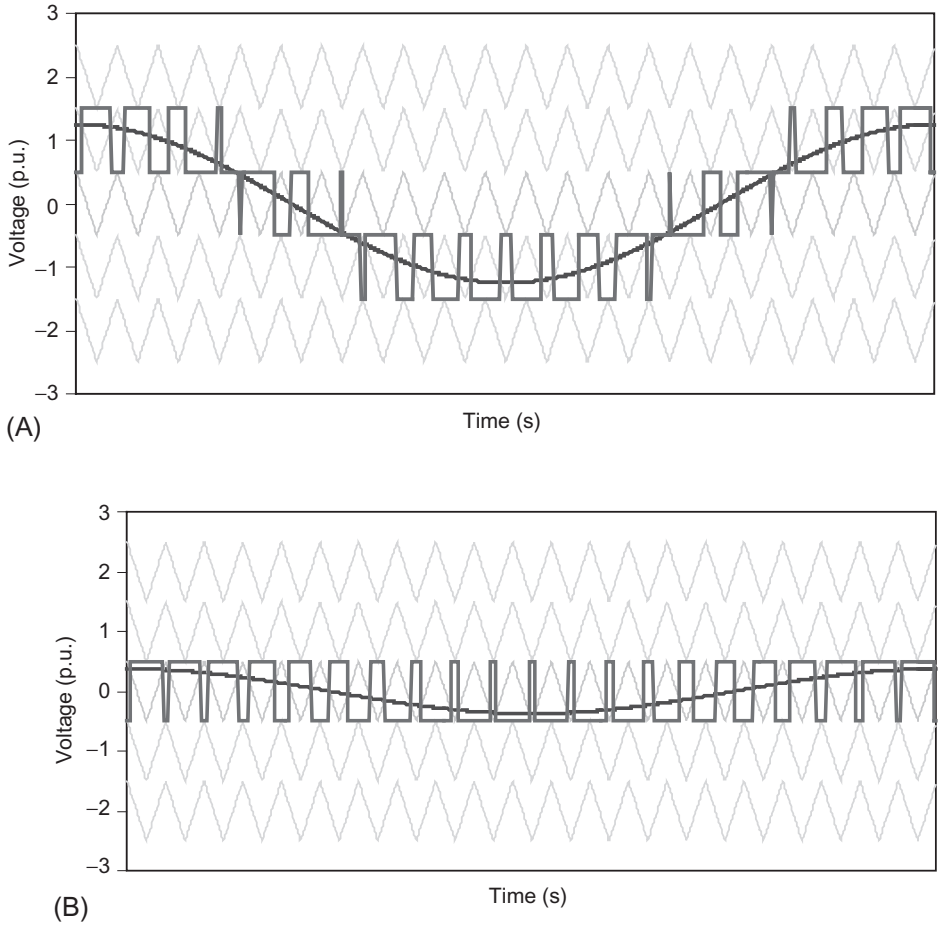

FIG. 13.26 Level reduction in a six-level inverter at low modulation indexes: (A) SH-PWM, $m = 6, m_a = 0.5$ and (B) SH-PWM, $m = 6, m_a = 0.15$.

TABLE 13.4 Modulation index ranges without level reduction (min) or pulse dropping because of overmodulation (max)

	SH-PWM		SFO-PWM	
Levels	Min	Max	Min	Max
3	0.000	1.000	0.000	1.155
4	0.333	1.000	0.385	1.155
5	0.500	1.000	0.578	1.155

As mentioned earlier, diode-clamped inverters have redundant line-line voltage states for low modulation indexes but have no phase redundancies [78]. For an output voltage state (i,j,k) in an m-level diode-clamped inverter, the number of redundant states available is given by

$$N_{\substack{\text{redundancies}\\\text{available}}} = m - 1 - [\max(i,j,k) - \min(i,j,k)] \qquad (13.17)$$

As the modulation index decreases, more redundant states are available. Table 13.5 shows the number of distinct and redundant line-line voltage states available in a six-level inverter for different output voltages.

In the next section, a carrier-based method is given that uses line-line redundancies in a diode-clamped inverter operating at a low modulation index so that active device usage is more balanced among the levels.

13.3.1.4 Increasing Switching Frequency at Low Modulation Indexes

For amplitude modulation indexes less than 0.5, the level usage in odd-level inverters can be sufficiently rotated so that the switching frequency can be doubled and still keep the thermal losses within the limits of the device. For inverters with an even number of levels, the modulation index at which frequency doubling can be accomplished varies with the levels as shown in Table 13.6. This increase in switching frequency enables the inverter to compensate for higher frequency harmonics and yields a waveform that more closely tracks a reference.

As an example of how to accomplish this doubling of inverter frequency, an analysis of a seven-level diode-clamped inverter with an amplitude modulation index of 0.4 is conducted. During the first cycle, the reference waveform is centered in the upper three carrier bands, and during the next cycle, the reference waveform is centered in the lower three carrier bands as shown in Fig. 13.27. This technique enables half of the switches to "rest" every other cycle and does not incur any switching losses. With this method, the switching frequency (or carrier frequency f_c in the case of multilevel inverters) can effectively be doubled to $2f_c$, but the switches will have the same thermal losses as if they were switching at f_c but every cycle.

This method is possible only for three-wire systems because the diode-clamped inverter has line-line redundancies and no phase redundancies. This means that at the discontinuity where the reference moves from one carrier band set to another, the

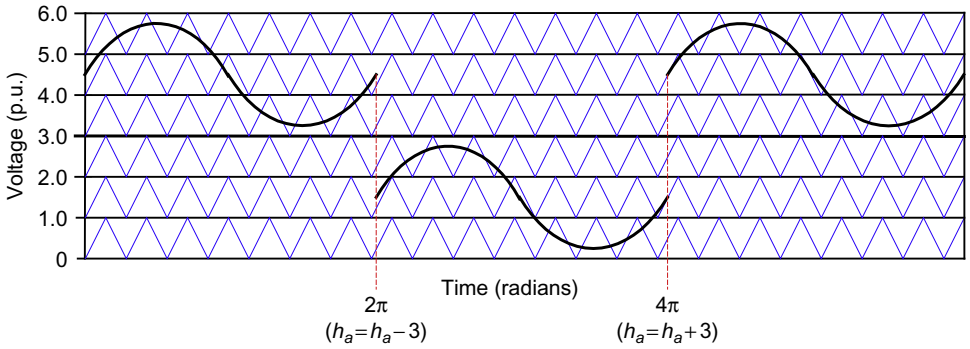

FIG. 13.27 Reference rotation among carrier bands at low modulation indexes ($m_a < 0.5$).

transition has to be synchronized such that all three phases are moved from one carrier set to the next set at the same time. In the case of frequency doubling, all three phases add or subtract the following number of states (or levels) every other reference cycle:

$$h_a(j+1) = h_a(j) + (-1)^j \cdot \frac{\lfloor m-1 \rfloor}{2} \tag{13.18}$$

At modulation indexes closer to zero, the switching frequency can be increased even more. This is possible because the reference waveform can be rotated among the carrier bands for a few cycles before returning to a previous set of switches for use. The switches are allowed to "rest" for a few cycles and thus are able to absorb higher losses during the cycle they are switched. Table 13.6 shows the possible increased switching frequencies available at lower amplitude modulation indexes for several different inverter levels.

Some additional switching loss is associated with the redundant switchings of the three phases at the end of each modulation cycle when rotating among carrier bands. For instance, for Fig. 13.28, each of the three phases in the seven-level inverter will have three switch pairs that change states at the end of every reference cycle. However, compared with the switching loss associated with just the normal PWM switchings, this redundant switching loss is quite small, typically less than 5% of the total switching loss.

Figs. 13.28 and 13.29 show two different methods of rotating the reference waveform among three different regions (top, middle, and bottom) for modulation indexes less than 0.333 in a seven-level inverter to enable the carrier frequency to be increased by a factor of three. The method shown in Fig. 13.28 is preferred over that shown in Fig. 13.29 because of less redundant state switching. The method shown in Fig. 13.28 requires only four redundant state switchings for every three reference cycles, whereas the method shown in Fig. 13.29 requires eight redundant switchings for every three reference cycles. In general, for any multilevel inverter regardless of the number of levels or number of rotation regions, using the preferred reference rotation method will have half of the redundant switching losses that the alternate method would have.

Unlike the diode-clamped inverter, the cascaded H-bridge inverter has phase redundancies in addition to the aforementioned line-line redundancies. Phase redundancies are much easier to exploit than line-line redundancies because the output voltage in each phase of a three-phase inverter can be generated independently of the other two phases when only phase redundancies are used. A method was given in [18] that makes use of

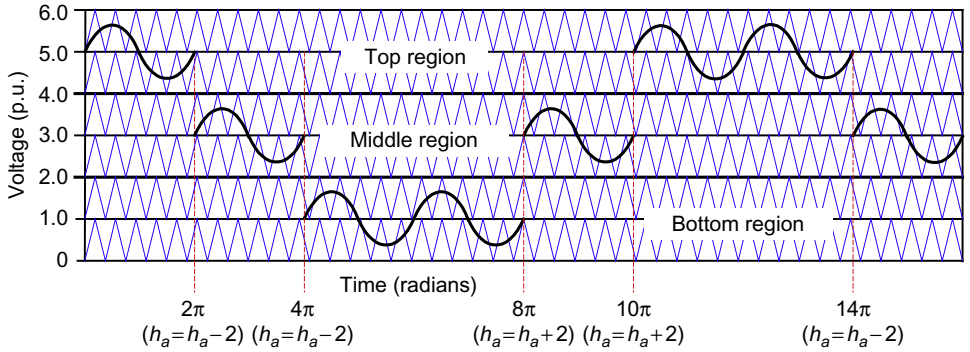

FIG. 13.28 Preferred method of reference rotation among carrier bands with 3× carrier frequency at very low modulation indexes.

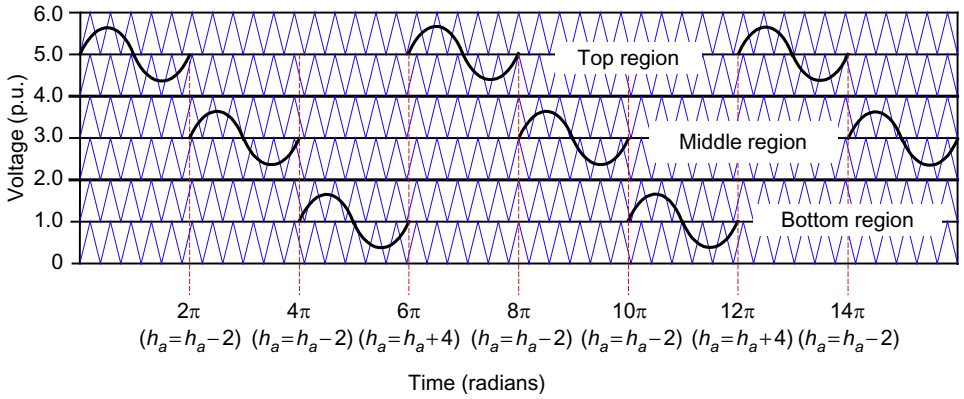

FIG. 13.29 Alternate method of reference rotation among carrier bands with 3× carrier frequency at very low modulation indexes.

these phase redundancies in a cascaded inverter so that duty cycle of each active device is balanced over $(m-1)/2$ modulation waveform cycles regardless of the modulation index. The same pulse rotation technique used for fundamental frequency switching of cascade inverters was used but with a PWM output voltage waveform [79], which is a much more effective means of controlling a driven motor at low speeds than continuing to do fundamental frequency switching. The effect of this control is that the output waveform can have a high switching frequency, but the individual levels can still switch at a constant switching frequency of 60 Hz if desired.

13.3.1.5 Multicarrier Modulation Techniques for MMC

The multicarrier techniques have also been successfully extended for MMC by using multiple carriers to control power switches of the converter topologies. It is mainly divided into two types: (1) carrier phase-shifted PWM (CPS-PWM) and (2) carrier level-shifted PWM (CLS-PWM) [80,81].

(1) *CPS-PWM*

For an MMC with 2N cells, the carrier waves (either sawtooth or triangular waveforms) with a phase shift of 360 degrees/N or 180 degrees/N can be employed to generate the staircase multilevel output waveform with low distortion. The modulation and output voltage waveforms for $N+1$ and $2N+1$ levels ($N=4$) are given in Figs. 13.30 and 13.31, respectively.

With $N+1$ level modulation scheme (phase shift of 360 degrees/N among carriers), N SMs per phase are inserted at all times, leading to a balanced capacitor voltage. In contrast, if $2N+1$ level modulation scheme (phase shift of 180 degrees/N among carriers) is used, $N+1$ or $N-1$ SMs will be inserted at certain time, causing issues with the capacitor voltage self-balancing algorithm and requiring additional balancing control. Using PS-PWM modulation algorithm, the effective switching frequency of the load voltage will be much higher that of each cell (Nf_c for $N+1$ level and $2Nf_c$ for $2N+1$ level, f_c is the carrier frequency). This property allows low switching frequency of each SM, thus reducing switching losses. In addition, it enables a high degree of linearity, outstanding control performance, and other advantages.

(2) *CLS-PWM*

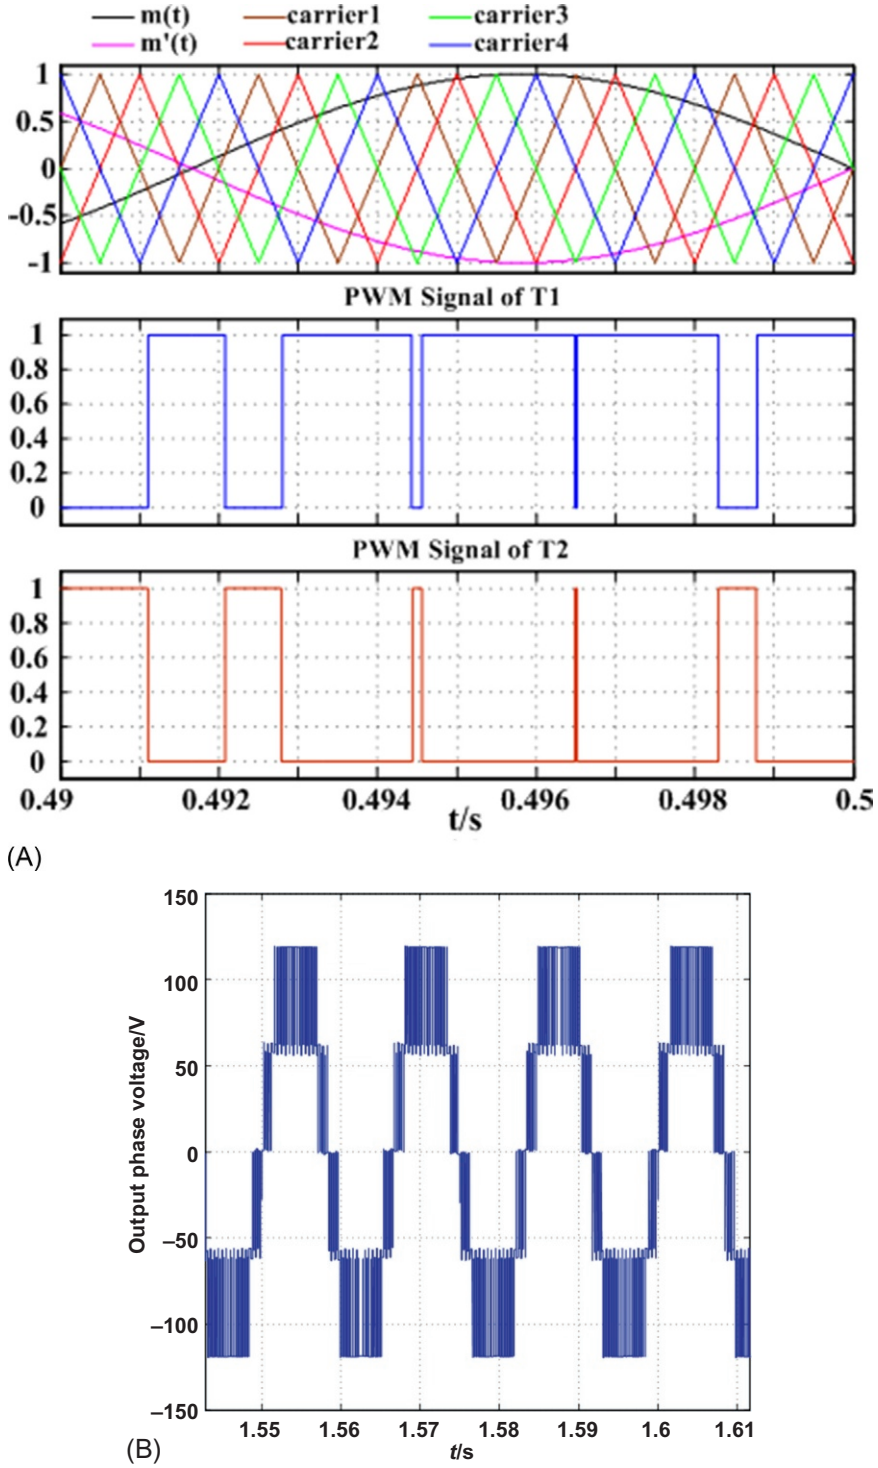
The carriers can also be arranged with shifts in amplitude, relating each carrier with the corresponding output voltage level generated by the multilevel inverter, which is the so-called level-shifted PWM (LS-PWM). Depending on the disposition of the carriers, three types of CLS-PWM have been developed: phase disposition (PD), phase opposition disposition (POD), and alternate phase opposition disposition (APOD), as shown in Fig. 13.32.

The PD-PWM method is realized through a comparison between a sinusoidal reference wave with vertically shifted carrier waves. N carrier signals will be created to generate an output voltage with $N+1$ levels. The carrier signals have the same amplitude and frequency, and all signals are in phase. In the POD-PWM method, all carrier signals above the zero axis (positive region) are in phase, and those below zero axis (negative region) are also in phase but 180 degrees phase shifted from the carrier waves in positive region. The APOD-PWM scheme requires N − 1 carrier signals with phase shift of 180 degrees from each other.

The LS-PWM methods can be adopted for any multilevel converter topology. However, they are not very suitable for CHB (cascaded H-bridge converter) and MMC inverters. According to the modulation principle, the uppermost SMs will be inserted for a short time, while the middle ones insert for most of the time during a fundamental cycle, producing an uneven power dissipation and large capacitor voltage differences among the SMs.

13.3.2 Multilevel Space Vector PWM

Choi et al. [82] were the first authors to extend the two-level space vector PWM technique to more than three levels for



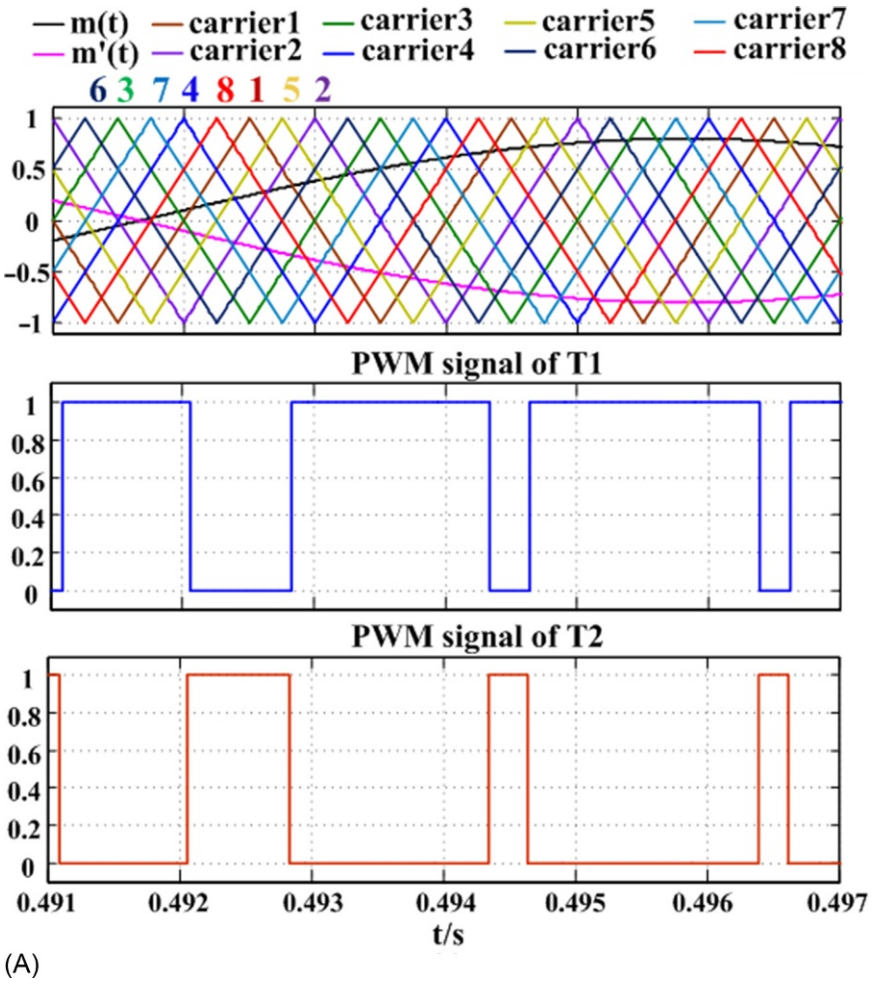


FIG. 13.30 Four cells in series connection with 360 degrees/*N* phase displacement in the carriers: (A) modulation waves and PWM signal for switches of the first SM and (B) simulation waveform of the output phase voltage.

the diode-clamped inverter. Fig. 13.33 shows how the space vector d-q plane looks like for a six-level inverter. Fig. 13.34 represents the equivalent dc link of a six-level inverter as a multiplexer that connects each of the three output phase voltages to one of the dc link voltage tap points [83]. Each integral point on the space vector plane represents a particular three-phase output voltage state of the inverter. For instance, the point (3, 2, and 0) on the space vector plane means that with respect to ground, "a" phase is at $3V_{dc}$, "b" phase is at $2V_{dc}$, and "c" phase is at $0V_{dc}$. The corresponding connections between the dc link

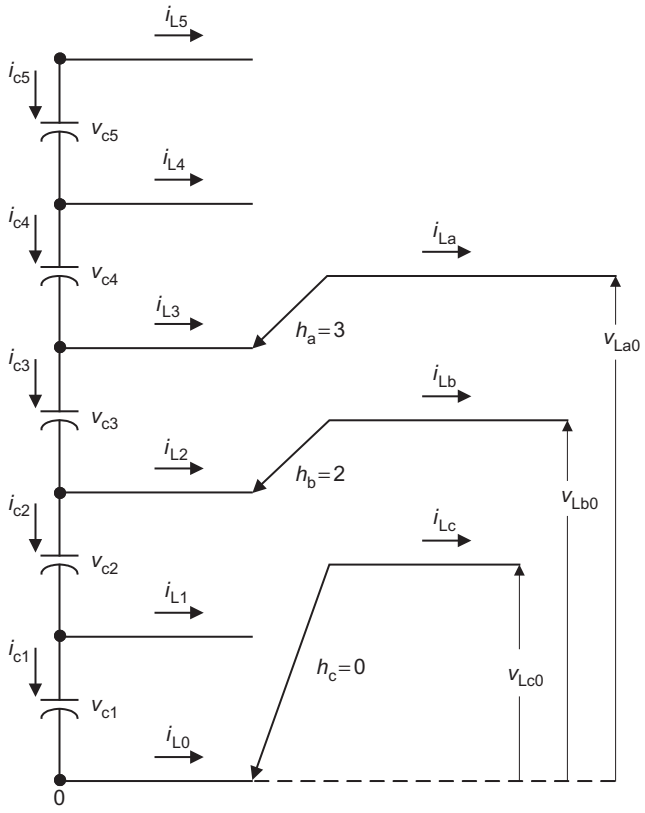

FIG. 13.34 Multiplexer model of diode-clamped six-level inverter.

and the output lines for the six-level inverter are also shown in Fig. 13.34 for the point (3, 2, 0). An algebraic way to represent the output voltages in terms of the switching states and dc link capacitors is described in the following [84]. For $n = m - 1$, where m is the number of levels in the inverter,

$$V_{abc0} = H_{abc} V_c \tag{13.19}$$

where

$$V_c = [V_{c1}\ V_{c2}\ V_{c3} \cdots V_{cn}]^T;$$
$$H_{abc} = \begin{bmatrix} h_{a1} & h_{a2} & h_{a3} & \dots & h_{an} \\ h_{b1} & h_{b2} & h_{b3} & \dots & h_{bn} \\ h_{c1} & h_{c2} & h_{c3} & \dots & h_{cn} \end{bmatrix};\quad V_{abc0} = \begin{bmatrix} V_{a0} \\ V_{b0} \\ V_{c0} \end{bmatrix}$$

and

$$h_{aj} = \sum_{j}^{n} \delta(h_a - j)$$

where h_a is the switch state and j is an integer from 0 to n and where $\delta(x) = 1$ if $x \geq 0, \delta(x) = 0$ if $x < 0$.

Besides the output voltage state, the point (3, 2, 0) on the space vector plane can also represent the switching state of the converter. Each integer indicates how many upper switches in each phase leg are on for a diode-clamped converter. As an example, for $h_a = 3, h_b = 2, h_c = 0$, the H_{abc} matrix for this particular switching state of a six-level inverter would be

$$H_{abc} = \begin{bmatrix} 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

Redundant switching states are those states for which a particular output voltage can be generated by more than one switch combination. Redundant states are possible at lower modulation indexes or at any point other than those on the outermost hexagon shown in Fig. 13.33. Switch state (3, 2, 0) has redundant states (4, 3, 1) and (5, 4, 2). Redundant switching states differ from each other by an identical integral value, that is, (3, 2, 0) differs from (4, 3, 1) by (1, 1, 1) and from (5, 4, 2) by (2, 2, 2).

For an output voltage state (x,y,z) in an m-level diode-clamped inverter, the number of redundant states available is given by $m-1-\max(x,y,z)$. As the modulation index decreases (or the voltage vector in the space vector plane gets closer to the origin), more redundant states are available. The number of possible zero states is equal to the number of levels, m. For a six-level diode-clamped inverter, the zero-voltage states are (0, 0, 0), (1, 1, 1), (2, 2, 2), (3, 3, 3), (4, 4, 4), and (5, 5, 5).

The number of possible switch combinations is equal to the cube of the level (m^3). For this six-level inverter, there are 216 possible switching states. The number of distinct or unique states for an m-level inverter can be given by

$$m^3-(m-1)^3=\left[6\sum_{n=1}^{m-1}n\right]+1. \tag{13.20}$$

Therefore, the number of redundant switching states for an m-level inverter is $(m-1)^3$. Table 13.7 summarizes the available redundancies and distinct states for a six-level diode-clamped inverter.

In two-level PWM, a reference voltage is tracked by selecting the two nearest voltage vectors and a zero vector and then by calculating the time required to be at each of these three vectors such that their sum equals the reference vector. In multilevel PWM, generally, the nearest three triangle vertices, V_1, V_2, and V_3, to a reference point V^* are selected to minimize the harmonic components of the output line-line voltage [85]. The respective time duration, T_1, T_2, and T_3, required for these vectors is then solved from the following equations:

$$\vec{V}_1T_1+\vec{V}_2T_2+\vec{V}_3T_3=V^*T_s \tag{13.21}$$

$$T_1+T_2+T_3=T_s \tag{13.22}$$

where T_s is the switching period. Eq. (13.21) actually represents two equations, one with the real part of the terms and one with the imaginary part of the terms:

$$V_{1d}T_1+V_{2d}T_2+V_{3d}T_3=V_d^*T_s \tag{13.23}$$

$$V_{1q}T_1+V_{2q}T_2+V_{3q}T_3=V_q^*T_s \tag{13.24}$$

Eqs. (13.22)–(13.25) can then be solved for T_1, T_2, and T_3 as follows:

$$\begin{bmatrix} T_1 \\ T_2 \\ T_3 \end{bmatrix} = \begin{bmatrix} V_{1d} & V_{2d} & V_{3d} \\ V_{1q} & V_{2q} & V_{3q} \\ 1 & 1 & 1 \end{bmatrix}^{-1} \begin{bmatrix} V_d^*T_s \\ V_q^*T_s \\ T_s \end{bmatrix} \tag{13.25}$$

Others have proposed space vector methods that did not use the nearest three vectors, but these methods generally add complexity to the control algorithm. Fig. 13.35 shows what a sinusoidal reference voltage (circle of points) and the inverter output voltages look like in the d-q plane.

TABLE 13.7 Line-line redundancies of six-level three-phase diode-clamped inverter

Redundancies	Distinct states	Redundant states	Unique state coordinates, (a,b,c), where $0 \le a,b,c \le 5$
5	1	5	(0,0,0)

Total	91	125	216 total states

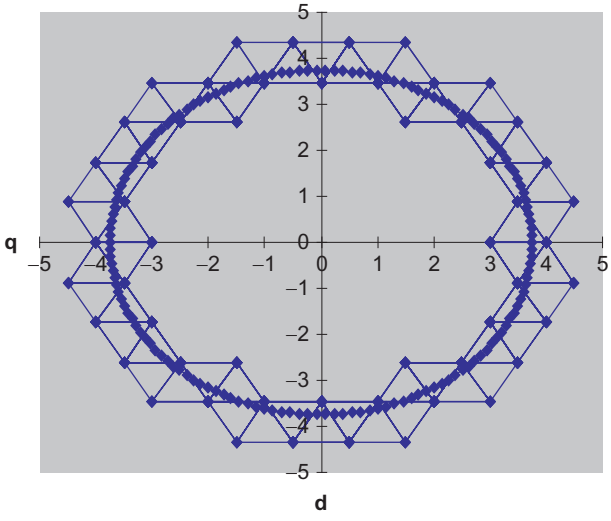

FIG. 13.35 Sinusoidal reference and inverter output voltage states in d-q plane.

Redundant switch levels can be used to help manage the charge on the dc link capacitors [86]. Generalizing from Fig. 13.34, the equations for the currents through the dc link capacitors can be given as

$$i_{cn} = -i_{Ln} \tag{13.26}$$

and

$$i_{c(n-j)} = -i_{L(n-j)} + i_{c(n-j+1)}, \quad \text{where } j = 1,2,3\ldots,n-1 \tag{13.27}$$

The dc link currents for $h_a = 3, h_b = 2, h_c = 0$ would be $i_{c5} = i_{c4} = 0, i_{c3} = -i_a, i_{c2} = -i_a - i_b, i_{c1} = -i_a - i_b$. To see how redundant states affect the dc link currents, consider the two redundant states for (3, 2, 0). In state (4, 3, 1), the dc link currents would be $i_{c5} = 0, i_{c4} = -i_a, i_{c3} = -i_a - i_b, i_{c2} = -i_a - i_b$, $i_{c1} = -i_a - i_b - i_c = 0$; and for the state (5, 4, 2), the dc link currents would be $i_{c5} = -i_a, i_{c4} = -i_a - i_b, i_{c3} = -i_a - i_b$, $i_{c2} = i_{c1} = -i_a - i_b - i_c = 0$.

From this example, one can see that the choice of redundant switching states can be used to determine which capacitors will be charged/discharged or unaffected during the switching period. Although this control is helpful in balancing the individual dc voltages across the capacitors that make up the dc link, this method is quite complicated in selecting which of the redundant states to use. Constant use of redundant switching states also results in a higher switching frequency and lower efficiency of the inverter because of the extra switchings. Optimized space vector switching sequences for multilevel inverters have been proposed in [87].

13.3.3 Selective Harmonic Elimination

13.3.3.1 Fundamental Switching Frequency

The selective harmonic elimination method is also called fundamental switching frequency method based on the harmonic elimination theory proposed by Patel and Hoft [88,89]. A typical 11-level multilevel converter output with fundamental frequency switching scheme is shown in Fig. 13.2. The Fourier series expansion of the output voltage waveform as shown in Fig. 13.2 is expressed in Eqs. (13.1) and (13.2).

The conducting angles, $\theta_1, \theta_2, \ldots, \theta_s$, can be chosen such that the voltage total harmonic distortion is a minimum. Normally, these angles are chosen so as to cancel the predominant lower frequency harmonics [19].

For the 11-level case in Fig. 13.2, the fifth, seventh, eleventh, and thirteenth harmonics can be eliminated with the appropriate choice of the conducting angles. One degree of freedom is used so that the magnitude of the fundamental waveform corresponds to the reference waveform's amplitude or modulation index, m_a, which is defined as V_L^*/V_{Lmax}. V_L^* is the amplitude command of the inverter for a sine wave output phase voltage, and V_{Lmax} is the maximum attainable amplitude of the converter, that is, $V_{Lmax} = s \cdot V_{dc}$. The equations from Eq. (13.2) will now be as follows:

$$\begin{aligned}
&\cos(5\theta_1) + \cos(5\theta_2) + \cos(5\theta_3) + \cos(5\theta_4) + \cos(5\theta_5) = 0\\
&\cos(7\theta_1) + \cos(7\theta_2) + \cos(7\theta_3) + \cos(7\theta_4) + \cos(7\theta_5) = 0\\
&\cos(11\theta_1) + \cos(11\theta_2) + \cos(11\theta_3) + \cos(11\theta_4) + \cos(11\theta_5) = 0\\
&\cos(13\theta_1) + \cos(13\theta_2) + \cos(13\theta_3) + \cos(13\theta_4) + \cos(13\theta_5) = 0\\
&\cos(\theta_1) + \cos(\theta_2) + \cos(\theta_3) + \cos(\theta_4) + \cos(\theta_5) = 5m_a
\end{aligned} \tag{13.28}$$

The above equations are nonlinear transcendental equations that can be solved by an iterative method such as the Newton-Raphson method. For example, using a modulation index of 0.8 obtains the following: $\theta_1 = 6.57$ degrees, $\theta_2 = 18.94$ degrees, $\theta_3 = 27.18$ degrees, $\theta_4 = 45.14$ degrees, $\theta_5 = 62.24$ degrees. Thus, if the inverter output is symmetrically switched during the positive half cycle of the fundamental voltage to $+V_{dc}$ at 6.57 degrees, $+2V_{dc}$ at 18.94 degrees, $+3V_{dc}$ at 27.18 degrees, $+4V_{dc}$ at 45.14 degrees and $+5V_{dc}$ at 62.24 degrees and similarly in the negative half cycle to $-V_{dc}$ at 186.57 degrees, $-2V_{dc}$ at 198.94 degrees, $-3V_{dc}$ at 207.18 degrees, $-4V_{dc}$ at 225.14 degrees, $-5V_{dc}$ at 242.24 degrees, the output voltage of the 11-level inverter will not contain the 5th, 7th, 11th, and 13th harmonic components [18]. Other methods to solve these equations include using genetic algorithms [90] and resultant theory [91,92].

Practically, the precalculated switching angles are stored as the data in memory (lookup table). Therefore, a microcontroller could be used to generate the PWM gate-drive signals. More recent methods have been developed that can generate the switching angles in real time using genetic algorithms.

13.3.3.2 Selective Harmonic Elimination PWM

In order to achieve a wide range of modulation indexes with minimized THD for the synthesized waveforms, a generalized selective harmonic modulation method [93,94] was proposed, which is called virtual stage PWM [90]. An output waveform is shown in Fig. 13.36. The virtual stage PWM is a combination of the unipolar programmed PWM and the fundamental frequency switching scheme. The output waveform of unipolar

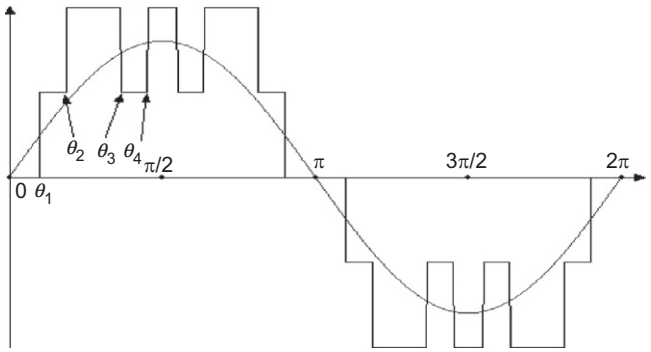

FIG. 13.36 Output waveform of virtual stage PWM control.

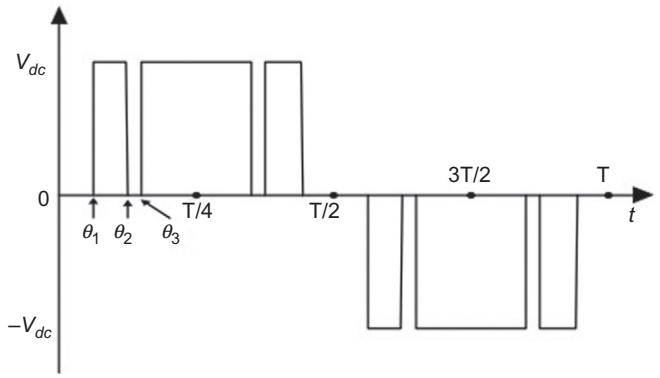

FIG. 13.37 Unipolar switching output waveform.

programmed PWM is shown in Fig. 13.37. When unipolar programmed PWM is employed on a multilevel converter, typically one dc voltage is involved, where the switches connected to the dc voltage are switched "on" and "off" several times per fundamental cycle. The switching pattern decides what the output voltage waveform looks like.

For fundamental switching frequency method, the number of switching angles is equal to the number of dc sources. However, for the virtual stage PWM method, the number of switching angles is not equal to the number of dc voltages. For example, in Fig. 13.36, only two dc voltages are used, whereas there are four switching angles.

Bipolar programmed PWM and unipolar programmed PWM could be used for modulation indexes too low for the applicability of the multilevel fundamental frequency switching method. Virtual stage PWM can also be used for low modulation indexes. Virtual stage PWM will produce output waveforms with a lower THD most of the time [90]. Therefore, virtual stage PWM provides another alternative to bipolar programmed PWM and unipolar programmed PWM for low modulation index control.

The major difficulty for selective harmonic elimination methods, including the fundamental switching frequency method and the virtual stage PWM method, is to solve the transcendental Eq. (13.28) for switching angles. Newton's method can be used to solve Eq. (13.28), but it needs good initial guesses, and solutions are not guaranteed. Therefore, Newton's method is not feasible to solving equations for large number of switching angles if good initial guesses are not available [95].

The resultant method has been proposed in [91,92,96] to solve the transcendental equations for switching angles. The transcendental equations characterizing the harmonic content can be converted into polynomial equations. Elimination resultant theory has been employed to determine the switching angles to eliminate specific harmonics, such as the 5th, 7th, 11th, and 13th. However, as the number of dc voltages or the number of switching angles increases, the degrees of the polynomials in these equations become bulky.

To overcome this problem, the fundamental frequency switching angle computation is solved by Newton's method. The initial guess can be provided by the results of lower order transcendental equations by the resultant method [95].

13.3.4 Other Modulation Strategies for Modular Multilevel Inverter

Space vector control (SVC) fully utilizes the large number of voltage vectors generated by multilevel converters, which approximates the voltage reference to the closest available state vector. This principle enables SVC with fundamental switching frequency and thus lower switching losses. Meanwhile, different from SHE PWM, the switching sequence can be produced online, resulting in a relatively easy implementation of SVC in closed-loop and high-bandwidth applications. The time domain version of SVC is the nearest level control (NLC), which approximates the closet voltage level instead of vector that can be generated by the converter, as illustrated in Fig. 13.38, where the inserted SM number equals to an integer closest to voltage reference v^* over SM capacitor voltage v_c. The basic idea of NLC is to first calculate how many SMs should be inserted and which SMs will be determined by the capacitors' voltage sorting and the direction of the arm current.

Based on an approximation instead of a modulation, both SVC and NLC are suitable for inverters with a high number of levels. On the other hand, due to the low and variable switching frequency, these two methods suffer high total harmonic distortion (THD) when the voltage levels and/or modulation indexes are low.

In summary, each multilevel modulation scheme has its own uniqueness, making it more suitable for specific converter topologies and applications. In general, low switching frequency modulation methods are preferred for high-power applications

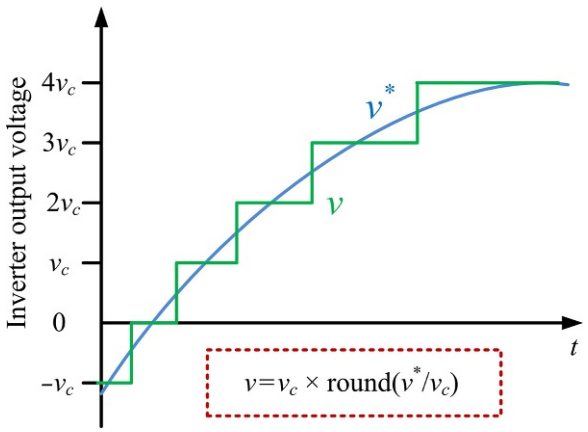

FIG. 13.38 Waveform synthesis using NLC.

due to lower switching loss, while high switching frequency algorithms enable better output power quality and higher bandwidth and thus are more suitable for high-dynamic-range applications.

13.4 Conclusion

This chapter has demonstrated the state of the art of multilevel power converter technology. Fundamental multilevel converter structures and modulation paradigms including the pros and cons of each technique have been discussed. Most of the chapter focuses on modern and more practical industrial applications of multilevel converters. The possible future enlargements of multilevel converter technology such as fault diagnosis system and renewable energy sources have been noted in earlier literature [97]. The development of wide bandgap power devices, especially medium-voltage SiC MOSFETs, IGBTs, diodes, and thyristors, in the next several years is expected to open more applications for multilevel converters. It should be noted that this chapter could not cover all multilevel, power converter-related applications; however, the basic principles of different multilevel converters have been discussed methodically. The main objective of this chapter is to provide a general notion to readers who are interested in multilevel power converters and their applications.

14.1 Introduction

A power electronic ac-ac converter, in generic form, accepts electric power from one system and converts it for delivery to another ac system with waveforms of different amplitude, frequency, and phase. Conventionally, the input system is of single-phase or three-phase type depending on the power ratings of the load, and the output system is of single-phase or three-phase type. However, recent research trend shows considerable orientation toward multiphase systems as they exhibit decrement in time and space harmonics, reduction in per phase current, increment in fault tolerance and reliability, etc. The ac-ac converters employed to vary the rms voltage across the load at constant frequency are known as *ac voltage controllers or ac regulators*. The voltage control is accomplished either by (1) *phase control* under natural commutation using pairs of silicon-controlled rectifiers (SCRs) or triacs or (2) by *on/off control* under forced commutation/self-commutation using fully controlled self-commutated switches, such as gate turn-off thyristors (GTOs), power transisto/rs, integrated-gate bipolar transistor (IGBTs), MOS-controlled thyristors (MCTs), and integrated-gate-commutated thyristor (IGCTs). Employment of switches depends on the power that is to be delivered (and thus on the switching frequency range of the device). The ac-ac power converters in which ac power at one frequency is directly converted to ac power at another frequency without any intermediate dc conversion link (as in the case of conventionally employed rectifier-inverter or back-to-back configurations) are known as *cycloconverters*, the majority of which uses naturally commutated SCRs for their operation when the maximum output frequency is limited to a fraction of the input frequency. With rapid advancements of fast-acting fully controlled switches, forced commutated cycloconverters, or *matrix converters* with bidirectional on/off control switches

provide independent control of the magnitude and the frequency of the generated output voltage, as well as sinusoidal modulation of output voltage and current.

Although typical applications of ac voltage controllers include lighting and heating control, online transformer tap changing, soft starting, and speed control of pump and fan drives, the cycloconverters are mainly used for high-power, low-speed, large ac motor drives for application in cement kilns, rolling mills, and ship propellers. The power circuits, control methods, and the operation of the ac voltage controllers, cycloconverters, and matrix converters are introduced in this chapter. A brief review is also made regarding their applications.

14.2 Single-Phase AC-AC Voltage Controller

The basic power circuit of a single-phase ac-ac voltage controller, as shown in Fig. 14.1A, comprises a pair of SCRs connected back-to-back (also known as inverse-parallel or antiparallel) between the ac supply and the load. This connection provides a *bidirectional full-wave symmetrical* control, and the SCR pair can be replaced by a triac (Fig. 14.1B) for low-power applications. Alternate arrangements are shown in Fig. 14.1C with two diodes and two SCRs to provide a common cathode connection for simplifying the gating circuit without requiring isolation and in Fig. 14.1D with one SCR and four diodes to reduce the device cost but with increased device conduction loss. An SCR and diode combination known as *thyrode controller*, as shown in Fig. 14.1E, provides a *unidirectional half-wave asymmetrical voltage* control with device economy but introduces dc component and more harmonics, and thus, it is not so practical to use except for very low-power-heating load.

With phase control, the switches conduct the load current for a chosen period of each input cycle of voltage, and with on/off control, either the switches connect the load for a few cycles of input voltage and disconnect it for the next few cycles (*integral cycle control*) or the switches are turned on and off several times within

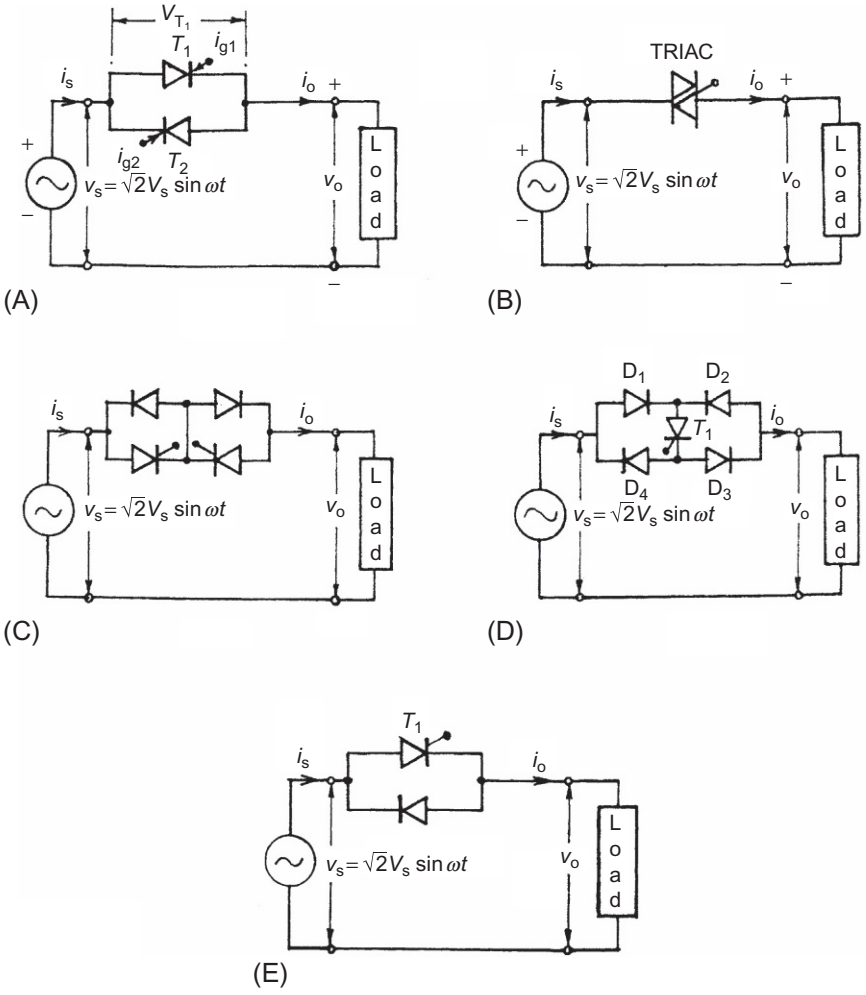

FIG. 14.1 Single-phase ac voltage controllers: (A) full wave, two SCRs in inverse-parallel; (B) full wave with triac; (C) full wave with two SCRs and two diodes; (D) full wave with four diodes and one SCR; and (E) half wave with one SCR and one diode in antiparallel.

alternate half cycles of input voltage (*ac chopper or pulse-width modulated* (*PWM*) *ac voltage controller*).

14.2.1 Phase-Controlled Single-Phase AC Voltage Controller

For a full-wave symmetrical phase control, the SCRs T_1 and T_2 in Fig. 14.1A are gated at α and $\pi+\alpha$, respectively, from the zero crossing of the input voltage; by varying α, the power flow to the load is controlled through voltage control in alternate half cycles. As long as one SCR is carrying current, the other SCR remains reverse-biased by the voltage drop across the conducting SCR. The principle of operation in each half cycle is similar to that of the controlled half-wave rectifier, and one can use the same approach for analysis of the circuit.

Operation with R-load. Fig. 14.2 shows the typical voltage and current waveforms for the single-phase bidirectional phase-controlled ac voltage controller of Fig. 14.1A with a resistive load. The output voltage and current waveforms have half-wave symmetry and so no dc component.

If $v_s = \sqrt{2}V_s \sin \omega t$ is the source voltage, the rms output voltage with T_1 triggered at α can be found from the half-wave symmetry as

$$V_o = \left[\frac{1}{\pi}\int_{\alpha}^{\pi} 2V_s^2 \sin^2 \omega t d(\omega t)\right]^{\frac{1}{2}} = V_s\left[1 - \frac{\alpha}{\pi} + \frac{\sin 2\alpha}{2\pi}\right]^{\frac{1}{2}} \quad (14.1)$$

Note that V_o can be varied from V_s to 0 by varying α from 0 to π:

$$\text{The rms value of load current, } I_o = \frac{V_o}{R} \quad (14.2)$$

$$\text{The input power factor} = \frac{P_o}{VA} = \frac{V_o}{V_s} = \left[1 - \frac{\alpha}{\pi} + \frac{\sin 2\alpha}{2\pi}\right]^{\frac{1}{2}} \quad (14.3)$$

$$\text{The average SCR current, } I_{A,\,SCR} = \frac{1}{2\pi R}\int_{\alpha}^{\pi} \sqrt{2}V_s \sin \omega t \mathrm{d}(\omega t) \quad (14.4)$$

Since each SCR carries half the line current, the rms current in each SCR is

$$I_{o,\,SCR} = \frac{I_o}{\sqrt{2}} \quad (14.5)$$

Operation with RL Load. Fig. 14.3 shows the voltage and current waveforms for the controller in Fig. 14.1A with RL load. Due to the inductance, the current carried by the SCR T_1 may not fall to zero at $\omega t = \pi$ when the input voltage goes

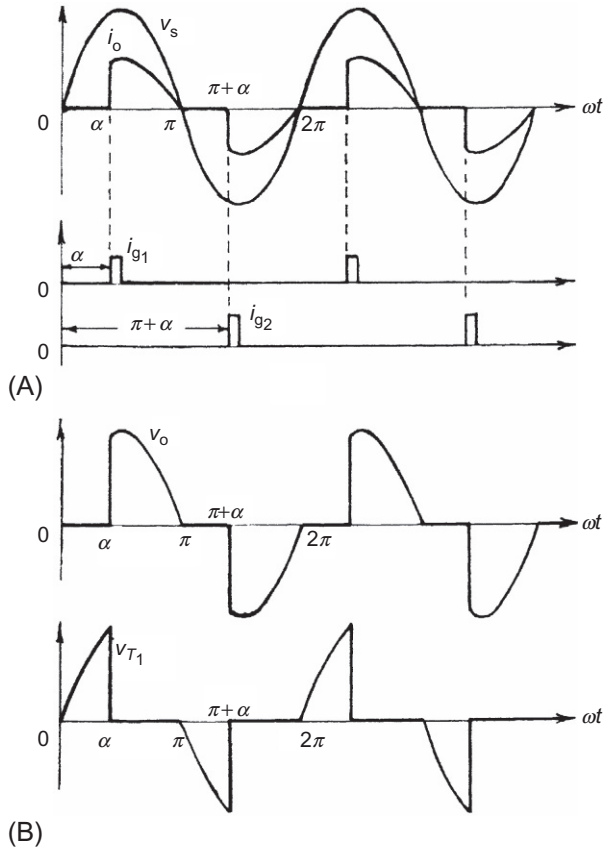

FIG. 14.2 Waveforms for single-phase ac full-wave voltage controller with R-load.

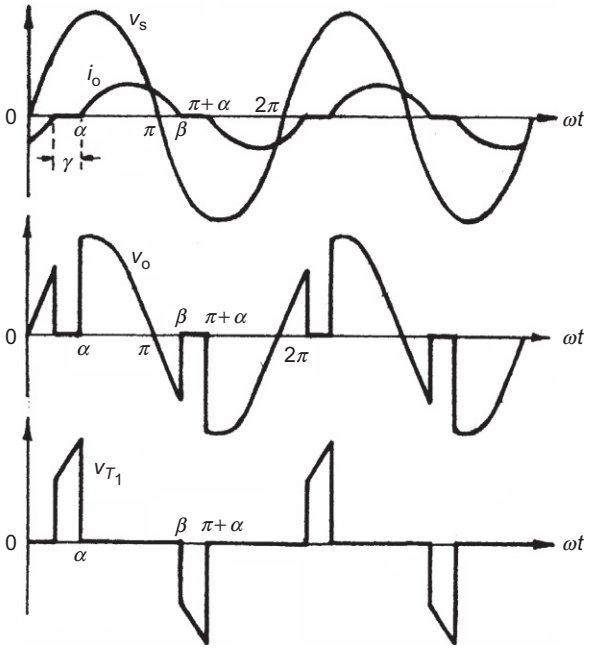

FIG. 14.3 Typical waveforms of single-phase ac voltage controller with an RL load.

negative and may continue till $\omega t = \beta$, the extinction angle, as shown. The conduction angle,

$$\theta = \beta - \alpha \tag{14.6}$$

of the SCR depends on the firing delay angle α and the load impedance angle ϕ.

The expression for the load current $I_o(\omega t)$, when conducting from α to β, can be derived in the same way as that used for a phase-controlled rectifier in a discontinuous mode by solving the relevant Kirchhoff's voltage equation:

$$i_o(\omega t) = \frac{\sqrt{2}V}{Z}\left[\sin(\omega t - \phi) - \sin(\alpha - \phi)e^{(\alpha - \omega t)/\tan\phi}\right], \quad \alpha < \omega t < \beta \tag{14.7}$$

where $Z = (R^2 + \omega^2 L^2)^{\frac{1}{2}} = \text{load impedance}$ and $\phi = \text{load impedance angle} = \tan^{-1}(\omega L/R)$.

The angle β, when the current i_o falls to zero, can be determined from the following transcendental equation resulted by using $i_o(\omega t = \beta) = 0$ in Eq. (14.7):

$$\sin(\beta - \phi) = \sin(\alpha - \phi) - \sin(\alpha - \phi)e^{(\alpha - \beta)/\tan\phi} \tag{14.8}$$

From Eqs. (14.6) and (14.8), one can obtain a relationship between θ and α for a given value of ϕ, as shown in Fig. 14.4, which shows that as α is increased, the conduction angle θ decreases, and thus, the rms value of the current decreases.

The rms output voltage

$$V_o = \left[\frac{1}{\pi}\int_{\alpha}^{\beta} 2V_s^2 \sin^2\omega t d(\omega t)\right]^{\frac{1}{2}} = \frac{V_s}{\pi}\left[\beta - \alpha + \frac{\sin 2\alpha}{2} - \frac{\sin 2\beta}{2}\right]^{\frac{1}{2}} \tag{14.9}$$

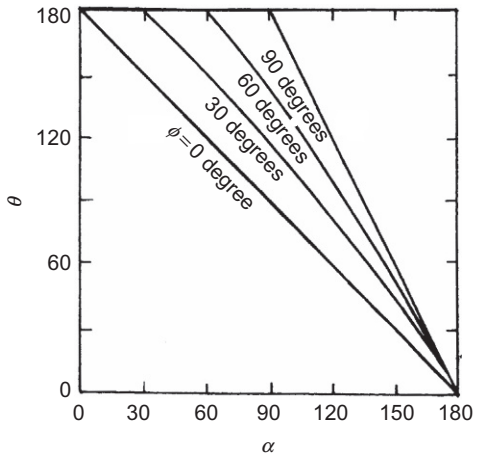

FIG. 14.4 θ versus α curves for single-phase ac voltage controller with RL load.

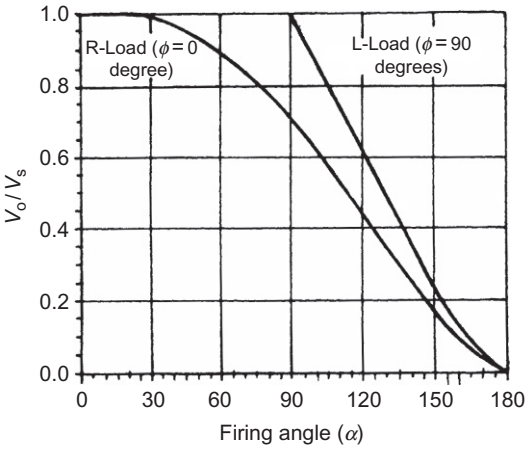

FIG. 14.5 Envelope of control characteristics of a single-phase ac voltage controller with RL load.

V_o can be evaluated for two possible extreme values of $\phi = 0$ when $\beta = \pi$, and $\phi = \pi/2$ when $\beta = 2\pi - \alpha$, and the envelope of the voltage control characteristics for this controller is shown in Fig. 14.5.

The rms SCR current can be obtained from Eq. (14.7) as follows:

$$I_{o,\,SCR} = \left[\frac{1}{2\pi}\int_{\alpha}^{\beta} i_o^2 d(\omega t)\right]^{\frac{1}{2}} \tag{14.10}$$

$$\text{The rms load current, } I_o = \sqrt{2}I_{o,\,SCR} \tag{14.11}$$

$$\text{The average value of SCR current, } I_{A,\,SCR} = \frac{1}{2\pi}\int_{\alpha}^{\beta} i_o d(\omega t) \tag{14.12}$$

Gating Signal Requirements. For the inverse-parallel SCRs as shown in Fig. 14.1A, the gating signals of SCRs must be isolated from one another because there is no common cathode. For R-load, each SCR stops conducting at the end of each half cycle and under this condition, single short pulses may be used for gating as shown in Fig. 14.2. With RL load, however, this single short pulse gating is not suitable as shown in Fig. 14.6. When SCR T_2 is triggered at $\omega t = \pi + \alpha$, SCR T_1 is still conducting due to the load inductance. By the time the SCR T_1 stops conducting at β, the gate pulse for SCR T_2 has already ceased and T_2 will fail to turn on resulting the converter to operate as a single-phase rectifier with conduction of T_1 only. This necessitates the application of a sustained gate pulse in the form of either a continuous signal for the half-cycle period or better a train of pulses (carrier frequency gating) as the former results in increased dissipation in SCR gate circuit, and a large isolating pulse transformer is required.

Operation with $\alpha < \phi$. If $\alpha = \phi$, then from Eq. (14.8),

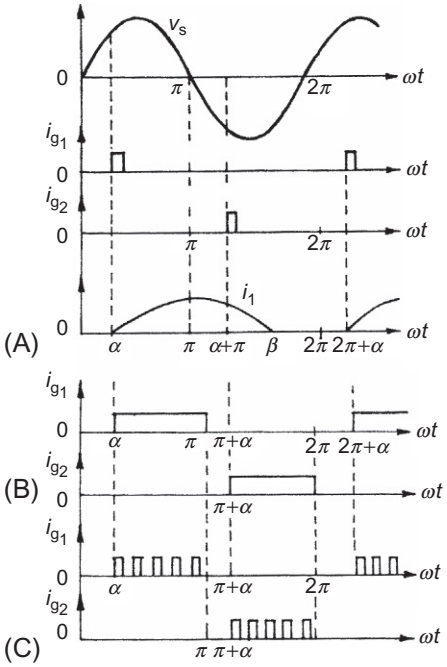

FIG. 14.6 Single-phase full-wave controller with RL load: gate pulse requirements.

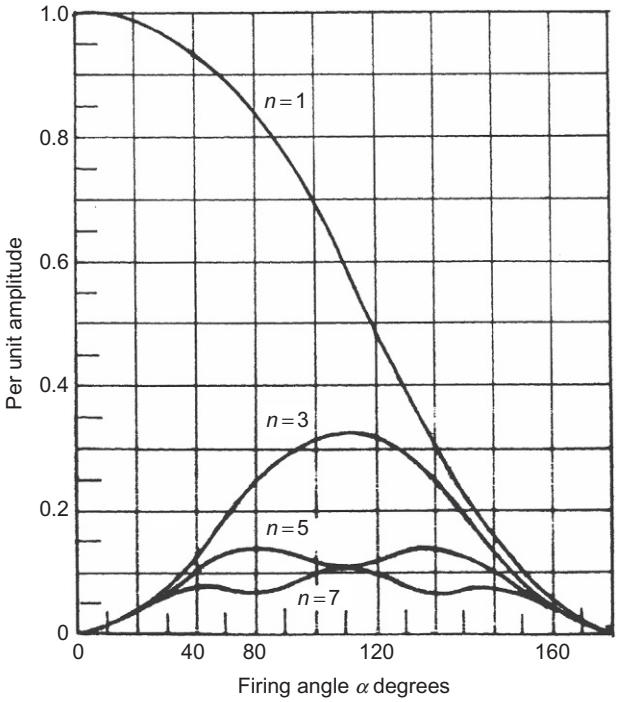

FIG. 14.7 Harmonic content as a function of the firing angle for a single-phase voltage controller with RL load.

$$\sin(\beta-\phi)=\sin(\beta-\alpha)=0 \tag{14.13}$$

and

$$\beta-\alpha=\theta=\pi \tag{14.14}$$

As the conduction angle θ cannot exceed π and the load current must pass through zero, the control range of the firing angle is $\phi \le \alpha \le \pi$. With narrow gating pulses and $\alpha < \phi$, only one SCR will conduct resulting in a rectifier action as shown. Even with a train of pulses, if $\alpha < \phi$, the changes in the firing angle will not change the output voltage and current but both the SCRs will conduct for the period π with T_1 becoming on at $\omega t = \pi$ and T_2 at $\omega t + \pi$.

The duration of this *dead zone* ($\alpha = 0$ to ϕ), which varies with the load impedance angle ϕ, is not a desirable feature in closed-loop control schemes. An alternative approach to the phase control with respect to the input voltage zero crossing has been visualized in which the firing angle is defined with respect to the instant when it is the load current, not the input voltage, that reaches zero, this angle being called *the hold-off angle* (γ) *or the control angle* (as marked in Fig. 14.3). This method needs sensing the load current, which may otherwise be required in a closed-loop controller for monitoring or control purposes.

Power Factor and Harmonics. As in the case of phase-controlled rectifiers, the important limitations of the phase-controlled ac voltage controllers are the poor power factor and the introduction of harmonics in the source currents. As seen from Eq. (14.3), the input power factor depends on α, and as α increases, the power factor decreases.

The harmonic distortion increases and the quality of the input current decreases with increase of firing angle. The variations of low-order harmonics with the firing angle as computed by Fourier analysis of the voltage waveform of Fig. 14.2 (with R-load) are shown in Fig. 14.7. Only odd harmonics exist in the input current because of half-wave symmetry.

14.2.2 Single-Phase AC-AC Voltage Controller with On/Off Control

Integral Cycle Control. As an alternative to the phase control, the method of integral cycle control or burst firing is used for systems with large time constants, for example, heating loads. Here, the switch is turned on for a time t_n with n integral cycles and turned off for a time t_m with m integral cycles (Fig. 14.8). As the SCRs or triacs used here are turned on at the zero crossing of the input voltage and turn off occurs at zero current, supply harmonics and radio-frequency interference are very low.

However, subharmonic frequency components may be generated, which are undesirable because they may set up subharmonic resonance in the power supply system, cause lamp flicker, and may interfere with the natural frequencies of motor loads causing shaft oscillations.

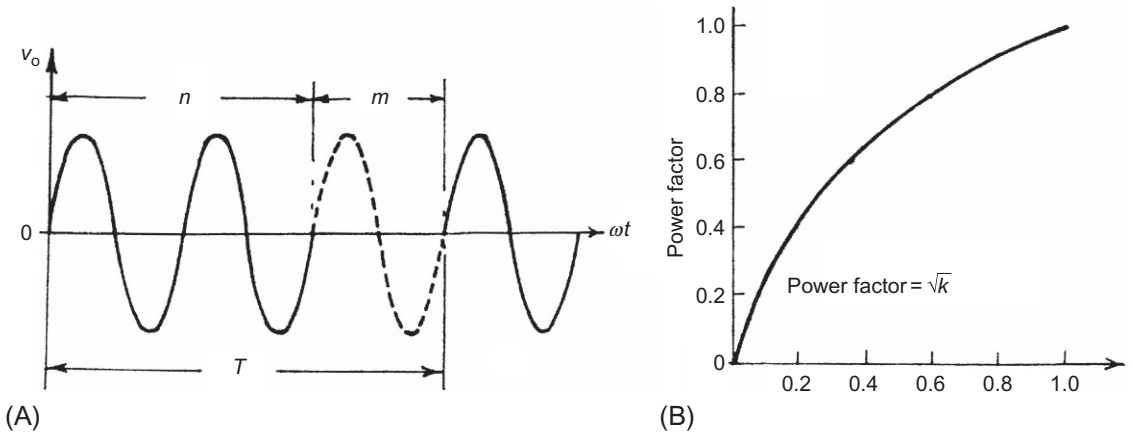

FIG. 14.8 Integral cycle control: (A) typical load voltage waveforms and (B) power factor with the duty cycle k.

For sinusoidal input voltage, $v = \sqrt{2}V_s \sin \omega t$, the rms output voltage

$$V_o = V_s\sqrt{k} \text{ where } k = n/(n+m) = \text{duty cycle and } V_s = \text{rms phase voltage} \quad (14.15)$$

$$\text{The power factor} = \sqrt{k} \quad (14.16)$$

which is poorer for lower values of the duty cycle k.

PWM AC Chopper. As in the case of controlled rectifier, the performance of ac voltage controllers can be improved in terms of harmonics, quality of output current, and input power factor by PWM control in PWM ac choppers; the circuit configuration of one such single-phase unit is shown in Fig. 14.9. Here, fully controlled switches S_1 and S_2 connected in antiparallel are turned on and off many times during the positive and negative half cycles of the input voltage, respectively. S_1' and S_2' provide the freewheeling paths for the load current when S_1 and S_2 are off. An input capacitor filter may be provided to attenuate the high switching frequency currents drawn from the supply and also to improve the input power factor. Fig. 14.10 shows the typical output voltage and load current waveform for a single-phase PWM ac chopper. It can be shown that the control characteristics of an ac chopper depend on the *modulation index M*, which theoretically varies from 0 to 1.

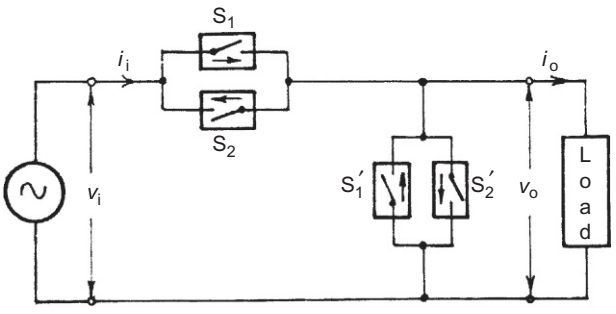

FIG. 14.9 Single-phase PWM ac chopper circuit.

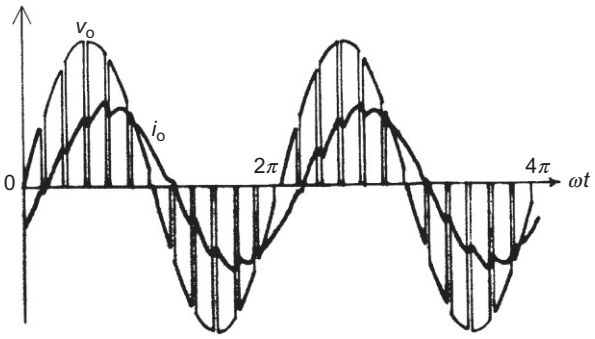

FIG. 14.10 Typical output voltage and current waveforms of a single-phase PWM ac chopper.

Three-phase PWM choppers consist of three single-phase choppers connected in either delta or four-wire (star) configuration.

14.3 Three-Phase AC-AC Voltage Controllers

14.3.1 Phase-Controlled Three-Phase AC Voltage Controllers

Various Configurations. Several possible circuit configurations for three-phase phase-controlled ac regulators with star- or delta-connected loads are shown in Fig. 14.11A–H.

The configurations in (A) and (B) can be realized by three single-phase ac regulators operating independently of each other, and they are easy to analyze. In (A), the SCRs are to be rated to carry line currents and withstand phase voltages, whereas in (B) they should be capable to carry phase currents and withstand the line voltage. In (B), the line currents are free from triplen harmonics while these are present in the closed

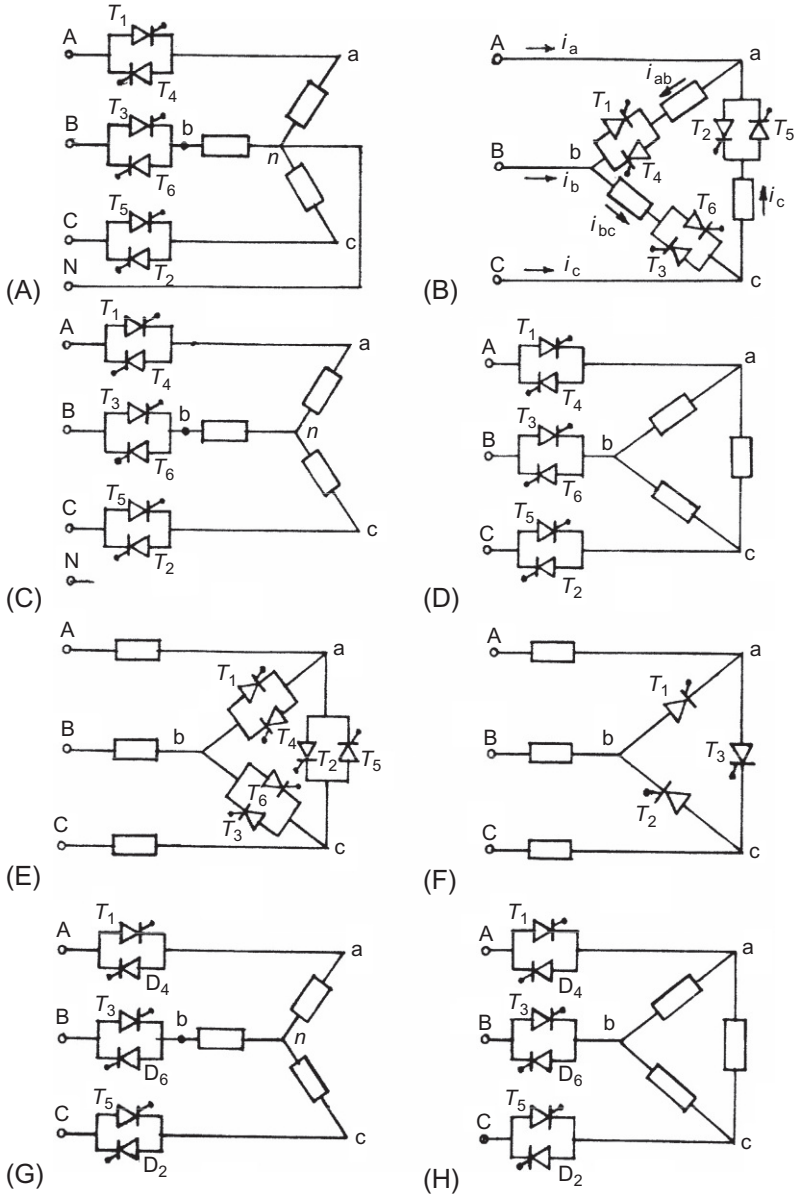

FIG. 14.11 Three-phase ac voltage controller circuit configurations.

delta. The power factor in (B) is slightly higher. The firing angle control range for both these circuits is 0–180 degrees for R-load.

The circuits in (C) and (D) are three-phase three-wire circuits and are complicated to analyze. In both these circuits, at least two SCRs, one in each phase, must be gated simultaneously to get the controller started by establishing a current path between the supply lines. This necessitates two firing pulses spaced at 60 degrees apart per cycle for firing each SCR. The operation modes are defined by the number of SCRs conducting in these modes. The firing control range is 0–150 degrees. The triplen harmonics are absent in both these configurations.

Another configuration is shown in (E) when the controllers are connected in delta and the load is connected between the supply and the converter. Here, current can flow between two lines even if one SCR is conducting so each SCR requires one firing pulse per cycle. The voltage and current ratings of SCRs are nearly the same as that of the circuit (B). It is also possible to reduce the number of devices to three SCRs in delta as shown in (F), connecting one source terminal directly to one load circuit terminal. Each SCR is provided with gate pulses in each cycle spaced at 120 degrees apart. In both (E) and (F), each end of each phase must be accessible. The number of devices in (F) is less, but their current ratings must be higher.

As in the case of single-phase phase-controlled voltage regulator, the total regulator cost can be reduced by replacing six SCRs by three SCRs and three diodes, resulting in three-phase *half-wave controlled* unidirectional ac regulators as shown in (G) and (H) for star- and delta-connected loads. The main drawback of these circuits is the large harmonic content in the output voltage—particularly, the second harmonic because of the asymmetry. However, the dc components are absent in the line. The maximum firing angle in the half-wave controlled regulator is 210 degrees.

14.3.2 Fully Controlled Three-Phase Three-Wire AC Voltage Controller

Star-connected Load with Isolated Neutral. The analysis of operation of the full-wave controller with isolated neutral as shown in Fig. 14.11C is, as mentioned, quite complicated in comparison with that of a single-phase controller, particularly for an RL or motor load. As a simple example, the operation of this controller with a simple star-connected R-load is considered here. The six SCRs are turned on in the sequence 1-2-3-4-5-6 at 60 degrees intervals, and the gate signals are sustained throughout the possible conduction angle.

The output phase voltage waveforms for $\alpha = 30$, 75, and 120 degrees for a balanced three-phase R-load are shown in Fig. 14.12. At any interval, either three SCRs or two SCRs or no SCRs may be on, and the instantaneous output voltages to the load are either a line-to-neutral voltage (three SCRs on) or one-half of the line-to-line voltage (two SCRs on) or zero (no SCR on).

Depending on the firing angle α, there may be *three* operating modes:

Mode I (*also known as Mode 2/3*). 0 degrees $\leq \alpha \leq$ 60 degrees; There are periods when *three* SCRs are conducting, one in each phase for either direction, and there are periods when just *two* SCRs conduct.

For example, with $\alpha = 30$ degrees in Fig. 14.12A, assume that at $\omega t = 0$, SCRs T_5 and T_6 are conducting, and the current through the R-load in a-phase is zero making $v_{an} = 0$. At $\omega t = 30$ degrees, T_1 receives a gate pulse and starts conducting; T_5 and T_6 remain on, and $v_{an} = v_{AN}$. The current in T_5 reaches zero at 60 degrees, turning T_5 off. With T_1 and T_6 staying on, $v_{an} = \frac{1}{2}v_{AB}$. At 90 degrees, T_2 is turned on, the three SCRs T_1, T_2, and T_6 are then conducting, and $v_{an} = v_{AN}$. At 120 degrees, T_6 turns off, leaving T_1 and T_2 on, so $v_{an} = \frac{1}{2}v_{AC}$. Thus, with the progress of firing in sequence till $\alpha = 60$ degrees, the number of SCRs conducting at a particular instant alternates between two and three.

Mode II (*also known as Mode 2/2*). 60 degrees $\leq \alpha \leq$ 90 degrees; Two SCRs, one in each phase, always conduct.

For $\alpha = 75$ degrees as shown in Fig. 14.12B, just prior to $\alpha = 75$ degrees, SCRs T_5 and T_6 were conducting, and $v_{an} = 0$. At 75 degrees, T_1 is turned on, and T_6 continues to conduct, whereas T_5 turns off as v_{CN} is negative. $v_{an} = \frac{1}{2}v_{AB}$. When

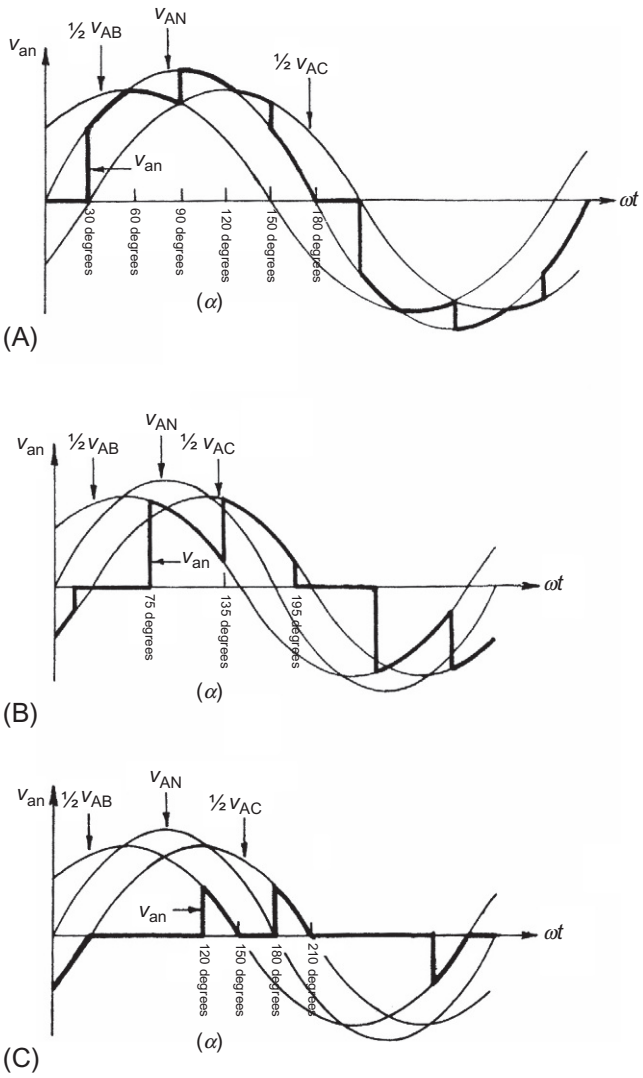

FIG. 14.12 Output voltage waveforms for a three-phase ac voltage controller with star-connected R-load: (A) v_{an} for $\alpha = 30°$, (B) v_{an} for $\alpha = 75°$, and (C) $v_{an} = 120°$.

T_2 is turned on at 135 degrees, T_6 is turned off, and $v_{an} = \frac{1}{2}v_{AC}$. The next SCR to turn on is T_3, which turns off T_1, and $v_{an} = 0$. One SCR is always turned off when another is turned on in this range of α, and the output voltage is either one-half line-to-line voltage or zero.

Mode III (*also known as Mode 0/2*). 90 degrees $\leq \alpha \leq$ 150 degrees, when *none* or *two* SCRs conduct.

For $\alpha = 120$ degrees, Fig. 14.12C, earlier, no SCRs were on, and $v_{an} = 0$. At $\alpha = 120$ degrees, SCR T_1 is given a gate signal, whereas T_6 has a gate signal already applied. Since v_{AB} is positive, T_1 and T_6 are forward-biased, and they begin to conduct, and $v_{an} = \frac{1}{2}v_{AB}$. Both T_1 and T_6 turn off when v_{AB} becomes negative. When a gate signal is given to T_2, it turns on, and T_1 turns on again.

For $\alpha > 150$ degrees, there is no period when two SCRs are conducting and the output voltage is zero at $\alpha = 150$ degrees.

Thus, the range of the firing angle control is 0 degrees $\leq \alpha \leq$ 150 degrees.

For *star-connected R-load*, assuming the instantaneous phase voltages as

$$\begin{aligned} v_{AN} &= \sqrt{2}V_s \sin \omega t \\ v_{BN} &= \sqrt{2}V_s \sin \omega t - 120 \text{ degrees} \\ v_{CN} &= \sqrt{2}V_s \sin \omega t - 240 \text{ degrees} \end{aligned} \tag{14.17}$$

the expressions for the rms output phase voltage V_o can be derived for the three modes as follows:

$$0 \text{ degrees} \leq \alpha \leq 60 \text{ degrees} \quad V_o = V_s \left[1 - \frac{3\alpha}{2\pi} + \frac{3}{4\pi} \sin 2\alpha\right]^{\frac{1}{2}} \tag{14.18}$$

$$60 \text{ degrees} \leq \alpha \leq 90 \text{ degrees} \quad V_o = V_s \left[\frac{1}{2} + \frac{3}{4\pi} \sin 2\alpha + \sin(2\alpha + 60 \text{ degrees})\right]^{\frac{1}{2}} \tag{14.19}$$

$$90 \text{ degrees} \leq \alpha \leq 150 \text{ degrees} \quad V_o = V_s \left[\frac{5}{4} - \frac{3\alpha}{2\pi} + \frac{3}{4\pi} \sin(2\alpha + 60 \text{ degrees})\right]^{\frac{1}{2}} \tag{14.20}$$

For *star-connected pure L-load*, the effective control starts at $\alpha >$ 90 degrees, and the expressions for two ranges of α are as follows:

$$90 \text{ degrees} \leq \alpha \leq 120 \text{ degrees} \quad V_o = V_s \left[\frac{5}{2} - \frac{3\alpha}{\pi} + \frac{3}{2\pi} \sin 2\alpha\right]^{\frac{1}{2}} \tag{14.21}$$

$$120 \text{ degrees} \leq \alpha \leq 150 \text{ degrees} \quad V_o = V_s \left[\frac{5}{2} - \frac{3\alpha}{\pi} + \frac{3}{2\pi} \sin(2\alpha + 60 \text{ degrees})\right]^{\frac{1}{2}} \tag{14.22}$$

The control characteristics for these two limiting cases ($\phi = 0$ for R-load and $\phi =$ 90 degrees for L-load) are shown in Fig. 14.13. Here also, like the single-phase case, the dead zone may be avoided by controlling the voltage with respect to the control angle or hold-off angle (γ) from the zero crossing of current in place of the firing angle α.

RL Load. The analysis of the three-phase voltage controller with star-connected RL load with isolated neutral is quite complicated, since the SCRs do not cease to conduct at voltage zero, and the extinction angle β is to be known by solving the transcendental equation for the case. In this case, the mode II operation disappears [1], and the operation shift from mode I to mode III depends on the so-called critical angle α_{crit} [2,3], which can be evaluated from a numerical solution of the relevant transcendental equations. Computer simulation by either PSPICE program [4,5] or switching-variable approach coupled

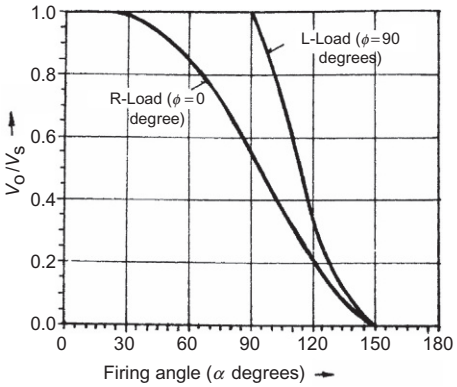

FIG. 14.13 Envelope of control characteristics for a three-phase full-wave ac voltage controller.

with an iterative procedure [6] is a practical means of obtaining the output voltage waveform in this case. Fig. 14.14 shows typical simulation results using the later approach [6] for a three-phase voltage controller-fed RL load for $\alpha =$ 60, 90, and 105 degrees, which agree with the corresponding practical oscillograms given in [7].

Delta-Connected R-Load. The configuration is shown in Fig. 14.11B. The voltage across an R-load is the corresponding line-to-line voltage when one SCR in that phase is on. Fig. 14.15 shows the line and phase currents for $\alpha =$ 130 and 90 degrees with an R-load. The firing angle α is measured from the zero crossing of the line-to-line voltage, and the SCRs are turned on in the sequence as they are numbered. As in the single-phase case, the range of firing angle is $0 \leq \alpha \leq$ 180 degrees. The line currents can be obtained from the phase currents as follows:

$$\begin{aligned} i_a &= i_{ab} - i_{ca} \\ i_b &= i_{bc} - i_{ab} \\ i_c &= i_{ca} - i_{bc} \end{aligned} \tag{14.23}$$

The line currents depend on the firing angle and may be discontinuous as shown. Due to the delta connection, the triplen harmonic currents flow around the closed delta and do not appear in the line. The rms value of the line current varies between the range

$$\sqrt{2}I_\Delta \leq I_{L,\,rms} \leq \sqrt{3}I_{\Delta,\,rms} \tag{14.24}$$

as the conduction angle varies from very small (large α) to 180 degrees ($\alpha = 0$).

14.4 Cycloconverters

In contrast to the ac voltage controllers operating at constant frequency discussed so far, a cycloconverter operates as a direct ac-ac frequency changer with inherent voltage control feature. The basic principle of this converter to construct an alternating voltage wave of lower frequency from successive segment of

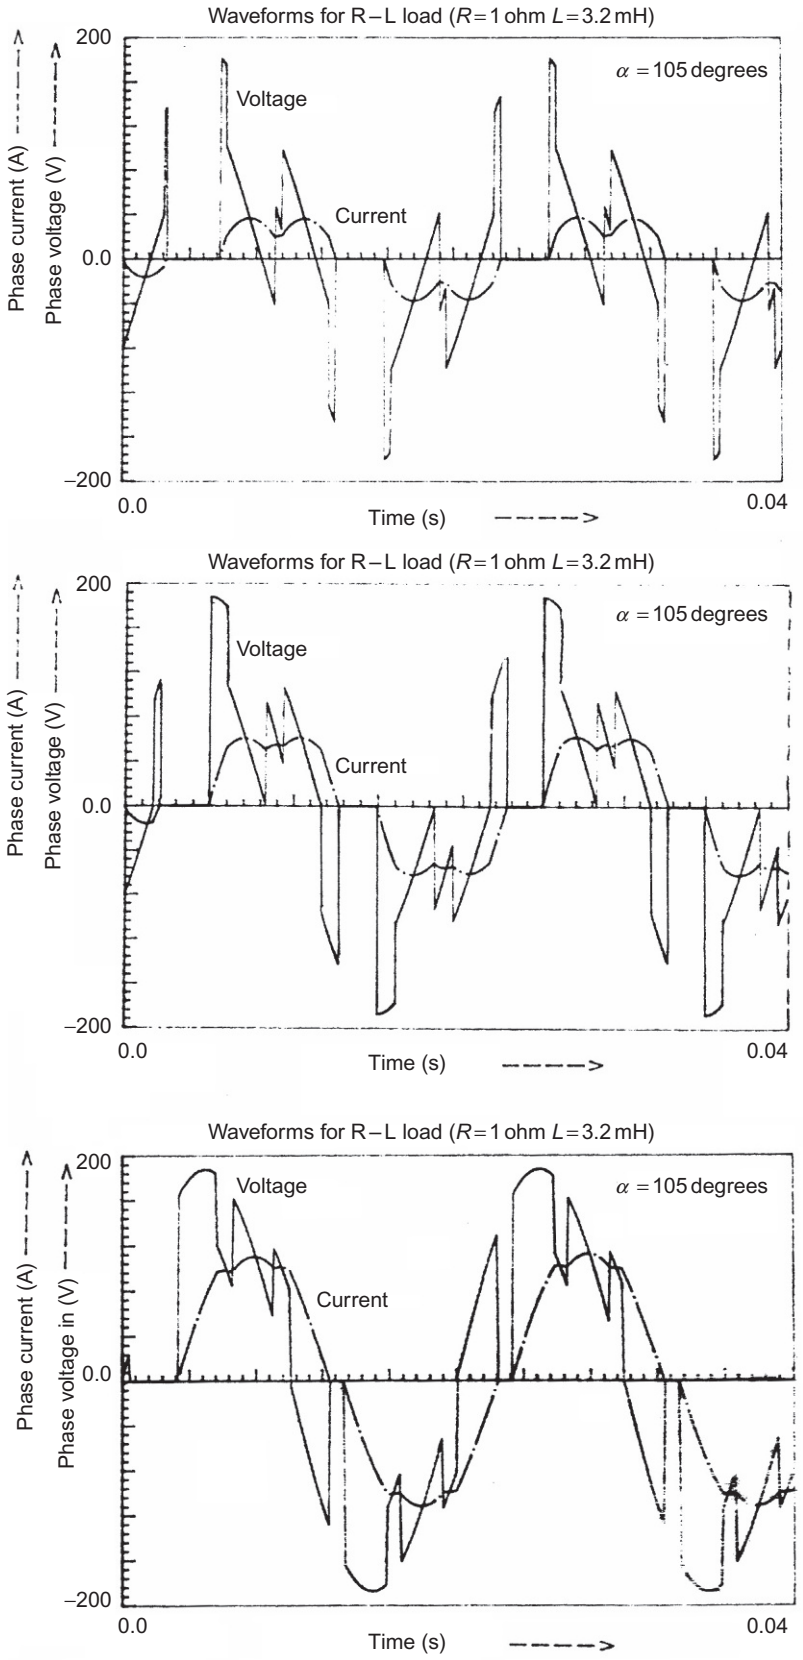

FIG. 14.14 Typical simulation results for three-phase ac voltage controller-fed RL load ($R = 1\,\Omega, L = 3.2\,\text{mH}$) for $\alpha = 60°$, 90°, and 105°.

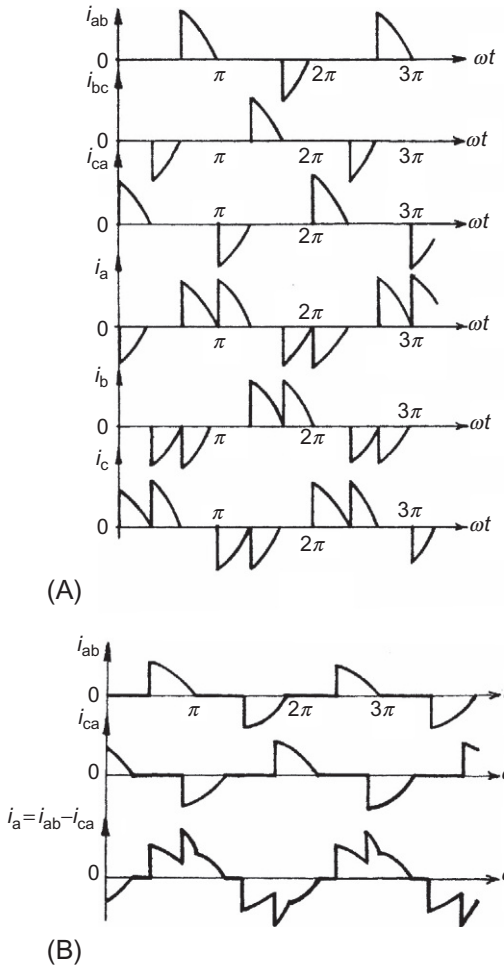

FIG. 14.15 Waveforms of a three-phase ac voltage controller with a delta-connected R-load: (A) $\alpha = 120°$ and (B) $\alpha = 90°$.

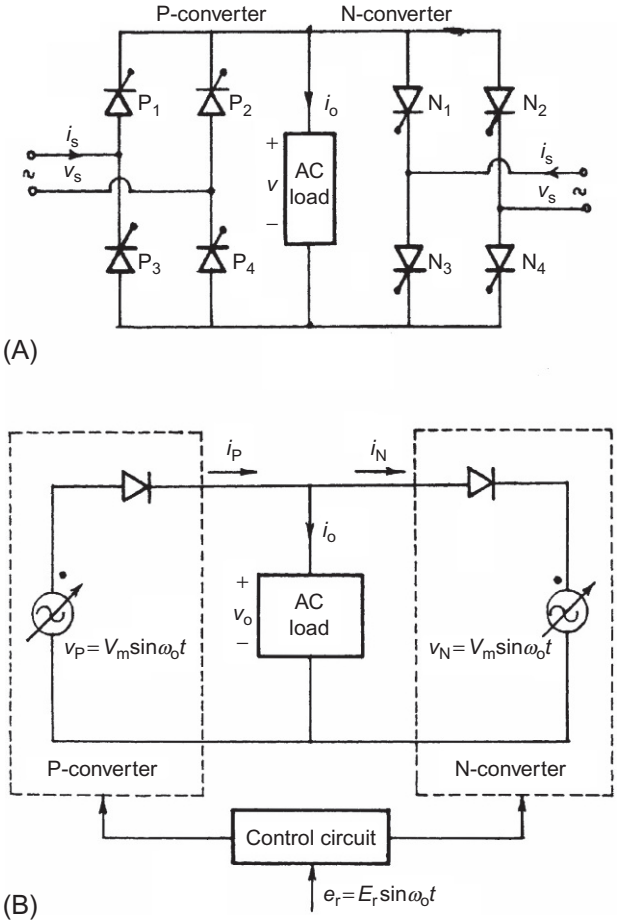

FIG. 14.16 (A) Power circuit for a single-phase bridge cycloconverter and (B) simplified equivalent circuit of a cycloconverter.

voltage waves of higher frequency ac supply by a switching arrangement was conceived and patented in the 1920s. Grid-controlled mercury-arc rectifiers were used in these converters installed in Germany in the 1930s to obtain $16\frac{2}{3}-$ Hz single-phase supply for ac series traction motors from a three-phase 50 Hz system, while at the same time, a cycloconverter using 18 thyratrons supplying a 400 hp synchronous motor was in operation for some years as a power station auxiliary drive in the United States. However, the practical and commercial utilization of these schemes waited till the SCRs became available in the 1960s. With the development of large-power SCRs and microprocessor-based control, the cycloconverter today is a matured practical converter for application in large-power low-speed variable-voltage variable-frequency (VVVF) ac drives in cement and steel rolling mills and in variable-speed constant-frequency (VSCF) systems in aircrafts and naval ships.

A cycloconverter is a naturally commuted converter with inherent capability of bidirectional power flow, and there is no real limitation on its size unlike an SCR inverter with commutation elements. Here, the switching losses are considerably low, the regenerative operation at full power over complete speed range is inherent and it delivers a nearly sinusoidal waveform resulting in minimum torque pulsation and harmonic heating effects. It is capable of operating even with blowing out of individual SCR fuse (unlike inverter), and the requirements regarding turn-off time, current rise time, and *dv*/*dt* sensitivity of SCRs are low. The main limitations of a naturally commutated cycloconverter are (1) limited frequency range for subharmonic free and efficient operation and (2) poor input displacement/power factor, particularly at low-output voltages.

14.4.1 Single-Phase to Single-Phase Cycloconverter

Though rarely used, the operation of a single-phase to single-phase cycloconverter is useful to demonstrate the basic principle involved. Fig. 14.16A shows the power circuit of a single-phase bridge type of cycloconverter, which has the same

arrangement as that of a single-phase dual converter. The firing angles of the individual two-pulse two-quadrant bridge converters are continuously modulated here, so that each ideally produces the same fundamental ac voltage at its output terminals as marked in the simplified equivalent circuit in Fig. 14.16B. Because of the unidirectional current-carrying property of the individual converters, it is inherent that the positive half cycle of the current is carried by the P-converter and the negative half cycle of the current by the N-converter regardless of the phase of the current with respect to the voltage. This means that for a reactive load, each converter operates in both rectifying and inverting region during the period of the associated half cycle of the low-frequency output current.

Operation with R-Load. Fig. 14.17 shows the input and output voltage waveforms with a pure R-load for a $50-16\frac{2}{3}-$ Hz cycloconverter. The P- and N-converters operate for alternate $T_o/2$ periods. The output frequency $(1/T_o)$ can be varied by varying T_o and the voltage magnitude by varying the firing angle α of the SCRs. As shown in the figure, three cycles of the ac input wave are combined to produce one cycle of the output frequency to reduce the supply frequency to one-third across the load.

If α_P is the firing angle of the P-converter, the firing angle of the N-converter α_N is $\pi-\alpha_P$, and the average voltage of the P-converter is equal and opposite to that of the N-converter.

The inspection of Fig. 14.17 shows that the waveform with α remaining fixed in each half cycle generates a square wave having a large low-order harmonic content. A near approximation to sine wave can be synthesized by a phase modulation of the firing angles as shown in Fig. 14.18 for a 50–10 Hz cycloconverter. The harmonics in the load voltage waveform are less compared with earlier waveform. The supply current, however, contains a subharmonic at the output frequency for this case as shown.

Operation with RL Load. The cycloconverter is capable of supplying loads of any power factor. Fig. 14.19 shows the idealized output voltage and current waveforms for a lagging power factor load where both the converters are operating as rectifier and inverter at the intervals marked. The load current lags the output voltage, and the load current direction determines

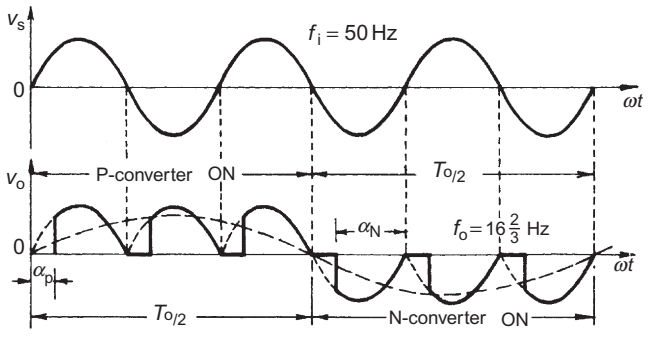

FIG. 14.17 Input and output waveforms of a $50-16\frac{2}{3}-$ Hz cycloconverter with RL load.

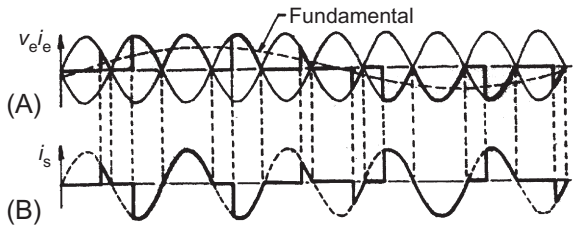

FIG. 14.18 Waveforms of a single-phase to single-phase cycloconverter (50–10 Hz) with RL load: (A) load voltage and load current and (B) input supply current.

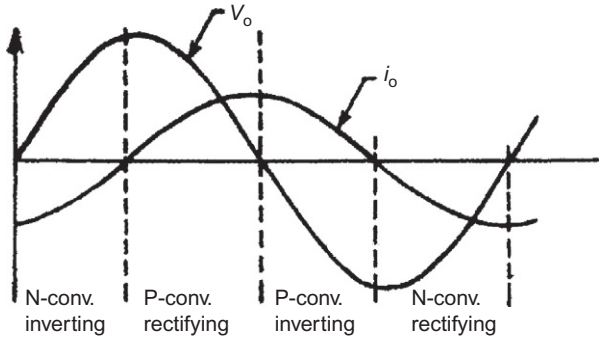

FIG. 14.19 Idealized load voltage and current waveform for a cycloconverter with RL load.

which converter is conducting. Each converter continues to conduct after its output voltage changes polarity, and during this period, the converter acts as an inverter, and the power is returned to the ac source. Inverter operation continues till the other converter starts to conduct. By controlling the frequency of oscillation and the *depth of modulation* of the firing angles of the converters (as shown later), it is possible to control the frequency and the amplitude of the output voltage.

The load current with RL load may be continuous or discontinuous depending on the load phase angle, ϕ. At light load inductance or for $\phi \le \alpha \le \pi$, there may be discontinuous load current with short zero-voltage periods. The current wave may contain even harmonics and subharmonic components. Further, as in the case of dual converter, although the mean output voltage of the two converters is equal and opposite, the instantaneous values may be unequal and a circulating current can flow within the converters. This circulating current can be limited by having a center-tapped reactor connected between the converters or can be completely eliminated by logical control similar to the dual converter case when the gate pulses to the converter remaining idle are suppressed, when the other converter is active. In practice, a zero-current interval of short duration is needed, in addition, between the operation of the P- and N-converters to ensure that the supply lines of the two converters are not short-circuited. With circulating current-free operation, the control scheme becomes complicated if the load current is discontinuous.

In the case of the circulating current scheme, the converters are kept in virtually continuous conduction over the whole range, and the control circuit is simple. To obtain reasonably good sinusoidal voltage waveform using the line-commutated two-quadrant converters and eliminate the possibility of the short circuit of the supply voltages, the output frequency of the cycloconverter is limited to a much lower value of the supply frequency. The output voltage waveform and the output frequency range can be improved further by using converters of higher pulse numbers.

14.4.2 Three-Phase Cycloconverters

14.4.2.1 Three-Phase Three-Pulse Cycloconverter

Fig. 14.20A shows the schematic diagram of a three-phase half-wave (three-pulse) cycloconverter feeding a single-phase load and Fig. 14.20B the configuration of a three-phase half-wave (three-pulse) cycloconverter feeding a three-phase load. The basic process of a three-phase cycloconversion is illustrated in Fig. 14.20C at 15 Hz, 0.6 power factor lagging load from a 50 Hz supply. As the firing angle α is cycled from zero at "a" to 180 degrees at "j," half a cycle of output frequency is produced (the gating circuit is to be suitably designed to introduce this oscillation of the firing angle). For this load, it can be seen that although the mean output voltage reverses at X, the mean output current (assumed sinusoidal) remains positive until Y. During XY, the SCRs A, B, and C in P-converter are "inverting."

A similar period exists at the end of the negative half cycle of the output voltage when D, E, and F SCRs in N-converter are "inverting." Thus, the operation of the converter follows in the order of "rectification" and "inversion" in a cyclic manner; the relative durations are dependent on load power factor. The output frequency is that of the firing angle oscillation about a quiescent point of 90 degrees (condition when the mean output voltage, given by $V_o = V_{do} \cos \alpha$, is zero). For obtaining the positive half cycle of the voltage, firing angle α is varied from 90 to 0 degrees, and then to 90 degrees and, for the negative half cycle, from 90, to 180 degrees, and back to 90 degrees. Variation of α within the limits of 180 degrees automatically provides for

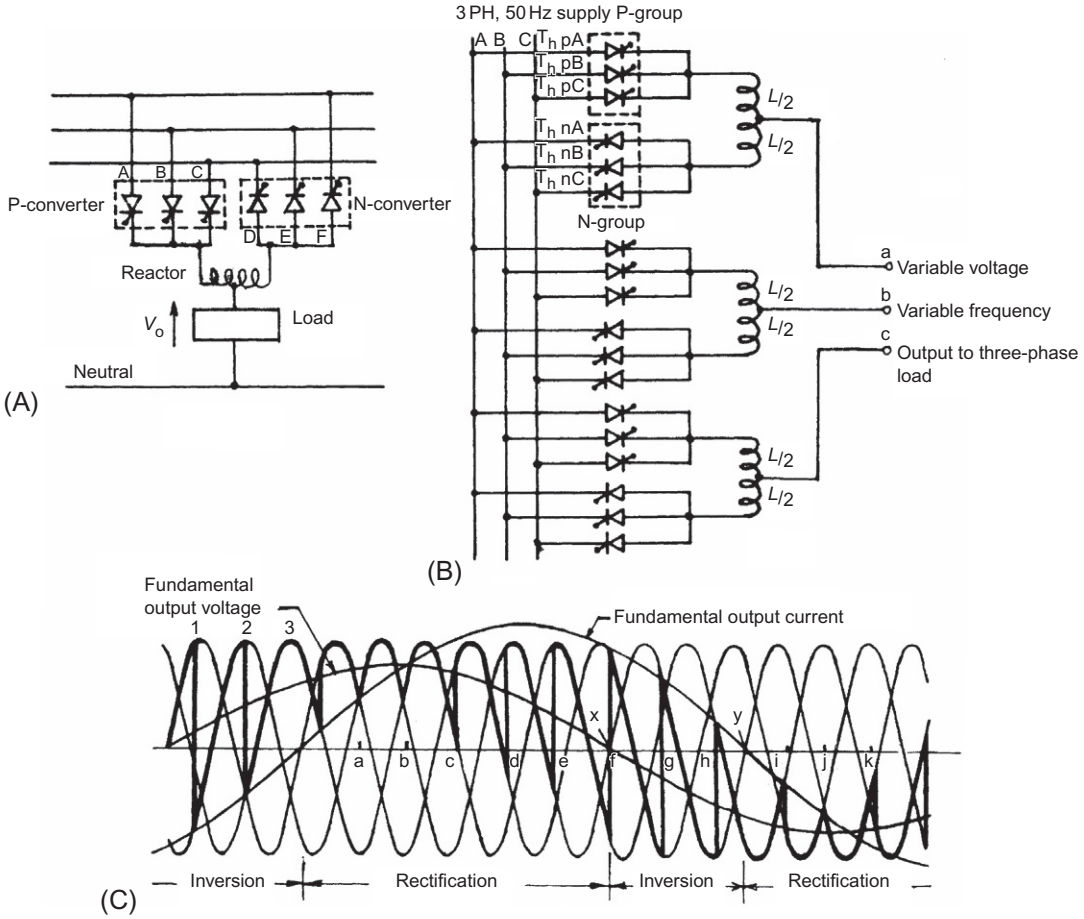

FIG. 14.20 (A) Three-phase half-wave (three-pulse) cycloconverter supplying a single-phase load, (B) three-pulse cycloconverter supplying a three-phase load, and (C) output voltage waveform for one phase of a three-pulse cycloconverter operating at 15 Hz from a 50 Hz supply and 0.6 power factor lagging load.

"natural" line commutation of the SCRs. It is shown that a complete cycle of low-frequency output voltage is fabricated from the segments of the three-phase input voltage by using the phase-controlled converters. The P-converter or N-converter SCRs receive firing pulses, which are timed such that each converter delivers the same mean output voltage. This is achieved, as in the case of single-phase cycloconverter or the dual converter, by maintaining the firing angle constraints of the two groups as $\alpha_P = 180\,\text{degrees} - \alpha_N$. However, the instantaneous voltages of two converters are not identical, and large circulating current may result unless limited by intergroup reactor as shown (*circulating current cycloconverter*) or completely suppressed by removing the gate pulses from the nonconducting converter by an intergroup blanking logic (*circulating current-free cycloconverter*).

Circulating-Current Mode Operation. Fig. 14.21 shows typical waveforms of a three-pulse cycloconverter operating with circulating current. Each converter conducts continuously with rectifying and inverting modes as shown, and the load is supplied with an average voltage of two converters reducing some of the ripple in the process, the intergroup reactor behaving as a potential divider. The reactor limits the circulating current; the value of its inductance to the flow of load current is one-fourth of its value to the flow of circulating current as the inductance is proportional to the square of the number of turns. The fundamental wave produced by both the converters is the same. The reactor voltage is the instantaneous difference between the converter voltages, and the time integral of this voltage divided by the inductance (assuming negligible circuit resistance) is the circulating current. For a three-pulse cycloconverter, it can be observed that this current reaches its peak when $\alpha_P = 60\,\text{degrees}$ and $\alpha_N = 120\,\text{degrees}$.

Output Voltage Equation. A simple expression for the fundamental rms output voltage of the cycloconverter and the required variation of the firing angle α can be derived with the following assumptions: (1) the firing angle α in successive half cycles is varied slowly resulting in a low-frequency output, (2) the source impedance and the commutation overlap are neglected, (3) the SCRs are ideal switches, and (4) the current is continuous and ripple-free. The average dc output voltage of a p-pulse dual converter with fixed α is

$$V_{do} = V_{domax}\cos\alpha, \quad \text{where } V_{domax} = \sqrt{2}V_{ph}\frac{p}{\pi}\sin\frac{\pi}{p} \tag{14.25}$$

For the p-pulse dual converter operating as a cycloconverter, the average phase voltage output at any point of the low frequency should vary according to the equation

$$V_{o,\,av} = V_{o1,\ \max}\sin\omega_o t \tag{14.26}$$

where $V_{o1,max}$ is the desired maximum value of the fundamental output of the cycloconverter.

Comparing Eq. (14.25) with Eq. (14.26), the required variation of α to obtain a sinusoidal output is given by

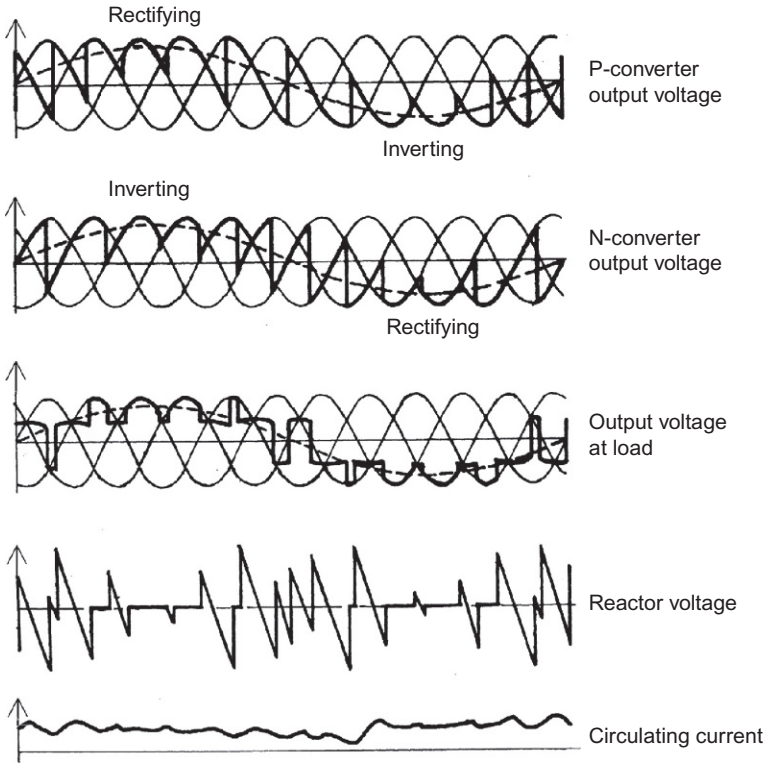

FIG. 14.21 Waveforms of a three-pulse cycloconverter with circulating current.

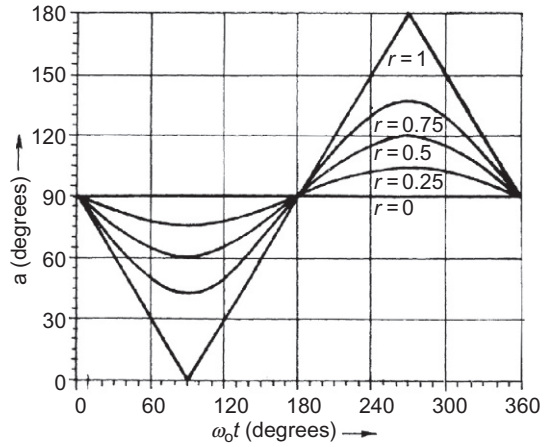

FIG. 14.22 Variations of the firing angle (α) with r in a cycloconverter.

$$\alpha = \cos^{-1}[(V_{o1,\ \max}/V_{domax})\sin\omega_o t] = \cos^{-1}[r\sin\omega_o t] \tag{14.27}$$

where r is the ratio ($V_{o1,max}/V_{domax}$), the *voltage magnitude control ratio*.

Eq. (14.27) shows α as a nonlinear function with r (≤ 1) as shown in Fig. 14.22.

However, the firing angle α_P of the P-converter cannot be reduced to 0 degrees as this corresponds to $\alpha_N = 180$ degrees for the N-converter, which, in practice, cannot be achieved because of allowance for commutation overlap and finite turn-off time of the SCRs. Thus, the firing angle α_P can be reduced to a certain finite value α_{min}, and the maximum output voltage is reduced by a factor cos α_{min}.

The fundamental rms voltage per phase of either converter is

$$V_{or} = V_{oN} = V_{op} = rV_{ph}\frac{p}{\pi}\sin\frac{\pi}{p} \tag{14.28}$$

Though the rms values of the low-frequency output voltage of the P-converter and that of the N-converter are equal, the actual waveforms differ, and the output voltage at the midpoint of the circulating current-limiting reactor (Fig. 14.21), which is the same as the load voltage, is obtained as the mean of the instantaneous output voltages of the two converters.

Circulating Current-free Mode Operation. Fig. 14.23 shows the typical waveforms for a three-pulse cycloconverter operating in this mode with RL load assuming *continuous-current* operation. Depending on the load current direction, only one converter operates at a time, and the load voltage is the same as the output voltage of the conducting converter. As explained earlier in the case of single-phase cycloconverter, there is a possibility of short circuit of the supply voltages at the crossover points of the converter unless taken care of in the control circuit. The waveforms drawn also neglect the effect of overlap due to the ac supply inductance. A reduction in the output voltage is possible by retarding the firing angle gradually at the points a, b, c, d, and e in Fig. 14.23. (This can be easily implemented by reducing the magnitude of the reference voltage in the control circuit.) The circulating current is completely suppressed by blocking all the SCRs in the converter, which is not delivering the load current. A current sensor is incorporated in each output phase of the cycloconverter, which detects the direction of the output current and feeds an appropriate signal to the control circuit to inhibit or blank the gating pulses to the nonconducting converter in the same way as in the case of a dual converter for dc drives. The circulating current-free

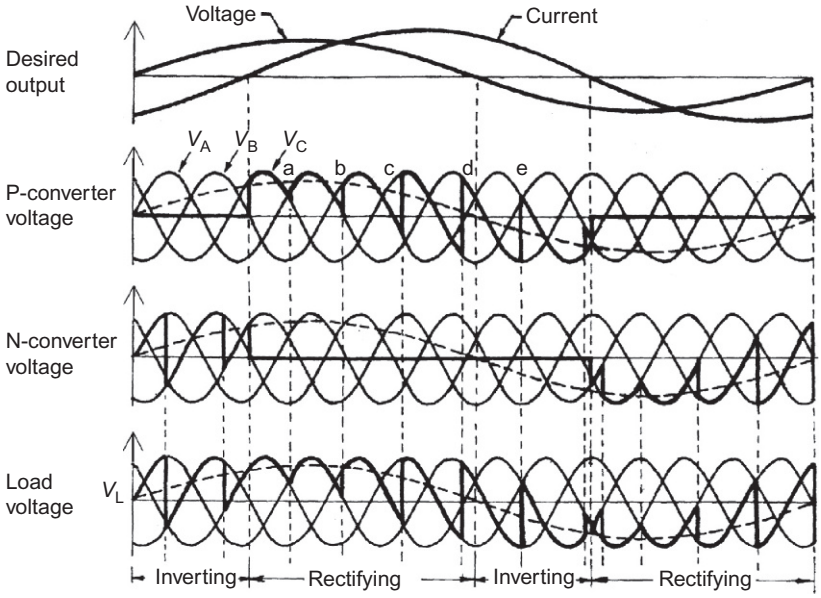

FIG. 14.23 Waveforms for a three-pulse circulating current-free cycloconverter with RL load.

operation improves the efficiency and the displacement factor of the cycloconverter and also increases the maximum usable output frequency. The load voltage transfers smoothly from one converter to the other.

14.4.2.2 Three-Phase Six-Pulse and Twelve-Pulse Cycloconverter

A six-pulse cycloconverter circuit configuration is shown in Fig. 14.24. Typical load voltage waveforms for 6-pulse (with 36 SCRs) and 12-pulse (with 72 SCRs) cycloconverters are shown in Fig. 14.25, the 12-pulse converter being obtained by connecting two six-pulse configurations in series and appropriate transformer connections for the required phase shift. It may be seen that the higher pulse numbers will generate waveforms closer to the desired sinusoidal form and thus permit higher frequency output. The phase loads may be isolated from each other as shown or interconnected with suitable secondary winding connections.

14.4.3 Cycloconverter Control Scheme

Various possible control schemes, analog and digital, for deriving trigger signals and for controlling the basic cycloconverter have been developed over the years.

Out of the several possible signal combinations, it has been shown [8] that a sinusoidal reference signal ($e_r = E_r \sin \omega_o t$) at desired output frequency f_o and a cosine modulating signal ($e_m = E_m \cos \omega_i t$) at input frequency f_i is the best combination possible for comparison to derive the trigger signals for the SCRs (Fig. 14.26 [9]), which produces the output waveform with the lowest total harmonic distortion. The modulating voltages can be obtained as the phase-shifted voltages (B-phase for

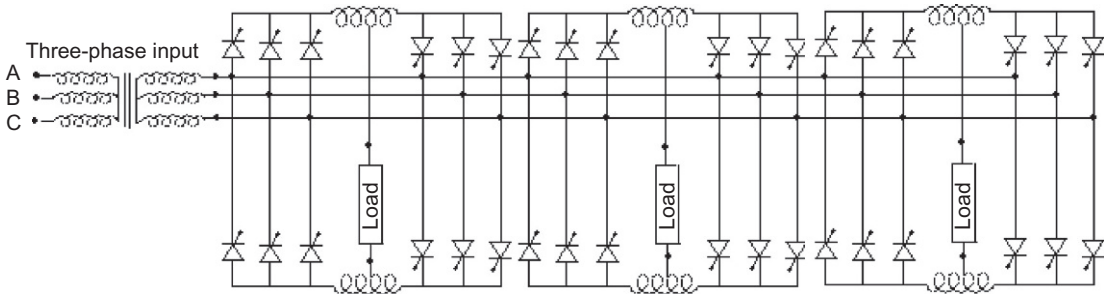

FIG. 14.24 Three-phase six-pulse cycloconverter with isolated loads.

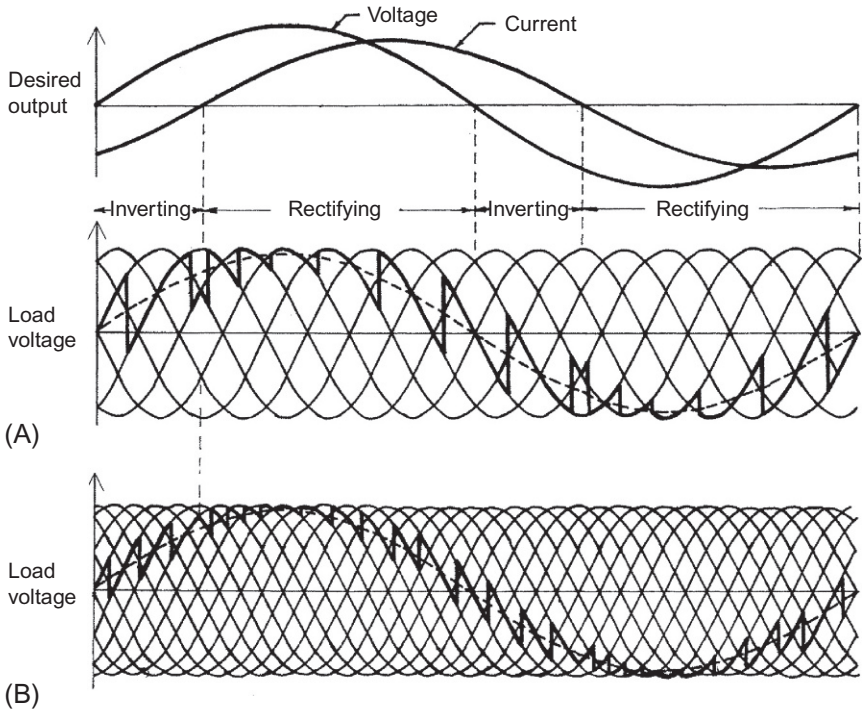

FIG. 14.25 Cycloconverter load voltage waveforms with lagging power factor load: (A) six-pulse connection and (B) twelve-pulse connection.

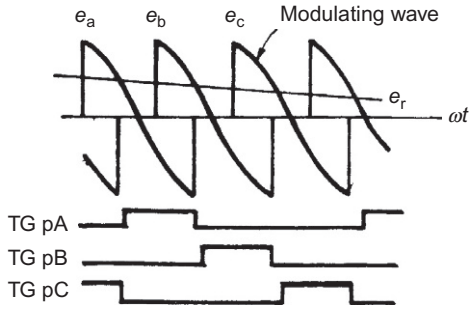

FIG. 14.26 Deriving firing signals for one converter group of a three-pulse cycloconverter.

A-phase SCRs, C-phase voltage for B-phase SCRs, and so on) as explained in Fig. 14.27, where at the intersection point "a"

$$E_m \sin(\omega_i t - 120 \text{ degrees}) = -E_r \sin(\omega_o t - \phi)$$
$$\text{or } \cos(\omega_i t - 30 \text{ degrees}) = (E_r/E_m)\sin(\omega_o t - \phi)$$

From Fig. 14.27, the firing delay for A-phase SCR, $\alpha = (\omega_i t - 30 \text{ degrees})$

$$\text{So, } \cos\alpha = (E_r/E_m)\sin(\omega_o t - \phi)$$

The cycloconverter output voltage for continuous-current operation,

$$V_o = V_{do}\cos\alpha = V_{do}(E_r/E_m)\sin(\omega_o t - \phi) \qquad (14.29)$$

in which the equation shows that the amplitude, frequency, and phase of the output voltage can be controlled by controlling corresponding parameters of the reference voltage, thus making the transfer characteristic of the cycloconverter linear. The derivation of the two complimentary voltage waveforms for the P-group or N-group converter "banks" in this way is illustrated in Fig. 14.28. The final cycloconverter output wave shape is composed of alternate half-cycle segments of the complementary P-converter and the N-converter output voltage waveforms that coincide with the positive and negative current half cycles, respectively.

Control Circuit Block Diagram. Fig. 14.29 [10] shows a simplified block diagram of the control circuit for a circulating current-free cycloconverter implemented with ICs in the early

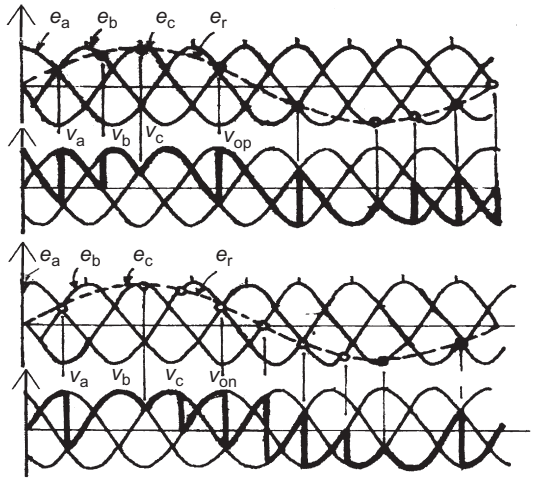

FIG. 14.28 Derivation of P-converter and N-converter output voltages.

seventies in the Power Electronics Laboratory at IIT Kharagpur in India. The same circuit is also applicable to a circulating current cycloconverter with the omission of the *converter group selection and blanking* circuit.

The *synchronizing circuit* produces the modulating voltages ($e_a = -Kv_b$, $e_b = -Kv_c$, $e_c = -Kv_a$), synchronized with the mains through step-down transformers and proper filter circuits.

The *reference source* produces variable-magnitude variable-frequency three-phase voltages (e_{ra}, e_{rb}, e_{rc}) for comparison with the modulation voltages. Various ways, analog or digital, have been developed to implement this reference source as in the case of the PWM inverter. In one of the early analog schemes, Fig. 14.30 [10], for a three-pulse cycloconverter, a variable-frequency UJT relaxation oscillator of frequency $6f_d$ triggers a ring counter to produce a three-phase square-wave output of frequency f_d that is used to modulate a single-phase fixed frequency (f_c) variable amplitude sinusoidal voltage in a three-phase full-wave transistor chopper. The three-phase output contains ($f_c - f_d$), ($f_c + f_d$), ($3f_d + f_c$), etc. frequency components from where the "wanted" frequency component ($f_c - f_d$) is filtered out for each phase using a low-pass filter. For example, with $f_c = 500$ Hz and frequency of the relaxation oscillator

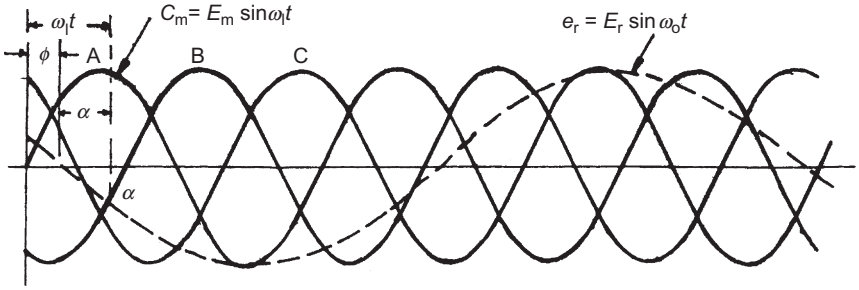

FIG. 14.27 Derivation of the cosine modulating voltages.

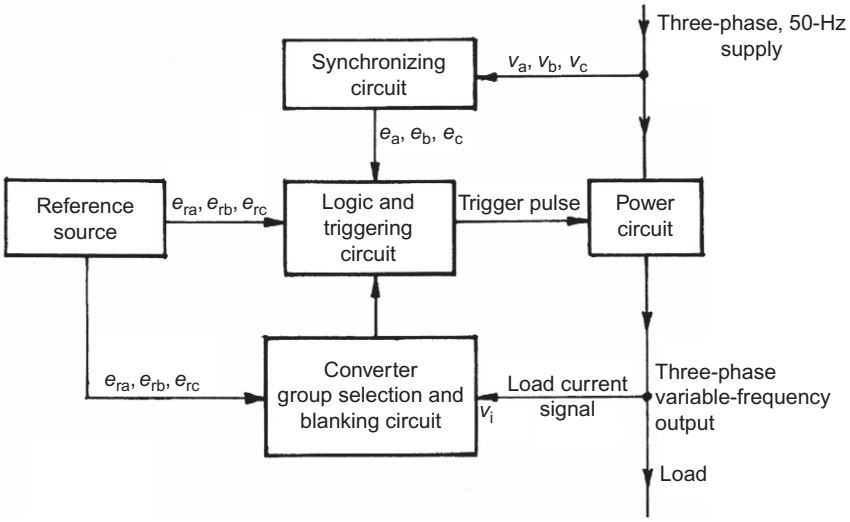

FIG. 14.29 Block diagram for a circulating current-free cycloconverter control circuit.

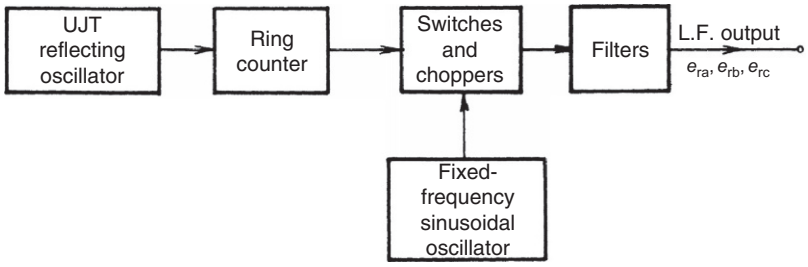

FIG. 14.30 Block diagram of a variable-voltage variable-frequency three-phase reference source.

varying between 2820 and 3180 Hz, a three-phase 0–30 Hz reference output can be obtained with the facility for phase sequence reversal.

The *logic and trigger circuit* for each phase involves comparators for comparison of the reference and modulating voltages and inverters acting as buffer stages. The outputs of the comparators are used to clock the flip-flops or latches whose outputs in turn feed the SCR gates through AND gates and pulse amplifying and isolation circuits; the second input to the AND gates is from the *converter group selection and blanking circuit*.

In the *converter group selection and blanking circuit*, the zero crossing of the current at the end of each half cycle is detected and is used to regulate the control signals to either P-group or N-group converters depending on whether the current goes to zero from negative to positive or positive to negative, respectively. However, in practice, the current being discontinuous passes through multiple zero crossings while changing direction, which may lead to undesirable switching of the converters. So, in addition to the current signal, the reference voltage signal is also used for the group selection, and a *threshold* band is introduced in the current signal detection to avoid inadvertent switching of the converters. Further, a delay circuit provides a blanking period of appropriate duration between the converter groups switching to avoid line-to-line short circuits [10]. In some schemes, the delays are not introduced when a small circulating current is allowed during crossover instants limited by reactors of limited size, and this scheme operates in the so-called "dual mode"—circulating current and circulating current-free mode for minor and major portions of the output cycle, respectively. A different approach to the converter group selection, based on the closed-loop control of the output voltage where a bias voltage is introduced between the voltage transfer characteristics of the converters to reduce circulating current, is discussed in [8].

Improved Control Schemes. With the development of microprocessors and PC-based systems, digital software control has taken over many tasks in modern cycloconverters, particularly in replacing the low-level reference waveform generation and analog signal comparison units. The reference waveforms can be easily generated in the computer, stored in the EPROMs, and accessed under the control of a stored program and microprocessor clock oscillator. The analog signal voltages can be converted to digital signals by using analog-to-digital converters (ADCs). The waveform comparison can then be made with the comparison features of the microprocessor system.

The addition of time delays and intergroup blanking can also be achieved with digital techniques and computer software. A modification of the cosine firing control using communication principles, such as *regular sampling* in preference to the *natural sampling* (discussed so far) of the reference waveform, yielding a stepped sine wave before comparison with the cosine wave [11] has been shown to reduce the presence of *subharmonics* (discussed later) in the circulating current cycloconverter and facilitate microprocessor-based implementation, as in the case of PWM inverter.

For a six-pulse noncirculating current cycloconverter-fed synchronous motor drive with a vector control scheme and a flux observer, a PC-based hybrid control scheme (a combination of analog and digital control) has been reported in [12]. Here, the functions such as comparison, group selection, blanking between the groups and triggering signal generation, and filtering and phase conversion are left to the analog controller and digital controller that take care of more serious tasks such as voltage decoupling for current regulation; flux estimation using observer; speed, flux and field current regulators using PI-controllers; and position and speed calculation leading to an improvement of sampling time and design accuracy.

14.4.4 Cycloconverter Harmonics and Input Current Waveform

The exact wave shape of the output voltage of the cycloconverter depends on (1) the pulse number of the converter, (2) the ratio of the output to input frequency (f_o/f_i), (3) the relative level of the output voltage, (4) the load displacement angle, (5) the circulating current or circulating current-free operation, and (6) the method of control of the firing instants. The harmonic spectrum of a cycloconverter output voltage is different and more complex than that of a phase-controlled converter. It has been revealed [8] that because of the continuous "to-and-fro" phase modulation of the converter firing angles, the harmonic distortion components (known as *necessary distortion terms*) have frequencies that are sums and differences between multiples of output and input supply frequencies.

Circulating Current-Free Operation. A derived general expression for the output voltage of a cycloconverter with circulating current-free operation [8] shows the following spectrum of harmonic frequencies for the 3-pulse, 6-pulse, and 12-pulse cycloconverters employing cosine modulation technique:

$$\begin{aligned} 3-\text{pulse}: f_{oH} &= |3(2k-1)f_i \pm 2nf_o| \quad \text{and} \quad |6kf_i \pm (2n+1)f_o| \\ 6-\text{pulse}: f_{oH} &= |6kf_i \pm (2n+1)f_o| \\ 12-\text{pulse}: f_{oH} &= |6kf_i \pm (2n+1)f_o| \end{aligned} \tag{14.30}$$

where k is any integer from 1 to infinity and n is any integer from 0 to infinity.

It may be observed that for certain ratios of f_o/f_i, the order of harmonics may be less or equal to the desired output frequency. All such harmonics are known as *subharmonics*, since they are not higher multiples of the input frequency. These subharmonics may have considerable amplitudes (e.g., with a 50 Hz input frequency and 35 Hz output frequency, a subharmonic of frequency $3 \times 50 - 4 \times 35 = 10$ Hz is produced whose magnitude is 12.5% of the 35 Hz component [11]) and are difficult to filter and so objectionable. Their spectrum increase with the increase of the ratio f_o/f_i and so limits its value at which a tolerable waveform can be generated.

Circulating-Current Operation. For circulating current operation with continuous current, the harmonic spectrum in the output voltage is the same as that of the circulating current-free operation except that each harmonic family now terminates at a definite term, rather than having infinite number of components. They are

$$\begin{aligned} 3-\text{pulse}: f_{oH} &= |3(2k-1)f_i \pm 2nf_o|, \quad n \le 3(2k-1)+1 \\ &\text{and} \quad |6kf_i \pm (2n+1)f_o|, \quad (2n+1) \le (6k+1) \\ 6-\text{pulse}: f_{oH} &= |6kf_i \pm (2n+1)f_o|, \quad (2n+1) \le (6k+1) \\ 12-\text{pulse}: f_{oH} &= |6kf_i \pm (2n+1)f_o|, \quad (2n+1) \le (12k+1) \end{aligned} \tag{14.31}$$

The amplitude of each harmonic component is a function of the output voltage ratio for the circulating current cycloconverter and the output voltage ratio and the load displacement angle for the circulating current-free mode.

From the point of view of maximum useful attainable output-to-input frequency ratio (f_i/f_o) with the minimum amplitude of objectionable harmonic components, a guideline is available in [8] for it as 0.33, 0.5, and 0.75 for 3-, 6-, and 12-pulse cycloconverter, respectively. However, with the modification of the cosine-wave modulation timings like *regular sampling* [11] in the case of circulating current cycloconverters only and using a *subharmonic detection and feedback control concept* [13,14] for both circulating and circulating current-free cases, the subharmonics can be suppressed, and useful frequency range for the naturally commutated cycloconverters can be increased.

Other Harmonic Distortion Terms. Besides the harmonics as mentioned, other harmonic distortion terms consisting of frequencies of integral multiples of desired output frequency appear if the transfer characteristic between the output and reference voltages is not linear. These are called *unnecessary distortion terms* that are absent when the output frequencies are much less than the input frequency. Further, some *practical distortion terms* may appear due to some practical nonlinearities and imperfections in the control circuits of the cycloconverter, particularly at relatively lower levels of output voltage.

Input Current Waveform. Although the load current, particularly for higher pulse cycloconverters can be assumed to be sinusoidal, the input current is more complex being made of

pulses. Assuming the cycloconverter to be an ideal switching circuit without losses, it can be shown from the instantaneous power balance equation that in cycloconverter supplying a single-phase load, the input current has harmonic components of frequencies ($f_1 \pm 2f_o$) called *characteristic harmonic frequencies* that are independent of pulse number, and they result in an oscillatory power transmittal to the ac supply system. In the case of cycloconverter feeding a balanced three-phase load, the net instantaneous power is the sum of the three oscillating instantaneous powers when the resultant power is constant, and the net harmonic component is much reduced compared with that of a single-phase load case. In general, the total rms value of the input current waveform consists of three components: in-phase, quadrature, and the harmonic. The in-phase component depends on the active power output, while the quadrature component depends on the net average of the oscillatory firing angle and is always lagging.

14.4.5 Cycloconverter Input Displacement/ Power Factor

The input supply performance of a cycloconverter such as displacement factor or fundamental power factor, input power factor, and the input current distortion factor is defined similar to those of the phase-controlled converter. The harmonic factor for the case of a cycloconverter is relatively complex as the harmonic frequencies are not simple multiples of the input frequency but are sums and differences between multiples of output and input frequencies.

Irrespective of the nature of the load, leading, lagging, or unity power factor, the cycloconverter requires reactive power decided by the average firing angle. At low-output voltage, the average phase displacement between the input current and the voltage is large, and the cycloconverter has a low input displacement and power factor. Besides load displacement factor and output voltage ratio, another component of the reactive current arises due to the modulation of the firing angle in the fabrication process of the output voltage [8]. In a phase-controlled converter supplying dc load, the maximum displacement factor is unity for maximum dc output voltage. However, in the case of the cycloconverter, the maximum input displacement factor is 0.843 with unity power factor load [8,15]. The displacement factor decreases with reduction in the output voltage ratio. The distortion factor of the input current is given by (I_1/I), which is always less than 1, and the resultant power factor (= distortion factor × displacement factor) is thus much lower (around 0.76 maximum) than the displacement factor, and this is a serious disadvantage of the naturally commutated cycloconverter (NCC).

14.4.6 Effect of Source Impedance

The source inductance introduces commutation overlap and affects the external characteristics of a cycloconverter similar to the case of a phase-controlled converter with the dc output. It introduces delay in transfer of current from one SCR to another and results in a voltage loss at the output and a modified harmonic distortion. At the input, the source impedance causes "rounding off" of the steep edges of the input current waveforms, resulting in reduction in the amplitudes of higher order harmonic terms and a decrease in the input displacement factor.

14.4.7 Simulation Analysis of Cycloconverter Performance

The nonlinearity and discrete time nature of practical cycloconverter systems, particularly for discontinuous-current conditions, make an exact analysis quite complex, and a valuable design and analytic tool is a digital computer simulation of the system. Two general methods of computer simulation of the cycloconverter waveforms for RL and induction motor loads with circulating current and circulating current-free operation have been suggested in [16] where one of the methods that is very fast and convenient is the *crossover point method* that gives the crossover points (intersections of the modulating and reference waveforms) and the conducting phase numbers for both P- and N-converters from which the output waveforms for a particular load can be digitally computed at any interval of time for a practical cycloconverter.

14.4.8 Power Quality Issues

Degradation of power quality (PQ) in a cycloconverter-fed system due to subharmonics/interharmonics in the input and the output has been a subject of recent studies [14,17]. In [17], the study includes the impact of cycloconverter control strategies on the total harmonic distortion (THD), distribution transformers, and communication lines, while in [14], the PQ indices are suitably defined and the effect on THD, input/output displacement factor, and input/output power factor for a cycloconverter-fed synchronous motor drive is studied together with a development of a simple feedback method of reduction of subharmonics/low-frequency interharmonics for the improvement of the power quality. The implementation of this scheme, detailed in [14], requires a simple modification of the control circuit of the cycloconverter in contrast to the expensive power level active filters otherwise required for suppression of such harmonics [18].

14.4.9 Forced Commutated Cycloconverter

The naturally commutated cycloconverter (NCC) with SCRs as devices, so far discussed, is sometimes referred to as a *restricted frequency changer*; in view of the allowance on the output voltage quality ratings, the maximum output voltage frequency is restricted ($f_o \ll f_i$), as mentioned earlier. With devices replaced

by fully controlled switches like forced commutated SCRs, power transistors, IGBTs, and GTOs, a forced commutated cycloconverter can be built where the desired output frequency is given by $f_o = |f_s - f_i|$, where f_s is the switching frequency, which may be larger or smaller than the f_i. In the case when $f_o \geq f_i$, the converter is called *unrestricted frequency changer* (*UFC*) and when $f_o \leq f_i$, it is called a *slow switching frequency changer* (*SSFC*). The early FCC structures have been comprehensively treated in [15]. It has been shown that in contrast with the NCC, where the input displacement factor (IDF) is always lagging, in UFC, it is leading when the load displacement factor is lagging and vice versa, and in SSFC, it is identical to that of the load. Further, with proper control in an FCC, the input displacement factor can be made unity displacement factor frequency changer (UDFFC) with concurrent composite voltage waveform or controllable displacement factor frequency changer (CDFFC), where P-converter and N-converter voltage segments can be shifted relative to the output current wave for control of IDF continuously from lagging via unity to leading.

In addition to allowing bilateral power flow, UFCs offer an unlimited output frequency range, offer good input voltage utilization, do not generate input current and output voltage subharmonics, and require only nine bidirectional switches (Fig. 14.31) for a three-phase to three-phase conversion. The main disadvantage of the structures treated in [15] is that they generate large unwanted low-order input current and output voltage harmonics that are difficult to filter out, particularly for low-output voltage conditions. This problem has largely been solved with an introduction of an imaginative PWM voltage control scheme in [19], which is the basis of the newly designated converter called the *matrix converter* (*also known as PWM cycloconverter*) that operates as a *generalized solid-state transformer* with significant improvement in voltage and input current waveforms resulting in sine-wave input and sine-wave output as discussed in the next section.

14.5 Matrix Converter

The matrix converter (MC) is a development of the FCC that employs bidirectional fully controlled switches, incorporating PWM voltage control, as mentioned earlier. With the initial

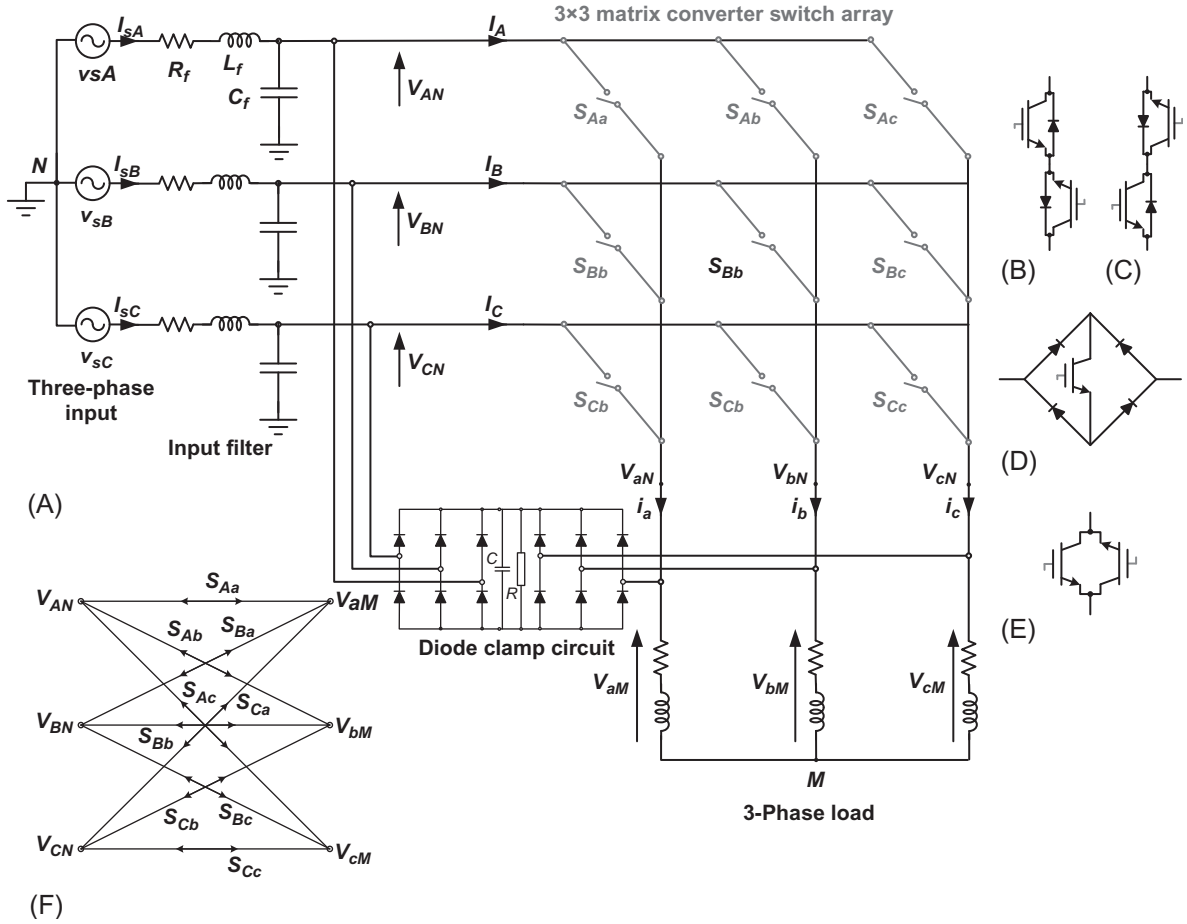

FIG. 14.31 (A) $3\varphi \times 3\varphi$ matrix converter circuit with input filter and clamp circuit; bidirectional switch configuration as (B) common emitter, (C) common collector, (D) transistor-diode bridge configuration, and (E) reverse blocking IGBT (RB-IGBT); and (F) switching matrix symbol for converter in (A).

progress made by Venturini [19–21], it has received considerable attention in recent years as it provides a good alternative to the conventionally employed rectifier-inverter topology or the back-to-back topology, having the advantages of being a single-stage converter with only nine switches for three-phase to three-phase conversion and inherent bidirectional power flow, sinusoidal input/output waveforms with moderate switching frequency, possibility of a compact design due to the absence of bulky dc link reactive components, and controllable input power factor independent of the output load current. Along with these theoretical advantages, [22] has mentioned advantages of MCs over conventional dc link variant as exhibition of better operation under high-temperature conditions, less voltage stress per switch, and less maintenance. The main disadvantages of the matrix converters developed so far are the inherent restriction of the *voltage transfer ratio* (0.866); more complex control, commutation, and protection strategy; and, above all, commercial nonavailability of a fully controlled bidirectional high frequency switch integrated in a silicon chip.

The power circuit diagram of the most practical three-phase to three-phase ($3\phi - 3\phi$) matrix converter is shown in Fig. 14.31A, which uses nine bidirectional switches so arranged that any of the three-input phases can be connected to any output phase as is shown symbolically in the switching matrix in Fig. 14.31F. The circuit is called a *matrix converter* as it provides exactly one switch for each of the possible connections between the input and the output. The voltage at any input terminal may be made to appear at any output terminal or terminals, while the current in any phase of the load may be drawn from any phase or phases of the input supply under following restrictions:

(a) *Only one* switch of the output leg can be closed due to the presence of capacitors.
(b) *At least one* switch in the output leg must be closed, as the inductive nature of the load makes it impossible to interrupt the load current suddenly.

Thus, *one and only one switch* in the output leg is to be closed. With these constraints, it can be visualized that out of the possible 512 $(=2^9)$ states of the converter, only 27 switch combinations are allowed as given in Table 14.1, which includes the resulting output line voltages and input phase currents. These combinations are divided into three groups. Group I consists of six combinations when each output phase is connected to a different input phase. In group II, there are three subgroups each having six combinations with two-output phases short-circuited (connected to the same input phase). Group III includes three combinations with all output phases short-circuited. For the switches, the inverse-parallel combination of reverse blocking self-controlled devices like power MOSFETs or IGBTs or transistor-embedded diode bridge as shown in Fig 14.3B–E has been used so far. Fig. 14.31B

and C are the conventionally employed common emitter and common collector configurations, respectively. These configurations allow *soft switching* from one bidirectional switch to other. The latter has an advantage that it requires less number of insulated power supplies to drive the switches than the former configuration [23]. New perspective configuration of the bidirectional switch is to use two RB-IGBTs with reverse blocking capability in antiparallel (symbol of which is shown in Fig 14.31E). This configuration leads to elimination of external diodes, which results in reduction in conduction losses and the transistor size [24].

With a given set of input three-phase voltages, any desired set of three-phase output voltages can be synthesized by adopting a suitable switching strategy. However, it has been shown [21,25,26] that regardless of the switching strategy, there are physical limits on the achievable output voltage with these converters as the maximum peak-to-peak output voltage cannot be greater than the minimum voltage difference between two phases of the input. To have complete control of the synthesized output voltage, the envelope of the three-phase reference or target voltages must be fully contained within the continuous envelope of the three-phase input voltages. Initial strategy with the output frequency voltages as references reported the limit as 0.5 of the input as shown in Fig. 14.32A. This can be increased to 0.866 by adding a third harmonic voltage of input frequency $(V_i/4)\cos 3\omega_i t$ to all target output voltages and subtracting from them a third harmonic voltage of output frequency $(V_o/6)\cos 3\omega_o t$ as shown in Fig. 14.32B [21,25]. The increase in amplitude is shown through line voltages (v_{ab}) in Fig. 14.32C. In fact, it is shown in [26] that the above optimization can be extended to m × n matrix converter (where m and n are both odd) by adding mth and subtracting the nth harmonic from all the target output voltages. Details on multiphase matrix converters are given in Chapter 16. However, this process involves considerable amount of additional computations in synthesizing the output voltages. The other alternative is to use the space vector modulation (SVM) strategy as used in PWM inverters without adding third harmonic components, but it also yields the maximum voltage transfer ratio as 0.866.

An ac input LC filter is used to eliminate the switching ripples generated in the converter, and the load is assumed to be sufficiently inductive to maintain continuity of the output currents. Work on input side filters can be seen in [27–29].

14.5.1 Operation and Control of Matrix Converter

The converter in Fig. 14.31 connects any input phase (A, B, and C) to any output phase (a, b, and c) at any instant. When connected, the voltages v_{an}, v_{bn}, and v_{cn} at the output terminals are related to the input voltages V_{Ao}, V_{Bo}, and V_{Co} as

$$\begin{bmatrix} v_{an} \\ v_{bn} \\ v_{cn} \end{bmatrix} = \begin{bmatrix} S_{Aa} & S_{Ba} & S_{Ca} \\ S_{Ab} & S_{Bb} & S_{Cb} \\ S_{Ac} & S_{Bc} & S_{Cc} \end{bmatrix} \begin{bmatrix} v_{Ao} \\ v_{Bo} \\ v_{Co} \end{bmatrix} \tag{14.32}$$

where S_{Aa} through S_{Cc} are the switching variables of the corresponding switches shown in Fig. 14.31. For a balanced linear star-connected load at the output terminals, the input phase currents are related to the output phase currents by

$$\begin{bmatrix} i_A \\ i_B \\ i_C \end{bmatrix} = \begin{bmatrix} S_{Aa} & S_{Ab} & S_{Ac} \\ S_{Ba} & S_{Bb} & S_{Bc} \\ S_{Ca} & S_{Cb} & S_{Cc} \end{bmatrix} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} \tag{14.33}$$

Note that the matrix of the switching variables in Eq. (14.33) is a transpose of the respective matrix in Eq. (14.32). The matrix converter should be controlled using a specific and appropriately timed sequence of the values of the switching variables, which will result in balanced output voltages having the desired frequency and amplitude, while the input currents are balanced and in phase (for unity IDF) or at an arbitrary angle (for controllable IDF) with respect to the input voltages. As the matrix converter, in theory, can operate at any frequency and at the output or input, including zero, it can be employed as a three-phase ac-dc converter, dc/three-phase ac converter, or even a buck/boost dc chopper and thus as a *universal power converter*.

The control methods adopted so far for the matrix converter are quite complex and are subjects of continuing research [21–39]. Out of several methods proposed for independent control of the output voltages and input currents, two methods are of wide use and will be briefly reviewed here: (1) the *Venturini* method based on a mathematical approach of transfer function analysis and (2) the *space vector modulation* (SVM) approach (as has been standardized now in the case of PWM control of the dc link inverter).

Venturini Method. Given a set of three-phase input voltages with constant amplitude V_i and frequency $f_i = \omega_i/2\pi$, this method calculates a switching function involving the duty cycles of each of the nine bidirectional switches and generates the three-phase output voltages by sequential piecewise sampling of the input waveforms. These output voltages follow a predetermined set of reference or target voltage waveforms and with a three-phase load connected, a set of input currents I_i and angular frequency ω_i should be in phase for unity IDF or at a specific angle for controlled IDF.

A transfer function approach is used in [36] to achieve the abovementioned features by relating the input and output voltages and the output and input currents as

$$\begin{bmatrix} V_{o1}(t) \\ V_{o2}(t) \\ V_{o3}(t) \end{bmatrix} = \begin{bmatrix} m_{11}(t) & m_{12}(t) & m_{13}(t) \\ m_{21}(t) & m_{22}(t) & m_{23}(t) \\ m_{31}(t) & m_{32}(t) & m_{33}(t) \end{bmatrix} \begin{bmatrix} V_{i1}(t) \\ V_{i2}(t) \\ V_{i3}(t) \end{bmatrix} \tag{14.34}$$

$$\begin{bmatrix} I_{i1}(t) \\ I_{i2}(t) \\ I_{i3}(t) \end{bmatrix} = \begin{bmatrix} m_{11}(t) & m_{21}(t) & m_{31}(t) \\ m_{12}(t) & m_{22}(t) & m_{32}(t) \\ m_{13}(t) & m_{23}(t) & m_{33}(t) \end{bmatrix} \begin{bmatrix} I_{o1}(t) \\ I_{o2}(t) \\ I_{o3}(t) \end{bmatrix} \tag{14.35}$$

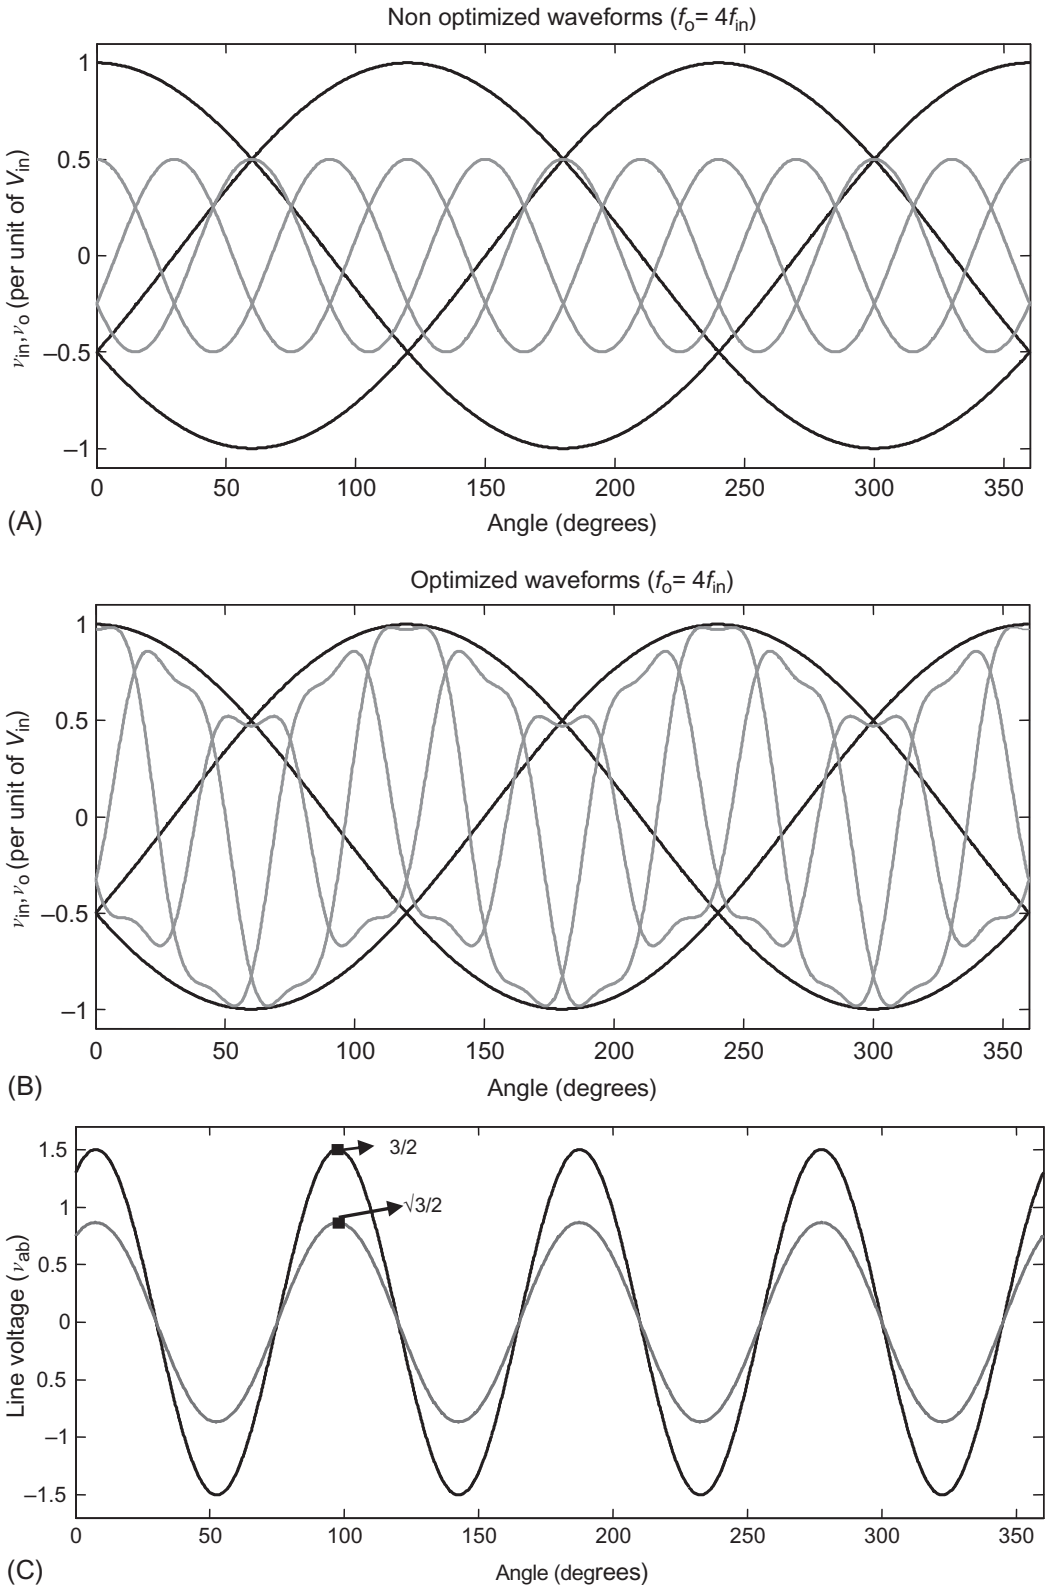

FIG. 14.32 Output phase voltage waveforms for three-phase ac-ac matrix converter: (A) without the addition of harmonics, (B) with inclusion of third harmonic voltages of input and output frequency to the target voltages, and (C) output line voltages (v_{ab}) of (A) and (B).

where the elements of the modulation matrix, $m_{ij}(t)$, $(i,j=1,2,3)$ represent the duty cycles of a switch connecting output phase i to input phase j within a sample switching interval. The elements of $m_{ij}(t)$ are limited by the constraints discussed above and are mathematically written as

$$0 \le m_{ij}(t) \le 1 \quad \text{and} \quad \sum_{j=1}^{3} m_{ij}(t) = 1 \quad (i=1,2,3)$$

The set of three-phase target or reference voltages to achieve the maximum voltage transfer ratio for unity IDF is

$$\begin{bmatrix} v_{o1} \\ v_{o2} \\ v_{o3} \end{bmatrix} = V_{om} \begin{bmatrix} \cos\omega_o t \\ \cos(\omega_o t - 120) \\ \cos(\omega_o t - 240) \end{bmatrix} + \frac{V_{im}}{4} \begin{bmatrix} \cos(3\omega_i t) \\ \cos(3\omega_i t) \\ \cos(3\omega_i t) \end{bmatrix} - \frac{V_{om}}{6} \begin{bmatrix} \cos(3\omega_o t) \\ \cos(3\omega_o t) \\ \cos(3\omega_o t) \end{bmatrix} \tag{14.36}$$

where V_{om} and V_{im} are the magnitudes of output and input fundamental voltages of angular frequencies ω_{o} and ω_{i}, respectively. With $V_{\text{om}} \le 0.866\, V_{\text{im}}$, a general formula for the duty cycles $m_{ij}(t)$ is derived in [36]. For unity IDF condition, a simplified formula is

$$\begin{aligned} m_{ij} = \frac{1}{3}\{1 + 2q\cos(\omega_1 t - 2(j-1)60\,\text{degrees}) \\ \times\left[\cos(\omega_{\text{o}} t - 2(i-1)60\,\text{degrees}) + \frac{1}{2\sqrt{3}}\cos(3\omega_{\text{i}} t) - \frac{1}{6}\cos(3\omega_{\text{o}} t)\right] \\ - \frac{2q}{3\sqrt{3}}[\cos(4\omega_{\text{i}} t - 2(j-1)60\,\text{degrees}) \\ - \cos(2\omega_{\text{i}} t - 2(1-j)60\,\text{degrees})]\} \end{aligned} \tag{14.37}$$

where $i,j=1,2,3$ and $q = V_{\text{om}}/V_{\text{im}}$.

The method developed as above is based on a *direct transfer function* (*DTF*) approach using a single modulation matrix for the matrix converter, employing the switching combinations of all the three groups in Table 14.1. Another approach called *indirect transfer function* (*ITF*) approach [30,31] considers the matrix converter as a combination of PWM voltage source rectifier-PWM voltage source inverter (VSR-VSI) and employs the already well-established VSR and VSI PWM techniques for MC control utilizing the switching combinations of group II and group III only of Table 14.1. The drawback of this approach is that the IDF is limited to unity, and the method also generates higher and fractional harmonic components in the input and the output waveforms. This method can also be found in [40].

A **simplified direct transfer function approach** at unity IDF can be developed. Eq. (14.34) and the constraint equations can be rewritten as follows:

$$\underbrace{\begin{bmatrix} v_{o1} \\ v_{o1} \\ v_{o1} \\ 1 \\ 1 \\ 1 \end{bmatrix}}_{Y_{6\times1}} = \underbrace{\begin{bmatrix} v_{in1} & v_{in1} & v_{in1} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & v_{in1} & v_{in1} & v_{in1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & v_{in1} & v_{in1} & v_{in1} \\ 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \end{bmatrix}}_{A_{6\times9}} \underbrace{\begin{bmatrix} m_{11} \\ m_{12} \\ m_{13} \\ m_{21} \\ m_{22} \\ m_{23} \\ m_{31} \\ m_{32} \\ m_{33} \end{bmatrix}}_{X_{9\times1}} \tag{14.38}$$

X is the modulation vector, and the elements can be derived as

$$X = A^{\text{T}}\left(AA^{\text{T}}\right)^{-1} Y \tag{14.39}$$

AA^{T} when solved will have terms $\sum_{i=1}^{3} v_{\text{in}_i}^2$ and $\sum_{i=1}^{3} v_{\text{in}_i}$, so, let $\sum_{i=1}^{3} v_{\text{in}_i}^2 = L$ and $\sum_{i=1}^{3} v_{\text{in}_i} = M$. Each term of X, when (14.39) is solved, is of similar pattern and can be shown as

$$m_{ji} = \frac{1}{(3L - M^2)}\left[v_{\text{o}_j}(3v_{\text{in}_i} - M) - Mv_{\text{in}_i} + L\right] \tag{14.40}$$

where M_{ji} is the time-based index corresponding to the switch S_{ji} that connects j-th output to the i-th input. The time duration for which this switch is on, is calculated by multiplying this index with sampling time. Further solving by considering m balanced input phases, and finally neglecting the terms with denominators with high value, solution for $m \times n$ matrix converter is written as

$$m_{ji} = \frac{1}{3}\left(1 + \frac{2v_{\text{in}_i} v_{\text{o}_j}}{V_{\text{in}}^2}\right) \tag{14.41}$$

A detailed simulation with this modulation scheme can be seen in [41].

SVM Method. The space vector modulation is a well-documented inverter PWM control technique that yields high-voltage gain and less harmonic distortion compared with the other modulation techniques. Here, the three-phase input currents and output voltages are represented as space vectors, and SVM is simultaneously applied to the output voltage and input current space vectors, while the matrix converter is modeled as a rectifying and inverting stage by the *indirect modulation method* (Fig. 14.33). Applications of SVM algorithm to control of matrix converters have appeared extensively in the literature [33–38,42–47] and shown to have inherent capability to achieve full control of the instantaneous output voltage vector and the instantaneous current displacement angle even under supply voltage disturbances. The algorithm is based on the concept that the MC output line voltages for each switching combination can be represented as a voltage space vector defined by

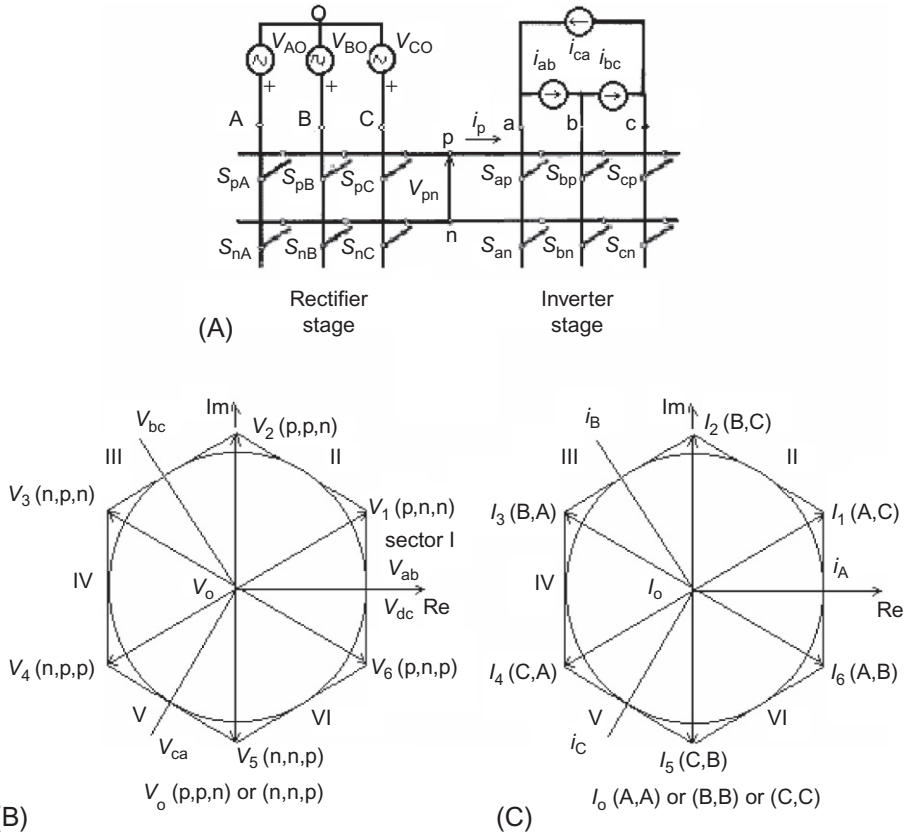

FIG. 14.33 Indirect modulation model of a matrix converter: (A) VSR-VSI conversion, (B) output voltage switching vector hexagon, and (C) input current switching vector hexagon.

$$v_o = \frac{2}{3}[v_{ab} + v_{bc}\exp(j120\,\text{degrees}) + v_{ca}\exp(-j120\,\text{degrees})] \tag{14.42}$$

Out of the three groups in Table 14.1, only the switching combinations of group II and group III are employed for the SVM method. Group II consists of switching state voltage vectors having constant angular positions and are called *active* or *stationary* vectors. Each subgroup of group II determines the position of the resulting output voltage space vector and the six-state space voltage vectors form a six-sextant hexagon used to synthesize the desired output voltage vector. Group III comprises the *zero* vectors positioned at the center of the output voltage hexagon, and these are suitably combined with the active vectors for the output voltage synthesis.

The modulation method involves selection of the vectors and their on-time computation. At each sampling period T_s, the algorithm selects four active vectors related to any possible combinations of output voltage and input current sectors in addition to the zero vector to construct a desired reference voltage. The amplitude and the phase angle of the reference voltage vector are calculated, and the desired phase angle of the input current vector is determined in advance. For computation of the on-time periods of the chosen vectors, these are combined into two sets leading to two new vectors adjacent to the reference voltage vector in the sextant and having the same direction as the reference voltage vector. Applying the standard SVM theory, the general formulas derived for the vector on-times that satisfy, at the same time, the reference output voltage and input current displacement angle in [36] are

$$t_1 = \frac{2qT_s}{\sqrt{3}\cos\phi_i}\sin(60\,\text{degrees} - \theta_o)\cdot\sin(60\,\text{degrees} - \theta_i)$$

$$t_2 = \frac{2qT_s}{\sqrt{3}\cos\phi_i}\sin(60\,\text{degrees} - \theta_o)\cdot\sin\theta_i$$

$$t_3 = \frac{2qT_s}{\sqrt{3}\cos\phi_i}\sin\theta_o\cdot\sin(60\,\text{degrees} - \theta_i)$$

$$t_4 = \frac{2qT_s}{\sqrt{3}\cos\phi_i}\sin\theta_o\cdot\sin\theta_i \tag{14.43}$$

where q is voltage transfer ratio, ϕ_i is the input displacement angle chosen to achieve the desired input power factor (with $\phi_i = 0$, a maximum value of $q = 0.866$ is obtained), and θ_o and θ_i are the phase displacement angles of the output voltage and input current vectors, respectively, whose values are limited within the 0–60 degrees range. The on-time of the zero vector is

$$t_o = T_s - \sum_{i=1}^{4} t_i \tag{14.44}$$

The integral value of the reference vector is calculated over one sample time interval as the sum of the products of the two adjacent vectors and their on-time ratios, and the process is repeated at every sample instant.

Control Implementation and Comparison of the Two Methods. Both the methods need a digital signal processor (DSP)-based system for their implementation. In one scheme [36] for the Venturini method, the programmable timers, as available, are used to time out the PWM gating signals. The processor calculates the six-switch duty cycles in each sampling interval, converts them to integer counts, and stores them in the memory for the next sampling period. In the SVM method, an erasable programmable read-only memory (EPROM) is used to store the selected sets of active and zero vectors, and the DSP calculates the on-times of the vectors. Then, with an identical procedure as in the other method, the timers are loaded with the vector on-times to generate PWM waveforms through suitable output ports. The total computation time of the DSP for the SVM method has been found to be much less than that of the Venturini method. Comparison of the two schemes shows that while in the SVM method the switching losses are lower, the Venturini method shows better performance in terms of input current and output voltage harmonics.

A *direct control* method as used in conjunction with the voltage source converters has been developed recently and implemented with a 10 kVA matrix converter [48]. Moreover, the voltage transfer ratio can be increased by going into overmodulation. Enhanced methods employing SVM are discussed in [49,50] in which VTR of 0.92 is achieved.

14.5.2 Commutation and Protection Issues in a Matrix Converter

As the matrix converter has no dc link energy storage, any disturbance in the input supply voltage will affect the output voltage immediately, and a proper protection mechanism has to be incorporated, particularly against overvoltage from the supply and overcurrent in the load side. As mentioned, two types of bidirectional switch configurations have hitherto been used: one, the transistor (now IGBT) embedded in a diode bridge and, the other, the two IGBTs in antiparallel with reverse voltage blocking diodes (shown in Fig. 14.31B and C). In the latter configuration, each diode and IGBT combination operates in two quadrants only, which eliminates the circulating currents otherwise built up in the diode bridge configuration that can be limited by only bulky commutation inductors in the lines.

Commutation. The MC does not contain freewheeling diodes that usually achieve safe commutation in the case of other converters. To maintain the continuity of the output current as each switch turns off, the next switch in sequence must be immediately turned on. In practice, with bidirectional switches, a momentary short circuit may develop between the input phases when the switches cross over, and one solution for the configurations shown in Fig. 14.31B, C, and E is to use a *semisoft current commutation* using a multistepped switching procedure to ensure safe commutation [51–53]. This method requires independent control of each two-quadrant switches, sensing the direction of the load current and introducing a delay during the change of switching states. The switching rule for proper commutation from S_1 to S_2 of the arrangement shown in Fig. 14.34 for $i_L > 0$ with the two-quadrant switches for *four-stepped commutation* [51,53] is (a) turn off S_{1B}, (b) turn on S_{2A}, (c) turn off S_{1A}, and (d) turn on S_{2B}.

Analogously, for $i_L < 0$, the switching rule will be (a) turn off S_{1A}, (b) turn on S_{2B}, (c) turn off S_{1B}, and (d) turn on S_{2A}. These steps for both the cases are shown diagrammatically in Fig. 14.35.

Typically, these commutation strategies are now implemented using programmable logic devices such as field-programmable gate array (FPGA) and programmable logic device (PLD) [53,54]. Also, it is worth mentioning that the configuration shown in Fig 14.31D has to stick to two-step commutation that despite of having a considerable advantage of employing less number of switches will produce more spikes in the output voltages.

A robust voltage commutation scheme without sacrificing the line side current waveform quality and with minimal information requirement has been reported recently [55]. Another way to achieve better commutation is by Z-sourcing the input of the matrix converter [56].

Protection Strategies. A clamp capacitor (typically 2 μF for a 3 kW permanent magnet (PM) motor) connected through two three-phase full-bridge diode rectifiers involving additional

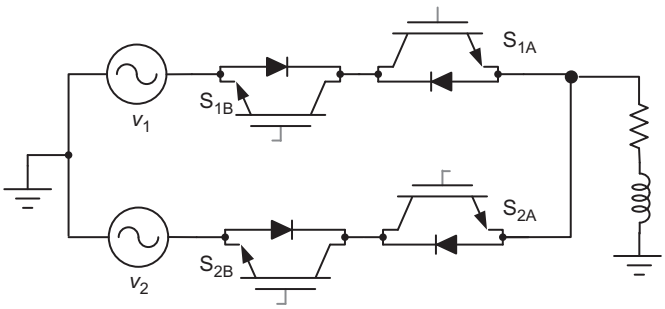

FIG. 14.34 Safe commutation scheme.

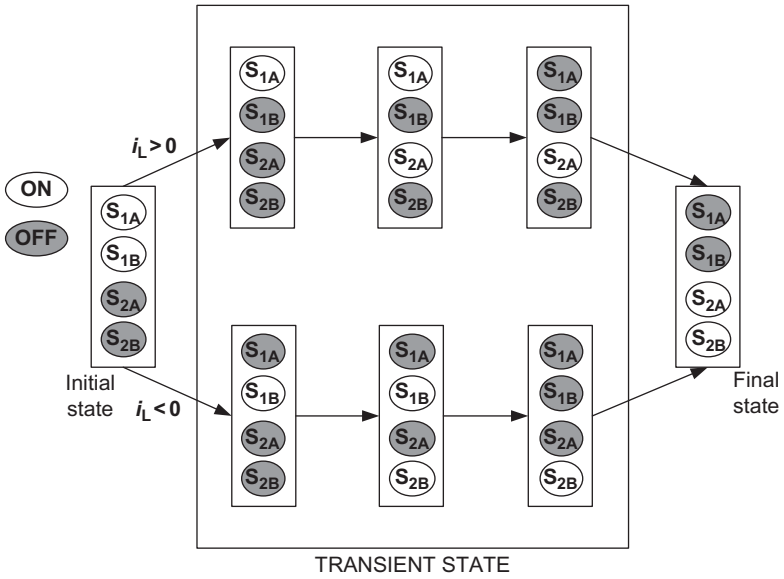

FIG. 14.35 Transition from one bidirectional switch to other employing *semisoft commutation*.

12 diodes as shown in Fig. 14.31A (a new configuration has been reported in [57] where the number of additional diodes is reduced to six using the antiparallel switch diodes at the input and output lines of the MC) serves as a voltage clamp for possible voltage spikes under normal and fault conditions. A new passive protection strategy involving suppressor diodes and varistors for excellent overvoltage protection is discussed recently in [58], which allows the removal of the large and expensive diode clamp. A snubberless solution for overvoltage protection is presented in [59].

Input Filter. A three-phase single-stage LC filter at the input consisting of three capacitors in star and three inductors in the line is used to adequately attenuate the higher order harmonics and render sinusoidal input current. Typical values of L and C based on a 415 V converter with a maximum line current of 6.5 A and a switching frequency of 20 kHz are 3 mH and 1.5 μF only [60]. The filter may cause minor phase shift in the input displacement angle that needs correction. Another filter designs can be seen in [28,29]. Ref. [61] lately has employed the input filter capacitors as an energy exchange devices to enhance the *ride-through capability* of the matrix converter. Ref. [62] discusses the designing of an EMI filter for matrix converter applications.

Fig. 14.36 shows typical experimental waveforms of output line voltage and line current of an MC. The output line current is mostly sinusoidal except a small ripple, when the switching frequency is around 1 kHz only.

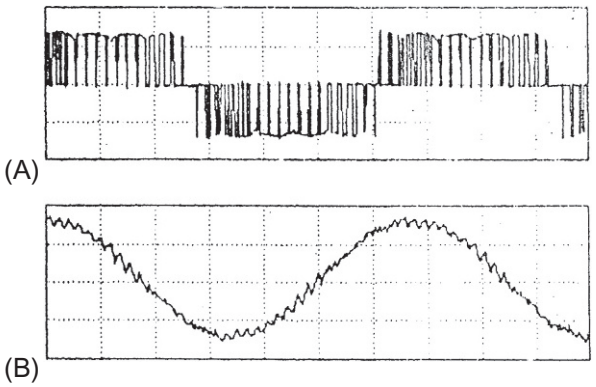

FIG. 14.36 Experimental waveforms for a matrix converter at 30 Hz frequency from a 50 Hz input: (A) output line voltage and (B) output line current.

14.5.3 Multilevel Matrix converter

Erickson and Al-Naseem [63] introduced a multilevel matrix converter with four-quadrant dc link H-bridge switching cells as shown in Fig 14.37 in 2001. These are suitable for medium- or high-voltage ac-to-ac power conversion. The use of four transistors in the switch cell of Fig. 14.37A allows the average current to be doubled, relative to the conventional matrix converter whose four-quadrant switches are realized using two transistors and two diodes. With dc capacitor, the switch cell is capable of producing instantaneous voltages +V, 0, −V. These converters can both increase and decrease the voltage amplitude with arbitrary power factors. With series connection of switch cells in each branch of the matrix, multilevel switching can be attained with device voltages locally clamped to dc capacitor voltages. Several types of multilevel matrix converter topologies have been proposed over the years, including a novel capacitor-clamped one and with a space vector modulation [64,65]. In [65], the converter utilizes flying capacitors to

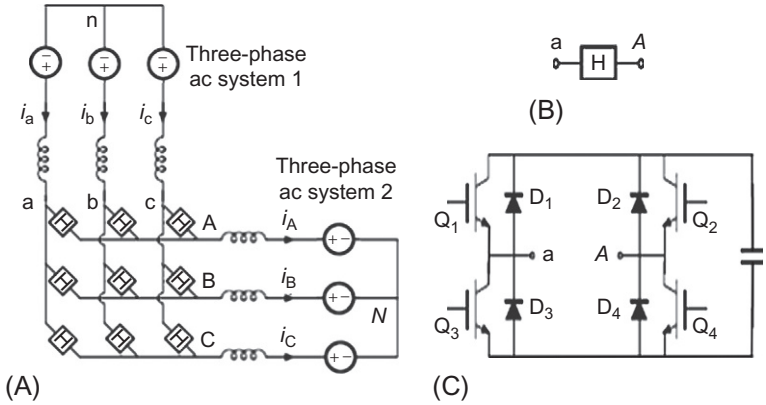

FIG. 14.37 Multilevel matrix converter: (A) configuration, (B) switch symbol, and (C) switch realization.

balance voltage distribution of series-connected bidirectional switches and provide middle-voltage levels.

Recently, with cascaded combination of multiple matrix converter (MC) modules, principles of high-power multimodular matrix converters (MMMCs) built from three-input two-output matrix converter (3×2 MC) have been presented in [66] with modulation schemes to synthesize sinusoidal waveforms on both sides of the converters. Recent work on modulation strategies on MMMCs can be seen in [67–69]. The circuit shown in Fig. 14.38 is known as MMMC-I. Another structure is discussed in these papers in which nine modules of 3×2 MCs are employed. This is an extension of the first topology and attains a multilevel structure for higher power output and better line side harmonic performance. These topologies feature modular design and bidirectional power flow and enable the use of low-voltage power devices. They may serve as potential candidates for high-power applications where regenerative capability and power density are of importance. However,

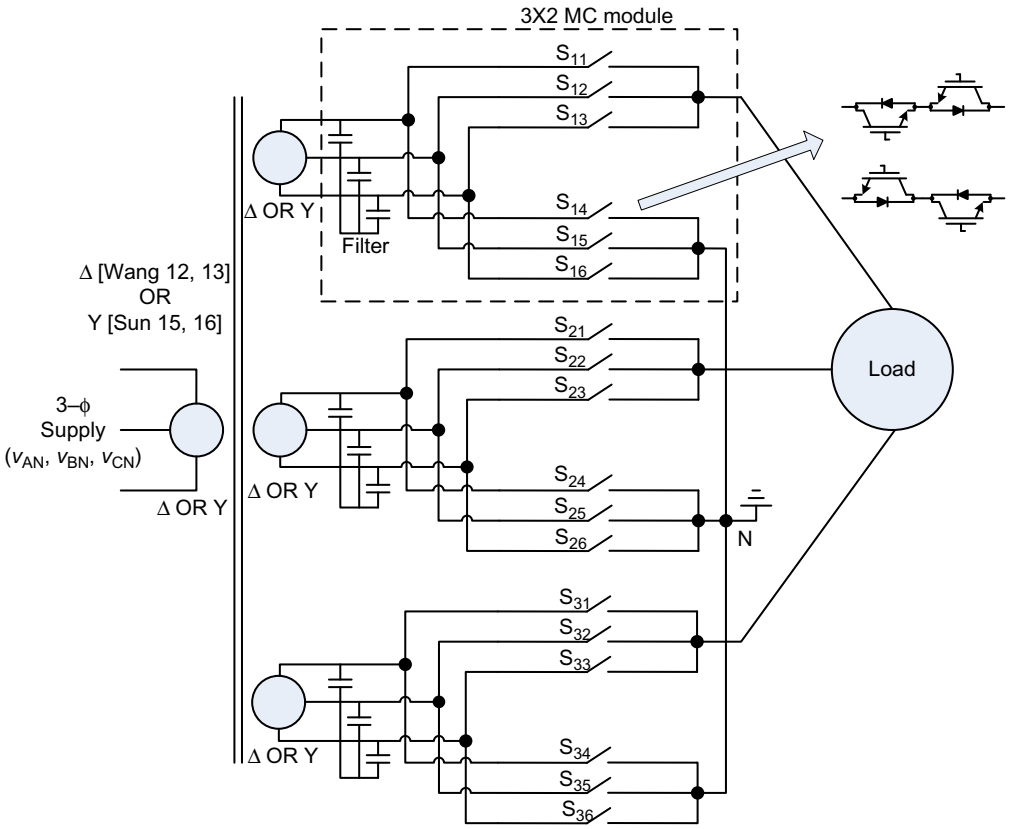

FIG. 14.38 Multimodular matrix converter (MMMC-I) topology.

the drawbacks of them are large number of devices and the use of the input transformer.

14.5.4 Indirect Matrix Converters

A conventional matrix converter (CMC) as shown in Fig. 14.31A requires nine bidirectional switches, usually constructed using 18 IGBTs, to switch the three-input phases between the three-output phases. The indirect matrix converters (IMCs), as seen in Fig. 14.40A also have 18 controllable switches. The difference lies in the control of such a converter. This configuration is easier to implement as the control strategies of controlled rectifiers, and inverters can be directly implemented. This topology was first introduced in [70] and later discussed in [71]. It employs 18 controllable switches out 12 are used in rectification and 6 in inversion process. The sparse matrix converter (SMC) (Fig. 14.39) is derived from the IMC that is split into an input stage and output stage without any capacitance in the dc link. The input stage is arranged so that only nine switches are required, while the output stage has a standard six-switch configuration. Thus, the SMC has a total of 15 switches compared with 18 for a CMC and IMC. The functional equivalence, the controllability, and the operating range of the SMC are the same as CMC despite the reduced number of unipolar turn-off power switches [72]. Further reduction of the number of IGBTs is possible with ultra sparse matrix converter (USMC) [73], Fig. 14.40 having 12 IGBTs, with restricted operation to a unidirectional power flow and controllability of the phase displacement of input voltage and current fundamental to $\pm\pi/6$ [73]. Very recently, a space vector modulation scheme for an indirect three-level sparse matrix converter (I3 SMC), which is a combination of a three-level neutral-clamped voltage source inverter and an indirect matrix converter, has been discussed in [74]. A 100 kHz SiC sparse matrix converter using 1300 V and 4 A SiC JFET cascade devices has been reported in [75], which is suitable for aircraft applications where a low-volume/low-weight converter is desired. Ref. [76] also introduced a topology with 12 switches employing unidirectional switches in the rectification process. Real-time implementation of an IMC employing SVM algorithms can be seen in [77].

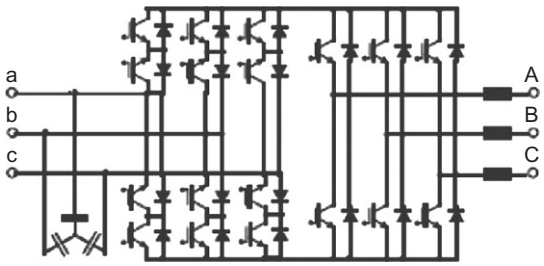

FIG. 14.39 Indirect matrix converter (IMC).

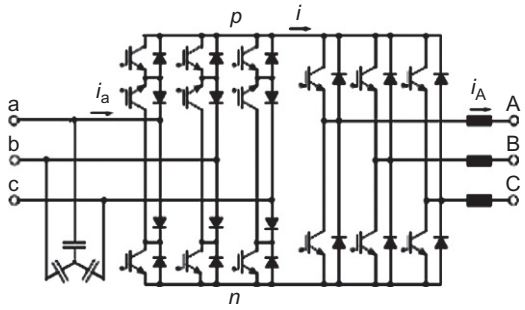

FIG. 14.40 Sparse matrix converter (SMC).

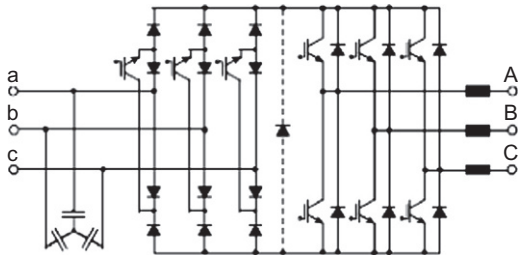

FIG. 14.41 Single-phase Z-source matrix converter.

14.5.5 Single-Phase Matrix Converters

The first single-phase matrix converter was studied by Zuckerberger in [78]. In this paper, converter operation was shown to step down the voltage and step up the frequency. Later in [79], step-up/down frequency operation with safe commutation strategy was developed. The limitation of above schemes lied in boosting of output voltages beyond input voltage. This was overcome by introducing single-phase Z-source matrix converter by Nguyen et al. shown in Fig. 14.41, and step-up/step-down of both voltage and frequency was achieved [80]. A family of high-frequency isolated single-phase Z-source matrix converter with safe commutation strategy is discussed in [81]. Another single-phase matrix converter can be seen in [82–86]. An ac Z-source converter based on gamma structure with safe commutation is discussed in [87]. A novel T-type single-phase ac-ac converter is proposed in [88]. A single-phase ac-ac modular multilevel converter is discussed for railway traction purpose in [89].

14.6 High Frequency Linked Single-Phase to Three-Phase Matrix Converters

Several kinds of single-phase to three-phase high frequency (typically, 20 kHz) cycloconverters (actually, matrix converters with MCT switches) using "soft switching" were reported for ac motor drive applications [90–92]. Fig. 14.42 [90] shows a typical configuration of such a converter in which an H-bridge inverter produces a high-frequency single-phase voltage, which

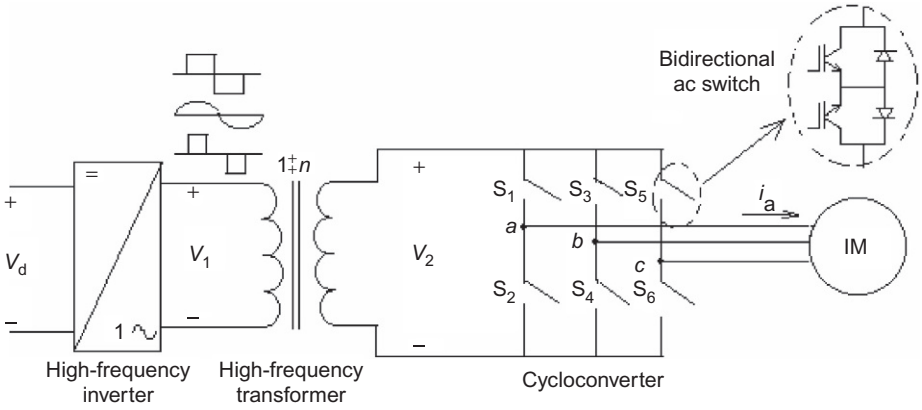

FIG. 14.42 Ultra sparse matrix converter (USMC).

is fed to the cycloconverter through a high-frequency transformer. The high frequency ac may be either sinusoidal generated by a resonant link inverter or quasisquare wave as shown. These systems have been developed at laboratories but not yet available commercially Fig. 14.43 [90].

14.6.1 High Frequency Integral-Pulse Cycloconverter

The input to these converters may be sinusoidal or quasi square wave, and it is possible to use integral half-cycle pulse-width modulation (IPM) principle to synthesize the output voltage waves. The advantage is that the devices can be switched at zero voltage reducing the switching loss. This converter can only work at output frequency, which are multiples of the input frequency [90].

14.6.2 High-Frequency Phase-Controlled Cycloconverter

Here, phase control principle as explained earlier is used to synthesize the output voltage. A sawtooth carrier wave is compared with the sine modulating wave to generate the firing instants of the switches. The phase control provides switching at zero current reducing switching loss, but this scheme has more complex control circuit compared with the previous one. However, it can work at any frequency [91].

14.7 Applications of AC-AC Converters

14.7.1 Applications of AC Voltage Controllers

AC voltage controllers are used either for control of the rms value of voltage or current in lighting control, domestic and industrial heating, speed control of fan, pump or hoist drives, soft starting of induction motors, etc. or as *static ac switches* (*on/off control*) in transformer tap changing, temperature control, speed stabilization of high-inertia induction motor drives like centrifuge, capacitor switching in static reactive power compensation, etc.

In *fan or pump drives* with induction motors, the torque varies as the square of the speed. So, the speed control is required in a narrow range, and an ac voltage controller is suitable for an induction motor with a full load slip of 0.1–0.2 in such applications. For these drives, braking or reverse operations are not

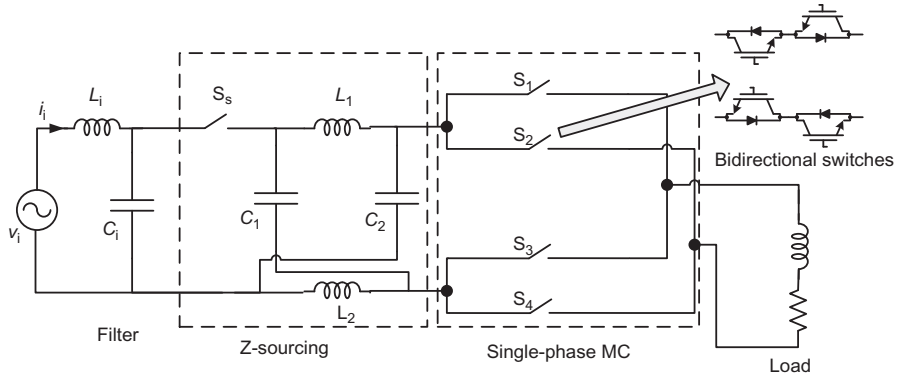

FIG. 14.43 High-frequency-linked single-phase to three-phase matrix converter.

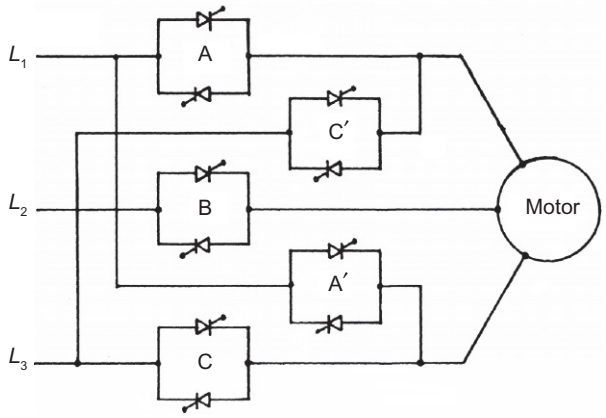

FIG. 14.44 Four-quadrant ac voltage controller.

needed, but for the crane hoist drive, both motoring and braking are needed, and a four-quadrant ac voltage controller can be obtained by a modification of the ac voltage controller circuit as shown in Fig. 14.44. SCR pairs A, B, and C provide operation in quadrants I and IV and A, B, and C in quadrants II and III. While changing from one set of SCR pairs to another, care should be taken to ensure that the incoming pair is activated only after the outgoing pair is fully turned off.

Ac voltage controllers are being increasingly used for *soft starting* of induction motors, as they have a number of advantages over the conventional starters such as smooth acceleration and deceleration, ease in implementation of current control, simple protection against single-phasing or unbalanced operation, reduced maintenance and losses, and the absence of current inrush. Even for the fixed-speed industrial applications, the voltage controllers can be used to provide a reduced stator voltage to an induction motor to improve its efficiency at light load and result in energy saving. Operation at an optimum voltage reduces the motor flux which, in turn, reduces the core loss and the magnetizing component of the stator copper loss. Considerable savings in energy can be obtained in applications where a motor operates at no load for a significant time such as in drills, machine tools, woodworking machines, and reciprocating air compressors. A popular approach to find an optimum operating voltage is to maximize the motor power factor by maintaining a minimum phase shift between the voltage and current after sensing them.

The ac switch with on/off control used in driving a high-inertia centrifuge involves switching on of the motor when the speed of the centrifuge drops below the minimum allowable level and switching off when the speed reaches the maximum allowable level—thus maintaining a constant average speed. An identical scheme of control is used with an ac switch for temperature control of an electric heater or air conditioner.

Integral cycle control is well suited to heating control while it may cause flicker in normal incandescent lighting control and speed fluctuations in motor control. However, with this control, less voltage distortion is produced in the ac supply system, and less radio-frequency interference is propagated when compared with the phase-controlled system.

14.7.2 Applications of Cycloconverters

Cycloconverters as frequency changers essentially find well-established applications in (1) high-power low-speed reversible ac motor drives with constant-frequency input and (2) constant-frequency power supplies with a variable-frequency input as in variable-speed constant frequency (VSCF) system, whereas they find potential applications in (3) controllable volt-ampere reactive (VAR) generators for power factor correction, and (4) ac system interties linking two independent power systems as demonstrated in [15].

Variable Speed AC Drives. In this category, the applications of cycloconverter-controlled induction motor and synchronous motor drives have been adequately reviewed in [9]. Cycloconverter-fed synchronous motors are well suited for low-speed drives with high torque at standstill, and high-capacity gear-less cement mills (tube or ball mill above 5 MW) have been the first applications of these drives.

Since the 1960s, as developed by Siemens and Brown Boveri, one of the early installations employs a motor rating of 6.4 MW having a rotor diameter of 5 m and length of 18.5 m, whereas the stator construction is similar to that of a hydroelectric generator with 44 poles requiring 5.5 Hz for maximum speed of 15 rpm. The motor is flanged with the mill cylinder without additional bearings or "wrapped" directly around it, known as a *ring motor* [93]. With the evolution of *field orientation* or *vector control*, cycloconverter-fed synchronous motors have replaced or are replacing the dc drives in the reversing rolling mills (2/4 MW) with extreme high-dynamic requirements for torque and speed control [94–96], in mine winders and haulage [96,97] of similar high ratings and in icebreakers and ships equipped with diesel generators with power ratings of about 20 MW/unit [98]. In these applications, the cycloconverter-fed synchronous motor is in *self-controlled* mode and known as *ac commutatorless motor* when the cycloconverter firing signals are derived from a rotor shaft position sensor, so that the frequency is slaved to the rotor speed and not vice versa with the result that the hunting and stability problems are eliminated, and the torque is not limited to pullout value. Further, with field control, the motor can be operated at leading power factor when the cycloconverter can operate with *load commutation* from the motor side at high speed in addition to the line commutation from the supply at low speed, thus providing speed control over a wide range. A cycloconverter-fed ac commutatorless motor is reported in [99] where the cycloconverter is operated both in sinusoidal and trapezoidal mode—the latter is attractive for better system power factor and higher voltage output at the cost of increased harmonic content [1]. A stator-flux-oriented vector control scheme for a six-pulse circulating current-free cycloconverter-fed synchronous motor with a flux

observer suitable for a rolling mill drive (300–0–300 rpm) is reported in [12]. A 12-pulse, 9.64 MVA, and 120/33.1 Hz cycloconverter-linear synchronous motor combination for Maglev Vehicle ML-500, a high-speed train, (517 km/h) is in the process of development in Japan since the early 1980s [100]. Several recent projects involving very high-power (larger than 15 MW) semiautogenous grinding (SAG) mills with cycloconverter-fed synchronous motor drives in mining applications in Peru and Brazil are reported in [101]. Latest technological advances, applications, and future trends of cycloconverters in industrial medium-voltage drives have been discussed in [102].

Regarding cycloconverter-fed induction motors, early applications were for control of multiple run-out table motors of a hot strip mill, high-performance servo drives, and controlled slip-frequency drive for diesel electric locomotives. Slip-power-controlled drives in the form of static Scherbius drives with very high ratings using cycloconverter in the rotor of a doubly fed slip ring induction motor have been in operation for high-capacity pumps, compressors [103], and even in a proton-synchrotron accelerator drive in CERN, Geneva [104]. Though synchronous motors have been preferred for very high-capacity low-speed drives because of their high rating, ability to control power factor, and precisely set speed independent of supply voltage and load variations, induction motors, because of their absence of excitation control loop, simple structure, easy maintainability, and quick response, have been installed for cycloconverter-fed drives in Japan. For example, a seamless tube piercing mill [105] where a squirrel cage six-pole 3 MW, 188/300 rpm, 9.6/15.38 Hz, and 2700 V motor is controlled by a cycloconverter bank of capacity 3750 KVA and output voltage 3190 V.

Constant Frequency Power Supplies. Some applications such as aircraft and naval ships need a well-regulated constant-frequency power output from a variable-frequency ac power source. For example, in aircraft power conversion, the alternator connected to the engine operating at a variable speed of 10,000–20,000 rpm provides a variable-frequency output power over 1200–2400 Hz range that can be converted to an accurately regulated fixed frequency output power at 400 Hz through a cycloconverter with a suitable filter placed within a closed loop. The output voltages of the cycloconverter are proportional to the fixed frequency (400 Hz) sine-wave reference voltage generator in the loop.

Both synchronous and induction motors can be used for VSCF generation. The static Scherbius system can be modified (known as Kramer drive) by feeding slip power through a cycloconverter to a shaft-mounted synchronous machine with a separate exciter for VSCF generation. A new application in very high power ratings of constant frequency variable speed motor generators with cycloconverter is in pumped storage schemes using reversible pump turbines for adaptation of the generated power to varying loads or keeping the ac system frequency constant. In 1993, a 400 MW variable speed pumped storage system was commissioned by Hitachi at Okhawachi hydropower plant [106] in Japan where the field windings of a 20-pole generator/motor are excited with three-phase low-frequency ac current via slip rings by a 72 MVA, three-phase 12-pulse line-commuted cycloconverter. The armature terminals rated at 18 kV are connected to a 500 kV utility grid through a step-up transformer. The output frequency of the circulating current-free cycloconverter is controlled within ± 5 Hz, and the line frequency is 60 Hz. The variable speed system has a synchronous speed of 360 rpm with a speed range $330 - 390$ rpm. The operational system efficiency in the pump mode is improved by 3% when compared with the earlier constant speed system.

Static VAR Generation. Cycloconverters with a high-frequency (HF) base, either an HF generator or an oscillating LC tank, can be used for reactive power generation and control, replacing synchronous condensers or switched capacitors as demonstrated in [15]. If the cycloconverter is controlled to generate output voltage waves whose wanted components are in phase with the corresponding system voltages, reactive power can be supplied in either direction to the ac system by amplitude control of the cycloconverter output voltages. The cycloconverter will draw leading current from (i.e., it will supply lagging current to) the ac system when its output voltage is greater than that of the system voltage and vice versa.

Interties between AC Power Systems. The naturally commutated cycloconverter (NCC) was originally developed for this application to link a three-phase, 50-Hz ac system with a single-phase $16\frac{2}{3} -$ Hz railway supply system in Germany in the 1930s. Applications involve slip-power-controlled motors with subsynchronous and supersynchronous speeds. The stator of the motor is connected to 50-Hz supply, which is connected to the rotor and through a cycloconverter, and the motor drives a single-phase synchronous generator feeding to $16\frac{2}{3} -$ Hz system [107,108]. A static asynchronous intertie between two different systems of different frequency can be obtained by using two NCCs in tandem, each with its input terminals connected to a common HF base. As long as the base frequency is appropriately higher than that of the either system, two system frequencies can be either same or different. The power factor at either side can be maintained at any desired level [15].

14.7.3 Applications of Matrix Converters and New Developments

The practical applications of the matrix converters, as of now, are very limited. The main reasons are (1) nonavailability of the bilateral fully controlled monolithic switches capable of high-frequency operation, (2) complex control law implementation, (3) an intrinsic limitation of the output/input voltage ratio, and (4) commutation and protection of the switches. The switches are assembled from existing discrete devices resulting in increased cost and complexity, and only experimental circuits of conventional matrix converters (CMC) of capacity up to

150 kVA [109] for a single unit have been built. However, with the advances in device technology, it is hoped that the problems will be solved eventually, and the MC will not only replace the NCCs in all the applications mentioned under Section 14.7.2 but also take over from the PWM rectifier-inverters as well. Yaskawa has introduced several drives based on matrix converters, most of which are for industrial purposes. U1000 [110] (Fig 14.45) is an industrial drive available in 200/400 V and power ranging from 5 to 500 hp. Another drive Z1000U [112] is an HVAC drive available between 7.5 and 350 hp. AC7 [111] is yet another smaller version with power range of 7.5–125 hp. AC7 is not commissioned in the Americas. Another interesting applications of multilevel and multicell matrix converters for medium-voltage high-power drives have been developed [113] Super energy-saving multicell medium-voltage matrix converters (FSDrive-MX1S) of rating 3 kV, 200–3000 kVA or 6 kV, and 400–6000 kVA have been built by Yaskawa Electric, Japan [114], where by intelligently phase shifting the carrier of each cell and combining them in the motor windings, medium voltages are achievable as shown in Fig. 14.46. The salient features of these medium-voltage converters are as follows:

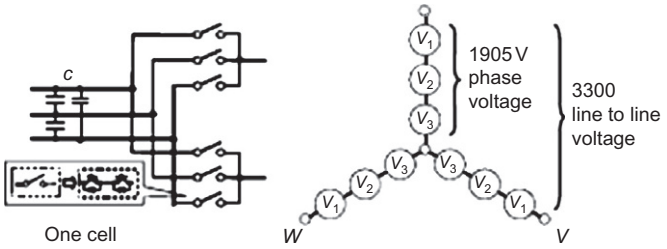

FIG. 14.46 Schematic of a multicell matrix converter with three cells in series in each phase.

- Four-quadrant operation;
- Excellent input current waveform due to multiple phase shifting winding of the input transformer;
- Flexible design, three cells in series yielding 3.3 kV and 200–3000 kVA and six cells in series yielding 6 kV and 400–6000 kVA system;
- Excellent output voltage waveform due to multistep configuration.

The applications for these drives as recommended are as follows: with heavy loads that require regenerative energy such as steel manufacturing process lines or cargo handling machinery, and also that need power regeneration for a long period such as winders for paper Fig. 14.47.

Recently, reverse blocking IGBTs have opened up the possibility of bidirectional switch (BDS) construction for a practical matrix converter with just two back-to-back devices [116–118]. A compact full matrix converter power module EconoMac

FIG. 14.45 An industrial matrix converter variant by Yaskawa (U1000, variants available between 5 and 500 hp, [111]).

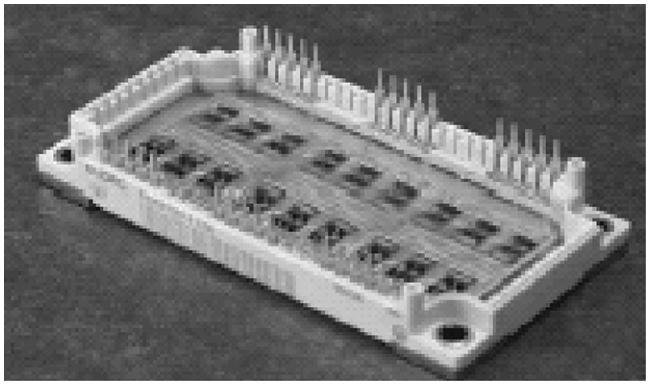

FIG. 14.47 EconoMac matrix converter module by Eupec [115].

[115] in a single package using 18 IGBT devices (35 A and 1200 V) and diodes in the common collector configuration (Fig. 14.44) is available with Eupec/Siemens, Germany. This packaging minimizes the stray inductance in the current commutation paths. Fuji and Powerex have developed engineering samples for matrix converter output leg in a module using RB-IGBTs. A new power electronic building block (PEBB) configuration for a low-cost MC has been proposed in [119]. Recently, an efficient approach to design discrete packaging of bidirectional resonant power switch for matrix converters has been proposed by computing the magnetic field orientation inside the switching cell [120]. Several new concepts in protection, commutation, switch design, and modulation strategy have been presented in [121].

Several new methods like overmodulation [122], adaptive rate regulation [123], and two-side modulation control [124] have been introduced with experimental results to achieve *higher voltage transfer ratio*. A matrix converter-based three-phase open-end winding ac machine drive having matrix converters, one at each side of the open-end winding with space vector PWN has been recently described in [125] to achieve several simultaneous benefits, such as converter voltage gain up to 1.5, controllable grid power factor, and elimination of the high-frequency common-mode voltage at the machine terminals. A generalized scalar PWM (GSPWM) technique to reduce the common-mode voltage in matrix converter without degrading the input currents' quality has been studied in a recent paper [126].

Design and loss comparison of matrix converters and dc link voltage source converters (VSC) have been discussed in [127,128]. It is shown that although MC requires 50% more semiconductors and gate drives excluding clamp circuit, the active silicon area and the number of gate unit power supplies are comparable with that of VSC of the same power rating. The losses of both converter systems are roughly the same at the typical range of 40%–70% of rated torque and speed and a switching frequency of 10 kHz. The MC realizes a distinct better efficiency (92.5%–96%) at 100% torque compared with VSC for the same IGBT modules. Also, the maximum switching frequency of the MC (30 kHz at 250% rated torque) is also substantially higher. The low losses allow a reduction of current ratings (by 33%) of IGBT modules in MC. The extra harmonic losses due to use of a matrix converter for a motor drive with two commonly used modulation techniques have been computed and compared in [129].

Various potential applications of matrix converters have been proposed, and experiments conducted in the field of VSCF systems such as wind turbine and microturbine [130], switched mode power supplies [131], doubly fed induction motor [132,133] including wind power system applications [134], and marine propulsion [135]. Few modern solutions for industrial matrix converter applications including a new integrated matrix converter motor (MCM) have been reported [136,137]. The range of published practical implementations varies from a 2 kW matrix converter using silicon carbide devices and switching at 150 kHz for aerospace applications built at ETH in Zurich, Switzerland, to a 150 kVA converter using 600 A IGBTs built at US army research labs in collaboration with the University of Nottingham, the United Kingdom [54,109]. A matrix converter using MCTs with enhanced commutation times is described in [138].

The complex control schemes of matrix converter demand higher test requirements, and one of the modern means of testing the controllers before final integration on actual apparatus is to make hardware-in-the-loop (HIL) real-time simulation tests as developed recently [139].

Matrix converter-fed adjustable speed drives (ASDs) have the advantages of inherent four-quadrant operation, the absence of bulky dc link electrolytic capacitors, clean input power characteristics with high input power factor, and increased power density with the possibilities of operating at higher temperatures. However, due to the absence of the dc link, these are more susceptible to input power disturbances, and a *ride-through module* is needed to be added for these drives under short-term power interruption. Such a module as developed with minimal addition of hardware and software into a matrix converter (230 V and 3 kVA) has been reported in [140]. A PWM modulation strategy for fault tolerant operation of the matrix-converter-based drives against opened switch, opened phase faults, and shorted winding failures has been proposed in [141]. This can improve the reliability of the matrix converter drives as it is possible to keep continuous by regulating the two remaining phases after isolating the faulted phase.

A novel application of a three-phase matrix converter as the static conversion unit for a ground power supply unit for aircraft servicing has been presented in [142] to provide a compact solution with no dc link and the capability to generate a high quality 400-Hz sinusoidal waveform in the steady state. Three-phase Z-source matrix converter is under consideration. The benefit of Z-sourcing is that firstly, a VTR more than 0.866, can be achieved. Ref. [143] discusses a family of Z-sourced DMCs in which a VTR of 0.992 is achieved. Secondly, it helps in overcoming the commutation problem. Work on Z-source IMC is also being done [144]. Comparative study on various Z-source and quasi-Z-source IMC is done in [145]. A detailed evaluation on various Z-source DMCs and IMCs is recently done in [56]. Z-source DMC and IMC are shown in Fig. 14.48. A direct ac-ac current source matrix converter for applications in industrial power systems is introduced in [146]. A dynamic voltage restorer (DVR) system employing matrix converter and flywheel storage has been proposed in [147] to cope with voltage sag problem in power system. The proposed topology eliminates the dc link passive components resulting in reduced maintenance requirement and improved power density.

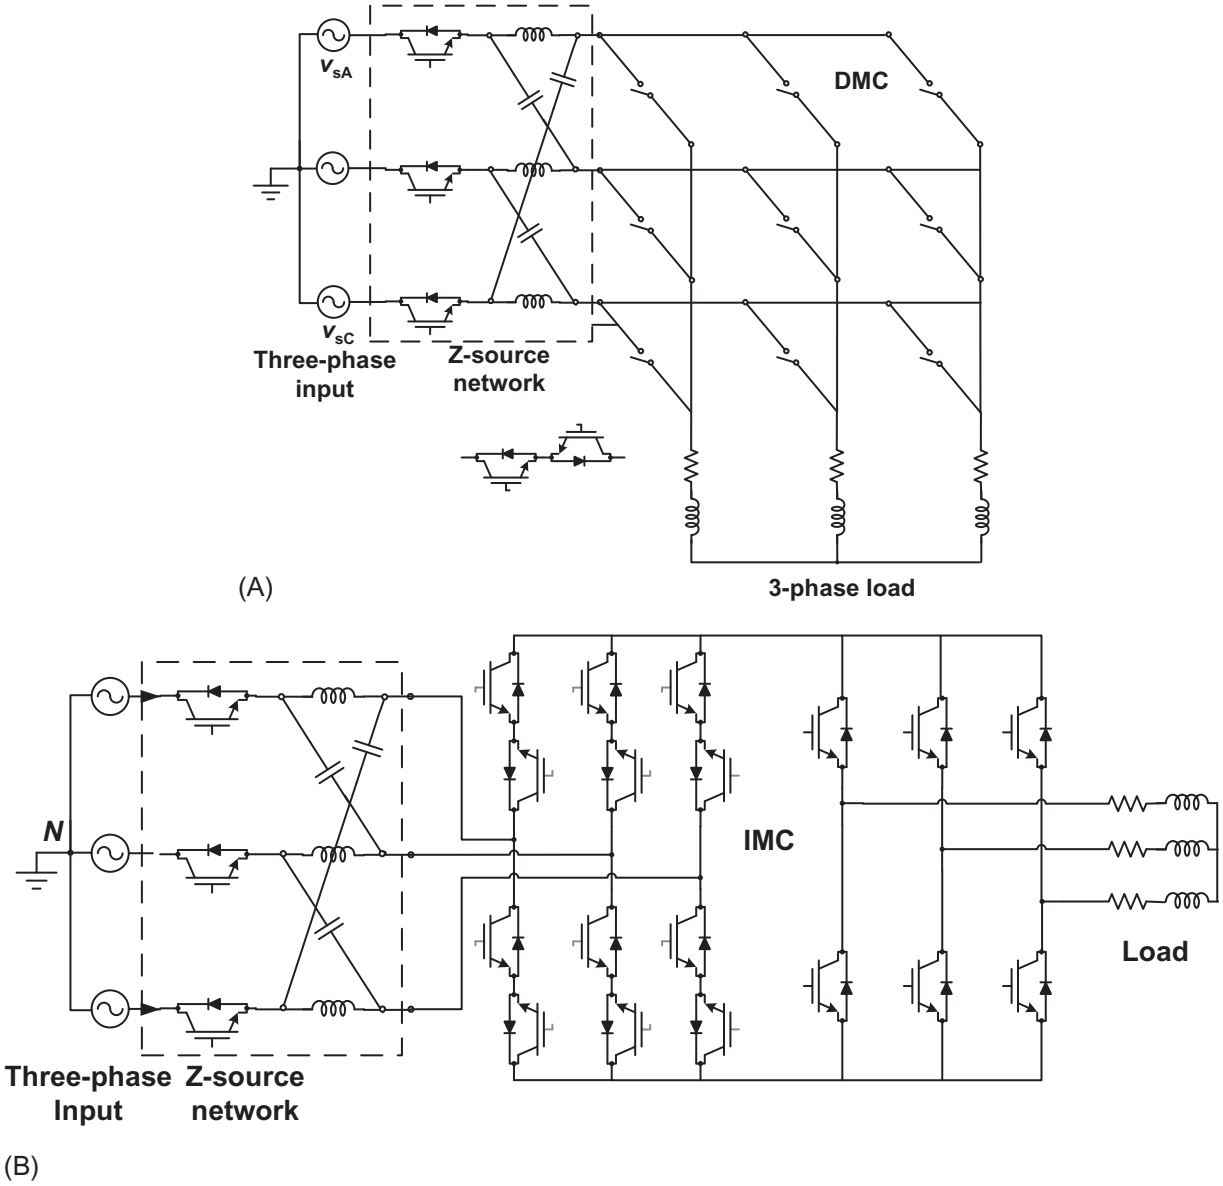

FIG. 14.48 Three-phase Z-source matrix converters: (A) Z-source DMC and (B) Z-source IMC.

15.1 Introduction

Multiphase converters refer to converters with more than three phases and are the extension of three-phase converters by adding extra legs. From hardware point of view, there is least difference. However, control becomes more flexible and complex, and higher degrees of redundancies are available. Multiphase power converters have gained popularity in the last decade because of the developments in the field of high-power switching devices and computational platform such as high-speed digital signal processors and high-density field-programmable gate arrays. The major push in the area of multiphase converter is seen due to concern in developing clean transportation systems, renewable energy generation system (especially wind energy system), and developing high-reliability variable-speed electric drive system. Multiphase power converters are used in numerous applications depending upon their role so as to convert AC to DC, DC to AC, AC to AC, or DC to DC. The major applications of DC to AC converters are found in adjustable-speed drives, while AC to AC and AC to DC are employed in multiphase renewable energy generation system. Multiphase DC-DC converter finds its application in automotive industry.

Multiphase power converter (DC-AC and AC-AC) fed adjustable-speed drives offer numerous advantages when compared with three-phase drives. The major advantages offered are enhanced torque density (since in concentrated winding multiphase electric machine low-order harmonics also contribute to the torque production unlike three-phase machines where only fundamental current components generate torque), lower torque pulsation, and higher frequency pulsation. The electromagnetic torque of inverter-fed induction motor drive possesses a considerable amount of ripple especially at low speed [1,2]. This arises due to the interaction of higher-order current harmonics with fundamental air-gap flux and higher-order air-gap harmonics with fundamental current. Sixth-harmonic pulsating torque is dominant in a three-phase induction motor when inverter feeding the motor operated

in six-step mode. In a five-phase drive the most dominant pulsating torque is a 10th harmonic and as such for n-phase it is $2n$th harmonic torque. Other advantages are lower per-leg current rating for the same voltage rating (due to lower current rating series and parallel switch combination is not required and hence cheaper solution is achieved), greater fault tolerance (machine can start and run even with loss of one or more phase supply), lower dc link current harmonics and lower harmonic losses.

Multiphase electric machines are becoming more popular in the range of medium- and high-power applications [1–5]. Considering an inverter-fed high-power electric motor with power rating exceeding the available rating of power semiconductor switches, the designer has to increase the number of feeding inverters. This implies higher number of phases on the stator of the electric motor as well. Two solutions can be sought for segmenting the power, either increase the number of phases in multiple of three (parallel-connected multiple three-phase inverters) or increase the number of legs of inverter with each leg handling a power of P/n (P is the total power, and n is the number of phases). The design solutions are shown in Fig. 15.1. The solutions given in Fig. 15.1B have n number of parallel-connected three-phase inverters each carrying power of P/n. The supplied motor has multiple three-phase windings with separate neutral points. The major advantage of these off-the-shelf standard three-phase inverters is to supply the motor with each inverter handling lower amount of power. However, the major issue of this drive topology is the circulating current due to the voltage mismatch of each three-phase inverter. The electric motor in this case is called asymmetrical or split-phase motor. This solution is preferred and most widely used in industries because of the fact that the three-phase system solution is well proved and a mature technology:

Solution of Fig. 15.1C, in contrast to the previous solution, works with a single inverter of n-phases supplying electric motor of n-phase. Each phase or leg now handles P/n power, and the circulating current is absent. The electric motor in this case is called symmetrical n-phase motor. This solution is also employed in high-power marine drive applications [6].

Reliability and fault tolerance are other driving forces leading to the development of multiphase system. Due to high phase number, fault tolerance is inherently guaranteed, which is of high importance in safety critical applications such as ship propulsion, more electric aircrafts, electric vehicles, and industrial setup where production loss is critical such as oil and gas plants and military. The multiphase motor drive guarantees continuous operation, however, with degraded performance under fault conditions. The higher the phase number, the better is the performance during faults. This make them highly attractive in applications mentioned above [7,8].

According to classical electric machine theory, the air-gap flux harmonic content improves and becomes close to sinusoidal with the increase in the number of phases. The improved flux density waveform leads to: (i) reduced rotor losses due to flux pulsation and eddy currents (this has importance for high-speed permanent magnet machines since the eddy current losses are very high at high speed in such kind of machines) and (ii) improved torque quality with reduced amplitude of torque pulsation that occurs at higher frequency (this is very important when machine is subjected to high distorted current, and limits are enforced on the maximum allowable torque pulsation).

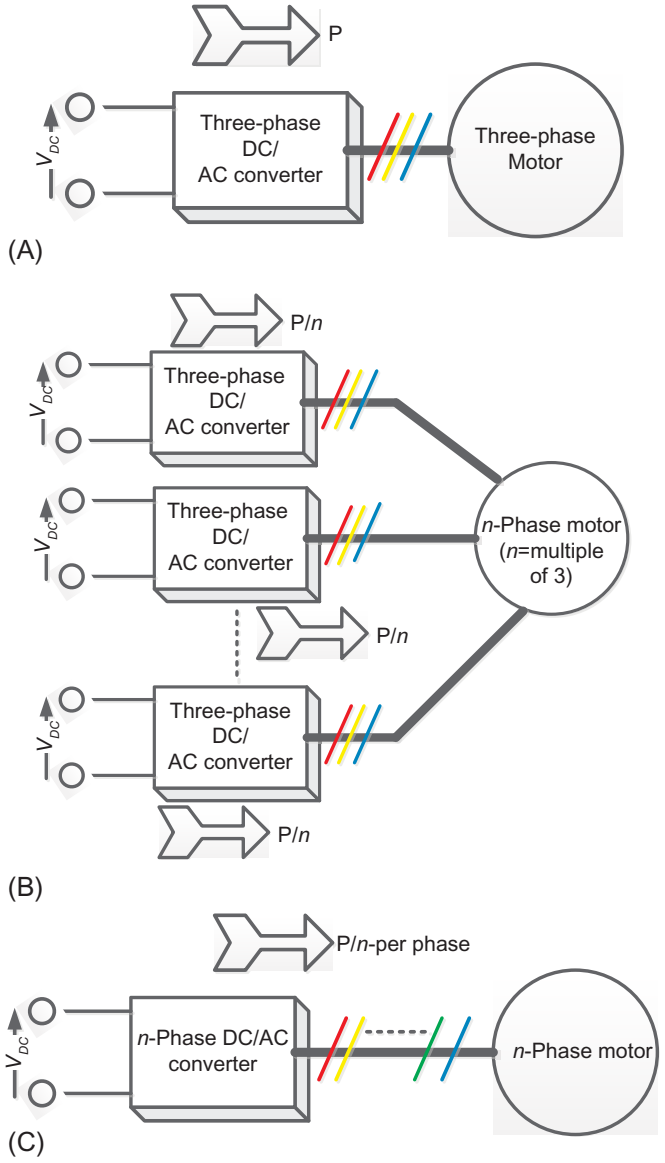

FIG. 15.1 (A) Three-phase drive, (B) multiple three-phase drive, and (C) multiphase drive.

Multiphase generators, specially five phases and more, have started to find a slot in the market due to their advantages over three-phase counterpart [9,10]. This multiphase system could be more suitable for direct drive wind energy, microturbines, and electric vehicle applications since the need for gears can be minimized. Multipulse rectifiers are employed, which have

the ability to reduce the line current harmonic distortion and normally do not require any LC filters or power factor improvement devices. Multipulse DC can be obtained either by increasing the number of phases of the converter or by the use of phase-shifting transformer along with special secondary winding connections in the conventional six-pulse rectifiers. In drive application, the use of phase-shifting transformer provides an effective means to block common-mode voltages generated by the rectifier and inverter, which would otherwise appear on motor terminals, leading to a premature failure of machine winding insulation. Normally AC-DC converters are classified into power factor control rectifiers operated at high switching frequency and line-commutated rectifiers (uncontrolled or controlled) operated at power frequency or generated frequency. The multiphase line-commutated converter normally offers simple control, simple construction, and low cost but suffers from poor input power factor, low input current THD, and unidirectional current flow. The shortcoming of line-commutated rectifiers is overcome by the use of high-switching-frequency PWM rectifiers, voltage-source rectifiers, or current-source rectifiers, but the switch current and voltage limitation may restrict the use of PWM rectifiers in high-power applications.

Multiphase DC-AC voltage-source inverter is obtained from three-phase voltage-source inverter by adding extra legs (each leg has two switches in two-level inverter and a higher number of switches for multilevel inverter). The two switches of the same leg are complimentary in operation (i.e., when upper switch is on, the lower switch must be off and vice versa). The power switches can assume only two states, that is, *on* (called level 1) or *off* (called level 0). Hence, as such for n-phase inverter, there can be 2^n number of switching states. Considering a three-phase inverter, the number of switching states are 8, and, for example, for a nine-phase inverter, the number of switching states are $2^9 = 512$ [5]. It is seen that the number of switching states increases significantly with the increase in the number of phases or legs. Higher numbers of switching states offer flexibility in devising control techniques. Thus, multiphase inverter control has several degrees of flexibility in control. Multiphase inverter can be controlled using different PWM techniques such as carrier-based sinusoidal PWM, harmonic injection PWM, selective harmonic PWM, hybrid PWM, and space-vector PWM. Each method can produce different output magnitudes. Simple carrier-based PWM for multiphase inverters works exactly the same as for three-phase inverters. The maximum possible output phase-to-neutral voltage is 0.5 V_{DC}, where V_{DC} is DC-link voltage magnitude for multiphase inverter [1]. However, the output phase-to-neutral voltage magnitude varies for different phase numbers when using space-vector PWM. Nevertheless, the output phase-to-neutral voltage of multiphase inverters is less than that of a three-phase inverter. Multiphase inverter space vectors are transformed into multiple orthogonal planes, and control is implemented in order to regulate each plane vectors. In multiphase variable-speed drives (with distributed winding multiphase machine), torque is controlled only from one plane vector (d-q), and the rest of the plane vectors produce distortion and hence need to be minimized using PWM techniques. When concentrated winding multiphase machines are supplied using multiphase voltage-source inverters, all plane vectors are used to enhance the torque production. This is a unique feature of concentrated winding multiphase machine not available in three-phase machines. When implementing high-performance control such as vector control and direct torque control, higher control flexibility is available, and different solutions can be implemented.

Multiphase AC-AC converter more popularly known as multiphase matrix converter (MPMC) is also formulated by adding extra legs in three-phase matrix converter configuration. They are classified as direct matrix converters (DMC) and indirect matrix converters (IMC). Each converter leg has three bidirectional power switches each connected to one phase of the utility grid system, and at the output, load is connected. The input is fixed voltage and fixed frequency supply, while the output is of variable voltage and variable frequency. There are configurations where the number of input phases is three while the output phase are more than three and vice versa [4,5]. The multiphase matrix converter encompasses the advantages of three-phase matrix converters and multiphase systems. The major application areas are envisaged in multiphase wind energy system. A matrix converter can be seen as an array of $m \times n$ bidirectional power semiconductor switches that can transform m-phase fixed voltage and fixed frequency input to n-phase variable voltage and variable frequency output without intermediate DC conversion stage. The input side of a matrix converter is voltage fed, while the output side is current fed, and hence, an inductive filter is required at the output side, and a capacitive filter is used at the input side. As the load is itself of inductive nature, the requirement of output filter diminishes. The size of the input filter used in matrix converter is significantly smaller than an equivalent voltage-source inverter.

Considering an $m \times n$ matrix converter, the number of switching states is $2^{m \times n}$. Large numbers of switching states are produced; however, not all of them are useful. Due to the nature of input (being voltage source) and output (being current source), the input should not short-circuited, and the output should not be open-circuited. As a consequence, only one switch in each leg conducts at one instant of time, and hence, a usable number of switching states are m^n. In matrix converter, the output (sinusoidal) is formed from input (sinusoidal), and hence, output can assume any level depending upon the instantaneous value of the input. This makes the switching logic of matrix converter quite complex. The output voltage of a three-phase input and three-phase output matrix converter is 86.6% of the input voltage. The output-voltage magnitude reduces for higher phase number of outputs; for example, for a three-phase input and five-phase output matrix converter, it is 78.86% [11], and this value decreases further with increase in the output number of phases. The output voltage becomes higher than the input for $m \times n$ matrix converter

for $m > n$; for example, for a five-phase input and three-phase output, it is 104.4%, and this value further increases as m is increased [4,12].

Multiphase matrix converters are constructed from bidirectional power switches that are realized in the same way as a three-phase matrix converter. The modulation strategies are complex and can be built upon the concept of three-phase matrix converter. However, significant challenges exist in obtaining proper modulation technique for a multiphase matrix converter. Some modulation strategies discussed in the literature are carrier-based PWM, space-vector PWM, and direct-duty-ratio-based PWM [13–19].

Multiphase matrix converters find its application in wind energy generation [20], power system [21,22], and ship propulsion [23]. When used in multiphase energy generation, usually the input side of the matrix converter is of higher phase, and the output side is three-phase connected to either utility grid or feeding isolated load. A 27-phase input and 3-phase output matrix converter of 100 MW power rating is presented in [24,25].

Present-day advancement in powering processors invariably uses multiphase buck converter topology because of higher output current and low-voltage requirement. Single-phase buck converter works well for low-voltage applications with currents up to 25 A. Higher filtering requirement and efficiency issue limits the use of single-phase topology in applications such as voltage regulator module (VRM). Interleaving as technically known reduces ripple currents at the input and output. A multiphase buck converter reduces considerably the i^2R current power dissipation in the controlled switches and inductors. The distribution of current in various paths in a multiphase converter reduces the current magnitude through the switches, thereby reducing the switching losses. The output filter requirement decreases in a multiphase implementation due to the higher frequency of ripple current as a result of ripple current cancelation in the power stage for each phase. The single-phase implementation has much higher ripple content. Load transient performance is also better because of the reduction in energy stored in each output inductor. The lower the ripple current is, the less the perturbation will be. The input capacitors supply all the input current to the buck converter if the input wire to the converter is inductive. Improvement in multiphase topologies and their control strategies promise improved performance compared to the conventional multiphase buck converter.

This chapter is organized into five different sections covering the topologies, operation, and control of different types of multiphase power converters. Section 15.2 describes the types and classifications of different multiphase power converters. Section 15.3 is dedicated to AC-DC converters considering multiphase and multipulse output. Section 15.4 is devoted to DC-AC converters especially focusing on five-phase and seven-phase voltage-source inverter. Section 15.5 covers the description of multiphase AC-AC converters, and multiphase DC-DC converters are discussed in Section 15.6.

15.2 Types and Topologies of Multiphase Converters

The requirements for the current and voltage continue to increase with an increase in power level, and systems become more and more complex. The amount of current/voltage of power source to meet such requirements usually needs a combination of several power controllers to improve the thermal stress of the individual power components. The driving mechanism for this combination leaves one with two choices: single phase or multiphase.

Multiphase converters reduce the input and output current ripples by interleaving the two or more stages of power converters. By increasing the phase number, the output-voltage ripple and the input capacitor size can be curtailed without increasing the switching frequency of the power devices. Load dynamic performance is significantly improved during transients due to lower-output-voltage ripple and smaller output inductors. The low switching losses and driver circuit losses of power semiconductor devices at relatively low switching frequency and the reduced power losses due to equivalent series resistance (ESR) of the capacitors help achieve overall high efficiency of converters. For multioutput applications, multiphase converters may also provide the benefit of smaller input side capacitors.

Single-phase versus multiphase converters are as follows:

(1) Single-phase converters work well for low voltages and up to certain amount of current say about 25 A, but power dissipation and efficiency start to become an issue at higher currents. One suitable approach is to develop multiphase converters [26].
(2) The output filter requirements decrease in multiphase implementation due to the reduced current in the power stage for each phase. Compared with single-phase approach, the inductance and inductor size are drastically reduced because of lower average current and lower saturation current.
(3) Ripple current cancelation in the output filter stage results in a reduced ripple voltage across the output capacitor compared with single-phase approach. This is another reason why a multiphase converter is preferred.
(4) Load transient performance is improved due to the reduction of energy stored in each output inductor. The reduction in ripple voltage as a result of current cancelation contributes to minimal output-voltage overshoot and undershoots because many cycles will pass before the loop responds. The lower the ripple current is, the less the perturbation will be.

Like single-phase or three-phase converters, multiphase converters are classified as AC-DC, DC-AC, DC-DC, and AC-AC converters. Multiphase converters are simple extension of three-phase converters. As far as hardware is concerned, there

is not much difference. However, the control complexity increases manyfold with the increase in the number of phases. There are further classifications in these converters. The classification of multiphase converters is shown in respective section.

15.2.1 Multiphase AC-DC Converters

A significant amount of work is done on developing novel topologies of multipulse AC-DC converters since they have huge potential applications for unidirectional and bidirectional power flow starting from six pulses to a large number of pulses. The major advantage of adopting a higher pulse number is the current ripple reduction.

The novel configurations in multiphase AC-DC converter were developed of unidirectional and bidirectional topologies with three or more number of phases. Classification of multiphase AC-DC converters is shown in Fig. 15.2, which is based on power flow, number of pulse used, isolated and nonisolated topologies, and various techniques used to improve AC current profile and output DC voltage waveform [27]. Based on the application and requirements, some systems require unidirectional power flow, and some require bidirectional power flow.

Unidirectional systems use diode rectifiers and transformer circuit configurations in isolated and nonisolated topologies. The unidirectional topologies have configurations of six pulses and its multiple. If the voltage difference is more between input and output, then isolated configuration is useful, and if the difference is less, nonisolated topologies are used. However, these are further classified as bridge and full-wave rectifiers. These types of full-wave multipulse converters (MPC) can also be further classified whether it uses double star or tapped polygon transformer secondary to create twelve phases to feed full-wave diode rectifiers. Both configurations have their own merits and demerits, but both MPC configurations show the same performance in terms of device and transformer utilization.

On the other hand, the bidirectional AC-DC converters have the power flow from AC mains to DC output or vice versa and normally use thyristors with phase angle control to obtain wide varying DC output voltages. These MPCs use multiple winding transformers to generate higher number of the phases. Like unidirectional, these MPCs are also divided as isolated and nonisolated. These are mainly used to feed DC motor drives and synchronous motor drives.

15.2.2 Multiphase DC-DC Converters

Multiphase topologies can be configured as a step-down (buck), step-up (boost), buck boost, and even forward converter. A multiphase DC/DC converter according to the present invention includes a plurality of DC/DC converters whose outputs are connected in common to supply electric power to a load and a load state detection portion that detects a state of the load connected to the plurality of DC/DC converters and outputs a detection result. Multiphase DC-DC converters classification is shown in Fig. 15.3.

15.2.3 Multiphase DC-AC Converters

Multiphase DC-AC converters are the main source of multiphase adjustable-speed drives. The major driving force behind the adoption of multiphase motor drive is due to the power segmentation in large number of converter legs. The power switching devices have limited voltage- and current-handling capabilities. Hence, when used in high-power application, series-and parallel combination of devices are required. This is cumbersome solution because of dynamic voltage sharing problem among the series-/parallel-connected power switching devices. Better solution is obtained when the power per phase or per leg is reduced by increasing the number of phases or number of legs, and this is termed as multiphase DC-AC

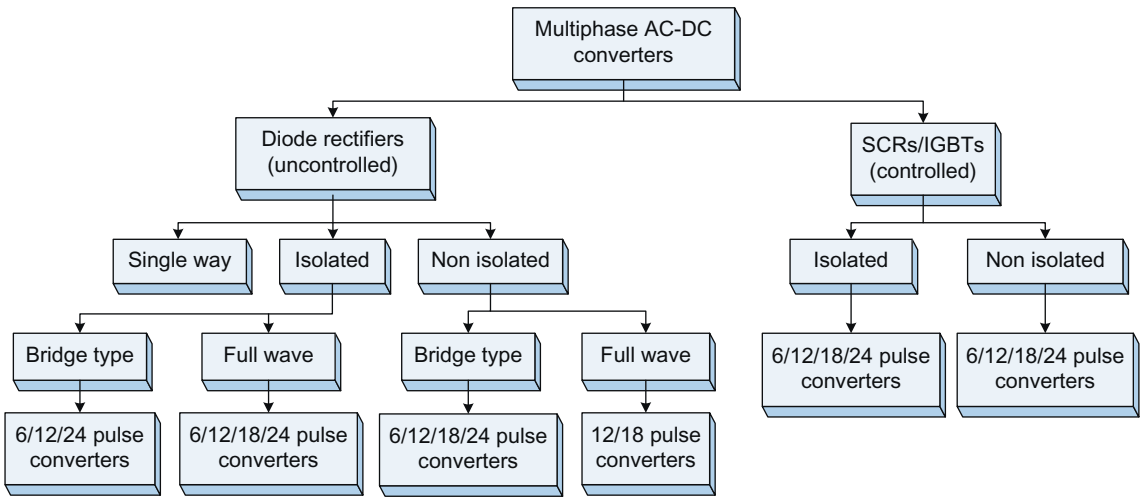

FIG. 15.2 Multiphase AC-DC converter classification.

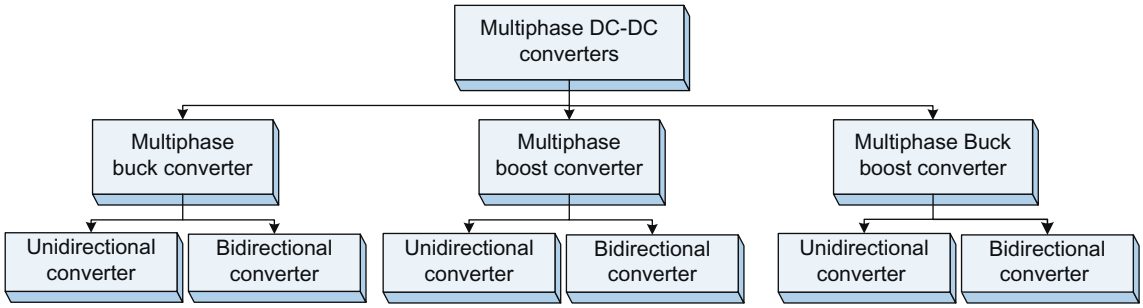

FIG. 15.3 Multiphase DC-DC converter classification.

inverters. Multiphase DC-AC inverters are simple in design as they are simple extension of three-phase DC-AC inverter. However, they offer large degree of switching redundancies and hence great flexibility in control. Although control becomes complex, the performance is improved manifold. Multiphase DC-AC inverters can be built in the same topologies as that of their three-phase counterparts and hence have the same calcifications and types. Multiphase AC-DC converters normally classified as shown in Fig. 15.4.

First version of multiphase inverter technology is five-phase VSI fed to star-connected five-phase load. Five-phase VSI configuration found application for five-phase induction machine and synchronous machine drives. Six-phase inverter configuration was built with two two-level standard three-phase VSIs, with two separate DC sources fed to dual three-phase induction motor. Seven-phase VSI fed to star-connected seven-phase load based on multiple space-vector modulation and seven-phase VSI configuration found applications for seven-phase permanent magnet synchronous and synchronous reluctance motor drives. Fig. 15.5 shows simple five-phase induction motor drive.

Multiphase inverters are also classified as cascaded H-bridge, diode clamped, and flying capacitor topologies. They can also be built in hybrid configuration. Multiphase impedance-source inverters (ZSI) and quasi impedance-source inverters (qZSI) are also reported in the literature [28]. ZSI and qZSI are special inverters that have the capability of boosting the source voltage and inverting DC to AC simultaneously. The boosting can be as high as 200%–300%. They are popular in solar PV applications

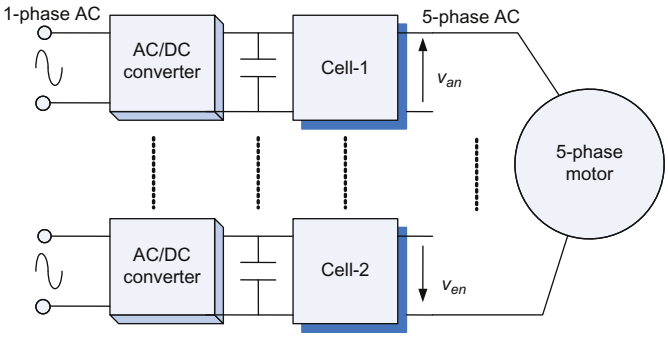

FIG. 15.5 Simplified five-phase drive.

since boosting and inversion is done in a single stage. Multiphase ZSI/qZSI is used to feed multiphase motor drives.

15.2.4 Multiphase AC-AC Converters

Multiphase AC-AC converters are generally classified as AC voltage controllers, matrix converters, and cycloconverters. Fig. 15.6 shows various topologies of multiphase AC-AC converters. AC voltage regulators are further classified as phase-controlled converters and fully controlled voltage converters.

Three-phase cycloconverters are of several types. For example, there are the 3-pulse cycloconverters, 6-pulse cycloconverters, and 12-pulse cycloconverters. Typically, the three-pulse converter is built with the three single, and the six-pulse converter is generally the combination of two three-pulse converters and

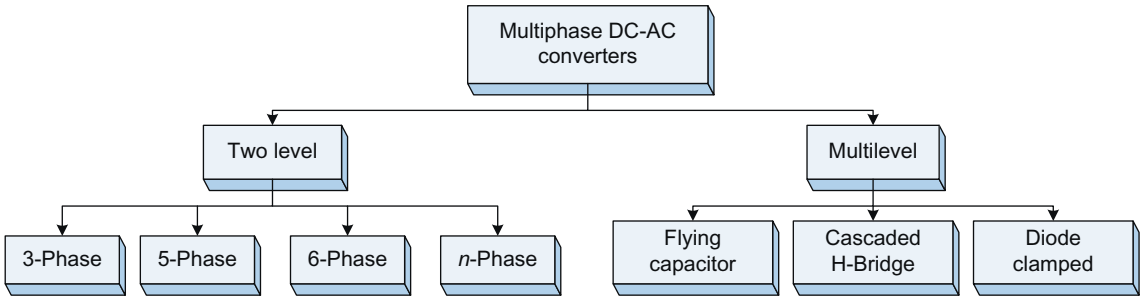

FIG. 15.4 Multiphase DC-AC converter classifications.

so on. The 12-pulse converter is obtained by connecting two six-pulse configurations in series and appropriate transformer connections for the required phase shifted. Multiphase AC-AC converter classification is shown in Fig. 15.6. By using the knowledge of constructing a DC-modulated single-stage AC/AC converter, a multistage AC/AC converter can be easily obtained. Examples with complex structures are Luo converter, superlift Luo converter, and multistage cascaded boost converter. Using the same technique, one can construct DC-modulated multiphase AC/AC converters where they are classified as multiphase AC/AC buck, boost, and buck-boost converter.

Cycloconverters are broadly classified as naturally commutated and forced commutated. The later one is also known as matrix converter. Multiphase matrix converters are in study and are being studied in detail [4]. Fig. 15.7 shows some of the possible configurations of frequency changers. The one

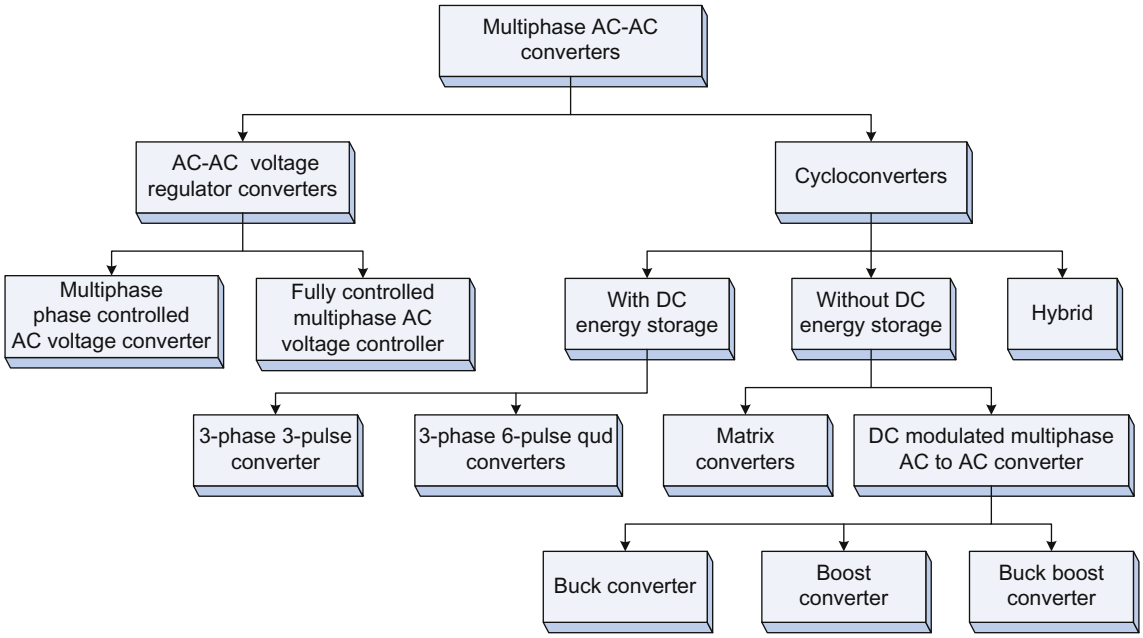

FIG. 15.6 Multiphase AC-AC converter classification.

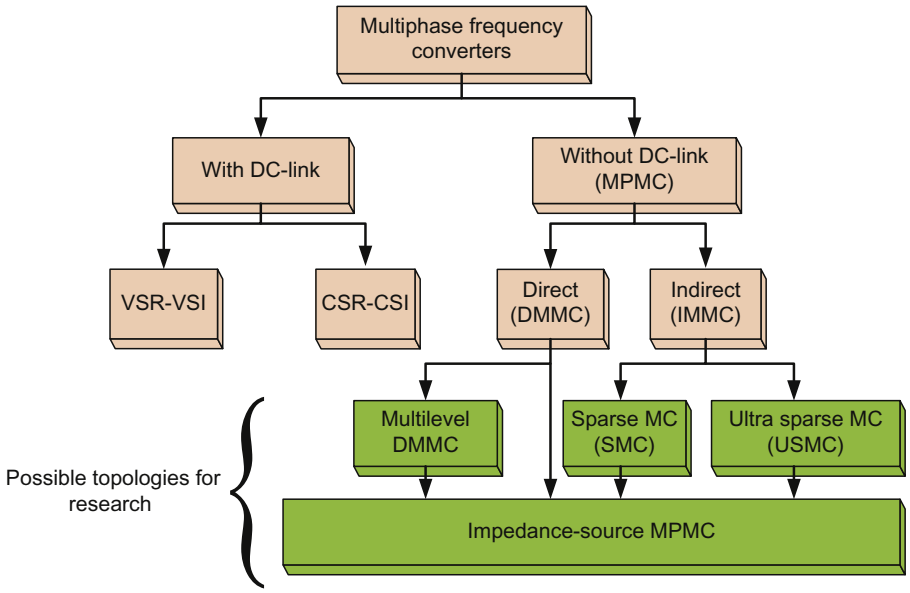

FIG. 15.7 Multiphase frequency changers. *VSR*, voltage source rectifier; *VSI*, voltage source inverter; *CSR*, current source rectifier; *CSI*, current source inverter; *MPMC*, multiphase matrix converter; *DMMC*, direct multiphase matrix converter; *IMMC*, indirect multiphase matrix converter; *SMC*, sparse matrix converter; *USMC*, ultra sparse matrix converter.

with a DC link is also commonly known as back-to-back (B2B) topology. Although B2B converter does the AC-AC conversion, it is sort of a paradigm to classify the topologies without the DC link under AC-AC converters. Also, the figure shows the possibility of research in the field of multiphase matrix converters.

15.3 Multiphase Multipulse AC-DC Converters

Solid-state AC-DC converters are widely used in a number of applications such as adjustable-speed drives (ASDs), high-voltage DC (HVDC) transmission, and electrochemical processes such as electroplating, telecommunication power supplies, battery charging, uninterruptible power supplies (UPS), high-capacity magnet power supplies, high-power induction heating equipment, aircraft converter systems, plasma power supplies, and converters for renewable energy conversion systems. These converters, which are also known as rectifiers, are generally fed from three-phase AC supply in power rating above few kilowatts. They exhibit the problems of power quality in terms of injected harmonics, resulting in poor power factor, AC voltage distortion, and rippled DC outputs. Because of these problems in AC-DC conversion, several standards and guidelines are laid down, which are to be referred by designers, manufacturers, and users. Therefore, various methods are used to mitigate these problems in AC-DC converters. Normally, filters are recommended in already existing installations, which may be passive, active, or hybrid types depending upon rating and economic considerations. These filters have been developed from small to large power ratings to reduce the power quality problems of AC-DC converters. However, in some cases, the ratings of these filters are close to the converter rating, which not only increases the cost but also increases the losses and component count, resulting in reduced reliability of the system. However, in future installations, it is preferred to modify the converter structure at design stage either using active or passive (magnetic) wave shaping of input currents or using multipulse AC-DC converters by using multiphase system or different connections of standard three-phase six-pulse AC-DC converters. At higher power level, generally, multiphase system is preferred. It reduces the ripples in the line current and load voltages drastically, and thus, EMI reduces, and the harmonic filter requirements also become very nominal.

15.3.1 Five Phase Uncontrolled Full Wave Bridge Rectifier

The circuit diagram of a simplified five-phase (ten pulses) uncontrolled rectifier consisting of 10 diodes (D1–D10) is shown in Fig. 15.8, where v_{an}, v_{bn}, v_{cn}, v_{dn}, and v_{en} are the supply phase voltages having peak value of V_m given by Eq (15.1):

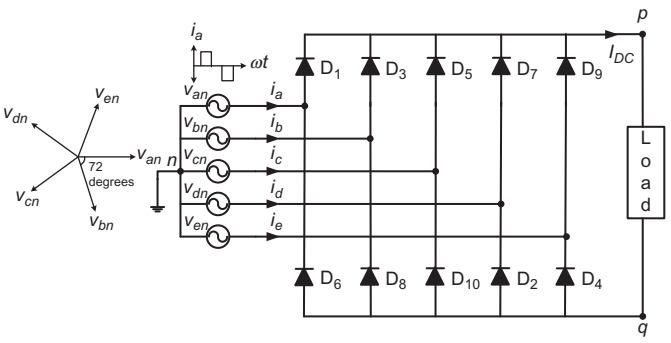

FIG. 15.8 Five-phase full-wave uncontrolled rectifier circuit.

$$\begin{aligned} v_{an} &= V_m \sin(\omega t) \\ v_{bn} &= V_m \sin(\omega t - 2\pi/5) \\ v_{cn} &= V_m \sin(\omega t - 4\pi/5) \\ v_{dn} &= V_m \sin(\omega t - 6\pi/5) \\ v_{an} &= V_m \sin(\omega t - 8\pi/5) \end{aligned} \tag{15.1}$$

The diodes are assumed ideal and are numbered according to their conduction sequence 1,2- ,3- 3,4- 4,5- 5,6- 6,7- 7,8- 8,9- 9,1.

The line voltages for adjacent phases will be different from that of nonadjacent phases. The line voltages for adjacent and nonadjacent phases can be obtained from the respective phasor diagrams shown in Figs. 15.9 and 15.10, respectively, as follows:

For adjacent phases,

$$\begin{aligned} v_{ab} &= v_{an} - v_{bn} \\ v_{ab} &= V_m \sin(\omega t) - V_m \sin(\omega t - 2\pi/5) \\ v_{ab} &= 2V_m \sin(\pi/5) \cos(\omega t - \pi/5) \\ &\left\{ \because \sin\alpha - \sin\beta = 2\cos\left(\frac{\alpha+\beta}{2}\right)\sin\left(\frac{\alpha-\beta}{2}\right) \right. \\ v_{ab} &= 1.1755\, V_m \sin(\omega t + 3\pi/10) \end{aligned} \tag{15.2}$$

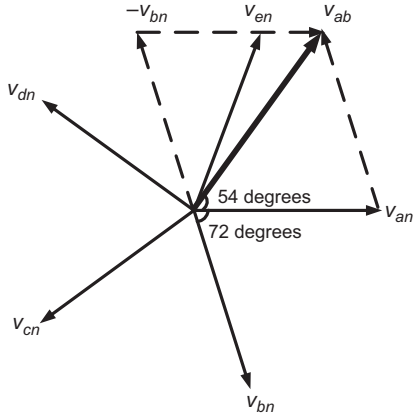

FIG. 15.9 Phasor diagram of the line voltages of adjacent phases.

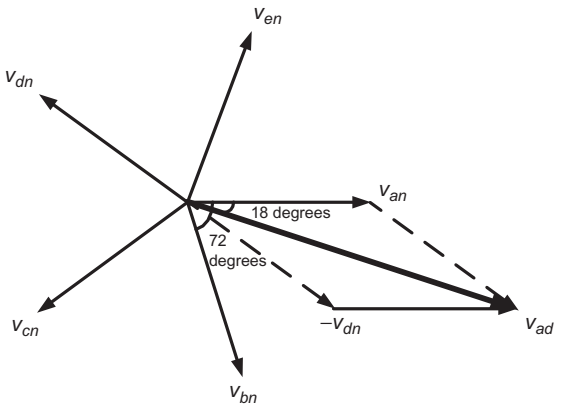

FIG. 15.10 Phasor diagram for the addition of nonadjacent phases.

For nonadjacent phases,

$$\begin{aligned} v_{ad} &= v_{an} - v_{dn} \\ &= V_m \sin(\omega t) - V_m \sin(\omega t - 6\pi/5) \\ &= 2V_m \sin(3\pi/5) \cos(\omega t - 6\pi/10) \\ v_{ad} &= 1.9021 V_m \sin(\omega t - \pi/10) \end{aligned} \tag{15.3}$$

Fig. 15.11A shows the waveforms of the maximum and minimum value of phase voltage in different intervals. The maximum phase voltage V_{pn} and minimum phase voltage V_{qn} described by Eq (15.4) will appear at the output terminals p and q. Both the diodes in the same leg never conduct simultaneously, which avoids direct short circuit in the leg. In the upper leg, the diodes (odd numbered) having its anode connected with phase voltage of highest value among phases will conduct. Similarly, in the bottom leg, the diodes (even numbered) having its cathode connected with lowest phase voltage will conduct at any instant of time:

$$\begin{aligned} V_{pn} &= \max(v_{an}, v_{bn}, v_{cn}, v_{dn}, v_{en}) \\ V_{qn} &= \min(v_{an}, v_{bn}, v_{cn}, v_{dn}, v_{en}) \end{aligned} \tag{15.4}$$

The output-voltage waveform shown in Fig. 15.11B is a 10-pulse waveform appearing across the load. For a purely resistive load, the waveform of the line current i_a shown in Fig. 15.11C has two humps per half cycle of the supply frequency. The other four line currents, i_b, i_c, i_d, and i_e, have the same waveform as i_a but lag from i_a by $2\pi/5$, $4\pi/5$, $6\pi/5$, and $8\pi/5$ radians, respectively. The average and rms value of output voltage at load can be calculated as

$$V_{DC} = \frac{1}{2\pi/10} \int_{\frac{\pi}{2}}^{\frac{7\pi}{10}} 1.902 V_m \sin(\omega t - \pi/10)\, d(\omega t) \tag{15.5}$$

$$V_{DC} = 1.87087 V_m$$

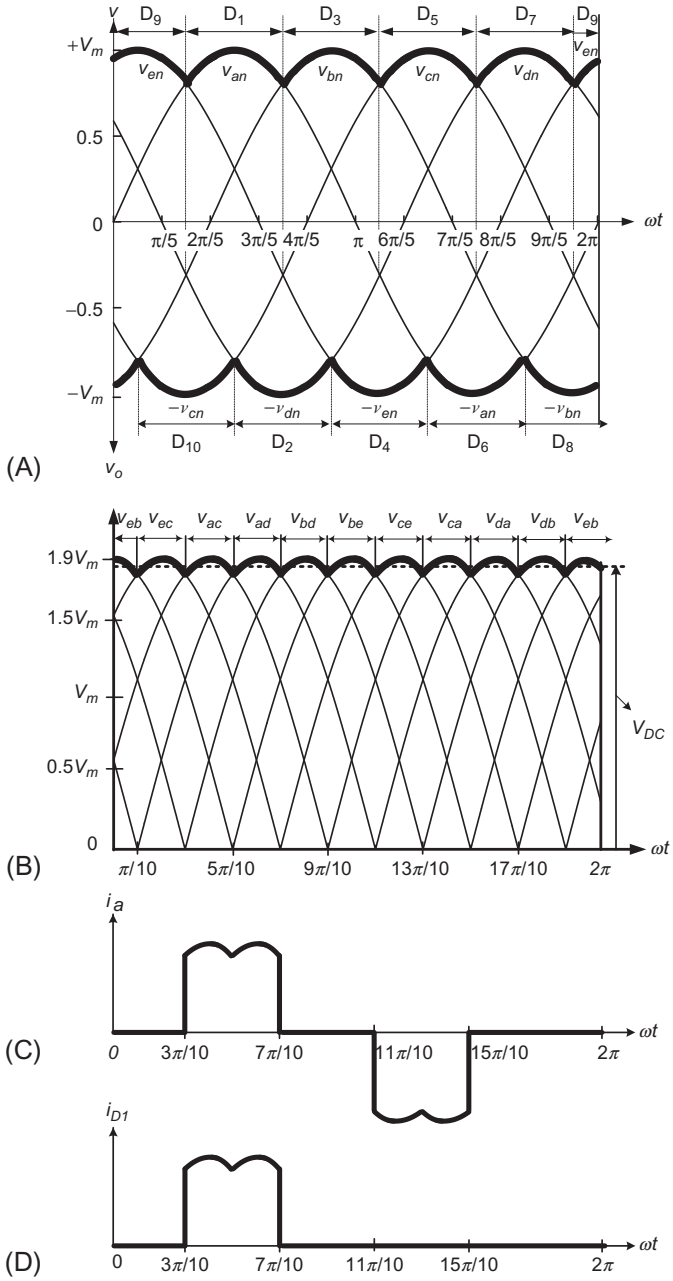

FIG. 15.11 (A) Phase voltages w.r.t p and q points, (B) output voltage across the load, (C) phase "a" current, and (D) diode current.

$$V_{rms} = \sqrt{\frac{1}{2\pi/10} \int_{\frac{\pi}{2}}^{\frac{7\pi}{10}} [1.902 V_m \sin(\omega t - \pi/10)]^2 d(\omega t)} \tag{15.6}$$

$$V_{rms} = 1.87107 V_m$$

For a resistive load, the harmonics of the output voltage can be found by using Fourier series analysis. To find the Fourier coefficients, we integrate v_{be} from $-\pi/10$ to $+\pi/10$. Considering the

half-wave symmetry, the Fourier coefficients will be calculated as follows:

$$b_n = 0 \tag{15.7}$$

$$a_n = \frac{1}{\pi/10}\int_{\frac{-\pi}{10}}^{\frac{\pi}{10}} 1.9021 V_m \cos(\omega t)\cos(n\omega t)\, d(\omega t)$$

$$= 6.067 V_m \left\{ \frac{(n+1)\sin\left[(n-1)\frac{\pi}{10}\right] + (n-1)\sin\left[(n+1)\frac{\pi}{10}\right]}{(n^2-1)} \right\}$$

$$a_n = \frac{12.134 V_m}{(n^2-1)}\left\{ n\sin\frac{n\pi}{10}\cos\frac{\pi}{10} - \cos\frac{n\pi}{10}\sin\frac{\pi}{10} \right\} \tag{15.8}$$

If the frequency of the source voltage is f, the output voltage has harmonics at $10f$, $20f$, $30f$ …etc. Eq. (15.8) is simplified as

$$a_n = -\frac{12.134 V_m}{(n^2-1)}\left\{ \cos\frac{n\pi}{10}\sin\frac{\pi}{10} \right\}$$
$$a_n = -\frac{3.75 V_m}{(n^2-1)}\cos\frac{n\pi}{10} \tag{15.9}$$

The DC component is found by putting $n = 0$ in Eq. (15.9), and its value is

$$V_{DC} = \frac{a_0}{2} = 1.87 V_m \tag{15.10}$$

This is the same value as calculated in Eq. (15.5). The Fourier series of the load voltage can be written as

$$v_L(t) = \frac{a_0}{2} + \sum_{n=10,20,\cdots}^{\infty} a_n \cos(n\omega t) \tag{15.11}$$

After substituting the values of the coefficients, we obtain

$$v_L(t) = 1.87 V_m \left(1 - \sum_{n=10,20,\cdots}^{\infty} \frac{2}{(n^2-1)}\cos\frac{n\pi}{10}\cos n\omega t \right) \tag{15.12}$$

$$v_L(t) = 1.87 V_m \left(1 + \frac{2}{99}\cos 10\omega t - \frac{2}{399}\cos 20\omega t + \cdots \right) \tag{15.13}$$

Fig. 15.12 shows the load voltage harmonics profile. Since each diode conducts one fifth of the time, the average diode current is given by Eq. (15.14).

$$I_{D,avg.} = \frac{1}{2\pi}\left[\int_{\frac{3\pi}{10}}^{\frac{7\pi}{10}} I_{DC}\, d(\omega t) \right] = 0.2 I_{DC} \tag{15.14}$$

Eq. (15.14) indicates that a five-phase rectifier will have switches with lower ratings as compared with the three-phase

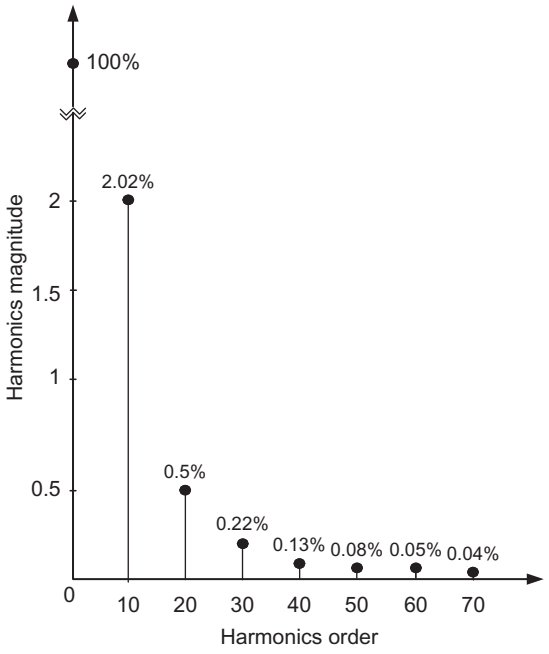

FIG. 15.12 Harmonics profile of output voltage.

counterpart, provided that both are feeding the same load as average value of switch current in three-phase system is 33.33% and in this case it is 20% [9,10]. The input phase current can be expressed as

$$i_s = \sum_{n=1,3,5....}^{\infty} \frac{4 I_{DC}}{n\pi}\sin\frac{n\pi}{5}\sin(n\omega t) \tag{15.15}$$

The fundamental component of input current is

$$i_{s1} = 0.7484 I_{DC}\sin(\omega t) \tag{15.16}$$

The rms value of the fundamental component of input current is

$$I_s = \sqrt{\frac{1}{\pi}\int_{\frac{3\pi}{10}}^{\frac{7\pi}{10}} I_{DC}^2\, d\omega t} = \sqrt{\frac{2}{5}} I_{DC} \tag{15.17}$$

Problem 15.1 A five-phase bridge rectifier delivers 60 A current at a voltage of 317.5 V to a purely resistive load. If the frequency of the source is 60 Hz, determine the following:

(a) Efficiency of rectification
(b) Form factor
(c) Ripple factor
(d) Peak inverse voltage (PIV) of each diode
(e) Peak current through a diode

Solution Since $V_{DC}=1.87087V_m$ and $V_{rms}=1.87101V_m$ and also $I_{DC}=V_{DC}/R$ and $I_{rms}=V_{rms}/R$,

(a) Efficiency of rectification $\eta=\dfrac{P_{ac}}{P_{DC}}=\dfrac{\frac{V_{rms}^2}{R}}{\frac{V_{DC}^2}{R}}=\dfrac{(1.87107)^2}{(1.87087)^2}=99.97\%$

(b) Form factor $FF=\dfrac{Vrms}{V_{DC}}=\dfrac{1.87107}{187087}=100.011\%$

(c) Ripple factor $RF=\sqrt{FF^2-1}=\sqrt{(1.00011)^2-1}=1.483\%$

(d) Peak inverse voltage of each diode $=1.902V_m$

Also, since $V_{DC}=1.87087\ V_m$ and peak value of phase voltage, $V_m=\dfrac{V_{DC}}{1.87087}=\dfrac{317.5}{1.87087}=169.70\,\text{V}$

Hence, $PIV=1.902\times169.70=322.78\,\text{V}$

(e) The average DC current through each diode is

$$I_{DC(Diode)}=\frac{I_{DC}}{5}=\frac{60}{5}=12\,\text{A}$$

$$\text{Also, } I_{DC(Diode)}=\frac{4}{\pi}\int_0^{\frac{\pi}{10}} I_m\cos\omega t\,d\omega t$$

$$I_{DC}=0.19673I_m$$

$$I_m=\frac{I_{DC}}{0.19673}=\frac{12}{0.19673}=61\,\text{A}$$

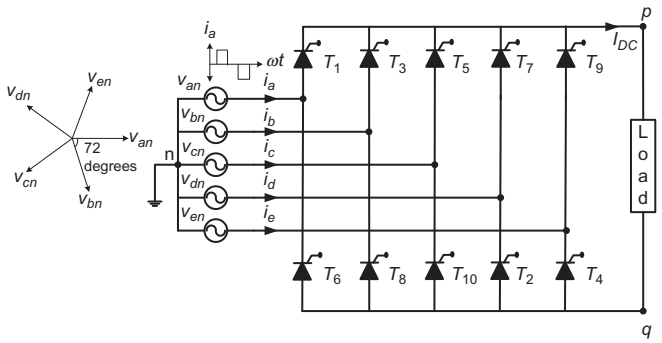

FIG. 15.13 Five-phase full-wave bridge rectifier basic circuit.

15.3.2 Five-Phase Controlled Full Wave Bridge Rectifier

Whenever a diode is in forward-biased condition, it conducts, but a thyristor (or controlled switch) requires a triggering signal for its conduction. If all the diodes of a 10-pulse full-wave uncontrolled converter are replaced by controlled switches (thyristors), it becomes a controlled converter. Fig. 15.13 shows the basic power circuit of a fully controlled 10-pulse 5-phase AC-DC converter. In this case, the thyristors are switched at an interval of 36 degrees sequentially as shown in Table 15.1. When T_1 and T_2 are conducting v_{an} and v_{bn} voltages with respect to neutral appear at the load, that is, $v_{ad}=v_{an}-v_{dn}$, which is the line voltage V_L ($v_{ad}=1.9021V_m\sin(\omega t-\pi/10)$). At $\omega t=\pi/2+\alpha$, T_1 is commutated, as on this instant of time $v_{bn}>v_{an}$, and the load current is transferred from T_1 to T_3. There are 10 voltage pulses, and the instantaneous output voltage may become negative for an RL load, but the V_{dc} will always have positive value, except for an active (RLE) load. It should be noted that the line voltage corresponding to the nonadjacent phase voltages is only appearing across the load. AC voltages applied to the rectifier is given by Eq. (15.1).

The delay angle reference is taken from the point the thyristor would begin to conduct if it were a diode. Thus, the delay angle is an interval from the thyristor being forward-biased and till the gate signal is applied. The corresponding waveforms are shown in Fig. 15.14A–H [9,10]. Since each voltage pulse corresponds to the line voltage and it appears for 1/10th period of the cycle $2\pi/10$, the average output voltage corresponding to v_{ad} shown in Table (15.1) is given by

$$V_{DC}=\frac{1}{2\pi/10}\int_{\frac{5\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha}1.902V_m\sin(\omega t-\pi/10)\,d(\omega t)$$

$$V_{DC}=\frac{5\times1.902V_m}{\pi}[-\cos(\omega t-\pi/10)]_{\frac{5\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha} \tag{15.18}$$

$$V_{DC}=1.87V_m\cos\alpha$$

TABLE 15.1 Thyristor firing instants and output voltage across the load

Time interval	Thyristor fired	Conducting thyristor	Output voltages across load
$[\pi/10+\alpha,\ 3\pi/10+\alpha]$	T_{10}	T_9 and T_{10}	$v_o=v_{ec}=1.902\,V_m\sin(\omega t+3\pi/10)$

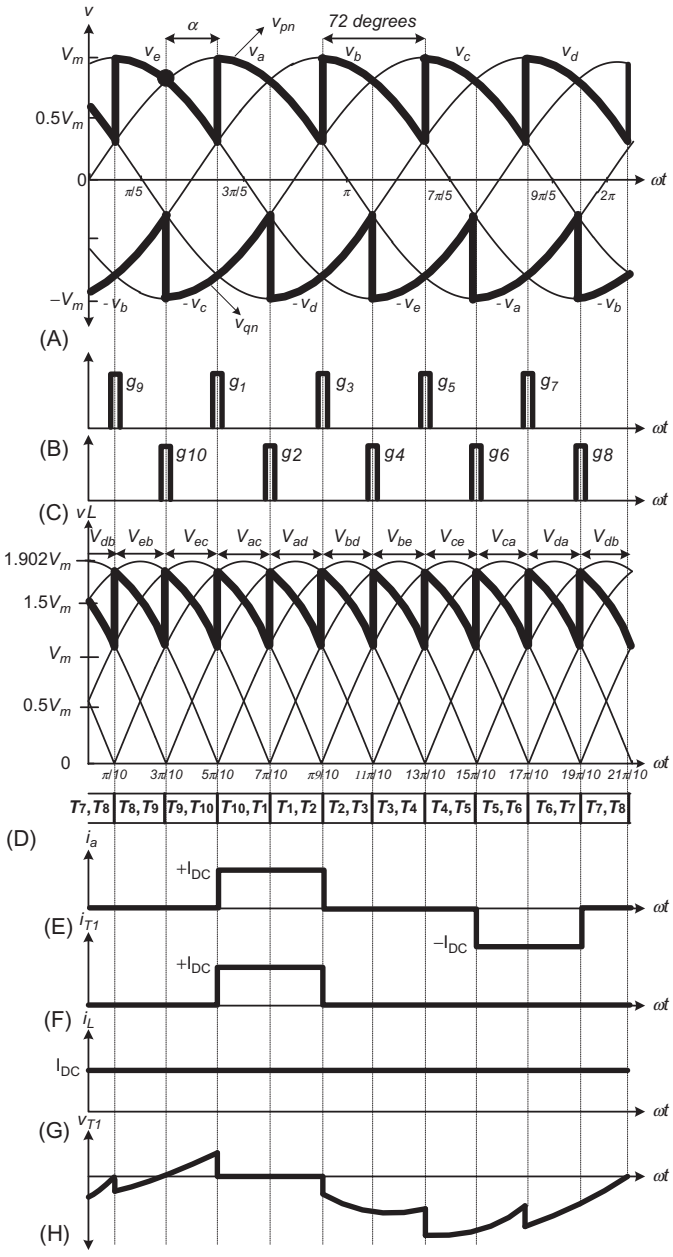

FIG. 15.14 (A) Supply voltage with positive and negative waveforms, (B) gate pulses for firing upper-leg switches, (C) gate pulses for firing lower-leg switches, (D) output-voltage waveform, (E) supply current of phase a, (F) switch 1 current, (G) load current, and (H) voltage across switch 1.

The rms output voltage is

$$V_{rms} = \sqrt{\frac{1}{2\pi/10}\int_{\frac{5\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha} (1.902V_m \sin(\omega t - \pi/10))^2}$$

$$V_{rms} = \sqrt{\frac{5\times 1.902^2 \times V_m^2}{\pi}\int_{\frac{5\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha}\left[\frac{1-\cos 2\left(\omega t-\frac{\pi}{10}\right)}{2}\right]d(\omega t)}$$

$$V_{rms} = \sqrt{\frac{5\times 1.902^2 \times V_m^2}{2\pi}\left[\omega t - \frac{1}{2}\sin 2\left(\omega t - \frac{\pi}{10}\right)\right]_{\frac{5\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha}}$$

$$V_{rms} = 1.902V_m\sqrt{\frac{1}{2}+\frac{5}{2\pi}\sin(\pi/5)\cos 2\alpha} \tag{15.19}$$

It is evident from Fig. 15.14D that the instantaneous output voltage is continuous for $\alpha < \pi/5$; therefore, for any passive load, the load current will be continuous. For $3\pi/10 < \alpha > \pi/5$, the continuity of load current depends on the phase angle of load (φ) and discontinuous for purely resistive load ($\varphi = 0$). For $\alpha > 3\pi/10$, the load current will be always discontinuous for the passive load ($V_{dc} > 0$), whereas for active load (RLE), there will be fourth-quadrant operation ($V_{dc} < 0$ and $I_{dc} > 0$).

Fig. 15.14E shows the input phase current, which is a quasi-square wave. Since the instantaneous value of load current is assumed to be constant, so the phase current will be $+I_{DC}$ in the interval ($3\pi/10+\alpha$ and $7\pi/10+\alpha$) and $-I_{DC}$ in the interval ($13\pi/10+\alpha$ and $17\pi/10+\alpha$). Also, each phase currents will be displaced from each other by $2\pi/5$, irrespective of thyristor firing angles. The input phase current i_a can be expressed in Fourier series as

$$\begin{aligned} i_a &= I_{DC} + \sum_{n=1,2,3,\ldots}^{\infty}(a_n \cos n\omega t + b_n \sin n\omega t) \\ i_a &= I_{DC} + \sum_{n=1,2,3,\ldots}^{\infty}\sqrt{2}I_n \sin(n\omega t + \varphi_n) \end{aligned} \tag{15.20}$$

where I_n is the rms value of nth harmonic component of the input current and is given by

$$I_n = \frac{1}{\sqrt{2}}\left(a_n^2 + b_n^2\right)^{\frac{1}{2}} \tag{15.21}$$

The φ_n is the nth harmonic phase shift and is given by

$$\varphi_n = \tan^{-1}\left(\frac{a_n}{b_n}\right) \tag{15.22}$$

Also, due to the symmetry of waveform,

$$I_{DC} = \frac{1}{2\pi}\int_0^{2\pi} i(\omega t)\, d\omega t = 0 \tag{15.23}$$

$$a_n = \frac{1}{\pi}\int_0^{2\pi} i_a \cos n\omega t \, d\omega t$$

$$a_n = \frac{1}{\pi}\left[\int_{\frac{3\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha} I_{DC}\cos n\omega t \, d\omega t - \int_{\frac{13\pi}{10}+\alpha}^{\frac{17\pi}{10}+\alpha} I_{DC}\cos n\omega t \, d\omega t\right]$$

$$a_n = -\frac{4I_{DC}}{n\pi}\sin\frac{n\pi}{5}\sin n\alpha, \quad n = 1,3,5,\ldots \tag{15.24}$$

Similarly,

$$b_n = \frac{1}{\pi}\int_0^{2\pi} i_a \sin n\omega t \, d\omega t$$

$$b_n = \frac{1}{\pi}\left[\int_{\frac{3\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha} I_{DC}\sin n\omega t \, d\omega t - \int_{\frac{13\pi}{10}+\alpha}^{\frac{17\pi}{10}+\alpha} I_{DC}\sin n\omega t \, d\omega t\right]$$

$$b_n = \frac{4I_{DC}}{n\pi}\sin\frac{n\pi}{5}\cos n\alpha, \quad n = 1,3,5,\ldots \tag{15.25}$$

Therefore, the rms value of *nth* harmonics current will be given by

$$I_n = \frac{1}{\sqrt{2}}\left(a_n^2 + b_n^2\right)^{\frac{1}{2}} = \frac{2\sqrt{2}}{n\pi} I_{DC}\sin\frac{n\pi}{5} \tag{15.26}$$

and

$$\varphi_n = \tan^{-1}\left(\frac{a_n}{b_n}\right) = -n\alpha \tag{15.27}$$

$n = 1$ will give the rms value of fundamental component of the input current:

$$I_1 = \frac{2\sqrt{2}}{\pi} I_{DC}\sin\frac{\pi}{5} = 0.529 I_{DC} \tag{15.28}$$

Hence, the input current can be given by

$$i_s = \sum_{n=1,3,5,\ldots}^{\infty} \frac{4I_{DC}}{n\pi}\sin\frac{n\pi}{5}\sin(n\omega t - n\alpha) \tag{15.29}$$

The fundamental input current, (substituting, $n = 1$), is

$$i_{s1} = \frac{4I_{DC}}{\pi}\sin\frac{\pi}{5}\sin(\omega t - \alpha) = 0.7484 I_{DC}\sin(\omega t - \alpha) \tag{15.30}$$

The rms value of the input current can be calculated as

$$\begin{aligned} I_{rms} &= \left[\frac{1}{2\pi}\int_0^{2\pi} i^2 d\omega t\right]^{\frac{1}{2}} \\ &= \left[\frac{2}{2\pi}\int_{\frac{3\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha} I_{DC}^2 d\omega t\right]^{\frac{1}{2}} \\ &= \sqrt{\frac{2}{5}} I_{DC} = 0.6324 I_{DC} \end{aligned} \tag{15.31}$$

The total harmonic distortion (THD) is given by

$$THD = \sqrt{\frac{I^2}{I_1^2} - 1} = \sqrt{\frac{(0.634 I_{DC})^2}{(0.529 I_{DC})^2} - 1} = 65.5\% \tag{15.32}$$

Displacement factor

$$DF = \cos(\varphi_1) = \cos(-\alpha) = \cos\alpha \tag{15.33}$$

Power factor

$$PF = \frac{\cos\alpha}{\sqrt{1 + THD^2}} = \frac{I_1}{I}\cos\alpha = \frac{0.529 I_{DC}}{0.634 I_{DC}}\cos\alpha = 0.8365\cos\alpha \tag{15.34}$$

The load current is constant as the load is considered highly inductive; from Fig. 15.14F, it is clear that each switch operates for $2\pi/5$ period of time in one cycle; accordingly, the switch average current can be calculated as

$$I_{sw_avg.} = \frac{1}{2\pi}\left[\int_{\frac{3\pi}{10}+\alpha}^{\frac{7\pi}{10}+\alpha} I_{DC} d\omega t\right] = 0.2 I_{DC} \tag{15.35}$$

When calculated, the switch current is only 20% of DC-link current [10]. The harmonic factor (HF_n) is defined as the normalized harmonic current of the supply with respect to the fundamental component (I_n/I_1) and is calculated using Eq. (6.36):

$$HF_n = \sqrt{\left(\frac{I_n}{I}\right)^2 - 1} \tag{15.36}$$

Problem 15.2 A five-phase full-wave bridge-controlled rectifier has an AC input of 120 V rms at 60 Hz and 100 Ω load resistor. The delay angle is $\alpha = \pi/12$ radians. Determine the following:

(a) Average current in the load
(b) Power absorbed by the load

(c) Efficiency of the rectifier
(d) The expression for the input current
(e) THD
(f) Power factor of the rectifier
(g) Form factor and ripple factor

Solution

(a) Average load voltage $V_{DC} = 1.87 V_m \cos\alpha = 1.87 \times \sqrt{2} \times 120 \times \cos(\pi/12) = 306.53\,\text{V}$

$$\text{Average load current } I_{DC} = \frac{V_{DC}}{R} = \frac{306.53}{100} = 3.06\,\text{A}$$

(b) Power absorbed by the load $P_{DC} = V_{DC} \times I_{DC} = 306.53 \times 3.06 = 938\,\text{W}$

(c) The rms value of the output voltage $V_{rms} = 1.902 V_m \sqrt{\frac{1}{2} + \frac{5}{2\pi} \sin\left(\frac{\pi}{5}\right) \cos 2\alpha}$

$$V_{rms} = 1.902 \times 120\sqrt{2}\sqrt{\frac{1}{2} + \frac{5}{2\pi} \sin\left(\frac{\pi}{5}\right) \cos\left(2 \times \frac{\pi}{12}\right)}$$

$$V_{rms} = 307.08\,\text{V}$$

$$\text{and } I_{rms} = \frac{V_{rms}}{R} = \frac{307.08}{100} = 3.071\,\text{A}$$

Therefore, efficiency $\eta = \frac{P_{DC}}{P_{ac}} = \frac{V_{DC} I_{DC}}{V_{rms} I_{rms}} = \frac{306.53 \times 3.06}{307.08 \times 3.071} = 99.46\%$

(d) The expression for the input current $i_s = \sum_{n=1,3,5,\ldots}^{\infty} \frac{4 I_{DC}}{n\pi} \sin\frac{n\pi}{5} \sin(n\omega t - n\alpha)$

$$i_s = \sum_{n=1,3,5,\ldots}^{\infty} \frac{3.9}{n} \sin\frac{n\pi}{5} \sin(n\omega t - n\pi/12)$$

(e) The rms value of the input current $I = \sqrt{\frac{2}{5}} I_{DC} = \sqrt{\frac{2}{5}} \times 3.06 = 1.935\,\text{A}$

The rms value of fundamental component of the input current

$$I_1 = \frac{2\sqrt{2}}{\pi} \sin\frac{\pi}{5} I_{DC} = 0.529 \times 3.06 = 1.6187$$

$$THD = \sqrt{\frac{I^2}{I_1^2} - 1} = \sqrt{\frac{(1.935)^2}{(1.6187)^2} - 1} = 65.5\%$$

(f) The power factor $PF = \frac{\cos\alpha}{\sqrt{1 + THD^2}} = \frac{\cos(\pi/15)}{\sqrt{1 + (0.655)^2}} = 0.818$

(g) Form factor $FF = \frac{V_{rms}}{V_{DC}} = \frac{307.08}{306.53} = 1.0018 = 100.18\%$

Ripple factor $RF = \sqrt{FF^2 - 1} = \sqrt{(1.0018)^2 - 1} = 0.06 = 6\%$

15.3.3 Multipulse Rectifiers

The multipulse uncontrolled rectifiers are suitable for VSI-fed drives, while the controlled rectifiers are employed for CSI drives. As the number of pulses per cycle increases, the output waveform gets improved. There are identical multipulse rectifiers connected in either parallel, series, or separate modes to achieve higher pulses in the output. Fig. 15.15 shows general layout of 12-, 18-, and 24-pulse rectifier circuits [29,30]. If we employ 10-pulse rectifiers, then we can obtain 20, 30, and 40 pulses in the output.

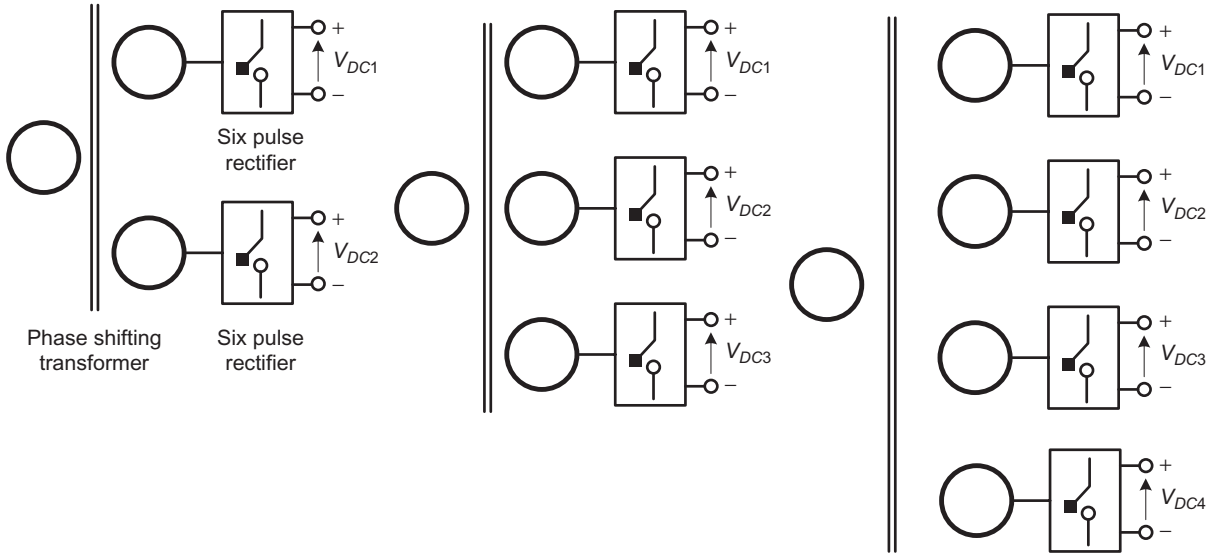

FIG. 15.15 Multipulse uncontrolled/controlled rectifier's arrangement.

15.3.3.1 12-Pulse Series Type Controlled Rectifier

Two six-pulse controlled rectifiers are powered by a phase-shifting transformer with two secondary windings in delta and star connections. Therefore, the phase angle between both secondary windings shifts 30 degrees each. In this case with 12 pulses per cycle, the quality of output-voltage waveform would definitely be improved with low ripple content [29].

Fig. 15.15 shows circuit configuration of a 12-pulse series-type controlled rectifier. A three-phase transformer with two secondary and one delta-connected primary feeds the two identical six-pulse controlled rectifiers. The upper three-phase bridge is fed from Y-connected secondary winding while lower with Δ-connected secondary winding. Therefore, this arrangement will result in the phase angle shifts between both secondary windings by 30 degrees. The outputs of the two six-pulse rectifiers are connected in series, and the conduction period of the line current for each converter is 120 degrees.

Consider an idealized 12-pulse rectifier where the line inductance L_s and the total leakage inductance L_{lk} of the transformer are assumed to be zero and the magnitude of the current is constant (ripple-free) [29]. In practical case, the ripple in the DC current will be relatively low due to the series connection of the two six-pulse rectifiers, where the leakage inductances of the secondary windings can be considered in series.

For the purpose of eliminating the dominate lower-order harmonics in the line current i_a, the line-to-line voltage v_{a1b1} of the Y-connected secondary winding (N_2 turns) is in phase with the primary winding (N_1 turns) voltage v_{ab}, while the Δ-connected secondary winding (N_3 turns) voltage v_{a2b2} leads v_{ab} by [29]:

$$\delta = \angle v_{a_2b_2} - \angle v_{ab} = 30 \text{ degrees} \tag{15.37}$$

For the sake of simplicity, let $N_1 = N, N_2 = N/2$ and $N_3 = \sqrt{3}/2N$ (i.e., N_1-N_2-N_3 = 1:0.5:0.866).

Therefore, the rms line-to-line voltage of each secondary winding will become

$$V_{a1b1} = V_{a2b2} = V_{ab}/2 \tag{15.38}$$

Since the two rectifiers are series-connected, net output, or load, voltage $V_{dc} = V_{dc1} + V_{dc2}$; since the waveforms of V_{dc1} and V_{dc2} are phase shifted from each other by 30 degrees , therefore, the waveform of output voltage V_{dc} consists of 12 pulses per cycle of supply voltage. The current waveforms are illustrated in Fig. 15.16, where i_{a1} and i_{c2a2} are the phase currents of secondary Y and Δ windings, respectively, and i'_{a1} and i'_{c2a2} are the currents referred from secondary side to the primary side. The waveforms of reflected current to primary side of secondary Y-connected winding i'_{a1} will be identical to that of i_{a1} except that the magnitude is changed in ratio of the number of turns of the two windings. However, when i_{a2} is referred to the primary side, the reflected waveform does not keep the same waveform and magnitude. This is due to phase displacements of the harmonic current when they are referred from Δ-Y windings. This phase displacement is advantageous as it will lead to the cancelation of low-order predominant fifth and seventh harmonics from the currents of transformer primary winding and does not appear in the line current, which is given by Eq. (15.39):

$$i_a = i'_{a1} + i'_{a2} \tag{15.39}$$

The secondary (Y-connected) line current i_{a1} can be expressed by Eq. (15.40):

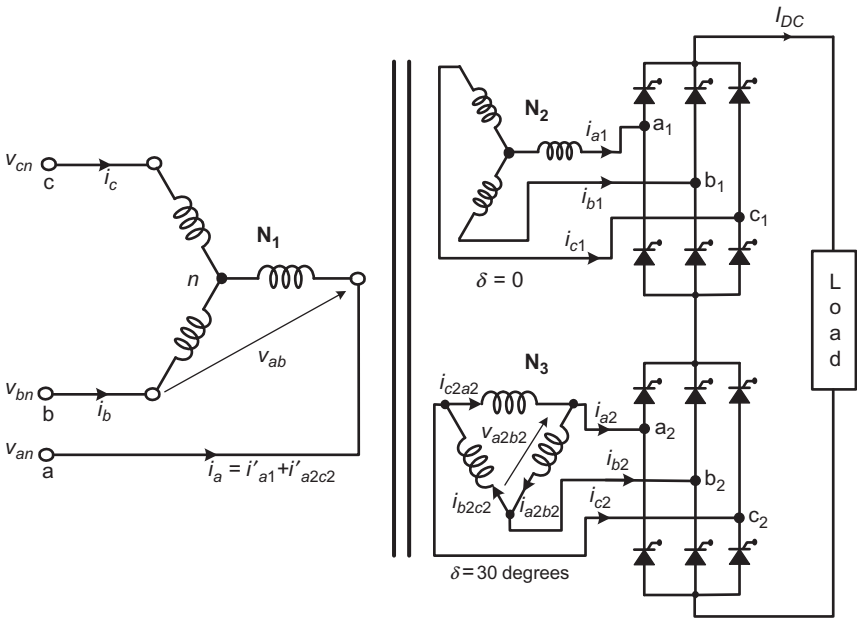

FIG. 15.16 Twelve-pulse series-type controlled rectifier connection circuit.

$$i_{a1}=\frac{2\sqrt{3}}{\pi}I_{dc}\left[\begin{array}{l}\sin\omega t-\frac{1}{5}\sin 5\omega t-\frac{1}{7}\sin 7\omega t+\frac{1}{11}\sin 11\omega t\\ +\frac{1}{13}\sin 13\omega t-\frac{1}{17}\sin 17\omega t-\frac{1}{19}\sin 19\omega t+\ldots\end{array}\right] \tag{15.40}$$

Since the waveform of current i_{a1} is of half-wave symmetry, it does not contain any even-order harmonics. Current i_a does not contain any triple harmonics either due to the consideration of balanced three-phase system. The line current in Δ-connected secondary winding such as i_{a2} leads i_{a1} by 30 degrees, and the Fourier expression of current i_{a2} is given by Eq. (15.41):

$$i_{a2}=\frac{2\sqrt{3}}{\pi}I_{dc}\left[\begin{array}{l}\sin(\omega t+30\,\text{degrees})-\frac{1}{5}\sin 5(\omega t+30\,\text{degrees})\\ -\frac{1}{7}\sin 7(\omega t+30\,\text{degrees})\\ +\frac{1}{11}\sin 11(\omega t+30\,\text{degrees})\\ +\frac{1}{13}\sin 13(\omega t+30\,\text{degrees})\\ -\frac{1}{17}\sin 17(\omega t+30\,\text{degrees})\\ -\frac{1}{19}\sin 19(\omega t+30\,\text{degrees})+\ldots\end{array}\right] \tag{15.41}$$

Similar equations for i_{b2} and i_{c2} can be obtained. The current i'_{a1}, which is identical to i_{a1} in wave shape, can be expressed in Fourier series by Eq. (15.42):

$$i'_{a1}=\frac{\sqrt{3}}{\pi}I_{dc}\left(\sin\omega t-\frac{1}{5}\sin 5\omega t-\frac{1}{7}\sin 7\omega t+\frac{1}{11}\sin 11\omega t+\frac{1}{13}\sin 13\omega t\ldots\right) \tag{15.42}$$

The phase currents in the Δ-connected secondary windings i_{a2b2}, i_{b2c2}, and i_{c2a2} can be obtained from its line currents using the transformation given in Eq. (15.43):

$$\begin{bmatrix}i_{a2b2}\\ i_{b2c2}\\ i_{c2a2}\end{bmatrix}=\frac{1}{3}\begin{bmatrix}-1 & 1 & 0\\ 0 & -1 & 1\\ 1 & 0 & -1\end{bmatrix}\begin{bmatrix}i_{a2}\\ i_{b2}\\ i_{c2}\end{bmatrix} \tag{15.43}$$

The phase currents in the Δ-connected secondary winding i_{a2b2}, i_{b2c2}, and i_{c2a2} have a stepped waveform, each step being of 60 degrees in width whereas $I_d/3$ and $2I_d/3$ the heights. The expression for phase current in the Δ-connected secondary winding can be written as Eq. (15.44).

$$i_{c2a2}=\frac{2}{\pi\sqrt{3}}I_{dc}\left[\begin{array}{l}\sin(\omega t+30\,\text{degrees})-\frac{1}{5}\sin 5(\omega t+30\,\text{degrees})\\ -\frac{1}{7}\sin 7(\omega t+30\,\text{degrees})\\ +\frac{1}{11}\sin 11(\omega t+30\,\text{degrees})+\cdots\\ -\sin(\omega t+150\,\text{degrees})\\ +\frac{1}{5}\sin 5(\omega t+150\,\text{degrees})\\ +\frac{1}{7}\sin 7(\omega t+150\,\text{degrees})\\ -\frac{1}{11}\sin 11(\omega t+150\,\text{degrees})\cdots\end{array}\right] \tag{15.44}$$

On simplification of Eq. (15.44), we have

$$i_{c2a2}=\frac{2}{\pi}I_{dc}\left[\begin{array}{l}\sin\omega t+\frac{1}{5}\sin 5\omega t+\frac{1}{7}\sin 7\omega t+\frac{1}{11}\sin 11\omega t\\ +\frac{1}{17}\sin 17\omega t+\frac{1}{19}\sin 19\omega t+\cdots\end{array}\right] \tag{15.45}$$

Similarly, the expressions for the currents i_{a2b2} and i_{b2c2} can be obtained. The corresponding reflected current to the primary side can be obtained from Eq. (15.45); by multiplying with turn ratio ($N_3:N_1=\sqrt{3}:2$), we can obtain Eq. (15.46) [31]:

$$i'_{c2a2}=\frac{\sqrt{3}}{\pi}I_{dc}\left[\begin{array}{l}\sin\omega t+\frac{1}{5}\sin 5\omega t+\frac{1}{7}\sin 7\omega t+\frac{1}{11}\sin 11\omega t\\ +\frac{1}{13}\sin 13\omega t+\frac{1}{17}\sin 17\omega t+\frac{1}{19}\sin 19\omega t\\ +\frac{1}{23}\sin 23\omega t+\frac{1}{25}\sin 25\omega t+\cdots\end{array}\right] \tag{15.46}$$

Therefore, the line current $i_a=i'_{a1}+i'_{c2a2}$ can be written as given in Eq. (15.47):

$$i_a=\frac{2\sqrt{3}}{\pi}I_{dc}\left[\begin{array}{l}\sin\omega t+\frac{1}{11}\sin 11\omega t+\frac{1}{13}\sin 13\omega t\\ +\frac{1}{23}\sin 23\omega t+\frac{1}{25}\sin 25\omega t+\cdots\end{array}\right] \tag{15.47}$$

Different current waveforms are shown in Fig. 15.17. It is evident from Eq. (15.47) that the two dominant harmonics, 5th and 7th, are absent along with 17th and 19th, which improves the THD of this type of converter configuration drastically.

15.3.3.2 Pulse Parallel-Type Controlled Rectifier

In this case, the outputs of the two six-pulse rectifiers are connected in parallel. Fig. 15.18 shows circuit configuration of a 12-pulse parallel-type controlled rectifier. The circuit in the figure simply uses an isolation transformer with a Δ-connected primary, a Y-connected secondary, and a second Δ-connected secondary to obtain 30 degrees (electrical degrees) phase shift. Since the instantaneous outputs of the two rectifiers are not

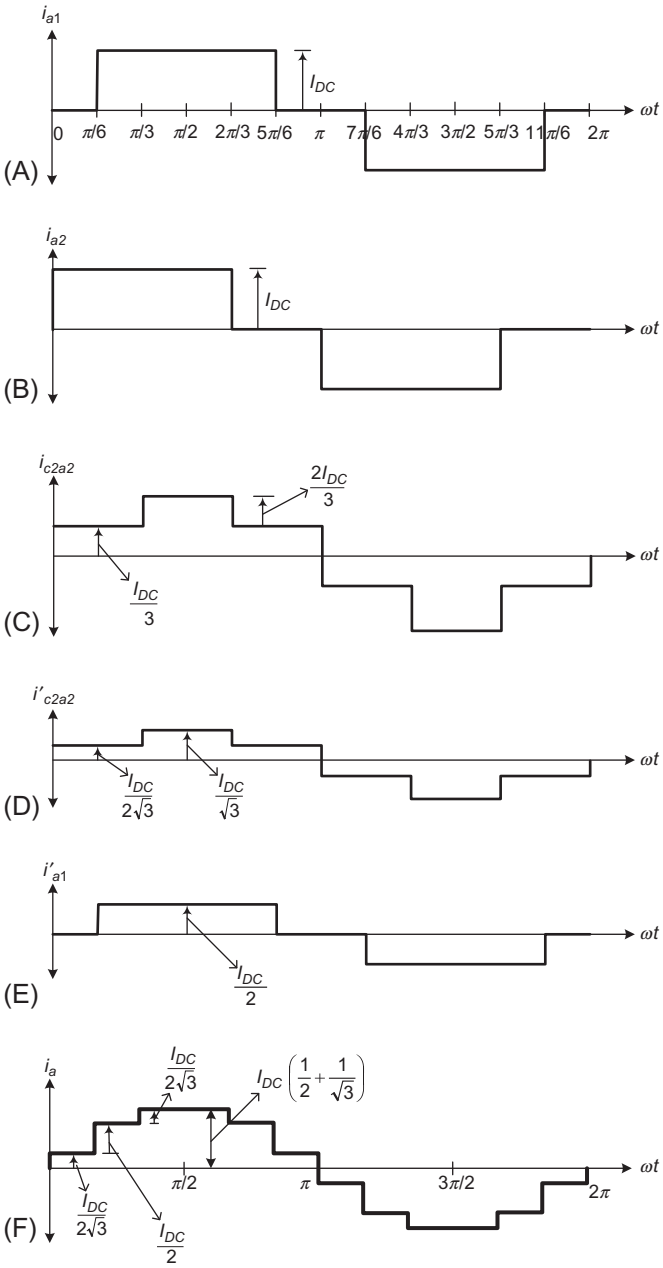

FIG. 15.17 Current waveforms of the 12-pulse series-connected controlled rectifier ($Ls = Llk = 0$). (A) Output line/phase current in star-connected secondary winding. (B) Output line current in delta-connected secondary winding. (C) Output phase current in delta-connected secondary winding. (D) Delta-connected secondary winding phase current reflected to primary side. (E) Star-connected secondary winding phase current reflected to primary side. (F) Total current in the primary side.

equal, an interphase reactor is necessary to support the difference in instantaneous rectifier output voltages and permit each rectifier to operate independently [29]. The line current in primary winding of the transformer is the sum of reflected currents from the two secondary windings, and it becomes stepped due to 30 degrees phase shift in two secondary currents

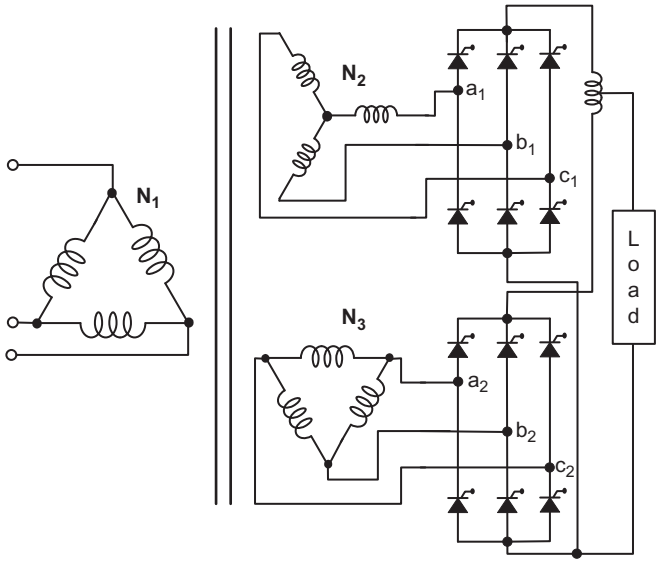

FIG. 15.18 Twelve-pulse parallel-type controlled rectifier connection circuit.

as discussed in Section 15.3.3.1. Therefore, the harmonics and requirement of filter circuit parameters are reduced. Theoretically, input current harmonics for rectifier circuit is a function of pulse number and can be expressed as

$$H = \left(N_p \pm 1\right) \tag{15.48}$$

where $N = 1, 2, 3\ldots$ and p is pulse number.

For example, in a three-phase six-pulse rectifier, the input current will have harmonic components at 5, 7, 11, 13, 17, 19, 23, 25, 29, 31, etc. multiples of the fundamental frequency. For the 12-pulse system shown in Fig. 15.16, the input current will have theoretical harmonic components at 11, 13, 23, 25, 35, 37, etc. multiples of the fundamental frequency as derived and discussed in Section 15.3.3.1. Since the magnitude of each harmonic is proportional to the reciprocal of the harmonic order, the 12-pulse system naturally has a lower harmonic distortion in input current.

The problem with the parallel connection of the rectifiers is that the two rectifiers must share exactly equal current to achieve the desired reduction in harmonics. This would be achieved if output voltages of both secondary windings matches exactly. Because of the differences in the transformer secondary impedances and open-circuit output voltages, this can be practically accomplished for a given fixed load (typically rated load), but not for loads varying over a range. This is the main problem of the parallel 12-pulse configuration connection. Whereas in the case of series connection of two rectifiers, the problems associated with current sharing are avoided, and an interphase reactor is not required. Parallel connections are normally preferred for applications where high current ratings rather than harmonics are the issue [32]. Generally, series connection of rectifiers is much simpler to implement than the parallel connection.

15.3.4 Single-Way Multiphase Systems Topologies

The structure of single-way, m-phase rectifier is shown in Fig. 15.19. In single-way structures, only one diode conducts for single stage, and the remaining diodes are blocked. Due to this, single-way structures are more convenient while increasing the number of phases. In an m-phase, the diodes used in the rectifier circuits are divided into a number of groups in star connection. Each group will have three diodes, that is, for a six-diode rectifier, there will be two groups, and for a 12-diode rectifier, there will be four groups [31]. In a normal connection, the star points will be connected together. But in this circuit, each group will have its all secondary windings, and instead of a direct connection, the star points will be connected through an interphase transformer. The common neutral point serves as the negative terminal of the DC output circuit.

For single-way topologies, the number of output pulses is equal to the number of phases, that is, $p=m$, and the number of diodes are equal to m. Each diode is conducting for $2\pi/m$ electric radians. Fig. 15.19 shows few pulses of output-voltage waveform for m-phase half-wave uncontrolled rectifier. In general, for an m-phase system, the average and rms value of the output voltage is expressed by Eqs. (15.49) and (15.50), respectively:

$$V_{DC}=\frac{V_m}{2\pi/m}\int_{-\frac{\pi}{m}}^{\frac{\pi}{m}}\cos\omega t\,d(\omega t)=\frac{V_m\sin\left(\frac{\pi}{m}\right)}{\pi/m} \tag{15.49}$$

$$\text{rms voltage } V_{rms}=\sqrt{\frac{1}{2\pi/m}\int_{-\frac{\pi}{m}}^{\frac{\pi}{m}}(V_m\cos\omega t\,d\omega t)^2}$$

$$V_{rms}=V_m\sqrt{\frac{1}{2}\left[1+\frac{\sin\left(\frac{2\pi}{m}\right)}{\frac{2\pi}{m}}\right]} \tag{15.50}$$

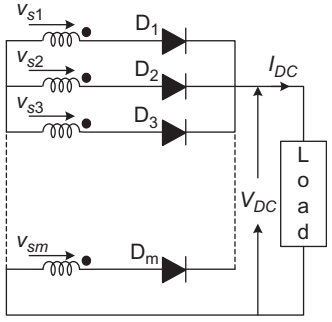

FIG. 15.19 m-Phase, single-way rectifier.

The form factor and ripple factors are expressed by Eqs. (15.51) and (15.52), respectively. From these equations, it is evident that if $m\to\infty\Rightarrow FF\to 1$ and $RF\to 0$,

$$FF=\frac{V_{rms}}{V_{DC}}=\frac{\sqrt{\frac{1}{2}\left[1+\frac{\sin\left(\frac{2\pi}{m}\right)}{\frac{2\pi}{m}}\right]}}{\frac{\sin\left(\frac{\pi}{m}\right)}{\frac{\pi}{m}}} \tag{15.51}$$

$$RF=\sqrt{1-(FF)^2} \tag{15.52}$$

which implies that by increasing the number of phases in a multiphase, single-way rectifier, the output voltage is improved, that is, it becomes smoother. By connecting to a conventional three-phase mains distribution, it is possible to increase the number of "phases" by using transformers with m separated secondary coils. The secondary coils can be connected in a large number of ways. Also, by increasing the number of phases (as stated before, in single-way topologies, $m=p$), the ripple frequency increases, and its amplitude decreases. This fact simplifies the filter design to reduce the ripple in the load [31,32]. The output waveform for m-phase half-wave diode rectifier is shown in Fig. 15.20. For highly inductive load, the output DC current may be considered as constant (I_{DC}).

The diode average current, rms current, and form factor can be obtained by Eqs. (15.53)–(15.55):

$$I_{D(avg.)}=\frac{I_{DC}}{m} \tag{15.53}$$

$$I_{D(rms)}=\frac{I_{DC}}{\sqrt{m}} \tag{15.54}$$

$$K_f=\frac{I_{D(rms)}}{I_{D(avg)}}=\sqrt{m} \tag{15.55}$$

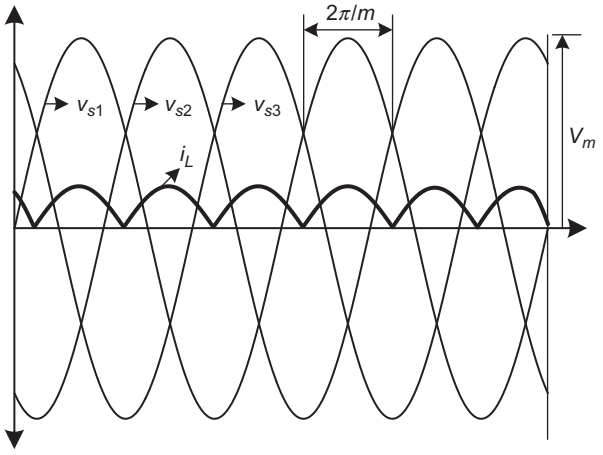

FIG. 15.20 Output waveform for m-phase half-wave diode rectifier.

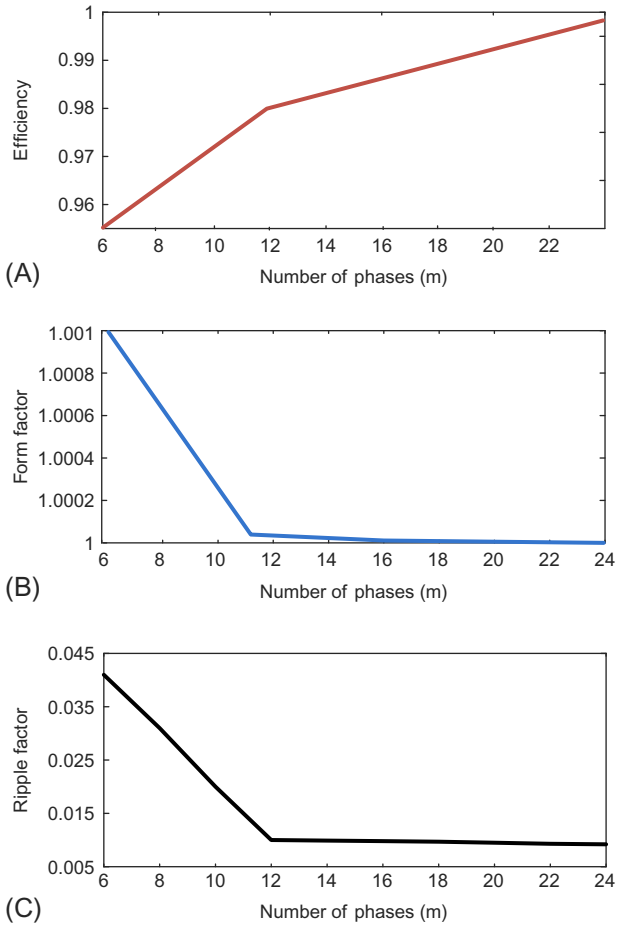

FIG. 15.21 Characteristics of the number of phases versus (A) efficiency, (B) form factor, and (C) ripple factor.

The values for V_{DC} and some of the parameters have been calculated for $m=6$, $m=12$, and $m=24$ and are reported in Fig. 15.21. It is clear from the figure (A)–(C) that the frequency of the ripple on the output is p times the mains frequency. As can be seen, passing from 6 to 12 pulses, one gets a 3.5% improvement in the rectified voltage, while passing from 12 to 24 pulses this improvement is less than 1%.

In practice, for single-way connections, the maximum number of pulses is normally limited to 12 because of the growing complexity of the connections of the transformer's secondary windings. Higher number of pulses can be obtained by using the combination of bridge structures. The best transformer utilization factor (*TUF*) that can be achieved with a single-way connection is 0.79, while with a bridge configuration it is possible to reach higher values, up to 0.955.

15.3.5 Six-Phase AC to DC Converters

Six-phase half-wave rectifiers generally have two configurations, namely, six phase with a neutral line circuit and double antistar with a balance-choke circuit.

15.3.5.1 Six-Phase Half Wave With a Neutral Line Circuit

The power supply of a six-phase balanced voltage source is given by Eq. (15.56), and the waveform is shown in Fig. 15.22; in this case, each phase is shifted by 60 degrees:

$$\begin{aligned} v_{an} &= V_m \sin \omega t \\ v_{bn} &= V_m \sin(\omega t - \pi/3) \\ v_{cn} &= V_m \sin(\omega t - 2\pi/3) \\ v_{dn} &= V_m \sin(\omega t - \pi) \\ v_{en} &= V_m \sin(\omega t - 4\pi/3) \\ v_{bn} &= V_m \sin(\omega t - 5\pi/3) \end{aligned} \tag{15.56}$$

The six-phase half-wave rectifiers are shown in Fig. 15.23. The first circuit is called a Y-Y circuit, and the second circuit is called a Δ/Y circuit. Each diode conducts for 60 degrees in a cycle.

$$V_{DC} = \frac{1}{\pi/3} \int_{\frac{\pi}{3}}^{\frac{2\pi}{3}} V_m \sin \omega t \, d\omega t = \frac{3V_m}{\pi} \tag{15.57}$$

$$V_{rms} = \sqrt{\frac{1}{\pi/3} \left[\int_{\frac{\pi}{3}}^{\frac{2\pi}{3}} (V_m \sin \omega t)^2 d\omega t \right]} = V_m \sqrt{\frac{1}{2} + \frac{3\sqrt{3}}{4\pi}} \tag{15.58}$$

$$FF = \frac{V_{rms}}{V_{dc}} = 1.0008 \tag{15.59}$$

$$RF = \sqrt{1.0008^2 - 1^2} = 0.04 \tag{15.60}$$

$$PF = 0.55 \tag{15.61}$$

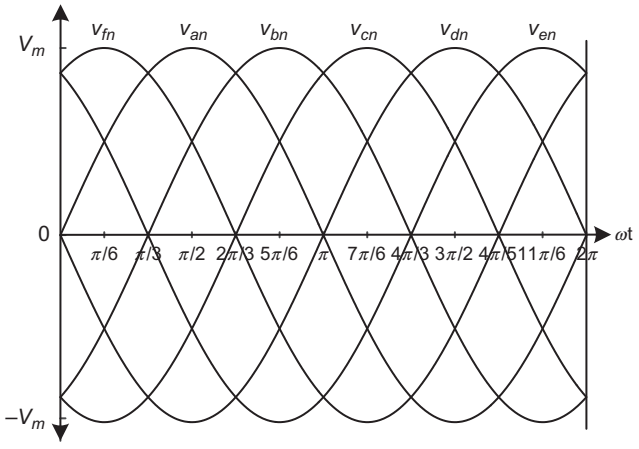

FIG. 15.22 Six-phase supply waveforms.

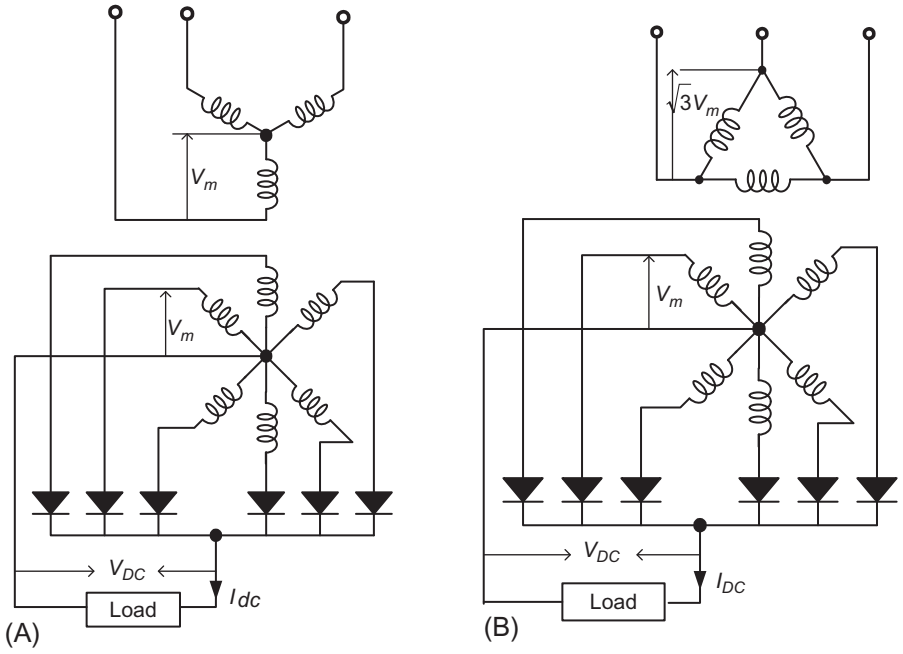

FIG. 15.23 Six-phase half-wave diode rectifiers: (A) Y/Y circuit and (B) Δ/Y circuit.

15.3.5.2 Six-Phase Double-Bridge Full-Wave Uncontrolled Rectifiers

Two circuits of the six-phase bridge full-wave diode rectifiers are shown in Fig. 15.24 and are called as a six-phase bridge circuit and hexagon bridge circuit [31]. In this case, each diode conducts for 60 degrees in a cycle. The average output voltage is given by Eq. (15.62):

$$V_{DC} = \frac{2}{\pi/3}\int_{\frac{\pi}{3}}^{\frac{2\pi}{3}} V_m \sin\omega t\, d\omega t = \frac{6V_m}{\pi} \tag{15.62}$$

15.3.5.3 Six-Phase Half-Wave Controlled Rectifiers

The six-phase half-wave controlled rectifiers are shown in Fig. 15.25 [31]. Each thyristor conducts for $\pi/3$ radians in a cycle. The firing angle $\alpha = \omega t - \pi/3$ in the range of 0–$2\pi/3$. The average output voltage is

$$V_{DC} = \frac{1}{\pi/3}\int_{\frac{\pi}{3}+\alpha}^{\frac{2\pi}{3}+\alpha} V_m \sin\omega t\, d\omega t = \frac{3V_m}{\pi}\cos\alpha \tag{15.63}$$

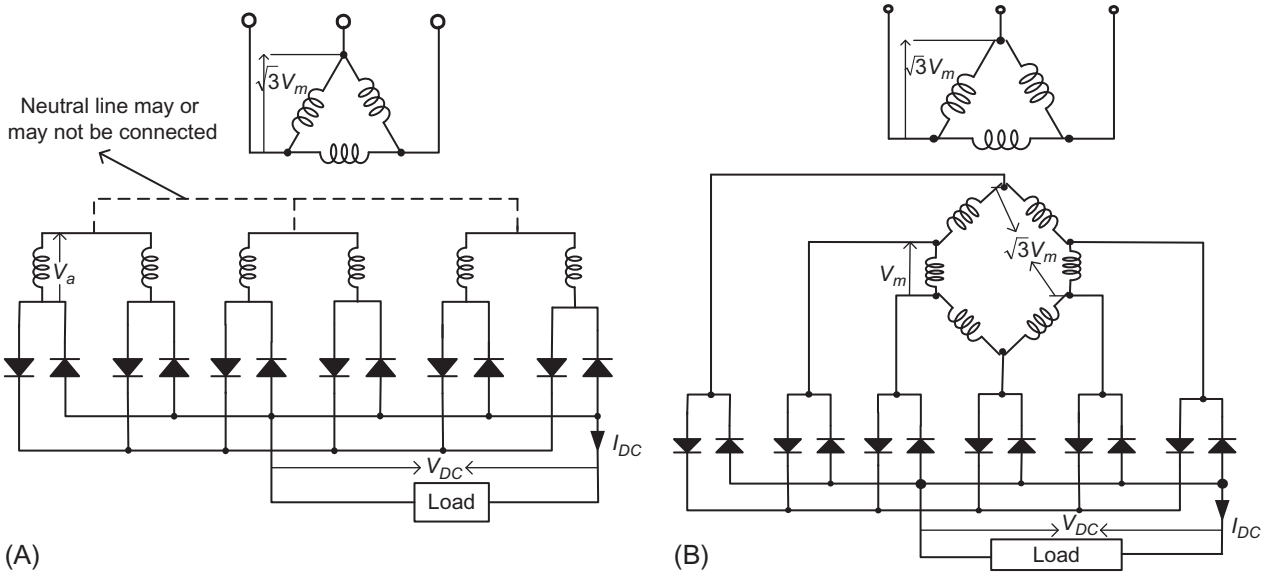

FIG. 15.24 Six-phase full-wave uncontrolled rectifiers: (A) six-phase bridge circuit and (B) six-phase hexagon bridge circuit.

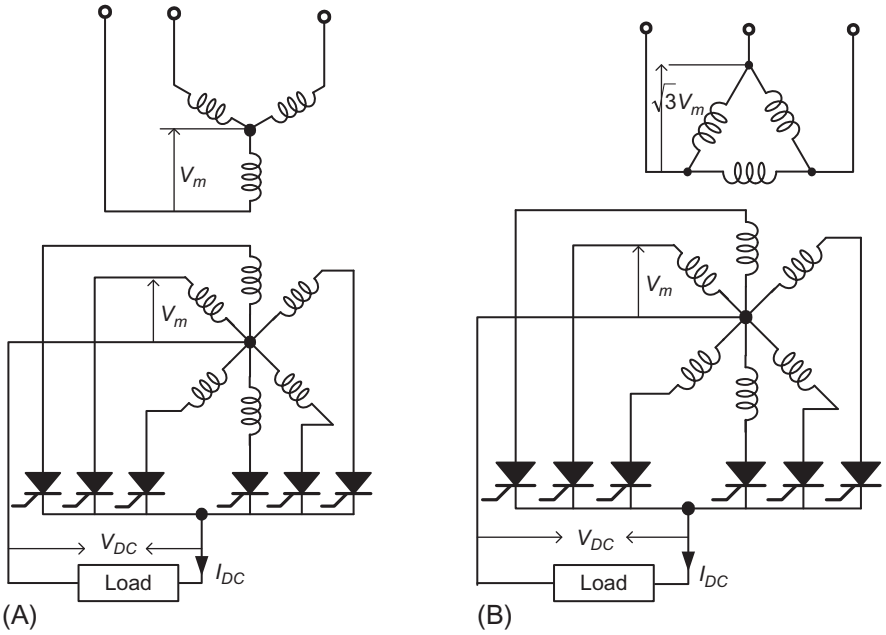

FIG. 15.25 Six-phase half-wave controlled rectifiers: (A) Y/Y circuit and (B) Δ/Y circuit.

$$V_{rms} = \sqrt{\frac{1}{\pi/3}\left[\int_{\frac{\pi}{3}+\alpha}^{\frac{2\pi}{3}+\alpha} (V_m \sin\omega t)^2 d\omega t\right]} = V_m\sqrt{\frac{1}{2} + \frac{3\sqrt{3}}{4\pi}\cos\alpha} \tag{15.64}$$

$$FF = \frac{V_{rms}}{V_{dc}} = 1.0008 \tag{15.65}$$

$$RF = \sqrt{1.0008^2 - 1^2} = 0.042 \tag{15.66}$$

$$PF = 0.956 \tag{15.67}$$

From Eq. (15.63), it is clear that the output voltage can have positive ($\alpha < \pi/2$) and negative ($\alpha > \pi/2$) values. When $\alpha < \pi/2$, the output current is ($I_{DC} = V_{DC}/R$), and when the firing angle α is $>\pi/2$, the output voltage can have negative values, but the output current can only have positive values.

15.4 Multiphase DC-AC Converters

15.4.1 Modeling and Control of a Five-Phase Voltage Source Inverter

This section is devoted to the development of a comprehensive model of a five-phase voltage-source inverter based on space-vector theory [32,33]. Proper modeling of voltage-source inverters is important in devising appropriate control algorithm. The complete model is broadly classified into two groups, namely, square-wave and PWM modes based on the operation of the inverter. The leg voltages and line voltages along with phase voltages are illustrated. The Fourier analysis of output phase-to-neutral voltages and nonadjacent voltages is performed for square-wave mode. The output phase-to-neutral voltage is shown to be essentially identical to those obtainable with a three-phase voltage-source inverter. At each step, simulation results are provided to support the analytic approach results. The relationship between the phase and line voltages for a five-phase system is also established.

For high-power application, stepped operation of inverter is preferred over PWM mode to avoid switching losses. Square-wave mode of operation is elaborated for 180 degrees conduction mode, and the performance is evaluated in terms of harmonic content of phase-to-neutral voltages.

15.4.1.1 Modeling of a Five-Phase VSI

Power circuit topology of a five-phase VSI is shown in Fig. 15.26. Each switch in the circuit consists of two power semiconductor devices, connected in antiparallel. One of these is a fully controllable semiconductor, such as a bipolar transistor, MOSFET, or IGBT, while the second one is a diode. The input of the inverter is a DC voltage, which is regarded further on as being constant. The inverter outputs are denoted in Fig. 15.26 with lowercase symbols (*a*, *b*, *c*, *d*, and *e*), while the points of connection of the outputs to inverter legs have symbols in capital letters (*A*,*B*,*C*,*D*,*E*). The basic operating principles of the five-phase VSI are developed in what follows assuming the ideal commutation and zero forward voltage drops.

15.4.1.2 Square Wave Mode of Operation

Discrete switching of power switches in an inverter leads to stepped wave output termed as square-wave operation of the inverter. Conventionally, 180 degrees conduction mode is considered leading to 10-step output phase voltages from the inverter. Each switch conducts for half of the fundamental cycle,

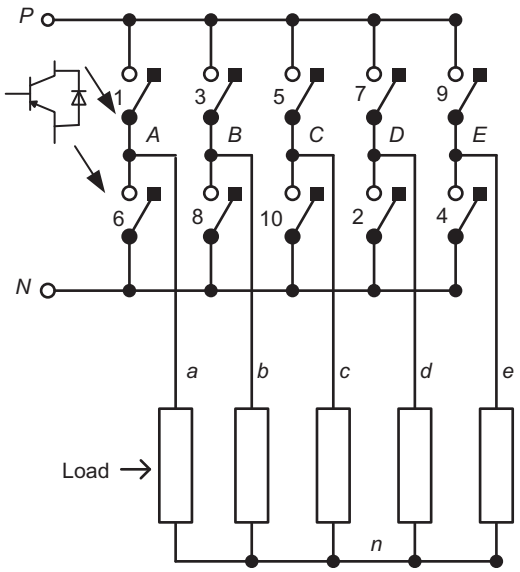

FIG. 15.26 Five-phase voltage-source inverter power circuit.

that is, 180 degrees. The operation of upper and lower switches is complimentary in operation, that is, when upper switch is on, the lower switch is off and vice versa. In real-time application, a dead time is provided between the turning on of lower switch and turning off of upper switch and vice versa. The incoming power switch cannot be turned on unless the outgoing switch is completely turned off. There is a finite time for complete turnoff of a power switching device, and hence, a dead time is to be provided. This is done in order to avoid short circuit of the source side.

180 degrees conduction mode

Each switch is assumed to conduct for 180 degrees(half of the fundamental cycle), and the phase delay between firing of two switches in any subsequent two phases is equal to 360/5 degrees = 72 degrees. The driving control gate/base signals for the 10 switches of the inverter in Fig. 15.26 are illustrated in Fig. 15.27. One complete cycle of operation of the inverter can be divided into 10 distinct modes indicated in Fig. 15.27 and summarized in Table 15.2. It follows from these that at any instant in time there are five switches that are "ON" and five switches that are "OFF." In the 10-step mode of operation, there are two conducting switches from the upper five and three from the lower five or vice versa.

Space vector of phase voltages in stationary reference frame is defined, using power variant transformation [33]:

$$\underline{v} = \frac{2}{5}\left(v_a + \underline{a}v_b + \underline{a}^2 v_c + \underline{a}^{*2} v_d + \underline{a}^* v_e\right) \tag{15.68}$$

where $\underline{a} = \exp(j2\pi/5)$, $\underline{a}^2 = \exp(j4\pi/5)$, $\underline{a}^* = \exp(-j2\pi/5)$, $\underline{a}^{*2} = \exp(-j4\pi/5)$, and * stands for a complex conjugate.

Leg voltages (i.e., voltages between points *A*,*B*,*C*,*D*, and *E* and the negative rail of the DC bus N in Fig. 15.26) are considered first. The leg voltages from Fig. 15.27 are substituted in expression (15.68) to obtain their corresponding space vectors given as in Eq. (15.69):

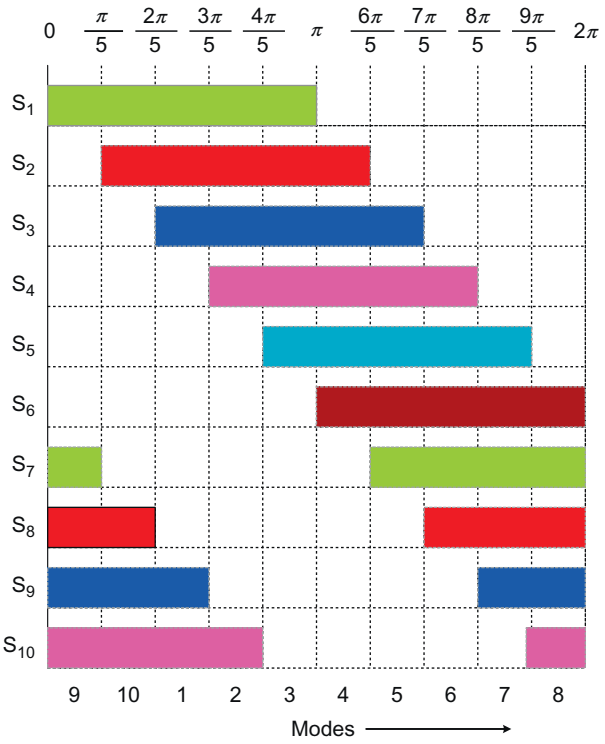

FIG. 15.27 Gating signals of a five-phase voltage-source inverter in square-wave mode.

TABLE 15.2 Modes of operation of the five-phase voltage-source inverter (10-step operation)

Mode	Switches ON	Terminal polarity
1	9,10,1,2,3	$A^+B^+C^-D^-E^+$
2	10,1,2,3,4	$A^+B^+C^-D^-E^-$
3	1,2,3,4,5	$A^+B^+C^+D^-E^-$
4	2,3,4,5,6	$A^-B^+C^+D^-E^-$
5	3,4,5,6,7	$A^-B^+C^+D^+E^-$
6	4,5,6,7,8	$A^-B^-C^+D^+E^-$
7	5,6,7,8,9	$A^-B^-C^+D^+E^+$
8	6,7,8,9,10	$A^-B^-C^-D^+E^+$
9	1,7,8,9,10	$A^+B^-C^-D^+E^+$
10	8,9,10,1,2	$A^+B^-C^-D^-E^+$

$$\begin{bmatrix} \vec{v}_{1leg} \\ \vec{v}_{2leg} \\ \vec{v}_{3leg} \\ \vec{v}_{4leg} \\ \vec{v}_{5leg} \\ \vec{v}_{6leg} \\ \vec{v}_{7leg} \\ \vec{v}_{8leg} \\ \vec{v}_{9leg} \\ \vec{v}_{10leg} \end{bmatrix} = \frac{2}{5} V_{DC}\left(2\cos\frac{\pi}{5}\right) \begin{bmatrix} e^{j0} \\ e^{j\pi/5} \\ e^{j2\pi/5} \\ e^{j3\pi/5} \\ e^{j4\pi/5} \\ e^{j\pi} \\ e^{j6\pi/5} \\ e^{j7\pi/5} \\ e^{j8\pi/5} \\ e^{j9\pi/5} \end{bmatrix} \tag{15.69}$$

It is seen that the leg voltages have magnitude of $\frac{2}{5}V_{DC}2\cos(\pi/5)$ and are 36 degrees apart forming a decagon. There are in total $2^5=32$ switching states (base is taken as 2 because the switching states can only assume two values either 0 (indicate off state) or 1 (indicate on state)). The first 10 states are described above, and the remaining 22 switching states are discussed in the next section.

Phase-to-neutral voltages are discussed next. Phase-to-neutral voltages of the star-connected load are most easily found by defining a voltage difference between the star point n of the load and the negative rail of the DC bus N. The following correlation then holds true:

$$\begin{aligned} v_A &= v_a + v_{nN} \\ v_B &= v_b + v_{nN} \\ v_C &= v_c + v_{nN} \\ v_D &= v_d + v_{nN} \\ v_E &= v_e + v_{nN} \end{aligned} \tag{15.70}$$

Since the phase voltages in a star-connected load sum to zero (sum of five-phase sine wave at one instant of time is zero), the summation of Eq. (15.70) produces

$$v_{nN} = (1/5)(v_A + v_B + v_C + v_D + v_E) \tag{15.71}$$

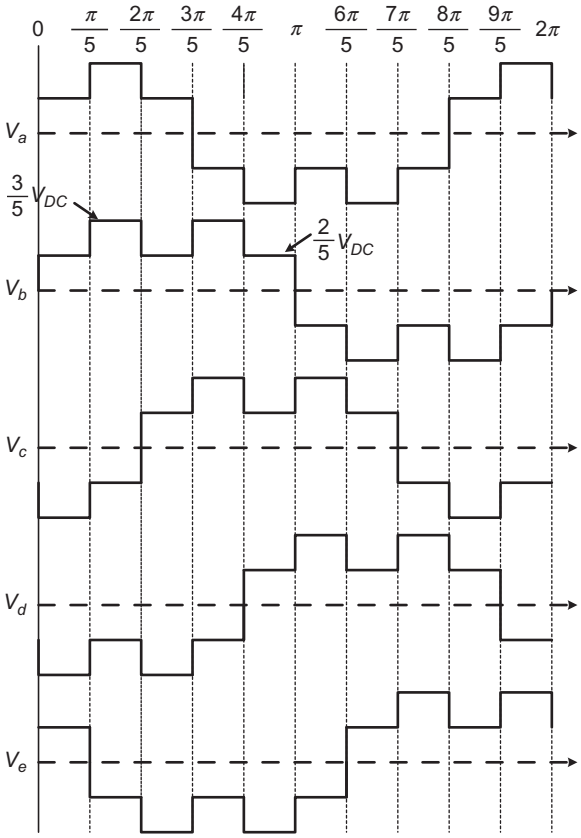

FIG. 15.28 Phase-to-neutral voltages of the five-phase VSI in the square-wave mode of operation.

Substitution of (15.71) into (15.70) produces phase-to-neutral voltages of the load in the following form:

$$\begin{aligned} v_a &= (4/5)v_A - (1/5)(v_B + v_C + v_D + v_E) \\ v_b &= (4/5)v_B - (1/5)(v_A + v_C + v_D + v_E) \\ v_c &= (4/5)v_C - (1/5)(v_A + v_B + v_D + v_E) \\ v_d &= (4/5)v_D - (1/5)(v_A + v_B + v_C + v_E) \\ v_e &= (4/5)v_E - (1/5)(v_A + v_B + v_C + v_D) \end{aligned} \tag{15.72}$$

The phase voltages in different modes are obtained by substituting leg voltages into Eq. (15.72), and their space vectors are determined using Eq. (15.68). The space vectors of phase-to-neutral voltage are identical to the leg voltage space vectors. The phase-to-neutral voltages for various modes are given in Fig. 15.28.

Fourier analysis of the voltage waveforms, which relates DC link voltage of the inverter with the output, is elaborated.

Using the definition of the Fourier series for a periodic waveform,

$$v(t) = V_o + \sum_{n=1}^{\infty}(A_n \cos n\omega t + B_n \sin n\omega t) \tag{15.73}$$

where the coefficients of the Fourier series are given with

$$\begin{aligned} V_o &= \frac{1}{T}\int_0^T v(t)dt = \frac{1}{2\pi}\int_0^{2\pi} v(\theta)d\theta \\ A_n &= \frac{2}{T}\int_0^T v(t)\cos n\omega t\,dt = \frac{1}{\pi}\int_0^{2\pi} v(\theta)\cos n\theta\,d\theta \\ B_n &= \frac{2}{T}\int_0^T v(t)\sin n\omega t\,dt = \frac{1}{\pi}\int_0^{2\pi} v(\theta)\sin n\theta\,d\theta \end{aligned} \tag{15.74}$$

Observing that the waveforms possess quarter-wave symmetry and can be conveniently taken as odd functions, one can represent phase-to-neutral voltages with the following expressions:

$$\begin{aligned} v(t) &= \sum_{n=1}^{\infty} B_{2n-1}\sin(2n-1)\omega t \quad \text{where} \quad B_{2n-1} \\ &= \frac{4}{\pi}\int_0^{\frac{\pi}{2}} v(\theta)\sin(2n-1)\theta\,d\theta \quad \text{and} \quad n = 1,2,3,\ldots \end{aligned} \tag{15.75}$$

In the case of the phase-to-neutral voltage v_b, shown in Fig. 15.28, one further has for the coefficients of the Fourier series:

$$B_{2n-1} = \frac{8V_{DC}}{5\pi(2n-1)}\left[1 + \cos(2n-1)\frac{3\pi}{5}\cos(2n-1)\frac{4\pi}{5}\right]$$

where $k = 1,2,3,\ldots$ (15.76)

The expression in brackets of Eq. (15.76) equals zero for all the harmonics whose order is divisible by five. For all the other harmonics, it equals 2.5. Hence, one can write the Fourier series of the phase-to-neutral voltage as

$$v(t)=\frac{2}{\pi}V_{DC}\left[\sin\omega t+\frac{1}{3}\sin 3\omega t+\frac{1}{7}\sin 7\omega t+\frac{1}{9}\sin 9\omega t+\frac{1}{11}\sin 11\omega t+\frac{1}{13}\sin 13\omega t+\ldots\right] \tag{15.77}$$

From (15.77), it follows that the fundamental component of the output phase-to-neutral voltage has an rms value equal to

$$V_1=\frac{\sqrt{2}}{\pi}V_{DC}=0.45V_{DC} \tag{15.78}$$

From Fig. 15.28, mean square value is determined as

$$\text{Mean square value}=\frac{1}{\pi}\left[\left(\frac{2}{5}V_{DC}\right)^2\times\frac{3\pi}{5}+\left(\frac{3}{5}V_{DC}\right)^2\times\frac{2\pi}{5}\right]=\frac{6}{25}V_{DC}^2 \tag{15.79}$$

$$V_{rms}=\frac{\sqrt{6}}{5}V_{DC} \tag{15.80}$$

Total harmonic rms voltage (per unit) is given by

$$V_{Hrms}=\sqrt{(V_{rms})^2-(V_1)^2}=\sqrt{\left(\frac{\sqrt{6}}{5}\right)^2-\left(\frac{\sqrt{2}}{\pi}\right)^2}=0.193281227 \tag{15.81}$$

Hence, total harmonic distortion is

$$THD=\frac{\text{r.m.s. total harmonic voltage}}{\text{r.m.s. total voltage}}=\frac{0.193281227}{\sqrt{6}/5}=0.3945336525 \text{ or } 39.45\% \tag{15.82}$$

This is the same voltage as obtainable with a three-phase VSI operating in six-step mode. It is important to note at this stage that the space vectors described by (15.68) provides mapping of inverter voltages into a two-dimensional space. However, since five-phase inverter essentially requires description in a five-dimensional space, not all the harmonics contained in (15.77) will be encompassed by the space vector of (15.68). In particular, space vectors calculated using (15.68) will only represent harmonics of the order $10k\pm1$, $k=0,1,2,3\ldots$, that is, the first, the ninth, the eleventh, and so on. Harmonics of the order $5k$, $k=1,2,3\ldots$ cannot appear due to the isolated neutral point. However, harmonics of the order $5k\pm2$, $k=1,3,5\ldots$ are present in (15.77) but are not encompassed by the space-vector definition of (15.68). These harmonics in essence appear in the second two-dimensional space, which requires introduction of the second space vector for the five-phase system.

Simulation is performed to obtain the harmonic spectrum of inverter phase voltage in 10-step mode of operation, shown in Fig. 15.29. The DC voltage is kept at 1 p.u. The harmonic spectrum is in compliance with the expression (15.77) and (15.78).

The fundamental component is equal to 0.4504 pu, which is the same as what is obtainable with a three-phase VSI. The subharmonic components are third and seventh in Fig. 15.29, and their magnitudes are 33.33% and 14.3%, respectively. These

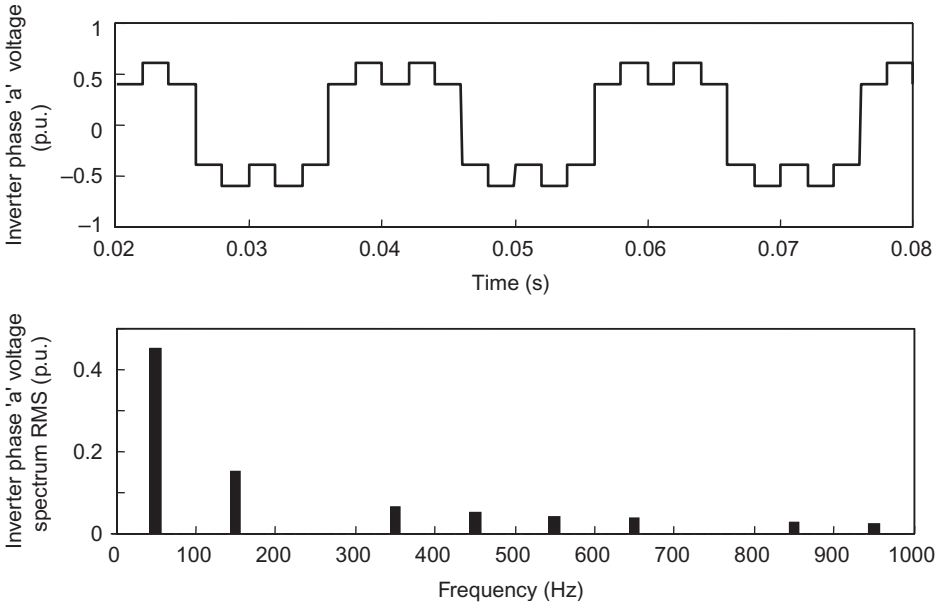

FIG. 15.29 Inverter phase "a" voltage time-domain waveform and its harmonic spectrum in frequency domain (fundamental frequency is 50 Hz, fundamental voltage 0.4504 (pu)).

subharmonics will appear in the *x-y* plane and will cause distortion in the stator currents and consequently increase the losses in the machine. The lowest harmonic appearing on *d-q* plane are 9th and 11th with their magnitude as 11.1% and 9.1%, respectively. These harmonic will further add to the losses in addition to 10th-harmonic pulsating torque under steady-state conditions.

The line-to-line voltages are expanded next. There are two systems of line-to-line voltage, adjacent and nonadjacent, in contrast to a three-phase system where only one line-to-line voltage is defined. The adjacent line-to-line voltages at the output of the five-phase inverter are defined in Fig. 15.30, for a fictitious load. Since each line-to-line voltage is a difference of corresponding two leg voltages, the values of nonadjacent line-to-line voltages will produce higher magnitude compared with the adjacent line voltages; hence, only former case is taken up in the thesis and later is omitted from further consideration.

There are two sets of nonadjacent line-to-line voltages. Due to symmetry, these two sets lead to the same values of the line-to-line voltage space vectors, with a different phase order. Only the set $v_{ac}, v_{bd}, v_{ce}, v_{da}, v_{eb}$ is analyzed for this reason. Table 15.3 lists the states and the values for these line-to-line voltages.

Space vectors of nonadjacent line-to-line voltages are determined once more using the defining expression (15.68) and are summarized as

$$\begin{bmatrix} \underline{v}_{1ll} \\ \underline{v}_{2ll} \\ \underline{v}_{3ll} \\ \underline{v}_{4ll} \\ \underline{v}_{5ll} \\ \underline{v}_{6ll} \\ \underline{v}_{7ll} \\ \underline{v}_{8ll} \\ \underline{v}_{9ll} \\ \underline{v}_{10ll} \end{bmatrix} = \frac{8}{5} V_{DC} \cos\left(\frac{\pi}{5}\right) \cos\left(\frac{\pi}{10}\right) \begin{bmatrix} e^{j\pi/10} \\ e^{j3\pi/10} \\ e^{j\pi/2} \\ e^{j7\pi/10} \\ e^{j9\pi/10} \\ e^{j11\pi/10} \\ e^{j13\pi/10} \\ e^{j15\pi/10} \\ e^{j17\pi/10} \\ e^{j19\pi/10} \end{bmatrix} \tag{15.83}$$

Time-domain waveforms of nonadjacent line-to-line voltages are illustrated in Fig. 15.31.

The Fourier analysis is further carried out for nonadjacent line-to-line voltage following the same procedure outlined in conjunction with Fourier analysis of phase voltages. The nonadjacent line voltages waveform possess quarter-wave odd symmetry; hence, the Fourier coefficient can be evaluated as

$$B_{2n-1} = \frac{4V_{DC}}{(2n-1)\pi}\left(\cos(2n-1)\frac{\pi}{10}\right) \quad \text{where} \quad n = 1,2,3,\ldots$$

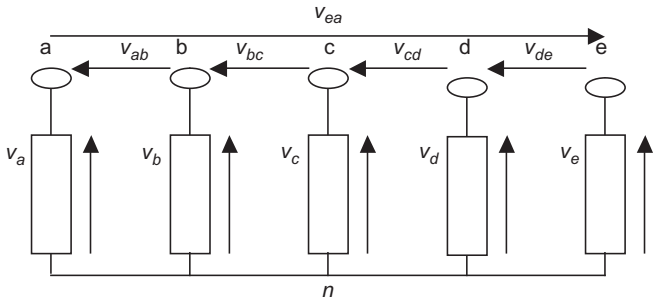

FIG. 15.30 Adjacent line-to-line voltages of a five-phase star-connected load.

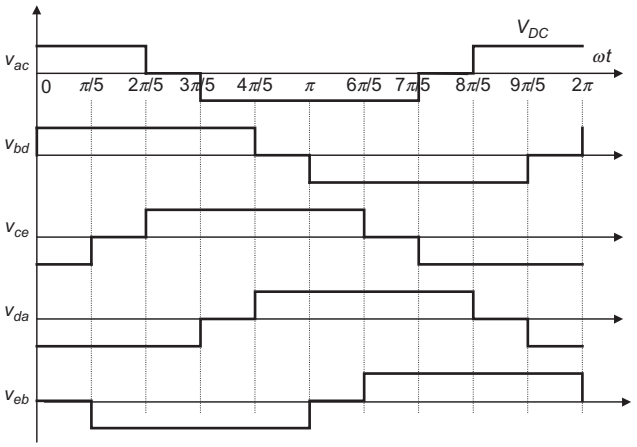

FIG. 15.31 Nonadjacent line-to-line voltages for 10-step operation of a five-phase VSI.

TABLE 15.3 Nonadjacent line-to-line voltages for 180 degrees conduction mode

Switching state	Switches ON	Space vector	v_{ac}	v_{bd}	v_{ce}	v_{da}	v_{eb}
1	9,10,1,2,3	$\underline{v}_{1ll}$	V_{DC}	V_{DC}	$-V_{DC}$	$-V_{DC}$	0
2	10,1,2,3,4	$\underline{v}_{2ll}$	V_{DC}	V_{DC}	0	$-V_{DC}$	$-V_{DC}$
3	1,2,3,4,5	$\underline{v}_{3ll}$	0	V_{DC}	V_{DC}	$-V_{DC}$	$-V_{DC}$
4	2,3,4,5,6	$\underline{v}_{4ll}$	$-V_{DC}$	V_{DC}	V_{DC}	0	$-V_{DC}$
5	3,4,5,6,7	$\underline{v}_{5ll}$	$-V_{DC}$	0	V_{DC}	V_{DC}	$-V_{DC}$
6	4,5,6,7,8	$\underline{v}_{6ll}$	$-V_{DC}$	$-V_{DC}$	V_{DC}	V_{DC}	0
7	5,6,7,8,9	$\underline{v}_{7ll}$	$-V_{DC}$	$-V_{DC}$	0	V_{DC}	V_{DC}
8	6,7,8,9,10	$\underline{v}_{8ll}$	0	$-V_{DC}$	$-V_{DC}$	V_{DC}	V_{DC}
9	7,8,9,10,1	$\underline{v}_{9ll}$	V_{DC}	$-V_{DC}$	$-V_{DC}$	0	V_{DC}
10	8,9,10,1,2	$\underline{v}_{10ll}$	V_{DC}	0	$-V_{DC}$	$-V_{DC}$	V_{DC}

And the Fourier series of nonadjacent line-to-line voltage can be written as

$$v_{ll}(t)=\frac{4}{\pi}V_{DC}\left[\begin{array}{c}\cos\left(\frac{\pi}{10}\right)\sin(\omega t)+\frac{1}{3}\cos\left(\frac{3\pi}{10}\right)\sin(3\omega t)\\ +\frac{1}{7}\cos\left(\frac{7\pi}{10}\right)\sin(7\omega t)+\ldots\end{array}\right] \tag{15.84}$$

Thus, the peak of the fundamental is

$$V_{ll}=\frac{4}{\pi}V_{DC}\cos\left(\frac{\pi}{10}\right)=1.211V_{DC} \tag{15.85}$$

From Fig. 15.31, mean square value is determined as

$$\text{Mean square value}=\frac{1}{\pi}\left[(V_{DC})^2\times\frac{4\pi}{5}\right]=\frac{4}{5}V_{DC}^2 \tag{15.86}$$

$$V_{rms}=\frac{2}{\sqrt{5}}V_{DC}=0.894427191V_{DC} \tag{15.87}$$

Total harmonic rms voltage (pu) is given by

$$V_{Hrms}=\sqrt{(V_{rms})^2-(V_1)^2}=\sqrt{\left(\frac{2}{\sqrt{5}}\right)^2-\left(\frac{2\sqrt{2}}{\pi}\cos\left(\frac{\pi}{10}\right)\right)^2}$$
$$=0.2585208456 \tag{15.88}$$

Hence, total harmonic distortion is

$$THD=\frac{\text{r.m.s. total harmonic voltage}}{\text{r.m.s. total voltage}}=\frac{0.2585208456}{2/\sqrt{5}}$$
$$=0.2890350922\ \text{ or }\ 28.9\%\ \text{ Or }\ 28.9035\% \tag{15.89}$$

15.4.1.3 Pulse Width Modulation Mode of Operation

If a five-phase voltage-source inverter is operated in PWM mode, apart from the already described 10 states, there are additional 22 switching states. These remaining 22 switching states encompass three possible situations: all the states when four switches from upper (or lower) half and one from the lower (or upper) half of the inverter are on (states 11–20), two states when either all the five upper (or lower) switches are "on" (states 31 and 32), and the remaining states with three switches from the upper (lower) half and two switches from the lower (upper) half in conduction mode (states 21–30). The corresponding space vectors for 11–30 are obtained using Eq. (15.68), and it is seen that the total of 32 space vectors, available in the PWM operation, fall into four distinct categories regarding the magnitude of the available output phase voltages. The phase voltage space vectors are summarized in Table 15.4 for all 32 switching states and are shown in Fig. 15.32.

Since adjacent line voltage yields lower output value, only nonadjacent line voltages are elaborated as well:

TABLE 15.4 Phase-to-neutral voltage space vectors for states 1–32

Space vectors	Value of the space vectors
$\underline{v}_{1phase}$ to $\underline{v}_{10phase}$	$2/5\,V_{DC}2\cos(\pi/5)\exp(jk\pi/5)$ for $k=0,1,2\ldots9$
$\underline{v}_{11phase}$ to $\underline{v}_{20phase}$	$2/5\,V_{DC}\exp(jk\pi/5)$ for $k=0,1,2\ldots9$
$\underline{v}_{21phase}$ to $\underline{v}_{30phase}$	$2/5\,V_{DC}2\cos(2\pi/5)\exp(jk\pi/5)$ for $k=0,1,2\ldots9$
$\underline{v}_{31phase}$ to $\underline{v}_{32phase}$	0

$$\begin{bmatrix}\vec{v}_{11ll}\\ \vec{v}_{12ll}\\ \vec{v}_{13ll}\\ \vec{v}_{14ll}\\ \vec{v}_{15ll}\\ \vec{v}_{16ll}\\ \vec{v}_{17ll}\\ \vec{v}_{18ll}\\ \vec{v}_{19ll}\\ \vec{v}_{20ll}\end{bmatrix}=\frac{2}{5}V_{DC}2\cos\left(\frac{\pi}{10}\right)\begin{bmatrix}e^{j\pi/10}\\ e^{j3\pi/10}\\ e^{j5\pi/10}\\ e^{j7\pi/10}\\ e^{j9\pi/10}\\ e^{j11\pi/10}\\ e^{j13\pi/10}\\ e^{j15\pi/10}\\ e^{j17\pi/10}\\ e^{j19\pi/10}\end{bmatrix} \tag{15.90}$$

$$\begin{bmatrix}\vec{v}_{21ll}\\ \vec{v}_{22ll}\\ \vec{v}_{23ll}\\ \vec{v}_{24ll}\\ \vec{v}_{25ll}\\ \vec{v}_{26ll}\\ \vec{v}_{27ll}\\ \vec{v}_{28ll}\\ \vec{v}_{29ll}\\ \vec{v}_{30ll}\end{bmatrix}=\frac{2}{5}V_{DC}2\cos\left(\frac{3\pi}{10}\right)\begin{bmatrix}e^{j\pi/10}\\ e^{j3\pi/10}\\ e^{j5\pi/10}\\ e^{j7\pi/10}\\ e^{j9\pi/10}\\ e^{j11\pi/10}\\ e^{j13\pi/10}\\ e^{j15\pi/10}\\ e^{j17\pi/10}\\ e^{j19\pi/10}\end{bmatrix} \tag{15.91}$$

15.4.1.4 Model Transformation Using Decoupling Matrix

Since the system under discussion is a five-phase one, the complete model can be only be elaborated in five-dimensional space. The first two-dimensional spaces are *d-q*, the second one is named as *x-y*, and the last is zero-sequence components that are absent due to the assumption of isolated neutral. On the basis of the general decoupling transformation matrix for an *n*-phase system, inverter voltage space vectors in the second two-dimensional subspace (*x-y*) are determined with Eq. (15.92):

$$\underline{v}_{xy}^{INV} = \frac{2}{5}\left(v_a + \underline{a}^2 v_b + \underline{a}^4 v_c + \underline{a} v_d + \underline{a}^3 v_e\right) \tag{15.92}$$

Thus, 32 space vectors of phase-to-neutral voltage in the *x-y* plane are obtained using Eq. (15.92) and are demonstrated in Fig. 15.33.

It can be seen from Figs. 15.32 and 15.33 that the outer decagon space vectors of the $d-q$ plane map into the innermost decagon of the *x-y* plane, the innermost decagon of *d-q* plane forms the outer decagon of *x-y* plane while the middle decagon space vector map into the same region. Further, it is observed from the above mapping that the phase sequence *a,b,c,d,e* of $d-q$ plane corresponds to *a,c,e,b,d* in *x-y* that are basically the third harmonic voltages.

15.4.1.5 Hardware Implementation of a Five-Phase VSI in 180 Conduction Mode

Hardware can be developed to implement the square-wave operation of a five-phase voltage-source inverter. The hardware can be developed using available power switch modules from different manufacturers such as Semikron, Mitsubishi, and Fairchild. The power switches are available in discrete form to implement inverter system. The gate driver circuit is also available from different manufacturers. The control can be implemented using microcontroller, digital signal processors (DSP), dSpace, and field-programmable gate arrays (FPGA). The control codes can be written in C/C++. Some of the DSPs and FPGAs are compatible with Matlab/Simulink, and hence, control codes can be implemented directly. In FPGA, system generator is used for writing the control code. System generator is a library in Matlab/Simulink software. The coding is done in the form of drag and drop in system generator.

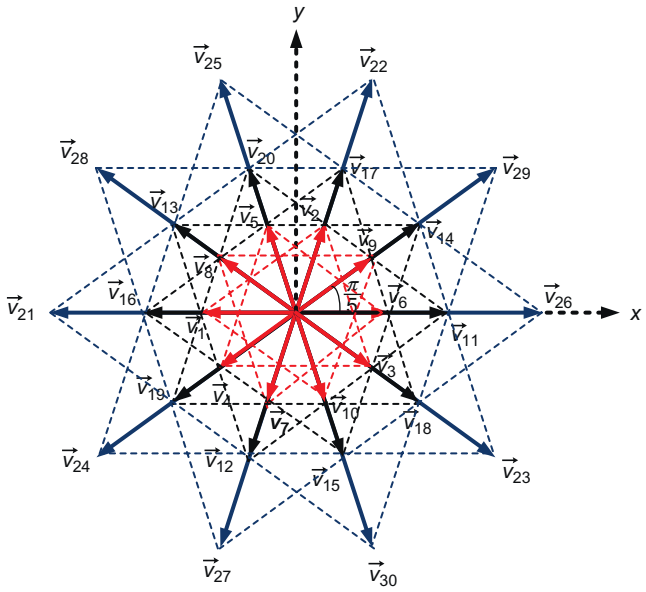

FIG. 15.33 Phase-to-neutral voltage space vectors for states 1–32 (states 31–32 are at origin) in *x-y* plane.

15.4.1.6 Hardware Set-up

The control of inverter can be implemented using sophisticated controllers such as microcontroller, digital signal processors (DSP), dSpace, and field-programmable gate arrays (FPGA). The output voltages from these controllers are generally 3.3 V that is not enough for turning on the IGBTs/MOSFETs/BJT. Further to turn off the power switching devices, the gate capacitors are to be fully and rapidly discharged. Gate drive circuit is thus required to match the voltage level requirement of turning on the power switches (about 15 V), and a discharge path for the gate capacitor is needed. Hence, a gate drive circuit is needed to successfully turn on and turn off the power devices. The following section describes the implementation of the control, gate drive, and power circuit using analog devices. The complete block diagram is shown in Fig. 15.34.

Power supply is obtained from a single-phase grid and is converted to 9-0-9 V using a transformer. The converted voltage of (9-0-9 V) is fed to the phase-shifting circuit shown in Fig. 15.35, to provide appropriate phase shift for operation at various conduction angle (the conduction angle refers to the conduction modes of inverter, e.g., 180, 144, and 108 degrees). The phase-shifted signal is then fed to the inverting/noninverting Schmitt trigger circuit and wave-shaping circuit (Figs. 15.36 and 15.37). The processed signal is then fed to the isolation and driver circuit shown in Fig. 15.38. This is then finally given to the gate of IGBTs. There are two separate circuits for upper and lower legs of the inverter.

The power circuit is made up of IGBT SGW20N60 having a rating of 20 A and 600 V DC, with snubber circuit consisting of the series combination of a resistance and a capacitor with a diode in parallel with the resistance.

15.4.1.7 Hardware Results

Experiment can be conducted for stepped operation of inverter with 180 degrees conduction modes for star-connected five-phase resistive load. A single-phase supply can be given to the control circuit through the phase-shifting network. The output of the phase-shifting circuit provides the required five-phase output voltage by appropriately tuning it. These five-phase signals are then further processed to generate the gate drive circuit.

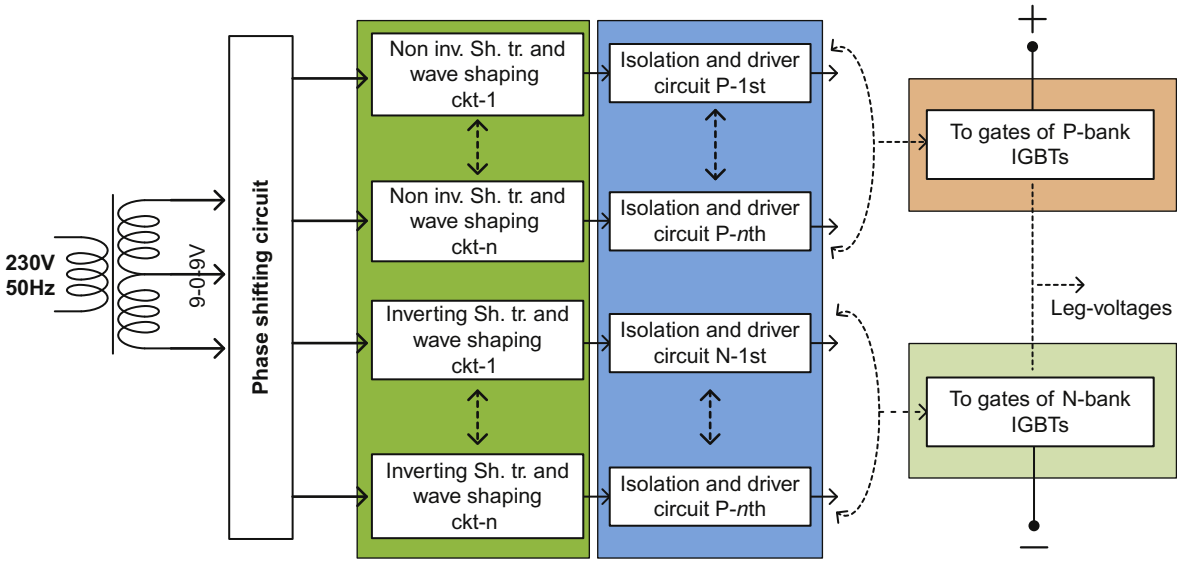

FIG. 15.34 Block diagram of the control circuit.

15.4.1.8 Results of 180 Degrees Conduction Mode

The output from the Schmitt trigger circuit is presented in Fig. 15.39. The driving control gate/base signals for the 10-step mode for legs A–B of the inverter are illustrated in Fig. 15.40. The corresponding phase voltage thus obtained is shown in Fig. 15.41, keeping the DC-link voltage at 60 V. The output phase voltage is called 10 step in one fundamental cycle ($1/5V_{dc}$, $2/5V_{dc}$, $1/5V_{dc}$, $2/5V_{dc}$, $1/5V_{dc}$, $-1/5V_{dc}$, $-2/5V_{dc}$, $-1/5V_{dc}$, $-2/5V_{dc}$, and $-1/5V_{dc}$).

Nonadjacent line voltage obtained is shown in Fig. 15.42. All currents are measured using AC/DC current probe giving the output of 100 mV/A.

The AC side input current is also measured and is depicted in Fig. 15.43. The analysis is presented in the last subsection.

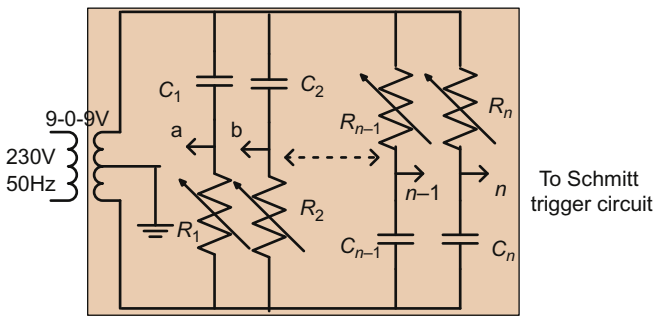

FIG. 15.35 Phase-shifting circuit (PSC).

15.4.1.9 DSP Implementation of Step Mode of Operation

The results obtained in Section 15.4.1.9 are verified using implementation through TMS320F2812 DSP under the same operating conditions. Control code is written in C++ and run in PC. It is transferred to the DSP using serial communication cable RS232. The DSP generate 10 gating signals that are fed to the power module of the inverter. The detail experimental setup is provided in Section 15.4.1.10. All the three conduction angles are implemented. The developed algorithm

is verified using a star-connected resistive load and a five-phase induction machine.

15.4.1.10 180 Degrees Conduction Mode

The inverter is operated in 180 degrees conduction mode, and a five-phase star-connected resistive load is connected across the output terminal. The resulting phase voltage, nonadjacent line voltages are illustrated in Figs. 15.44 and 15.45, respectively.

It is observed that the phase voltage generated using cheap analog-circuit-based inverter shown in Fig. 15.41 is identical to the one obtained using DSP as shown in Fig. 15.44. Similarly, the nonadjacent line voltage of Fig. 15.42 is identical to the one shown in Fig. 15.45. This verifies the correct design of the analog-based inverter and also verifies the DSP code. The same study is carried out using a five-phase induction motor as a load. The resulting voltage and stator current waveforms are presented in Fig. 15.46. The waveform is typical for such load.

15.4.2 Carrier-Based PWM

15.4.2.1 With Zero Sequence Signal

Carrier-based sinusoidal PWM is the most popular and widely used PWM technique because of their simple implementation in both analog and digital realization [32,34]. The principle of carrier-based PWM true for a three-phase VSI is also applicable to a multiphase VSI. The PWM signal is generated by comparing a sinusoidal modulating signal with a triangular (double edge) or a saw-tooth (single edge) carrier signal. The frequency of the carrier is normally kept much higher compared to the

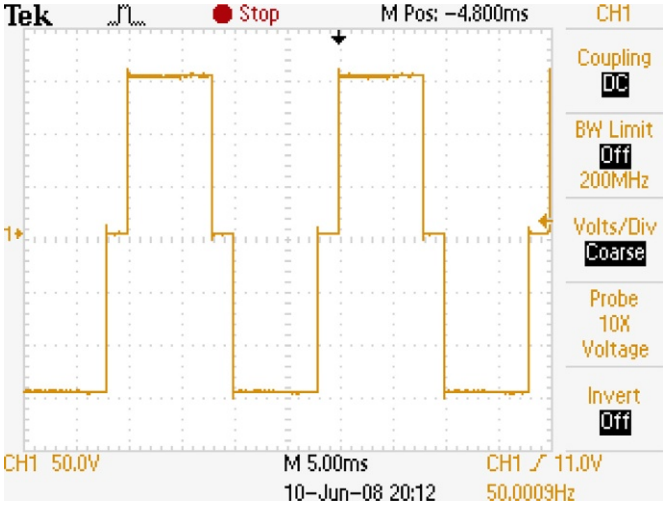

FIG. 15.45 Nonadjacent line voltage for 180 degrees conduction mode.

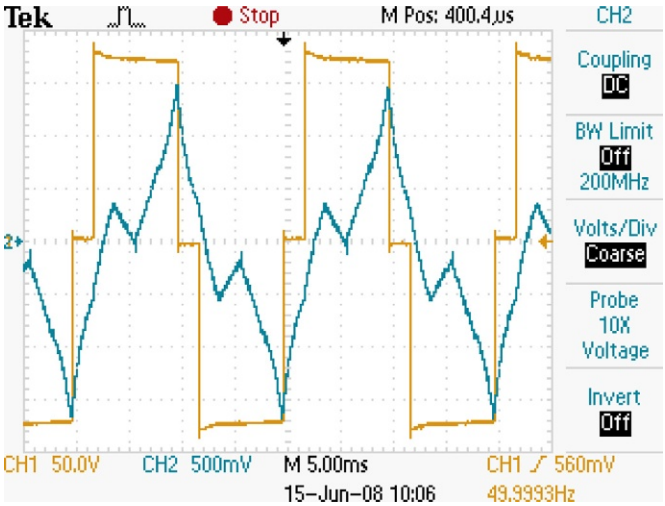

FIG. 15.46 Nonadjacent line voltage and stator current.

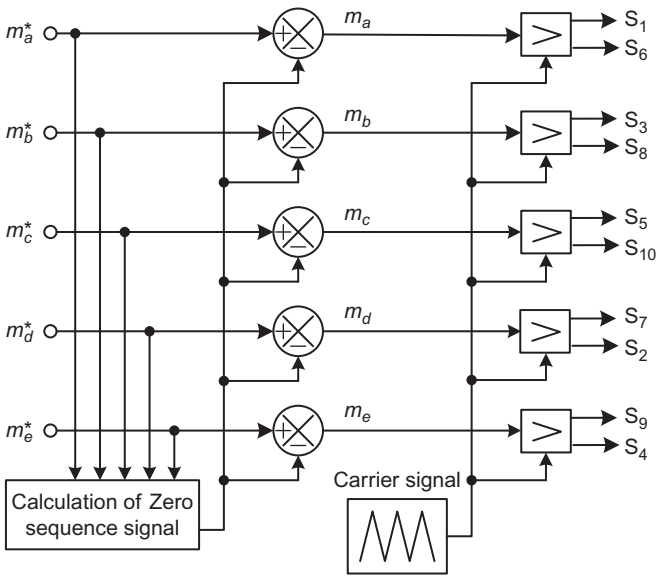

FIG. 15.47 Principle of carrier-based PWM technique.

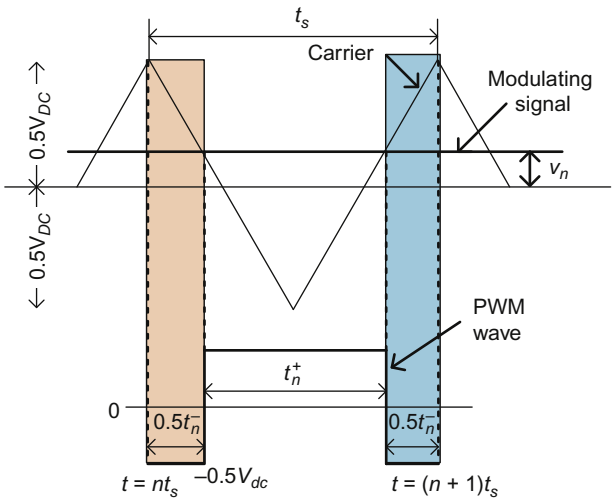

FIG. 15.48 PWM waveform generation in carrier-based sinusoidal method.

modulating signal. The principle of operation of a carrier-based PWM modulator is shown in Fig. 15.47, and generation of PWM waveform is illustrated in Fig. 15.48. Modulation signals are obtained using five fundamental sinusoidal signals (displaced in time by $\alpha = 2\pi/5$), which are summed with an appropriate zero-sequence signal. These modulation signals are compared with high-frequency carrier signal (saw-tooth or triangular shape), and all five switching functions for inverter legs are obtained directly. In general, modulation signal can be expressed as

$$v_i(t) = v_i^*(t) + v_{nN}(t) \tag{15.93}$$

where $i = a,b,c,d,e$ and v_{nN} represents zero-sequence signal and v_i^* is fundamental sinusoidal signals. Zero-sequence signal represents a degree of freedom that exits in the structure of a carrier-based modulator, and it is used to modify modulation signal waveforms and thus to obtain different modulation schemes. Continuous PWM schemes are characterized by the presence of switching activity in each of the inverter legs over the carrier signal period, as long as peak value of the modulation signal does not exceed the carrier magnitude.

The following relationship holds true in Fig. 15.48:

$$t_n^+ - t_n^- = v_n t_s \tag{15.94}$$

where

$$t_n^+ = \left(\frac{1}{2} + v_n\right) t_s \tag{15.95}$$

$$t_n^- = \left(\frac{1}{2} - v_n\right) t_s \tag{15.96}$$

where t_n^+ and t_n^- are the positive and negative pulse widths in the nth sampling interval, respectively, and v_n is the normalized amplitude of modulation signal. The normalization is done with respect to V_{dc}. Eqs. (15.95) and (15.96) are referred as the equal volt-second principle as applied to a three-phase inverter [32,35,36]. The normalized peak value of the triangular carrier wave is ±0.5 in linear region of operation. Modulator gain has the unity value while operating in the linear region, and peak value of inverter output fundamental voltage is equal to the peak value of the fundamental sinusoidal signal. Thus, the maximum output phase voltages from a five-phase VSI are limited to 0.5 p.u. This is also evident in [32,37]. Thus, the output phase voltage from a three-phase and a five-phase VSI are the same when utilizing carrier-based PWM.

15.4.2.2 Sinusoidal Pulse Width Modulation (SPWM)

The simplest continuous carrier-based PWM is obtained with the selection of the zero-sequence signal as $v_{vN}(t) = 0$. Modulation signals for all five inverter legs are equal to five sinusoidal fundamental signals. Thus, while operating in the linear region, maximum value of the modulation index of the SPWM has the unity value, $M_{SPWM} = 1$. Modulation index is defined as the ratio of the fundamental component amplitude of the line-to-neutral inverter output voltage to one-half of the available DC bus voltage. Thus,

$$M = \frac{V_1}{0.5 V_{dc}} \tag{15.97}$$

where V_1 is the fundamental output phase voltage.

15.4.2.3 Fifth Harmonic Injection PWM

The effect of the addition of harmonic with reverse polarity in any signal is to reduce the peak of the reference signal. Aim here is to bring the amplitude of the reference as low as possible, so that the reference can then be pushed to make it equal to the carrier, resulting in the higher output voltage and better DC bus utilization. Using this principle, third harmonic injection PWM scheme is used in a three-phase VSI that results in increase in the fundamental output voltage to $0.575 V_{dc}$ [32,35]. Third harmonic voltages do not appear in the output phase voltages and are restricted to the leg voltages only. Following the same principle, fifth harmonic injection PWM scheme can be developed to increase the modulation index of a five-phase VSI.

The reference leg voltages are given as

$$\begin{aligned}
V_{ao}^* &= 0.5 M_1 V_{dc} \cos(\omega t) + 0.5 M_5 V_{dc} \cos(5\omega t) \\
V_{bo}^* &= 0.5 M_1 V_{dc} \cos(\omega t - 2\pi/5) + 0.5 M_5 V_{dc} \cos(5\omega t) \\
V_{co}^* &= 0.5 M_1 V_{dc} \cos(\omega t - 4\pi/5) + 0.5 M_5 V_{dc} \cos(5\omega t) \\
V_{do}^* &= 0.5 M_1 V_{dc} \cos(\omega t + 4\pi/5) + 0.5 M_5 V_{dc} \cos(5\omega t) \\
V_{eo}^* &= 0.5 M_1 V_{dc} \cos(\omega t + 2\pi/5) + 0.5 M_5 V_{dc} \cos(5\omega t)
\end{aligned} \tag{15.98}$$

It is to be noted that fifth harmonic has no effect on the value of the reference waveform when $\omega t = (2k+1)\pi/10$, since $\cos(5(2k+1)\pi/10) = 0$ for all odd k. Thus, M_5 is chosen to make the peak magnitude of the reference of (15.98) that occurs where the fifth harmonic is zero. This ensures the maximum possible value of the fundamental component. The reference voltage reaches a maximum when

$$\frac{dV_{ao}^*}{dt} = -0.5 M_1 V_{dc} \sin \omega t - 0.5 \cdot 5 M_5 V_{dc} \sin 5\omega t = 0 \tag{15.99}$$

This yield

$$M_5 = -M_1 \frac{\sin(\pi/10)}{5} \quad \text{for} \quad \omega t = \pi/10 \tag{15.100}$$

Thus, the maximum modulation index can be determined from

$$\begin{aligned}
\left|V_{ao}^*\right| &= \left|0.5 M_1 V_{dc} \cos(\omega t) - 0.5 \frac{\sin(\pi/10)}{5} M_1 V_{dc} \cos(3\omega t)\right| \\
&= 0.5 V_{dc}
\end{aligned} \tag{15.101}$$

The above equation gives

$$M_1 = \frac{1}{\cos(\pi/10)} \quad \text{for} \quad \omega t = \pi/10 \tag{15.102}$$

Thus, the output fundamental voltage is increased by 5.15% higher than the value obtainable using simple carrier-based PWM by injecting 6.18% fifth harmonic in fundamental. The fifth harmonic is in opposite phase to that of the fundamental.

15.4.2.4 Offset or Triangular Zero-Sequence Injection PWM

Another way of increasing the modulation index is to add an offset voltage to the references. This will effectively do the same function as above. The offset voltage is given as

$$V_{offest} = -\frac{V_{\max} + V_{\min}}{2} \tag{15.103}$$

where $v_{\max} = \max(v_a, v_b, v_c, v_d, v_e)$ and $v_{\min} = \min(v_a, v_b, v_c, v_d, v_e)$. Note that this is the same as for a three-phase inverter.

In case of three-phase VSI, the offset voltage is simply third harmonic triangular wave of 25% magnitude of fundamental. The peak of the fundamental is 0.575 p.u., (0.406 p.u. rms), the peak of the resultant modulating signal is 0.5 p.u. (0.353 p.u. rms), and the peak of the offset is 0.147 p.u. (0.104 p.u. rms). Hence, offset peak is 25% of the fundamental peak.

In a five-phase VSI, the offset is found as the fifth-harmonic triangular wave of 9.55% of the fundamental input reference. This value has been established by simulations. Offset addition requires only addition operation and hence is suitable for practical implementation.

A generalized formula of offset voltage is obtained, which is to be injected along with the fundamental in case of five-phase VSI. The expression is

$$V_{no} = -0.5528(V_{\max} - V_{\min}) + 3/5(1-2\mu)V_{DC}/2 - 3/5(1-2\mu)(V_{\max} - V_{\min})$$

where $V_{\max}$ is the maximum of the five-phase references, $V_{\min}$ is the minimum of the five-phase references, and μ is the factor that decides the placement of the two zero-vector states. If it is 0.5, then the two zero states are placed equally, and this corresponds to symmetrical zero-vector placement.

It is important to note that not only the fifth harmonic but also all the additional $5k$ ($k=1,3,5\ldots$) harmonics are included in the modulation signal in this technique. Maximum modulation index has the same value as in the previous case, $M_{TIPWM} = 1.0515$. To illustrate the effects of fifth-harmonic and triangular signal injection, the overall modulating signals are shown in Fig. 15.49.

In general, an extension of the linear region is obtained through the repositioning of the peak value of the modulating signal. While sinusoidal fundamental signals have peak values at $\frac{l\pi}{2}$, zero sequence modifies this, and now, peak values of the modulating signals occur at $\frac{l\pi}{2} \pm \frac{\pi}{2n}$, $l=1,3,5,\ldots$ Hence, for five-phase carrier-based continuous PWM methods with zero-sequence signal addition, new peak values of modulating signals appear at angles $\frac{l\pi}{2} \pm \frac{\pi}{10}$. This allows the peak value of the fundamental signal to exceed unity, up to the value when peak of the modulating signal reaches saturation level ($\pm 0.5V_{dc}$, in accordance with (15.97)). It is obvious from Fig. 15.49 that fifth-harmonic injection and offset injection have the same maximum value of the modulation index in the limit of the linear region.

15.4.2.5 Space Vector Pulse Width Modulation

Space-vector pulse-width modulation has become one of the most popular PWM techniques because of its easier digital implementation and higher DC bus utilization, when compared with the sinusoidal PWM method. The principle of SVPWM lies in the switching of inverter in a special way to apply a set of space vector for specific time. There is a lot of flexibility available in choosing the proper space-vector combination for an effective control of multiphase VSIs because of the large numbers of space vectors available in multiphase power converters.

Advantages of space vector PWM:

i. SVPWM increases fundamental output without distorting line-to-line waveform.
ii. The fundamental output of SVPWM is 94.02% that is 15.47% greater than sinusoidal PWM of 78.55% fundamental.
iii. SVPWM compares a single modulating wave with a carrier instead of using three waves.
iv. When the neutral of the load is connected to a DC supply voltage, SVPWM considers interaction among phases, whereas other PWM method does not.

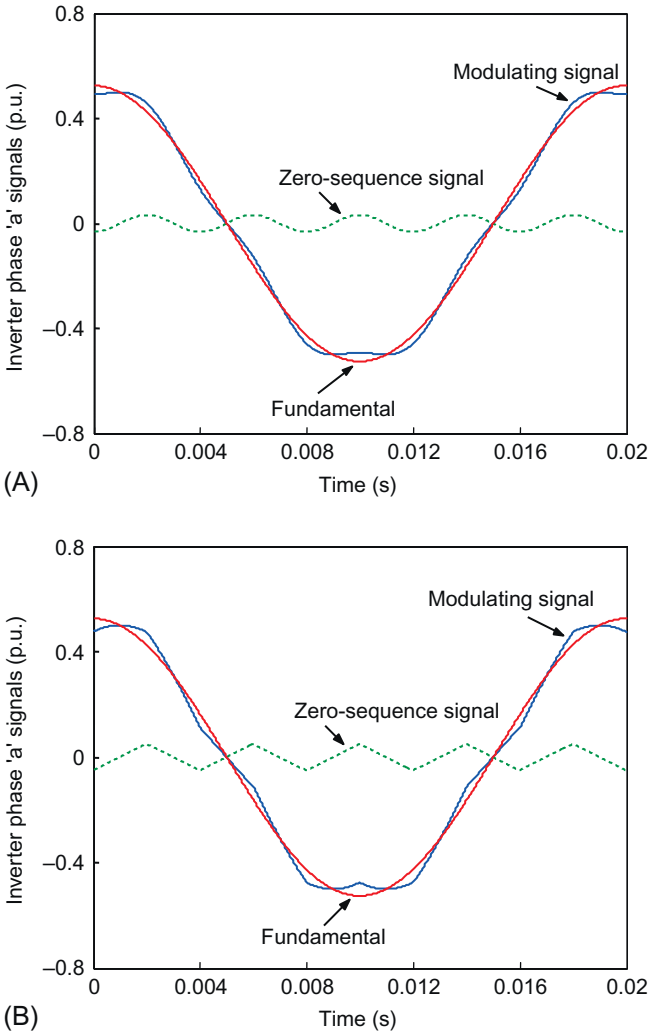

FIG. 15.49 Characteristics signals of carrier-based PWM (A) with fifth-harmonic injection and (B) with triangular harmonic injection.

v. Designing of heat sinks is an important factor for power dissipation. Power dissipation includes conduction and switching loss. Switching losses in sine PWM is difficult to compute that depend on modulation index, while computation is easier in space-vector PWM.
vi. SVPWM implementation is completely digital.
vii. Vector control implementation is completely digital, and thus, it is easy to implement SVPWM-based vector control scheme.
viii. Over modulation can easily be implemented.
ix. For high modulation index, the harmonics of current and torque of space-vector PWM will be much less than sine PWM.

In the case of a five-phase VSI, there are a total of $2^5 = 32$ space vectors available, of which 30 are active state vectors and two are zero state vectors forming three concentric decagons. For the implementation of space-vector PWM in linear range, two different approaches can be adopted. One approach is the

simple extension of method used in a three-phase inverter (use of two adjacent large length vectors) and second approach where four adjacent vectors are used (two large and two medium lengths). The first approach gives higher output voltage; however, the output voltages contain lower-order harmonics, more specifically, the third and seventh. The second approach offers sinusoidal output voltage; however, the magnitude is lower.

The first approach used only 10 outer large length vectors to implement the symmetrical SVPWM. Two neighboring active space vectors and two zero space vectors are utilized in one switching period to synthesize the input reference voltage. In total, 20 switchings take place in one switching period, so that the state of each switch is changed twice. The switching is done in such a way that, in the first switching half period, the first zero vector is applied, followed by two active state vectors and then by the second zero state vector. The second switching half period is the mirror image of the first one. The symmetrical SVPWM is achieved in this way. This method is the simplest extension of space-vector modulation of three-phase VSIs.

An ideal SVPWM of a five-phase inverter should satisfy a number of requirements. Firstly, in order to keep the switching frequency constant, each switch can change state only twice in the switching period (once "on" to "off" and once "off" to "on" or vice versa). Secondly, the rms value of the fundamental phase voltage of the output must be equal to the rms of the reference space vector. Thirdly, the scheme must provide full utilization of the available DC bus voltage. Finally, since the inverter is aimed at supplying the load with sinusoidal voltages, the low-order harmonic content needs to be minimized (this especially applies to the third and seventh harmonic). These criteria are used in assessing the merits and demerits of various SVPWM.

15.4.2.6 Space Vector PWM for Sinusoidal Output

The purpose here is to generate sinusoidal output phase voltages using space-vector PWM. Application of two neighboring medium active space vectors together with two large active space vectors in each switching period makes it possible to maintain zero average value in the second plane and consequently providing sinusoidal output. Use of four active space vectors per switching period requires the calculation of four application times, labeled here $t_{ab}, t_{bb}, t_{am}, t_{bm}$. The expressions used for the calculation of dwell times of various space vector are [32,38]

$$
\begin{aligned}
t_{al} &= \frac{|v_s^*|}{V_m \sin(\pi/5)} \left(\frac{\tau}{1+\tau^2}\right) t_s \sin\left(\frac{\pi}{5}k - \alpha\right) \\
t_{bl} &= \frac{|v_s^*|}{V_m \sin(\pi/5)} \left(\frac{\tau}{1+\tau^2}\right) t_s \sin\left(\alpha - (k-1)\frac{\pi}{5}\right) \\
t_{am} &= \frac{|v_s^*|}{V_m \sin(\pi/5)} \left(\frac{1}{1+\tau^2}\right) t_s \sin\left(\frac{\pi}{5}k - \alpha\right) \\
t_{bm} &= \frac{|v_s^*|}{V_m \sin(\pi/5)} \left(\frac{1}{1+\tau^2}\right) t_s \sin\left(\alpha - (k-1)\frac{\pi}{5}\right) \\
t_0 &= t_s - t_{al} - t_{bl} - t_{am} - t_{bm}
\end{aligned}
\tag{15.104}
$$

where $t_a = t_{al} + t_{am}$; $t_b = t_{bl} + t_{bm}$. This is in essence allocates 61.8% more dwell times to large space vectors compared with medium space vector, thus satisfying the constraints of producing zero average voltage in the x-y plane. This can be more clearly seen from Fig. 15.50.

It is seen from Fig. 15.50 that the vectors in x-y plane are in such a position to cancel each other by using the dwell time Eq. (15.104). The applications of active and zero space vectors are arranged in such a way as to obtain a symmetrical SVPWM. The space-vector disposition in sector I is illustrated in Fig. 15.51. Modulation signals of SVPWM are identical to those obtained with offset addition. Switching pattern is a symmetrical PWM with two commutations per inverter leg. The space vectors are applied in odd sectors using sequence $[\underline{v}_{31}, \underline{v}_{al}, \underline{v}_{bm}, \underline{v}_{am}, \underline{v}_{bl}, \underline{v}_{32}, \underline{v}_{bl}, \underline{v}_{am}, \underline{v}_{bm}, \underline{v}_{al}, \underline{v}_{31}]$, while the sequence is $[\underline{v}_{31}, \underline{v}_{bl}, \underline{v}_{am}, \underline{v}_{bm}, \underline{v}_{al}, \underline{v}_{32}, \underline{v}_{al}, \underline{v}_{bm}, \underline{v}_{am}, \underline{v}_{bl}, \underline{v}_{31}]$ in even sectors.

It can be easily observed from Eq. (15.104) that the zero-vector application time remains positive for $0 \leq |v_s^*| \leq 0.5257 V_{dc}$. Thus, the output phase voltage from a VSI using this Space Vector PWM scheme is $0.5257 V_{dc}$, which is 5.15% higher compared with the output obtainable with carrier-based sinusoidal PWM without harmonic injection and equal to the output obtainable with zero-sequence (fifth-harmonic) signal injection.

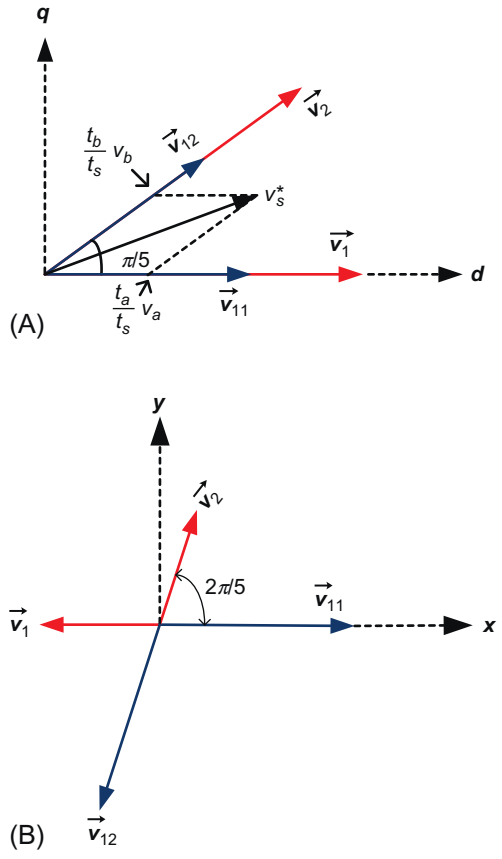

FIG. 15.50 Principle of the calculation of vector application times, (A) d-q plane and (B) x-y plane.

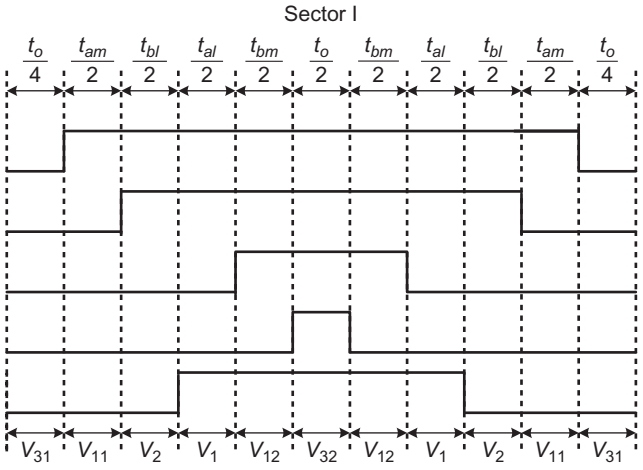

FIG. 15.51 Switching pattern in sector I using large and medium space vectors.

Simulation is carried out using Matlab/Simulink to implement the SVPWM with application of four active and a zero vector. The resulting waveform and harmonic spectrum are shown in Fig. 15.52. The average leg voltage is depicted in Fig. 15.51, and it is observed that the leg voltage is now quite similar to one obtained in three-phase VSI. The phase voltage is completely sinusoidal without any low-order harmonics. The spectrum of phase voltage shows the maximum achievable output equals to 0.5257 p.u. (keeping DC-link voltage equals to unity).

15.4.2.7 Experimental Implementation

Experimental setup is prepared in the laboratory to implement the carrier-based and space-vector PWM techniques discussed in the previous section. A five-phase voltage-source inverter is developed using intelligent power module. Texas Instrument DSP TMS320F2812 is used as the processor to implement the control algorithm. Since this DSP can be coded in C or C ++, it is more user-friendly, and they have dedicated 16 hardware PINS to generate the desired PWM signals. The PWM circuits associated with compare units make it possible to generate up to eight PWM output channels (per Event Manger) with programmable dead band and polarity. This DSP is specifically meant for use in motor drive purposes, and it can control up to eight-phase two-level inverter. The control code is written in C ++ language in Code composer studio 3.1 that runs in a PC. The control signal generated by PC is transferred to the DSP board through RS 232 cable connected in parallel printer port of the PC. The DSP board is connected to the power module through dedicated control cable. The DSP interfacing circuit along with required A/D and D/A converter is built on the DSP board itself procured from VI Microsystems.

Five-phase carrier-based PWM is implemented keeping the switching frequency equal to 10 kHz. The resulting waveform of leg voltage and corresponding phase voltage along with phase 'a', 'b', and 'c' are shown in Figs. 15.53 and 15.54, respectively.

Fifth-harmonic injection scheme is also implemented using DSP coding with fifth-harmonic signal equal to 0.0618 p.u. The resulting waveform of leg and corresponding phase voltage (unfiltered) are shown in Figs. 15.55 and 15.56, respectively.

Triangular zero sequence injection PWM (TIPWM) is also implemented. The resulting waveform of phase voltage along with phase 'a', 'b', and 'c' currents and triangular zero-sequence injection are shown in Figs. 15.57 and 15.58, respectively.

15.4.3 Modeling and Control of a Seven-Phase VSI-Square Wave Mode

This section details the modeling and control of a seven-phase VSI. The modeling of seven-phase VSI is done for 14-step operation using space-vector approach [39]. The PWM operation

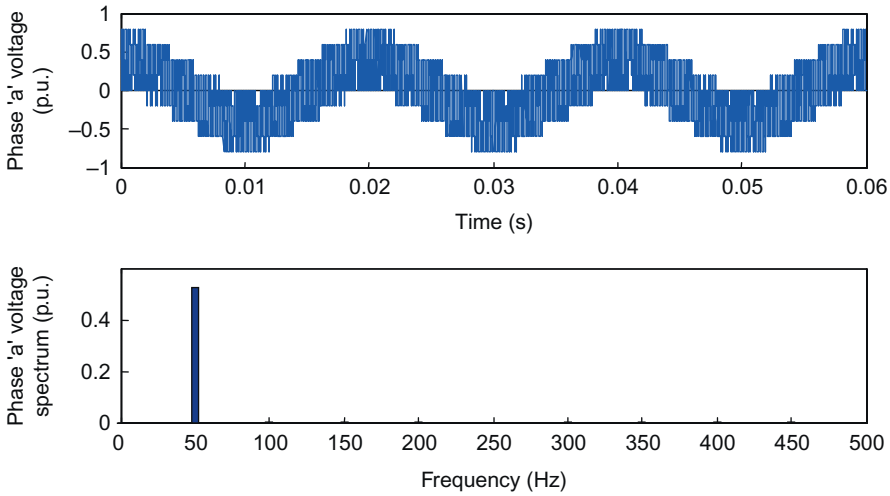

FIG. 15.52 Spectrum of phase "a" voltage for sinusoidal output of SVPWM.

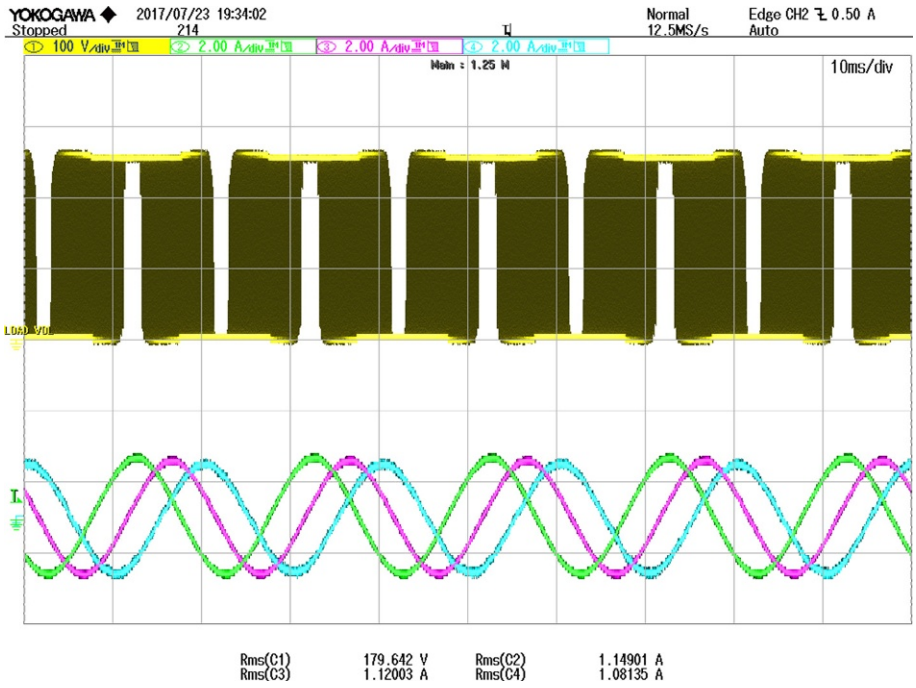

FIG. 15.53 Unfiltered leg "A" voltage along with phase 'a', 'b', and 'c' currents using carrier-based PWM.

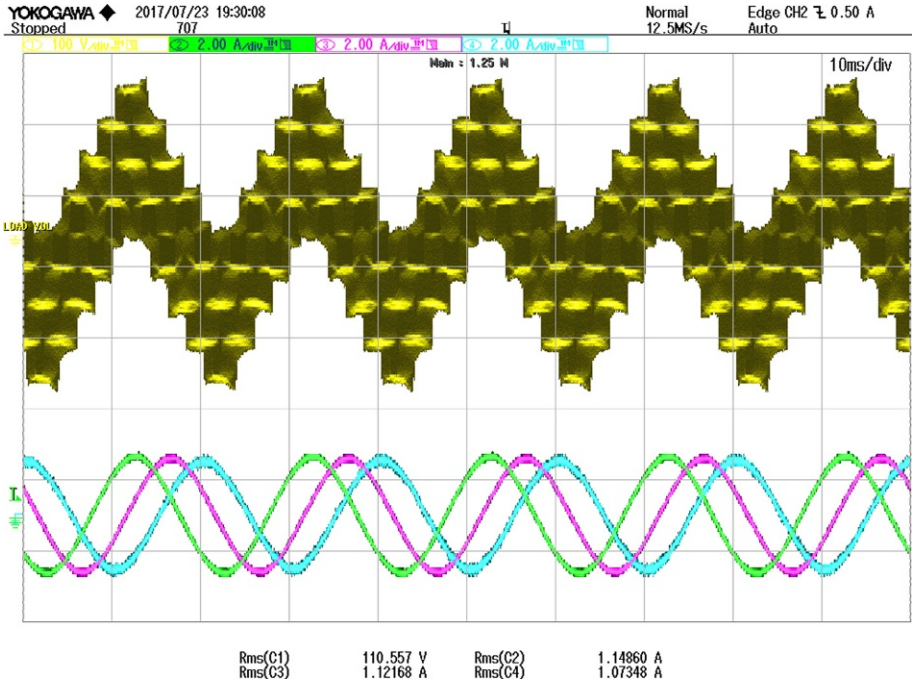

FIG. 15.54 Unfiltered phase "a" voltage along with phase 'a', 'b', and 'c' currents using carrier-based PWM.

mode is elaborated in Section 15.4.4 [40,41]. Conventional 180 degrees conduction mode is considered. The procedure adopted here follows from Section 15.4.1. The analytic expressions for harmonic components and THD are derived for phase voltages and second nonadjacent line voltages. The same is then verified using simulation and experimental results.

Section 15.4.3.2 deals with the modeling and control of a seven-phase voltage-source inverter in pulse-width modulation mode. There are a total of 128 switching state where the first 14 states lead to 14-step mode of operation and the rest of 114 switching states fall in PWM mode. Out of total 128 space vectors, two space vectors corresponding to the switching states

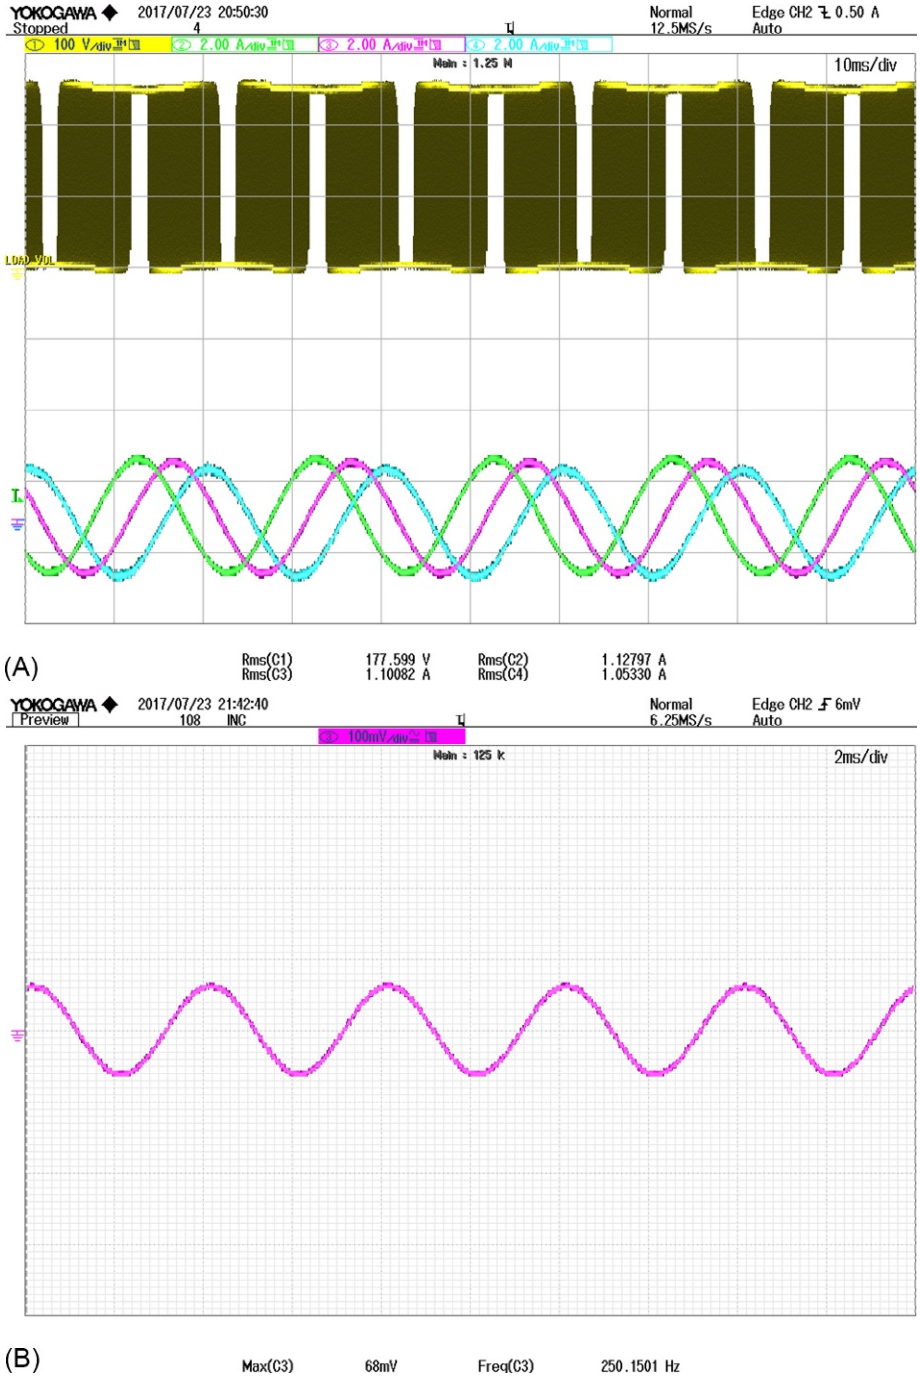

FIG. 15.55 (A) Unfiltered leg "A" voltage along with phase 'a', 'b', and 'c' currents using carrier-based PWM with fifth-harmonic injection. (B) Fifth harmonic signal injected in the carrier.

0000000 and 1111111 yield null vectors, and the rest 126 that produce finite length vectors are called active vectors. The model obtained is transformed into three different planes, namely, d-q, x_1-y_1, and x_2-y_2. Out of these three planes, only d-q produces torque in the machines supplied by the inverter, while the space vectors of other planes produce distortion in the stator currents. The complete model using space-vector approach is elaborated. The simulation results are included to validate the modeling procedure.

15.4.3.1 Fourteen-Step Operation of a Seven-Phase Voltage Source Inverter

Power circuit topology of a seven-phase VSI is shown in Fig. 15.59. Each switch in the circuit consists of two power

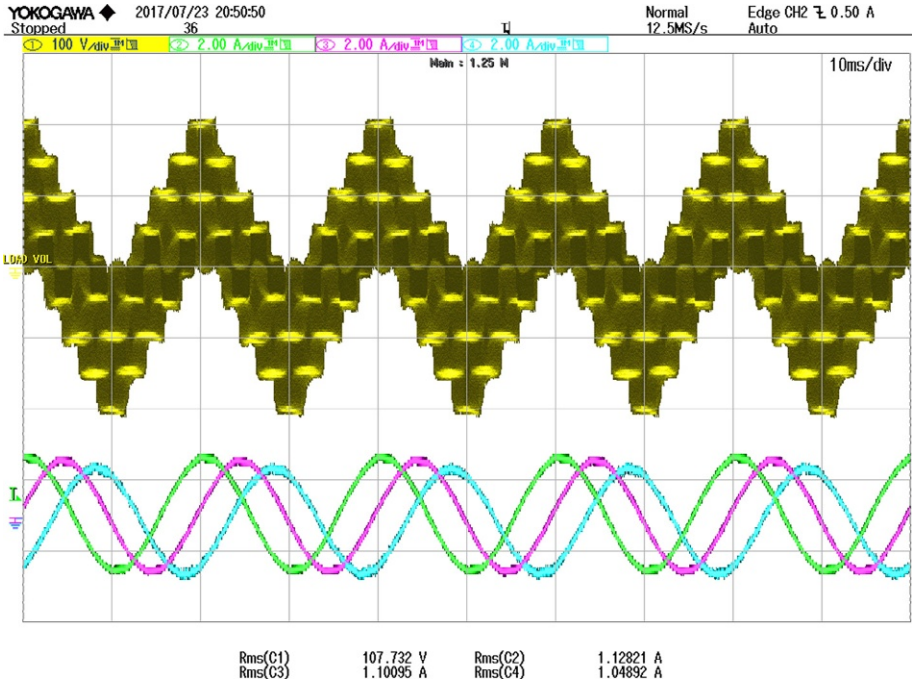

FIG. 15.56 Unfiltered phase "a" voltage along with phase 'a', 'b', and 'c' currents using fifth-harmonic signal injected in the carrier.

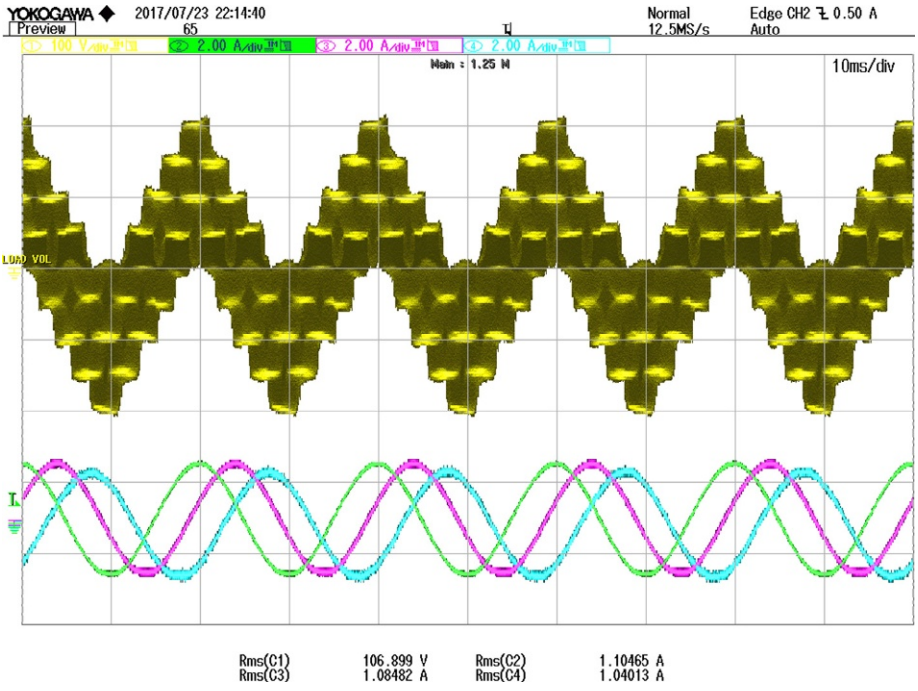

FIG. 15.57 Phase voltage along with phase 'a', 'b', and 'c' currents using triangular zero sequence injection PWM (TIPWM).

semiconductor devices, connected in antiparallel. One of these is a fully controllable semiconductor, such as a bipolar transistor or IGBT, while the second one is a diode. The input of the inverter is a DC voltage, which is regarded further on as being constant. The inverter outputs are denoted in Fig. 15.59 with lowercase symbols (*a*,*b*,*c*,*d*,*e*,*f*,*g*), while the points of connection of the outputs to inverter legs have symbols in capital letters (*A*,*B*,*C*,*D*,*E*,*F*,*G*). The basic operating principles of the seven-

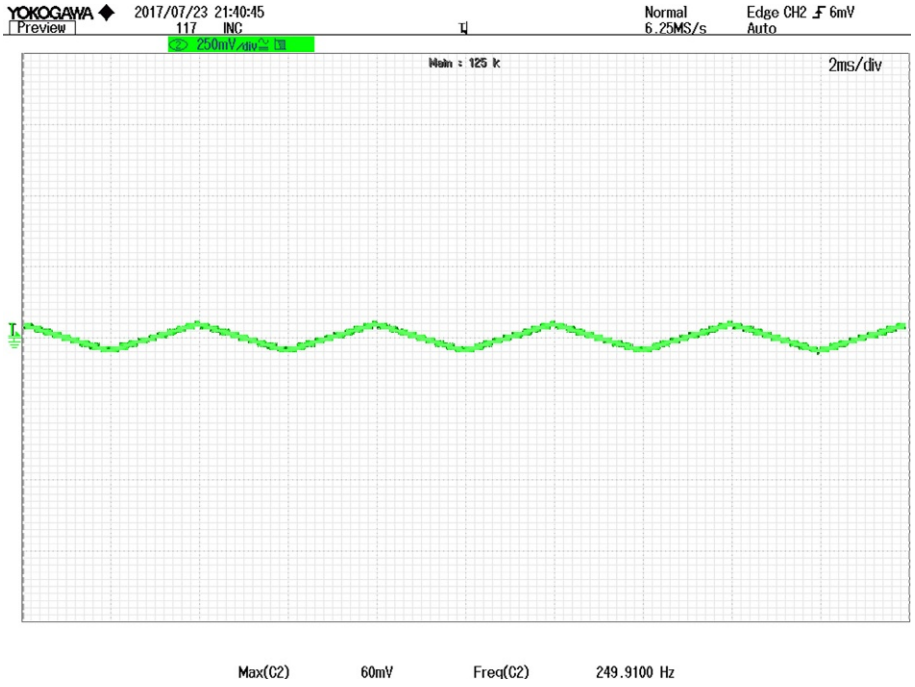

FIG. 15.58 Triangular fifth harmonic zero sequence injected signal.

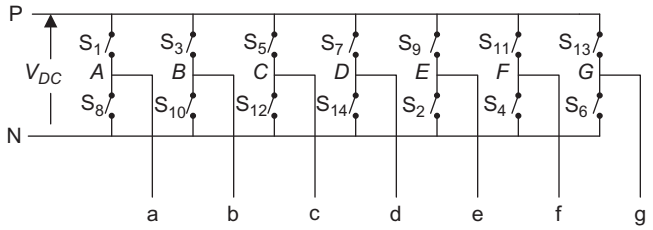

FIG. 15.59 Seven-phase voltage-source inverter power circuit.

phase VSI are developed in what follows assuming the ideal commutation and zero forward voltage drops. Each switch is assumed to conduct for 180 degrees, leading to the operation in the 14-step mode. Phase delay between firing of two switches in any subsequent two phases is equal to 360/7 degrees = 51.43 degrees (approx.).

The driving control gate/base signals for the 14 switches of the inverter in Fig. 15.59 are illustrated in Fig. 15.60. One complete cycle of operation of the inverter can be divided into 14 distinct modes indicated in Fig. 15.60 and summarized in Table 15.5. It follows from Fig. 15.60 and Table 15.5 that at any instant of time there are seven switches that are "on" and seven switches that are "off." In the 14-step mode of operation, there are three conducting switches from the upper 7 and 4 from the lower 7 or vice versa.

Leg voltages (i.e., voltages between points *A*,*B*,*C*,*D*,*E*,*F*,*G* and the negative rail of the DC bus N in Fig. 15.59) are considered first. The leg voltages obtained from the gate drive signal of Fig. 15.60.

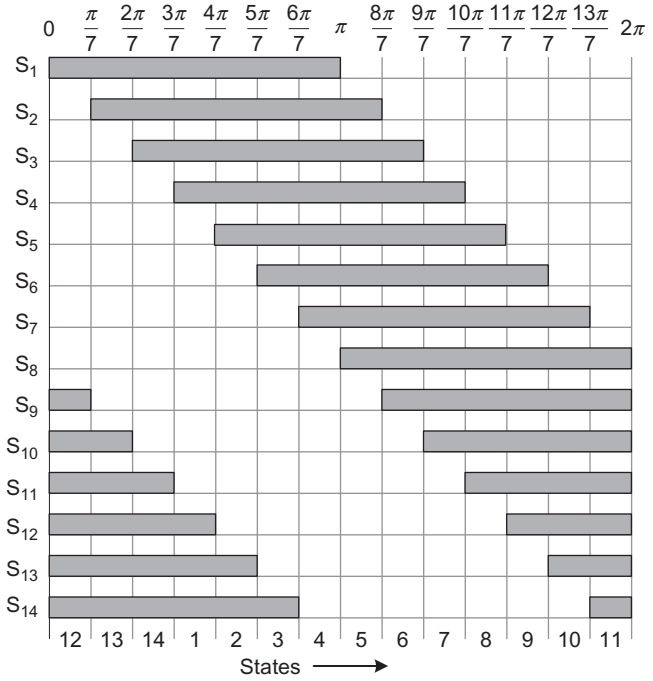

FIG. 15.60 Driving switch signals for the 14-step mode.

Space-vector model of the inverter is developed in the following subsection. Space vector of phase voltages in stationary reference frame is defined, using power invariant transformation, as

TABLE 15.5 Fourteen-step operation of a seven-phase VSI

11	8,9,10,11,12,13,14	$A^- B^- C^- D^- E^+ F^+ G^+$

$$\underline{v} = \frac{2}{7}\left(v_a + \underline{a}v_b + \underline{a}^2 v_c + \underline{a}^3 v_d + \underline{a}^{*3} v_e + \underline{a}^{*2} v_f + \underline{a}^* v_g\right) \quad (15.105)$$

where $\underline{a} = \exp(j2\pi/7)$, $\underline{a}^2 = \exp(j4\pi/7)$, $\underline{a}^3 = \exp(j6\pi/7)$, $\underline{a}^* = \exp(-j2\pi/5)$, $\underline{a}^{*2} = \exp(-j4\pi/5)$, $\underline{a}^{*3} = \exp(-j6\pi/7)$, and * stands for a complex conjugate.

Space vectors of leg voltages are obtained using Fig. 15.60 and Eq. (15.105) and are given as in Eq. (15.106).

$$\begin{bmatrix} \vec{v}_1 \\ \vec{v}_2 \\ - \\ - \\ \vec{v}_{14} \end{bmatrix} = \left(\frac{2}{7}\right) \frac{V_{DC}}{2\cos(3\pi/7)} \begin{bmatrix} e^{j0} \\ e^{j\pi/7} \\ - \\ - \\ e^{j13\pi/7} \end{bmatrix} \quad (15.106)$$

It is seen that the leg voltages have magnitude of $(2/7)V_{DC}(2\cos(\pi/7))$ and are 25.7142857 degrees spatially apart.

Phase-to-neutral voltages of the star-connected load are most easily found by defining a voltage difference between the star point n of the load and the negative rail of the DC bus N. The following correlation then holds true:

$$\begin{aligned} v_A &= v_a + v_{nN} \\ v_B &= v_b + v_{nN} \\ v_C &= v_c + v_{nN} \\ v_D &= v_d + v_{nN} \\ v_E &= v_e + v_{nN} \\ v_F &= v_f + v_{nN} \\ v_G &= v_g + v_{nN} \end{aligned} \quad (15.107)$$

Since the phase voltages in a star-connected load sum to zero, the summation of Eq. (15.107) yields

$$v_{nN} = (6/7)(v_A + v_B + v_C + v_D + v_E + v_F + v_G) \quad (15.108)$$

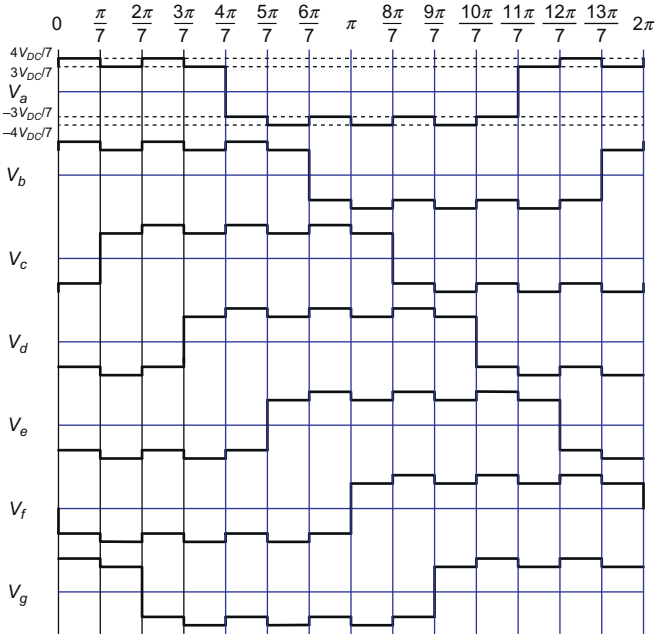

FIG. 15.61 Phase-to-neutral voltages of the seven-phase VSI in the 14-step mode of operation.

Substitution of (15.107) into (15.108) yields phase-to-neutral voltages of the load in the following form:

$$\begin{aligned} V_a &= (6/7)V_A - (1/7)(V_B + V_C + V_D + V_E + V_F + V_G) \\ V_b &= (6/7)V_B - (1/7)(V_A + V_C + V_D + V_E + V_F + V_G) \\ V_c &= (6/7)V_C - (1/7)(V_A + V_B + V_D + V_E + V_F + V_G) \\ V_d &= (6/7)V_D - (1/7)(V_A + V_B + V_C + V_E + V_F + V_G) \\ V_e &= (6/7)V_E - (1/7)(V_A + V_B + V_C + V_D + V_F + V_G) \\ V_f &= (6/7)V_F - (1/7)(V_A + V_B + V_C + V_D + V_E + V_G) \\ V_g &= (6/7)V_G - (1/7)(V_A + V_B + V_C + V_D + V_E + V_F) \end{aligned} \quad (15.109)$$

The phase voltages in different modes are obtained by substituting leg voltages into Eq. (15.109), and their space vectors are determined using Eq. (15.105). The waveform of phase voltages for seven phases is shown in Fig. 15.61. The space vectors for the first 14 states are obtained as

$$\begin{bmatrix} \vec{v}_{1phase} \\ - \\ - \\ - \\ \vec{v}_{14phase} \end{bmatrix} = \left(\frac{2}{7}\right) \frac{V_{DC}}{2\cos(3\pi/7)} \begin{bmatrix} e^{j0} \\ - \\ - \\ - \\ e^{j13\pi/7} \end{bmatrix} \quad (15.110)$$

The Fourier analysis can be carried out, recognizing the quarter-wave symmetry; the waveform may be considered as odd function. The Fourier coefficients are obtained as

$$B_{2n-1}=\sum_{n=1}^{\infty}\left(\frac{4}{7\pi}\right)\left(\frac{V_{DC}}{2n-1}\right)\left[3+\cos(2n-1)\frac{\pi}{7}+\cos(2n-1)\frac{3\pi}{7}-\cos(2n-1)\frac{2\pi}{7}\right] \tag{15.111}$$

The expression in third bracket of Eq. (15.111) equals to zero for all the harmonics whose order is divisible by seven. Hence, one can write the phase-to-neutral voltages as

$$V(t)=\left(\frac{2V_{DC}}{\pi}\right)\left(\begin{array}{c}\sin\omega t+\frac{1}{3}\sin(3\omega t)+\frac{1}{5}\sin(5\omega t)+\frac{1}{9}\sin(9\omega t)\\+\frac{1}{11}\sin(11\omega t)+\frac{1}{13}\sin(13\omega t)+\ldots\end{array}\right) \tag{15.112}$$

From (15.112), it follows that the fundamental component of the output phase-to-neutral voltages has an rms value equal to

$$V_a=\frac{\sqrt{2}}{\pi}V_{DC}=0.45V_{DC} \tag{15.113}$$

From Fig. 15.61, the mean square value is determined as

$$\text{Mean square value}=\frac{1}{\pi}V_{DC}^2\left[\left(\frac{3}{7}\right)^2+\left(\frac{4}{7}\right)^2+\left(\frac{3}{7}\right)^2+\left(\frac{4}{7}\right)^2+\left(\frac{3}{7}\right)^2+\left(\frac{4}{7}\right)^2+\left(\frac{3}{7}\right)^2\right]\times\frac{\pi}{7}=\frac{12}{49}V_{DC}^2 \tag{15.114}$$

$$V_{rms}=\sqrt{\text{Mean square value}}=\frac{2\sqrt{3}}{7}V_{DC} \tag{15.115}$$

Total harmonic rms voltage (p.u.) is given by

$$V_{Hrms}=\sqrt{(V_{rms})^2-(V_1)^2}=\sqrt{\left(\frac{2\sqrt{3}}{7}\right)^2-\left(\frac{\sqrt{2}}{\pi}\right)^2}=0.2055616499 \tag{15.116}$$

Hence, total harmonic distortion is

$$THD=\frac{\text{r.m.s. total harmonic voltage}}{\text{r.m.s. total voltage}}=\frac{0.2055616499}{2\sqrt{3}/7}=0.4153837586 \text{ or } 41.54\% \tag{15.117}$$

There are three systems of line-to-line voltage: adjacent, first nonadjacent and second nonadjacent, in contrast to a three-phase system where only one line-to-line voltage is defined and five-phase system where two systems of line voltages exist. The second nonadjacent line voltages yield highest magnitude, and hence, it is taken up for discussion, and the other two types are omitted. The values of line voltages are obtained as the difference between the leg voltages and are plotted in Fig. 15.62.

The second nonadjacent line-line voltage space vectors are calculated by substituting the values from Table 15.6 into the defining expression (15.105) and are

$$\begin{bmatrix}\vec{v}_{1lll}\\-\\-\\-\\\vec{v}_{14lll}\end{bmatrix}=\left(\frac{2}{7}\right)8V_{DC}\cos\left(\frac{2\pi}{7}\right).\cos\left(\frac{\pi}{7}\right).\cos\left(\frac{\pi}{14}\right)\begin{bmatrix}e^{j\pi/14}\\e^{j3\pi/14}\\-\\-\\-\\e^{j27\pi/14}\end{bmatrix} \tag{15.118}$$

Fourier analysis can be done, and the resulting coefficients of the Fourier series for second nonadjacent line-to-line voltages, by considering odd quarter-wave symmetry, are

$$B_{2n-1}=\frac{4V_{Dc}}{\pi(2n-1)}\left[\cos(2n-1)\frac{\pi}{14}\right] \tag{15.119}$$

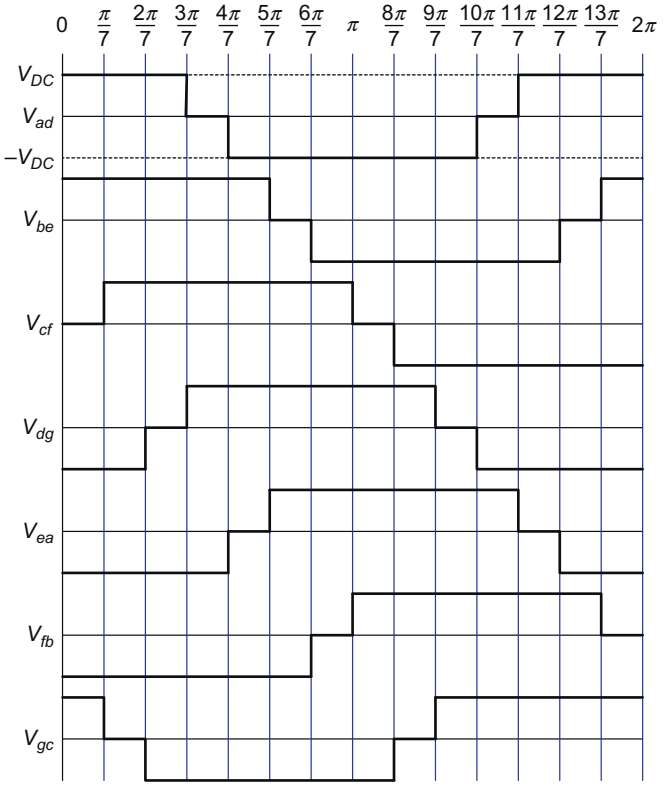

FIG. 15.62 The second nonadjacent line-to-line voltages of seven-phase VSI for various modes.

TABLE 15.6 Second nonadjacent line-to-line voltages of seven-phase VSI

States	Switches ON	Space vectors	V_{ad}	V_{be}	V_{cf}	V_{dg}	V_{ea}	V_{fb}	V_{gc}
1	12,13,14,1,2,3,4	$\vec{v}_{1III}$	V_{DC}	V_{DC}	0	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$	V_{DC}
2	13,14,1,2,3,4,5	$\vec{v}_{2III}$	V_{DC}	V_{DC}	V_{DC}	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$	0
3	14,1,2,3,4,5,6	$\vec{v}_{3III}$	V_{DC}	V_{DC}	V_{DC}	0	$-V_{DC}$	$-V_{DC}$	V_{DC}
4	1,2,3,4,5,6,7	$\vec{v}_{4III}$	0	V_{DC}	V_{DC}	V_{DC}	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$
5	2,3,4,5,6,7,8	$\vec{v}_{5III}$	$-V_{DC}$	V_{DC}	V_{DC}	V_{DC}	0	$-V_{DC}$	$-V_{DC}$
6	3,4,5,6,7,8,9	$\vec{v}_{6III}$	$-V_{DC}$	0	V_{DC}	V_{DC}	V_{DC}	$-V_{DC}$	$-V_{DC}$
7	4,5,6,7,8,9,10	$\vec{v}_{7III}$	$-V_{DC}$	$-V_{DC}$	V_{DC}	V_{DC}	V_{DC}	0	$-V_{DC}$
8	5,6,7,8,9,10,11	$\vec{v}_{8III}$	$-V_{DC}$	$-V_{DC}$	0	V_{DC}	V_{DC}	V_{DC}	$-V_{DC}$
9	6,7,8,9,10,11,12	$\vec{v}_{9III}$	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$	V_{DC}	V_{DC}	V_{DC}	0
10	7,8,9,10,11,12,13	$\vec{v}_{10III}$	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$	0	V_{DC}	V_{DC}	V_{DC}
11	8,9,10,11,12,13,14	$\vec{v}_{11III}$	0	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$	V_{DC}	V_{DC}	V_{DC}
12	1,9,10,11,12,13,14	$\vec{v}_{12III}$	V_{DC}	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$	0	V_{DC}	V_{DC}
13	10,11,12,13,14,12	$\vec{v}_{13III}$	V_{DC}	0	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$	V_{DC}	V_{DC}
14	11,12,13,14,1,2,3	$\vec{v}_{14III}$	V_{DC}	V_{DC}	$-V_{DC}$	$-V_{DC}$	$-V_{DC}$	0	V_{DC}

The series will be

$$V(t)=\sum_{n=1}^{\infty}\frac{4V_{Dc}}{\pi(2n-1)}\left[\cos(2n-1)\frac{\pi}{14}\right]\sin(2n-1)\omega t \tag{15.120}$$

From (15.120), it follows that the fundamental component of the output phase-to-neutral voltages has an rms value equal to

$$V_a=0.8777435064V_{DC} \tag{15.121}$$

From Fig. 15.62, the mean square value is determined as

$$\text{Mean square value}=\frac{1}{\pi}\left[V_{DC}^2\right]\times\frac{6\pi}{7}=\frac{6}{7}V_{DC}^2 \tag{15.122}$$

$$V_{rms}=\sqrt{\text{Mean square value}}=\frac{\sqrt{42}}{7}V_{DC} \tag{15.123}$$

Total harmonic rms voltage (p.u.) is given by

$$V_{Hrms}=\sqrt{(V_{rms})^2-(V_1)^2}=\sqrt{\left(\frac{\sqrt{42}}{7}\right)^2-(0.8777435064)^2}$$
$$=0.2944642493 \tag{15.124}$$

Hence, total harmonic distortion is

$$THD=\frac{\text{r.m.s. total harmonic voltage}}{\text{r.m.s. total voltage}}$$
$$=\frac{0.2944642493}{\sqrt{42}/7}=0.3180577408 \quad \text{or} \quad 31.81\% \tag{15.125}$$

The distortion in the line voltages is quite high.

It is important to note at this stage that the space vectors described by (15.105) provide mapping of inverter voltages into a two-dimensional space. However, since seven-phase inverter essentially requires description in a seven-dimensional space, not all the harmonics contained in (15.111) and (15.112) will be encompassed by the space vector of (15.105). In particular, space vectors calculated using (15.105) will only represent harmonics of the order $14k\pm1$, $k=0,1,2,3\ldots..$, that is, the 1st, the 13th, the 15th, and so on. Harmonics of the order $7k$, $k=1,2,3,\ldots$, cannot appear due to the isolated neutral point. However, harmonics of the order $7k\pm2$ and $7k\pm4$, $k=1,3,5,\ldots$ are present in (15.111) and (15.112) but are not encompassed by the space-vector definition of (15.105). These harmonics in essence appear in the second and third two-dimensional space, which requires introduction of the second and third space vectors for the seven-phase system. This issue is addressed in Section 15.4.3.3.

15.4.3.2 PWM Mode of Operation

If a seven-phase VSI is operated in PWM mode, apart from the already described 14 states, there will be additional 114 switching states. The number of possible switching states is in general equal to 2^n, where n is the number of inverter legs (i.e., output phases). This correlation is valid for any two-level VSI. Table 15.7 summarizes the additional switching states that are associated with PWM mode of operation and are absent in the 14-step mode of operation. Switches that are "on" and the corresponding terminal polarity are included in Table 15.7 As can be seen from Table 15.7, the remaining 114 switching states encompass four possible situations: all the states when four switches from upper (or lower) half and three from the lower (or upper) half of the inverter are "on" (states 1–14, 29–42, 43–56, 85–99, and 98–112); two states when either all the seven upper (or lower) switches are "on" (states 127 and 128); all the states when five

TABLE 15.7 Modes of operation of seven-phase voltage-source inverter

States	Switches ON	Polarity of terminal	States	Switches ON	Polarity of terminal

switches from upper (or lower) and two from upper (or lower) half of the inverter are "on" (states 15–28, 57–70, and 113–126); and remaining states with six switches from the upper (or lower) half and one switch from the lower (or upper) half in conduction mode (states 71–84). The phase-to-neutral voltages are described using the same approach as that of the previous sections.

The phase voltage values are listed in Table 15.8, and the corresponding space vectors for 15–126 can be obtained using Eq. (15.105) and are given by expressions (15.126)–(15.133). The complete space-vector model of phase voltage is shown in Fig. 15.63.

$$\begin{bmatrix} \vec{v}_{15phase} \\ - \\ - \\ - \\ \vec{v}_{28phase} \end{bmatrix} = 2(2/7)V_{DC}\cos\left(\frac{\pi}{7}\right)\begin{bmatrix} e^{j0} \\ - \\ - \\ - \\ e^{j13\pi/7} \end{bmatrix} \tag{15.126}$$

$$\begin{bmatrix} \vec{v}_{29phase} \\ - \\ - \\ - \\ \vec{v}_{42phase} \end{bmatrix} = \sqrt{2}(2/7)V_{DC}\begin{bmatrix} e^{j0.3052\pi/7} \\ - \\ - \\ - \\ e^{j13.3052\pi/7} \end{bmatrix} \tag{15.127}$$

$$\begin{bmatrix} \vec{v}_{43phase} \\ - \\ - \\ - \\ \vec{v}_{56phase} \end{bmatrix} = \sqrt{2}(2/7)V_{DC}\begin{bmatrix} e^{j0.6948\pi/7} \\ - \\ - \\ - \\ e^{j13.6948\pi/7} \end{bmatrix} \tag{15.128}$$

$$\begin{bmatrix} \vec{v}_{57phase} \\ - \\ - \\ - \\ \vec{v}_{70phase} \end{bmatrix} = 2(2/7)V_{DC}\cos\left(\frac{2\pi}{7}\right)\begin{bmatrix} e^{j0} \\ - \\ - \\ - \\ e^{j13\pi/7} \end{bmatrix} \tag{15.129}$$

$$\begin{bmatrix} \vec{v}_{71phase} \\ - \\ - \\ - \\ \vec{v}_{84phase} \end{bmatrix} = (2/7)V_{DC}\begin{bmatrix} e^{jo} \\ - \\ - \\ - \\ e^{j13\pi/7} \end{bmatrix} \tag{15.130}$$

$$\begin{bmatrix} \vec{v}_{85phase} \\ - \\ - \\ - \\ \vec{v}_{98phase} \end{bmatrix} = (2/7)\frac{V_{DC}}{2\cos(2\pi/7)}\begin{bmatrix} e^{j0} \\ - \\ - \\ - \\ e^{j13\pi/7} \end{bmatrix} \tag{15.131}$$

$$\begin{bmatrix} \vec{v}_{99phase} \\ - \\ - \\ - \\ \vec{v}_{112phase} \end{bmatrix} = (2/7)\frac{V_{DC}}{2\cos(\pi/7)}\begin{bmatrix} e^{j0} \\ - \\ - \\ - \\ e^{j13\pi/7} \end{bmatrix} \tag{15.132}$$

$$\begin{bmatrix} \vec{v}_{113phase} \\ - \\ - \\ - \\ \vec{v}_{126phase} \end{bmatrix} = 2(2/7)V_{DC}\cos\left(\frac{3\pi}{7}\right)\begin{bmatrix} e^{j0} \\ - \\ - \\ - \\ e^{j13\pi/7} \end{bmatrix} \tag{15.133}$$

It can be seen that the total of 128 space vectors, available in the PWM operation, fall into 10 distinct categories regarding the magnitude of the available output phase voltages. The phase voltage space vectors are summarized in Table 15.9 for all 128 switching states including 14-step operation.

15.4.3.3 Model Transformation using Decoupling Matrix

Since the system under discussion is a seven-phase one, the complete model can only be elaborated in seven-dimensional space. The first two-dimensional spaces are d-q, the second one is x_1-y_1, the third one is x_2-y_2, and the last is zero-sequence component that is absent due to the assumption of isolated neutral. On the basis of the general decoupling transformation matrix for an n-phase system, inverter voltage space vectors in the second two-dimensional subspace (x_1-y_1) and third two-dimensional subspace (x_2-y_2) are determined as

$$\begin{aligned} \underline{v}_{x1y1}^{INV} &= \frac{2}{7}\left(v_a + \underline{a}^2 v_b + \underline{a}^4 v_c + \underline{a}^6 v_d + \underline{a} v_e + \underline{a}^3 v_f + \underline{a}^5 v_g\right) \\ \underline{v}_{x2y2}^{INV} &= \frac{2}{7}\left(v_a + \underline{a}^3 v_b + \underline{a}^6 v_c + \underline{a}^2 v_d + \underline{a}^5 v_e + \underline{a} v_f + \underline{a}^4 v_g\right) \end{aligned} \tag{15.134}$$

Thus, 128 space vectors of phase-to-neutral voltage in the x_1-y_1 and x_2-y_2 planes are obtained using Eq. (15.134) and are illustrated in Figs. 15.64 and 15.65. It can be seen from Figs. 15.63–15.65 that the outermost, that is, first (black), second (pink), third (orange), fourth (green), fifth (turquoise), sixth (blue), seventh (gray 80%), eighth (violet), and ninth (red) tetradecagon space vectors of the d-q plane map into the eighth (violet), fifth (turquoise), fourth (green), third (orange), ninth (red), sixth (blue), first (black), seventh (gray 80%), and second (pink) of the tetradecagon (violet) of the x_1-y_1 plane, respectively, and seventh (gray 80%), ninth (red), fourth (green), third (orange), second (pink), sixth (blue), eighth (violet), first (black), and fifth (turquoise) of the tetradecagon (violet) of the x_2-y_2 plane, respectively. Further, it is observed from the above mapping that the phase sequence a,b,c,d,e,f,g of d-q plane corresponds to a,c,e,g, b,d,f of x_1-y_1 plane and a,d,g,c,f,b,e of x_2-y_2 plane, respectively. In the black and white version of Figs. 15.63–15.65, they can be distinguished by the vector numbers of d-q plane mapped into x_1-y_1 and x_2-y_2 planes.

It is important to note at this stage that the harmonics of the order $14k \pm 1$, $k = 0, 1,2,3\ldots$, (1, 13, 15…) map into the d-q plane (Fig. 15.63), harmonics of the order $7k \pm 2$, $k = 1,3,5\ldots$, (5, 9, 19…) map into the x_1-y_1 plane (Fig. 15.64), and

15.4.4 Space Vector PWM Techniques for a Seven-Phase Voltage Source Inverter

This section is devoted to the development of space-vector PWM for a seven-phase voltage-source inverter. The aim of this section is to describe a set of continuous SVPWM in linear modulation range. Four different schemes are defined with the aim to reduce or eliminate the low-order harmonics in the output phase voltages. The outer large length space vectors are used to implement the SVPWM method at first followed by using four and then six active space vectors. Two methods are devised with four active vectors, eliminating certain set of low-order harmonics in each method. The six active vector applications yield sinusoidal output voltages, and the other two methods produce low-order harmonics. The analysis is done in terms of quality of output voltages and the range of applicability of each space-vector PWM methods.

Simulation results are provided to support the analytic and theoretical findings. It is demonstrated in Section 15.4.3 that there are a total of 14 distinct sectors with 25.714286 degrees ($\pi/7$ radians) spacing. The innermost space vectors in d-q plane are redundant and are therefore omitted from further discussion. This is in full compliance with observation where it is stated that only subset with maximum length vectors has to be used for any given combination of the switches that are "on" and "off" (3–4 and 4–3 in this case). The middle region space vectors correspond to two switches being "on" from upper (lower) set and five switches being "off" from lower (upper) set or vice versa and one switch being "on" from upper (lower) set and six switches being "off" from lower (upper) set or vice versa. It follows that, there are nine, 14sided regular polygons are formed by the vectors. The "*set number*" of vectors forming these polygons is already defined in Table 15.9.

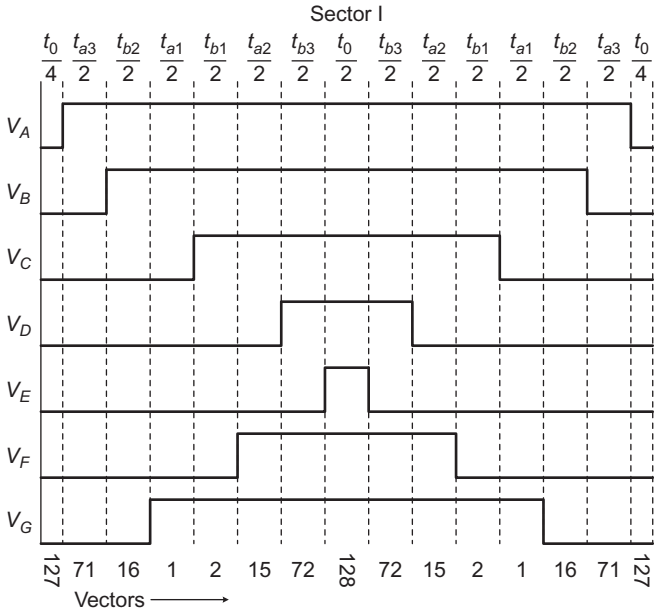

FIG. 15.66 Switching pattern and space-vector disposition for one cycle of operation.

15.4.4.1 Space Vector Pulse Width Modulation (SVPWM) With Sinusoidal Output

This section develops SVPWM schemes for a seven-phase VSI. At first, the conventional method of using only set-1 vectors is taken up followed by set-1 plus set-2 and set-1 plus set-2 plus set-6 vectors (SVPWM with sinusoidal output) schemes.

The methods discussed in the preceding sections generate low-order harmonic since they utilize either two or four active vectors in one switching period. As emphasized in [40], the number of applied active space vectors for multiphase VSI with an odd phase number should be equal to $(n-1)$, n is the number of phases of inverter, for sinusoidal output. This means that one needs to apply six active vectors in each switching period, rather than two or four for obtaining sinusoidal output. Moreover, the dwell time of each vector should be chosen in such a way as to eliminate vectors of both x_1-y_1 and x_2-y_2 planes. Thus, six active vectors (in sector 1, active vectors no. 1, 2, 15, 16, 71, and 72 are used) and one zero vector are chosen to implement the SVPWM. The chosen vectors belong to the first, second, and sixth sets.

The switching pattern and the sequence of the space vectors for this scheme are illustrated in Fig. 15.66. It is observed from the switching pattern of Fig. 15.66 that the switching in all the phases is staggered, that is, all switches change state at different instants of time. The total number of switching in each switching period is still 28, thus preserving the requirement that each switch changes state only twice in a switching period. The selection of space vectors for other sectors is listed in Table 15.10.

The vector disposition of sector I is shown in Fig. 15.67 in all the three planes.

TABLE 15.10 Sector-wise switching sequence when the first, second, and sixth set of vectors are applied

Sector number	Sequence of vectors in operation														
I	127	71	16	1	2	15	72	128	72	15	2	1	16	71	127

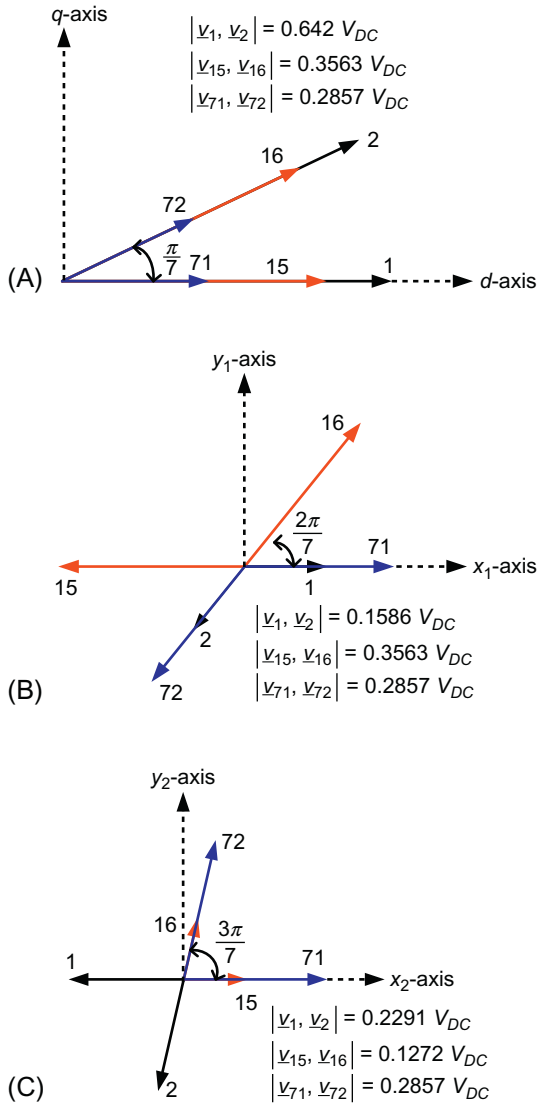

FIG. 15.67 Space-vector disposition in sector I: (A) d-q plane, (B) x_1-y_1 plane, and (C) x_2-y_2 plane.

Using equal volt-second criterion, for sector I, the following is obtained:

$$\begin{aligned} v_{d-q} &= 0.642\delta_1 + 0.5148\delta_{15} + 0.2857\delta_{71} \\ v_{x1-y1} &= 0.1586\delta_1 - 0.3563\delta_{15} + 0.2857\delta_{71} \\ v_{x2-y2} &= -0.2291\delta_1 + 0.1272\delta_{15} + 0.2857\delta_{71} \end{aligned} \tag{15.143}$$

Or the above equations can be represented as

$$\begin{bmatrix} \underline{v}_d \\ \underline{v}_{x1} \\ \underline{v}_{x2} \end{bmatrix} = [K] * \begin{bmatrix} \delta_1 \\ \delta_{15} \\ \delta_{71} \end{bmatrix}$$
$$\begin{bmatrix} \underline{v}_q \\ \underline{v}_{y1} \\ \underline{v}_{y2} \end{bmatrix} = [K] * \begin{bmatrix} \delta_2 \\ \delta_{16} \\ \delta_{72} \end{bmatrix}$$

where

$$[K] = \begin{bmatrix} 0.642 & 0.5148 & 0.2857 \\ 0.15686 & -0.3563 & 0.2857 \\ -0.2291 & 0.1272 & 0.2857 \end{bmatrix}$$

and δ_1, δ_{15}, δ_{71}, δ_2, δ_{16}, and δ_{72} are duty cycles of vector numbers 1, 15, 71, 2, 16, and 72, respectively; their coefficiants are the respective magnitudes of the vectors and negative sign showing the opposite to normal direction.

Since [K] is nonsingular matrix, its inverse is existing (det $[K] = -0.1634$). Therefore, expressions for duty cycles can be written as

$$\begin{bmatrix} \delta_1 \\ \delta_{15} \\ \delta_{71} \end{bmatrix} = [K]^{-1} * \begin{bmatrix} \underline{v}_d \\ \underline{v}_{x1} \\ \underline{v}_{x2} \end{bmatrix}$$
$$\begin{bmatrix} \delta_2 \\ \delta_{16} \\ \delta_{72} \end{bmatrix} = [K]^{-1} * \begin{bmatrix} \underline{v}_q \\ \underline{v}_{y1} \\ \underline{v}_{y2} \end{bmatrix} \tag{15.144}$$

where $[K]^{-1} = \begin{bmatrix} 0.8455 & 0.6792 & -1.5248 \\ 0.6792 & -1.5248 & 0.8455 \\ 0.3754 & 1.2209 & 1.9002 \end{bmatrix}$

Solving for δ_1, δ_{15}, δ_{71}, δ_2, δ_{16}, and δ_{72} by assuming $\underline{v}_{x1} = \underline{v}_{x2} = \underline{v}_{y1} = \underline{v}_{y2} = 0$, from (15.144), one gets

$$\begin{bmatrix} \delta_1 \\ \delta_{15} \\ \delta_{71} \end{bmatrix} = \underline{v}_d * \begin{bmatrix} 0.8455 \\ 0.6792 \\ 0.3754 \end{bmatrix}$$
$$\begin{bmatrix} \delta_2 \\ \delta_{16} \\ \delta_{72} \end{bmatrix} = \underline{v}_q * \begin{bmatrix} 0.8455 \\ 0.6792 \\ 0.3754 \end{bmatrix} \tag{15.145}$$

Expression for duty cycle of zero is given as

$$\delta_0 = 1 - (\delta_1 + \delta_{15} + \delta_{71} + \delta_2 + \delta_{16} + \delta_{72}) \tag{15.146}$$

Since $\delta_0 \geq 0$, therefore,

$$(\delta_1 + \delta_{15} + \delta_{71} + \delta_2 + \delta_{16} + \delta_{72}) \leq 1 \tag{15.147}$$

Subtituting the values of duty cycles from (15.145) in (15.147), one gets

$$\underline{v}_d + \underline{v}_q = 0.526288$$

Hence,

$$\left|v_s^*\right|_{\max} = \left|\underline{v}_d + \underline{v}_q\right| \cos\left(\frac{\pi}{14}\right) = 0.513 \tag{15.148}$$

where δ_1, δ_{15}, and δ_{71} are duty cycles and suffixes denote the vector numbers; their coefficiants are their respective

magnitudes and negative sign showing their directions that are opposite to normal direction. Solving Eq. (15.143) for δ_1, δ_{15}, and δ_{71} by assuming $v_{d-q} = 0.513$ p.u. (maxium achievable output voltage) and v_{x1-y1} and v_{x2-y2} equal to zero, one gets $\delta_1 = 0.43338$, $\delta_{15} = 0.3484$, and $\delta_{71} = 0.1926$. Same duty-cycles can be applied for vector numbers 2, 16, and 72, respectively.

The time of application of zero space vectors is now given as $t_0 = t_s - t_{a1} - t_{a2} - t_{a3} - t_{b1} - t_{b2} - t_{b3}$ where t_{a1}, t_{a2}, and t_{a3} are timings of vector number 1, 15, and 71, respectively, and t_{b1}, t_{b2}, and t_{b3} are timings of vector number 2, 16, and 72, respectively.

Once again, the same procedure as that of previous section can be adopted to determine the range of applicibility of proposed method. It is seen that the maximum available output voltage with this SVPWM method is $0.513 V_{dc}$. The simulation is done to obtain the maximum acheivable output value (0.513 p.u. peak), with the commanded input equal to 0.6259 p.u., thus ensuring the equality of the fundamental output magnitude and the reference magnitude. The other simulation conditions are identical to those in application of large medium vectors. The filtered phase voltages are shown in Fig. 15.68 along with the harmonic spectrum for maximum achievable fundamental voltage shown in Fig. 15.69.

It is seen from Fig. 15.69 that the spectrum contains fundamental (0.363551 p.u. rms or 0.514 p.u. peak, 50 Hz) component and harmonic only at multiple of switching frequency and low-order harmonics are completely eliminated. The ouptut is sinusoidal because of the fact that the proportion of time of application of the chosen space vectors is such that it cancels all the undesirable x_1-y_1 and x_2-y_2 components (as can be seen from Fig. 15.67). It is to be noted here that for lower values of the input reference phase voltage, the output phase voltages preserve the shape, while there will be a correponding reduction in amplitude.

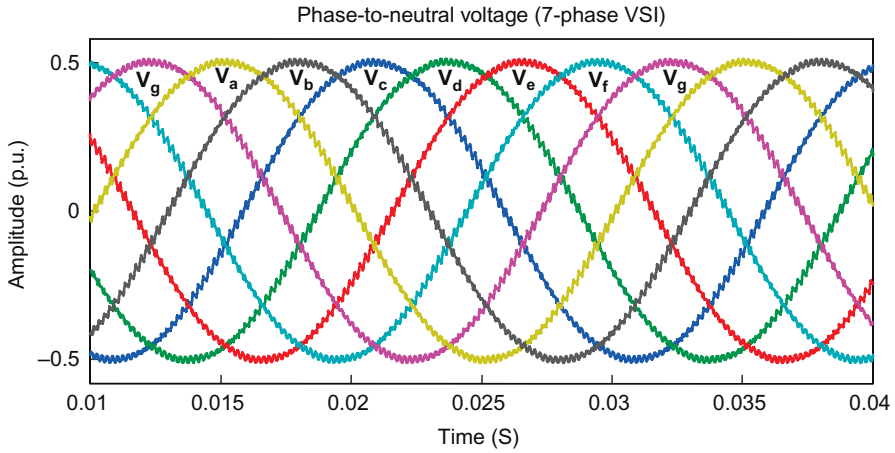

FIG. 15.68 Output filtered phase voltage of VSI for the maximum achievable output fundamental voltage (82.14% of the one obtainable with set-1 vectors only).

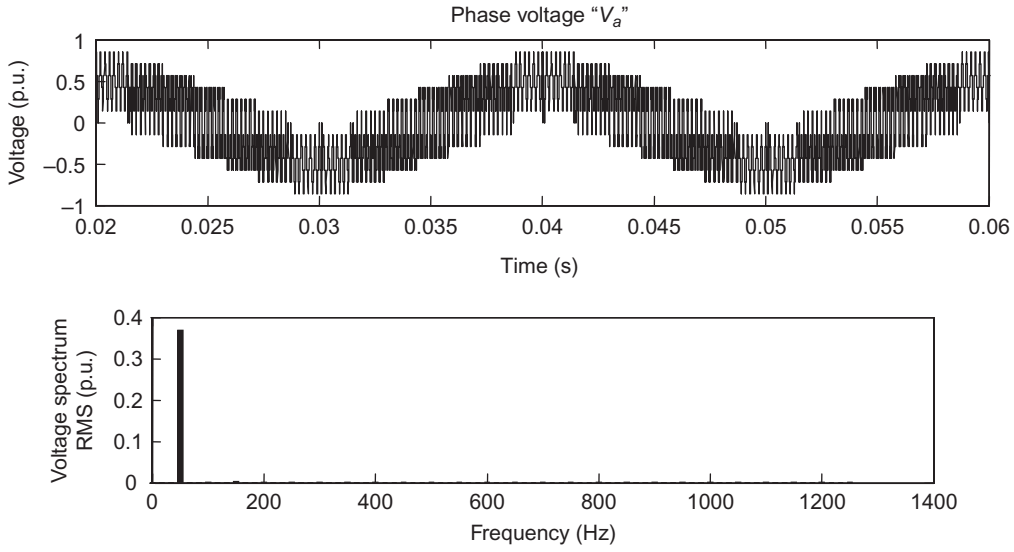

FIG. 15.69 Time-domain and frequency-domain phase "a" voltage waveform for maximum output 0.513 p.u.

15.4.4.2 Summary

Section 15.4.1 develops a space-vector model of a five-phase voltage-source inverter, and it is shown that two sets of space vectors exist, namely, *d-q* and *x-y*. The second set of space vectors termed here as *x-y* space is essentially third harmonic of the space vector in *d-q* plane. Altogether, there exist 32 space vectors out of which 30 are active and 2 are zero vectors. Complete mapping of the space vectors are provided in Section 15.4.1. Step operation of the inverter is elaborated in terms of different conduction mode, that is, 180 degrees is taken up as conduction angle. Fourier analysis is presented in terms of analytic expressions, and simulation results are provided to support the analytic expressions.

Carrier-based PWM and space-vector PWM schemes for a five-phase VSI are analyzed and compared using analytic, simulation and experimental approach. Relationship between modulation signal (fundamental and zero-sequence signal) and space vector is established, which indicates a transformation between arbitrary carrier-based PWM and space-vector modulation. A direct relationship is formulated between line-to-line voltage and space vector. It is found that the line-to-line voltage is determined by only active vectors and is independent of zero vectors. Relationship between modulation signals and space-vector sectors is identified. Analytic expressions of distribution of zero-vector application times for sinusoidal, fifth-harmonic injection, and triangular zero-sequence injection are determined. Equivalence between switching pattern of space-vector PWM and carrier type is highlighted. Performance of modulator in terms of THD of output phase voltages is determined for triangular and saw-tooth carrier signals, and the poor performance of saw-tooth carrier is indicated.

Four different space-vector PWM schemes for a seven-phase voltage-source inverter are described. At first, the conventional technique of using the largest set of space vectors is extended to a seven-phase inverter. This technique provides maximum DC bus utilization (0.6259), but the output phase voltages are distorted with significant amount of low-order harmonics especially third and fifth. These harmonics are due to free flow of x_1-y_1 and x_2-y_2 plane vectors. The second proposed method cancels the x_1-y_1 plane space vectors, and thus, the low-order harmonic more than three is eliminated in the output phase voltage waveform. Third method is investigated that eliminates vectors of x_2-y_2 plane. The modulation index is the same for the second and third methods with the elimination of different set of harmonics. The DC bus utilization is intermediate. The last method cancels all the space vectors x_1-y_1 and x_2-y_2 planes, thus providing a sinusoidal output voltage with least DC bus utilization. The experimental setup and the results are also provided.

15.5 Multiphase AC-AC Converter

15.5.1 Introduction

AC-AC converter refers to a topology of converters in which the amplitude, frequency, and phase of the AC supply can be altered according to the requirement of the load without employing reactive DC link in between. As discussed in Chapter 14, polyphase AC-AC converters can be classified as naturally commutated cycloconverters (NCC) and forced commutated cycloconverters (FCC). FCCs when implemented for low- and medium-power drives by employing high switching semiconductor bidirectional switches result in what is commonly known as *matrix converter* (MC). This section deals with the multiphase matrix converters (with phase numbers more than three) and the theory that pertains to it. It is observed that as number of phases increase, the number of vectors to be dealt with in space-vector modulation-based techniques is quite large. For an $m \times n$ MC, the *useful* number of states is m^n [4]. Thus, for a 3×7 MC, 2187 vectors are to be handled. Other way is to resort to classical methods in which output target voltages are defined and friendly harmonics are added to the target phase voltages such that the sinusoidal nature of line voltages are not altered. These target voltages are then fabricated from the input side voltages such that the average in one time sample follows the target voltage sample.

Multiphase matrix converters (MPMC) (Fig. 15.70) can be broadly classified into direct multiphase matrix converters (DMMC) and indirect multiphase matrix converters (IMMC). Although the maximum output voltage achievable is the same for both, the advantage with the indirect multiphase matrix converters is that the established modulation strategies employed for controlled rectifiers and inverters are readily applicable. In this section, the target is to present the theory on DMMC. The bidirectional switches that are employed for the multiphase matrix converters are the same as employed for conventional 3×3 matrix converter. Although the work on MPMCs is still in research domain and a statement of encouragement can be given to young researchers, possible applications of MPMCs can be wind energy systems (WES) employing multiphase generator sets, or multiphase motors can be interfaced with the existing three-phase grid using MPMCs.

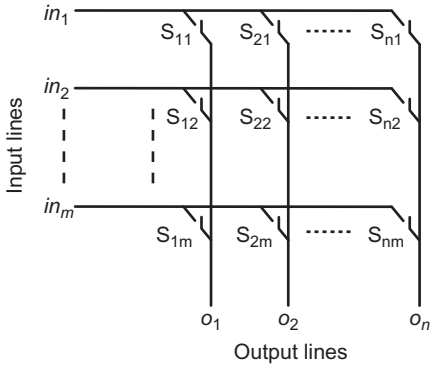

FIG. 15.70 DMMC with m input lines and n input lines.

15.5.2 Brief Review

A time line of research in the field of MPMC is shown in Fig. 15.71. The first theory addressing MPMC for odd number of input and output phases was given way back in 1989 [42]. The theory was recently extended to all configurations in [12]. This paper also extends the Venturini method to $3 \times n$ case, where n can be even or odd. Further, it also presents a simplified modulation strategy for MPMC for any number of phases. The first work on the modulation strategy of MPMC was reported in [18]. In this work, the authors use a continuous carrier and the predetermined duty ratio signals to directly generate the gating signals. This explains the origin of the name, that is, the "direct-duty-ratio-based PWM." A duty ratio is calculated for each switch, and since this applies to each output phase independently, it can be used to supply multiphase loads. The input number of phases is restricted to three since the modulation requires identification of the values of the input voltages as the maximum, medium, and minimum. Another approach applied on 3×9 MC is shown by the same authors in [16], named as carrier-based PWM scheme. Venturini method is also explored for 3×5 MC in [11,43]. Space-vector approach is the most explored approach and is discussed for various configurations in [17,44–47]. Multiphase open-end loads can also be supplied through dual MPMCs and are practically assessed in [48,49]. A 3×5 MC is discussed in [50], in which a least number of commutations are employed in one time sample. This leads to the reduction in common-mode voltage. IMMC has recently received commendable attention in [51,52]. The former paper gives carrier-based approach for a 3×5 MC that can also be realized employing space-vector approach. The later one discussed space-vector-based approach for a 3×5 MC in the overmodulation range and achieves a VTR of 0.923, which otherwise is 0.7886.

15.5.3 Defining the Voltage Transfer Ratio

All modulation strategies whether scalar or space-vector-based require the understanding of maximum achievable output voltage, that is, the maximum voltage transfer ratio (VTR_{max}) and its implementation. In scalar methods, the output reference voltages are maneuvered by the addition of friendly harmonics in order to achieve VTR_{max}. For this, a detailed understanding of how to manipulate the sinusoids is required. Thus, in this section, the theory of VTR_{max} that is achievable in an MPMC is discussed, and expressions for all the possible cases are derived. The approach will be general for any number of input and output phases until and unless specified. Illustrations are mainly done for 3×5 MC.

15.5.3.1 The Unutilized Region

Consider initially, an $m \times 1$ converter. The m-phase input voltage set is defined as

$$\begin{aligned} \underline{v}_{in}(t) &= [v_{in_1}(t), v_{in_2}(t), \ldots, v_{in_m}(t)] \\ &= V_{in}\left\{ \cos\left(\omega_{in} t + (i-1)\frac{2\pi}{m}\right)\right\}_{i=1}^{m} \end{aligned} \tag{15.149}$$

Let the duty cycles for which the output is connected to the inputs through switches S_1, S_2,…,S_m be

$$[M(t)] = [M_1(t), M_2(t), \ldots, M_m(t)] \tag{15.150}$$

The actual output voltage (w.r.t. input neutral) is obtained as

$$v_o(t) = [M(t)] \cdot \underline{v}_{in}^{T}(t) \tag{15.151}$$

The duty cycle of each switch is such calculated that in one time sample, the average of the actual output voltages follows the reference voltage. Thus, for all arbitrary output frequencies, the VTR for a three-input system can have a maximum reach up to 0.5. Generalizing this for multiple input phases, the VTR_{max} is given as

$$V_o \leq \cos\left(\frac{\pi}{m}\right) \tag{15.152}$$

This leaves a region of $1 - \cos(\pi/m)$ unutilized. This region decreases with the increase in the number of input lines. The utilized and unutilized regions are shown for three-phase input case in Fig. 15.72.

For five-phase input set, according to (15.151), approximately 19.1% of the input voltage space still remains unutilized.

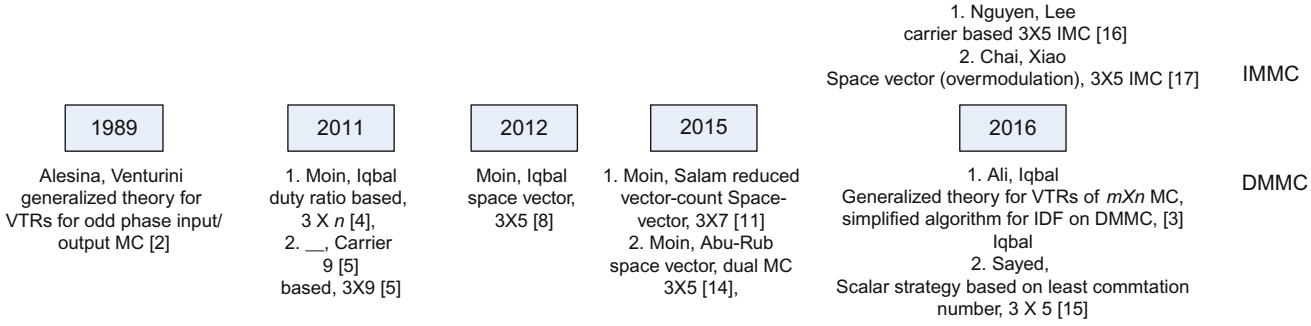

FIG. 15.71 Year-wise development of MPMC.

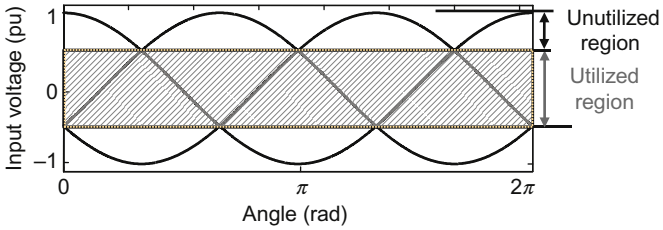

FIG. 15.72 Region (shaded) in three-phase input MC where output-voltage references are defined.

Now, consider an MPMC whose n output reference voltage set with respect to input neutral is expressed as

$$\begin{aligned}\underline{v}_o(t) &= [v_{o_1}(t), v_{o_2}(t), \ldots, v_{o_m}(t)] \\ &= V_o \left\{ \cos\left(\omega_o t + (j-1)\frac{2\pi}{n}\right) \right\}_{j=1}^{n} \end{aligned} \tag{15.153}$$

where V_o is limited by (15.152). A periodic function is such added to (15.152) that the amplitude of the output reference phase voltages and thus the line voltages increases, line voltages retain their sinusoidal nature, and the phase difference between voltages do not change. Let this function be $f_h(t)$. As this function is common to all the reference output voltages given in (15.5.5), the new output-voltage vector is expressed as

$$\begin{aligned}\underline{v}_o(t) &= [v_{o_1}(t), v_{o_2}(t), \ldots, v_{o_n}(t)] \\ &= \left\{ V_o \cos\left(\omega_o t + (j-1)\frac{2\pi}{n}\right) + f_h(t) \right\}_{j=1}^{n} \end{aligned} \tag{15.154}$$

Maximum utilizable region

After acknowledging the fact that there is space in which the output phase voltages can expand, it is desirable to know maximum output-voltage level attainable. Before addressing the issue, terms pertaining to the discussion ahead are described. These terms are exhibited in Fig. 15.73 as upper and lower bounds of input voltage set and upper and lower bounds of output-voltage set (v_{iu}, v_{il}, v_{ou}, and v_{ol}, respectively). It is seen in Fig. 15.73 that at every instant of time

$$v_{il}(t) \le v_{ol}(t) \le v_{ou}(t) \le v_{iu}(t) \tag{15.155}$$

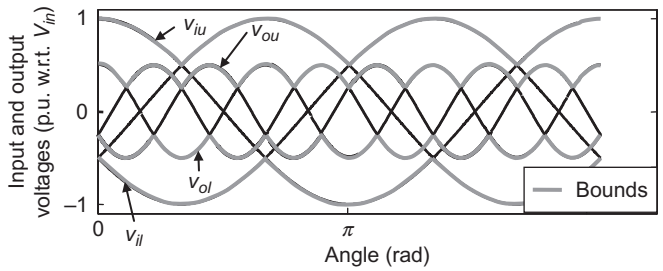

FIG. 15.73 Bounds of input and output voltages ($f_o = 3f_{in}$).

Thus, the input voltage set creates an envelope in which the output target voltage has to remain. Also, as $f_h(t)$ is a common term, the difference between $v_{ou}(t)$ and $v_{ol}(t)$ does not contain $f_h(t)$. The maximum output voltage is attained when the minima of input voltage range coincide with the maxima of output-voltage range. If the maxima of the output-voltage range are more than the minima of the input voltage range, the condition of over modulation occurs. This condition is mathematically expressed as

$$\min_{0 \le \omega_{in} t \le 2\pi} \{v_{iu}(t) - v_{il}(t)\} = \max_{0 \le \omega_o t \le 2\pi} \{v_{ou}(t) - v_{ol}(t)\} \tag{15.156}$$

Next step is to find out how the waves are optimized. The conditions differ for odd and even number of phases. The analysis of both waves is shown one by one subsequently. The analysis given below is done on a set of phases, *ignoring the input/output terminology*.

The region of 0 to 2π for x odd phases is divided into $2x$ sectors. Six sectors of three-phase set are shown in Fig. 15.74. The difference of the upper limit and lower limit generates the same wave in each sector exhibited by $v_u(t) - v_l(t)$ with the same min$\{v_u(t) - v_l(t)\}$ and max$\{v_u(t) - v_l(t)\}$ values. According to the sequence of phases in (15.153), the voltage that defines $v_u(t)$ is the first phase and $v_l(t)$ is defined by the $\left(\frac{x+1}{2}\right)^{\text{th}}$ phase:

$$\begin{aligned} v_1 - v_{\frac{x+1}{2}} &= V\left\{ \cos\omega t - \cos\left(\omega t + \left(\frac{x+1}{2} - 1\right)\frac{2\pi}{x}\right) \right\} \\ &= V\left\{ \cos\omega t - \cos\left(\omega t + \frac{(x-1)\pi}{x}\right) \right\} \end{aligned} \tag{15.157}$$

Now, the minimum value occurs at $\omega t = 0$; thus,

$$\min\left\{ v_1 - v_{\frac{x+1}{2}} \right\} = V\left\{ 1 - \cos\left(\frac{(x-1)\pi}{x}\right) \right\} \tag{15.158}$$

And as x is odd, $x-1$ is even, thus, $\cos\left(\frac{(x-1)\pi}{x}\right) = -\cos\frac{\pi}{x}$, and so,

$$\min\left\{ v_1 - v_{\frac{x+1}{2}} \right\} = V\left\{ 1 + \cos\left(\frac{\pi}{x}\right) \right\} = \min_{0 \le \omega t \le 2\pi} \{v_u(t) - v_l(t)\} \tag{15.159}$$

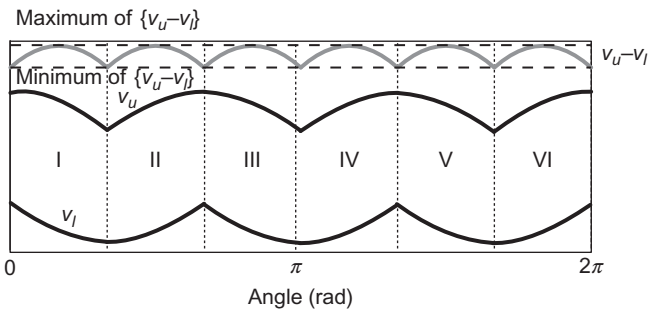

FIG. 15.74 Sectors for odd number of phases (three-phase set).

Now, the $\max\{v_u(t)-v_l(t)\}$ occurs at $\pi/2x$. Thus,

$$\max\left\{v_1 - v_{\frac{x+1}{2}}\right\} = 2V\cos\left(\frac{\pi}{2x}\right) = \max_{0\le\omega t\le 2\pi}\{v_u(t)-v_l(t)\} \tag{15.160}$$

Now, particularization of (15.158) and (15.159) in terms of m inputs and n outputs and substitution in (15.155) results in $\text{VTR}_{\max}$ as

$$\frac{V_o}{V_{in}} = \frac{1+\cos(\pi/m)}{2\cos(\pi/2n)} \tag{15.161}$$

Now, if the analysis is done for even-phase set in similar fashion as above, x-phase set is furcated into x sectors, and this is exhibited for six-phase set in Fig. 15.75. In the first sector, $v_u(t)$ is defined by the first phase, and $v_l(t)$ is defined by $v_{\frac{x+2}{2}}$. This leads to

$$v_1 - v_{\frac{x+2}{2}} = 2V\cos(\omega t) \tag{15.162}$$

The $\max\{v_u(t)-v_l(t)\}$ in this case in the first sector occurs at $\omega t = 2\pi/x$ and the $\min\{v_u(t)-v_l(t)\}$ is at $\omega t = \pi/x$. Thus,

$$\max\left\{v_1 - v_{\frac{x+2}{2}}\right\} = 2V = \max_{0\le\omega t\le 2\pi}\{v_u(t)-v_l(t)\} \tag{15.163}$$

and

$$\min\left\{v_1 - v_{\frac{x+2}{2}}\right\} = 2V\cos\pi/x = \min_{0\le\omega t\le 2\pi}\{v_u(t)-v_l(t)\} \tag{15.164}$$

Thus, if the analysis is extended to MC having both even input and output sets, then substituting (15.162) and (15.163) in (15.155) will result in

$$\frac{V_o}{V_{in}} = \cos\frac{\pi}{m} \tag{15.165}$$

MC having odd input phase set and even output phase set, substituting (15.158) and (15.162) in (15.155) results in

$$\frac{V_o}{V_{in}} = \frac{1}{2}\cdot\left(1+\cos\frac{\pi}{m}\right) \tag{15.166}$$

For a 3×6 converter, $V_o = 0.75V_{in}$.

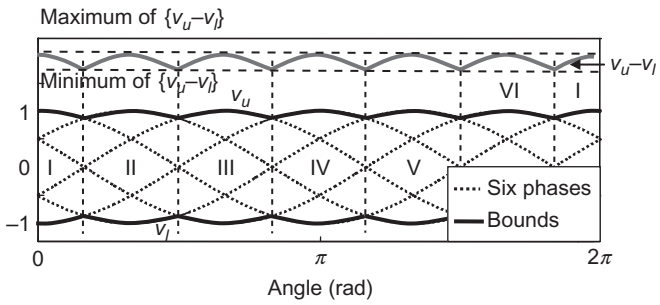

FIG. 15.75 Sectors for even number of phases (six-phase set).

Lastly, if MC has even input phase set and odd output phase set, then employing (15.159) and (15.163) in (15.155), $\text{VTR}_{\max}$ is expressed as

$$\frac{V_o}{V_{in}} = \frac{\cos(\pi/m)}{\cos(\pi/2n)} \tag{15.167}$$

For a 6×3 converter $V_o = V_{in}$. Hence, unity VTR is achievable in a six-phase input and three-phase output MC. The $\text{VTR}_{\max}$ for various configurations of MCs are shown in Table 15.11.

15.5.3.2 Target Output Voltages

After analyzing the maximum output voltage achievable, it is necessary for one to derive the derivation of the expression for $f_h(t)$ described in (15.153). This function depends on input and output frequencies. Analyzing Fig. 15.75, it is easy to realize that *odd phase can only be manipulated*. This is because the occurrence of the $\min\{v_{ul}\}$ and the $\max\{v_{ul}\}$ is at different time instances. This aspect is beneficial in defining a periodic function such that the $\min\{v_{ul}\}$ is pulled up and the $\max\{v_{ul}\}$ is pulled down, as exhibited for three-phase set in Fig. 15.76. On the contrary, the even-phase set is unalterable as the occurrence of the above stated condition occurs at the same time instant and, thus, cannot be pulled up or down employing a periodic function and hence extra region cannot be generated. Considering these facts, first of all, synthesis is done for $f_h(t)$ for the case when both input and output phase set is odd and for illustration 3×5 MC is considered. As both the voltage sets are to be optimized, the harmonic voltage, $f_h(t)$, contains a term that depends on input frequency and the other that depends

TABLE 15.11 Maximum voltage transfer ratios for various configurations of MPMC

Outputs→	3	4	5	6	7	8	9
Inputs↓							
3	0.866	0.750	0.788	0.750	0.769	0.750	0.762
4	0.816	0.707	0.743	0.707	0.750	0.707	0.718
5	1.044	0.904	0.951	0.905	0.928	0.904	0.918

8	1.067	0.924	0.971	0.924	0.948	0.924	0.938
9	1.120	0.970	1.020	0.970	0.995	0.970	0.985

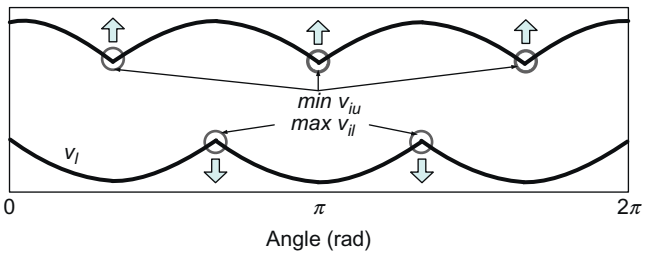

FIG. 15.76 Illustration of $\min\{v_{iu}\}$ and $\max\{v_{iu}\}$for odd number of phases (three-phase set).

on output frequency. Hence, $f_h(t)$ is written as $f_h(t) = f_{h_{in}}(t) + f_{h_o}(t)$, where $f_{h_{in}}(t)$ and $f_{h_o}(t)$ are optimizing functions for input and output voltages, respectively.

15.5.3.3 Input Voltage Optimization

As stated, $\min\{v_{iu}\}$ and $\max\{v_{il}\}$ are at different time instances, as shown for the three-phase set in Fig. 15.76. Therefore, the difference between upper and lower limit is not symmetrical, and thus, optimization is needed so that symmetrical output waveforms are developed. Clamping up of $\max\{v_{il}\}$ and clamping down of $\max\{v_{il}\}$ are done and are exhibited in Fig. 15.77. This is done by superimposing a periodic function whose frequency is m times the input frequency. Now, the amplitude of this harmonic is equal to the offset by which the *points* (*encircled in* Fig. 15.76) *are displaced*. Offset for three-phase set is 0.25 p.u., as it is the maximum to which the input voltage *points* must displace. For m input phases, the offset is

$$\text{offset} = 0.5\left(1 - \cos\left(\frac{\pi}{m}\right)\right) \tag{15.168}$$

This leads to the following expression for $f_{h_{in}}(t)$:

$$f_{h_{in}}(t) = 0.5\left(1 - \cos\left(\frac{\pi}{m}\right)\right) \cdot \cos\left(m \cdot \omega_{in} t\right) \tag{15.169}$$

For three-phase input, $f_{h_{in}}(t) = 0.25\cos(3\omega_{in}t)$. When this function is added to the input voltages, changes occur as illustrated in Fig. 15.77.

It is seen that after *subtracting* $f_{h_{in}}(t)$ from the input voltages, the output voltage with $0.75V_{in}$ is accommodated instead of $0.5V_{in}$. For m-phase input set, the condition of the peak is derived as

$$V_o = (1 - \text{offset})V_{in} \tag{15.170}$$

As the input-voltage set is unalterable, the modification is done to output-voltage set by the *addition* of $f_{h_{in}}(t)$ to the reference output-voltage equations of (15.152). So, new odd output reference voltage set, with the consideration of odd input phase set is given as

$$\underline{v}_o(t) = \left\{ V_o \cos\left(\omega_o t + (j-1)\frac{2\pi}{n}\right) + 0.5\left(1 - \cos\left(\frac{\pi}{m}\right)\right) \cdot V_{in} \cdot \cos\left(m \cdot \omega_{in} t\right) \right\}_{j=1}^{n} \tag{15.171}$$

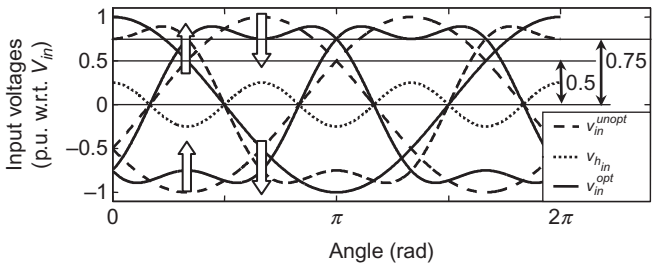

FIG. 15.77 Optimization of three-phase input voltage set.

where, V_o is given by (15.169). For 3×7 MC, (15.170) is written as

$$\underline{v}_o(t) = \left\{ V_o \cos\left(\omega_o t + (j-1)\frac{2\pi}{7}\right) + 0.25 \cdot V_{in} \cdot \cos\left(3 \cdot \omega_{in} t\right) \right\}_{j=1}^{7}$$

and $V_o = 0.75\ V_{in}$. Phase-1 voltage (v_{o1}) of the above equation is illustrated in Fig. 15.78A. It is found that v_{o1} is going beyond input voltage envelope. Thus, further optimization is needed in this case that is achieved by defining $f_{h_o}(t)$.

Output voltage optimization

A periodic function is such defined that $\min\{v_{ou}\}$ is lifted upward and $\max\{v_{ol}\}$ is dragged downward. Obviously, the frequency of this function is n times the output frequency, where f_o is the frequency of the reference output-voltage set. For five-phase output set, this must be $5f_o$. Let this function be defined as

$$f_{h_o}(t) = a \cdot \cos n\omega_o t \tag{15.172}$$

In order to calculate the amplitude of the function, consider the output voltage (v_{o1}) with the addition of (15.171) that is written as

$$u(\omega_o t) = V_o \cos\omega_o t + a \cdot \cos n\omega_o t = 0 \tag{15.173}$$

The value of the offset a is chosen such that a minimum value of $\max\{u(\omega_o t)\}$ is achieved. Also, the coefficient a is negative to clamp down $\max\{v_{ou}\}$. To find the magnitude of a, a condition that $\max\{u(\omega_o t)\}$ is located where $\cos(n\omega_o t) = 0$ is imposed. This is done as follows:

$$\frac{d}{d\omega_o t}u(\omega_o t) = -V_o \sin(\omega_o t) - a \cdot \sin(n\omega_o t) = 0 \tag{15.174}$$

Now, taking $\cos(n\omega_o t) = 0$, $\omega_o t = \pi/2n$, it is found that

$$a = -\frac{1}{n}\sin\left(\frac{\pi}{2n}\right)V_o \tag{15.175}$$

For five-phase output, $a = -0.0618V_o$. Substituting this value in (15.171),

$$f_{h_o} = -\frac{1}{n}\sin\left(\frac{\pi}{2n}\right)V_o \cos n\omega_o t \tag{15.176}$$

Now, $\max\{u(\omega_o t)\}$ occurs when $\omega_o t = \pi/2n$; therefore,

$$\max\{u(\omega_o t)\} = V_o \cos\frac{\pi}{2n} \tag{15.177}$$

This value is $0.951V_o$ for five-phase output. Fig. 15.78B exhibits the optimization of five-phase output waves. It is seen, as derived in (15.173), the maximum of the new wave occurs at $\omega_o t = \pi/10$. As the optimization of input and output phase sets is done one by one, that is, while considering the

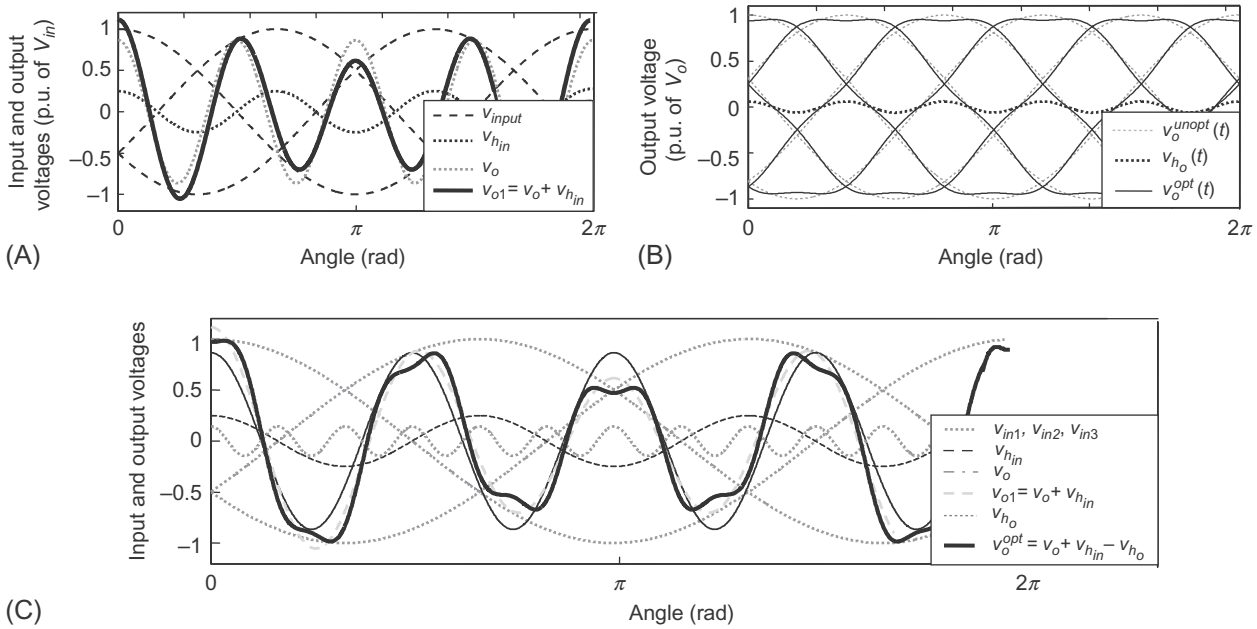

FIG. 15.78 (A) Optimization of input voltages extended to v_{o1} of five-phase set ($f_o = 4f_{in}$), (B) optimization of output voltages (five-phase set) at 50 Hz, and (C) final optimized phase voltage (v_{o1}) of a five-phase set, $f_o = 4f_{in}$.

output waves, it is considered that the input waves are unoptimized. That is why the output waves shown in Fig. 15.78B are shown with respect to V_o. Therefore, by considering input-voltage set as unoptimized and output-voltage set optimized, the condition for peak values by applying (15.176) on (15.155) is stated as

$$V_o \cos\left(\frac{\pi}{2n}\right) = 0.5 V_{in} \tag{15.178}$$

For five-phase output $V_o = 0.526 V_{in}$.

Now, considering input-voltage set and output-voltage set optimization, the peak value, by combining (15.155), (15.168), and (15.176), is expressed as

$$V_o \cos\frac{\pi}{2n} \le \left\{0.5\left(1 + \cos\left(\frac{\pi}{m}\right)\right)\right\} V_{in} \tag{15.179}$$

$$\Rightarrow V_{o_{\max}} = \frac{0.5\left(1 + \cos\left(\frac{\pi}{m}\right)\right)}{\cos\left(\frac{\pi}{2n}\right)} V_{in} \tag{15.180}$$

The $\text{VTR}_{\max}$ achievable for 3×5 MC from (15.179) is 0.78859, which is in accordance with values shown in Table 15.11.

The optimized output-voltage set is finally given by combining (15.153), (15.167), (15.168), and (15.175) as

$$\underline{v}_o(t) = \left\{ \begin{array}{l} V_o \cos\left(\omega_o t + (j-1)\frac{2\pi}{n}\right) \\ +0.5\left(1 - \cos\frac{\pi}{m}\right) \cdot V_{in} \cdot \cos\left(m \cdot \omega_{in} t\right) \ldots \\ \ldots - \frac{1}{n} \sin\left(\frac{\pi}{2n}\right) V_o \cos n\omega_o t \end{array} \right\}_{j=1}^{n} \tag{15.181}$$

where V_o is given by (15.79). Fig. 15.78C exhibits the implementation of (15.180) for 3×5 converter for output phase 1 with respect to input neutral (v_o^{opt}). All the phases of five-phase voltage set are shown in Fig. 15.79.

15.5.3.4 Other Cases

This section deals with the remaining cases of MPMCs. As discussed in previous sections, the even-phase set cannot be optimized as its $\min\{v_{iu}\}$ and $\max\{v_{il}\}$ occur at the same time, and hence, a periodic function that pushes both the points at the same instant is not feasible to obtain. Considering the configurations one by one, we have the following:

Odd-phase input and even-phase output MC

For this type of configuration of MC, only input-voltage set can be optimized, and thus, the even-phase output reference voltages are expressed as

$$\underline{v}_o(t) = \left\{ V_o \cos\left(\omega_o t + (j-1)\frac{2\pi}{n}\right) + 0.5\left(1 - \cos\left(\frac{\pi}{m}\right)\right) \cdot V_{in} \cdot \cos\left(m \cdot \omega_{in} t\right) \right\}_{j=1}^{n} \tag{15.182}$$

where $V_o = (\text{VTR}_{\max}) V_{in}$ is according to (15.169). Taking 3×6 converter for illustration, the reference output voltages of (15.181) for 3×6 MC is written as

$$\underline{v}_o(t) = \left\{ V_o \cos\left(\omega_o t + (j-1)\frac{2\pi}{n}\right) + 0.25 \cdot V_{in} \cdot \cos\left(3 \cdot \omega_{in} t\right) \right\}_{j=1}^{6}$$

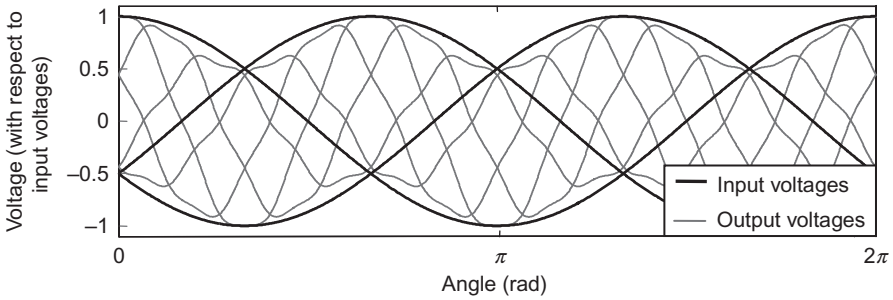

FIG. 15.79 Optimized output voltages for 3×5 matrix converter ($q=0.7886$, $f_o=3f_{in}$).

where $V_o=(\text{VTR}_{\max})V_{in}$, and $\text{VTR}_{\max}=0.75$. The optimized output voltages for this case are seen in Fig. 15.80.

Even-phase input and odd-phase output MC

When inputs are even and outputs are odd, only output-voltage optimization is done. So in accordance with (15.175), the reference output voltages are written as

$$\underline{v}_o(t)=\left\{V_o\cos\left(\omega_o t+(j-1)\frac{2\pi}{n}\right)-\frac{1}{n}\sin\left(\frac{\pi}{2n}\right)V_o\cos n\omega_o t\right\}_{j=1}^{n} \tag{15.183}$$

where $V_o=(\text{VTR}_{\max})V_{in}$ and $\text{VTR}_{\max}$ is defined by (15.166). For 6×3 MC, (15.182) is written as

$$\underline{v}_o(t)=\left\{V_o\cos\left(\omega_o t+(j-1)\frac{2\pi}{n}\right)-\frac{1}{6}V_o\cos 3\omega_o t\right\}_{j=1}^{n}$$

$V_o=qV_{in}$ and $\text{VTR}_{\max}=1$. This is illustrated in Fig. 15.81. The appreciable fact is that $\text{VTR}_{\max}$ is unity, which is 0.7321 only, if optimization is not done.

15.5.4 Simplified Modulation Strategy

This method is discussed in [12] lately. It is simple and is applicable to any MC configuration. Moreover, unity input displacement factor (IDF) is achieved. The results clearly exhibit the IDF.

Matrix operations are done to derive the modulation matrix $[M]_{n\times m}$. Considering matrix $m\times n$ converter shown in Fig. 15.70 and applying Kirchhoff's voltage law, combining with constraint equation is derived as

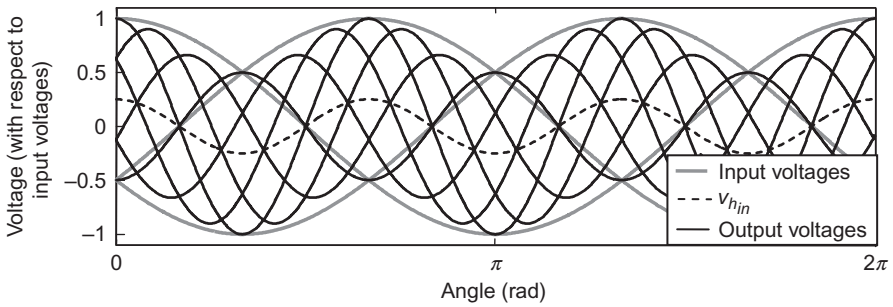

FIG. 15.80 Optimized output voltages for 3×6 matrix converter ($q=0.75$, $f_o=3f_{in}$).

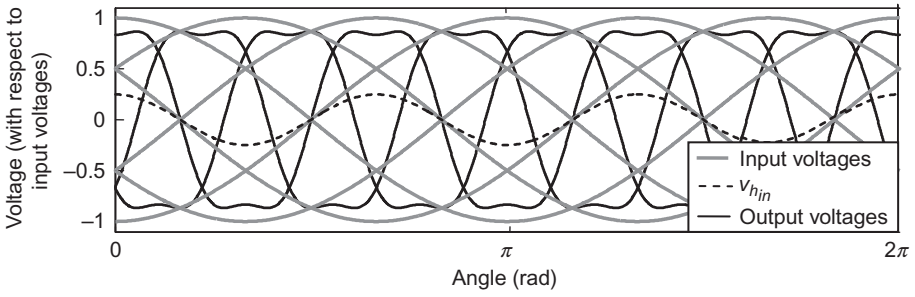

FIG. 15.81 Optimized output voltages for 6×3 matrix converter ($q=1$, $f_o=3f_{in}$).

$$\underbrace{\begin{bmatrix} v_{o1} \\ v_{o2} \\ v_{o3} \\ \vdots \\ v_{on} \\ 1 \\ 1 \\ 1 \\ \vdots \\ 1 \end{bmatrix}}_{Y}_{2n\times 1} = \underbrace{\begin{bmatrix} \overbrace{v_{in1}\ v_{in2}\ \dots\ v_{inm}}^{1}\ \overbrace{0\ 0\ \dots\ 0}^{2}\ \overbrace{0\ 0\ \dots\ 0}^{3}\ \cdots\ \overbrace{0\ 0\ \dots\ 0}^{n} \\ 0\ 0\ \dots\ 0\ v_{in1}\ v_{in2}\ \dots\ v_{inm}\ 0\ 0\ \dots\ 0\ \cdots\ 0\ 0\ \dots\ 0 \\ 0\ 0\ \dots\ 0\ 0\ 0\ \dots\ 0\ v_{in1}\ v_{in2}\ \dots\ v_{inm}\ \cdots\ 0\ 0\ \dots\ 0 \\ \vdots \\ 0\ 0\ \dots\ 0\ 0\ 0\ \dots\ 0\ 0\ 0\ \dots\ 0\ \cdots\ v_{in1}\ v_{in2}\ \dots\ v_{inm} \\ 1\ 1\ \dots\ 1\ 0\ 0\ \dots\ 0\ 0\ 0\ \dots\ 0\ \cdots\ 0\ 0\ \dots\ 0 \\ 0\ 0\ \dots\ 0\ 1\ 1\ \dots\ 1\ 0\ 0\ \dots\ 0\ \ 0\ 0\ \dots\ 0 \\ \vdots \\ 0\ 0\ \dots\ 0\ 0\ 0\ \dots\ 0\ 0\ 0\ \dots\ 0\ \ 1\ 1\ \dots\ 1 \end{bmatrix}}_{A}_{2n\times nm} \underbrace{\begin{bmatrix} [M_{11}\ M_{12}\ M_{13}\ \cdots\ M_{1m}]^T \\ [M_{21}\ M_{22}\ M_{23}\ \cdots\ M_{2m}]^T \\ [M_{31}\ M_{32}\ M_{33}\ \cdots\ M_{3m}]^T \\ \vdots \\ [M_{n1}\ M_{n2}\ M_{n3}\ \cdots\ M_{nm}]^T \end{bmatrix}}_{X}_{nm\times 1} \tag{15.184}$$

X denotes the modulation vector, and Y is the vector of desired output voltages. Now, X is derived as

$$X = A^T\left(AA^T\right)^{-1}Y \tag{15.185}$$

AA^T when solved will have terms $\sum_{i=1}^{m} v_{in_i}^2$ and $\sum_{i=1}^{m} v_{in_i}$, so, let $\sum_{i=1}^{m} v_{in_i}^2 = L$ and $\sum_{i=1}^{m} v_{in_i} = M$. Each term of X when Eq. (15.184) is solved is of similar pattern and can be shown as

$$M_{ji} = \frac{1}{(mL - M^2)}\left[v_{o_j}(mv_{in_i} - M) - Mv_{in_i} + L\right] \tag{15.186}$$

where M_{ji} is the time-based index corresponding to the switch S_{ji} that connects jth output to the ith input. The time duration for which this switch is on is calculated by multiplying this index with sampling time. Further solving by considering m balanced input phases and finally neglecting the terms with denominators with high value, solution for $m \times n$ matrix converter is written as

$$M_{ji} = \frac{1}{m}\left(1 + \frac{2v_{in_i}v_{o_j}}{V_{in}^2}\right) \tag{15.187}$$

This formula is general for all input and output cases and does not carry any discrimination of odd or even. v_{oj} is the target output voltage, which for optimum output voltages are referred to expressions derived in previous sections. Experimental prototype of 3×9 MC is shown in Fig. 15.82, and experimental results for 3×5 matrix converter obtained are shown in Fig. 15.83.

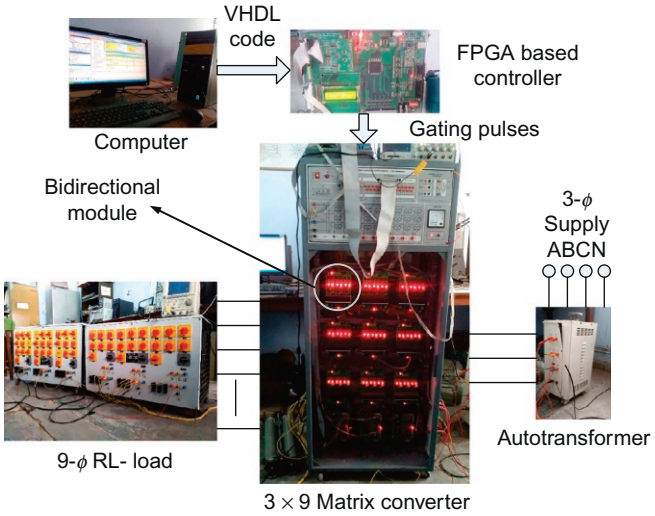

FIG. 15.82 Experimental prototype of a 3×9 MC.

15.5.5 Other Control Techniques

Other modulation strategies that are discussed for MPMCs are space-vector modulation [17], sinusoidal carrier-based modulation [16], and direct-duty-ratio-based method [18]. Novel methods like reduced commutation method [50] is also considered.

Space-vector PWM technique is highly recommended for VSIs as it increases the DC bus utilization and is easily digitally realized. This method is extended to multiphase matrix converters and is realized for 3×5 MC in [17]. In this algorithm, the input currents and output line voltages are represented on space-vector planes as shown in Fig. 15.84. The number of switching states for an $m \times n$ MC is $2^{m\times n}$. However, after applying the constraints discussed in Chapter 14, these reduce to m^n. For example, for a 3×5 MC, a total number of combinations can be 2^{15}, that is, 32,768, and with constraints, this figure reduces to 3^5, that is, 243 combinations. However, in [17], only 93 active and three zero vectors are utilized and are further categorized into 4 groups, namely, large vectors (30 vectors), medium vectors (30 vectors), small vectors (30 vectors), and zero vectors (3 vectors). Fig. 15.84 exhibits input current and output line voltage space vectors in which only large (L) and medium (M) vectors are shown. The detailed calculations of the dwelling times can be seen in [17]:

A new modulation technique is introduced in [50], where least *commutation number* is achieved. According to normal SVPWM, Venturini or the method discussed in Section 15.5.5, in one switching time cycle, the output voltage must ride on all input voltage, and the average of these samples must be equal to the reference output voltage. This leads to $(m-1) \times n$

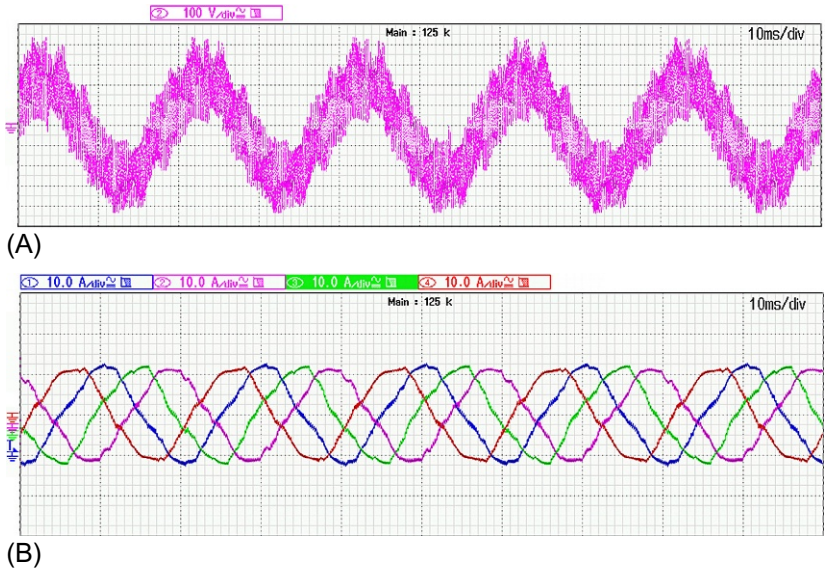

FIG. 15.83 Experimental output (A) phase voltage and (B) currents ($f_o = 50$ Hz).

commutations per switching cycle. For 3×5 MC, this will be 10 commutations and are shown in Fig. 15.85A. However, the method proposed in [50] employs only five commutations per cycle, as shown in Fig 15.85B. This provides low THD in output voltages and reduction in the stress on the switches.

15.5.6 Future Prospects

In the above sections, the main focus was on DMMC; however, IMMC is now getting considerable attention [51,52]. Research on MPMCs is still under progress, and there is a lot of scope left in this area. The possible areas of research are summarized, which in conjunction with one another may create a new area of research:

In Terms of Topology

- Z-source DMMC and IMMC
- Multiphase multilevel MC
- Multiphase multimodular matrix converters
- Sparse and ultrasparse multiphase MC

In Terms of Control

- Overmodulation in DMMC
- Enhanced SVPWM techniques
- Reactive power control
- Predictive control
- Periodic control
- Low-switching-frequency PWM

There are many more areas to be considered. Moreover, filter design, EMI considerations, and consideration of faults and unbalanced supplies for MPMCs are also the areas of research.

15.6 Multiphase DC-DC Converter

A multiphase DC-DC converter consists of two or more DC-DC converters operating in parallel at the same frequency with a proper phase shift existing between each other. The parallel operating converters has a common DC source (battery, PV panel, etc.) that feeds power to a common load. Consequently, this type of circuit configuration enables the load to be subjected to an effective frequency that is a multiple of the converter frequency (f), thereby increasing the ripple frequency of the supply harmonic current. The filter requirement is reduced compared with a single-level implementation. The multiphase DC-DC step-down converter or buck converter offers a viable solution for the voltage regulator module (VRM), which is used to power the microprocessors in computers and other applications. At present, VRMs require output voltage less than 1 V and an output current of more than 100 A [53].

Various topologies have been reported in literature with varying control strategy [53,54]. The most common topologies are as follows:

1. Multiphase interleaved buck topology
2. Multiphase synchronous buck topology
3. Multiphase tapped-inductor buck topology
4. Multiphase interleaved boost topology

15.6.1 Multiphase Interleaved Buck Topology

Fig. 15.86 shows an n phase multiphase interleaved buck converter. The individual phase ripple frequency is added to obtain an output current with high ripple frequency. The ripple cancellation of inductor current for a three phase converter

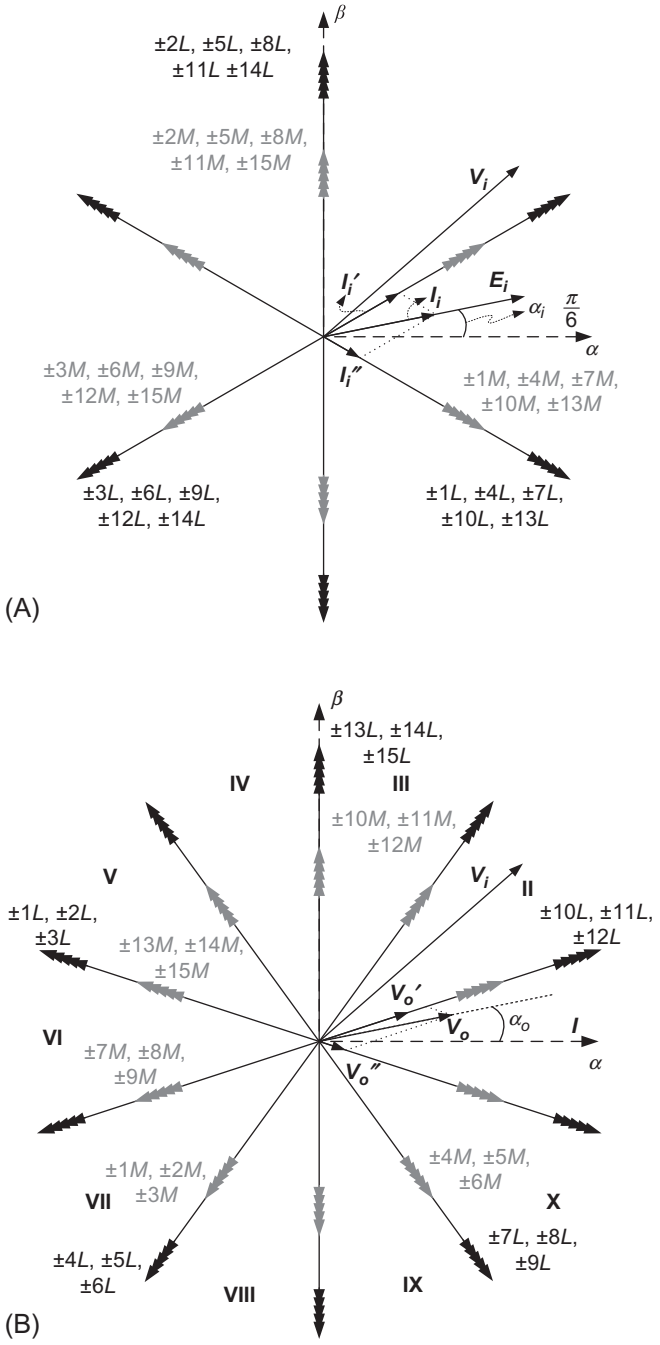

FIG. 15.84 (A) Input current and (B) output-voltage space vectors corresponding to large and medium vectors [17].

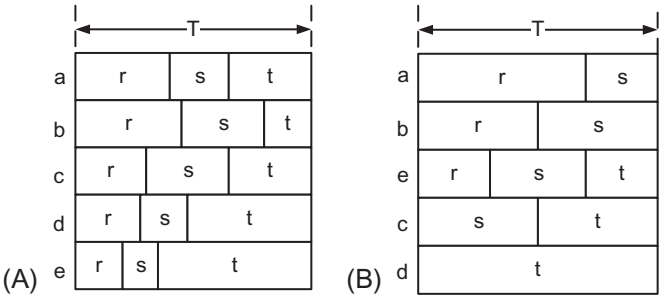

FIG. 15.85 (A) Commutation in one time cycle with conventional schemes [43] and (B) commutation in one time cycle observed in [50].

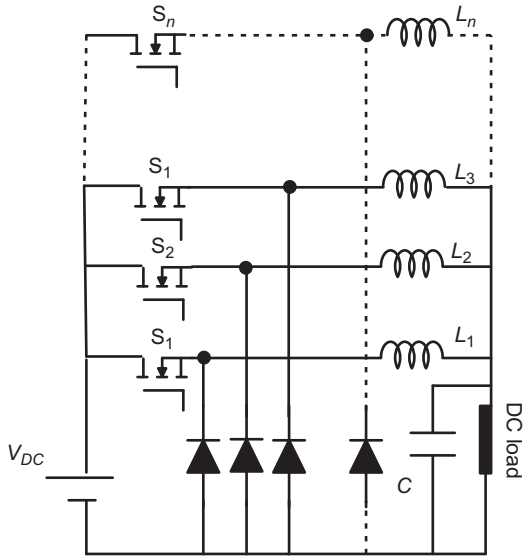

FIG. 15.86 *n*-Phase interleaved buck converter.

is shown in Fig. 15.87A. The inductor current ripples add up to give three times the ripple frequency with respect to the converter operating individually. The magnitude of output current also increases. The ripple cancellation of the output inductor current reduces the requirement of the output capacitance and consequently lowers the cost and reduces the power dissipation. The increased input ripple current frequency causes the multiphase buck converter to have reduced input ripple current magnitude (Fig. 15.87B), thereby reducing the size requirement of input capacitor and cost reduction of the overall system.

15.6.1.1 Operation of Multiphase Buck Converter

The operation of a two-phase interleaved buck converter (Fig. 15.88) has been discussed in detail. The operating principle remains the same in all higher phases of the converter. Inductors ensure that continuous current flows through the load and the resultant current through output is the sum of the current through each inductor. The frequency of ripples in the current through load is twice that of frequency of ripple current through each inductor. The sum of duty ratios of the two switches is less than or equal to 1.

15.6.1.2 Modes of Operation

Mode 1. S_1 is on and S_2 is off (T_1)

When S_1 is on, current flows through the circuit as shown in Fig. 15.89. The diode D_1 is reverse-biased because of the

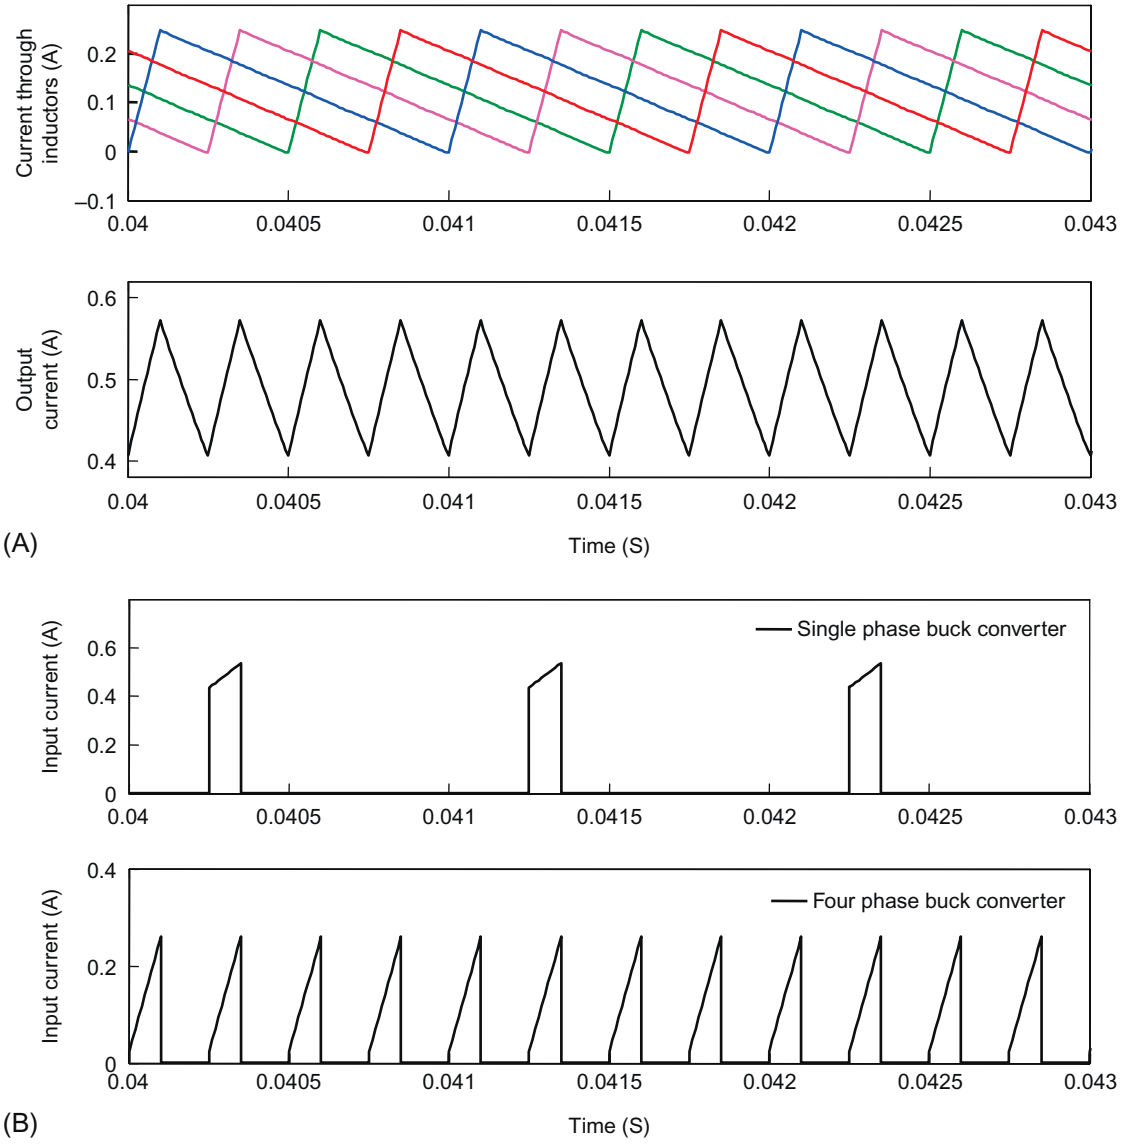

FIG. 15.87 (A) Inductor current cancelation in a four-phase converter (simulation result) and (B) comparison of single-phase and four-phase input current (simulation result).

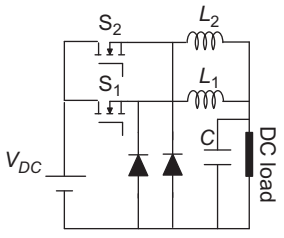

FIG. 15.88 Two-phase buck converter topology.

polarity of inductor L_1 and does not conduct, whereas the diode D_2 is forward-biased and freewheels the current through L_2. During the interval when S_1 is turned on (T_1), the current through L_1 increases while the current through L_2 decreases linearly. i_{L_1} and i_{L_2} varies according to the following relations:

$$\Delta i_{L_1} = \frac{(v_{DC} - v_o)}{L_1} T_1 \tag{15.188}$$

$$\Delta i_{L_2} = \frac{(-v_o)}{L_1} T_1 \tag{15.189}$$

where V_{DC} is the input side voltage and v_O is the output side voltage.

Mode 2. Both S_1 and S_2 are off (T_2)

The duty ratio for each phase of the converter operation is less than 0.5 which reduces for higher phase converter. During transition of switching from S_1 to S_2 both the switches will be off. In this mode, diodes D_1 and D_2 conduct. Inductors L_1 and L_2 release the energy stored in the previous modes to the

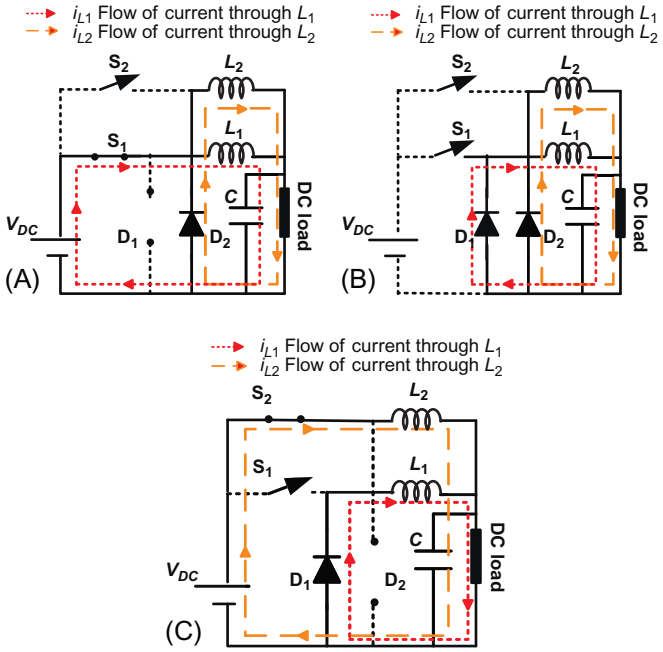

FIG. 15.89 Switching diagrams under various modes of operation for a two-phase buck converter: (A) Mode 1, (B) Mode 2, and (C) Mode 3.

load through the freewheeling diodes D_1 and D_2. The current through inductors L_1 and L_2, i.e. i_{L_1} and i_{L_2} decrease linearly. i_{L_1} and i_{L_2} varies according to the following relations:

$$\Delta i_{L_1} = \frac{(-v_o)}{L_1} T_2 \tag{15.190}$$

$$\Delta i_{L_2} = \frac{(-v_o)}{L_2} T_2 \tag{15.191}$$

Mode 3. S_2 is on and S_1 is off (T_3)

When S_2 is on, current flows in the circuit as shown in Fig. 15.89C. The diode D_2 is reverse-biased because of the polarity of inductor L_2 and does not conduct, whereas the diode D_1 is forward-biased and freewheels the current through L_1. While S_2 is on, the inductor L_2 gets charged while inductor L_1 discharges through load. i_{L_1} and i_{L_2} (currents flowing through L_1 and L_2, respectively) during T_3 are given by the equations:

$$\Delta i_{L_1} = \frac{(-v_o)}{L_1} T_3 \tag{15.192}$$

$$\Delta i_{L_2} = \frac{(v_{DC} - v_o)}{L_2} T_3 \tag{15.193}$$

State space analysis

The converter system can be expressed in state equation of the form

$$\dot{X} = AX + BU \tag{15.194}$$

$$V = C^T X \tag{15.195}$$

where the state-space variables are defined as

$$\dot{X} = \begin{bmatrix} \frac{di_{L_1}}{dt} & \frac{di_{L_2}}{dt} & \frac{dv_C}{dt} \end{bmatrix}^T$$

$$X = \begin{bmatrix} i_{L_1} & i_{L_2} & v_C \end{bmatrix}^T$$

$$U = \begin{bmatrix} v_{DC} & 0 & 0 \end{bmatrix}^T$$

V is the output-voltage vector.

15.6.1.3 Modes of Operation

Mode 1

$$\begin{bmatrix} \frac{di_{L_1}}{dt} \\ \frac{di_{L_2}}{dt} \\ \frac{dv_C}{dt} \end{bmatrix} = \begin{bmatrix} 0 & 0 & \frac{-1}{L_1} \\ 0 & 0 & 0 \\ \frac{1}{C} & 0 & \frac{-1}{RC} \end{bmatrix} \begin{bmatrix} i_{L_1} \\ i_{L_2} \\ v_C \end{bmatrix} + \begin{bmatrix} \frac{1}{L_1} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} v_{DC} \\ 0 \\ 0 \end{bmatrix} \tag{15.196}$$

$$\dot{X} = A_1 X + B_1 U$$

Mode 2

$$\begin{bmatrix} \frac{di_{L_1}}{dt} \\ \frac{di_{L_2}}{dt} \\ \frac{dv_C}{dt} \end{bmatrix} = \begin{bmatrix} 0 & 0 & \frac{-1}{L_1} \\ 0 & 0 & \frac{-1}{L_2} \\ \frac{1}{C} & \frac{1}{C} & \frac{-1}{RC} \end{bmatrix} \begin{bmatrix} i_{L_1} \\ i_{L_2} \\ v_C \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} v_{DC} \\ 0 \\ 0 \end{bmatrix} \tag{15.197}$$

$$\dot{X} = A_2 X + B_2 U$$

Mode 3

$$\begin{bmatrix} \frac{di_{L_1}}{dt} \\ \frac{di_{L_2}}{dt} \\ \frac{dv_C}{dt} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & \frac{-1}{L_2} \\ 0 & \frac{1}{C} & \frac{-1}{RC} \end{bmatrix} \begin{bmatrix} i_{L_1} \\ i_{L_2} \\ v_C \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ \frac{-1}{L_2} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} v_{DC} \\ 0 \\ 0 \end{bmatrix} \tag{15.198}$$

$$\dot{X} = A_3 X + B_3 U$$

15.6.1.4 State Space Averaging

State-space averaging can be done to replace the above sets of state-space equations by a single equation that describe the system over one switching period:

$$A = A_1 D_1 + (1 - D_1 - D_3) A_2 + A_3 D_3 \tag{15.199}$$

$$B = B_1D_1 + (1 - D_1 - D_3)B_2 + B_3D_3 \tag{15.200}$$

Assuming the duty ratio of mode 1 and 3 are same, then for mode 2, it is $1 - D$

Therefore,

$$A = (A_1 + A_3)D + (1 - 2D)A_2 \tag{15.201}$$

$$B = (B_1 + B_3)D + (1 - 2D)B_2 \tag{15.202}$$

15.6.1.5 Small Signal Analysis

In small-signal analysis, it is assumed that all variables are perturbed around steady-state operating point. Applying perturbations to above equation leads to

$$\begin{aligned}\dot{X}^- + \dot{x} = &\{(A_1 + A_3)(D + d) + 1 - 2(D + d)A_2\}\left(\bar{X} + x\right) \\ &+ \{(B_1 + B_3)(D + d) + 1 - 2(D + d)B_2\}\left(\bar{U} + u\right)\end{aligned} \tag{15.203}$$

Where average term is represented by a superscript while small signal term is represented by small letters. Neglecting the product of terms containing small signal and taking the derivative of steady-state component as zero simplify the above equation to

$$\begin{aligned}\dot{x} = &\{(A_1 + A_3)D + (1 - 2D)A_2\}x + [(B_1 + B_3)D \\ &+ (1 - 2D)B_2]u + [(A_1 + A_3 - 2A_2)X + (B_1 + B_3 - 2B_2)U]d\end{aligned} \tag{15.204}$$

Taking Laplace transform on both sides,

$$\begin{aligned}s\dot{x} = &\{(A_1 + A_3)D + (1 - 2D)A_2\}x(s) + [(B_1 + B_3)D \\ &+ (1 - 2D)B_2]u(s) + [(A_1 + A_3 - 2A_2)X \\ &+ (B_1 + B_2 - 2B_3)U]d(s)\end{aligned} \tag{15.205}$$

$$\begin{aligned}\dot{x} = &[SI - A]^{-1}\{[(B_1 + B_3)D + (1 - 2D)B_2]u(s) \\ &+ \left[M^{'}X + NU\right]d(s)\}\end{aligned} \tag{15.206}$$

where $M^{'} = (A_1 + A_3 - 2A_2)$ and $N = (B_1 + B_2 - 2B_3)$:

$$V_o(S) = C^T x(s) \tag{15.207}$$

Putting the value of Eq. (15.204) into Eq. (15.205), we have

$$\frac{v_o(s)}{v_{DC}(s)} = \frac{s(1 - D)(L_1 + L_2)}{s^3L_1L_2C + s\dfrac{L_1L_2}{R} + s(1 - D)^2(L_1 + L_2)} \tag{15.208}$$

$$\frac{v_o(s)}{d(s)} = \frac{s(1 - D)(L_1 + L_2) - s^2L_1L_2(i_{L_1} + i_{L_2})}{s^3L_1L_2C + s\dfrac{L_1L_2}{R} + s(1 - D)^2(L_1 + L_2)} \tag{15.209}$$

In the above analysis, ESR, ESL, and other parasitic parameters have been neglected. The detailed analysis including the parasitic parameters has been carried out by [55,56]. The waveform of current through the inductors and the output current for a two-phase buck converter are shown in Fig. 15.90. The frequency of ripple in output current is clearly seen to be twice compared with the single-phase counterpart.

Small signal analysis can be extended for an n phase converter. The time-interleaved control will ensure higher-frequency ripple pulses, thereby lesser requirement of filtering. Moreover, the cost and space requirement will also come down.

15.6.1.6 Discontinuous Conduction Mode

When the value of L_1 and L_2 is small, the current through load could be discontinuous. This is undesirable as the output voltage then becomes function of inductance complicating the control operation [55].

15.6.1.7 Variation of Output Current Ripple With Duty Ratio and Design Consideration

The main advantage of multiphase topology is the cancellation of ripple in the output current, which reduces the size of inductance and improves the transient response and the output capacitance requirement is minimized. The voltage tolerance criteria under varying load make multiphase buck converters working as VRMs use small inductance so that the power can be transferred quickly from the source side to the load side. However, small value of inductance causes large ripples in inductor current under steady state condition. So a compromise between the two has be taken into consideration while designing. The magnitude of inductor current ripples (considering inductance to be same in each buck converter loop) and the inductance value are related to each other by the equation:

$$\Delta i_L = \frac{d * v_{DC}(1 - d)}{L * f_s} \tag{15.210}$$

Multiphase buck converters interleave (alternate flow of current through the inductor in each of the converter cycle) the inductor currents in each converter operating in parallel, and hence drastically reduces the total ripples in the current which flows through the output capacitor. With the reduction in current ripple, the output voltage ripple is also greatly reduced. Therefore with lesser filter requirement, the transient response of the system improves. Hence, a smaller value of capacitance at the output can be used for meeting the transient requirement. Moreover, there is more space for variations in output voltage magnitude during load transient. Consequently, multiphase operation enhances the performance under load transient condition [57,58].

In multiphase converters, the current ripple cancelation effect K_i can be defined as the ratio of the magnitudes of output current ripple (Δi_O) and inductor current ripple (Δi_L). For n phase buck converter, the current ripple cancellation factor K_i is defined as [57]

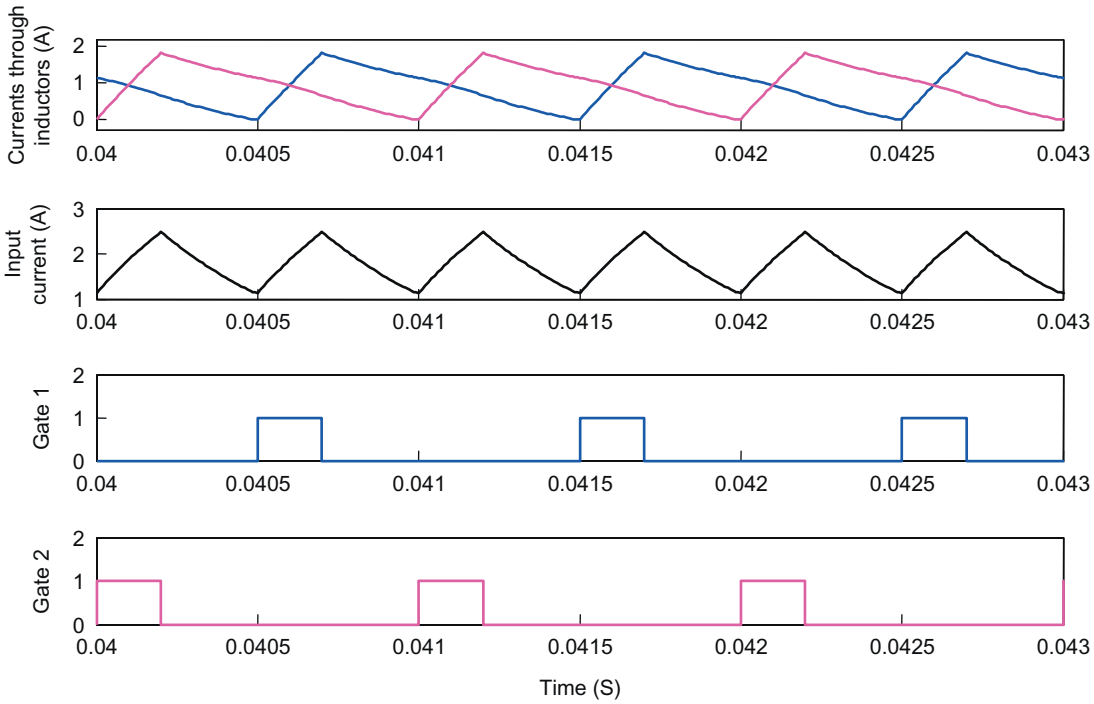

FIG. 15.90 Output current and gate pulses (simulated).

$$K_i = \frac{\Delta i_O}{\Delta i_L} = \left(1 - \frac{m}{n*d}\right)(1 + m - n*d) \tag{15.211}$$

where $m = \text{floor}\,(n*d)$, the maximum integer that does not exceed $n*d$.

For a small duty ratio, the current ripple cancellation is poor. The output current ripples increases for small duty ratios further because of the increase in the individual inductor current ripples, which can be seen from the Eq. (15.210). Substituting the Eq. (15.210) into Eq. (15.209), the output current ripples magnitude for multiphase buck converters can be derived, as follows [57]

$$\Delta i_O = \Delta i_L * K_i = \frac{d * v_{DC}(1-d)}{L * f_s} * \left(1 - \frac{m}{n*d}\right)(1 + m - n*d) \tag{15.212}$$

Fig. 15.91 shows the effect of duty ratio on the ripple of the output current for multiphase buck converters. Multiphase interleaved buck converters are basically governed by the same design equations as that of the single phase buck converter. There are n interleaved paths in a multiphase buck converter where the number of phases of the converter is represented by n. Each channel behaves as an independent buck converter. Let the output voltage and output current in a multiphase buck converter are denoted by v_o and i_o respectively. The relation of output frequency and output current of multiphase converter with one phase of multiphase buck converter is given by

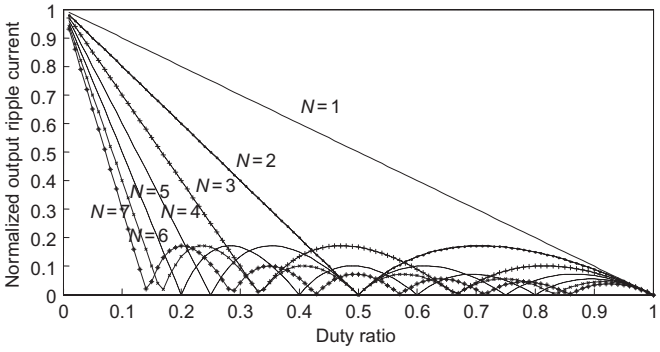

FIG. 15.91 Variation of ripple with duty ratio and phases.

$$f_O = N * f_S \tag{15.213}$$

where f_O represents is the output current ripple frequency and f_S represents the frequency of single phase ripple current. Volt second balance relationship can be used to develop the design equation for the inductor at the output.

$$V_L = L\frac{di}{dt} \tag{15.214}$$

or

$$L = V_L\frac{dt}{di} \tag{15.215}$$

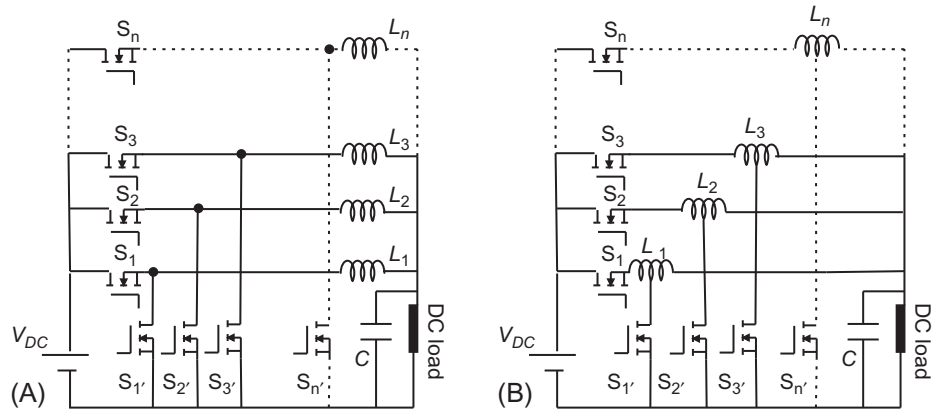

FIG. 15.92 (A) Synchronous multiphase buck converter and (B) synchronous tapped inductor multiphase buck converter.

where $di = \Delta i_L =$ the ripple current through the output inductor of each channel.

For small change in i_L we can comfortable consider $di = \Delta i_L =$ the ripple current flowing through inductor at the output of each interleaved channel. During off cycle $dt = (1-d)T_S$ where T_S represents the switching period and d represents the duty ratio of the individual switch,

Eq. (15.214) becomes

$$L = \frac{v_O(1-d)}{\Delta i_L * f_s} \tag{15.216}$$

or

$$L = \frac{d * v_{DC}(1-d)}{\Delta i_L * f_s} \tag{15.217}$$

The output voltage is kept almost constant with the selection of proper output capacitor. Equivalent series resistance (ESR) and an equivalent series inductance (ESL) are added to the output capacitor to represent a real model. At high frequency switching, ESR is dominant over ESL. So, for the purpose of analysis ESL can be neglected. The minimum capacitance for a multiphase converter can then be given by the following equation

$$C_O = \frac{\Delta i_O}{8 * f_S * \Delta v_O} \tag{15.218}$$

15.6.2 Synchronous Multiphase Buck Topology

The disadvantage of a conventional multiphase buck converter is the significant power loss during the diode conduction period, which is the product of the forward voltage drop and its current. Synchronous buck topology has a better efficiency than standard multiphase interleaved buck converter. This is obtained by replacing the diodes of multiphase buck converter by MOSFETs. Theoretical study done by [57] shows that the losses in a multiphase buck converter is more due to the forward conduction loss of the diode. The on-resistance ($R_{DS,ON}$) of MOSFET connected in place of diode is in the milliohm range during conduction hence the losses during conduction is quite less compared to its conventional counterpart thus efficiency improves.

As shown in Fig. 15.92A, a synchronous multiphase interleaved buck topology is obtained by replacing the diodes with MOSFET. Dead-times between (S_1, $S_{1'}$), (S_2, $S_{2'}$) and other switch pairs are introduced to prevent shoot-through. For a two phase synchronous converter, the current through the inductor continues to flow through internal body diode of MOSFET (S_2) during the dead time. On application of gate signal on MOSFET (S_2), the current through inductor flows through S_2. As mentioned earlier, with technological advancement there is a requirement for larger current by the processors to meet the growing diverse application demand. The multiphase synchronous buck topology has been adopted in industry to handle such high current processors. The majority of VRC for laptop processor and embedded system board are using synchronous topology today instead of conventional buck. The Intel roadmap suggests that the voltage will be reduced by 0.6 fraction with each passing generation of processor. Currently, the input supply voltage to microprocessors embedded system board is in the range of 0.8–1.6 V [58–60]. But to generate a very low output voltage from higher output voltage, the duty ratio for multiphase synchronous buck converters should be very small. This increases the losses across the switches and the overall converter efficiency reduces. So a synchronous tapped inductor multiphase buck converter topology has been proposed [57] to overcome this disadvantage. A synchronous tapped inductor multiphase buck converter is shown in Fig. 15.92B. To realize a tapped inductor buck converter, only a minor modification in the original buck converter circuit is required.

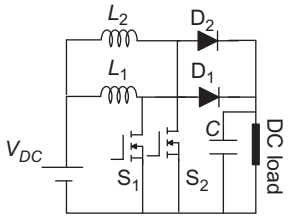

FIG. 15.93 Multiphase boost topology.

15.6.3 Multiphase Boost Converter

There is an increasing popularity for high power boost converters among power electronic designers in the industrial, automotive and telecom industries for high power application. For large power levels, efficiency becomes quite important in the power converter components. The multiphase boost converter is a viable option for such applications (Fig. 15.93). The ripple voltage and currents in both the input and output capacitors of a multiphase boost converter is very less. Therefore smaller components are required for filtering purpose. Thus, the requirement of bulky heat sinks and forced-air cooling is not there is case of multiphase boost converter [61,62]. Hence, the efficiency of such converters are quite high. The direction of power flow is different in a multiphase buck and boost converter which otherwise have same circuit topology. The input of the buck converter and the output of the boost converter are pulsating type current. On the other hand, the output of the buck converter and the input to the boost converter are continuous currents.

15.6.3.1 Modes of Operation

Mode 1

During mode 1, both the switches S_1 and S_2 are on, and the diodes D_1 and D_2 are in the off condition:

$$\frac{di_{L_1}}{dt}=\frac{V_{DC}}{L_1} \tag{15.219}$$

$$\frac{di_{L_2}}{dt}=\frac{V_{DC}}{L_2} \tag{15.220}$$

$$\frac{dv_O}{dt}=\frac{-V_O}{RC} \tag{15.221}$$

The coefficient matrix for this mode can be written as

$$A_1=\begin{bmatrix}0 & 0 & 0\\ 0 & 0 & 0\\ 0 & 0 & \frac{-1}{RC}\end{bmatrix} B_1=\begin{bmatrix}\frac{-1}{L_1}\\ \frac{-1}{L_2}\\ 0\end{bmatrix} \tag{15.222}$$

Mode 2

During mode 2, switch S_1 is in on condition, switch S_2 is in off condition, and the corresponding diodes are in the complementary switching states, that is, D_1 is in off condition and D_2 is in on condition, respectively:

$$\frac{di_{L_1}}{dt}=\frac{V_{DC}}{L_1} \tag{15.223}$$

$$\frac{di_{L_2}}{dt}=\frac{V_{DC}}{L_2}-\frac{V_O}{L_2} \tag{15.224}$$

$$\frac{dv_O}{dt}=\frac{i_{l_2}}{C}-\frac{-V_O}{RC} \tag{15.225}$$

$$A_2=\begin{bmatrix}0 & 0 & 0\\ 0 & 0 & \frac{-1}{L_2}\\ 0 & \frac{1}{C} & \frac{-1}{RC}\end{bmatrix} B_2=\begin{bmatrix}\frac{1}{L_1}\\ \frac{1}{L_2}\\ 0\end{bmatrix} \tag{15.226}$$

Mode 3

In mode 3, switch S_1 is in off condition, switch S_2 is in on condition, and the corresponding diodes D_1 and D_2 are in on and off conditions, respectively:

$$\frac{di_{L_1}}{dt}=\frac{V_{DC}}{L_1}-\frac{V_O}{L_1} \tag{15.227}$$

$$\frac{di_{L_2}}{dt}=\frac{V_S}{L_2} \tag{15.228}$$

$$\frac{dv_0}{dt}=\frac{i_{L_1}}{C}-\frac{-V_O}{RC} \tag{15.229}$$

$$A_3=\begin{bmatrix}0 & 0 & \frac{-1}{L_1}\\ 0 & 0 & 0\\ \frac{1}{C} & 0 & \frac{-1}{RC}\end{bmatrix} B_3=\begin{bmatrix}\frac{1}{L_1}\\ \frac{1}{L_2}\\ 0\end{bmatrix} \tag{15.230}$$

Mode 4

During mode 4, the semiconductor switches S_1 and S_2 are in off condition, and the diodes D_1 and D_2 are in on condition:

$$\frac{di_{L_1}}{dt}=\frac{V_{DC}}{L_1}-\frac{V_O}{L_1} \tag{15.231}$$

$$\frac{di_{L_2}}{dt}=\frac{V_{DC}}{L_2}-\frac{V_O}{L_2} \tag{15.232}$$

$$\frac{dv_O}{dt}=\frac{i_{l_1}}{c}+\frac{i_{l_2}}{c}-\frac{V_O}{RC} \tag{15.233}$$

$$A_4 = \begin{bmatrix} 0 & 0 & \frac{-1}{L_1} \\ 0 & 0 & \frac{-1}{L_2} \\ \frac{1}{C} & \frac{1}{C} & \frac{-1}{RC} \end{bmatrix} B_4 = \begin{bmatrix} \frac{1}{L_1} \\ \frac{1}{L_2} \\ 0 \end{bmatrix} \quad (15.234)$$

The coefficient matrix for the two-phase boost converter are defined as

$$[A] = A_1 d_1 + A_2 d_2 + A_3 d_3 + A_4 d_4 \quad (15.235)$$

$$[B] = B_1 d_1 + B_2 d_2 + B_3 d_3 + B_4 d_4 \quad (15.236)$$

$$[U] = V_S \quad (15.237)$$

$$d_1 + d_2 + d_3 + d_4 = 1 \quad (15.238)$$

Expressions for A_1, A_2, A_3, and A_4 are defined above.

Output equation can be written as $y(t) = [0 \;\; 0 \;\; 1] \begin{bmatrix} i_{L_1} \\ i_{L_2} \\ v_O \end{bmatrix}$

Fig. 15.94 shows switching diagram for a multiphase boost converter while Fig. 15.95 shows current through inductors and output current.

15.6.4 Coupled Inductor for Multiphase Buck

Ripple cancelation in the output or input current for buck and boost operation, respectively, is one of the major advantage of interleaving technique. But, there is reduction in total input current and output current ripple only while large ripples are still present in the individual inductor present in each interleaved converter [13]. Moreover, the large current ripples in the inductor causes large copper loss. These large conduction losses in inductors and switching losses in the switch cannot be resolved by interleaving technique. Therefore, in order to overcome this problem, multiphase interleaved buck and boost converters have coupled inductors. The equivalent inductances of the coupling inductor reduces in case of coupled inductor multiphase buck topology thereby reducing the ripple current in the coupled inductors. The transient response is not compromised. Fig. 15.96 shows a two level Coupled inductor multiphase boost converter. In Fig. 15.97, current flowing through inductors in case of coupled and uncoupled configuration has been compared.

15.6.4.1 Modes of Operation

Mode 1

During mode 1, the switches S_2 is on, and the diode D_1 is conducting:

$$v_{L_1} = L_1 \frac{di_{L_1}}{dt} + M \frac{di_{L_2}}{dt} = V_{DC} - V_O \quad (15.239)$$

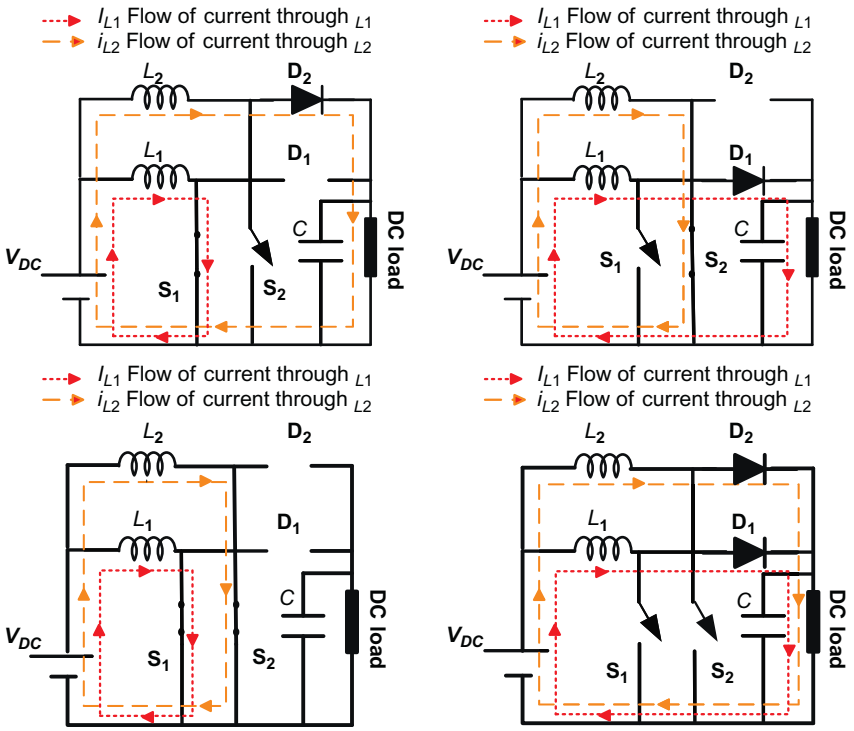

FIG. 15.94 Switching diagram for multiphase boost converter: (A) Mode 1 and Mode 2, (B) Mode 3 and Mode 4.

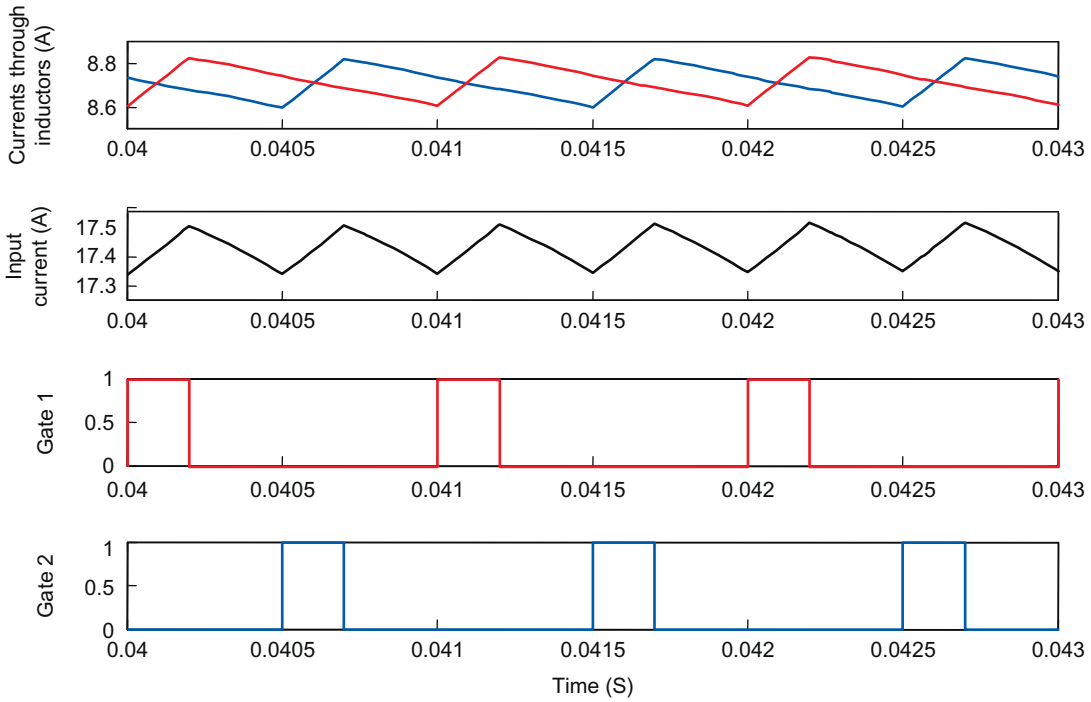

FIG. 15.95 Current through inductors and output with switching pulses.

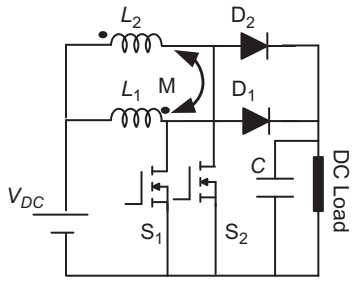

FIG. 15.96 Coupled inductor multiphase boost converter.

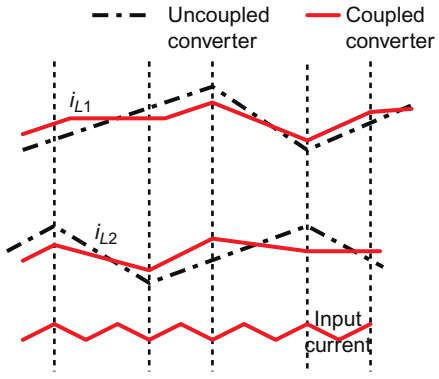

FIG. 15.97 Input current waveforms for coupled inductor multiphase buck converter.

$$v_{L_2} = L_2 \frac{di_{L_2}}{dt} + M \frac{di_{L_1}}{dt} = V_{DC} \tag{15.240}$$

In this case, inductances L_1 and L_2 are given by

$$L_{1,\text{ equiv.}} = \frac{L_1^2 - M^2}{L_1 - \frac{d}{d'}.M} \tag{15.241}$$

$$L_{2,\text{ equiv}} = \frac{L_2^2 - M^2}{L_2 - \frac{d}{d'}.M} \tag{15.242}$$

When $L_1 = L_2 = L$, equivalent inductance is

$$L_{\text{mode, 1}} = \frac{L^2 - M^2}{L - \frac{d}{d'}.M} \tag{15.243}$$

Mode 2

During mode 2, switch S_1 and switch S_2 are in off condition, and the corresponding diodes are in on condition.

In this case, the equivalent inductance is given by

$$L_{1,\text{equiv.}} = L_1 - M \tag{15.244}$$

$$L_{2,\text{equiv.}} = L_2 - M \tag{15.245}$$

When $L_1 = L_2 = L$, equivalent inductance is

$$L_{\text{mode},2} = L - M \tag{15.246}$$

Mode 3

During mode 3, switch S_1 is on, and the diode D_2 is conducting.

The equivalent inductance will be same as in mode 1.

Mode 4

During mode 4, switch S_1 and switch S_2 are in off condition, and the corresponding diodes are in on condition. The equivalent inductance will be the same as in mode 2.

The peak-to-peak current in the case of coupled and uncoupled converter topologies are given by

$$\Delta I_{ripple} = \frac{V_{DC} d}{L_{\text{mode},1} f_s} \tag{15.247}$$

$$\Delta I_{ripple} = \frac{V_{DC} d}{L f_s} \tag{15.248}$$

where f_s is the switching frequency and $L_{\text{mode},1}$ and L are inductances of coupled and uncoupled converter. Clearly, the peak variation of input current in the case of coupled inductor is less compared with uncoupled inductor topology.

15.6.5 Advantages of Multiphase DC-DC Converters

Some of the advantages associated with multiphase DC-DC converters are listed below:

- Output ripple increases in multiplicity, reducing the filter requirements
- Reduction in the size and cost of output inductor and capacitor
- Reduction in the size and cost of input capacitor
- Reduced overall loss in the circuit compared with same rated single-phase counterpart
- Ideally suited for application requiring tight current regulation like VRM
- High-power and load current application like DC motor drives

16.1 Introduction

Today, there is an increased proliferation of power electronics converters, mainly in industrial and domestic applications due to their high inherent flexibility for ensuring the power conversion management at all power levels. Unfortunately, these converters are considered to be the major sources of power quality degradation in terms of current and voltage waveform distortion and power factor degradation. Indeed, power electronics converter is characterized by a nonlinear behavior which contributes to the pollution of the main utility power supply. On the other side, since ac electric energy is the most convenient form of energy to be generated, transmitted, and distributed through the main ac power systems, the stage of power conversion is primordial to ensure the required converted forms to the consumers in industry and residence applications. Therefore, the power electronics converter is unavoidable to be as an essential part of different power supply and a flexible control device in many applications. During the last years, large electricity consumers such as electrochemical and electrometallurgical industries applied capacitors as static var compensator (SVC) to their systems to ensure an effective cost solution by minimizing the demanded charges from utility companies and to ensure the dynamic voltage stabilization support, the efficiency, and the required reliability of the supply voltages. Indeed, this solution was highly recommended due to its low-cost, its high reliability, and its simple and easy integration within the existing and new infrastructures without the necessity of adding other new network extensions. As these capacitors present low impedance in the system, they contribute remarkably in drawing harmonic currents from the power supply. It is well evident that due to the nonzero system impedance along the lines, the circulating of the harmonic currents through these lines will create distorted drop voltages that will propagate. Consequently, the voltages at the points of different users' connection will be contaminated. The contaminative harmonics can decline power quality and affect the system performance in several ways [1–15]:

(a) The line *rms* current harmonics do not deliver any real power in watts to the load that is supplied by a sine waveform voltage, resulting in inefficient use of equipment capacity (i.e., low-power factor).
(b) Harmonics will increase conductor loss and iron loss in transformers of the transmission system. Therefore, the thermal problems will be increased, and the systems transmission system efficiency will be decreased.
(c) Beside the current unbalance in three-phase system, the odd harmonics are extremely harmful, contributing to the overload of the neutral conductor.
(d) The propagation of harmonics within the power system may cause oscillations that will absolutely affect the stability of system operation.
(e) High peak harmonic currents may cause automatic relay protection devices to mistrigger.

(f) Harmonics could cause other problems such as electromagnetic interference to interrupt communication, degrading reliability of electric equipment, increasing product defective ratio, insulation failure, and audible noise.

Perhaps the greatest impact of harmonic pollution appeared in the early 1970s when SVCs were extensively used for electric arc furnaces, metal rolling mills, and other high-power appliances. The harmonic currents produced by partial conduction of SVC are odd order, which are especially harmful to three-phase power system, especially for the star connection; if the star connection point is connected to the neutral line, this line will be overloaded; otherwise, this point will be supporting nonzero voltage. Harmonics can affect operations of other devices that are connected to the same system and, in some situation, the operations of themselves that generate the harmonics.

The ever deteriorated supply environment did not become a major concern until the early 1980s when the first technical standard IEEE519-1981 with respect to harmonic control at point of common coupling (PCC) was issued [16]. The significance of issuing this standard was not only that it provided the technical reference for design engineers and manufactures but also that it opened the door of research area of harmonic reduction and power factor correction (PFC). These two main objectives are really meaning the input current shaping (ICS), although most researchers refer their work as PFC. This is why the term "PFC" is used through the whole chapter.

Stimulated by the harmonic control regulation, researchers and industry users started to develop low-cost devices and power electronic systems to reduce harmonics since it is neither economical nor necessary to eliminate the harmonics.

Research on harmonic reduction and PFC has become intensified in the early 1990s. With the rapid development in power semiconductor devices, power electronic systems have matured and expanded to new and wide application range from residential, commercial, and aerospace to military and others. Power electronic interfaces, such as switch-mode power supplies (SMPS), are now clearly superior over the traditional linear power supplies, resulting in more and more interfaces switched into power systems. While the SMPSs are highly efficient, but because of their nonlinear behavior, they draw distorted current from the line, resulting in high total harmonic distortion (THD) and low power factor (PF). To achieve a smaller output voltage ripple, practical SMPSs use a large electrolytic capacitor in the output side of the single-phase rectifier. Since the rectifier diodes conduct only when the line voltage is higher than the capacitor voltage, the power supply draws high *rms* pulsating line current. As a result, high THD and poor PF (usually less than 0.67) are present in such power systems [1,7,8,17–19].

Even though each device, individually, does not present much serious problem with the harmonic current, utility power supply condition could be deteriorated by the massive use of such systems. In recent years, declining power quality has become an important issue and continues to be recognized by government regulatory agencies. With the introduction of compulsory and more stringent technical standard such as IEC1000-3-2, more and more researchers from both industries and universities are focusing in the area of harmonic reduction and PFC, resulting in numerous circuit topologies and control strategies. Generally, the solution for harmonic reduction and PFC are classified into passive approach and active approach. The passive approach offers the advantages of high reliability, high-power-handling capability, and easy to design and maintain. However, the operation of passive compensation system is strongly dependent on the power system and does not achieve high PF. While the passive approach can be still the best choice in many high-power applications, the active approach dominates the low to medium power applications due to their extraordinary performance (PF and efficiency approach to 100%), regulation capabilities, and high density. With the power-handling capability of power semiconductor devices being extended to megawatts, the active power electronic systems tend to replace most of the passive power processing devices [1,3–5].

Actually, harmonics reduction and PFC techniques to improve the power quality within the network power supply are attracting very important researches in different applications for the lower power level, the medium power level, and the high-power level. Indeed power supply industries are undergoing the change of adopting more and more PFC techniques in all off-line power supplies. This chapter presents an overview of various active harmonic reduction and PFC techniques in the open literature up to date. The primary objective of writing this chapter is to give a brief introduction of these techniques and provide references for future researchers in this area. The discussion here includes definition of THD and PF, commonly used control strategies, and various types of converter topologies. Finally, the possible future research trends are stressed in the summary section.

16.2 Definition of PF and THD

Power factor is a very important parameter in power electronics because it gives a measure of how effective the real power utilization in the system is. It also represents a measure of distortion of the line voltage and the line current and phase shift between them. Referring to Fig. 16.1A, the input PF at terminals $a-a'$ is defined as the ratio of the average of the instantaneous power or the real instantaneous power and the apparent power measured at terminals $a-a'$ as described in Eq. (16.1) [1,16,18,19]:

$$\text{Power Factor(PF)} = \frac{\text{Real Power (Average)}}{\text{Apparent Power}} \tag{16.1}$$

where the apparent power is defined as the product of *rms* values of instantaneous voltage $v_s(t)$ and instantaneous current

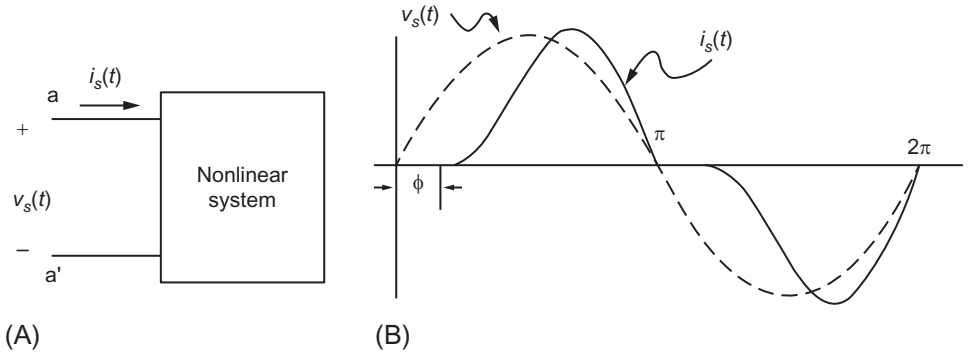

FIG. 16.1 Nonlinear load draws distorted line current.

$i_s(t)$. It is well-known that if the load is linear, it draws purely sinusoidal current under sinusoidal voltage. In this case, the PF is only determined by the phase shift between $v_s(t)$ and $i_s(t)$. Hence, Eq. (16.1) becomes

$$\mathrm{PF} = \frac{I_{s,rms} V_{s,rms} \cos\theta}{I_{s,rms} V_{s,rms}} = \cos\theta \tag{16.2}$$

where $I_{s,rms}$ and $V_{s,rms}$ are *rms* values of the current drawn by the load and the voltage applied to the load, respectively, and θ is the phase shift between instantaneous drawn current and instantaneous applied voltage. Hence, if the power system delivers a pure sine waveform voltage and the load is linear, the PF is simply equal to the cosine of the phase shift angle between the instantaneous current and instantaneous voltage. However, in power electronics system, due to the nonlinear behavior of active switching power devices, Eq. (16.2) is not valid anymore, and the phase-angle representation alone is not enough for the calculation of the PF which becomes more delicate. Fig. 16.1B shows a typical distorted current drawn from the pure sinusoidal power source. It is obvious that the calculation of the PF for distorted waveforms of the current or/and voltage is more complex when compared with the sinusoidal current and voltage waveforms. If both line voltage and line current are distorted, in this case Eqs. (16.3) and (16.4) give the Fourier expansion representations for the instantaneous drawn current and instantaneous power source voltage, respectively [1]:

$$\begin{aligned} i_s(t) &= I_{\mathrm{DC}} + \sum_{n=1}^{\infty} I_{sn} \sin(n\omega t + \theta_{\mathrm{in}}) \\ &= I_{\mathrm{DC}} + I_{s1} \sin(\omega t + \theta_{i1}) + \sum_{n=2}^{\infty} I_{sn} \sin(n\omega t + \theta_{\mathrm{in}}) \end{aligned} \tag{16.3}$$

$$\begin{aligned} v_s(t) &= V_{\mathrm{DC}} + \sum_{n=1}^{\infty} V_{sn} \sin(n\omega t + \theta_{vn}) \\ &= V_{\mathrm{DC}} + V_{s1} \sin(\omega t + \theta_{v1}) + \sum_{n=2}^{\infty} V_{sn} \sin(n\omega t + \theta_{vn}) \end{aligned} \tag{16.4}$$

Practically, the two DC (average value) of the instantaneous current and voltage that are expected to be seen from the power supply side are equal to zero due to the symmetry of the positive and negative parts of the voltage and current during one period; therefore, $I_{\mathrm{DC}} = V_{\mathrm{DC}} = 0$. Applying the definition of PF given in Eq. (16.1) to the distorted current and voltage waveforms of Eqs. (16.3) and (16.4), PF may be expressed as:

$$\mathrm{PF} = \frac{\sum_{n=1}^{\infty} I_{sn,rms} V_{sn,rms} \cos\theta_n}{I_{s,rms} V_{s,rms}} = \frac{\sum_{n=1}^{\infty} I_{sn,rms} V_{sn,rms} \cos\theta_n}{\sqrt{\sum_{n=1}^{\infty} I_{sn,rms}^2 \sum_{n=1}^{\infty} V_{sn,rms}^2}} \tag{16.5}$$

where $V_{sn,rms}$ and $I_{sn,rms}$ are the *rms* values of the nth harmonic voltage and current, respectively, and θ_n is the phase shift between the instantaneous voltage and current corresponding to the nth harmonic $(\theta_n = \theta_{in} - \theta_{vn})$.

Since most of power electronic systems draw their input voltage from a pure sine waveform power supply voltage $v_s(t)$, the above expression can be significantly simplified by assuming that the power supply voltage has a pure sine waveform and the distortion is only included in the instantaneous current $i_s(t)$, that is,

$$v_s(t) = V_s \sin\omega t \tag{16.6}$$

$$i_s(t) = \mathrm{distorted(nonsinusoidal)} \tag{16.7}$$

Then, it can be shown that the PF can be expressed as

$$\mathrm{PF} = \frac{I_{s1,rms}}{I_{s,rms}} \cos\theta_1 = k_{\mathrm{dist}} \times k_{\mathrm{disp}} \tag{16.8}$$

where

θ_1: the phase-angle between the voltage $v_s(t)$ and the fundamental component of $i_s(t)$,
$I_{s1,rms}$: *rms* value of the fundamental component in line current,
$I_{s,rms}$: total *rms* value of line current,
$k_{\mathrm{dist}} = I_{s1,rms}/I_{s,rms}$: distortion factor,
$k_{\mathrm{disp}} = \cos\theta_1$: displacement factor.

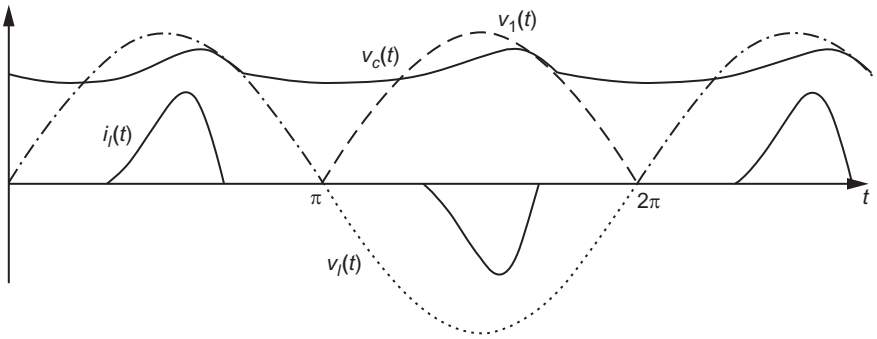

FIG. 16.2 Typical waveforms in a poor PF system.

Another important parameter which measures the percentage of current distortion is known as the current total harmonic distortion (THD_i), which is defined as follows:

$$THD_i = \sqrt{\frac{\sum_{n=2}^{\infty} I_{sn,rms}^2}{I_{s1,rms}^2}} = \sqrt{\frac{1}{k_{dist}^2} - 1} \tag{16.9}$$

Conventionally, SMPSs use capacitive rectifiers in front of the ac line that results in the capacitor voltage v_c and high *rms* pulsating line current $i_l(t)$ as shown in Fig. 16.2, when $v_l(t)$ is the line voltage. The typical input current harmonic distortion THD_i for this kind of rectification is usually in the range of 55%–65%, and the PF is about 0.65 [20,21]. It can be said also that the actual current wave shape and the resulting harmonics depend on the line impedance. This input current character creates several problems within the distribution network and consequently affecting the other electric apparatus in the vicinity of the rectifier. However, some solution has been proposed to overcome these drawbacks especially for high-power. The present chapter is focusing mainly on the study of the improvement of the current shape and PFC related to line current of single-phase rectifier followed by DC-DC converter that are mainly used for limited power level.

As we can see from Eqs. (16.8) and (16.9), PF and THD are related to distortion and displacement factors. Therefore, improvement in PF, that is, PFC, also implies harmonic reduction, especially the low order harmonics [1].

16.3 Power Factor Correction

16.3.1 Energy Balance in PFC Circuits

Fig. 16.3 shows a diagram of an AC-DC PFC unit. Let $v_i(t)$ and $i_l(t)$ be the line voltage (the power source voltage) and line current (the drawn current from the power source), respectively. For an ideal PFC unit (PF = 1), we assume

$$v_l(t) = V_{lm} \sin \omega_l t \tag{16.10a}$$

$$i_l(t) = I_{lm} \sin \omega_l t \tag{16.10b}$$

where V_{lm} and I_{lm} are amplitudes of line voltage and line current, respectively, and ω_l is the angular line frequency. The instantaneous input power is given by

$$p_{in}(t) = v_l(t) \cdot i_l(t) = V_{lm} I_{lm} \sin^2 \omega_l t = P_{in}(1 - \cos 2\omega_l t) \tag{16.11}$$

where $P_{in} = V_{in} \cdot I_{in}/2$ is constant value that is presenting the average of the instantaneous input power $p_{in}(t)$. It is important to clarify that only this part of power is contributing for the production of the effective energy that can be used by the load;

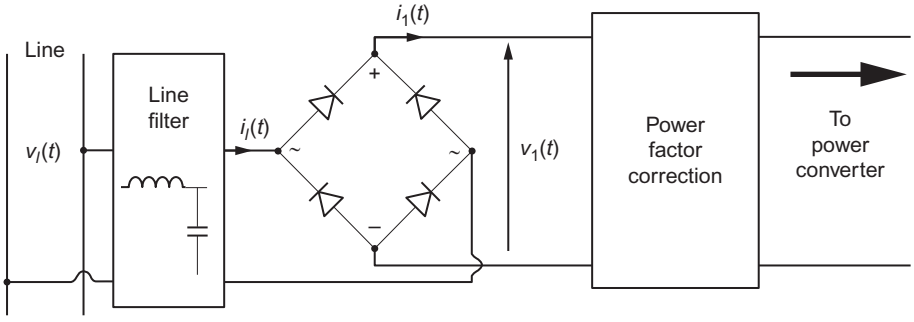

FIG. 16.3 Block diagram of ac-dc PFC unit.

therefore, it is often called the real power. On the other side, $p_{in}(t)$ possesses also an alternative component with frequency $2\omega_l$ as shown in Fig. 16.4 (i.e., 100 or 120 Hz, following the used power supply 50 or 60 Hz, respectively). Therefore, the operation principle of a PFC circuit is to process the input power in a certain way that it stores the excessive input energy when $p_{in}(t)$ is greater than $P_{in}(=P_o)$ and releases the stored energy when $p_{in}(t)$ is less than $P_{in}(=P_o)$, where a compensation is achieved between the stored energy and the released energy in these two stages (Fig. 16.4). The average value between these two terms of energy is equal to zero. We can estimate the instantaneous excessive power as

$$p_{ex}(t) = p_{in}(t) - P_0 = -P_0 \cos 2\omega_l t \tag{16.12}$$

Hence, the instantaneous excessive input energy, $w_{ex}(t)$, is given by

$$w_{ex}(t) = \int_{\frac{T_l}{8}}^{t} p_{ex}(t)dt = \frac{P_0}{2\omega_l}(1 - \sin 2\omega_l t) \tag{16.13}$$

At $t = T_l/8$ and $t = 5T_l/8$, the excessive input energy is null, and at $t = 3T_l/8$, the excessive input energy reaches the peak value

$$w_{ex,\max} = \frac{P_0}{2\omega_l}\left(1 - \sin\frac{3\pi}{2}\right) = \frac{P_0}{\omega_l} \tag{16.14}$$

To achieve this concept of the dynamic behavior of the excessive input energy variation, the PFC circuit has to ensure this both functionality of storing the excessive energy and realizing the stored excessive energy by integrating the basic dynamic components (inductor and capacitor) in the PFC circuit. Indeed, in most of the PFC circuits that have been used in such applications, an input inductor is used to carry the line current. To obtain a unity PF, it is well obvious that the inductor current (or averaged inductor current in switch-mode PFC circuit) must be a pure sinusoidal and in phase with the line voltage. The energy stored in the inductor ($1/2Li_L^2(t)$) cannot completely match the change of the excessive energy as shown in Fig. 16.4. Therefore, to maintain the output power constant, another energy storage component (usually the output capacitor) is needed [1].

16.3.2 Passive Power Factor Corrector

Because of their high reliability and high-power-handling capability, passive power factor correctors are normally used in

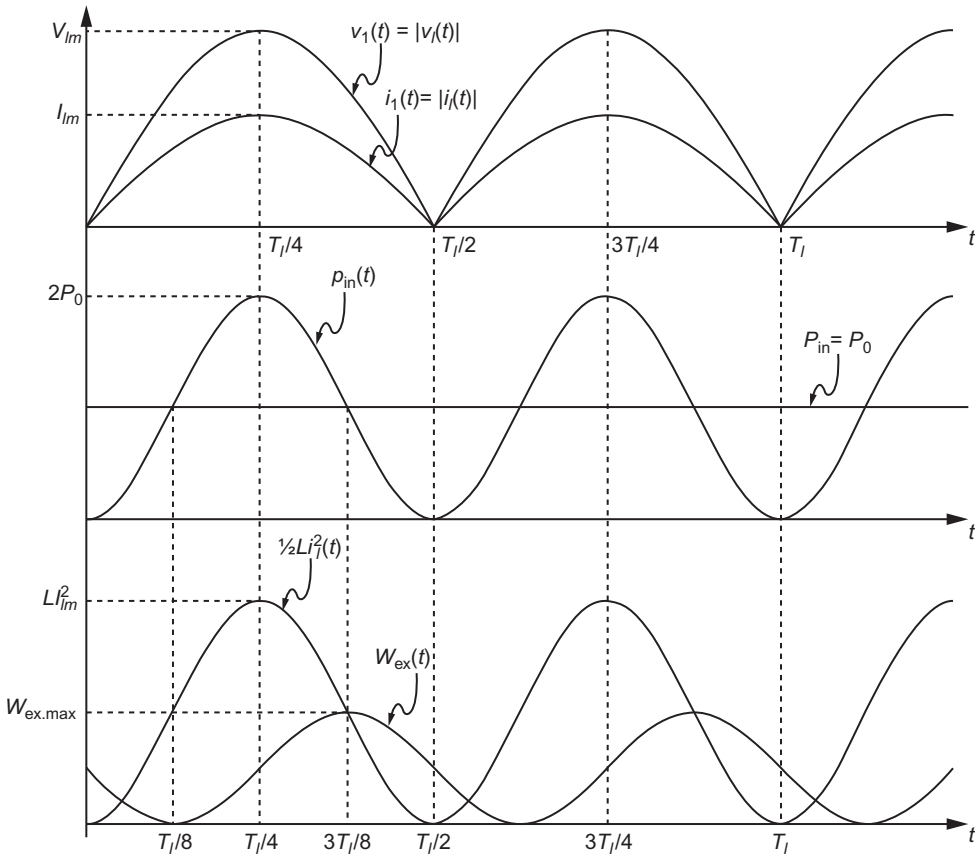

FIG. 16.4 Energy balance in PF corrector.

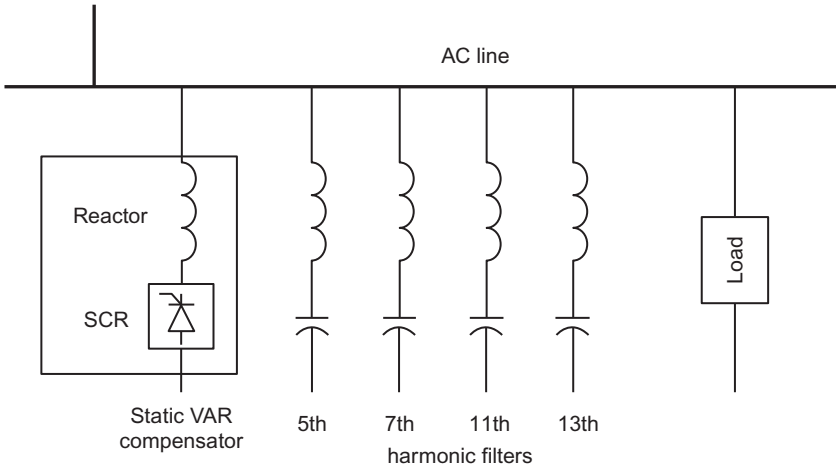

FIG. 16.5 Series-tuned *LC* harmonic filter PF corrector.

high-power-line applications. Series-tuned *LC* harmonic filter is commonly used for heavy plant loads such as arc furnaces, metal rolling mills, and electric locomotives [1]. Fig. 16.5 shows a connection diagram of a selective low frequency harmonic filter together with line frequency switched reactor SVC. By tuning the filter branches to odd harmonic of low frequencies, the filter shunts the harmonic currents. Since each branch presents capacitive at line frequency, the filter also provides capacitive SVC for the system, whereas the integration of the thyristor-controlled reactor (TCR) in parallel with this selected group of low frequency filters keeps an optimized static var compensation for the system so that higher PF can be maintained.

The design of the tuned filter PF corrector is particularly difficult because of the uncertainty of the system impedance and the characteristics of the harmonic sources. Besides, this method involves too many expensive components and takes huge space in comparison with the active PFC method.

For the applications where the power level is less than 10 kW, the tuned filter PF corrector may not be a better choice. The most common off-line passive PF corrector is the inductive-input filter, shown in Fig. 16.6. This filter can operate either in the continuous conduction mode (CCM), in which the rectifier bridge is always conducting, or in the discontinuous conduction mode (DCM) where the rectifier is off during a portion of the line period [22,23]. A conduction parameter K_l is defined in the literature based on the values of the filter parameters, the inductance L, the assumed resistor R, and the line input frequency ω_l as follows:

$$K_l = \frac{\omega_l L}{\pi R} = \frac{2L}{RT} \tag{16.15}$$

The assumed resistor represents the ratio between the average value of the voltage and the average value of the current at the output side of the filter.

For operation in CCM, the PF is defined as [22,23]:

$$\mathrm{PF} = \frac{2\sqrt{2}}{\pi} \frac{1}{\sqrt{1 + \left(\frac{5}{24} - \frac{2}{\pi^2}\right)/K_l^2}} = \frac{0.9}{\sqrt{1 + 0.075/K_l^2}} \tag{16.16}$$

Depending on the filter inductance, this circuit can achieve a maximum PF of 90%, which is corresponding to the theoretical value of $K_l = \infty$. On the other side, it was found in [22,23] that

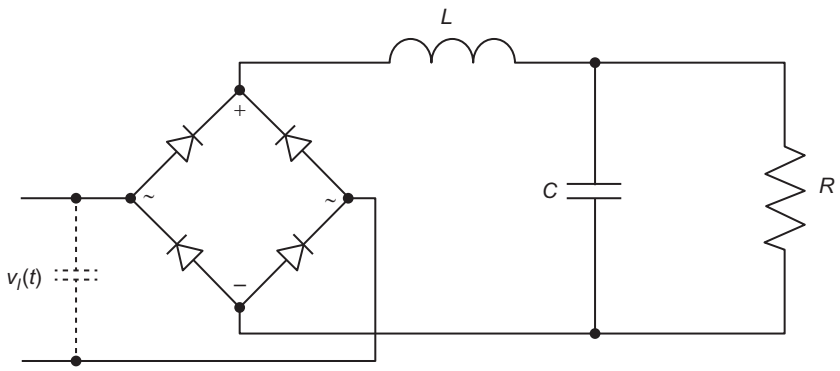

FIG. 16.6 Inductive-input PF corrector.

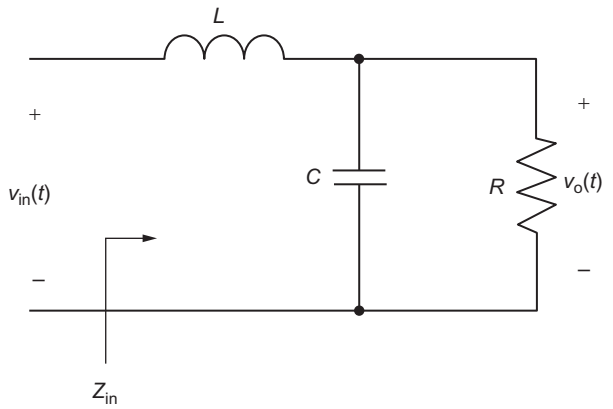

FIG. 16.7 Low-pass inductive filter.

the critical value of $K_l(K_{lcrit})$ that makes the minimum of the inductor current reach the zero value is $K_{lcrit} = 0.1053$; this value makes the PF to fall to the value of 73.2%. In case where $K \prec K_{lcrit}$, the current passes to the DCM [23].

The PF corrector is simply a low-pass inductive filter as shown in Fig. 16.7, whose transfer function and input impedance are given by [1]

$$H_0(s) = \frac{v_0(s)}{v_{in}(s)} = \frac{1}{s^2LC + sL/R + 1} \tag{16.17}$$

$$Z_{in0}(s) = \frac{v_{in}(s)}{i_{in}(s)} = R\frac{s^2LC + sL/R + 1}{sRC + 1} \tag{16.18}$$

This kind of filter shown in Fig. 16.6 is characterized by the following main advantages:

(a) It has a simple structure.
(b) It is reliable.
(c) The cost is very low because only a filter is required.
(d) The high-frequency switching losses are absent, and it is not sensitive to noises and surges.
(e) The equipments used in this circuit do not generate high-frequency EMI.

The above equations show that the unavoidable phase displacement is incurred in the inductive filter corrector. Because the filter frequency of operation is low (line frequency), large value inductor and capacitor have to be used. As a result, the following main disadvantages are presented in the most passive PF correctors:

(a) Only less than 0.9 PF can be achieved.
(b) The output voltage cannot be regulated under uncontrolled rectifier.
(c) The efficiency is low.
(d) THD is high.
(e) It cannot provide satisfactory results for wide load range.
(f) They are heavy and bulky, because, for achieving a better power factor, the size of the filter increases.
(g) The output is unregulated.
(h) The dynamic response is poor due to the time lag associated with the passive elements.
(i) They are sensitive to circuit parameters.
(j) Although by filtering the harmonics that can be filtered out, the fundamental component may get phase-shifted, thus reducing the power factor.
(k) The shape of input current is dependent upon what kind of load is connected.
(l) Optimization of the design is difficult.

16.3.3 Basic Circuit Topologies of Active Power Factor Correctors

In recent years, using the switched-mode topologies, many circuits and control methods are developed up to date to comply with certain standard (such as IEEE Std 519 and IEC1000-3-2). To achieve this, high-frequency switching techniques have been used to shape the input current waveform successfully [1]. Basically, the active PF correctors that are used to accomplish the PFC function in single-phase power supply are based on the well-known basic converter topologies or their developed versions.

16.3.3.1 The Buck Corrector

Fig. 16.8A shows the buck PF corrector. By using PWM switch modeling technique [24], the circuit topology can be modeled by the equivalent circuit shown in Fig. 16.8B. It should be pointed out that the circuit model is a large signal model; therefore, analysis of PF performance based on this model is valid. It can be shown that the transfer function and input impedance are given by [1]

$$H(s) = \frac{v_0(s)}{v_{in}(s)} = \frac{d}{s^2LC + sL/R + 1} = d \cdot H_0(s) \tag{16.19}$$

$$Z_{in}(s) = \frac{v_{in}(s)}{i_{in}(s)} = \frac{R}{d^2}\frac{s^2LC + sL/R + 1}{sRC + 1} = \frac{Z_{in0}(s)}{d^2} \tag{16.20}$$

where d is the duty ratio of the switching signal.

Notice that Eqs. (16.18) and (16.19) are different from Eqs. (16.16) and (16.17), in that they have introduced the control variable d. By properly controlling the switching duty ratio to modulate the input impedance and the transfer function, a pure resistive input impedance and constant output voltage can be approached [1]. Thereby, unity PF and output regulation can both be achieved. These control techniques will be discussed in the next section.

Comparing with the other type of high-frequency PFC circuits, the buck corrector offers inrush-current limiting, overload or short-circuit protection, and overvoltage protection for the converter due to the existence of the power switch in front of the line. Another advantage is that the output voltage is lower than the peak of the line voltage, which is usually the

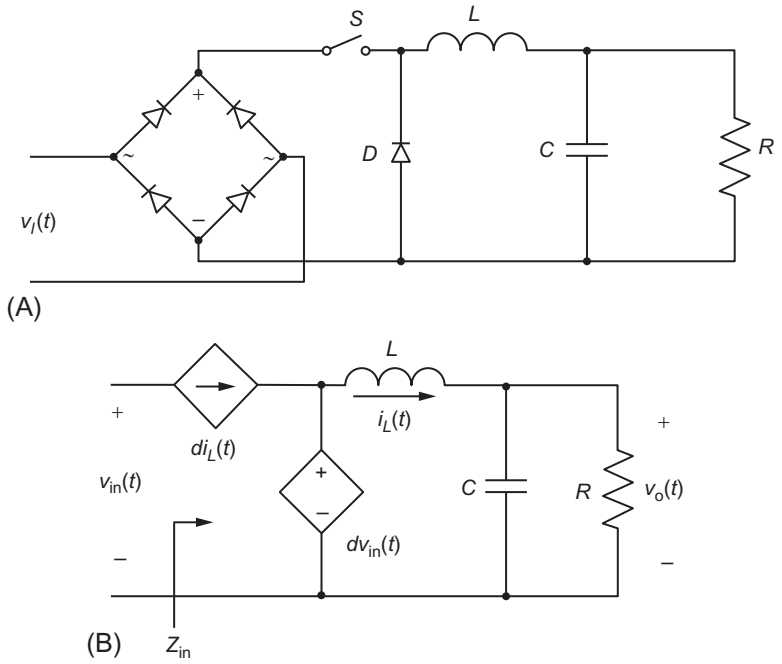

FIG. 16.8 (A) Buck corrector and (B) PWM switch model for buck corrector.

case normally desired. The drawbacks of using buck corrector may be summarized as follows [1]:

(a) When the output voltage is higher than the line voltage, the converter draws no current from the line, resulting in significant line current distortion near the zero-across of the line voltage.
(b) The input current is discontinuous, leading to high differential mode EMI.
(c) The current stress on the power switch is high.
(d) The power switch needs a floating drive.

16.3.3.2 The Boost Corrector

The boost corrector and its equivalent PWM switch modeling circuit are shown in Fig. 16.9A and B. Its transfer function and input impedance are given by [1]

$$H(s) = \frac{1/d'}{s^2\left(L/d'^2\right)C + s\left(L/d'^2\right)/R + 1} \tag{16.21}$$

$$Z_{in}(s) = d'^2 R \frac{s^2\left(L/d'^2\right)C + s\left(L/d'^2\right)/R + 1}{sRC + 1} \tag{16.22}$$

where $d' = 1 - d$.

Unlike in the buck case, it is interesting to note that in the boost case, the equivalent inductance is controlled by the switching duty ratio. Consequently, both the magnitude and the phase of the impedance, and both the dc gain and the pools of the transfer function are modulated by the duty ratio, which implies a tight control of the input current and the output voltage. Other advantages of boost corrector include less EMI and lower switch current and grounded drive. The shortcomings with the boost corrector are summarized as [1]

(a) the output voltage must be higher than the peak of line voltage;
(b) inrush-current limiting, overload, and overvoltage protections are not available.

16.3.3.3 The Buck-Boost Corrector

The buck-boost corrector and its equivalent circuit are shown in Fig. 16.10A and B. The expressions for transfer function and input impedance are [1]

$$H(s) = \frac{d/d'}{s^2\left(L/d'^2\right)C + s\left(L/d'^2\right)/R + 1} \tag{16.23}$$

$$Z_{in}(s) = \left(\frac{d'}{d}\right)^2 R \frac{s^2\left(L/d'^2\right)C + s\left(L/d'^2\right)/R + 1}{sRC + 1} \tag{16.24}$$

The buck-boost corrector combines some advantages of the buck corrector and the boost corrector. Like a buck corrector, it can provide circuit protections and step-down output voltage, and like a boost corrector its input current waveform and output voltage can be tightly controlled. However, the buck-boost corrector has the following disadvantages [1]:

(a) The input current is discontinued by the power switch, resulting in high differential mode EMI.
(b) The current stress on the power switch is high.
(c) The power switch needs a floating drive.
(d) The polarity of output voltage is reversed.

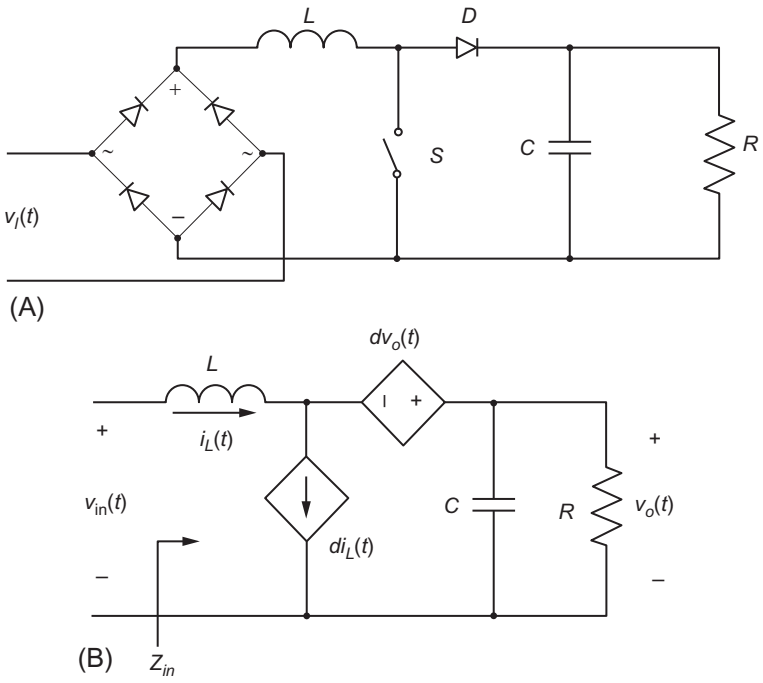

FIG. 16.9 (A) Boost corrector and (B) PWM switch model of boost corrector.

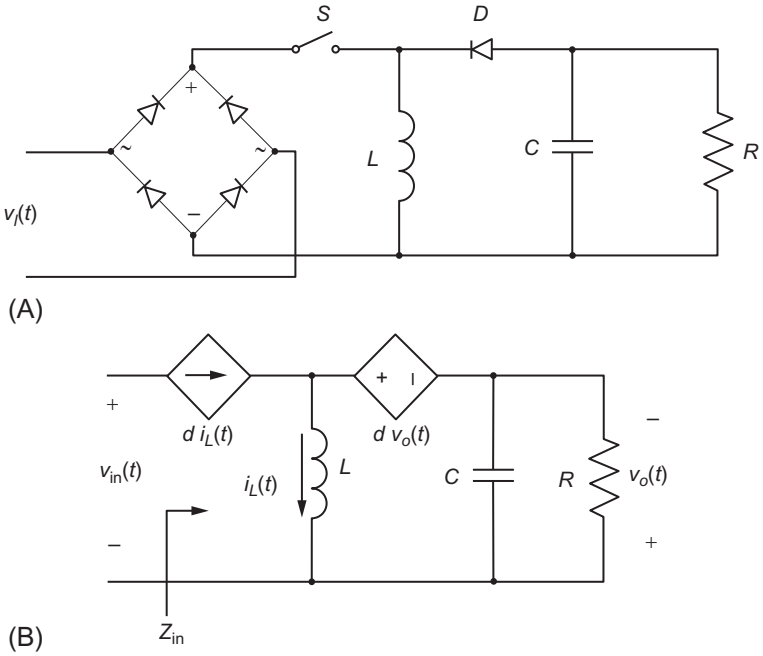

FIG. 16.10 (A) Buck-boost corrector and (B) PWM switch model of buck-boost corrector.

16.3.3.4 The Cuk, Sepic, and Zeta Correctors

Unlike the previous converters, the Cuk, Sepic, and Zeta converters are fourth-order switching-mode circuits. Their circuit topologies for PFC are shown in Fig. 16.11A–C, respectively. Because there are four energy storage components available to handle the energy balancing involved in PFC, second-harmonic output voltage ripples of these correctors are smaller when compared with the second-order buck, boost, and buck-boost topologies. These PF correctors are also able to provide overload protection. However, the increased count of components and current stress are undesired [1].

16.3.3.5 Flyback Corrector

The flyback corrector allows to the input current to be shaped into a rectified sine wave, which is in phase with the input voltage, thus achieving a high PF and low harmonics content. Indeed, it is one of the most used active PFC converters, which has been widely used as an isolated front-stage PFC converter [25,26] and as a single-stage PFC [27–32]. Indeed, this topology presents many advantages such as isolation between input and output, low-cost, and simple structure. However, the large voltage stress on the primary switch and the large current stress through the output diode have limited its application to low-power level Fig. 16.12 [33–39].

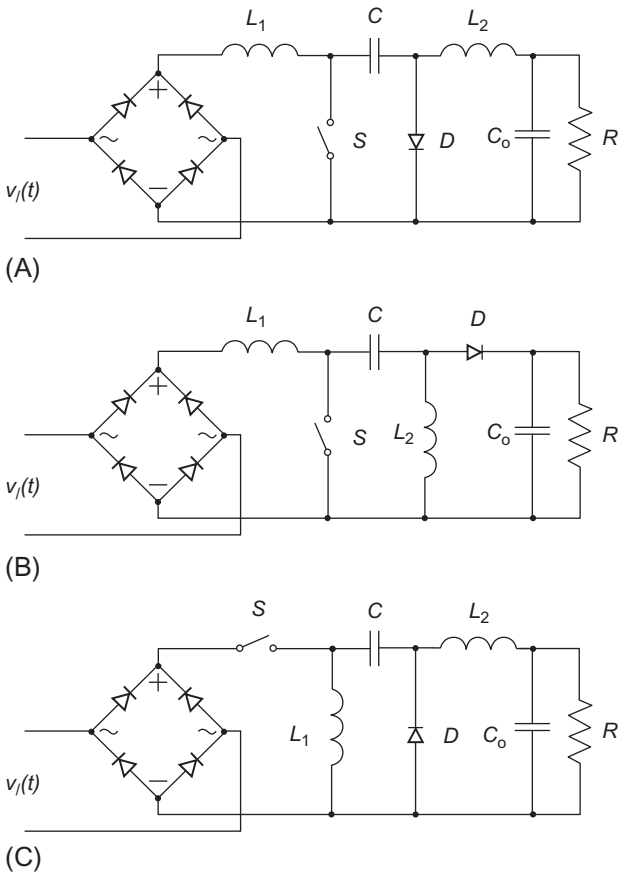

FIG. 16.11 Fourth-order corrector: (A) Cuk corrector, (B) Sepic corrector, and (C) Zeta corrector.

The flyback PFC topology can operate under the three modes: continuous current mode (CCM), discontinuous current mode (DCM), and critical conduction mode (CRM). The operating mode is chosen upon the behavior of the freewheeling diode at the isolating transformer secondary side when the main switch "S" is turned off in one switch period.

The CCM operation of the flyback PFC converter requires two control loops. The first control loop is used to control the current to ensure the line current wave shape and a zero shift phase between the line voltage and line current, consequently a unity PF, can be obtained. The second control loop is used to control the output voltage to achieve its regulation. For DCM and CRM flyback PFC converters, only voltage control loop is required, which allows to obtained circuits that are simpler than that of CCM flyback PFC converter, this makes the DCM and CRM flyback PFC converters to be more widely used [35–42].

16.3.3.6 Forward, Forward-Flyback Correctors

The forward converter is presenting the simplest isolated buck-type converter, which has been widely applied for DC/DC conversions. The use of the basic topology and the practical topology shown in Fig. 16.13A and B of the forward converter for PFC applications include several disadvantages: (1) The typical single-ended forward converter requires a third additional auxiliary winding to ensure the transformer energy reset demagnetization [43], (2) it has the same drawbacks and limits of the basic topology of the buck PFC converter [43–45], and (3) as shown in Fig. 16.13A, when the output voltage V_0 is greater than the input rectified voltage V_{in}, dead zones appear in the input current waveforms i_{in}, that can degrade the PF and contribute to the increase of the harmonics content. These main disadvantages make the basic topology forward PFC difficult to be used in PFC applications. However, many works have presented improved topologies of this kind of converter to fulfill the requirement of decreased input current harmonics distortion and higher PF. One of such topologies that was proposed to overcome the main disadvantages of the basic

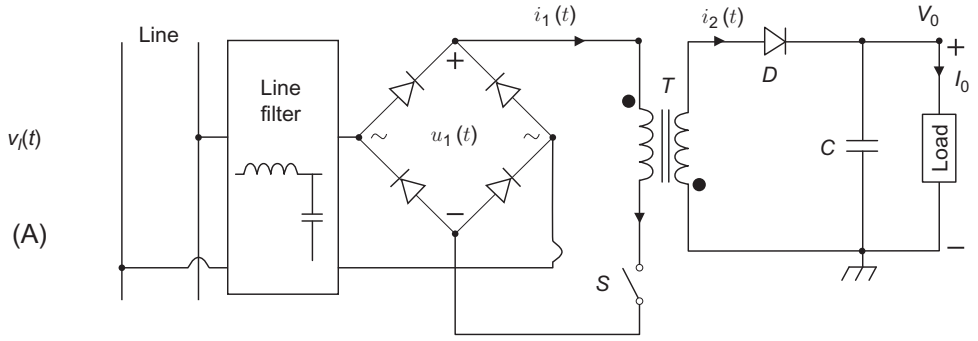

FIG. 16.12 Flyback corrector.

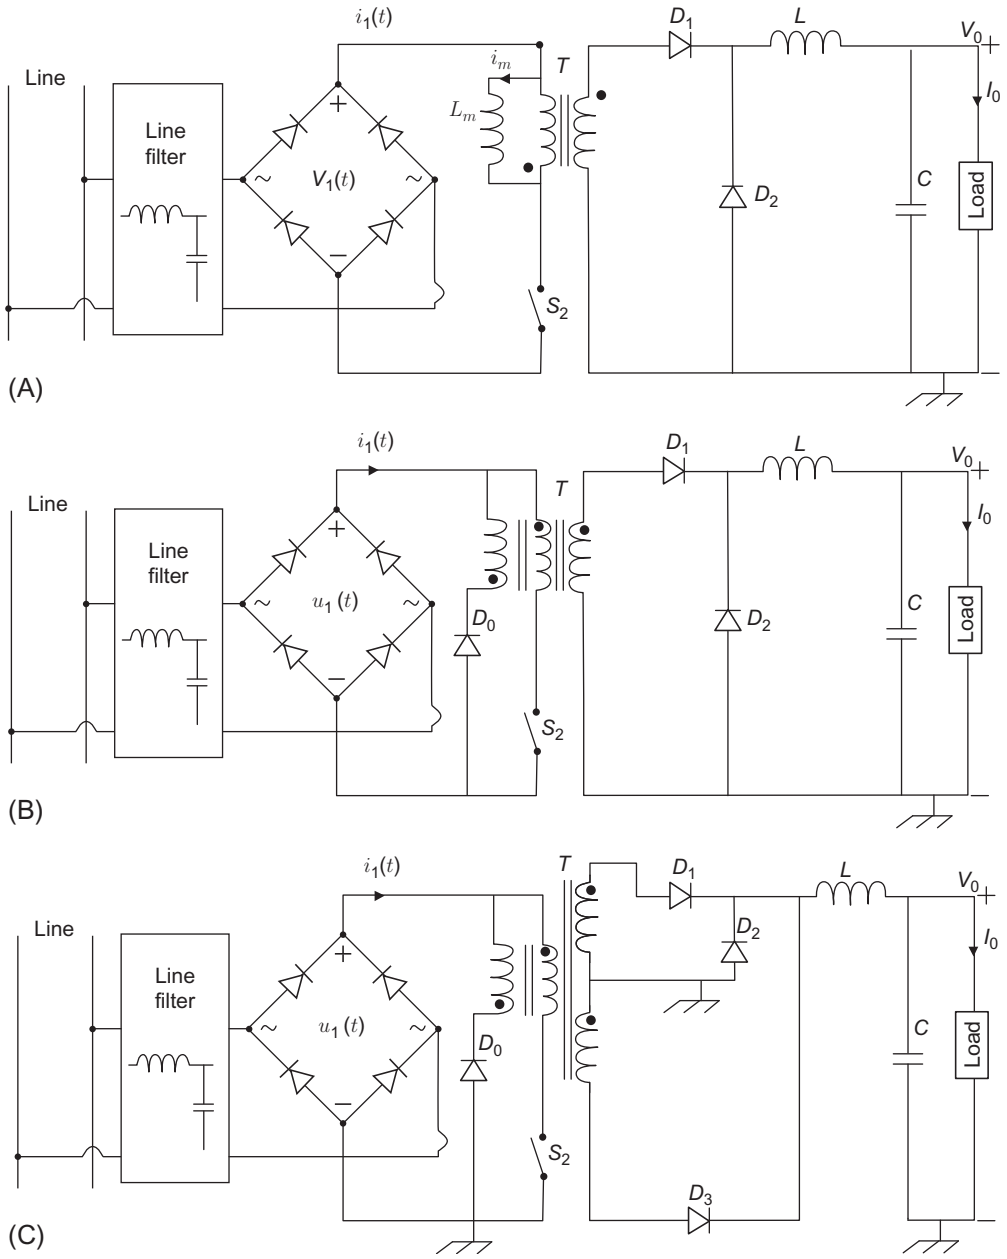

FIG. 16.13 Forward converter topology, (A) forward converter basic topology, (B) forward converter practical topology, and (C) forward-flyback converter topology.

topology of the forward converter is the forward-flyback PFC topology that combines the basic forward topology and the basic flyback topology, where only one common switch and one common transfer are used as shown in Fig. 16.13C [46–50]. In this topology, when the input voltage is not large enough to enable the forward operation, the flyback converter contributes to the power transfer. The main advantages of the proposed topology are the following [24,46–50]:

1. The dead zones existing in the convention forward PFC topology are eliminated.
2. The transformer is reset during the flyback converter operation.
3. The additional reset winding for the forward converter is no more needed.

16.3.3.7 A Single-Stage Quasi *Z*-Source Corrector

The quasi-Z-Source (qZS) topology and their different improved topologies have been introduced recently in several DC-DC converter applications [51–53]. The single-stage qZS converter topology was proposed to ensure the PFC converter in single-phase application [54,55]. This topology, even it is different from the other topologies DC-DC converter topologies previously presented, but it has several features such as low-voltage stress on switches; lossless clamping, without using

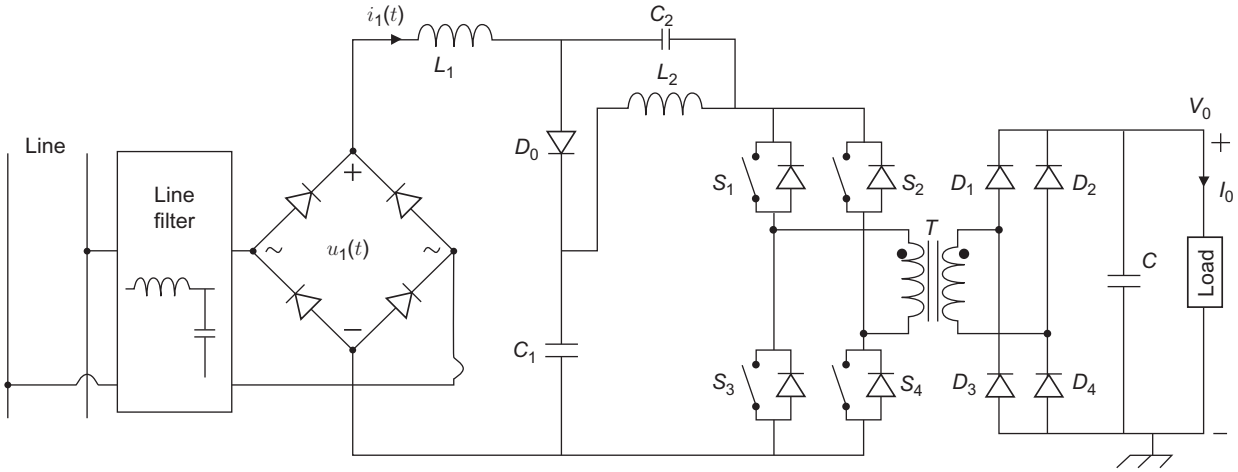

FIG. 16.14 A single-stage quasi-Z-source corrector.

auxiliary switch; and duty-cycle-control scheme and improved efficiency. The circuit of this PFC converter is shown in Fig. 16.14. The single-phase power supply provides the line input to the load via the qZS, the full-bridge diode rectifier, and the transformer and the second full-bridge diode rectifier. The same control strategies that are used for the other DC-DC converter topologies are used for these topologies with more or less modifications, where the main aim is to shape the input line current into a sinusoidal wave and in phase with the input line voltage to obtain a unity PF.

16.3.4 System Configurations of PFC Power Supply

The most common configurations of AC-DC power supply with PFC are two-stage scheme and one-stage (or single-stage) scheme. In two-stage scheme as shown in Fig. 16.15A, a non-isolated PFC AC-DC converter is connected to the line to create an intermediate DC bus. This DC bus voltage is usually full of second-harmonic ripple and which is followed by a cascaded DC-DC converter to provide electric isolation and tight voltage regulation. The advantage of two-stage structure PFC circuits is that the two power stages can be controlled separately, and thus, it makes it possible to have both converters optimized. The drawbacks of this scheme are lower efficiency due to twice processing of the input power, two control systems which leads to complex control circuits, higher cost, bulky due to the used intermediary circuits between the two stages, and low reliability. Although the two-stage scheme approach is commonly adopted in several industrial applications, it received limited attention by the common research, since the input stage and the output stage can be studied independently. One-stage scheme possesses a simplified structure that combines the PFC circuit and the

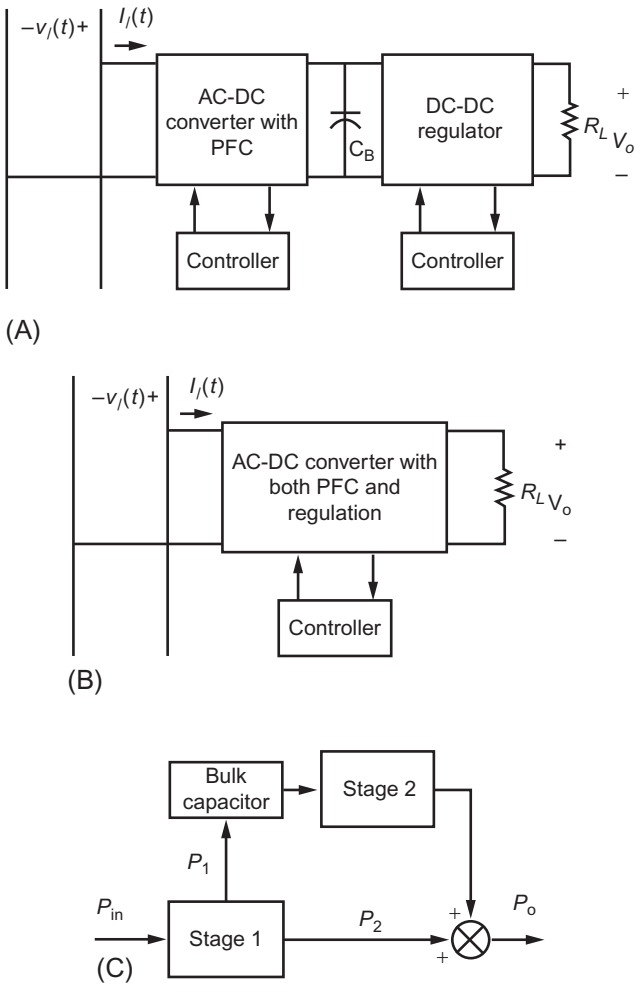

FIG. 16.15 System configurations of PFC power supply: (A) two-stage scheme, (B) one-stage scheme, and (C) parallel scheme.

power conversion circuit in one-stage as shown in Fig. 16.15B. Therefore, this topology is potentially more efficient and is very attractive in low to medium power level applications, particularly in those cost-sensitive applications. The one-stage scheme, therefore, becomes the main stream of contemporary research due to the ever-increasing demands for inexpensive power supply applications, such as residential and office appliance [1].

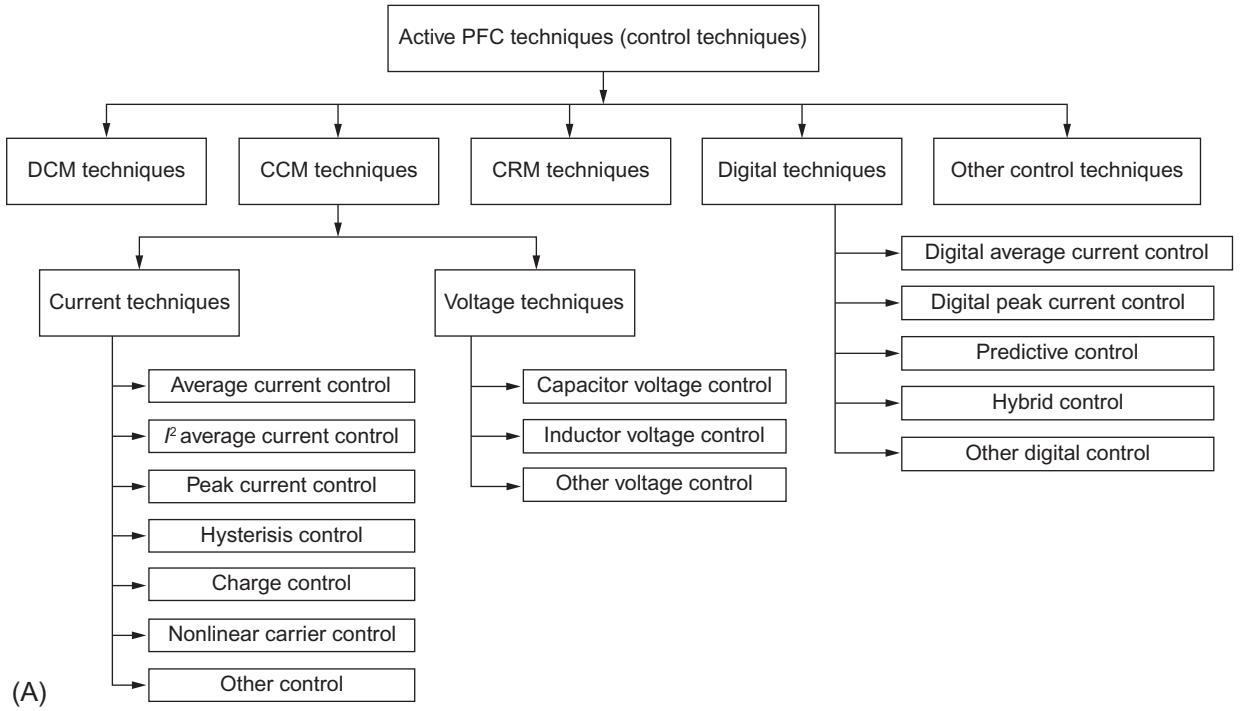
For many single-stage PFC converters, one of the most important issues is the slow dynamic response under line and load changes. To remove the low frequency ripple caused by the line (120 or 100 Hz) from the output and keep a nearly constant operation duty ratio, a large volume output capacitor is normally used. Consequently, a low frequency pole (typically less than 20 Hz) must be introduced into the feedback loop. This results in very slow dynamic response of the system [1,56,57].

The behavior of energy transfer in single-phase PFC converter and the behavior of the required storage decoupling element can be understood through the representation of the converter instantaneous input power and the average output power waveforms in more details as shown in Fig. 16.17. It can be seen clearly that the converter has to transfer a peak power equals to twice the average output power, whereas this power has to be stored and then restored to the converter output side. Typically, an output capacitor (placed at the output side of the converter) is not the desired solution to store this energy for two reasons. Firstly, the output voltage possesses voltage fluctuation with double line frequency because tight output voltage regulation will require a small output capacitor. Secondly, the converter requires a holdup time. Therefore, the right solution is the use of a decoupling capacitor to ensure the main operation of storing and restoring the energy during the two stages. The location of the energy storage element becomes critical and general configuration of the topology will play an important role [58]. The waveform presented in Fig. 16.17 can be used to find the relation between P_1 *and* P_2 based on the calculation of the areas corresponding to each power:

$$S_{P_2} = \int_{\pi/4\omega_l}^{3\pi/4\omega_l} (p_{\text{in}}(t) - P_0)\, dt = P_0 \int_{\pi/4\omega_l}^{3\pi/4\omega_l} -\cos(2\omega_l t)\, dt = \frac{P_0}{\omega_l} \tag{16.25}$$

$$S_{P_1} = \int_0^{\pi/\omega_l} (p_{in}(t))\, dt - S_{P_1} = P_0 \int_0^{\pi/\omega_l} (1 - \cos(2\omega_l t))\, dt - S_{P_1}$$
$$= P_0 \left(\frac{\pi}{\omega_l}\right) - \frac{P_0}{\omega_l} = \frac{P_0}{\omega_l}(\pi - 1) \tag{16.26}$$

It is found that 68.17% $\left(\frac{S_{P_1}}{S_{P_1}+S_{P_2}}\%\right)$ of the energy can be transferred directly to the output, and only 31.83% $\left(\frac{S_{P_2}}{S_{P_1}+S_{P_2}}\%\right)$ of the energy has to be stored and then reprocessed to the output.



It is obvious that the double frequency will be hidden from the output voltage ripple if P_1 energy is directly transferred to the output due to the power storage excesses. Based on this analysis, improved and modified topologies of the basic converter topologies can be attained to achieve the direct energy transfer topology and the parallel energy transfer topology. Indeed, several works have been presented focusing mainly on the improvement of the PFC converter topology structure to ensure reduced number of components while delivering maximum energy directly to the output under enhanced efficiency [58–65].

To avoid twice power process in two-stage scheme, two converters can be connected in parallel to form so-called parallel PFC scheme (PPFC) as shown in Fig. 16.18 [66,67]. In parallel PFC circuit, power from the ac main to the load flows through two parallel paths, shown in Fig. 16.15C. The main path is a rectifier, in which power is not processed twice for PFC (about 68% of the average input power), whereas the other path processes the input power twice for PFC purpose. It is shown that to achieve both unity PF and tight output voltage regulation, only the difference between the input and output power within a half cycle (about 32% of the average input power) needs to be processed twice [1,66,67]. Therefore, high efficiency can be obtained by this method. In the PPFC topology, the common connection point of the two parallel paths appears at the output, where an isolation transformer is required for each stage (Fig. 16.18). Hence, this converter can be used effectively for the applications where the power level is high enough to justify the using of two isolations transformers that are too expensive and add more complexity to the converter topology [67].

An improved topology has been used to avoid the main disadvantages of the presented PPFC of Fig. 16.18. It combines the auxiliary stage with the main stage, and, therefore, only one isolation transformer is required. This used PPFC topology power process transfer principle is shown in Fig. 16.19, where only one power stage is used to transfer the input power (P_{in}) and the extra 32% power (P_2). Two application have been presented based on this PPFC topology, single-stage flyback PPFC converter and single-stage boost PPFC as shown in Fig. 16.20A and B; both topologies are using only one isolation transformer [67].

The continuous research in improving system PF up to date has resulted in countless circuit topologies and control strategies. Classified by their principles to realize PFC, they can be mainly categorized into three categories depending especially on the conduction current behavior of the input current of the converter that is related generally to the inductance of the equalizer PFC:

- Continuous conduction mode (CCM) that is based on the techniques of current shaping (current shaping technique (CST)) in Fig. 16.21
- Discontinuous conduction mode (DCM) that is based on current input control technique (CICT) in Fig. 16.22
- Critical conduction mode (CRM) that is similar to boundary conduction mode (BCM) or transition mode (TM) in Fig. 16.23

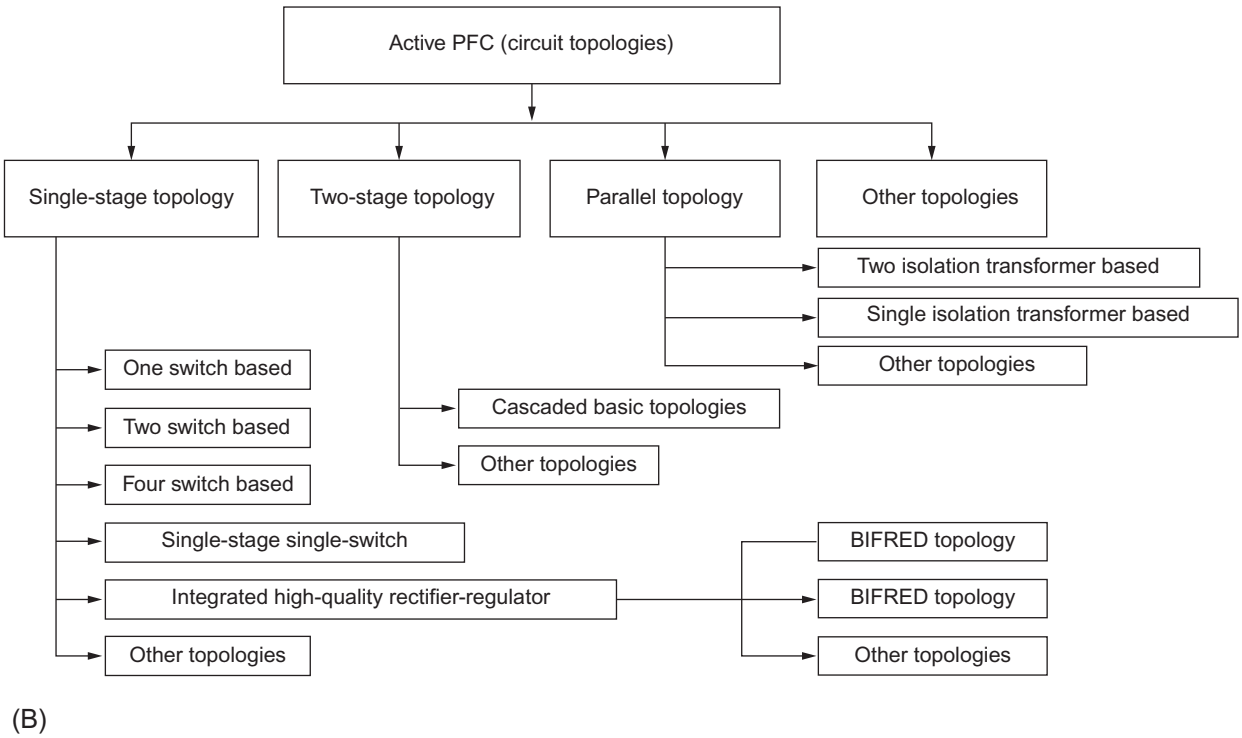


FIG. 16.16 Overview of (A) PFC control techniques and (B) PFC circuit topologies.

The recent research interest in DCM input technique is focused on developing PFC circuit topologies with a single power switch, result in single-stage single-switch converter (so-called S^4-converter) [1]. The CCM shaping technique emphasizes on the used control strategies and on the improved topologies to achieve high input PF for medium and high-power levels. When this technique is applied for the control of a continuous flow of current, a fixed or a variable switching frequency can be used [68].

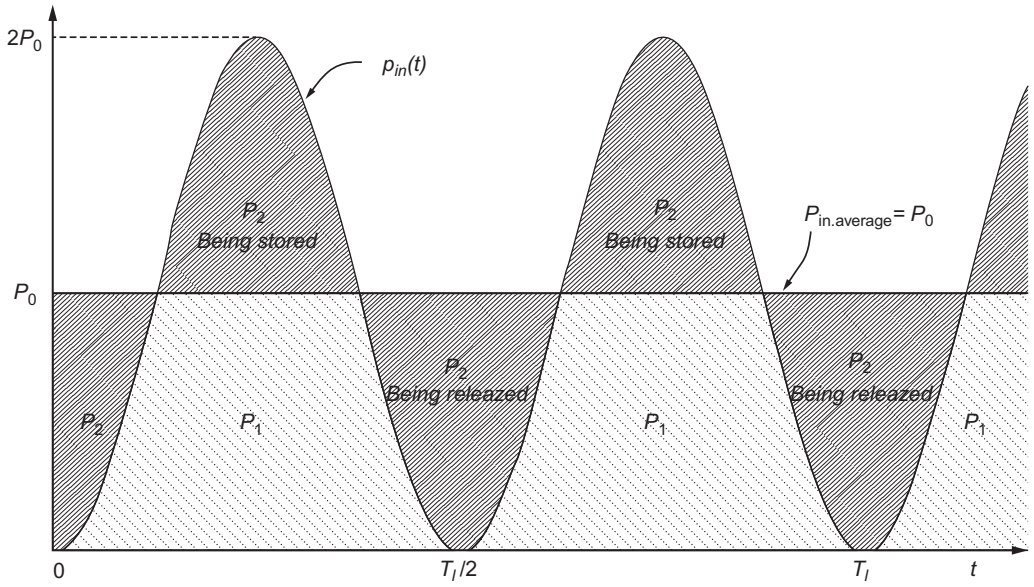

FIG. 16.17 The instantaneous single-phase input power waveform.

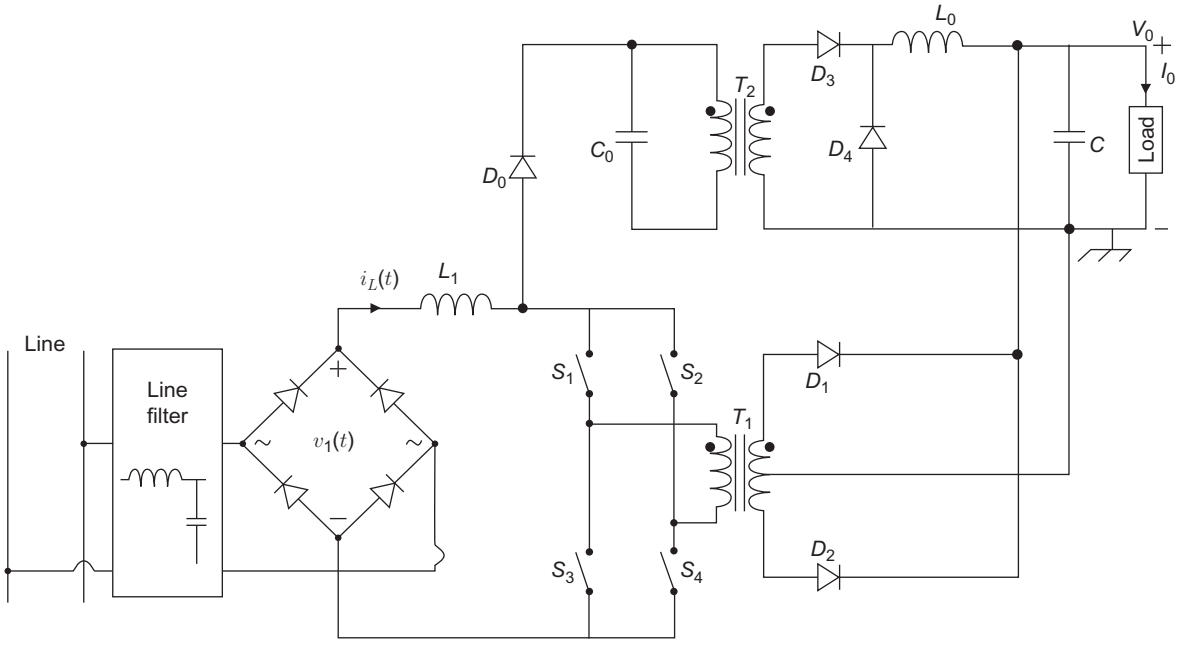

FIG. 16.18 The parallel power factor corrector (PPFC).

The CRM technique is on the boundary between CCM and DCM techniques. It was proved that it can ensure moderate switch losses, and in the same time, it can reduce the eventual diode reverse-recovery problems. The two main CRM PFC controller strategies of voltage mode and current mode can be used; however, the need to the voltage or the current sensors, depending on the used control strategy, adds more complexity to the used circuits [69].

The hot topics in this line of research are concentrated on degrading complexity of the control circuit and enhancing dynamic response of the system, resulting in some new control methods. Fig. 16.16 shows an overview of these techniques based on conduction mode and system configuration types [1]. It is obvious that the new developed and improved topologies based on the existing classical basic topologies can achieve the main objective of higher PF and lower THD than those of traditional topologies; this can be fulfilled by improving at the same time the control strategies for different modes of conduction.

16.4 CCM Shaping Technique

Like other power electronic apparatus, the core of a PFC unit is its converter, which can operate either in DCM, in CCM, or in CRM. As shall be discussed in the next section, the benefit from DCM technique is that low-cost power supply can be achieved because of its simplified control circuit. However, the peak input current of a DCM converter is at least twice as high as its corresponding average input current, which causes higher current stresses on switches than that in a CCM converter, resulting in intolerable conduction and switching losses and transformer copper losses in high-power applications. In practice, DCM technique is only suitable for low- to medium-level power application, whereas CCM is used in high-power cases. However, a converter operating in CCM does not have PFC ability inherently, that is, unless a certain control strategy is applied, the input current will not follow the waveform of line voltage. This is why most of the research activities in improving PF under CCM condition have been focused on developing new current shaping control strategies. Depending on the system variable being controlled (either current or voltage), PFC control techniques may be classified as current control and voltage control. Current control is the most common control strategy since the primary objective of PFC is to force the input current to trace the shape of line voltage [1].

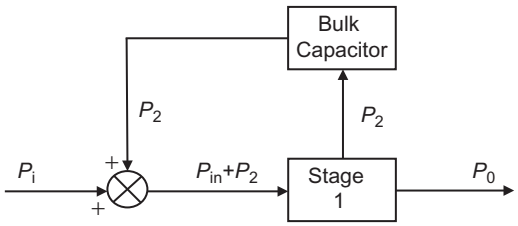

FIG. 16.19 The power process transfer principle under the improved PPFC topology.

To achieve both PFC and output voltage regulation by using a converter operating in CCM, multiloop controls are generally used. Fig. 16.24 shows the block diagram of AC-DC PFC converter with CCM shaping technique, where H_l is a line voltage compensator, H_x is a controlled variable compensator, and $x(t)$ is the control variable that can be either current or voltage [1].

Normally, in order to obtain a sinusoidal line current and a constant dc output voltage, line voltage $v_l(t)$, output voltage V_o, and a controlled variable $x(t)$ need to be sensed. Depending on whether the controlled variable $x(t)$ is a current (usually the line current or the switch current) or a voltage (related

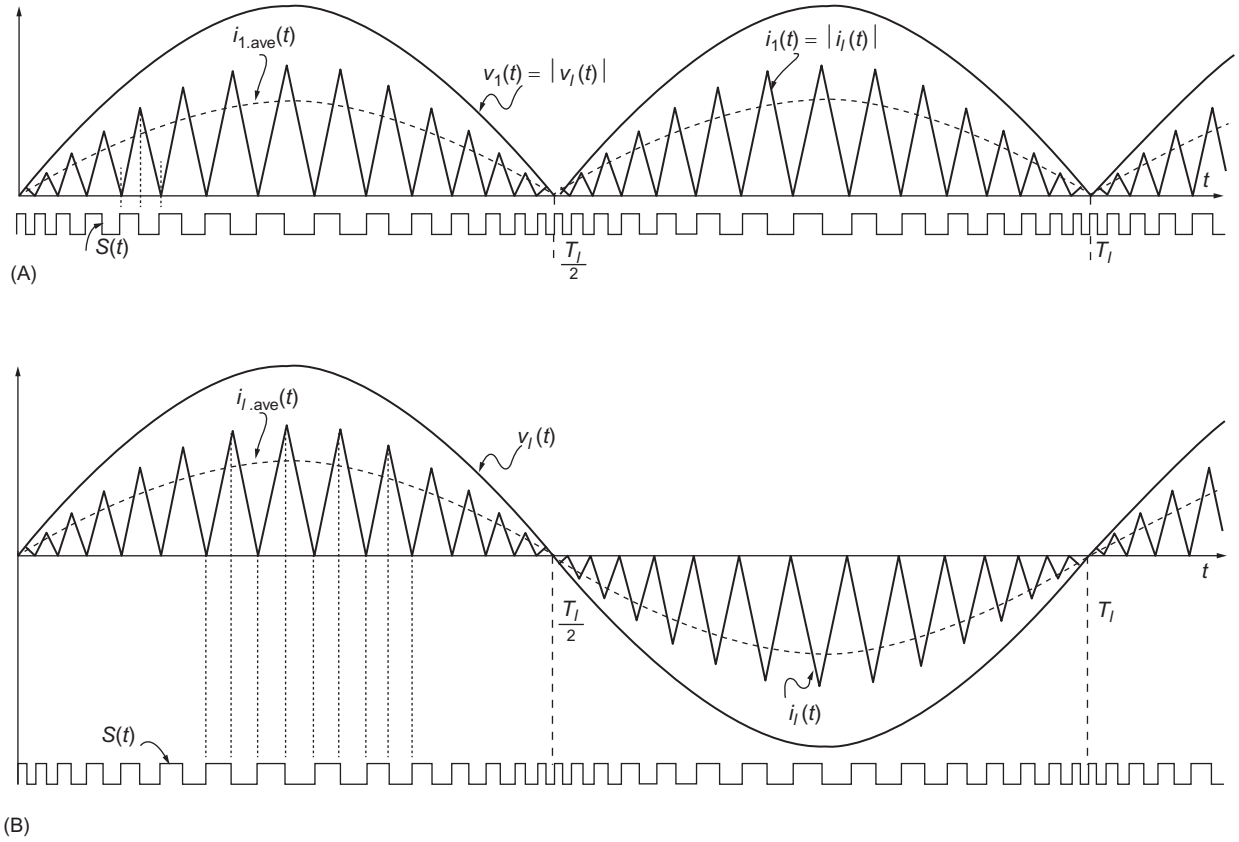

FIG. 16.23 Critical conduction mode (CRM) principle: (A) the input current waveform of the PFC circuit and (B) the line current waveform.

to the line voltage or rectified line voltage), the control technique is called "current mode control" or "voltage mode control," respectively. In Fig. 16.24, two control loops have been applied: the feedforward loop and the feedback loops. The feedforward loop is also called "inner loop," which keeps the line current to follow the line voltage in shape and phase, while the feedback loop (also called "outer loop") keeps the output voltage to be tightly controlled. These two loops share the same control command generated by the product of output voltage error signal and the line voltage (or rectified line voltage) signal [1].

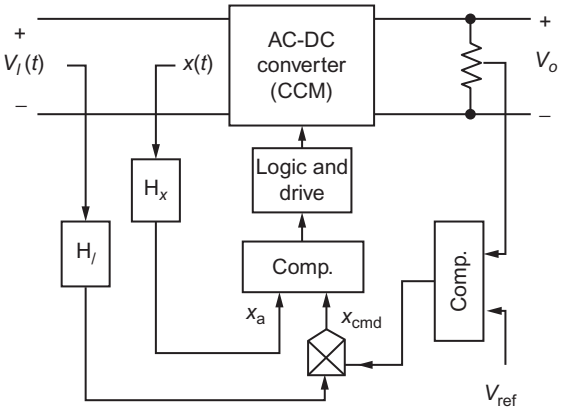

FIG. 16.24 Block diagram of PFC converter with CCM shaping technique.

16.4.1 Current Mode Control

Over many years, different current mode control techniques were developed. In this section, we will review several known methods.

16.4.1.1 Average Current Control

In average current control (ACM) strategy, the average line current of the converter is controlled to be shaped to a sine waveform which in phase with the line voltage. It is more desired than the other control strategies because the line current in a SMPS can be approximated by the average current (per switching cycle) through an input EMI filter. This control strategy is widely used in several industries due to the improved noise immunity, the lower input ripple, and the stable operation [56,70–73].

Fig. 16.22 shows a boost PFC circuit using ACM strategy. In the feedforward loop, a low value resistor R_s is used to sense the line current. Through the op-amp network formed by R_i, R_{imo}, R_f, C_p, C_z, and A_2, average line current is detected and compared with the command current signal, i_{cmd}, which is generated by the product of line voltage signal and the output voltage error signal.

There is a common issue in CCM shaping technique, that is, when the line voltage increases, the line voltage sensor provides an increased sinusoidal reference for the feedforward loop. Since the response of feedback loop is much slow than the feedforward loop, both the line voltage and the line current increase, that is, the line current is heading to wrong changing direction (with the line voltage increasing, the line current should decrease). This results in excessive input power, causing overshoot in the output voltage. The square block, x^2, in the line voltage-sensing loop shown in Fig. 16.25 provides a typical solution for this problem. It squares the output of the low-pass filter (LPF), which is in proportion to the amplitude of the line voltage and provides the divider $(A \times B)/C$ with a squared line voltage signal for its denominator. As a result, the amplitude of the sinusoidal reference i_{cmd} is negatively proportional to the line voltage, that is, when the line voltage changes, the control circuit leads the line current to change in the opposite direction, which is the desired situation. The detailed analysis and design issues can be found in [1,70–72].

As it can be seen, the ACM is a very complicated control strategy. It requires sensing the inductor current, the input voltage, and the output voltage. An amplifier for calculating the average current and a multiplier are needed. Actually, due to the advances made in IC technology, these circuits are integrated in a single chip, where many control ICs are available from different manufacturers.

16.4.1.2 I^2 Average Current Mode Control

This control technique is proposed to improve the transient response and the light load efficiency of the existing average current mode control [74]. The main principle of this control technique is applied to buck converter as shown in Fig. 16.26.

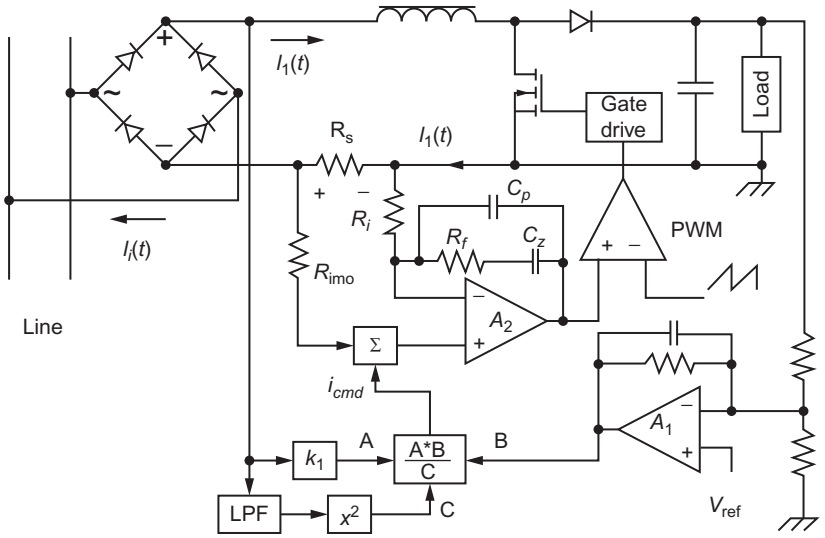

FIG. 16.25 Boost corrector using average current control.

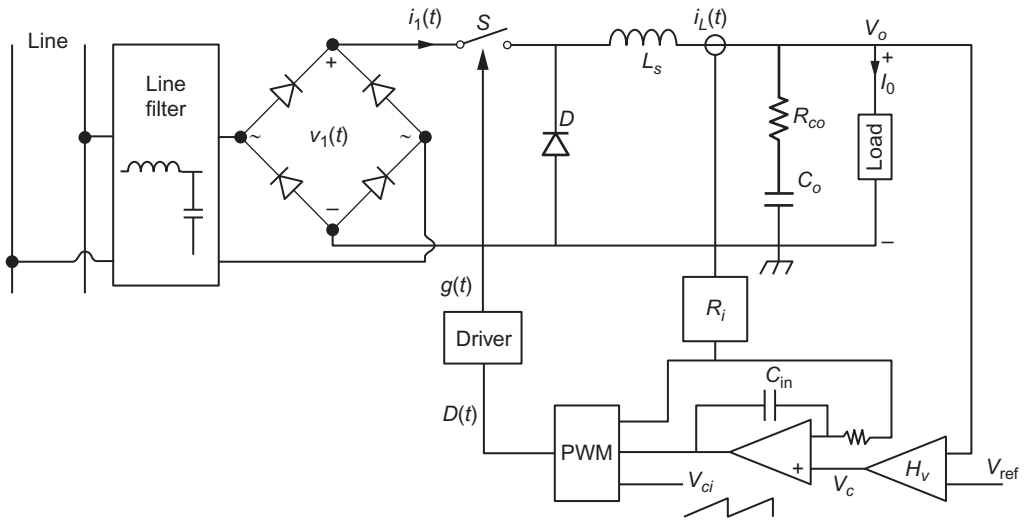

FIG. 16.26 The concept of I^2 average current mode control.

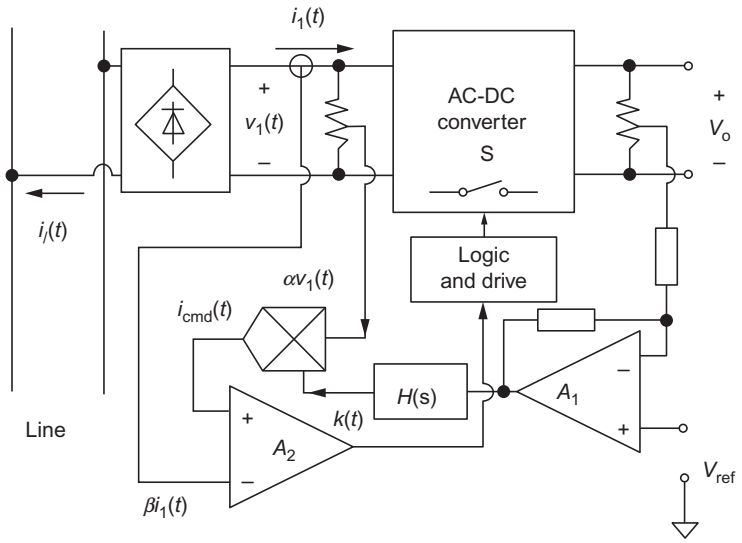

FIG. 16.27 Block diagram for variable frequency peak current control.

It is based on the use of three loops, two current inner loops and one voltage outer loop. The first current loop presents a slow integral feedback that integrates the error between the output voltage of the voltage loop V_c and the current through L_s. The second current loop presents a fast direct feedback of the current through L_s without LPF that is compared with the integrator output of the first current loop to generate the PWM signal. The third loop is dedicated to ensure the output voltage regulation. As the current through L_s is measured once and it is used twice in the two control loops, the proposed control technique is named as I^2 control. In general, this concept is applicable to constant frequency modulations and variable frequency modulations [74,75].

16.4.1.3 Variable Frequency Peak Current Control

Although the ACM is a more desired strategy, the peak current control has been widely accepted because it improves the converter efficiency and has a simpler control circuit [57,76–80]. In variable frequency peak control strategy, shown in Fig. 16.27, the output error signal $k(t)$ is fed back through its outer loop. This signal is multiplied by the line voltage signal $\alpha v_1(t)$ to form a line current command signal $i_{cmd}(t)$ $(i_{cmd}(t) = \alpha k(t) \cdot v_1(t))$. The command signal $i_{cmd}(t)$ is the desired line current shape since it follows the shape of the line voltage. The actual line current is sensed by a transducer, resulting in signal $\beta i_1(t)$ that must be reshaped to follow $i_{cmd}(t)$ by feeding it back through the inner loop. After comparing the line current signal $\beta i_1(t)$ with the command signal $i_{cmd}(t)$, the following control strategies can be realized, depending on its logic circuit [1]:

Constant on-time control: Its input current waveform is given in Fig. 16.28A. Letting the fixed on time to be T_s, the control rules are the following:

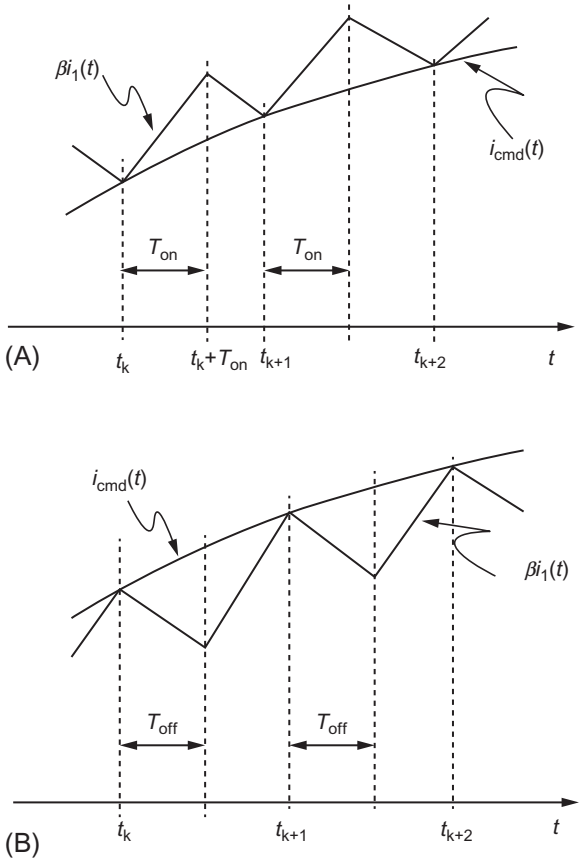

FIG. 16.28 Input current waveforms for variable frequency peak current control: (A) constant on-time control and (B) constant off-time control.

- At $t = t_k$ when $\beta i_1(t_k) = i_{cmd}(t_k)$, S is turned on.
- At $t = t_k + T_{on}$, S is turned off.

Constant off-time control: The input current waveform is shown in Fig. 16.28B. Assuming the offtime is T_{off}, the control rules are the following:

- At $t = t_k$ when $\beta i_1(t_k) = i_{cmd}(t_k)$, S is turned off.
- At $t = t_k + T_{off}$, S is turned on.

16.4.1.4 Constant Frequency Peak Current Control

Generally speaking, to make it easier to design the EMI filter and to reduce harmonics, constant switching frequency AC-DC PFC converter is preferred. Based on the block diagram shown in Fig. 16.29, with T_s is the switching period, the following control rules can be considered to realize a constant frequency peak current control (shown in Fig. 16.30B) [1]:

- At $t = nT_s$, S is turned on.
- At $t = t_n (t_n \in [(n-1)T_s, nT_s])$ when $\beta i_1(t_n) = i_{cmd}(t_n)$, S is turned off.

The logic circuit for the above control rules can be realized by using an R-S flip-flop with a constant frequency setting clock pulse (CP), as shown in Fig. 16.29. Unfortunately, this logic circuit will result in instability when the duty ratio exceeds 50%. This problem can be solved by subtracting a stabilizing ramp signal from the original command signal. Fig. 16.30A shows a complete block diagram for typical constant frequency peak current control strategy. The line current waveform is shown in Fig. 16.30B [1].

It should be noticed that in both variable frequency and constant frequency peak current control strategies, either the input current or the switch current could be controlled. Thus, it makes possible to apply these control methods to buck-type converters. There are several advantages of using peak current control [1]:

- The peak current can be sensed by current transformer, resulting in reduced transducer loss.
- The current-error compensator for average control method has been eliminated.

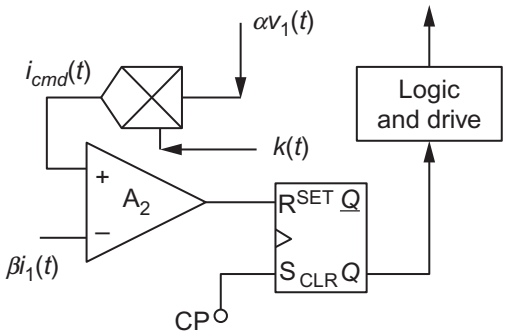

FIG. 16.29 Logic circuit for constant frequency peak current control.

- Low gain in the feedforward loop enhances the system stability.
- The instantaneous pulse-by-pulse current limit leads to increased reliability and response speed.

However, the three signals, line voltage, peak current, and output voltage signals, are still necessary to be sensed and multiplier is still needed in each of the peak current control method. Comparing with the ACM method, the input current ripple of these peak current control methods may be high when the line voltage is near the peak value. As a result, considerable line current distortion exists under high-line voltage and light low operation conditions [1].

16.4.1.5 Hysteresis Control

Unlike the constant on-time (COT) and the constant off-time control, in which only one current command is used to limit either the minimum input current or the maximum input current, the hysteresis control has two current commands, $i_{hcmd}(t)$ and $i_{lcmd}(t)$ ($i_{lcmd}(t) = \delta i_{hcmd}(t)$); $\delta$is the hysteresis band width which is supposed to be constant to limit both the minimum and the maximum of input current [81–84]. To achieve smaller ripple in the input current, we desire a narrow hysteresis band. However, with a reduced hysteresis band width a higher switching frequency is required. Therefore, the hysteresis bandwidth should be optimized based on circuit components such as switching devices and magnetic components. Moreover, the switching frequency varies with the change of line voltage, resulting in difficulty in the design of the EMI filter. The circuit diagram and input current waveform are given in Fig. 16.31A and B, respectively. When $\beta i_1(t) \geq i_{hcmd}(t)$, a negative pulse is generated by comparator A_1 to reset the R-S flip-flop. When $\beta i_1(t) \leq i_{lcmd}(t)$, a negative pulse is generated by comparator A_2 to set the R-S flip-flop. The control rules are the following:

- At $t = t_k$ when $\beta i_1(t_k) = i_{lcmd}(t_k)$, S is turned on.
- At $t = t_{k+1}$ when $\beta i_1(t_{k+1}) = i_{hcmd}(t_{k+1})$, S is turned off.

Like the above mentioned peak current control methods, the hysteresis control method has simpler implementation, enhanced system stability, and increased reliability and response speed. In addition, it has better control accuracy than that the peak current control methods have. However, this improvement is achieved on the penalty of wide range of variation in the switching frequency. It is also possible to improve the hysteresis control in a constant frequency operation [85,86], but usually, this will increase the complexity of the control circuit [1].

16.4.1.6 Charge Control

In order to make the average control method to be applicable for buck-derived topologies where the switch current instead of the inductor current needs to be controlled, an alternative method to realize ACM, namely, charge control was proposed in [87–89]. Since the total charge of the switch current per

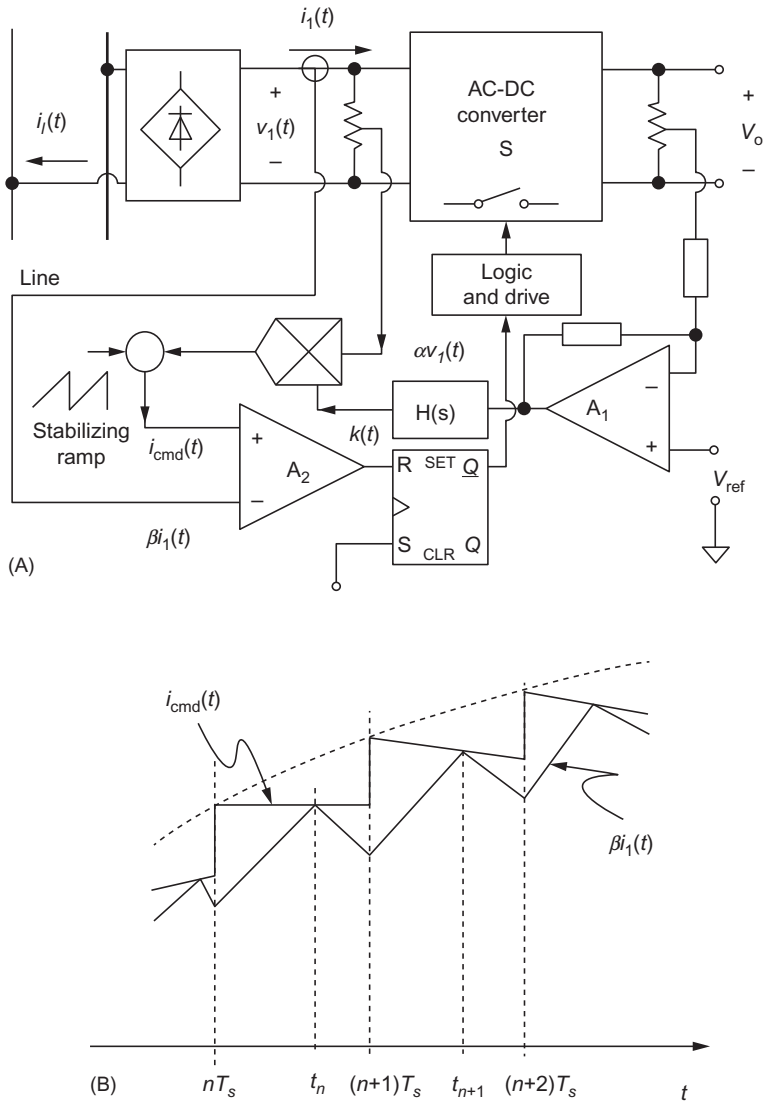

FIG. 16.30 (A) Constant frequency peak current control with stabilizing ramp compensation and (B) line current waveform for constant frequency peak current control.

switching cycle is proportional to the average value of the switch current, the average current can be detected by a capacitor-switch network. Fig. 16.32 shows a block diagram for charge control. The switch current is sensed by current transformer T_1 and charges the capacitor C_T to form average line current signal. As the switch current increases, the charge on capacitor C_T also increases. When the voltage reaches the control command v_c, the power switch turns off. At the same time, the switch S_d turns on to reset the capacitor. The next switching cycle begins with the power switch turning on and the switch S_d turning off by a CP [1].

The advantages of charge control are the following:

- Ability to control average switch current
- Better switching noise immunity than peak current control
- Good dynamic performance
- Elimination of turn-off failure in some converters (e.g., multiresonant converter) when the switch current reaches its maximum value

The disadvantages are the following:

- Synthesis of the reference v_c still requires sensing both input and output voltage and use of a multiplier.
- Subharmonic oscillation may exist.

16.4.1.7 Nonlinear-Carrier Control

To further simplify the control circuitry, nonlinear-carrier (NLC) control methods were introduced [90,91]. In CCM operation, since the input voltage is related to the output voltage through the conversion ratio, the input voltage information can be recovered by the sensed output voltage signal. Thus, the sensing of input voltage can be avoided, and therefore, the

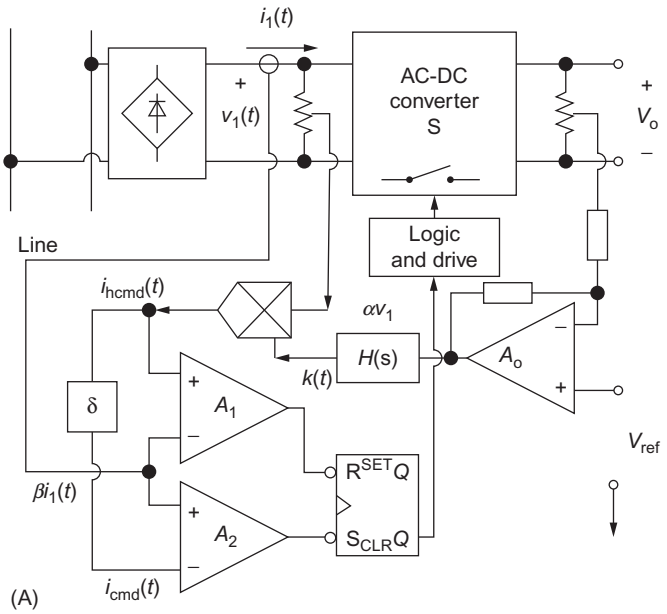

FIG. 16.31 Hysteresis control: (A) block diagram for hysteresis control and (B) line current waveform of hysteresis control.

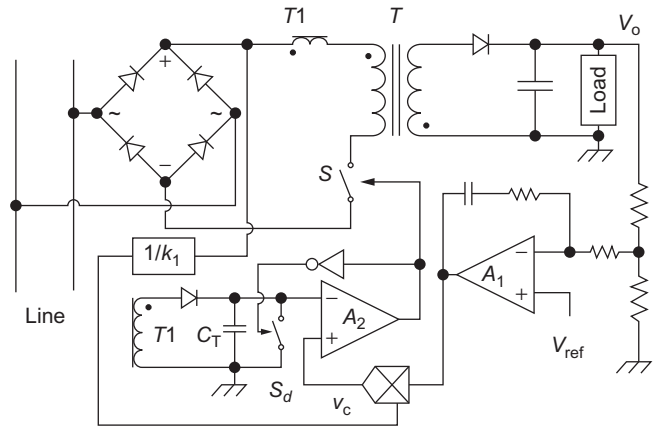

FIG. 16.32 Flyback PFC converter using charge control.

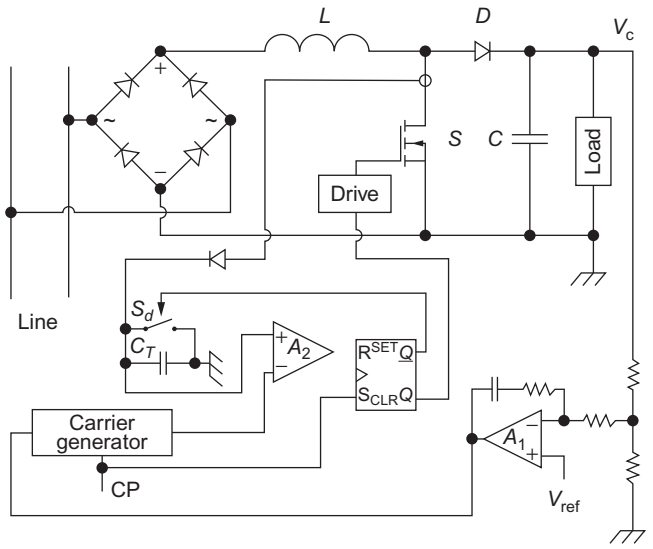

FIG. 16.33 Boost PFC converter using NLC control.

multiplier is not needed, resulting in significant simplification in the control circuitry. However, complicated NLC waveform generator and its designs are involved. Fig. 16.33 shows the block diagram of the NLC charge control first introduced in [90,1].

16.4.2 Voltage Mode Control

Generally, current mode control is preferred in current source driven converters, as the boost converter. To develop controllers for voltage source driven converter, like the buck converter and to improve dynamic response, voltage mode control (VMC) strategy was proposed [92,93]. Fig. 16.34 shows the input circuit of an AC-DC converter and its phasor diagram representation, where ϕ is the phase shift between the line current and the capacitor voltage. An *LC* network could be added to the input either before a switch-mode rectifier (SMR) or after a passive rectifier to perform such kind of control. In boost type converter, the inductor L_i is the input inductor. It can be seen from the phasor diagram that to keep the line current in phase with the line voltage, we can control either the capacitor voltage or the inductor voltage. If the capacitor voltage is chosen as controlled variable, the control strategy is known as delta modulation control [1].

16.4.2.1 Capacitor Voltage Control

Fig. 16.35 gives a SMR with PFC using capacitor voltage control [92]. The capacitor voltage $v_{c1}(t)$ is forced to track a sinusoidal command signal $v_{c1}{}^*(t)$ to indirectly adjust the line current $i_l(t)$ to be in phase with the line voltage $v_l(t)$. The command signal is the product of the line voltage signal with a phase shift of ϕ and the feedback error signal. The phase shift ϕ that has to be measured accurately is a function of the magnitudes of line voltage and line current; therefore, achieving the delta modulation control is not really simple. In addition, since ϕ is usually very small, a small change in capacitor voltage that may occur

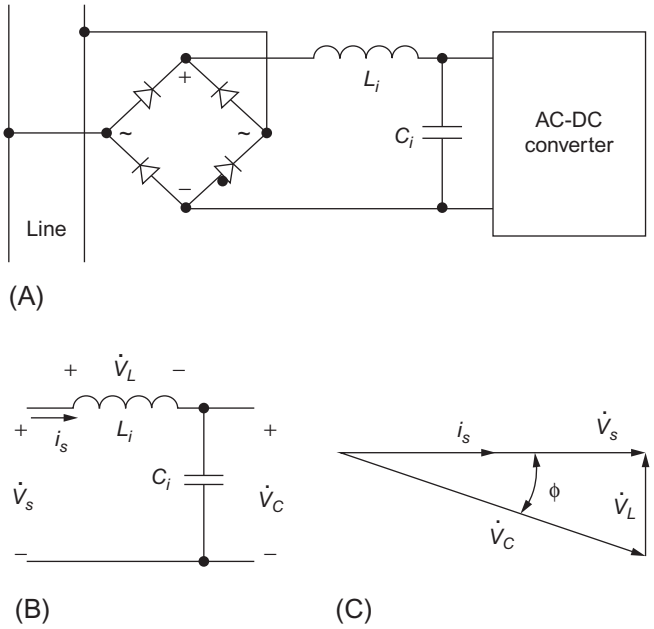

FIG. 16.34 Input circuit and phasor diagram for voltage control: (A) input circuit of voltage control ac-dc converter, (B) simplified input circuit, and (C) phasor diagram.

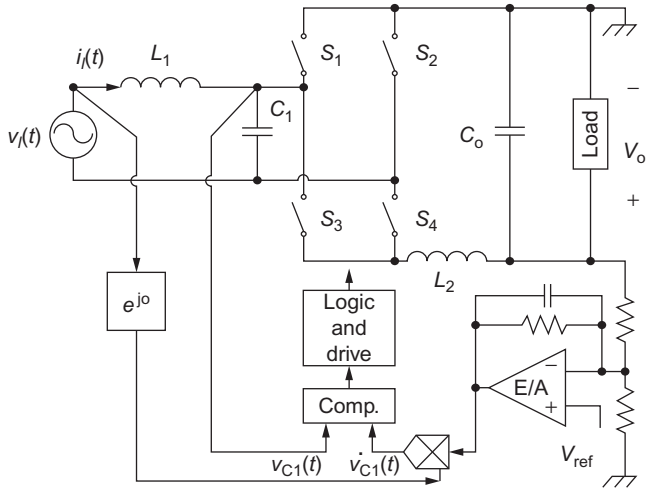

FIG. 16.35 SMR using capacitor voltage control.

due to small load change or to small output voltage reference change V_{ref} will cause a large change in the inductor voltage and hence in the line current. Thus, it makes the circuit very sensitive to parameter variations and perturbations [1].

16.4.2.2 Inductor Voltage Control

To overcome the above shortcomings, inductor voltage control (IVC) strategies were reported in [93]. Fig. 16.36 shows an SMR with PFC using IVC. As the phase difference between the line voltage and the inductor voltage is fixed at 90 degrees ideally, the control circuit is simpler in implementation than that of

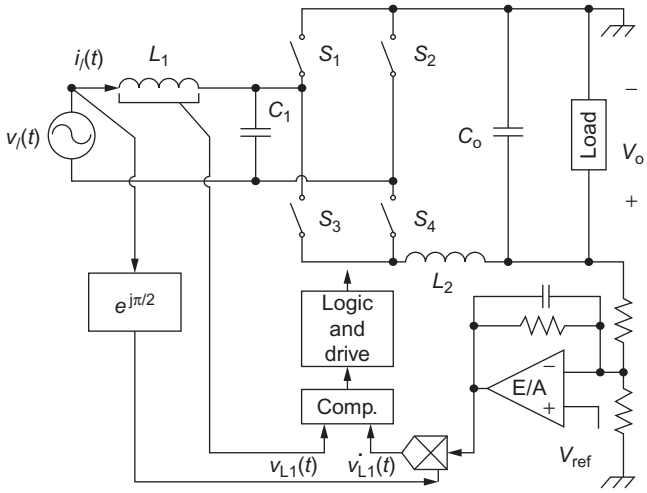

FIG. 16.36 SMR using inductor voltage control.

capacitor voltage control. As the inductor voltage is sensitive to the phase shift ϕ, but not sensitive to the change in magnitude of reference, the IVC method is more effective in keeping the line current in phase with the line voltage. However, in the implementations of both the two kinds of voltage control methods hysteresis technique is normally used. Therefore, unlike the previous current mode control, variable frequency problem is encountered in these control methods [1].

Generally speaking, by using CCM shaping technique, the input current can trace the wave shape of the line voltage well. Hence, the PF can be improved efficiently. However, this technique involves in the designing of complicated control circuits. Multiloop control strategy is needed to perform ICS and output regulation. In most CCM shaping techniques, current sensor and multiplier are required, which result in higher cost in practical applications. In some cases, variable frequency control is inevitable, resulting in additional difficulties in its closed-loop design. Table 16.1 gives a comparison among these control methods [1].

16.5 DCM Input Technique

The DCM can be considered as a special case of the CCM. It presents more than one structural change during one switching period. To get rid of the complicated control circuit invoked by CCM shaping technique and reduce the cost of the electronic interface, DCM input technique can be adopted in low-power to medium power level application.

In DCM, the inductor current of the core converter is no longer a valid state variable since its state in a given switching cycle is independent of the value in the previous switching cycle [94]. The peak of the inductor current is sampling the line voltage automatically, resulting in sinusoidal-like average input current (line current). This is why DCM input circuit is also called

TABLE 16.1 Comparison of CCM shaping techniques

	Average current	I^2 average current	VF peak current	CF peak current	Hysteresis	Charge	Nonlinear-carrier	Capacitor voltage	Inductor voltage
Input ripple	Low	Low	High	High	Low	Low	Low	Low	Low
Switching frequency	Constant	Constant and variable	Variable	Constant	Variable	Constant	Constant	Variable	Variable
Dynamic response	Slow	Improved transient response	Slow	Slow	Fast	Fast	Fast	Fast	Fast
Control signal sensed for inner loop	Input current and input voltage	Two input current and input voltage	Input (or switch) current and input voltage	Input (or switch) current and input voltage	Input current and input voltage	Input (or switch) current and input voltage	Input (or switch) current	Input voltage and capacitor voltage	Input voltage and inductor voltage
Inner loop E/A	Yes	Yes	No	No	Yes	No	No	No	No
Multiplier	Yes	No	Yes	Yes	Yes	Yes	No	Yes	Yes

"voltage follower" or "automatic controller" [1]. The benefit of using DCM input circuit for PFC is that no feedforward control loop is required, because with this approach, the internal current loop is completely eliminated, so that the switch is operated at COT and frequency. This is also the main advantage over a CCM PFC circuit, in which multiloop control strategy is essential. However, the input inductor operating in DCM cannot hold the excessive input energy because it must release all its stored energy before the end of each switching cycle. As a result, a bulky capacitor is used to balance the instantaneous power between the input and output. In addition, in DCM, the input current is normally a train of triangle pulses with nearly constant duty ratio. In this case, an input filter is necessary for smoothing the pulsating input current [1]. With the converter working in DCM, the DCM PWM control technique allows unity PF when used with converter topologies like flyback, Cuk, and Sepic. Instead, with the boost PFC, this technique causes some harmonic distortion in the line current [95].

16.5.1 PFC Capabilities of the Basic Converter Topologies in DCM

The DCM input circuit can be one of the basic DC-DC converter topologies. However, when they are applied to the rectified line voltage, they may draw different shapes of average line current. In order to examine the PFC capabilities of the basic converters, we first investigate their input characteristics. Because the input currents of these converters are discrete when they are operating in DCM, only averaged input currents are considered. Since switching frequency is much higher than the line frequency, let's assume the line voltage is constant in a switching cycle. In steady state operation, the output voltage is nearly constant, and the variation in duty ratio is slight. Therefore, constant duty ratio is considered in deriving the input characteristics [1]. To simplify the analysis of different topologies of converter working in DCM for achieving the main objective of current shaping, the following assumptions were made:

1. The converter is lossless.
2. The duty ratio of the converter is kept constant throughout the entire line cycle.
3. The switching frequency is much higher than the line frequency.
4. The leakage inductances of transformers are negligible.
5. Despite of slight changes in DC bus voltage, it is considered to be constant during each line cycle.

16.5.1.1 Buck Converter

The basic buck converter topology and its input current waveform when operating in DCM are shown in Fig. 16.37A and B, respectively. The instantaneous output current of the rectifier is presented as follows:

$$i_1(t) = \frac{|v_1(t)| - V_0}{L} t \tag{16.27}$$

It can be shown that the average output current of the rectifier in one switching cycle is given by

$$i_{1,\text{avg}}(t) = \frac{1}{2} \cdot D^2 T_s \frac{|v_1(t)| - V_0}{L} = \frac{D^2 T_s}{2L} (|v_1(t)| - V_0) \tag{16.28}$$

The average line current or the average input current of the rectifier during one switching cycle is given as follows:

$$\begin{cases} i_l(t) = \dfrac{D^2 T_s}{2L} (|v_1(t)| - V_0) & \text{if } v_1(t) \geq V_0 \\ i_l(t) = -\dfrac{D^2 T_s}{2L} (|v_1(t)| - V_0) & \text{if } v_1(t) \leq -V_0 \\ i_l(t) = 0 & \text{if } |v_1(t)| \geq V_0 \end{cases} \tag{16.29}$$

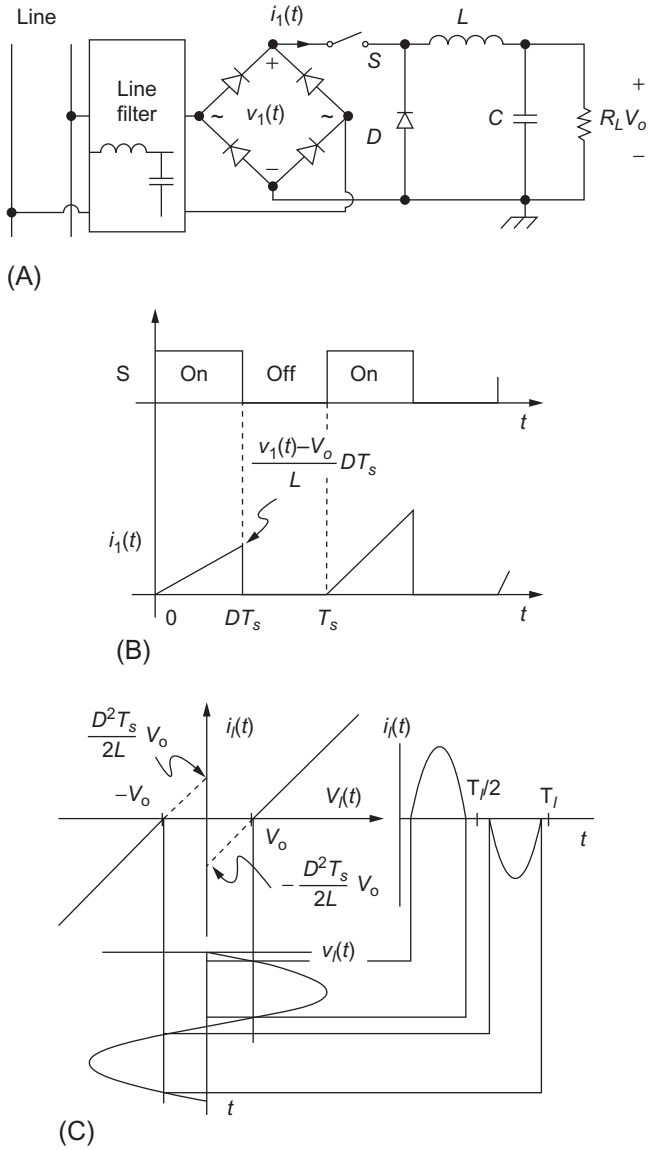

FIG. 16.37 Input *I-V* characteristic of basic buck converter operating in DCM: (A) buck converter, (B) input current, and (C) input *I-V* characteristic.

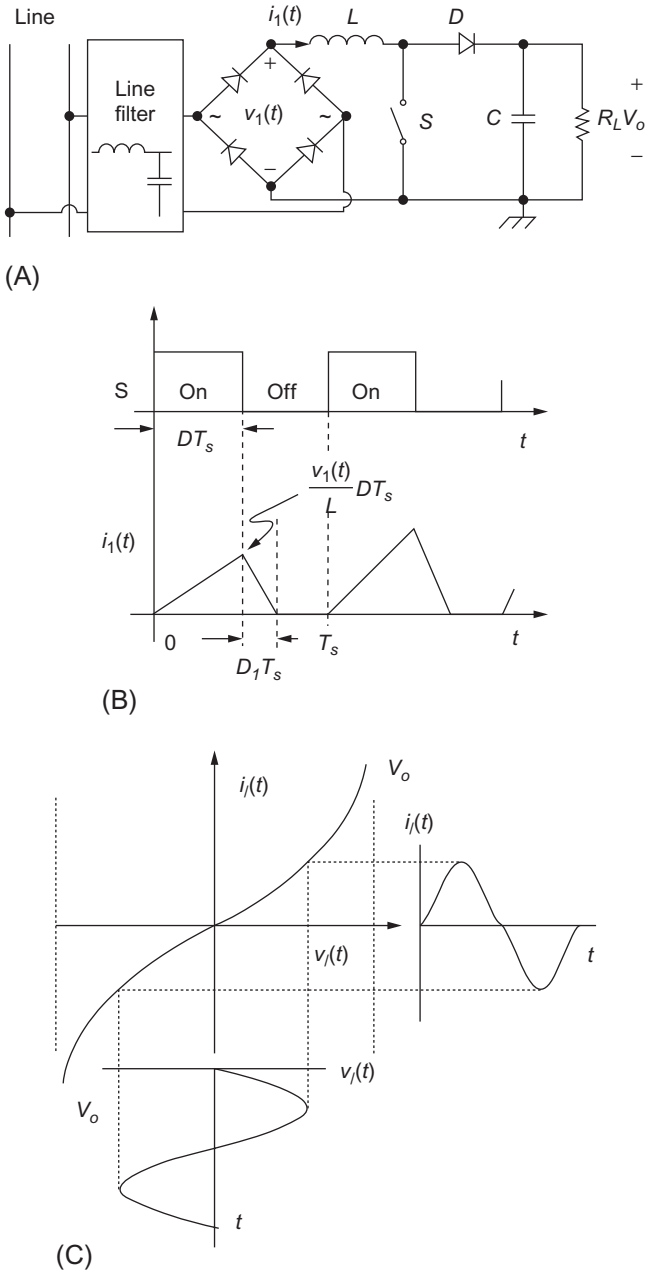

FIG. 16.38 Input *I-V* characteristic of basic boost converter operating in DCM: (A) boost converter, (B) input current, and (C) input *I-V* characteristic.

Where it is supposed that the input voltage waveform is sinusoidal and the drop voltage along the rectifier is neglected. Based on Eq. (16.27), Fig. 16.37C shows that the input voltage-input current *I-V* characteristic consists of two straight lines in quadrants I and III. These straight lines that are presenting the average instantaneous input current versus the input voltage do not go through the origin. It is obvious that the instantaneous average value of the input current is equal to zero within the interval $v_1 \in [-V_0 V_0]$. When $v_1(t) \geq 0 \& v_1(t) \geq V_0$, positive input current would occurs when $v_1(t) \leq 0 \& v_1(t) \leq -V_0$ and negative input current occurs. As a result, due to the zero regions of the input current as shown in Fig. 16.37C. The input current is distorted simply because the buck converter can work only under the condition when the input voltage is larger than the output voltage. Therefore, the basic buck converter cannot fulfill the requirement of a good candidate that can be used to achieve the DCM input PFC.

16.5.1.2 Boost Converter

The basic boost converter and its input current waveform are shown in Fig. 16.38A and B, respectively. This current can be presented by the following expression:

$$\begin{cases} i_1(t)=\dfrac{|v_1(t)|}{L}t & kT_s\le t\le kT_s+DT_s \\ i_1(t)=-\dfrac{V_0-|v_1(t)|}{L}(t-(D+D_1)T_s) & kT_s+DT_s\le t\le kT_s+(D+D_1)T_s \\ i_1(t)=0 & kT_s+(D+D_1)T_s\le t\le (k+1)T \end{cases} \tag{16.30}$$

The average instantaneous input current of the boost converter in one switching cycle is given as follows:

$$\begin{aligned} i_{1,\text{avg}}(t)&=\frac{1}{2}\cdot DT_s\frac{|v_1(t)|}{L}(D+D_1) \\ &=\frac{D^2T_s}{2L}\frac{|v_1(t)|V_0}{V_0-|v_1(t)|} \end{aligned} \tag{16.31}$$

where DT_s is the interval of time during which the inductor current increases from zero to the current peak and D_1T_s is the time during which the inductor current decreases from the current peak to zero.

The average line current or the average input current of the rectifier during one switching cycle is given as follows:

$$\begin{aligned} i_{l,\text{avg}}(t)&=\frac{D^2T_s}{2L}\frac{|v_1(t)|V_0}{V_0-|v_1(t)|}v_1(t)\ge 0 \\ i_{l,\text{avg}}(t)&=-\frac{D^2T_s}{2L}\frac{|v_1(t)|V_0}{V_0-|v_1(t)|}v_1(t)\le 0 \end{aligned} \tag{16.32}$$

By plotting Eq. (16.32), we obtain the input *I-V* characteristic curve as given in Fig. 16.35C. As we can see that as long as the output voltage is larger than the peak value of the line voltage in certain range, the relationship between $v_1(t)$ and $i_{1,\text{avg}}(t)$ is nearly linear. When the boost converter is connected to the line, it will draw almost sinusoidal average input current from the line, shown as in Fig. 16.38C [1].

Because of the above reasons, boost converter is comparably superior to most of the other converters when applied to do PFC. However, it should be noted that boost converter can operate properly only when the output voltage is higher than its input voltage. When low-voltage output is needed, a step-down DC-DC converter must be cascaded [1].

16.5.1.3 Buck-Boost Converter

Fig. 16.39A shows a basic buck-boost converter topology; its input current waveform is shown in Fig. 16.39B. This current can be presented by the following expression:

$$\begin{cases} i_1(t)=\dfrac{|v_1(t)|}{L}t & kT_s\le t\le kT_s+DT_s \\ i_1(t)=0 & kT_s+DT_s\le t\le (k+1)T_s \end{cases} \tag{16.33}$$

The averaged input current of this converter can be found according to Eq. (16.33) as follows:

$$i_{1,\text{avg}}(t)=\frac{D^2T_s}{2L}|v_1(t)| \tag{16.34}$$

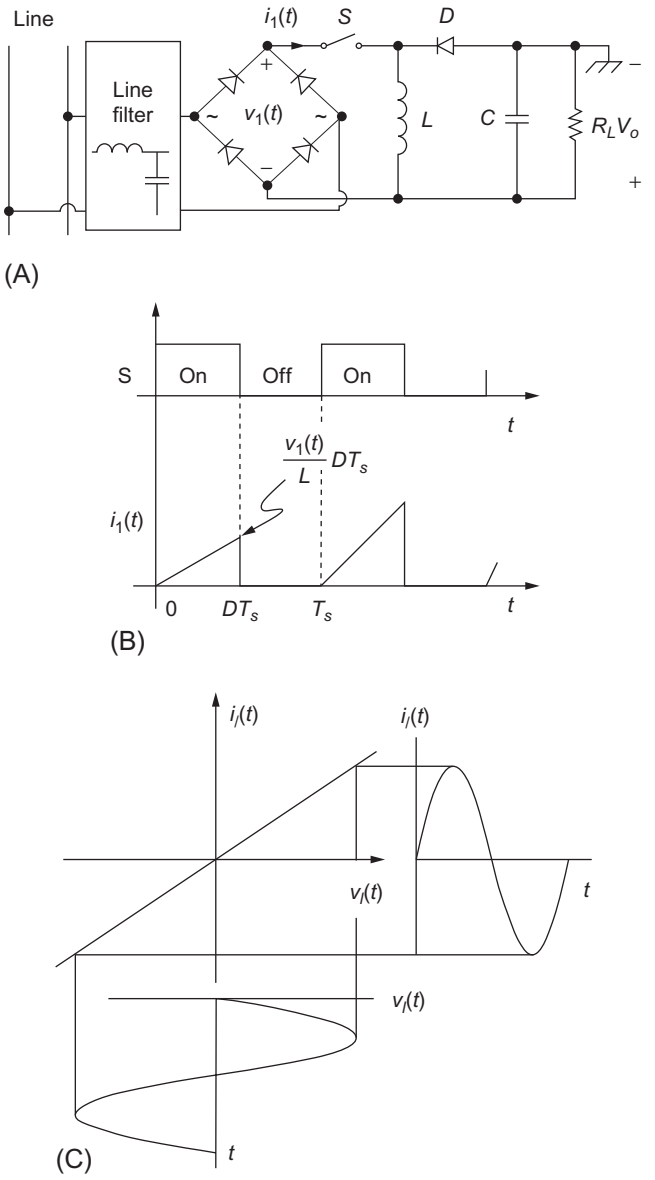

FIG. 16.39 Input *I-V* characteristic of basic buck-boost converter operating in DCM: (A) buck-boost converter, (B) input current, and (C) input *I-V* characteristic.

The average line current or the average input current of the rectifier during one switching cycle is given as follows:

$$i_{l,\text{avg}}(t)=\frac{D^2T_s}{2L}v_1(t) \tag{16.35}$$

Eq. (16.35) gives a perfect linear relationship between $i_{l,\text{avg}}(t)$ and $v_1(t)$, which proves that the buck-boost topology has an excellent automatic PFC property. It is obvious that the input current of this kind of converter is independent of the discharging behavior of the inductor. Its input *I-V* characteristics and input voltage and current waveforms are shown in Fig. 16.39C.

Furthermore, the main objective of the buck-boost converter is to ensure an output voltage that can be either higher or lower than the input voltage; in the same time and due to the continuous linear relationship between $i_{l,\text{avg}}(t)$ and $v_1(t)$ based on the DCM technique, this topology demonstrates strong availability to achieve a sine waveform of the input current and in phase with the input voltage that means a good PFC function.

Theoretically, buck-boost converter is a perfect candidate. Unfortunately, this topology has two limitations: (1) The polarity of its output voltage is reversed, that is, the input voltage and the output voltage cannot have the common ground, and (2) it needs floating drive for the power switch. The first limitation circumscribes this circuit into a very narrow scope of applications. As a result, it is not widely used [1].

16.5.1.4 Flyback Converter

Flyback converter is an isolated converter whose topology is presented in Fig. 16.40A; its input current waveform is shown in Fig. 16.40B, and it is presented by the following equation:

$$\begin{cases} i_1(t) = \dfrac{|v_1(t)|}{L_m} t & kT_s \le t \le kT_s + DT_s \\ i_1(t) = 0 & kT_s + DT_s \le t \le (k+1)T_s \end{cases} \tag{16.36}$$

It can be seen clearly that this current is similar to the buck-boost converter input current, where L_m is the magnetizing inductance of the output transformer. The averaged input current of this converter can be found according to Eq. (16.36) as follows:

$$i_{1,\text{avg}}(t) = \frac{D^2 T_s}{2L_m} |v_1(t)| \tag{16.37}$$

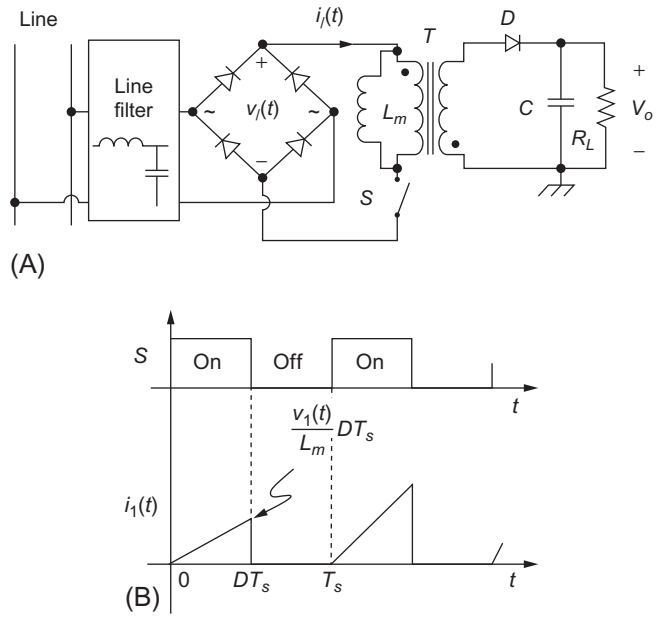

FIG. 16.40 Input *I-V* characteristic of basic flyback converter operating in DCM: (A) flyback converter and (B) input current.

The average line current or the average input current of the rectifier during one switching cycle is given as follows:

$$i_{l,\text{avg}}(t) = \frac{D^2 T_s}{2L_m} v_1(t) \tag{16.38}$$

Therefore, the flyback converter topology has the same input *I-V* characteristic as the buck-boost converter topology, and hence, it has the same input voltage and input current waveforms as shown in Fig. 16.40C.

Comparing with buck-boost converter, flyback converter has all the advantages of the buck-boost converter. What's more, input-output isolation can be provided by flyback converter. These advantages make flyback converter well suitable for PFC with DCM input technique. Comparing with boost converter, the flyback converter has better PFC, and the output voltage can be either higher or lower than the input voltage. However, due to the use of power transformer, the flyback converter has some drawbacks such as high d_i/d_t noise, lower efficiency, and lower density (larger size and heavier weight) [1].

16.5.1.5 Forward Converter

The forward converter topology is shown in Fig. 16.41. In order to avoid transformer saturation, it is well-known that forward converter needs the third winding to demagnetize (reset) the transformer.

The forward converter topology, when compared with the flyback topology, has the advantages of lower peak output current and less leakage energy-related problems; it is generally more energy efficient, and it is used for applications requiring little higher power output (in the range of 100–200 W). However, the circuit topology, especially the output filtering circuit, is not as simple as in the flyback converter, and when its basic

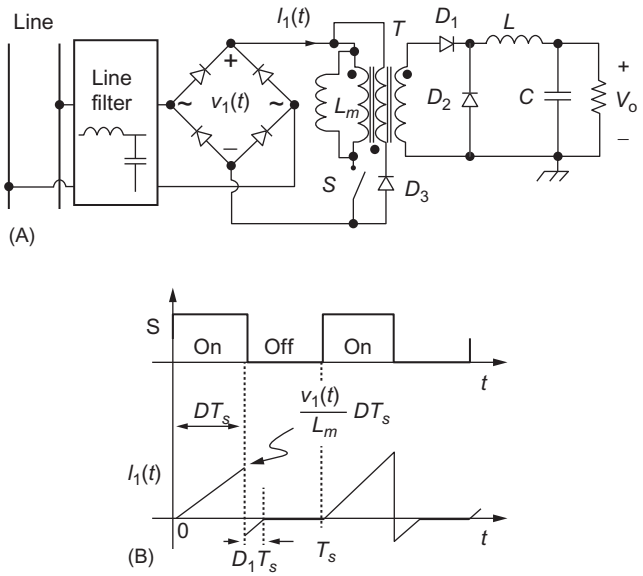

FIG. 16.41 (A) Forward converter and (B) input current waveform.

topology is connected to the rectified line voltage, the path of the demagnetizing current through the third winding is blocked by the rectifier bridge diodes during the turn-off period of the main switch *S*. Moreover, energy transfer to output ceases during the interval when the rectified input voltage $|v_1(t)|$ is lower than the reflected output voltage on the primary (i.e., $V_0 \cdot n_1/n_3$), resulting in distorted input current. Therefore, this basic topology cannot be used to achieve the PFC purpose unless a certain circuit modification is applied such as forward converter with a resistor-capacitor-diode (RCD) clamp circuit, the forward converter with an active clamp (FAC).

16.5.1.6 Cuk Converter and Sepic Converter

It can be shown that Cuk converter and Sepic converter given in Fig. 16.42A and B, respectively, have the same input *I-V* characteristic. Each of these converter topologies has two inductors, with one located at its input and the other at its output. Let's consider the case when the input inductor operates in DCM, while the output inductor operates in CCM. In this case, the capacitor C_1 can be designed with large value to balance the instantaneous input/output power, resulting in high PF in the input and low second-harmonic ripple in the output voltage. To investigate the input characteristic of these converters, let's take the Cuk converter as an example. One should note that the results from the Cuk converter are also suitable for Sepic converter [1].

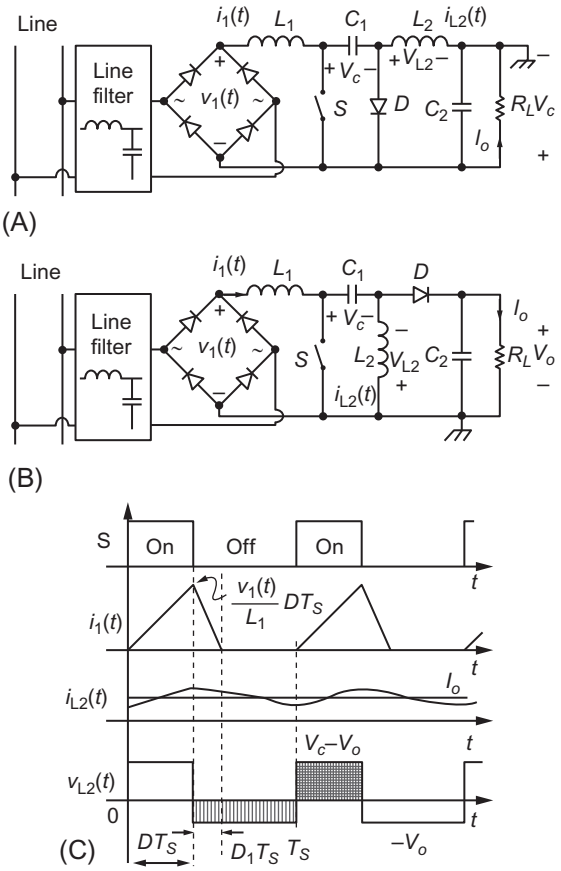

FIG. 16.42 Input *I-V* characteristic of basic Cuk converter and Sepic converter operating in DCM: (A) Cuk converter, (B) Sepic converter, and (C) typical waveforms of Cuk converter with input inductor operating in DCM.

For the Cuk converter shown in Fig. 16.42A, the waveforms for input inductor current (the same as the input current), output inductor current, and the voltage across the output inductor are depicted in Fig. 16.42C [1]. Assume that the capacitor C_1 is large enough to be considered as a voltage source V_c, in steady state, employing volt-second equilibrium principle on L_2, we obtain

$$V_C = \frac{1}{D} V_o \tag{16.39}$$

The input inductor current (the same as the input converter current) can be presented by the following expression:

$$\begin{cases} i_1(t) = \dfrac{|v_1(t)|}{L} t & kT_s \le t \le kT_s + DT_s \\ i_1(t) = -\dfrac{D|v_1(t)| - V_0}{DL}(t - (D+D_1)T_s) & kT_s + DT_s \le t \le kT_s + (D+D_1)T_s \\ i_1(t) = 0 & kT_s + (D+D_1)T_s \le t \le (k+1)T_s \end{cases} \tag{16.40}$$

The input inductor current reset time ratio D_1 is given by

$$D_1 = -\frac{D^2|v_1(t)|}{V_0 - D|v_1(t)|} \tag{16.41}$$

Therefore the averaged input current can be found as

$$\begin{aligned} i_{1,\text{avg}}(t) &= \frac{1}{2} \cdot DT_s \frac{|v_1(t)|}{L}(D+D_1) \\ &= \frac{D^2 T_s}{2L} \frac{|v_1(t)| V_0}{V_0 - D|v_1(t)|} \end{aligned} \tag{16.42}$$

It can be seen that Eq. (16.42) is very similar to Eq. (16.32) except that the denominator in the former equation is $(V_o - Dv_1(t))$ instead of $(V_o - v_1(t))$. This will lead to some improvement in that *I-V* characteristic in Cuk converter. Referring to the *I-V* characteristic shown in Fig. 16.38C, Cuk converter has a curve more close to a straight line. Such improvement, however, is achieved at the expense of using more circuit components. It can be proved that the same results can be obtained by the Sepic converter [1].

16.5.1.7 Zeta Converter

Fig. 16.43A gives a Zeta converter connected to the line. In DCM operation, the key waveforms are illustrated in Fig. 16.43B, where we presume the capacitor being equivalent to a voltage source V_c. As we can see that the converter input current waveform is exactly the same as that drawn by a buck-boost converter [1]. Thus, the instantaneous input current for

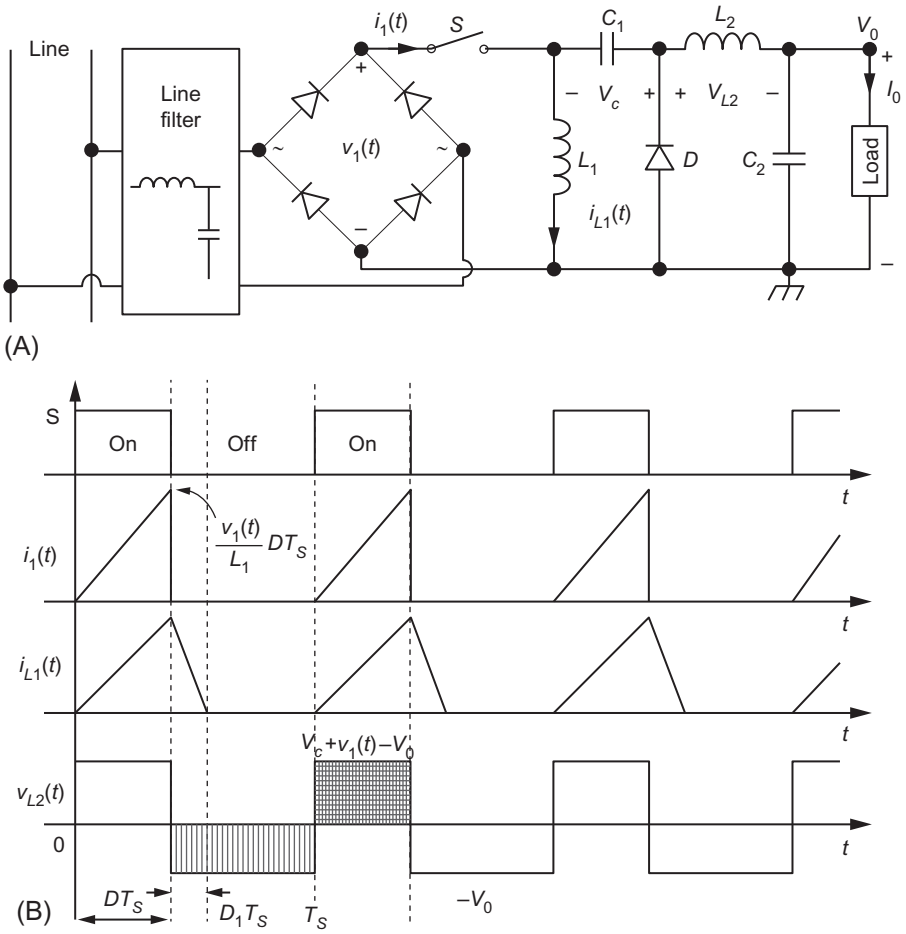

FIG. 16.43 Input *I-V* characteristic of basic Zeta converter operating in DCM: (A) Zeta converter and (B) typical waveforms of Zeta converter with input inductor operating in DCM.

the Zeta converter is identical to that for the buck-boost converter. It is expressed as follows:

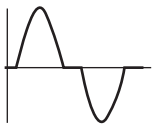
$$\begin{cases} i_1(t) = \dfrac{|v_1(t)|}{L}t & kT_s \le t \le kT_s + DT_s \\ i_1(t) = 0 & kT_s + DT_s \le t \le (k+1)T_s \end{cases} \tag{16.43}$$

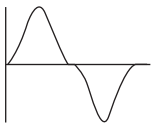
The averaged input current of this converter can be found according to Eq. (16.43) as follows:

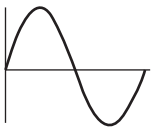
$$i_{1,\text{avg}}(t) = \frac{D^2 T_s}{2L}|v_1(t)| \tag{16.44}$$

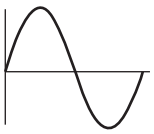
The average line current or the average input current of the rectifier during one switching cycle is given as follows:

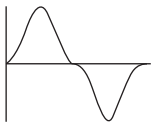
$$i_{l,\text{avg}}(t) = \frac{D^2 T_s}{2L}v_1(t) \tag{16.45}$$

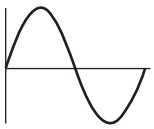












which is the same as the one given by Eq. (16.33). As a result, the Zeta converter has as good automatic PFC capability as the buck-boost converter. The improvement achieved here is the noninverted output voltage. However, like the buck converter, floating drive is required for the power switch [1].

Based on the above discussion, we may conclude that all the eight basic converters except forward converter have good inherent PFC capability and are available for DCM PFC usage. Among them, boost converter and flyback converter are especially suitable for single-stage PFC scheme because they have minimum component count and grounded switch drive, and their power switches are easy to be shared with the output DC-DC converter. Hence, these two converters are most preferable by the designers for PFC purpose. The other converters could also be used to perform certain function such as circuit protection and small output voltage ripple. The characteristics of the eight basic converter topologies are summarized in Table 16.2 [1].

16.5.1.8 Flyboost Converter

Unlike the aforementioned converter used for PFC applications, the flyboost converter was proposed in [96,97] to benefit simultaneously from the advantages of both flyback power transfer and boost power transfer. This proposed topology gains

TABLE 16.2 Comparison of basic converter topologies operating for DCM input technique

	Buck	Boost	Buck-boost	Flyback	Forward[a]	Cuk and Sepic	Zeta
Line current waveform					–		
Switch drive	Floating	Grounded	Floating	Grounded	Grounded	Grounded	Floating

[a]The standard forward converter is not recommended as a PF corrector since the rectifier at the input will block the demagnetizing current through the tertiary winding.

the features of the flyback and boost converter from point of view of power transfer process to achieve a unify PF and a very reduced input current harmonics. Indeed, it can be said that the difference of this topology from the basic topologies such as boost, SEPIC, buck-boost, Cuk, and buck is not so important; however, the operation principle is very different. It is obvious that there are only two operation modes for flyboost converter, the flyback mode and the boost mode. A derived flyboost converter topology has been used as shown in Fig. 16.44. It consists mainly of one switch, a flyboost transformer T_1, tow input transformer T_2, two capacitor, an output inductor, and six diodes [98,99]. This derived PFC topology has some advantages in comparison with other PFC topologies such as [96]

- one switch is used that means easy control implementation,
- high-performance capability for power transfer process,
- high PF and high efficiency,
- automatic clamping of the intermediate dc bus voltage within a desirable range,
- relatively low-voltage stress on power devices,
- capability to support input inrush and to ensure self-surge current protection,
- can be used in medium power level with low-cost.

16.5.2 AC-DC Power Supply with DCM Input Technique

In two-stage PFC power supply, the DCM converter is connected in front of the ac line to achieve high input PF and provide a roughly regulated dc bus voltage, as shown in Fig. 16.45. This stage is also known as "preregulator." The duty ratio of the preregulator should be maintained relatively stable so that high PF is ensured. To stabilize the dc bus voltage, a bank capacitor is

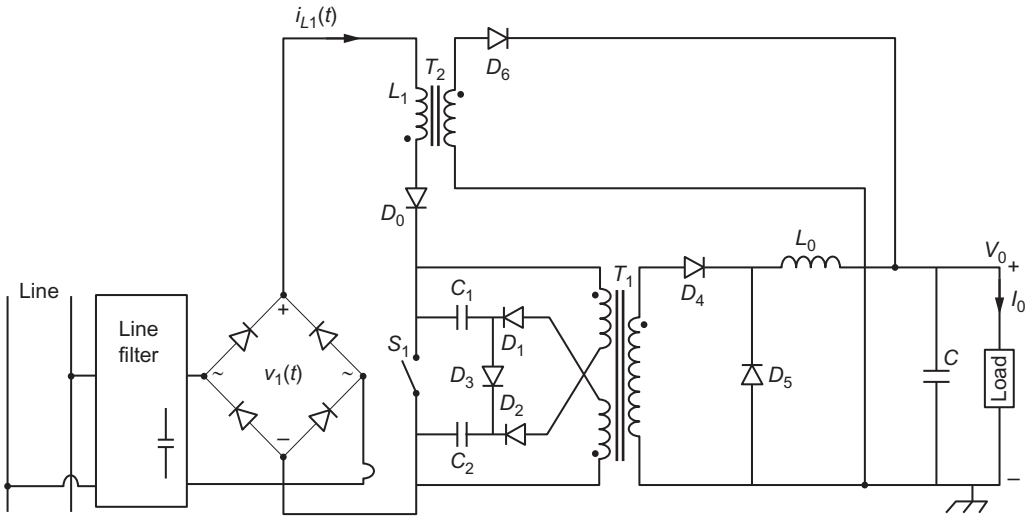

FIG. 16.44 The improved topology of the flyboost converter.

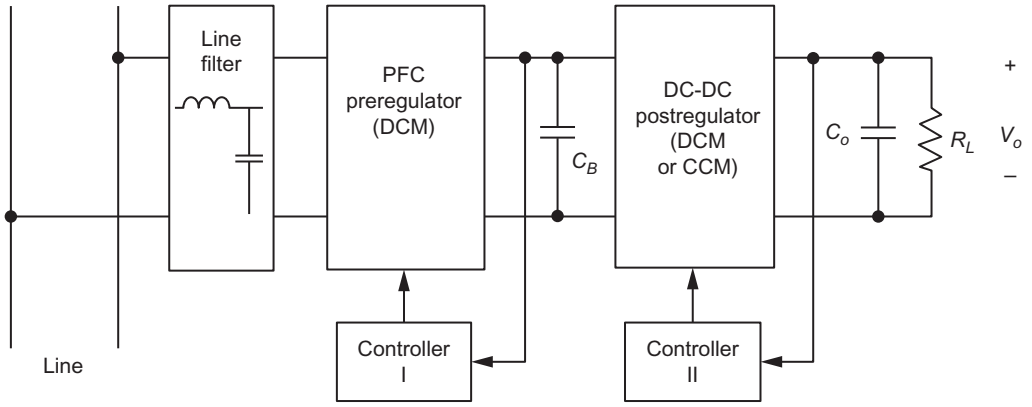

FIG. 16.45 DCM input preregulator in two-stage ac-dc power supply.

used at the output of the preregulator. The second stage, followed by the preregulator, is a DC-DC converter, called postregulator, with its output voltage being tightly controlled. This stage can operate either in DCM or in CCM. However, CCM is normally preferred to reduce the output voltage ripple [1].

DCM input technique has been widely used in one-stage PFC circuit configurations. Using a basic converter (usually boost or flyback converter) operating in DCM, combining it with another isolation converter can form a one-stage PFC circuit. A storage capacitor is generally required to hold the dc bus voltage in these combinations. Unlike the two-stage PFC circuit, in which the bus voltage is controlled, the single-stage PFC converter has only one feedback loop from the output. The input circuit and the output circuit must share the same control signal. In [100–102], a number of combinations have been studied. Figs. 16.46 and 16.47 show a few examples of successful combinations. Since the input circuit and the output circuit are in a single-stage, it is possible for them to share the same power switch. Thus it results in single-stage single-switch PFC (S_4-PFC) circuit, as shown in Fig. 16.47 [100,103,104,1].

The boost integrated with flyback rectifier/energy storage/dc-dc converter (BIFRED) and boost integrated with buck rectifier/energy storage/dc-dc converter (BIBRED) are two single-stage converters of the integrated high-quality rectifier-regulator (IHQRR) family that have been firstly presented by [103–106]. Both topologies are able to ensure an input current with a low harmonic content and, also, a regulated and isolated output voltage bus using only one switch. The two topologies of BIFRED and BIBRED are designed so that the input inductor and the output inductive element both operate in the DCM mode. It is obvious that BIFRED topology presents a strong similarity with the isolated version of the Sepic converter. Furthermore, the BIBRED topology resembles to the isolated version of the Cuk converter [107]. As it was explained, the two topologies of the BIFRED and BIBRED converters are composed of two integrated converters, where only one switch is used. The BIFRED converter is an integration of a discontinuous conduction mode (DCM) boost converter and a flyback converter. In the BIBRED, the corresponding parts are a DCM boost converter and a forward converter. Schematics of the BIFRED and BIBRED converters are shown in Fig. 16.47A and B, respectively.

Due to the simplicity and low-cost, DCM boost converter is most commonly used for unity PF operation. The main drawback of using boost converter is that it shows considerable distortion of the average line current owing to the slow discharging of the inductor after the switch is turned off [1].

The output DC-DC converter can operate either in DCM or in CCM if small output ripple is desired. If the output circuit operates in CCM, there exists a power unbalance in S^4-PFC converter when the load changes. Because the duty ratio is only sensitive to the output voltage in CCM operation, when the output power (output current) decreases, the duty ratio will keep unchanged. As both the input and the output circuit share the power switch, the input circuit will draw an unchanged power from the ac source. As a result, the input power is higher than the output power. The difference between the input power and the output power has to be stored in the storage capacitor, and hence, increase in the dc bus voltage occurs. With the dc bus voltage's rising, the duty ratio decreases. This process will be finished until a new power balance is built. As we can see, the new power balance is achieved at the penalty of increased voltage stress, resulting in high conduction losses in circuit components. Particularly, the high bus voltage causes difficulties in developing S^4-converter for universal input (input line voltage *rms* value from ac 90–260 *V*) application [1].

Recent research on solving this problem can be found in [108–116]. The circuit in [108] uses two bulk capacitors that share the dc bus voltage change, shown in Fig. 16.48A. As a result, lower voltage is present at each of the capacitor. Ref. [109] proposed a modified boost-forward PFC converter, in which a negative current feedback is introduced to the input circuit by the coupled windings of forward transformer, shown in Fig. 16.48B. In [110], a series resonant circuit called charge pump circuit is introduced into S^4-PFC circuit, shown in Fig. 16.48C. As the load decrease, the charge pump circuit can suppress the dc bus voltage automatically [1].

16.5.3 CRM Technique

In this control technique, the switch is turned on when the inductor current falls to zero (when it reaches the time axis), where the switch is kept on for a constant duration during the line cycle and the switch off duration is controlled by a given signal loop. It is clear that the converter operates at the boundary between the continuous and discontinuous current mode (CCM-DCM) [117,118]. It can be said that this type of control is a particular case of hysteretic control in which the lower current command is zero anywhere.

It was proved that the CRM technique has some interesting advantages when it is applied to the boost converter, where the line current is shaped to be sinusoid under COT control [117,119]. Unfortunately, the CRM technique when it is

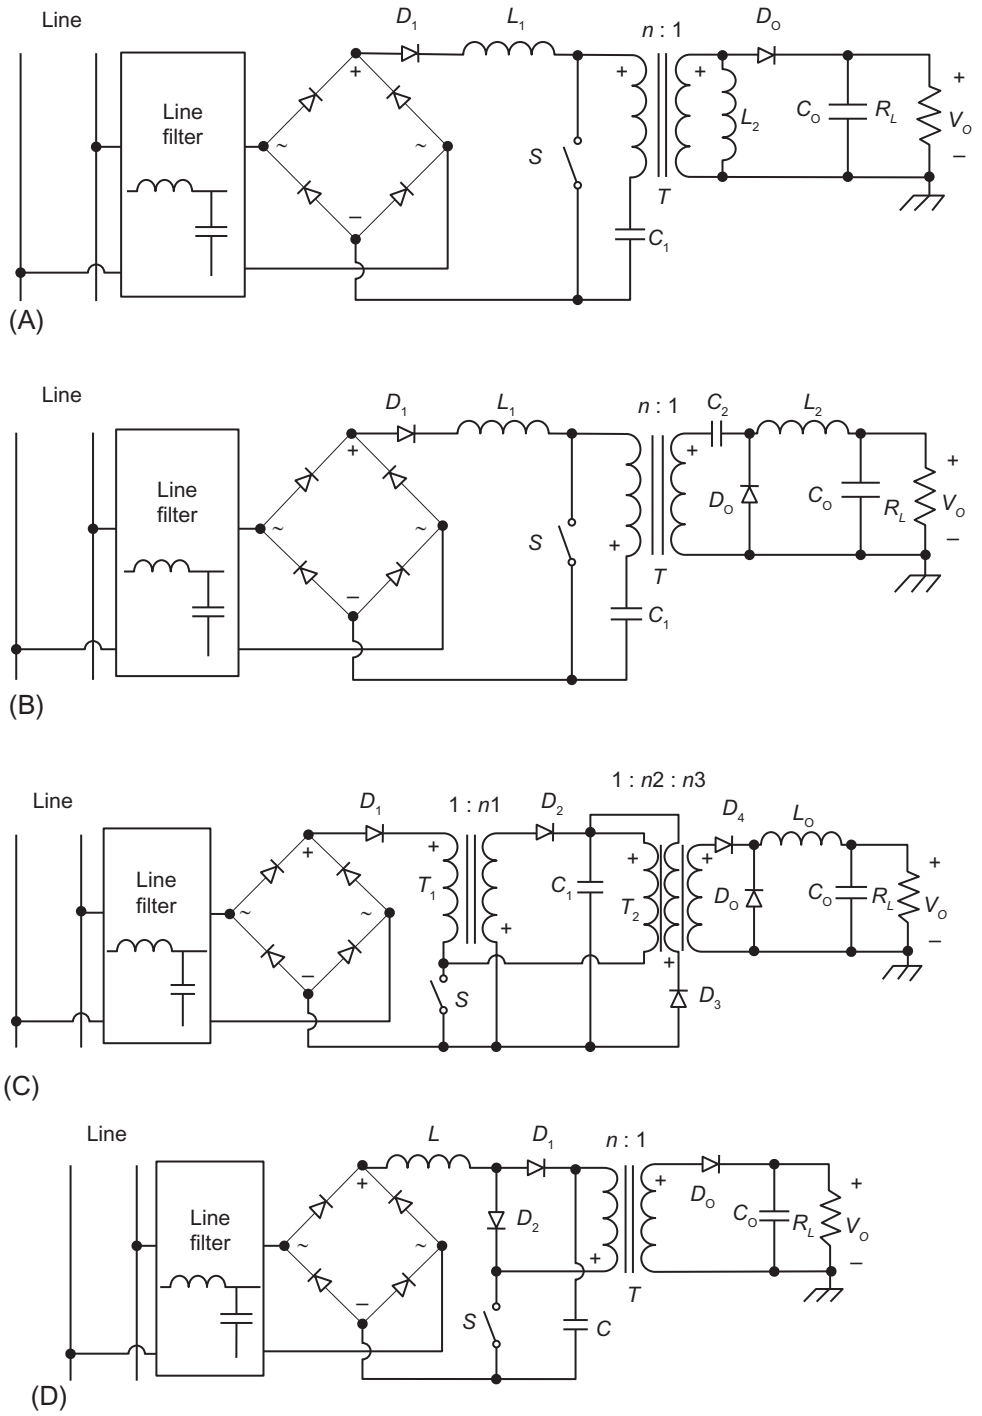

FIG. 16.47 Single-stage single-switch PFC circuit: (A) boost-flyback combination circuit (BIFRED), (B) boost-buck combination circuit (BIBRED), (C) flyback-forward combination, and (D) boost-flyback combination.

applied to the buck and flyback converters and their derived topologies such as buck-boost, Sepic, and Cuk under COT control leads to a somewhat distorted line current. Hence, the application of CRM technique to these kinds of converters will not allow to meet the PF and THD requirements within the known standards [117,119,120]. To overcome the drawbacks of the CRM control technique, variable on-time (VOT) control technique was proposed and applied to the buck PFC converter [121,122] to achieve high PF and low THD requirement given by the standards. In the same way, based on the input voltage,

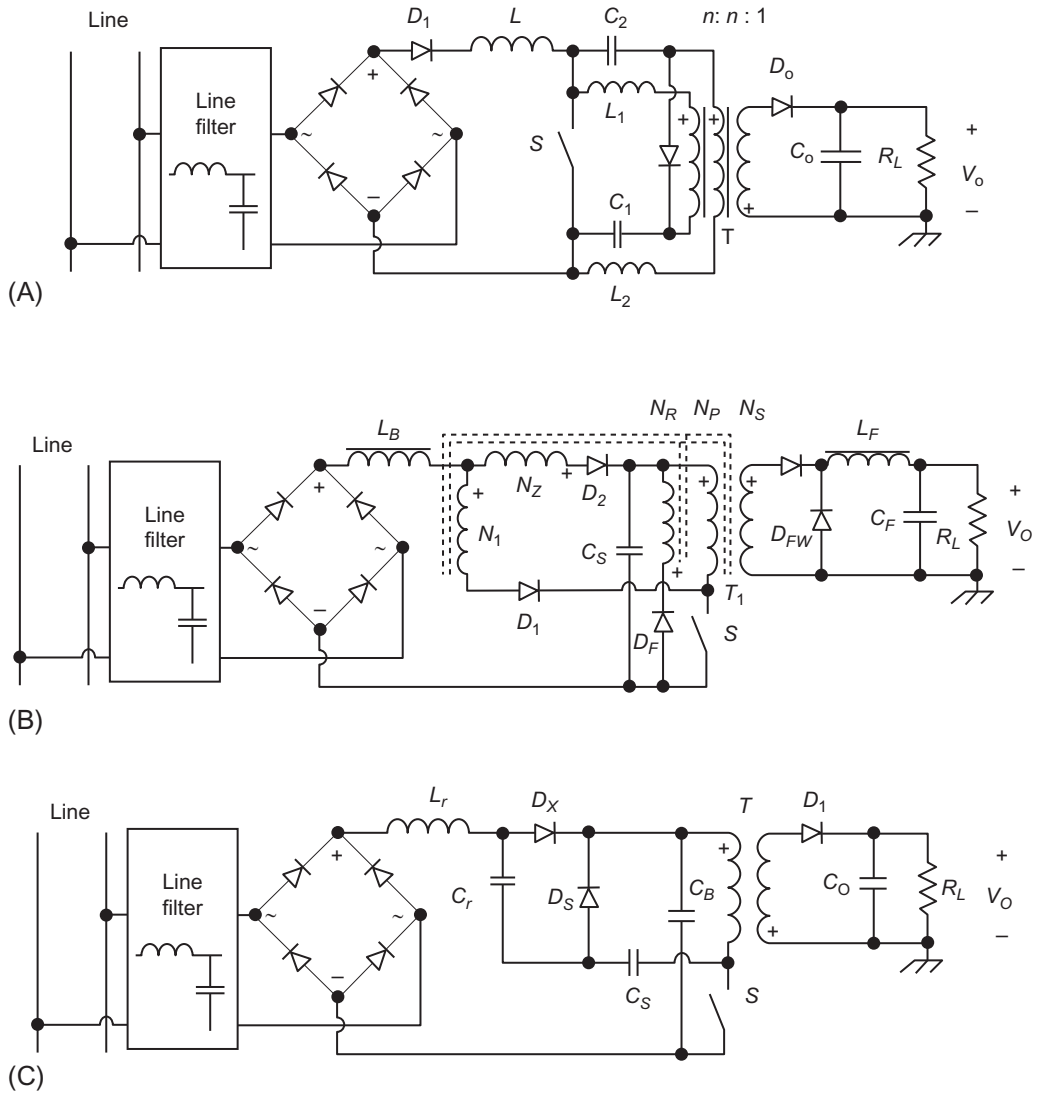

FIG. 16.48 Improved S^4-PFC converter: (A) boost-forward PFC circuit using two bulk capacitors, (B) boost-forward PFC circuit with reduced bus voltage, and (C) boost-flyback PFC circuit with charge pump circuit.

an improved CRM technique is applied on flyback PFC converter by modulating the turn-on time, However, as the output voltage is not used to modulate the on-time of the switch, when output voltage is varying under constant output current power supply, unity PF is very difficult to be ensured [123]. It is important to clarify that in this control technique, the inductor and switch peak currents are twice the ac system input current peak value. Therefore, the CRM technique is not suitable for high-power applications. However, the CRM technique is attractive in low-power applications such as the PFC for "electronic ballasts" where the following advantages can be achieved: (1) the switch can be easily oversized without increasing cost; (2) the switch operates under zero-current turn-on, avoiding turn-on losses and electromagnetic interference problems; and (3) the smaller sized inductor can be used to reduce the size and cost of the system.

16.5.4 Other PFC Techniques

Extensive research in PFC continues to yield countless new techniques [58,61,124–152]. The research topics are mainly focused on improvements of the PFC circuit performs such as fast performance, high efficiency, low-cost, small input current distortion, and output ripple. The classification of PFC techniques presented here can only cover those methods that are frequently documented in the open literature. There are still many PFC methods that do not fall into the specified categories. The following are some examples [1]:

- *Second-harmonic-injected method* [126]: In DCM input technique, even the converter operates at constant duty ratio, current distortion still exists. The basic idea of second-harmonic-injected method is compensating the duty ratio by injecting a certain amount of second-

harmonic into the duty ratio to modify the input *I-V* characteristic of the input converter. However, the output voltage may be affected by the modified duty ratio.

- *Cycle control technique* [127]: It is a new a method recently proposed for harmonics reduction in dc-dc converter that has the simplicity of voltage follower technique. In this technique, a periodic signal proportional to the rectified ac line voltage is used to modulate the duty-cycle of the power switch, where the main goal is to reduce the line current THD and to improve the PF; it offers the following advantages: (1) The generation of the injected signal is based on sensing the output voltage of the bridge rectifier that permits to have a simpler circuit without any additional circuit of phase detecting and phase synchronization, and (2) the modulation index can be used to obtain constant content of harmonics under a wide range of load variation, just with a simple PI controller, and (3) can have a good dynamic behavior under input voltage and load transients.
- *Interleaved method* [128]: An interleaved PFC circuit composed of several input converters in parallel. The peak input current of these converters follow the line voltage and are interleaved. A sinusoidal total line current is obtained by superimposing all the input current of the converters. The advantage of this method is that the converter input current can be easily smoothed by input EMI filter.
- *Waveform synthesis method* [129]: This method combines passive and active PFC techniques. Since the rectifier in the passive inductive-input PF corrector has a limited conduction angle, the input current is a single pulse around the peak of the line voltage, whereas the boost converter draws a nonzero current around the zero cross of the line voltage. By controlling the operation mode of the active switch (enable and disable the boost converter at certain line voltage), the waveforms of active and passive PFC circuits are tailored to extend the conduction angle of the rectifier. The resulting current waveform has a PF greater than 0.9 and a THD lower than 20%.
- *Digital PFC control technique* [130–152]: The digital control of PFC (DPFC) is expected to replace the analog PFC control, especially in medium- and high-power-level applications, due to its several advantages and to the great development in digital circuits. The main advantages of digital PFC control that push and motivate the application of the digital PFC control over other control techniques are mainly summarized in the following points [135]:
  a. Reduced sensitivity to circuits' parameter changes.
  b. Reduced of analog electronics components.
  c. An easy implementation of the controller.
  d. An easy adjustment of control parameters.
  e. An easy adaptation of the control against the changes of the measured or sensed variables.
  f. Digital controller is less expensive compared with the analog controller.
  g. Digital controller can be modified easily.

In this chapter, we are not focusing in digital PFC control; however, all the control techniques that have been presented in this chapter in DCM, CCM, and CRM modes can be furthermore extended to digital application for medium- and high-power-level applications (output power range between 200 and 2 kW) when high converter efficiency is desired. As an example, the following digital PFC control techniques have been already investigated:

1. Digital average current mode PFC control (DACM) [135–138]: In this PFC control, the instantaneous sensed variables of the rectified input voltage, the input/inductor current, and the output voltage are digitized. On the other side, a digital PWM (DPWM) is used for the output of the digital-current-loop compensator feeds, a DPWM that generates a discrete time gate driving waveform.
2. Predictive PFC control [139–141]: This control technique allows the computing of the next control value using the current sensed values based on the equations presenting the behavior of the concerned converter to fulfill the requirement of tracking the input reference current shape. The performance of this PFC control is depending on the used sampling frequency; therefore, under high sampling frequency, better result and performance are obtained.
3. Hybrid PFC control [135–146]: This control technique has several advantages that make it a very attractive technique. It is based on combining the digital and the analog techniques, where the analog technique is used for the current loop and the digital technique is used for the voltage loop. The HPFCC gains the merit of both techniques for obtaining improved performances for tracking the input current shape and the desired output voltage under ease and less cost of the hardware implementation, reduced control circuit, rapid dynamic response, and compacted topology.
4. Other digital PFC control techniques [135–152]: All the techniques mentioned in Sections 16.4 and 16.5 can be used under the digital PFC control technique and under the hybrid PFC technique, where in all case the main aim is that the technical advantages and economical advantages have to be respected during the design of the appropriated PFC control technique for the concerned converter topology and the level of the required power.

16.6 Summary

To reduce losses and decrease weight and size associated with converting ac power to dc power in linear power supply, SMPSs were introduced. The high nonlinearity of this kind of power

electronic systems that are connected to the power systems supply, handicaps itself by providing the utility power system with low PF and high THD. These unwanted harmonics are commonly corrected by incorporating PFC technique into the SMPS. This chapter gives a technical review of current research in high-frequency PFC, including the definition of PF and THD, configuration of PFC circuit, DCM input technique, CRM technique, and CCM shaping technique. The common issue of these techniques is to properly process the power flow so that the constant power dissipation at the output is reflected into ac power dissipation with two times the line frequency. Technically, PFC techniques encounter the following trade-offs:

(a) *Simplicity and accuracy*: Single-stage PFC circuit has simple topology and simple control circuit but has less control accuracy, while two-stage PFC circuit has the contrary performance.
(b) *Control simplicity and power-handling capability*: DCM input technique requires no input current control but has less power-handling capability, while CCM has multiloop control and has more power-handling capability;
(c) *Switching frequency and conversion efficiency*: To reduce weight and size of the PFC converter, higher switching frequency is desired. However, the associated switching losses result in decrease in conversion efficiency.
(d) *Frequency response and bandwidth*: To have good dynamic response, wider bandwidth is desired; however, to achieve high PF, bulk storage capacitor and output capacitor have to be used.

In the past decades, research in PFC techniques has led to the development of more efficient circuits and control strategies in order to optimize the design without compromising the above trade-offs. Moreover, since the growth in power electronics strongly relies on the development of semiconductor devices and the recent advent of higher rating power devices, it is believed that the switching-mode PF correctors will completely replace the existing passive reactive compensators in power system. In the distributed power system (DPS) where small size and high efficiency are of extreme importance, a new soft-switching technique has been used in designing PFC circuits. With the ever-increasing market demanding for ultrafast computer, the need for low output voltage (typically less than 1 *V*) with high output currents and high efficiency converters has never been greater. Research efforts in developing high-frequency high efficiency PFC circuits will continue to grow.

17.1 Introduction

The evolution of power electronics since the middle of the 20th century has largely depended on the introduction of semiconductor devices. The invention of the SCR in the late 1950s led to the expansion of the field of motor drives both DC and AC. The coming of age of the power MOSFET in the 1970s presaged the era of efficient switch-mode power supplies. This was followed by the insulated gate bipolar transistor (IGBT) that opened up the possibility of inverter variable speed drives and their ever-expanding range of application by combining the gate drive of a MOSFET with the current and voltage capability of the bipolar junction transistor. The new millennium saw innovation in wide bandgap materials such as the silicon carbon (SiC) devices and gallium nitride (GaN). The devices based on these materials have enabled further developments in resonant power supplies.

All of these innovations and advances along with their associated circuit and topology enhancements have placed the role of magnetics center stage. Furthermore, each device in turn has facilitated an increase in the frequency of operation with the result that magnetic components in the MHz range for power electronics applications are now the norm.

The most basic transformer equation informs us that the size of the transformer is directly reduced in proportion to increasing frequency. The reality of losses in the transformer winding and in the core material places limits on the size reduction. More recent developments in the movement to high-frequency operation have introduced additional losses in the form of fringing around air gaps. Multiple strands in conductors in the form of litz wire to mitigate high-frequency skin and proximity effects have in themselves introduced new sources of losses.

The switch-mode power supply greatly improved the overall converter efficiency; size reduction followed from the high operating frequency (up to 500 kHz). Of course losses during the turn-on and turn-off processes increased with frequency, and the presence of parasitic inductance and capacitance limited the turn-on and turn-off times, placing further restrictions on the upper operating frequency of the magnetic components. The advent of soft switching with zero voltage switching (ZVS) or zero-current switching (ZCS) coped with the switching losses and led to another leap in frequencies (and consequent reduction in the size of the magnetics). This conceptually removed the barrier to high-frequency operation. More advantages followed: reduced electromagnetic interference (EMI)

http://dx.doi.org/10.1016/B978-0-12-811407-0.00019-2

and smaller filter components. Evidently, all roads lead to high-frequency operation.

Recall that the transformer performs three basic functions in an electric circuit: to provide isolation, to reduce voltage stress in a switching device by adjusting the voltage, and to allow operation at high-frequency to reduce size. Major losses occur in the magnetic materials and improvements in the materials must parallel improvements in topologies and devices. The main magnetic materials encountered in power electronics will be described in Section 17.2, along with their characteristics. An understanding of the basic laws of electromagnetism is the essential starting point for magnetic design. The basic elements will be covered in Section 17.3. Transformer design for modern power electronics will be the subject of Section 17.4. The objective here is to establish a straightforward and robust set of equations to select the transformer core in applications ranging from switch-mode power supplies to resonant converters.

Selecting the core is just the starting point. Additional considerations are required for high-frequency effects including fringing around air gaps. The proper selection and use of litz wire where appropriate and mitigation techniques for winding losses such as interleaving will be treated in Section 17.5.

By their very nature, circuits in power electronics that usually involve switching elements give rise to nonsinusoidal waveforms of voltage and current. Traditional definitions of power factor and loss mechanisms based on sinusoidal waveforms must be revisited and modified to take the nonsinusoidal waveforms into account in the design of magnetic components.

17.2 Magnetic Materials and Characteristics

The main purpose of magnetic core materials in power electronics is to provide a low reluctance path to magnetic flux produced by current flowing in inductors and transformers. Traditionally, iron-based silicon-steel materials performed this role in mains frequency transformers, and they continue to do so in existing power systems, although tape wound amorphous core materials are now being considered. For application at higher frequencies typical of switching mode power supplies (SMPS), eddy current losses are excessive and cannot be controlled without significantly reducing the thickness of silicon-steel sheets. For operation at mains frequencies, typical silicon sheet thicknesses are in the range of 0.2–0.5 mm [1], and thinner forms are emerging to enable operation at frequencies up to several kHz [2].

Ferrite and powdered (distributed air gap) materials have been developed specifically for application in high-frequency power electronic circuits, where their material structures are designed to limit eddy current loss by restricting the magnetic particle size within an insulating binder. For both material types, manufacturers provide different material grades that are optimized for operation within different frequency ranges to support standard applications up to 500 kHz. More recently, amorphous and nanocrystalline materials have emerged as potential competitor materials, due to their higher saturation flux density and low loss characteristics at frequencies up to approximately 100 kHz [3]. Meanwhile, with the ongoing drive toward system integration in power-supply-in-package (PwrSiP) and power supply on chip (PwrSoC), the integration of magnetic materials within power supply packaging has driven developments in magnetic materials well into the MHz range. This includes electroplating and lamination of metal core layers within PCB's [4,5] and electroplating and sputtering of magnetic films onto silicon [6–8]. Nanoparticle-based materials are also being developed for use as discrete miniaturized cores in PwrSiP and PwrSoC at frequencies up to 30 MHz [9].

17.2.1 Magnetic Material Properties

Magnetic materials are highly nonlinear with many properties varying with magnetic field excitation level, operating frequency, and temperature, thereby complicating the design of magnetic components. For instance, the primary property of a magnetic material is its relative permeability, μ_r, which relates the magnetic flux density B, within the material to the magnetic field intensity H, according to

$$B = \mu_r \mu_0 H \tag{17.1}$$

where $\mu_o = 4\pi \times 10^{-7}$ H/m is the permeability of free space. However, the value of μ_r is dependent on the level of magnetic flux density B as shown in the B-H plot of a magnetic material in Fig. 17.1. Indeed, it is seen that magnetic materials exhibit hysteretic behavior, where the interdependence between B and H depends not only on their relative levels but also on the rate of change of B with H; that is, the magnetic flux density level corresponding to a given value of magnetic field intensity H_x as it increases is different to that found for the same value as

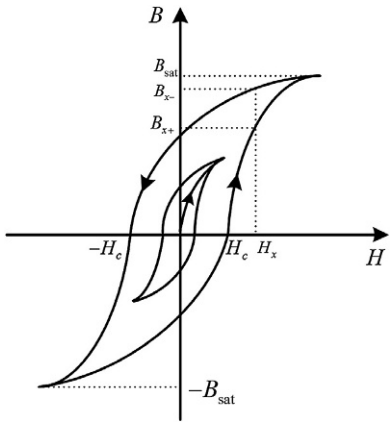

FIG. 17.1 B-H loops of a magnetic material.

it decreases. This is illustrated in Fig. 17.1, where B_{x+} is the magnetic flux density at H_x as it increases, while B_{x-} corresponds to H_x as it decreases over the given B-H loop. This difference is due to magnetic coercivity, H_c, which is the minimum value of magnetic field intensity for which the material responds to a varying magnetic flux density. Alternatively, it is the value of magnetic field intensity remaining within a material after the applied magnetic flux density reduces to zero. Ideally, for soft magnetic materials, such as those used in inductors and transformers, H_c should be as small as possible, while it should be as high as possible in permanent magnet materials in order to preserve magnetism.

Practically, in magnetic component design for power electronics, a linear relationship between B and H is assumed between their peak applied values (as shown in Fig. 17.1) to enable definition of relative permeability based on the amplitude of applied magnetic flux density:

$$\mu_r = \frac{1}{\mu_0}\frac{\hat{B}}{\hat{H}} \tag{17.2}$$

Examination of Fig. 17.1 shows that due to the hysteretic behavior, μ_r typically increases with increasing amplitude of magnetic flux density, so long as this amplitude is lower than the saturation flux density, B_{sat}. Beyond this value, there is no further increase in magnetic flux density with increasing magnetic field intensity, and therefore, magnetic saturation imposes a limit on the useful operating range of a magnetic material.

Similarly, under DC bias conditions, the relative permeability depends on both the DC and AC levels of magnetic flux density. As an aid to magnetic component design, the manufacturers of magnetic cores provide graphs to quantify the level of variation under typical application conditions levels. For example, ferrite materials can have relative permeability values that vary by up to 200% over a typical range of AC magnetic flux density.

In terms of operating frequency, relative permeability generally remains constant for frequencies up to the point where eddy current losses become dominant. For ferrite and powdered materials, this frequency is usually higher than the optimal one at which overall core losses can be tolerated, and therefore, variations in relative permeability are not significant. However, eddy current losses are more dominant in metal film cores, and therefore, variations the relative permeability with frequency may impact on designs based on metal film cores.

Loss in magnetic materials includes contributions from eddy current, hysteresis, and anomalous effects. Eddy current loss is conductive I^2R loss produced by circulating currents induced in response to AC flux linkage, flowing against the internal resistance of the core. In ferrite materials, it is limited by restricting the size of individual ferrite particles within an insulating binder, while in metal film layers, its effect is limited so long as the film thickness is maintained smaller than the material skin depth δ where

$$\delta = \frac{1}{\sqrt{\pi f \mu_r \mu_0 \sigma}} \tag{17.3}$$

f is the operating frequency and σ is the conductivity of the material.

Hysteresis loss is thought to be due to frictional effects between magnetic domains within the material structure as they rotate in response to AC magnetic fields. Hysteresis loss per unit volume may be estimated in terms of the area enclosed by the material BH loop under given AC and DC conditions:

$$P_{hys} = f\oint_B H dB \tag{17.4}$$

where the integral is performed over a complete cycle of the given magnetic flux density excitation levels.

Anomalous loss, also termed excess eddy current loss, is due to the presence of magnetic domains within magnetic material structures. The exact nature of this effect is not fully understood, but it is thought to be attributed to nonuniform magnetic flux density distributions produced within magnetic domains. However, a lack of understanding of the variation in magnetic domain sizes and orientations under field excitation further complicates its contribution [10]. Anomalous loss is most prominent in tape wound and metal film core materials where classical eddy current loss is controlled by maintaining film thicknesses lower than the material skin depth.

Practically, total core loss per unit volume, P_{fe}, may be estimated using the Steinmetz equation:

$$P_{fe} = K_c f^{\alpha} \hat{B}^{\beta} \tag{17.5}$$

for which manufacturers provide material parameters, K_c, α and β, that are based on measurements of loss characteristics performed over a range of sinusoidal magnetic flux density excitation levels and frequencies. Given that the loss parameters are based on measurements, the Steinmetz equation therefore accounts for the combined contributions of all loss effects.

In power electronics applications, voltage and current waveforms applied to magnetic components are more often rectangular than sinusoidal, and therefore, due to significant contributions of voltage/current harmonics, direct application of the Steinmetz equation does not produce accurate predictions of total core loss. Instead, the Steinmetz equation has been modified to account for nonsinusoidal waveforms, by recognizing the general dependence of core loss on both the magnetic flux density and the rate of change of magnetic flux density with respect to time in the generalized Steinmetz equation (GSE) [11]. In a further development, the effects of minor BH loop excursions are incorporated in the improved generalized Steinmetz equation (iGSE):

$$P_{fe} = \frac{1}{T}\int_0^T k_i \left|\frac{dB(t)}{dt}\right|^{\alpha} |\Delta B|^{\beta-\alpha} dt \tag{17.6}$$

where

$$k_i = \frac{K_c}{2^{\beta-1}\pi^{\alpha-1}\int_0^{2\pi} |\cos\theta|^{\alpha} d\theta} \tag{17.7}$$

and where ΔB is the peak-to-peak amplitude of magnetic flux density over each minor loop as it contributes during the excitation waveform [12]. A further modification to the Steinmetz equation has been proposed to account for the effects of magnetic relaxation effects during periods of zero applied voltage [13]. However, it should be remembered that the Steinmetz parameters themselves are based on experimental data and that they vary over different operating frequency ranges. Therefore, the accuracy of models based on these parameters relates directly to the original manufacturers' measurement accuracy. Practically, Eqs. (17.5) or Eqs. (17.6–17.7) are best applied to estimate initial values of core loss, with follow-up measurements recommended to confirm losses under applied operating conditions.

The temperature range and temperature stability of magnetic materials should be considered because standard ferrite and powdered material loss properties vary by up to 500% from room temperature to 140°C. Some ferrite grades are designed to have more stable loss properties with temperature variation, while others are optimized to have minimum loss at a standard operating temperature such as 140°C for automotive applications.

17.2.2 Comparison of Magnetic Material Types

The properties of magnetic core materials used in switched-mode power electronic applications are compared in Table 17.1, while power loss density values are compared in Fig. 17.2. The most commonly applied material type is ferrite, which consists of a combination of metal oxide particles that are pressed and sintered together to form one of several standard core shapes (E, C, toroid, planar E, I, etc.). Owing to the small particle size (of the order of μm), eddy currents are restricted so that ferrites are characterized by high resistivity

TABLE 17.1 Properties of magnetic core materials commonly used in power electronics

Materials	Ferrites	Nanocrystalline	Amorphous	Si iron	Ni-Fe (permalloy)	Powdered iron
Model	Ferroxcube 3F3	VIROPERM 500 F	METGLAS 2605	AK Oriented M-4	MAGNETICS PERMALLOY 80	MICROMETALS 35 μ
Permeability, μ_i	2000–4500	15,000	10,000–150,000	5000–10,000	20,000	3–550
B_{peak}, T	0.34–0.42	1.2	1.56	2.0	0.82	0.6–1.3
ρ, μΩm	2×10^6	1.15	1.3	0.51	0.57	10^6
Curie temp. T_c, °C	200	600	399	746	460	665
P_{loss}	210 mW/cm^3 at 0.1 T/200 kHz	588 mW/cm^3 at 0.3 T/100 kHz	72 mW/cm^3 at 0.2 T/25 kHz	2.295–30.6 mW/cm^3 at 1.5 T/50 Hz	192.28 mW/cm^3 at 0.2 T/5 kHz	126–315 mW/cm^3 at 0.1 T/10 kHz

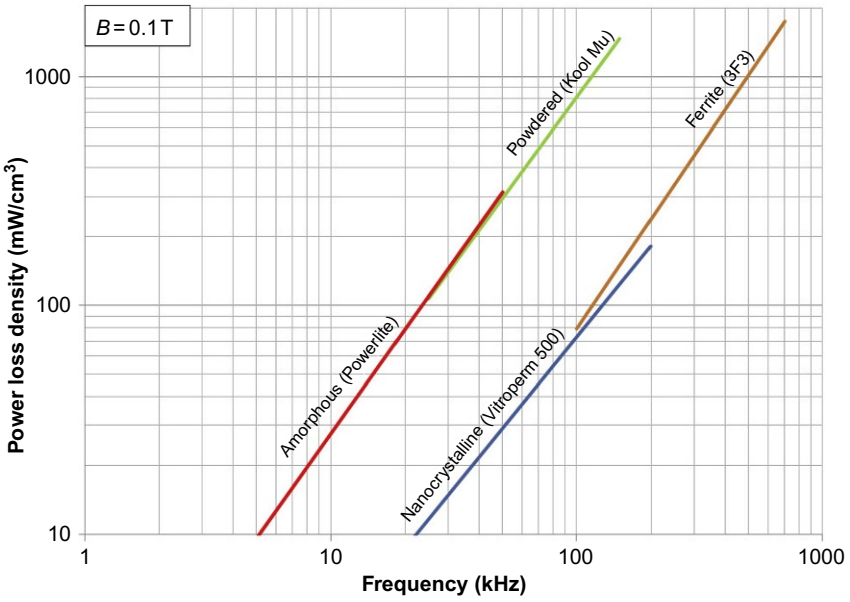

FIG. 17.2 Core loss density versus frequency for common magnetic materials.

and high relative permeability, with the properties of each ferrite grade depending on the relative concentration and particle size of constituent metal oxides. Typically, Mn-Zn ferrites are most widely applied in power electronics applications, with manufacturers providing a range of grades having loss properties suitable for operation at frequencies up to 2 MHz. On the other hand, Ni-Zn grades are more suited to signal level applications at frequencies in the 1–10 MHz range. The main limitation of ferrites is their low saturation flux density of 300–450 mT, which is at least half that of silicon-steel.

In inductor and transformer applications where the core is subjected to a DC bias field, magnetic powder materials provide a suitable alternative to ferrites. With ferrite, a lumped gap is generally needed to ensure that the material is not saturated under DC bias conditions. This results in a significantly reduced effective relative permeability and causes increased eddy current losses due to the interaction of fringing fields with windings placed in the vicinity of the gap (see Section 17.5.2). In powder materials, the gap is distributed throughout the bulk material, which consists of magnetic alloy grains bound together within an insulating material. Magnetic powder materials are therefore also known as distributed air gap material. They contribute little or no fringing field effects. Constituent magnetic alloys include various combinations of nickel, iron, silicon, aluminum, molybdenum, and boron. Relative permeability values are in the range of 10–550, which are comparable with the effective permeability of gapped ferrite cores, and saturation flux density can be as high as 1.6 T. While bulk core loss properties are not as competitive as ferrite (see Fig. 17.2), when the effects of eddy current losses in windings surrounding a discrete gap are accounted for, powder materials can provide an overall reduced loss design.

In the 1980s, the development of new rapid cooling methods for hot-spun melt magnetic tape materials led to the emergence of amorphous and nanocrystalline materials as competitors initially to silicon-steel and nickel-iron metal alloys in tape wound cores. With ongoing research, these material types have since been developed for application in common mode choke and other power electronic applications. Due to the similarity in their composition and manufacturing processes, both materials have similar structures and properties, much of which result from their nanoscale magnetic particle sizes (10–20 nm). They comprise various concentrations of iron, cobalt, and nickel, with silicon and boron included to ensure stabilization of the amorphous structure. After rapid cooling of the molten metal, a tape of amorphous material with a thickness of approximately 20 μm is produced. Nanocrystalline materials are amorphous tapes that have further heat treatment applied that provides them with superior loss and saturation properties. The materials are characterized by very high permeability values (100,000's), high saturation flux density (up to 1.7 T), and loss properties that are competitive to ferrites for power electronic applications in the range of 100–200 kHz. Research is continuing to develop these materials and core shapes for a wider range of applications.

17.2.3 Future Developments

Much of the latest research in magnetic materials is focused on the development of core materials suitable for operation in the multi-MHz range and on processes to integrate them into power electronics packaging, that is, within printed circuit boards (PCBs) or onto silicon. The main drivers are reduced size and improved response rate of low power applications, both of which are achieved by increased operating frequency. At a larger power scale, developments in SiC and GaN semiconductors are progressing to enable higher switching frequencies in high-voltage, smart grid, and renewable energy applications. This in turn will lead to developments in compatible core materials, where the high saturation flux density and competitive loss properties of amorphous and nanocrystalline materials make them the most suitable solutions.

17.3 Magnetic Circuits

Faraday's law and Ampere's law have built the relationship between the electric characteristics and magnetic characteristics and are key principles guiding the transformer and inductor design in power electronics. The typical analytic model for a magnetic circuit is the magnetic reluctance model that is based on a reluctance-resistance analogy.

17.3.1 Faraday's Magnetic Circuit Law

Faraday's law states that a time-varying magnetic flux $\phi(t)$ passing through the interior of a winding generates a voltage $v(t)$ in the winding. Fig. 17.3 illustrates time-varying flux $\phi(t)$ passing through the interior of a loop of wire and the voltage $v(t)$ induced in the closed loop enclosing the flux.

The loop cross-sectional area is expressed by A_c. According to Faraday's law, the flux induces a voltage $v(t)$ in the termination of the wire, given by

$$v(t) = \frac{d\phi(t)}{dt} \tag{17.8}$$

For a winding with N turns, the induced voltage can be expressed as

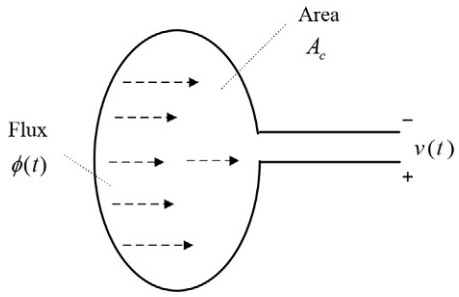

FIG. 17.3 Illustration of Faraday's law.

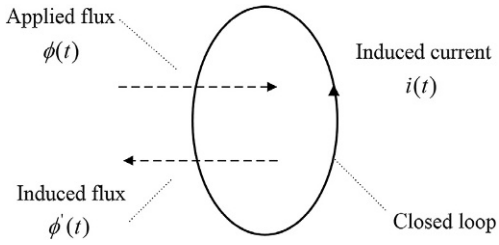

FIG. 17.4 Illustration of Lenz's law in a closed loop.

$$v(t) = N \cdot \frac{d\phi(t)}{dt} \tag{17.9}$$

The induced flux ϕ may link with each turn of the winding, so that the flux linkage is

$$\lambda = N \cdot \phi \tag{17.10}$$

For a uniform flux distribution, the expression (17.9) can be rewritten as

$$v(t) = N \cdot A_c \cdot \frac{dB(t)}{dt} \tag{17.11}$$

where $B(t)$ is magnetic flux density passing through the winding.

Lenz's law states that the current induced in the closed loop due to the changing flux tends to oppose the flux change. Fig. 17.4 shows an example of Lenz's law. The flux $\phi(t)$ induces current $i(t)$, which in turn generates flux $\phi'(t)$ that tends to oppose changes in $\phi(t)$.

The induced voltage opposes the creating flux by generating secondary currents called eddy currents. Lenz's law can well explain the eddy current effects in magnetic cores and in the winding conductors.

17.3.2 Ampere's Magnetic Circuit Law

Ampere's law states that a time-varying current $i(t)$ induces a time-varying magnetic field $H(t)$, as shown in Fig. 17.5. The net magnetomotive force (MMF) in the core is equal to the total currents passing though the interior of the magnetic core loop. The line integral of H around any closed contour is equal to the total current enclosed by that contour, and it may be stated in the integral form:

$$\oint_C H \cdot dl = i \tag{17.12}$$

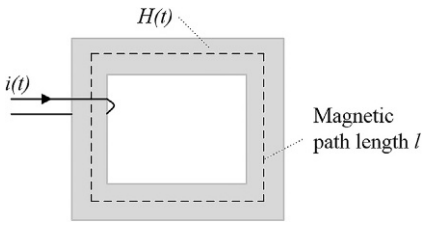

FIG. 17.5 Illustration of Ampere's law.

For the winding with N turns, Ampere's law is

$$\oint_C H \cdot dl = N \cdot i \tag{17.13}$$

The magnetic field intensity H leads to a resulting magnetic flux density B due to the B-H characteristics of core materials. The nonlinearity of the characteristics is neglected in this section, and therefore, the relation of the B-H characteristic is given by Eq. (17.1).

17.3.3 Reluctance and Inductance

When making an analogy between magnetic circuits and electric circuits, it is natural to regard the magnetomotive force (MMF) between the two terminations of the winding as analogous to the voltage and magnetic flux, ϕ, as analogous to the current. As shown in Fig. 17.6, the MMF, $F = N \cdot i$, is visualized as a force like quantity that pushes a magnetic flux, ϕ, around the magnetic circuit. Magnetic core reluctance, R, in a magnetic circuit is then the counterpart of resistance of an electric circuit. $\phi = F/R$, directly corresponding to Ohm's law. The reluctance opposes the magnetic flux flow, similarly to the way the resistance opposes the electric current flow. Therefore, magnetic circuits described by Eq. (17.14) can be solved in a similar manner as electric circuits described by Ohm's law.

$$F = H \cdot l = N \cdot i = \phi \cdot R \tag{17.14}$$

Fig. 17.6 illustrates a coil with N turns wound on a closed magnetic core of mean length l_c and cross-sectional area A_c. The reluctance of a basic magnetic circuit element is given by

$$R = \frac{l_c}{\mu_0 \cdot \mu_r \cdot A_c} (At/H) \tag{17.15}$$

The self-inductance L relates the flux linkage produced by a coil to the current in that coil:

$$L = \frac{\lambda}{i} = \frac{N \cdot \phi}{i} = \frac{N^2}{R} = \frac{\mu_0 \cdot \mu_r \cdot A_c \cdot N^2}{l_c} \tag{17.16}$$

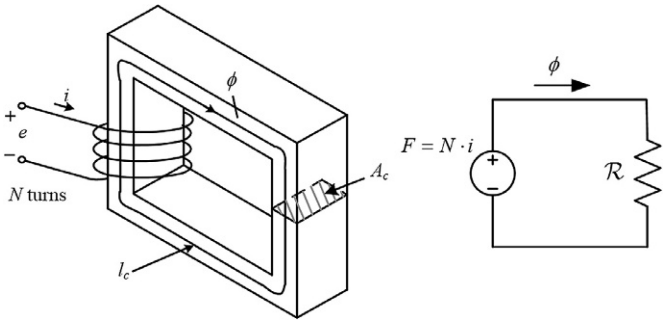

FIG. 17.6 Example of magnetic circuit and equivalent magnetic reluctance circuit.

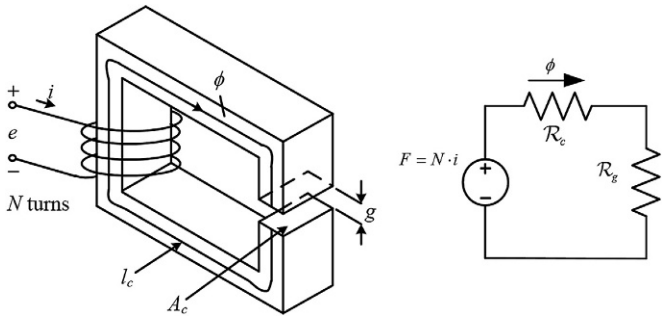

FIG. 17.7 Example of magnetic circuit for gapped inductor.

In fact, the *B-H* characteristic is a nonlinear function of the applied magnetic field intensity in ferromagnetic materials. In the magnetic core of Fig. 17.6, the flux density B is limited by the core material, and a small current with sufficient turns can easily drive the magnetic core material into saturation. To avoid the core saturation, an air gap is often introduced into the core as shown in Fig. 17.7, a larger current can pass through the winding without reaching saturation because of the increased reluctance. The analysis to follow also shows that the air gap gives rise to more energy storage.

In the structure of Fig. 17.7, there are two reluctances in series, so,

$$F = N \cdot i = \phi \cdot \left(R_c + R_g\right) \tag{17.17}$$

The individual reluctances are given by their respective physical properties of length and cross section; subscript c refers to the core and subscript g refers to the air gap. For the core reluctance,

$$R_c = \frac{l_c}{\mu_0 \cdot \mu_r \cdot A_c} \tag{17.18}$$

and for the air gap reluctance, $\mu_r = 1$,

$$R_g = \frac{g}{\mu_0 \cdot A_g} \tag{17.19}$$

where g is the length of the air gap. Since $\mu_r \gg \mu_0$, the reluctance of the core R_c can be ignored, $R_c \ll R_g$, invoking Eq. (17.17) yields

$$F = N \cdot i = \phi \cdot R_g \tag{17.20}$$

Therefore, the gapped inductance L is

$$L = \frac{N^2}{R_g} = \frac{\mu_0 \cdot A_g \cdot N^2}{g} \tag{17.21}$$

The air gap increases the total reluctance of the magnetic circuit and decreases the inductance.

17.4 Transformer Design

The basic transformer model is shown in Fig. 17.8.

This is a transformer with a turns ratio a:1. The winding resistance is R_1 and R_2 for the primary and secondary, respectively. X_{l1} and X_{l2} represent the leakage reactance in the primary windings and secondary windings, respectively. R_c represents the core loss and X_c represents the magnetizing inductance. For an ideal transformer, the permeability of the core material is considered infinite and the magnetizing current is negligible.

The voltage across the primary winding is [14]

$$E_1 = K_v f N_1 B_{\max} A_c \tag{17.22}$$

where f is the frequency, N_1 is the number of turns, $B_{\max}$ is the maximum flux density in the core, and A_c is the cross-sectional area of the core. These are shown in Fig. 17.9.

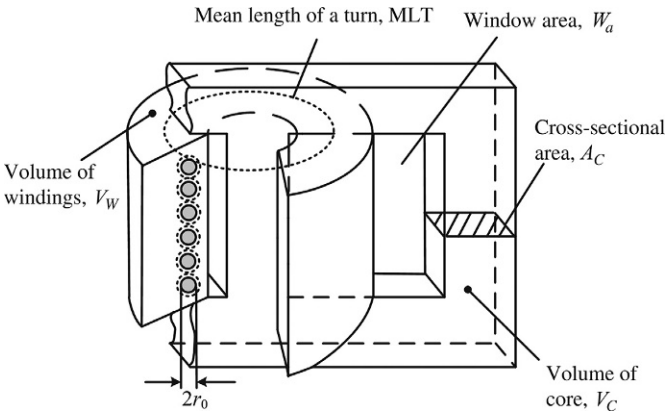

FIG. 17.9 Physical dimensions of a transformer.

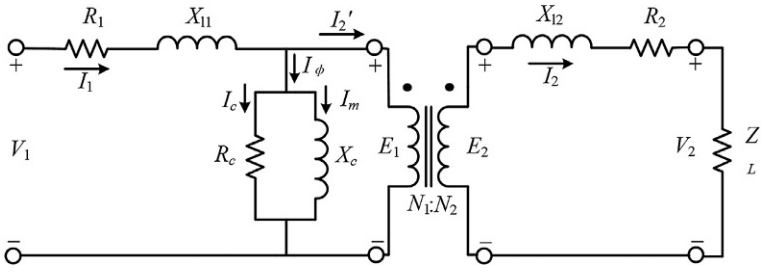

FIG. 17.8 The basic electric circuit of a practical transformer.

K_v depends on the shape of the voltage waveform. It has the value of 4.44 for sinusoidal waveforms and 4.0 for a square waveform. It may be calculated for any other waveform; the approach to calculate K_v will be outlined in an example later on.

The first step in developing the design methodology is to apply Eq. (17.22) to each of n windings and calculate the total VA rating of all the windings.

It may be shown that in a magnetic component with multiple windings, the optimum layout of the coils in terms of wire size is to maintain a constant current density J_o. Taking A_{wi} as the area of the conductor in winding i summing up the VA rating of each winding using Eq. (17.22) yields

$$\sum VA = K_v f N_i B_{\max} A_c J_o A_{wi} \tag{17.23}$$

Define the window utilization factor k_u as the rate of the window area W_a occupied by copper

$$k_u = \frac{\sum_{i=1}^{n} N_i A_{wi}}{W_a} \tag{17.24}$$

and Eq. (17.23) becomes

$$\sum VA = K_v f B_{\max} k_u J_o W_a A_c \tag{17.25}$$

The product $W_a \cdot A_c$ is the window area product A_p of the core. This result establishes the connection between the transformer rating and core size. The next step is the establishment of the winding loss and the core loss.

The copper loss in each winding is RI^2. At this point, we will take R to be the DC resistance and take the high-frequency skin and proximity effects into account later on. The mean length of a turn in the transformer winding is MLT and the total length of a coil i is $N_i \cdot$MLT. The copper loss is

$$P_{cu} = \sum_{i=1}^{n} \frac{\rho N_i MLT}{A_{wi}} (J_o A_{wi})^2 \tag{17.26}$$

Invoking the definition of the window utilization factor, Eq. (17.24) becomes

$$P_{\text{cu}} = \rho MLT\, W_a k_u J_o^2 \tag{17.27}$$

MLT $\cdot W_a$ is simply the volume of the windings, V_w.

Combining Eqs. (17.26) and (17.27) yields a new expression for the copper loss:

$$P_{cu} = \rho_w MLT\, W_a k_u \left[\frac{\sum VA}{K_v k_u W_a A_c}\right]^2 \frac{1}{f^2 {B_{\max}}^2} \tag{17.28}$$

The core loss under sinusoidal excitation is given by the celebrated Steinmetz formula Eq. (17.5):

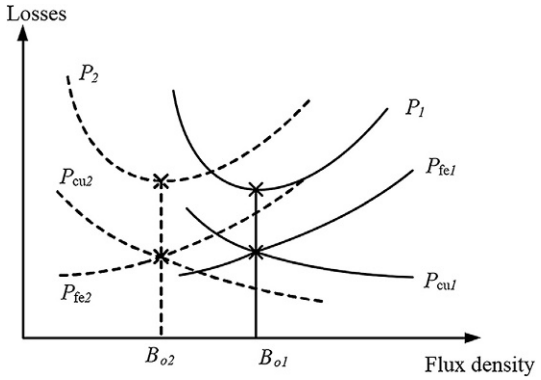

FIG. 17.10 Core and winding losses as a function of frequency and maximum flux density.

$$P_{\text{fe}} = V_c K_c f^{\alpha} \hat{B}^{\beta} \tag{17.29}$$

where K_c, α and β are constants supplied by the manufacturer. V_c is the volume of the core. Here, $\hat{B}$ is the amplitude of the sinusoidal flux density.

The total loss (at this point) is the sum of the two components given by Eqs. (17.28) and (17.29).

Evidently, the copper loss is inversely proportional to the product of frequency and maximum flux density Eq. (17.28), and the core loss is proportional to frequency and maximum flux density Eq. (17.29). These are illustrated in Fig. 17.10 for two different frequencies, $f_2 > f_1$.

The minimum value of the total losses occurs at

$$\frac{\partial P_{\text{total}}}{\partial \hat{B}} = 0 \tag{17.30}$$

and for a given frequency

$$P_{\text{fe}} = \frac{2}{\beta} P_{\text{cu}} \tag{17.31}$$

It follows that

$$P_{\text{total}} = P_{\text{cu}} + P_{\text{fe}} = \frac{\beta + 2}{\beta} P_{\text{cu}} \tag{17.32}$$

We can split the copper loss as follows:

$$P_{\text{cu}}^{1/12} P_{\text{cu}}^{7/12} = P_{\text{cu}}^{2/3} \tag{17.33}$$

Combining Eqs. (17.31) and (17.32) with Eq. (17.33) after some rearranging,

$$\frac{(\beta+2)^{2/3}}{2^{7/12}\beta^{1/12}} P_{\text{cu}}^{1/12} P_{\text{fe}}^{7/12} = P_{\text{total}}^{2/3} \tag{17.34}$$

As a first step, we assume the heat loss from the surface of the transformer is predominately by convection

$$P_{\text{total}} = hA_t\Delta T \tag{17.35}$$

where h is the coefficient of heat transfer by convection, A_t is the surface area of the transformer assembly and ΔT is the temperature rise in the transformer due to the losses. Taking this, Eqs. (17.28) and (17.29), and substituting them into Eq. (17.34) yields

$$\frac{(\beta+2)^{2/3}}{2^{7/12}\beta^{1/12}}\left[\rho MLT\,W_a k_u J_o^2\right]^{1/12}\left[V_c K_c f^{\alpha}\hat{B}^{\beta}\right]^{7/12} = \left[hA_t\Delta T\right]^{2/3} \tag{17.36}$$

At this point, we need dimensional analysis to simplify Eq. (17.36). The physical quantities, surface area A_t, the volume of the core V_c and the volume of the winding V_w are all related to the core window area product $A_p = W_a \cdot A_c$.

$$V_w = k_w A_p^{3/4} \tag{17.37}$$

$$V_c = k_c A_p^{3/4} \tag{17.38}$$

$$A_t = k_t A_p^{1/2} \tag{17.39}$$

The constants k_w, k_c, and k_t may be found from the dimensions of typical cores, and for the present purposes, $k_w = 10$, $k_c = 5.6$, and $k_t = 40$ would typify the cores used in modern power electronics.

Returning to Eq. (17.36), with these dimensionless constants

$$\frac{(\beta+2)^{2/3}}{2^{7/12}\beta^{1/12}}\left[\rho k_w k_u\right]^{1/12}\left[k_c K_c f^{\alpha}\hat{B}^{\beta}\right]^{7/12}\left[J_o A_p\right]^{1/6} = \left[hk_t\Delta T\right]^{2/3} \tag{17.40}$$

We need to return to Eq. (17.25) to find an expression for $J_o A_p$

$$\left[J_o A_p\right]^{1/6} = \left[\frac{\sum VA}{K_v f k_u B_{\max}}\right]^{1/6} \tag{17.41}$$

This result, substituted into Eq. (17.40), yields an expression for B_o and f at the optimum point in Fig. 17.10, that is, for minimum losses:

$$B_o^{7\beta-2} f_o^{7\alpha-2} = \frac{2^7\beta}{(\beta+2)^8}\frac{\left[hk_t\Delta T\right]^8}{\left[\rho k_w\right]\left[k_c K_c\right]^7}\left[\frac{{K_v}^2 k_u}{\sum VA^2}\right] \tag{17.42}$$

Note that $B_{\max}$ in Eq. (17.22) may include a DC component, but for the present purposes, we assume, it is the amplitude of the sinusoidal component, and we can adjust K_v if necessary.

The first and second terms on the right-hand side are fixed quantities. The third term is dependent on the circuit conditions and specifications. Normally, frequency is specified so this allows us to calculate the optimum value of maximum flux density in the core.

At this point, we need an expression for the current density in the windings. Taking Eq. (17.32) with Eqs. (17.27) and (19.35)

$$\rho MLT\,k_u W_a J_o^2 = \frac{\beta}{\beta+2}hA_t\Delta T \tag{17.43}$$

Adapting the dimensional analysis,

$$J_o = \sqrt{\frac{\beta}{\beta+2}\frac{hk_t}{\rho k_w}}\sqrt{\frac{\Delta T}{k_u}\frac{1}{{A_p}^{1/8}}} = K_\theta\sqrt{\frac{\beta}{\beta+2}}\sqrt{\frac{\Delta T}{k_u}\frac{1}{{A_p}^{1/8}}} \tag{17.44}$$

for $h = 10$ W/m^2°C, $k_w = 10$, $k_t = 40$, $\rho = 1.72\times10^{-8}$ Ω-m, and $K_\theta = 48.224\times10^3$.

Combining this expression for the current density with the optimum value of $f_o B_o$ given by Eq. (17.42) in Eq. (17.35) results in an expression for A_p that is found from the specifications of the circuit.

$$A_p = \left[\frac{\beta+2}{\beta}\frac{1}{k_u\Delta T}\right]^{4/7}\left[\frac{\sum \text{VA}}{K_v f_o B_o K_\theta}\right]^{8/7} \tag{17.45}$$

17.4.1 Design Example: Push-pull Converter

A 600 W push-pull converter operates at 80 kHz with a nominal DC input voltage of 325 V and the DC output voltage is 24 *V*. The allowable temperature rise is 50°C and the ambient temperature is 70°C. Using an EE ferrite core (N87 material), select the transformer core and calculate the copper loss in the windings and the core loss.

The push-pull converter and its associated waveforms are shown in Figs. 17.11 and 17.12.

The RMS value of the voltage waveform in the primary winding is

$$V_{\text{rms}} = \sqrt{D}V_s \tag{17.46}$$

Consider the time period 0-DT′:

$$V_s = N_p\frac{d\phi}{dt} = N_p A_c\frac{dB}{dt} = N_p A_c\frac{2B_{\max}}{DT'} = N_p A_c\frac{4B_{\max}}{DT} \tag{17.47}$$

Combining Eqs. (17.46) and (17.47),

$$V_{\text{rms}} = \frac{4}{\sqrt{D}}fN_p B_{\max}A_c = K_v f N_p B_{\max}A_c \tag{17.48}$$

So by the definition in Eq. (17.23),

$$K_v = \frac{4}{\sqrt{D}} \tag{17.49}$$

We also need the power factor of the input and output windings.

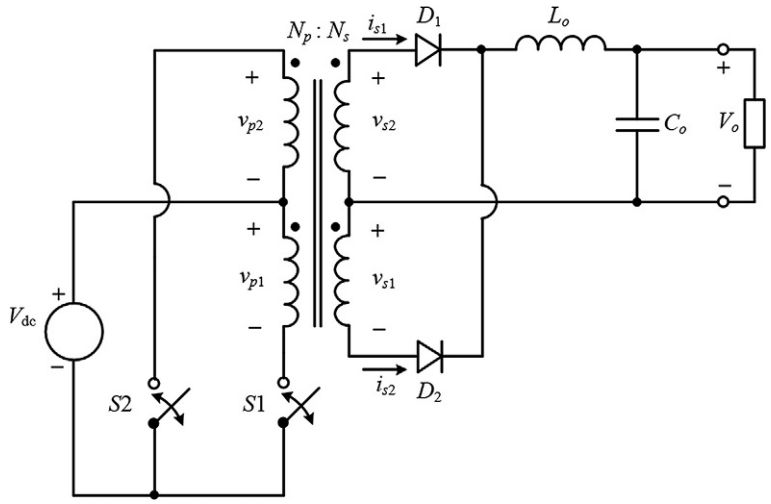

FIG. 17.11 Push-pull converter.

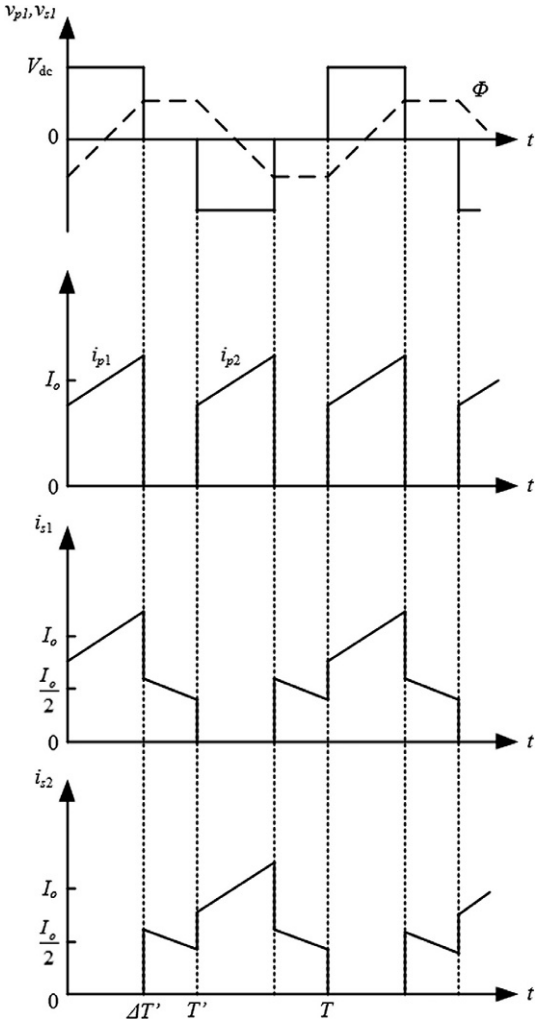

FIG. 17.12 Push-pull converter waveforms.

Input winding:

$$V_{p\text{rms}} = \sqrt{D}V_s$$
$$I_{p\text{rms}} = \sqrt{D/2}I_s \tag{17.50}$$

The average power delivered by each of the primary windings is

$$< p >= \int_0^{DT'} v(t)i(t)dt = \frac{1}{T}V_s I_s DT' = \frac{D}{2}V_s I_s \tag{17.51}$$

$$k_{pp} = \frac{< p >}{V_{p\text{rms}} I_{p\text{rms}}} = \frac{1}{\sqrt{2}} \tag{17.52}$$

The power factor of the secondary winding is found by the same approach and is given by

$$k_{ps} = \sqrt{\frac{D}{1+D}} \tag{17.53}$$

The switch stress parameter must be reduced by selecting a turns ratio of $a = 6$, and the duty cycle ratio is then

$$D = \frac{V_o}{V_s/a} = \frac{24}{325/6} = 0.443 \tag{17.54}$$

K_v from Eq. (17.49) is 6.0.

We can now establish the VA rating for all the windings, noting that each winding carries half of the load on average.

$$\sum \text{VA} = \left(\frac{1}{k_{pp}}\left(\frac{P_o}{2} + \frac{P_o}{2}\right) + \frac{1}{k_{ps}}\left(\frac{P_o}{2} + \frac{P_o}{2}\right)\right) = 1931\,\text{VA} \tag{17.55}$$

17.4.2 Step 1 Core Selection

EPCOS N87 Mn-Zn ferrite has constants $K_c = 16.9$, $\alpha = 1.25$, and $\beta = 2.35$. The saturation flux density is 0.4 T.

The first step is to find B_o from Eq. (17.42) with $f_o = 80$ kHz, $\Delta T = 50$, $K_v = 6.0$, $\sum VA = 1931$ VA, $k_u = 0.4$, $\beta = 2.35$, $h = 10$ W/m^2°C, $k_w = 10$, $k_c = 5.6$, and $k_t = 40$:

$$B_o = 0.038\ T$$

The window area product is given by Eq. (17.45) with $K_\theta = 48.224 \times 10^3$:

$$A_p = 9.647\,\text{cm}^4.$$

The EPCOS ETD 55/28/21 core meets the requirement with $A_P = 9.723$ cm^4.

The core has the following physical dimensions:

$W_a = 2.77$ cm^2, $A_c = 3.51$ cm^2, and MLT = 11.3 cm, and the volume of the core is $V_c = 43.5$ cm^3.

17.4.3 Step 2 Winding Selection

The number of turns in the primary winding is found from Eq. (17.47)

$$N_p = 30\,\text{turns}$$

With a 6:1 turns ratio, the secondary winding is 5 turns.

The current density in the windings is obtained from Eq. (17.44)

$$J_o = 2.982\,\text{A/mm}^2.$$

The primary current is a pulsed waveform with duty cycle $D/2$, so the RMS value is

$$I_{p,\text{rms}} = \sqrt{\frac{D}{2}}\frac{1}{a} I_o = 1.96\,\text{A} \tag{17.56}$$

and the conductor area is $A_w = I_{p,\text{rms}}/J_o = 0.658$ mm^2.

This corresponds to a 0.915 mm diameter wire. The skin depth at 80 kHz is 0.233 mm and therefore the diameter of the wire should be less than 0.5 mm to avoid skin depth losses (see Fig. 17.14). Four 0.45 mm diameter parallel wires will suffice with a combined DC resistance of 27.0 mΩ/m at 20°C.

The secondary current must take into account the conduction when both switches are open; it follows from Fig. 17.12

$$I_{s,\text{rms}} = \frac{I_o}{2}\sqrt{1+D} = \frac{25}{2}\sqrt{1+0.443} = 15.02\,A \tag{17.57}$$

and the conductor area is $A_w = I_{s,\text{rms}}/J_o = 5.035$ mm^2.

This is equivalent to a 2.5 mm diameter round conductor or a 0.2×24.5 mm copper foil. As the skin depth at 80 kHz is 0.233 mm, the round conductor is unsuitable, and the thickness of the foil should be less than 0.1 mm to avoid proximity effect losses (see Fig. 17.16). Two 0.1 mm foils in parallel will meet this requirement and with a combined DC resistance of 4.73 mΩ/m at 20°C.

17.4.4 Step 3 Losses

The total DC resistance of each primary winding at the maximum operating temperature is

$$R_p = N_p \times \text{MLT} \times (\Omega/m) \times [1 + \alpha_{20}(T_{\text{amb}} + \Delta T - 20°\text{C})] \tag{17.58}$$

With $T_{\text{amb}} = 70$°C, $R_p = 127.5$ mΩ, and the copper loss in each primary winding is

$$127.5 \times 10^{-3}(1.96)^2 = 0.49\,\text{W}.$$

The total DC resistance of each secondary winding at the maximum operating temperature is 3.723 mΩ, and the copper loss in each secondary winding is $2.792 \times 10^{-3}(15.02)^2 = 0.831$ W.

Later we will take the proximity effect into account in Section 17.5.

Then total copper loss is 2.642 W.

The core loss is found from the Steinmetz equation Eq. (17.29), $P_{\text{fe}} = 0.599$ W, so that the total loss is 3.241 W.

The thermal resistance of the core assembly, given by the manufacturer, is 10°C/W.

The maximum dissipation is then

$$P_D = \frac{\Delta T}{R_\theta} = \frac{50}{10} = 5.0\,\text{W} \tag{17.59}$$

The design meets this specification; however, there will be additional high-frequency proximity effect losses to include later.

17.5 High-Frequency Effects

A major effect of high-frequency inductors and transformers is ac loss in windings, which include skin and proximity effect losses. Both effects can be alleviated, to a greater or lesser extent with careful design. Winding layers can be optimized to minimize the proximity effect loss. Interleaving can further reduce the loss associated with proximity effects. Both skin effect and proximity effects may be mitigated by the use of litz wire. Design of inductors and transformers with litz wire conductors encompasses different challenges such as the modeling and calculation of ac resistance, the selection of the number and diameter of strands, and the optimal balance between the cross-sectional copper area and the stranding level. Fringing of the flux field around air gaps interacts with the adjoining conductors in a proximity type effect and introduces further losses. All of these effects will be discussed in this section.

Skin effect arises in a conductor due to the varying magnetic field generated by the AC current in the conductor itself. Eddy currents flow to counter the AC field, and the net effect is to reduce the current in the center of the conductor and to increase it at the outer edges, with the overall current remaining the same.

This is illustrated in Fig. 17.13 in a round conductor at three frequencies. At low frequency, the current is uniformly distributed over the conductor cross section. As the frequency increases, the current density increases toward the outside illustrated by the red band. At 1 MHz in the example shown, most of the current is in an annular ring at the outer radius of the conductor. Fig. 17.14 shows the factor Φ_{skin}, which represents the increase of the resistance due to the skin effect, per unit of length, with respect to the ratio of the conductor radius, r_s, to the skin depth. The skin depth is defined by Eq. (17.3).

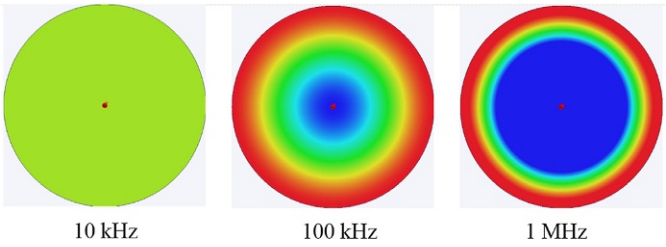

FIG. 17.13 Current distribution in a round conductor.

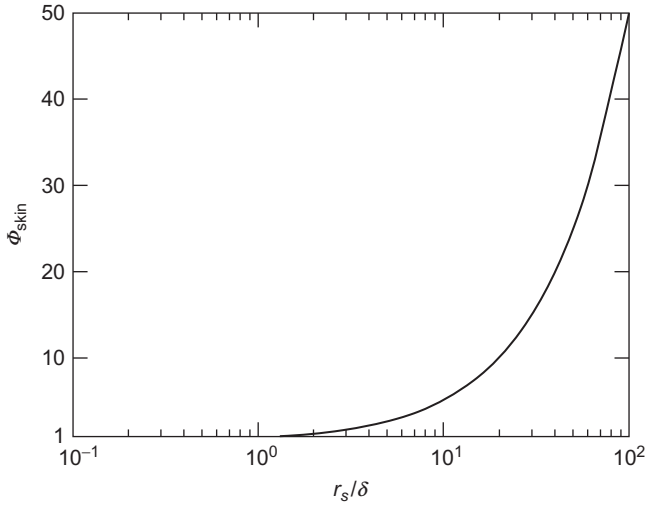

FIG. 17.14 Skin effect loss of a round conductor with respect to the ratio of the strand radius to the skin depth.

Both DC resistance and skin effect may be represented by a resistive element called conduction resistance. The conduction resistance per unit of length of a round strand of radius r_s, R_{cond}, is

$$R_{cond} = R_{dc}\Phi_{skin}(r_s/\delta) \tag{17.60}$$

where R_{dc} is the dc resistance of the conductor. For round conductors, the exact expression of Φ_{skin} is [15]

$$\Phi_{skin}(r_s/\delta) = \mathrm{Re}\left[\frac{(-1+j)(r_s/\delta)}{2}\frac{J_0((-1+j)(r_s/\delta))}{J_1((-1+j)(r_s/\delta))}\right] \tag{17.61}$$

where J_0 and J_1 are the Bessel functions of the first kind and order 0 and 1, respectively.

For practical designs, the ratio r_s/δ would be less than 2 to control the skin effect loss and a useful approximation is [14]

$$\Phi_{skin}(r_s/\delta) = 1 + \frac{(r_s/\delta)^4}{48 + 0.8(r_s/\delta)^4} \quad r_s/\delta < 2 \tag{17.62}$$

The proximity effect is more complicated and depends on the layout of the winding.

Consider the case illustrated in Fig. 17.15. It consists of a transformer with a solenoidal winding with two turns in the primary and three turns in the secondary. In an ideal transformer with infinite permeability in the core, the magnetic field between the turns can be found from Ampere's law. The eddy currents flow as illustrated to counter the magnetic fields on each side of the conducting layer. The red band shows the region with the high current density. Dowell's formula [16] was derived to deal with this case; the resistance due to proximity is

$$R_{prox} = R_{dc}\Phi_{prox}(\Delta) \tag{17.63}$$

$$\begin{aligned}\Phi_{prox}(\Delta) &= \mathrm{Re}\left(\Delta(1+j)\left[\coth(\Delta(1+j)) + \frac{2(p^2-1)}{3}\tanh\left(\frac{\Delta}{2}(1+j)\right)\right]\right)\\ &= \Delta\left[\frac{\sinh 2\Delta + \sin 2\Delta}{\cosh 2\Delta - \cos 2\Delta} + \frac{2(p^2-1)}{3}\frac{\sinh\Delta - \sin\Delta}{\cosh\Delta + \cos\Delta}\right]\end{aligned} \tag{17.64}$$
