With the abovementioned types of frequency decoupling strategies, the transients in the total power demand profile are captured, a safe operating condition for FC-based system can be provided and lifetime of the power sources can be extended [15].

33.5.2.4 Other Methods for Use in Energy Management

Existing methods in the literature in addition to the before mentioned techniques include basic linear proportional-integral (PI)-based approaches, complex adaptive control, robust control, and flatness-based control. A conventional linear PI controller is a basic approach that may be useful for use in real-time implementations of PEMFC systems. Many researchers utilized PI controller especially with a main supervisory controller design. As an example, Thounthong et al. [84,85] utilized a multiobjective PI-based linear technique for SoC sustaining and DC link voltage stabilization. Besides, Payman et al. [86] applied PI controller for the power electronics converter duty cycle determination in order to regulate the desired values of the system parameters determined by a nonlinear flatness-based supervisory control approach.

Another common approach, adaptive control technique, involves modifying the control law used by a controller to cope with the fact that the parameters of the system being controlled are slowly time-varying or uncertain. For example, as an aircraft flies, its mass will slowly decrease as a result of fuel consumption; we need a control law that adapts itself to such changing conditions. Adaptive control does not need a priori information about the bounds on these uncertain or time-varying parameters. Besides, adaptive control is precisely concerned with control law changes. There are mainly two types of adaptive controllers: feedforward and feedback adaptive controllers. There are many types of feedback adaptive controllers such as model reference adaptive controllers (MRACs) and model identification adaptive controllers (MIACs) that are reported in the literature [15].

Robust control methods, which explicitly deal with uncertainty, are designed to function properly so long as uncertain parameters or disturbances are within a typical limit. Robust methods aim to achieve robust performance and/or stability in the presence of bounded modeling errors. In contrast with an adaptive control policy, a robust control policy is static; rather than adapting to measurements of variations, the controller is designed to work assuming that certain variables will be unknown [15].

33.5.3 Current Status and Future Trends of Fuel Cell based Vehicles

Leading automakers have started to make their light-duty hydrogen FCEVs for testing and commercial applications. Available FCEVs are on the road in selected regions like California, Europe, Japan, where access to hydrogen stations are available. Some of these vehicle models include Honda FCV (2016), Toyota Mirai (2017), Mercedes-Benz B-Class F-Cell (2015), Hyundai Tuscon, and SUV (2016). All of these FCEVs uses 100 kW fuel cell stack. They also have quick refueling time of less than 10 min and driving range of around 200–300 mi [21,54,87–89].

The California Fuel Cell Partnership (CaFCP) plays a vital role in preparing to demonstrate and commercialize the vehicle technology of the twenty-first century. This organization is a unique collaborative of automakers, energy and FC technology companies, and government agencies. Currently CaFCP is focused on the marketization and industrialization and while emphasizing the importance for market introduction of FCEVs [90].

Although automakers have produced FC-based commercial vehicles, actually, they started to develop FCEV prototypes many years ago. For example, Toyota has developed various types of FCEVs, after it began its fuel-cell efforts in 1992. Ballard developed and demonstrated a hydrogen-fueled transit bus in 1993. GM demonstrated an FC/battery hybrid FCEV in 1998. Nearly 200 B-Class FC-based Mercedes-Benz vehicles have been with customers in the United States and Europe since 2010 [89]. AC Transit has the most comprehensive program to obtain real-world driving impressions and experiences and realize the earlier phase of the hydrogen FCEVs in North America [17,90]. The new Mercedes GLC F-CELL and next generation Honda FCEVs combine fuel cell and energy storage unit (lithium-ion battery) using plug-in hybrid technology that is planned to come to the market in 2017 and 2018, respectively [21,91].

Some governments (e.g., US and Japan) and automakers (e.g., Honda, Toyota, Daimler, Nissan, and Ford) are working together to support hydrogen infrastructure, public awareness, decrease operational costs of infrastructure firms. By cost reduction and mass production of competitive parts such as the FC stack, hydrogen, fueling stations, compact packaging, storage (battery and ultracapacitors), silicon carbide-based innovative power electronics, and electric motor technologies, these vehicles can be commercialized and introduced to the market for widespread use [18,21,37].

It is necessary to carry out further investigation on the performance, reliability, durability, and cost reduction of FC

systems. FCEV design architecture plays a significant role while considering the performance, packaging, interior-space, efficiency, real-world performance, and durability issues. FCEV systems should be environmentally safe and commercially viable. Without doubt, technologies of a stable supply of highly pure hydrogen and inexpensive cell components are a prerequisite for market penetration of FC systems. In this case, since the number of renewable energy sources is increasing rapidly, new business models and marketing strategies can be developed. For example, the production of green hydrogen from renewable sources (biomass, biowaste, electrolyzers powered by photovoltaic, and wind energy systems) and also other feasible and viable hydrogen production methods can be used to feed the FCEVs and to balance the electric and gas grids under the smart grid concept [5,20]. Besides, as a part of sustainable energy and transportation chain, FCEVs, and their modular infrastructures like power inverter and hydrogen stations can contribute to the efficiency of the smart energy systems (as V2G, V2H, flexible load, storage, combined heat power, grid balancing, energy exchange, feed-in tariffs, and emerging application concepts). These kinds of EVs, like FCEVs, can also be used as an investment tool and as a major player of energy market in the future smart grids and smart cities.

Demonstration infrastructure should be sufficient for envisioned commercialization roadmap [5]. Demonstration projects and proof of concept experiments will act as a seed in addressing problems associated with practical applications, data collection for standardization, durability of FCEVs and accelerate awareness of using hydrogen in our daily life [5,17,21,92]. From the viewpoint of FCEVs market penetration, currently, there are limited commercial FCEVs, but in medium- and long-term periods, there will be huge numbers of FCEVs on the road depending on the abovementioned strategies of developed and developing countries. Thus, they can contribute significantly toward sustainable transportation and hydrogen chain.

33.5.4 Safety

Hydrogen FCs can revolutionize many sectors, since hydrogen is as safe as or even safer than other flammable fuels such as gasoline or natural gas. However, with the lack of professional design and management, hydrogen fuel cells pose several other risks that other flammable fuels do not.

Nowadays, FCEVs, hydrogen refueling stations and other values of hydrogen chain started to operate in different regions, despite pending answers to potential questions (How safe is hydrogen? What are potential hazards of hydrogen? Which improvements does it require to avoid danger?) [5]. Hazards and associated risks for hydrogen fuel cells should be considered by all stakeholders such as designers, regulators, and users in various situations when FCEVs are inoperable, in normal operation and in collision [5,16].

The main potential hazards can be listed as follows [5,16,21]:

- Hydrogen burns (rather than explosion)
- Higher flammability range
- Danger posed by invisible hydrogen flames (adding chemicals like odorant for required luminosity can provide an easier detection)
- Hard detection of hydrogen leak
- Higher tendency to leak since hydrogen is the smallest molecule (professional design may prevent leaks)
- Potential of hydrogen to asphyxiate people
- Frostbite/cold burns of liquid hydrogen
- Refueling station accidents

These hazards may be prevented or the impacts can be decreased with more R&D studies, administrative supports, efforts of all stakeholders, etc. For instance, Honda improved several designs to prevent FCEVs from collision impacts such as fastening bar as an impact resistant to prevent cells, straight frame structure to protect components, and load path structure to disperse the collision load and for efficient absorption of energy [21].

33.6 Conclusion

Almost all major companies have publicized ambitious plans to introduce hydrogen-powered vehicles in the market. Moreover, FCEVs are sold in selected regions with access to hydrogen stations. This vehicle type promises very clean operation and shows higher energy efficiency compared with conventional vehicles. When the FCEV technologies become mature, FCs can also be extended in many diverse areas from portable devices to silent heavy vehicles or aerospace applications. Besides, FCEVs and their infrastructure systems can also be used as a backup or integrated system for renewable energy sources.

In the near future, as a part of smart grid, FCEVs and hydrogen energy chain should be considered for sustainable development.

34.1 Introduction to Wireless Electric Vehicles

In this section, a new concept of "wireless electric vehicles (WEVs)," which is coined by the author, is introduced, and wireless power transfer (WPT) technologies including inductive power transfer (IPT) and capacitive power transfer (CPT) are explained. Then, introduction to electric vehicles (EVs) is briefly provided.

34.1.1 The Needs for Wireless Electric Vehicles

Why most people are still not daily driving an electric vehicle?

As a customer, I feel that EVs are still very expensive and inconvenient compared with existing conventional internal combustion engine (ICE) vehicles. The structure of an EV is relatively simple and easy to have maintenance; however, it is not cheap and heavy because of its onboard batteries. Still, most EVs have much shorter driving distance for a full charge compared with ICE vehicles.

Therefore, it can be said that EVs have not been widely commercialized because of battery and charging problems, as shown in Fig. 34.1.

Remark that battery EV (BEV) had been commercialized since the late 19th century, which is about 20 years earlier than the commercialization of ICE vehicles. The original BEVs disappeared from markets because the battery was too heavy, required long time to recharge, had a relatively short driving distance, and was expensive. Amazingly, these problems of battery still exist compared with current ICE vehicles nevertheless the drastic improvement of EV batteries. The expensive price of EVs is mainly due to battery price. The improvement of battery is very slow and does not follow the Moore's law because it is not governed by electronics but governed by chemistry.

Another major obstacle for commercialization of EVs is the charging problem. Even though innovative batteries will become available, still we have charging problems. We should have 30 C (1 C corresponds to the rated power or energy capacity of a battery for an hour) charging capacity in order to recharge an EV in 2 min in case we have such a good battery. For a 50 kWh battery example, which is common to a long-distance EV now, we should have at least 1.5 MW power rating charger and power distribution facility to support it. In practice, we should recharge an EV frequently in order to avoid the battery empty. If a cable charger is used, it is very inconvenient to plug in and plug out daily, and it is potentially

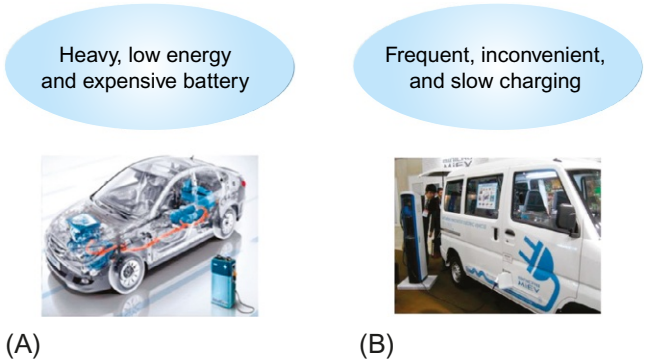

FIG. 34.1 Major obstacles for commercialization of electric vehicles. (A) Battery problems, (B) charging problems.

dangerous to deal with the connector of a cable manually under wet conditions. Currently, a quick charger can recharge an EV battery up to 80% within 20 min, which is still too long time for customers accustomed to 2 min refueling.

Two possible solutions to the abovementioned problems are summarized in Fig. 34.2.

The first solution is to adopt the road-powered EV (RPEV) [1,2] or online electric vehicle (OLEV) [3–19], which does not rely on the battery but gets power directly from roadway power supply rails. This charging method is often referred "the dynamic wireless charging" or simply "dynamic charging" because power is delivered to an EV when it is in motion. An RPEV has a battery for temporary energy storage, but its size is a few times smaller than a BEV, which is not an obstacle for commercialization. As shown in Fig. 34.2A, RPEVs have replaced conventional conductive EVs that have wearable pantographs and cumbersome power lines.

The second solution is stationary wireless charging [20–25], often called as "static charging," by which the inconvenient and dangerous cable charging problems can be completely solved, as shown in Fig. 34.2B. The stationary wireless charging can be applicable to both plug-in EVs (PHEVs) and BEVs. Of course, the slow charging problem cannot be directly solved by the wireless charging, and it must be mitigated by other means such as "interoperable road-powered supply rails [26]," on which this stationary wireless charging is also made together with RPEVs.

I would like to call the stationary and dynamic charging EV solutions as wireless EVs (WEVs), which embrace WPT and wireless communications for EVs. As EVs evolve to information platforms in the future, wireless communications will be essential to every EV, which results in ubiquitously connected cars. WPT will make the WEV complete.

34.1.2 What is Wireless Power Transfer?

In general, the methods of power transfer (PT) can be classified to the stationary PT and mobile PT depending on the movement of loads, as shown in Fig. 34.3. WPT is nowadays the most preferable way of mobile PT that embraces inductive PT (IPT), capacitive PT (CPT), radio-frequency PT (RFPT), and optical PT (OPT), whereas the wired PT can also provide power over a flexibly long distance if properly designed. Currently, IPT is the most widely used one among WPTs, which will play a significant role in realization of the Internet of things (IoT), comprising of digital communication devices, sensors, software, and power sources.

An experiment kit, for example, WPT, is shown in Fig. 34.4, where two air coils are used to transfer power "wirelessly" through "magnetic coupling" or "inductive coupling" of the coils and compensation capacitors are used to nullify the reactance of LC resonant circuits. An inverter is used to provide high-frequency AC current to a transmitter (Tx) coil, and a load transformer is used to adapt the induced voltage of a received (Rx) coil to a load voltage level.

What do you think about the characteristics that a WPT system should have?

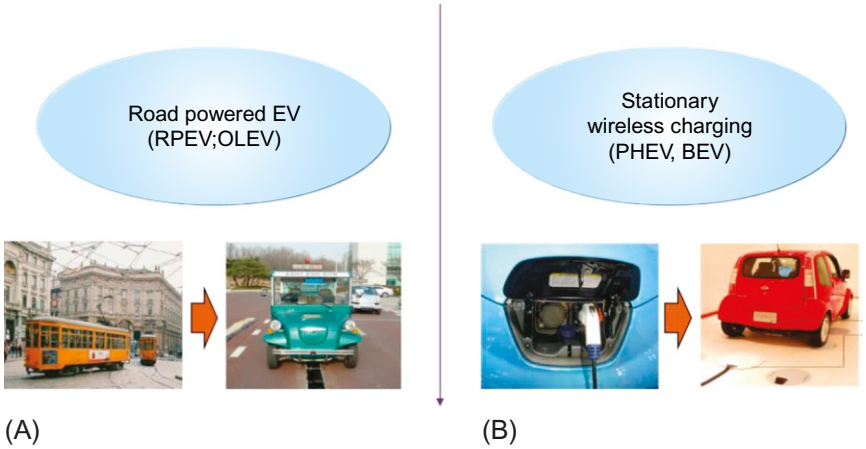

FIG. 34.2 Two possible solutions for current electric vehicles. (A) Road powered EVs, (B) wireless charging.

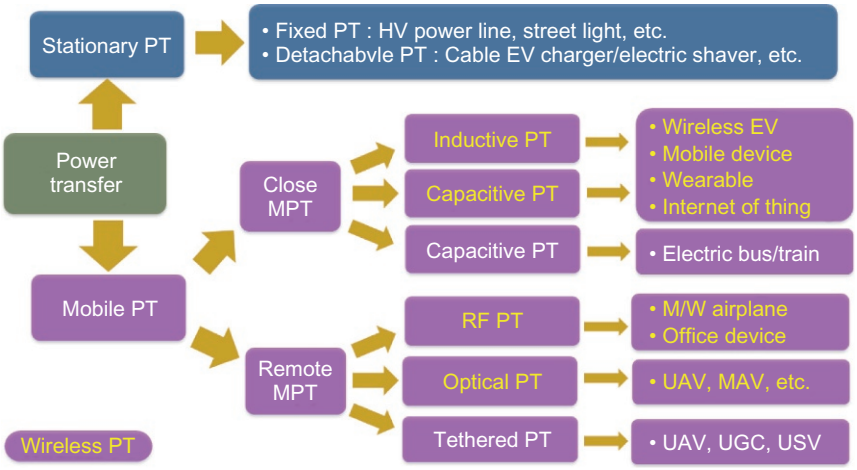

FIG. 34.3 Classification of power transfer method.

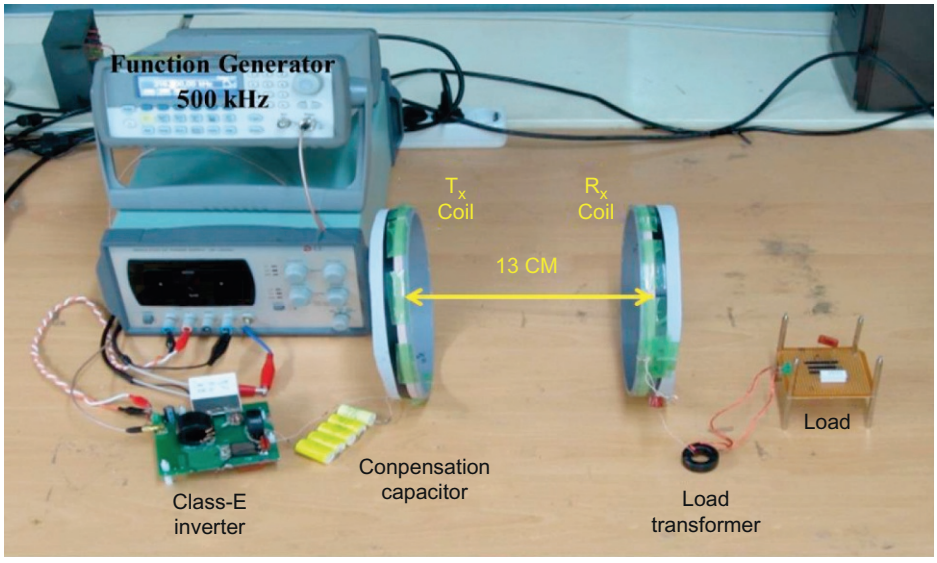

FIG. 34.4 An example IPT of a WPT system consists of two coils operating at 500 kHz switching frequency.

First, the delivered power level for a load should be enough, and its power efficiency should be also high enough not to generate excessive heat and waste electric energy.

Second, the cost, mass, and volume of a WPT system are quite often problems compared with existing wired solutions.

Third, system resilience against resonance parameter changes, load changes, input voltage changes, proximity object movement, electromagnetic interference (EMI), and environment changes such as temperature, humidity, vibration is found to be very important in a WPT system.

Fourth, system dynamics such as response time, stability, and dynamic operating range should be met.

Fifth, accommodation, deployment, and user interfaces of a WPT system should be well considered from design phase for a successful development.

The abovementioned aspects of a WPT system are not necessarily in the order of importance, and they are strongly correlated with each other. Like other systems, the WPT system is a complex system of mechanical and electric compartments, and the design of a WPT system requires comprehensive trade-offs among the requirements. It can be said that the development of a WPT system is not a systematic science but an art of system engineering.

34.1.3 Introduction to Inductive Power Transfer

In general, it can be said that the IPT is governed by Ampere's law and Faraday's law among four Maxwell equations, as shown in Fig. 34.5. The governing equations of IPT in the

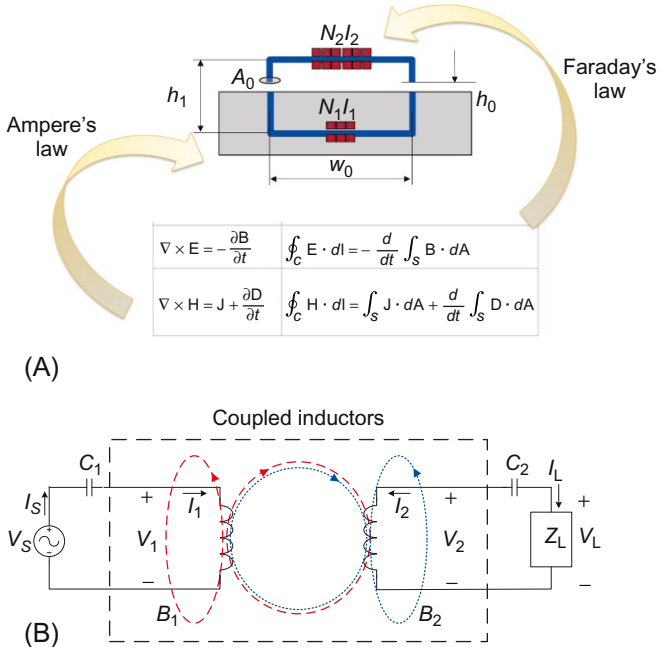

FIG. 34.5 The fundamental principle of IPT. (A) Governing equations of IPT in general, (B) an equivalent circuit of an IPT system in phasor domain, including compensation circuits in the steady state.

steady state for a sinusoidal magnetic field, electric field, and current density at low frequency are approximated by letting $\boldsymbol{D}=0$ as follows:

$$\nabla \times \mathbf{H} = \mathbf{J} \quad \text{(Ampere's law)} \tag{34.1a}$$

$$\nabla \times \mathbf{E} = -j\omega\mathbf{B} \quad \text{(Faraday's law)}. \tag{34.1b}$$

The principle of IPT power delivery can be sequentially explained as follows:

(1) Time-varying magnetic flux is generated from the Tx coil according to Ampere's law.
(2) Induced voltage is generated at the Rx coil according to Faraday's law, where magnetic flux comes from the Tx coil.
(3) Induced voltage, called back emf (counter electromotive force), is also generated at the Tx coil by the Rx coil current.
(4) Power is provided to the Tx coil and fetched from the Rx coil; thus, wireless power is delivered through the coils.

As identified from the above four steps, the IPT is essentially a transformer. A major difference from an ideal transformer, however, is relatively large leakage inductances at both the primary and secondary sides because of weakly coupled inductors. This is why we need the capacitors, as shown in Fig. 34.5B, which are mostly used to compensate the reactance of corresponding leakage inductances. Depending on the source and load types, the compensating capacitors can be connected in series or parallel; Fig. 34.5B shows a series-series (S-S) compensation example.

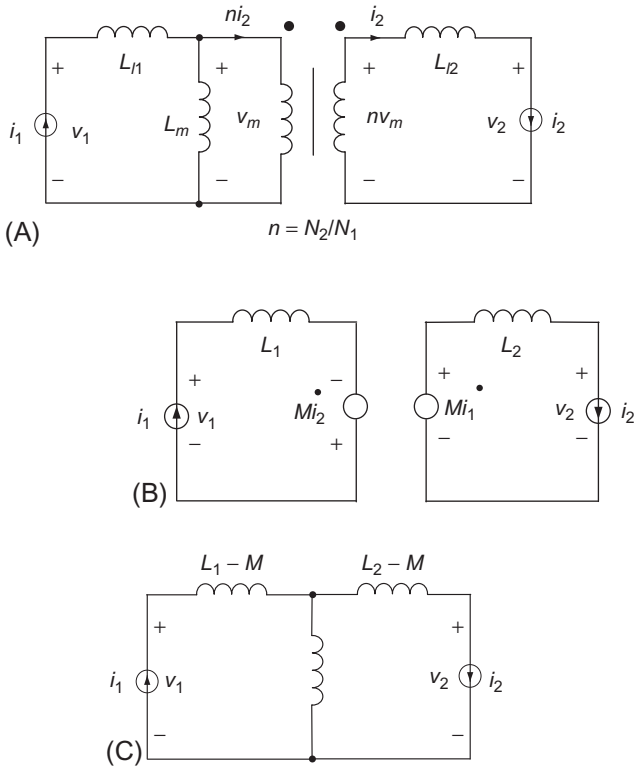

FIG. 34.6 Equivalent circuit models for two coupled coils. (A) Transformer model, (B) M-model, (C) T-model.

For the circuit level analysis of IPT, an equivalent circuit for the coupled inductors in the dotted box of Fig. 34.5B is highly needed. There are three equivalent circuit models widely used for the coupled inductors in IPT, as shown in Fig. 34.6. As shown in Fig. 34.6A, the transformer model is convenient for designing parameters when explicit circuit variables are sought for. The mutual coupling model (M model) of Fig. 34.6B is conveniently used when each side is regarded as an inductor and a back emf voltage source, which represents mutual inductive coupling. Though the trivial galvanic isolation is not countered, the most simplified IPT model would be the "T"-shape model (T model), as shown in Fig. 34.6C, which comprises three inductors only and does not apparently show any turn ratio. Note that the three models are valid not only in the steady state but also in the transient state [27].

The governing equations for the transformer model and M model can be related as follows:

$$v_1 = L_{l1}\dot{i}_1 + L_m\left(\dot{i}_1 - n\dot{i}_2\right) = \left(L_{l1}+L_m\right)\dot{i}_1 - nL_m\dot{i}_2 \equiv L_1\dot{i}_1 - M\dot{i}_2 \tag{34.2a}$$

$$\begin{aligned} v_2 &= \left(nL_m\dot{i}_1 - n^2L_m\dot{i}_2\right) - L_{l2}\dot{i}_2 \\ &= nL_m\dot{i}_1 - \left(n^2L_m + L_{l2}\right)\dot{i}_2 \equiv M\dot{i}_1 - L_2\dot{i}_2 \end{aligned} \tag{34.2b}$$

$$\because M \equiv nL_m, \quad L_1 \equiv L_{l1} + L_m, \quad L_2 \equiv L_{l2} + n^2L_m. \tag{34.2c}$$

Note that the upper dot of a variable is the time derivative of the variable, and the equations are valid for in general.

The T model can be derived from the M model of (34.2) by rearranging terms as follows:

$$v_1 = L_1\dot{i}_1 - M\dot{i}_2 = (L_1 - M)\dot{i}_1 + M\left(\dot{i}_1 - \dot{i}_2\right) \tag{34.3a}$$

$$v_2 = M\dot{i}_1 - L_2\dot{i}_2 = -(L_2 - M)\dot{i}_2 + M\left(\dot{i}_1 - \dot{i}_2\right). \tag{34.3b}$$

34.1.4 Introduction to Capacitive Power Transfer

CPT has not been widely used in WPT compared with IPT due to its low power delivery capacity and high operating frequency. However, CPT has advantages for compact and thin layer applications with low power. The configuration of a CPT system is shown in Fig. 34.7, where other modules are very similar with IPT except for Tx and Rx plates and electric-field-based communication links. The application of CPT to EV is available in a few literatures [25].

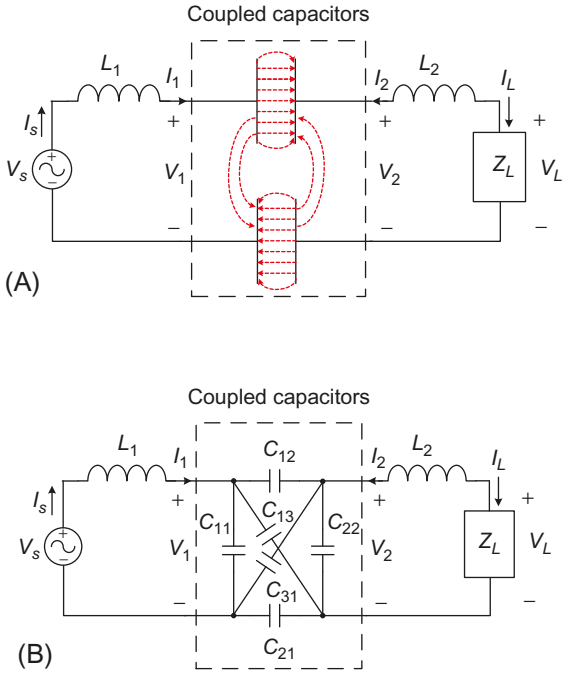

FIG. 34.7 An equivalent CPT system in the phasor domain, including compensation circuits in the steady state. (A) Distributed capacitance model with electric field distribution, (B) lumped capacitance model with six capacitances.

34.1.5 Introduction to Electric Vehicles

Generally speaking, an EV comprises a conventional car body, and EV-specific components such as energy refuel equipment (electric chargers), onboard energy storage (batteries), power converters (inverters and rectifiers), and locomotive (electric motors and transmissions), as shown in Fig. 34.8.

It is instructive to find the analogy between EVs and ICE vehicles: electric charger versus fueling station, battery versus fuel tank, inverter versus fuel injector, and electric motor versus ICE [28].

Depending on the energy source/refueling method, EV-specific components mentioned above, and various applications, EVs can be classified into many categories. EVs can be classified, according to energy source or energy refueling method, as wired power EVs, wireless-powered EVs (WEVs), solar- or RF-powered EVs, and battery-swap EVs. Depending on the onboard energy sources, EVs can be classified as ICE-powered EVs, called hybrid EVs (HEVs) or plug-in hybrid EVs (PHEVs), fuel-cell-powered EVs (FCEVs), and even nuclear-powered EVs though not likely to be commercialized in the near future. EVs can be also classified into applications such as ground (road and rail), aerial, sea (ship/underwater), and space EVs.

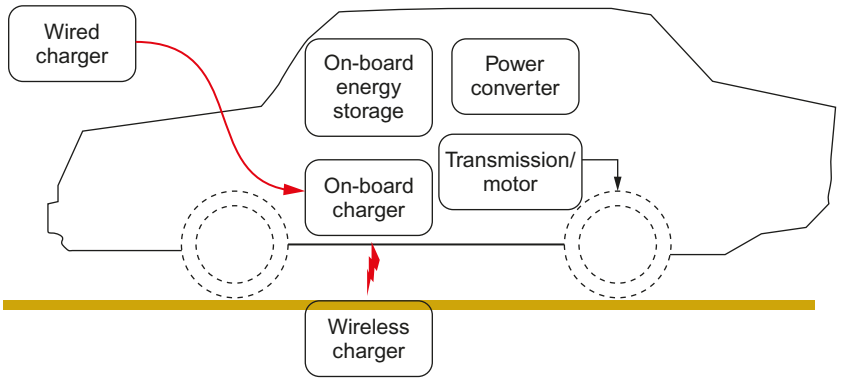

FIG. 34.8 A general configuration of EV, charged by both wired and wireless chargers example.

34.2 Static Inductive Charging of Battery Electric Vehicles

In this section, it is explained how IPT is applied to the static chargers for EVs such as BEVs and PHEVs.

34.2.1 Overview of Static EV Chargers

Because automatic refueling of a vehicle is a wonderful thing for the person, boring of repeated daily cable charging of EVs, static EV chargers of this category are expected to be widely used in the near future. As identified from recently developed autonomous vehicles and self-controlled vehicles, future vehicles will be not only transportation tools but also information platforms. EVs are inherently the most electrified vehicles, which make the information platform be possible.

Among numerous static EV chargers, a few implemented examples are shown in Figs. 34.9 and 34.10.

A static EV charger can be decomposed into a Tx subsystem on ground and an onboard Rx subsystem. The system requirements of a static EV charger include cost, reliability, lifetime, availability, power, efficiency, tolerances (height, longitudinal, and lateral), electromagnetic field (EMF), foreign object detection (FOD), and robustness against mechanical shock for a given source and load conditions, air gap, load change, and operating temperature. Hardware and software implementation issues such as insulation, waterproof, user interface, monitor, communications, and information are also important for the development of the system. Standardization and regulation issues are crucial for commercialization.

34.2.2 Coil Design Issues

Coil design would be the most substantial part of IPT system design because the Tx coil and Rx coil determine power transfer performances such as output voltage, power level, coil-to-coil efficiency, and height/lateral tolerances. The configuration of a static charger includes Tx and Rx windings and cores, as shown in Fig. 34.11. The goal of coil design is to focus magnetic field from the Tx to Rx coils so that leakage flux is minimized to lower EMF. In detail, to design the coil is to determine the ampere-turns (N_1, N_2, I_1, and I_2) and detail dimensions of coils for a given air gap, width of coil, operating frequency, power supply voltage, delivered output power, and ambient operating temperature (h_s, w_p, f_s, V_s, P_o, and T).

(A) (B)

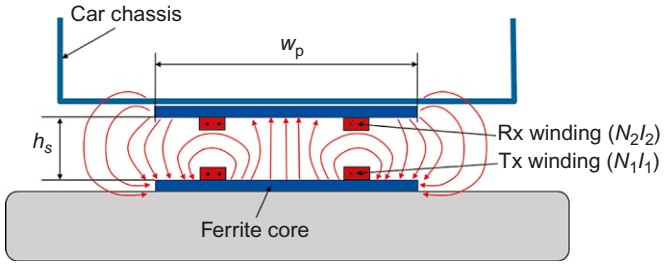

FIG. 34.11 Configuration of Tx and Rx coils of a static EV charger when Tx coil is energized and Rx coil current is zero.

There are a few decision issues in the design of Tx and Rx coils of static EV chargers. One of them is the coil shape, as shown in Fig. 34.12. The merits of the two types are listed below. The thick arrows depict lateral tolerances of two directions: the larger the arrow length, the bigger the tolerance. "S" and "N" denote magnetic polarity. There could be other shapes such as round shape, which is basically rectangular but its corners are round, and octagonal shape. Basically, the shape of the coil is largely governed by the shape of the mother body, that is, a car underbody, depending on applications.

As shown in Fig. 34.13, the lateral tolerance of a dual-pole coil could be better than that of a single-pole coil because the number of magnetic pole is only two for the dual-pole coil. The demerits are written in italic letters in Fig. 34.13.

You should also determine the coil type depending on magnetic field shape you want, as shown in Fig. 34.14, where loop coil and dipole coil examples are selected. For a given size of the Tx and Rx coil, the dipole coil has larger lateral tolerance in side direction but has large EMF that needs more magnetic shield.

The core could be dense or sparse structures, as shown in Fig. 34.15. Note that the total amount of core use could be unchanged by the average density of core if the core thickness of dense core structure is optimized. If not the case, the core use of sparse structure tends to be smaller than the dense structure.

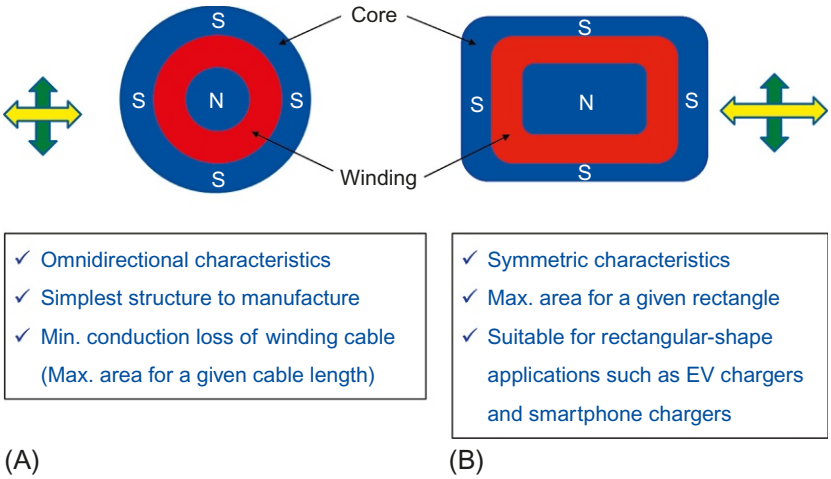

FIG. 34.12 Shape of Tx and Rx coils (plane view). (A) Circular, (B) rectangular.

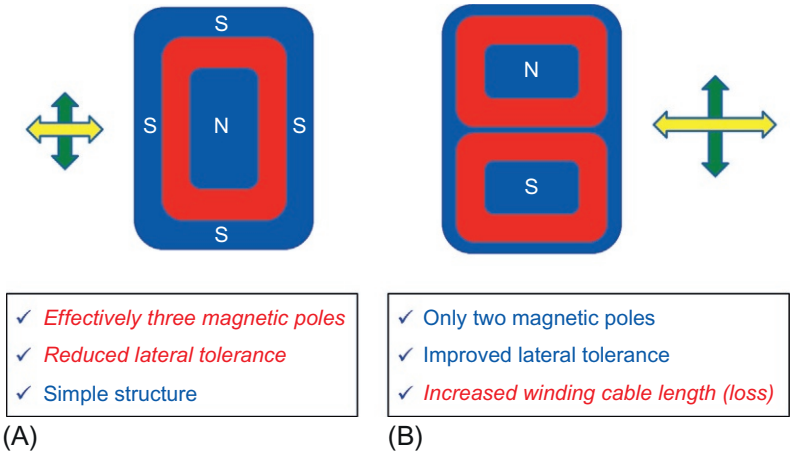

FIG. 34.13 Number of poles in Tx and Rx coils (plane view). (A) Single pole, (B) dual pole.

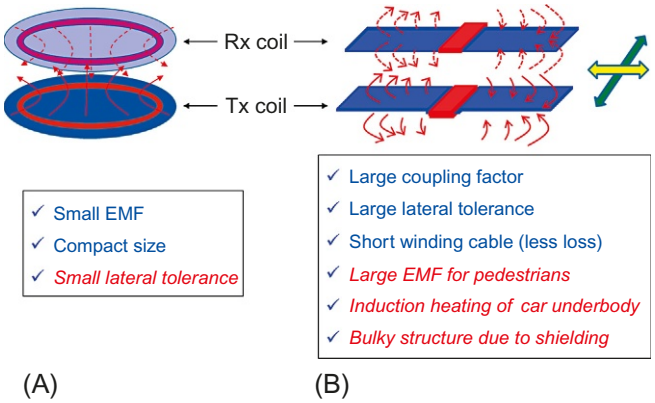

FIG. 34.14 Magnetic field shape of Tx and Rx coils (bird's-eye view). (A) Loop coil, (B) dipole coil.

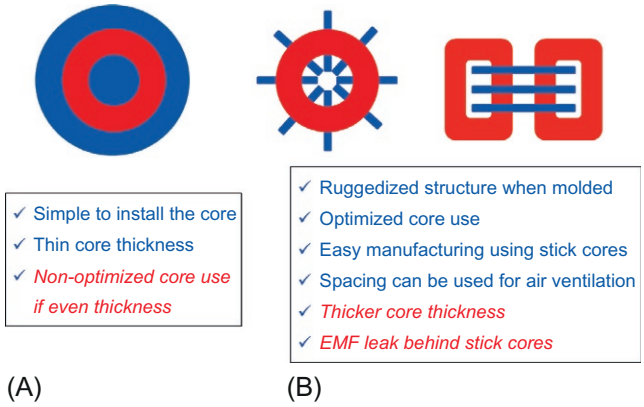

FIG. 34.15 Core structure of Tx and Rx coils (plane view). (A) Dense core structure, (B) sparse core structures.

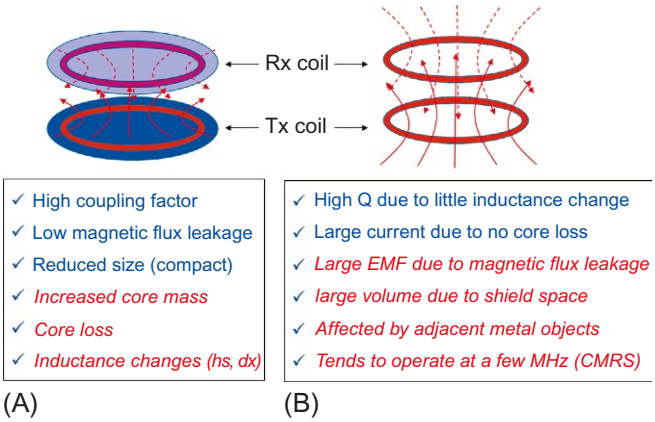

FIG. 34.16 Core use of Tx and Rx coils (bird's-eye view). (A) With core, (B) coreless.

Another category of core structure is the use of core, as shown in Fig. 34.16. Core is not necessarily always used, especially when the operating frequency is too high to use any core, as shown in Fig. 34.16B. Note that the coreless coil is quite often referred as the coupled magnetic resonance system (CMRS),

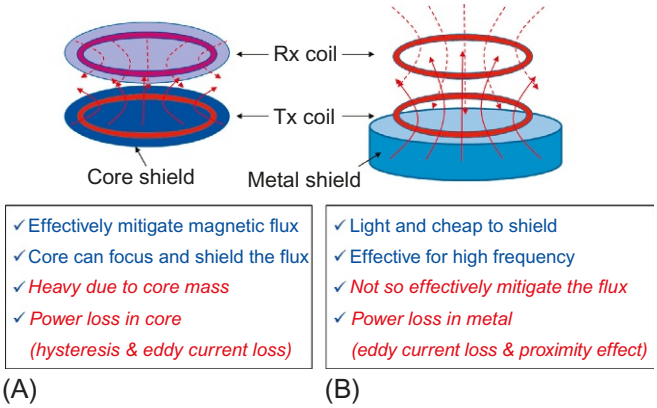

FIG. 34.17 Magnetic field shield of Tx and Rx coils (bird's-eye view). (A) Core shield, (B) metal shield.

whereas the coil with core is called conventional inductive power transfer system (IPTS). The beginner who studies CMRS often thinks that it is quite different from IPTS due to its inherent large Q and no change of primary and secondary inductances against air-gap change. The wonderful characteristics of CMRS, however, do not come from its resonant type but come from its coreless structure, as the author announced at the Special Session of Wireless Power Transfer of the 2013 IEEE ECCE conference. As an evidence, 5 m-long-distance IPTS was built and first demonstrated that long-distance WPT is possible not only by CMRS but also by IPTS [29]. As denoted in Fig. 34.16, there are a lot of penalties for the coreless structure.

We have two shielding methods: core shield and metal shield, as shown in Fig. 34.17. Both shields are often used to enhance magnetic shielding effect. Note again that there are not many theories available for metal shield design compared with core shield design.

34.2.3 Misalignment Issues

A very important and difficult problem in IPT design is position tolerance issue arising from air-gap change and misalignments between Tx and Rx coils, as shown in Fig. 34.18. As the coils are misaligned each other, induced voltage drops in general, and resonant frequencies of Tx and Rx sides usually change as well. Therefore, the position tolerance affects to not only coil design but also compensation circuit, controller, and converter designs such as power rating, zero voltage switching (ZVS) condition, and power factor.

34.3 Dynamic Inductive Charging of Road Powered Electric Vehicles

In this section, the WPT system (WPTS) for RPEVs is explained. Most recently commercialized OLEVs including narrow-width power rails of I-type and ultraslim power rails

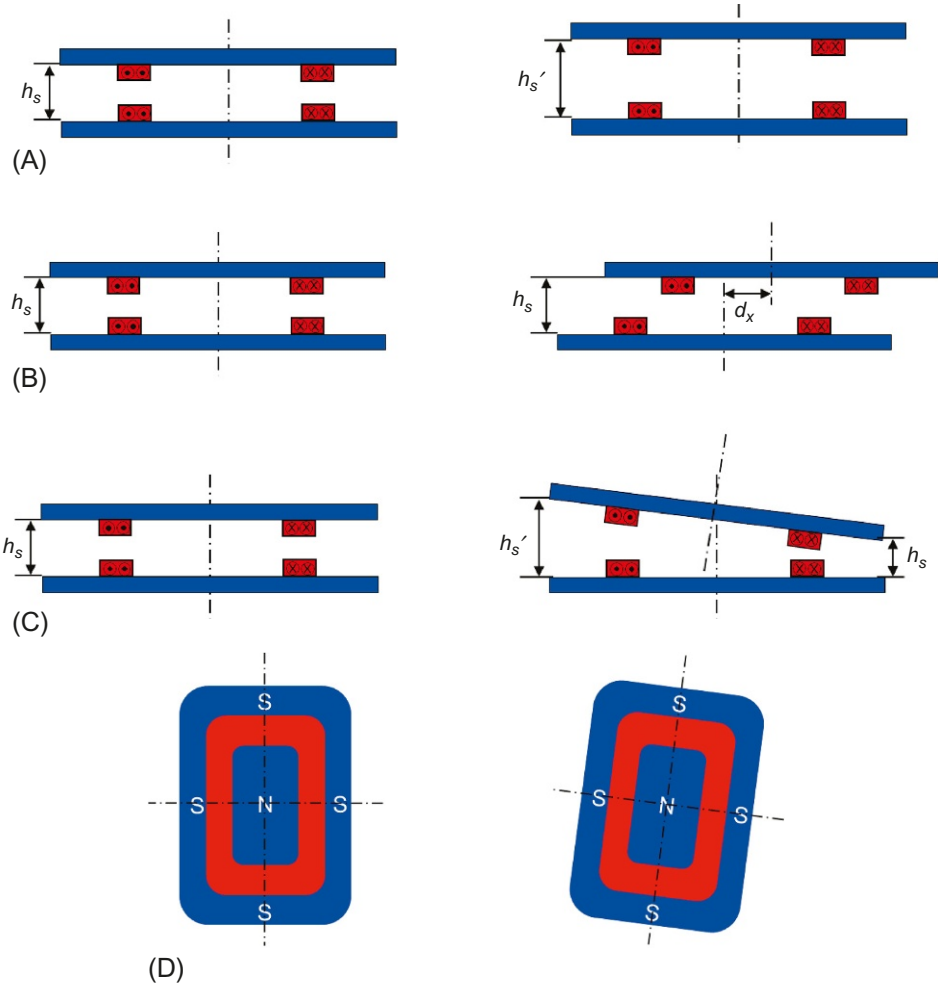

FIG. 34.18 Position tolerance problem, arising from relative position changes of Tx and Rx coils. (A) Airgap change (side view), (B) lateral misalignment (side view), (C) tilt misalignment (side view), (D) rotation misalignment (plane view).

of S-type are explained, where the width of power rail is important in road construction of infrastructure for RPEVs.

34.3.1 Overall Configuration of RPEVs

The WPTS for an RPEV should be capable of delivering high power efficiently through a moderate air gap for avoiding collisions between the RPEV and ground. The WPTS is composed of two subsystems: One is the roadway subsystem for providing power, which includes a rectifier, a high-frequency inverter, a primary capacitor bank, and a power supply rail, and another is the onboard subsystem for receiving power, which includes a pickup coil, a secondary capacitor bank, a rectifier, and a regulator for battery, as shown in Fig. 34.19. The roadway subsystem should be so robust and cheap that it may withstand severe road environments for a lifetime of an EV and should be economic to install over a long distance, whereas the onboard subsystem should be compact in size and light in weight so that it may be adopted into the RPEV.

An example overall circuit diagram of an IPTS developed for OLEVs is shown in Fig. 34.20, where the inverter provides constant current to the Tx power rail by a feedback control.

The overall system breakdown of an RPEV mission system is shown in Fig. 34.21, which is drawn, reflecting the experience of developing OLEV systems by the author. The RPEV mission system includes not only the WPTS system but also the control system and EV system. The control system is unique and crucial for RPEV because it senses and identifies the EV and then appropriately turns on and off the inverters. Moreover, it monitors the health of IPTS and RPEV and provides accounting service and communication links.

IPTS for RPEV is differentiated from conventional IPTS for stationary charging because additional requirements such as larger lateral tolerance, higher air gap, and lower construction cost should be considered for dynamic charging [3–19]. Moreover, IPTS for RPEV should survive from harsh road conditions such as extremely high and low temperatures, high humidity, and repetitive mechanical shocks for at least 10 years. Basically,

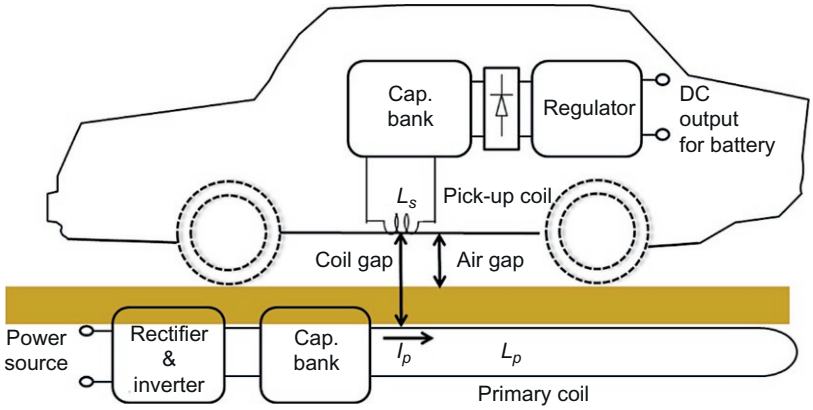

FIG. 34.19 Overall configuration of an RPEV.

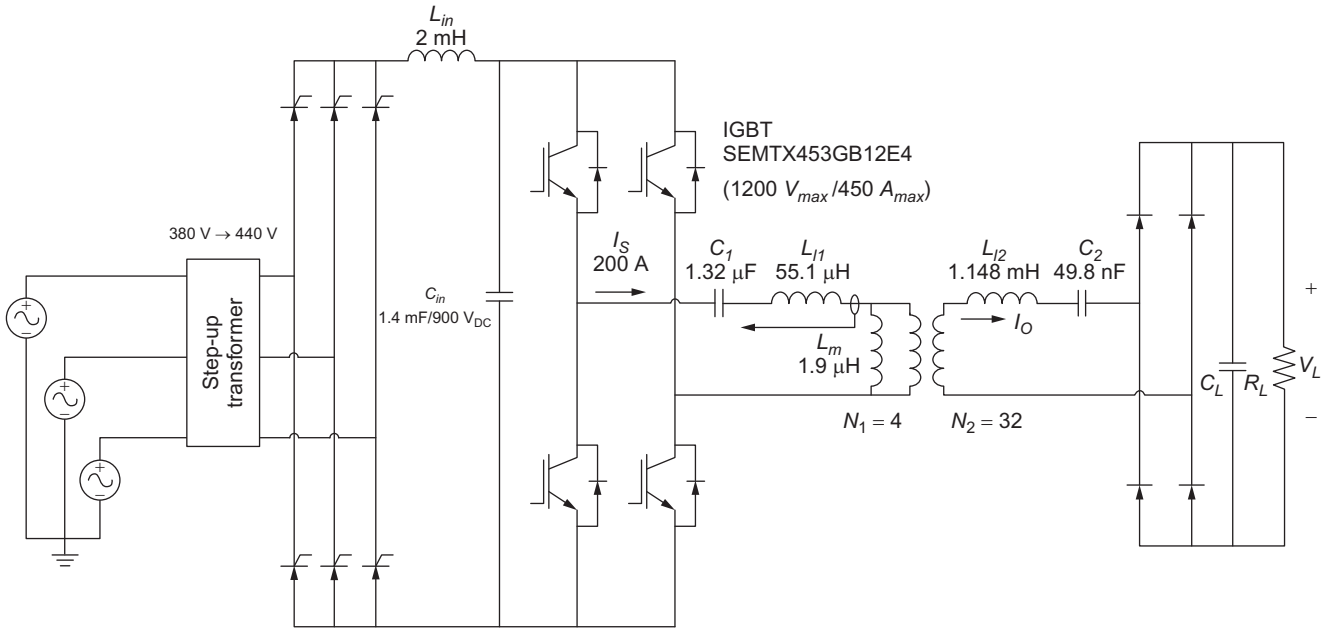

FIG. 34.20 Overall circuit diagram of the IPTS for OLEVs (an example).

the high-voltage power rail under a road should be electrically and mechanically protected well, but electricity under the conditions of a wet and fragile structure is not compatible with a road, in general. Therefore, it is quite challenging to build the roadway subsystem robustly. On the other hand, the onboard subsystem should also survive from the harsh road conditions and vibrating RPEV operating conditions, where strict technical and legislative regulations for vehicles should be met.

34.3.2 Design Issues of Dynamic Inductive Charging

The design goals of IPTS are summarized as follows:

(1) To increase magnetic coupling as much as possible so that higher induced voltage can be obtained.
(2) To increase power efficiency for a given power capacity, device ratings, and cost.
(3) To make modules as compact as possible to accommodate for a given space and weight.
(4) Not to increase or cancel out EMF.
(5) To manage resonance frequency variation and coupling factor change due to misalignment of pickup position, air-gap change, and even temperature change.

In order to meet the design goals, several important design issues of the IPTSs, which are unique for RPEVs, should be resolved as follows:

1. *Switching frequency*: The switching frequency of the inverter and rectifier of an RPEV governs overall performances. As the switching frequency f_s increases, the coil

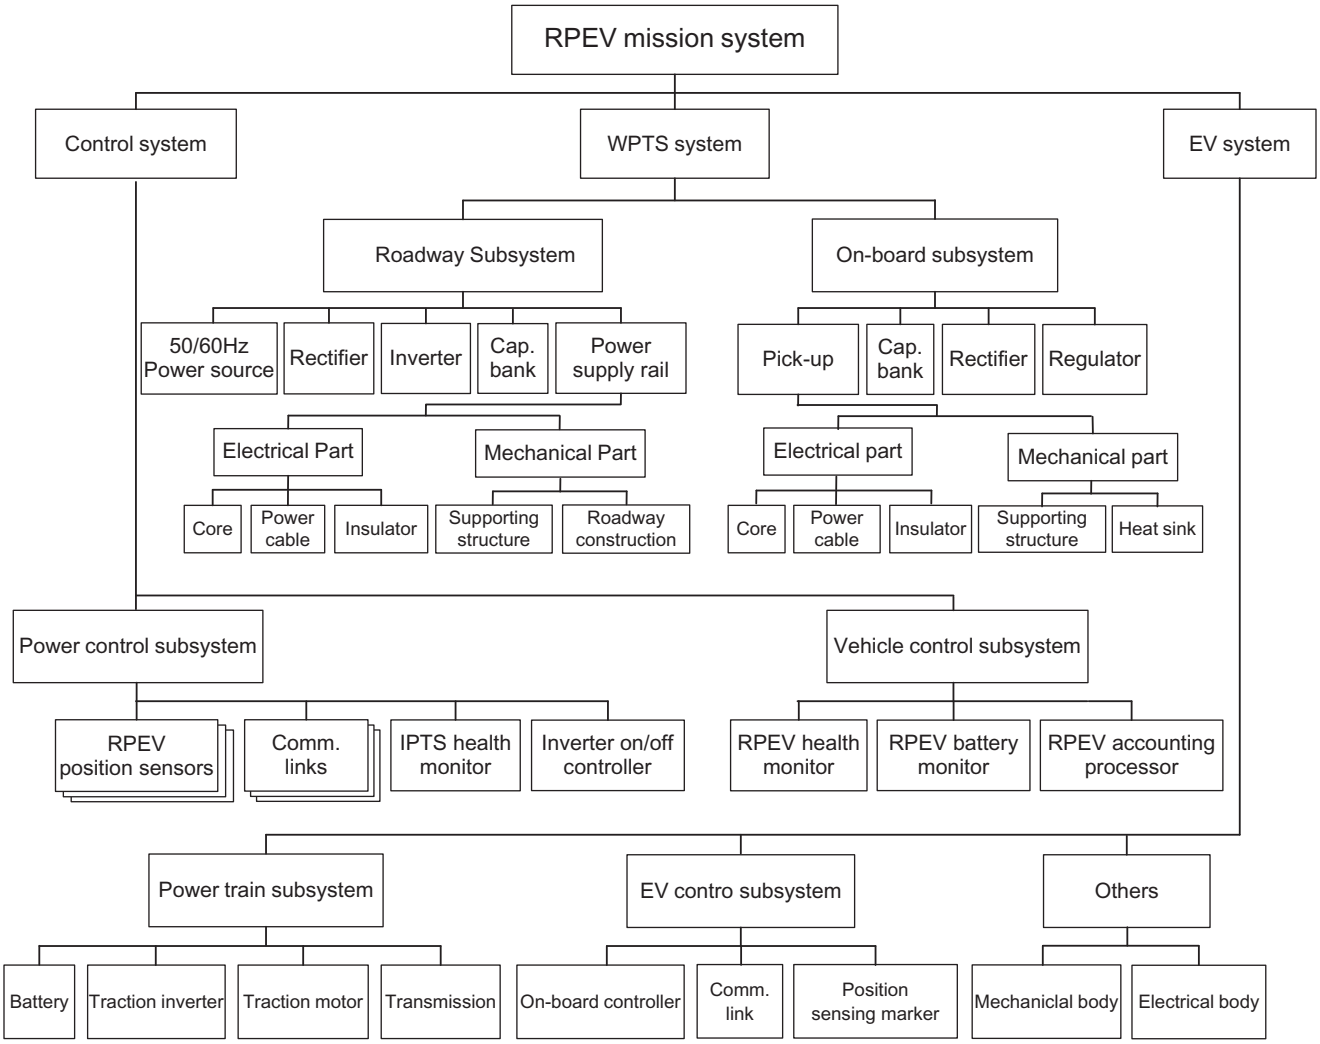

FIG. 34.21 Overall system breakdown of an RPEV.

and capacitor size decreases for the same required power, but the switching loss and core loss as well as the conduction loss of wires due to the skin effect increase. In the case of the switching frequency lower than 20 kHz, acoustic noise may be a problem [1]. Another unique feature of RPEVs concerning frequency is the increased voltage stress in a distributed power supply rail V_{l1} for higher switching frequency, which is proportional to the frequency and line current I_s as follows:

$$V_{l1} = j\omega_s L_{l1} I_s \tag{34.4a}$$

$$\frac{\partial V_{l1}}{\partial x} = j\omega_s I_s \frac{\partial L_{l1}}{\partial x}. \tag{34.4b}$$

Because of these restrictions, the switching frequency tends to be no less than 20 kHz but not far beyond 50 kHz. For OLEVs, the frequency was finally selected as 20 kHz after examining for 20 kHz, 25 kHz, and 30 kHz.

The interoperability of IPTS between RPEVs and stationary wireless EVs is an important issue that needs further study because the design of IPTSs for RPEVs is not a direct extension of that of stationary chargers. The design goals of IPTS of RPEV such as low infra cost, high power, continuity of power delivery, and low fluctuation during in-motion are not so important for stationary chargers.

2. *High power and large current*: In addition to the high operating frequency of RPEVs, high power of hundreds of kW with large current of hundreds of A makes it difficult to handle cables, converters, and devices. For example, a Litz wire of 300 A rating with 20 kV insulation capability is not commercially produced. Capacitors and IGBTs, which have high voltage and large current ratings with an operating frequency higher than 100 kHz, become scarce. Furthermore, all the inverters, rectifiers, coils, capacitors, and cables used in the IPTS of RPEV are operated outdoors, where debris and salty and wet material may damage them.

3. *Power efficiency*: In order to make RPEV competitive against internal combustion engine vehicle (ICEV), the power efficiency or energy efficiency should not be too low. The bottom line of the overall power efficiency, which is defined from the AC power source to the DC output power for battery, would be about 50%, considering grid loss and fuel cost. Fortunately, modern IPTSs have fairly good power efficiency larger than 80%. More importantly, power loss rather than power efficiency is a serious problem in designing the inverter and pickup due to over temperature.
4. *Coil design*: In order to focus magnetic field for Tx and Rx coils and to mitigate magnetic leakage flux so that large induced voltage and low EMF level can be achieved, a novel coil design is crucial for IPTS. This design is unique for the roadway subsystem in that the cost per km is critical; therefore, the roadway power supply rail should be cheap enough not to deteriorate the economic feasibility of overall RPEV solution, whereas the pickup should be neither heavy nor thick so that it can be successfully implemented on the bottom of an RPEV.
5. *Insulation*: In order to guarantee stable operation of IPTS, a few kV level insulations of the roadway subsystem and onboard subsystem should be provided. The insulation of a roadway power supply is of great importance because high voltage is induced along through the distributed power rail over a road rather than over a point and is increased by the back emf of the pickup coil abruptly displaced on the power supply rail. The insulation of the pickup coil is also an important issue when high power output is sought because the large output current of the pickup coil induces high voltage, which could be as much as 10 kV if not appropriately mitigated.
6. *Segmentation of power supply rail*: RPEV typically requires many IPTS along a road because a power supply rail cannot be infinitely deployed. It should be segmented so that each segment can be independently turned on and off. The length of a power supply rail is an important design issue because it would be too expensive if the length is very short due to an increased number of inverters and switch boxes, whereas the power loss would be too large if the length is very long due to increased resistance. Besides these issues, the amount of cable use, EMF level, and car length should be considered when determining the segmentation scheme.
7. *Roadway construction*: In order to minimize traffic obstruction, the roadway construction time of IPTS should be as short as possible. Moreover, there are numerous difficulties in roadway work because of debris and dirt. Keeping all of the electric components of IPTS clean during roadway construction for a few days or weeks is a serious problem in practice. There should be a smart way to overcome these problems.
8. *Resonant frequency variation*: The resonant frequencies of the roadway subsystem and onboard subsystem are significantly varied as the magnetic coupling between a power supply rail and a pickup changes due to air-gap change, lateral misalignment, and longitudinal movement. Moreover, the frequency changes are different from time to time for different cars and different numbers of cars on a power supply rail. There should be either the smart coil design or inverter design to cope with these frequency changes or *in situ* frequency tuning capability.
9. *Control of dynamic resonating circuits*: The resonant circuit, as shown in Fig. 34.20, has finite dynamic response times and may arise high voltage and current peaks that can destroy electric devices. They should be moderately controlled so that the voltage and current level can be mitigated, where the frequency response of AC circuits can be managed with the recently developed Laplace phasor transformation [30,31]. A resonating LC circuit has a first-order response in the dynamic phasor domain [32]; hence, high-order IPTS with more than two resonating circuits can be managed with the general phasor transforms [33,34].

After the two frontier projects of RPEV, the Partners for Advanced Transit and Highways (PATH) program began in 1992 to determine the technical viability of RPEV in the University of California, Berkeley. Throughout the PATH program, broad research and field tests on RPEV, as shown in Fig. 34.22, including designs of IPTS, installations of an IPTS to a bus, road constructions of power supply rails, and environmental impact studies, were performed. The PATH team achieved an efficiency of 60% at an output power of 60 kW with a 7.6 cm air gap [1].

The PATH program, however, had not been successfully commercialized due to high-power rail construction cost of around 1 M$/km, heavy coils, and acoustic noises, as well as relatively low power efficiency and large primary current of thousand amperes owing to a low operating frequency of 400 Hz. Furthermore, the small air gap does not meet road safety regulations, and lateral displacement of less than 10 cm is not acceptable for practical use. Despite the limitations for practical applications, the PATH team's work was well documented and stimulated subsequent research and development on modern RPEVs.

34.3.3 Developments of On-Line Electric Vehicles

34.3.3.1 Overview of OLEV

A stream of modern RPEVs is the OLEV, which has solved most of the remaining problems of the PATH team's work, as shown in Fig. 34.23. The OLEV project has started since 2009 by a research team led by KAIST, including the author, Korea [3–19]. Innovative coil designs and roadway

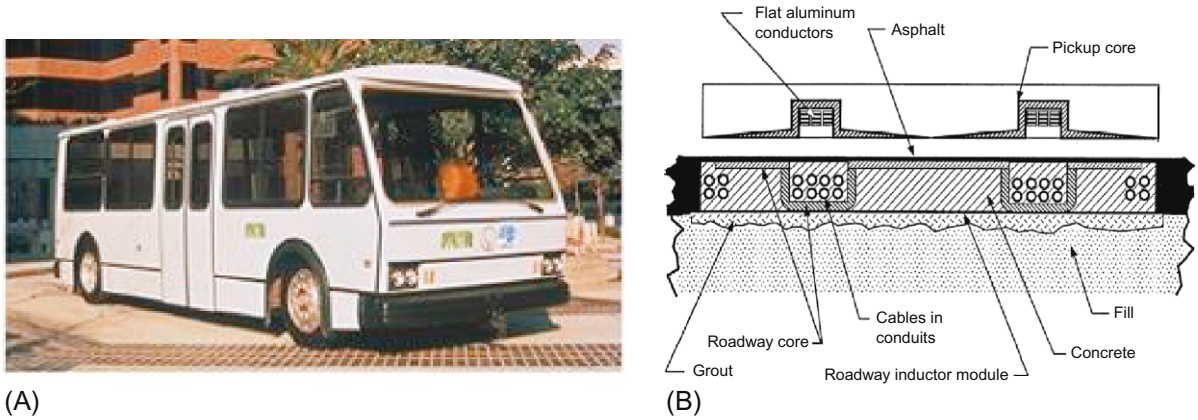

FIG. 34.22 The first operational prototype RPEV developed by the PATH team in the 1990s. (A) Appearance of the developed RPEV bus, (B) prototype coils of the IPTS.

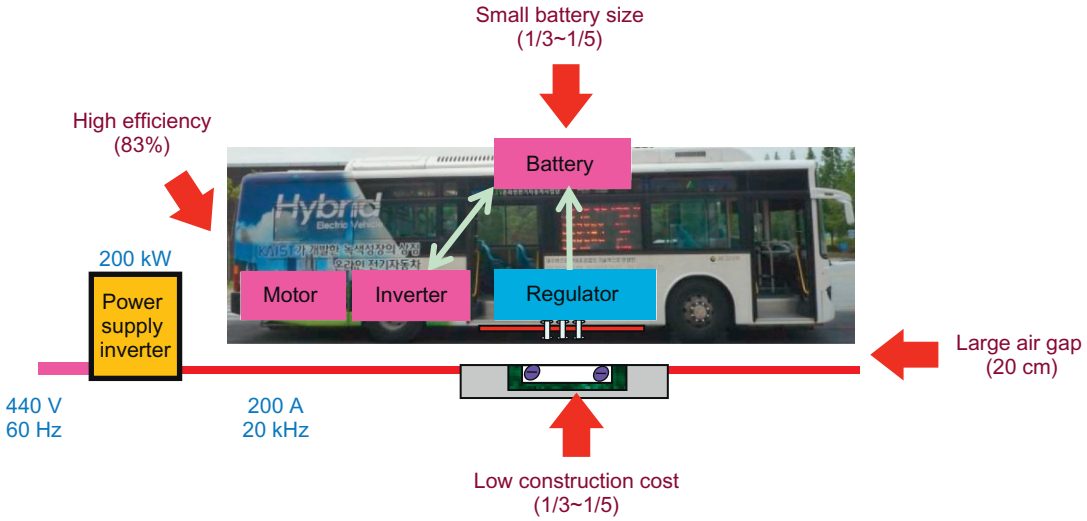

FIG. 34.23 The development concepts of the OLEV bus developed by KAIST.

construction techniques and all of the systems operating at a reasonably high frequency of 20 kHz made it possible to achieve the highest power efficiency of 83% at an output power of 60 kW with a large air gap of 20 cm and a fairly good lateral tolerance of 24 cm. Moreover, the power rail construction cost of the OLEV, which is responsible for more than 80% of the total deployment cost for RPEVs, has been dramatically reduced to at least a third of that of the PATH project. The primary current has been also reasonably mitigated as low as 200 A, and the battery size has been significantly reduced to 20 kWh, which can be further reduced by increasing the length of the power supply rails.

The first-generation (1G) concept demonstration car of OLEV, the second-generation (2G) OLEV buses, and the third-generation (3G) OLEV passenger car were developed and extensively tested at the test sites of KAIST since 2009, and three OLEV trains (3^+G) had been successfully deployed at the Seoul Grand Park, Korea, since 2010. Two upgraded OLEV buses (3^+G) were deployed at the 2012 Yeosu EXPO, Korea, and other two OLEV buses (3^+G) have been in full operation at the main campus of KAIST since 2012. Recently, two OLEV buses (3^+G) were firstly commercialized at a 48 km route in Gumi, Korea. The fourth-generation (4G) OLEV, showing more practical performances such as a very narrow rail width of 10 cm, a larger lateral displacement of 40 cm, lower EMF level, and lower power rail construction cost compared with the previous generation OLEV, has been also developed. The development of the fifth-generation (5G) OLEV is in progress, where an ultraslim S-type power supply coil of 4 cm rail width is proposed for power rail construction with much less cost and time [18,19].

34.3.3.2 2G OLEV

The 2G OLEV, announced on 14 July 2009, focused on drastically improving the air gap of the 1G OLEV without mechanical moving parts and finally achieved a 17 cm air gap, which

meets road regulations, 12 cm in Korea and 16 cm in Japan. At the same time, it achieved a maximum efficiency of 72% and a maximum output power of 60 kW using 10 pickups. The power supply rail, where the width is 1.4 m and the total length is 240 m, is paved with asphalt to provide the same friction force as normal roads. In order to realize the 17 cm air gap, the U-type power supply rail and the flat pickup coil of IPTS have been developed, where the name "U-type" stems from the cross section of the power supply rail, as shown in Fig. 34.24. A pair of return power cables is used to mitigate the EMF from the power supply rail for the ICNIRP guidelines [35,36]. With the U-type power supply rail and I-type pickup coil, it is found that an effective area of the magnetic path between the power supply rail and the pickup coil increases as the air gap increases due to fringe effect, as shown in Figs. 34.24 and 34.25.

The cross section of the core plates of the power rail, as shown in Fig. 34.24, is significantly reduced by using the high operating frequency of 20 kHz, which is 50 times of the PATH team. The reason for selecting 20 kHz is that it is the lowest inaudible frequency, which mitigates the line voltage stress, as in (34.4). The upward magnetic flux generated from the pickup coil was appropriately shielded by an aluminum plate with a 5 cm distance.

34.3.3.3 3G OLEV

The 3G OLEV sports utility vehicle (SUV), announced on Aug. 14, 2009, adopted the W-type power supply rail and the flat pickup with overlapped double coils for higher power and increased lateral tolerance. Thus, the upward magnetic leakage flux from the pickup of 2G OLEV had been drastically mitigated by using the flat pickup core, which prohibits the magnetic flux between the power supply rail and pickup from leaking. The magnetic field shield such as an aluminum plate or additional space is no longer required.

The overall efficiency and air gap of the 3G OLEV were 71% and 17 cm, respectively, which are respectable, but slightly disappointing numbers; therefore, overall systems including a roadway rectifier and inverter, power supply rail, pickup, and onboard regulator were redesigned to achieve a maximum efficiency of 83% with a 20 cm air gap, and this new design was called the $3G^{+}$ OLEV.

The W-type power supply rail, as shown in Fig. 34.26, has many cores of "W" shape, where the total magnetic resistance becomes three-quarters smaller than that of the 2G OLEV for the same air gap, and this eventually leads to the increase of the output power from 6 to 15 kW for each pickup. Moreover, the width of the power supply rail is decreased to 70 cm, which is just a half of that of the 2G OLEV, and it can reduce the deployment cost of OLEV for commercialization. The EMF at 1.75 m distance meets the ICNIRP guideline because the two power cables of opposite polarity of magnetic flux cancel each other out [18,19].

One of the problems found during the development of 2G OLEV was the inherently weak structure of the power supply

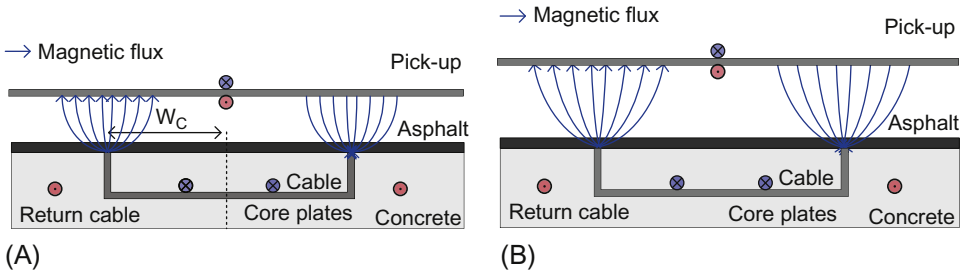

FIG. 34.24 Cross section of the U-type power supply rail and I-type pickup coil. (A) Small air-gap, (B) large air-gap.

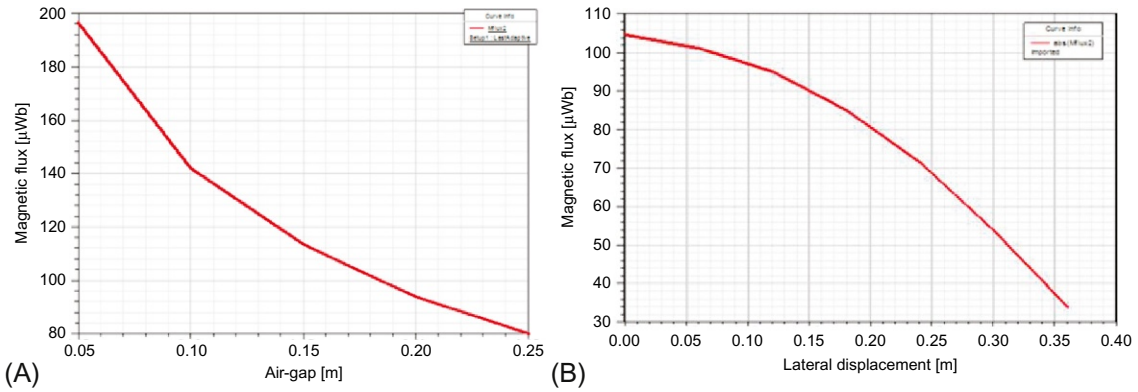

FIG. 34.25 Magnetic flux characteristics of the 2G IPTS [18]. (A) Along the air-gap, (B) along the lateral displacement.

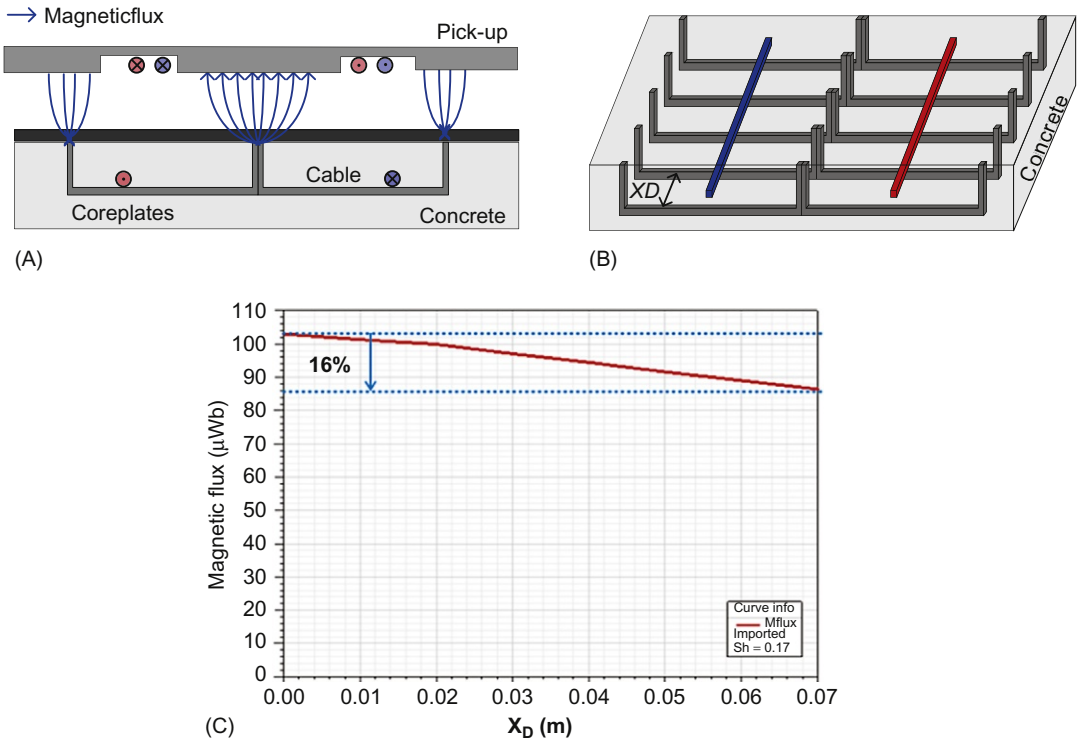

FIG. 34.26 Views of the W-type power supply rail and flat pickup coil [18]. (A) Cross-section view, (B) Bird's eye view of a bone structure, (C) simulated magnetic flux characteristics for different bone core-gap X_D.

rail, where the core separates the concrete into two and undergoes severe mechanical stress from heavy vehicles. As a remedy for this mechanical weakness, bone structure core of the power supply rail, as shown in Fig. 34.26B, has been proposed, where the bone structure core is installed with the bone core-gap X_D. Despite the large gap between cores, the magnetic flux does not decrease considerably, as shown in Fig. 34.26C.

In addition, during power rail road construction, concretes can percolate down through the bone structure cores. Therefore, the power supply rail, which is reinforced with two iron bars and in which power cables are protected by fiber-reinforced plastic (FRP) pipes, has almost the same endurance of concrete, as shown in Fig. 34.27. In practice, roadway construction of the power supply rail takes a few weeks, being affected by weather and debris, and this delay obstructs the commercialization of OLEV.

34.3.3.4 4G OLEV

As shown in Fig. 34.28, the 4G OLEV, announced in 2010, has an innovative I-type structure of a power supply rail with a maximum output power of 27 kW for a double pickup coil having a 20 cm air gap and 24 cm lateral displacement. As shown in Fig. 34.28A, the I-type power supply rail, where the name "I-type" stems from its front shape, has only 10 cm width,

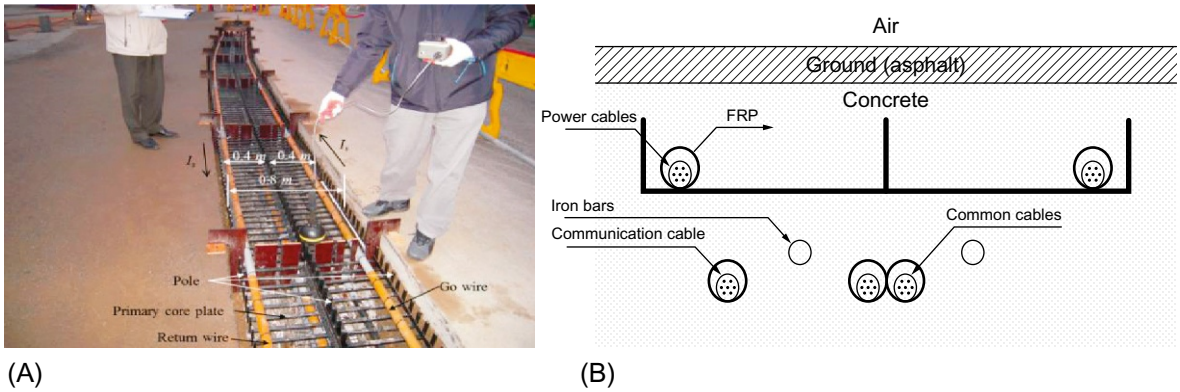

FIG. 34.27 The W-type power supply rail of the 3G OLEV [18]. (A) Under road construction, (B) cross-section view.

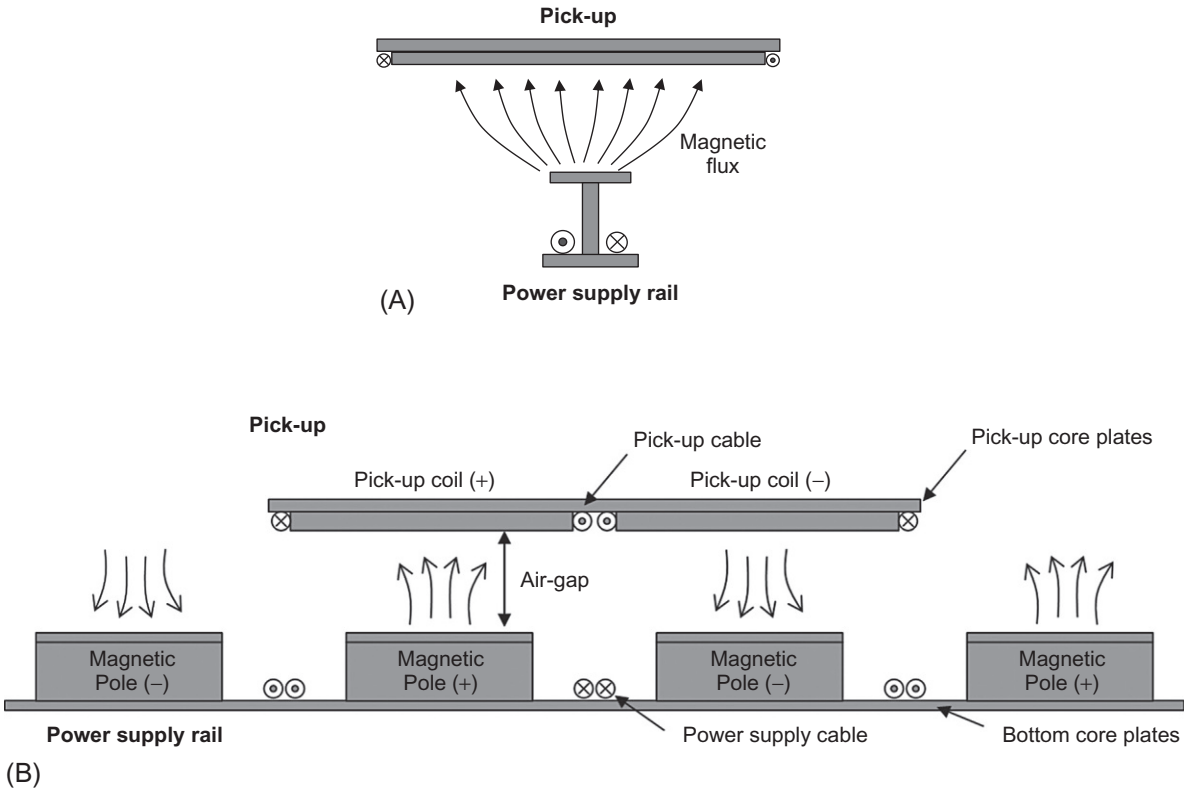

FIG. 34.28 The I-type power supply rail and double flat pickup coil [18]. (a) Front view, (b) side view.

which leads to a deployment cost reduction of 20% compared with the 3G OLEV. Unlike previous generations of OLEV, a very low EMF for pedestrians, as low as 1.5 μT at a distance of 1 m from the center of the power supply rail, can be obtained because the power supply rail has alternating magnetic poles along the road, as shown in Fig. 34.28B.

As shown in Fig. 34.29, the 4G OLEV adopted a module concept for the I-type power supply rail to reduce the deployment time within a few hours, which had been one of the drawbacks of the 3G OLEV. The I-type power supply module, which includes the power supply rail and capacitor banks inside, as shown in Fig. 34.29A, should be robust to high humidity and external mechanical impacts at least for 10 years, for example.

34.3.3.5 5G OLEV

To further reduce the construction cost and to increase the robustness of power supply rails, the 5G OLEV of ultraslim S-type core was recently proposed, which has an S-shape when viewed from the front, as shown in Fig. 34.30C.

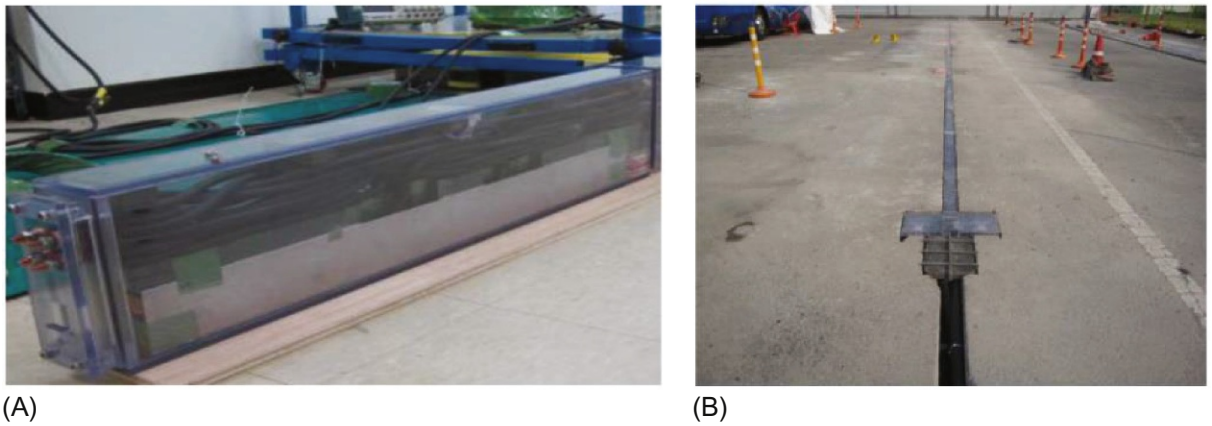

FIG. 34.29 The I-type power supply module of the 4G OLEV [18]. (A) A prototype module, (B) deployed modules at the 24 m test site.

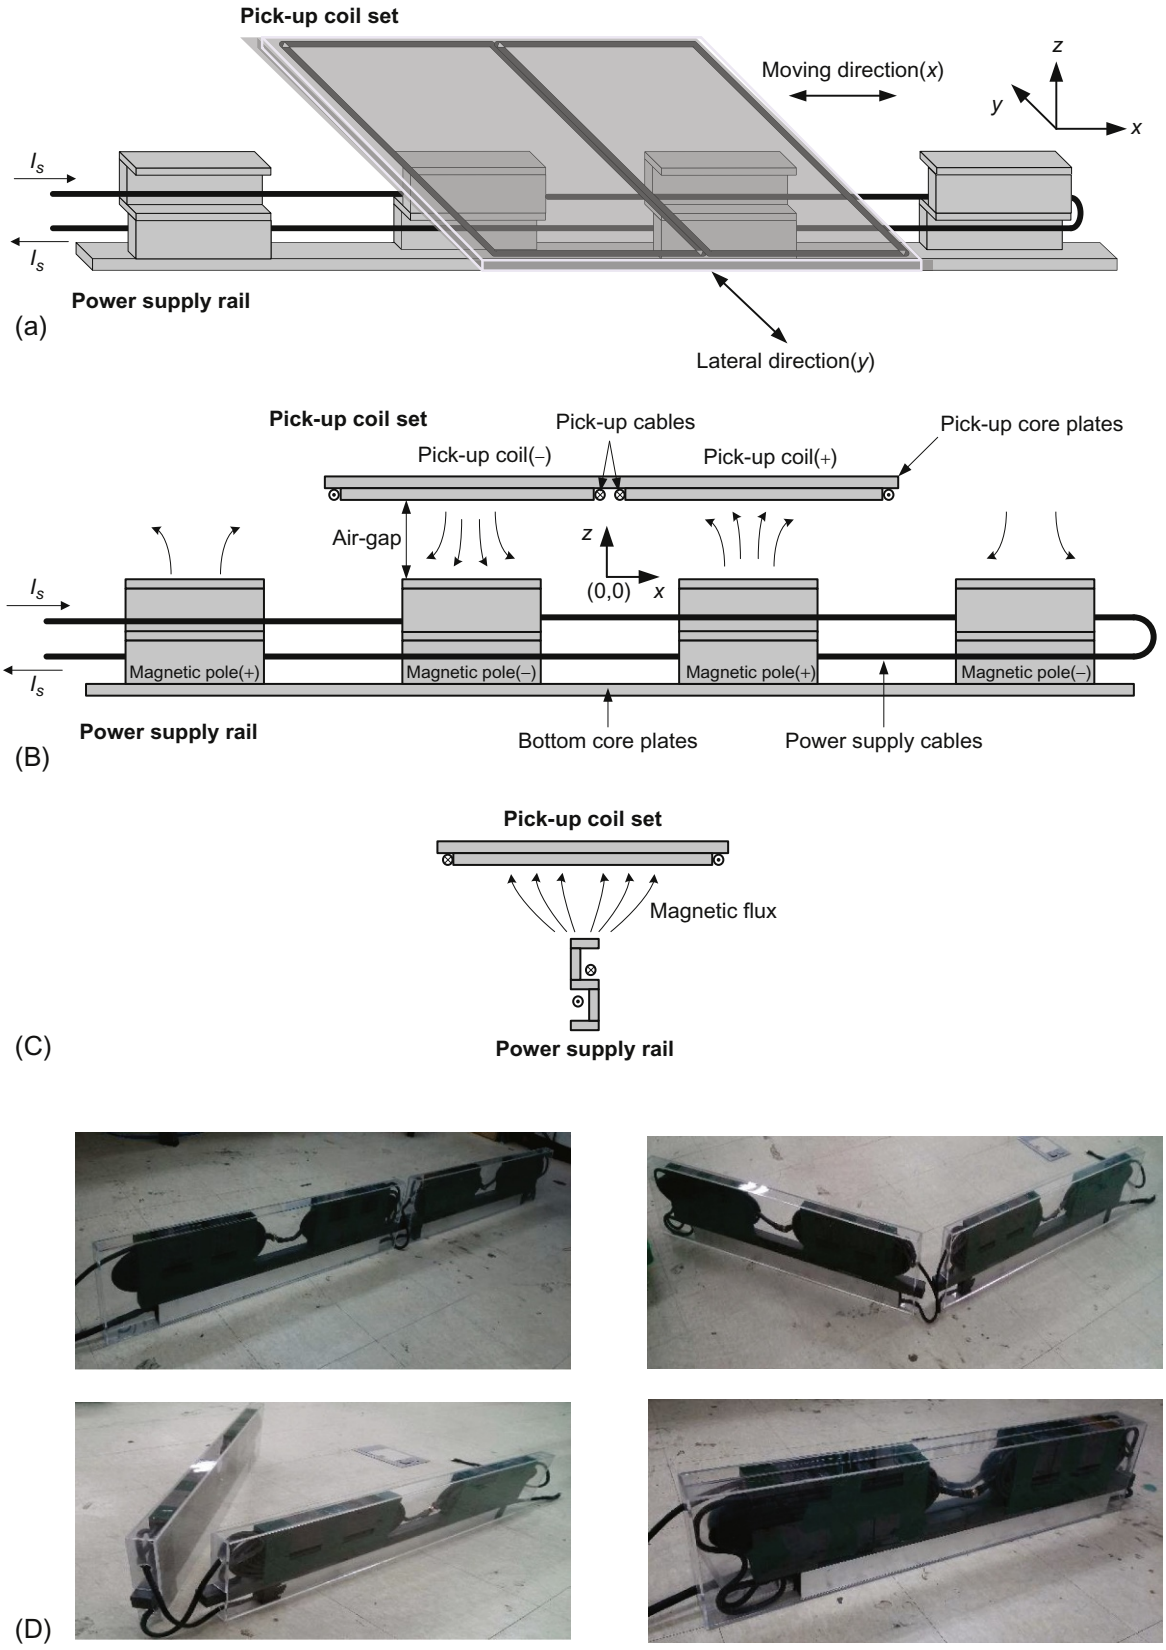

FIG. 34.30 The concept and fabrication of ultraslim S-type power supply modules [18]. (A) Bird's view, (B) side view, (C) front view, (D) deployment process.

The S-type power supply module has a width of only 4 cm, which has been decreased from the I-type width of 10 cm; hence, the S-type model leads to less construction cost and deployment time. Moreover, the S-type model makes it easier to fold itself, which means connecting power cables is no longer necessary after being deployed. The impact of deploying the S-type power supply modules on the surface of roads is now minimal, which fortunately does not change existing road operation conditions.

34.4 Design Considerations of Wireless Electric Vehicles

A few common design consideration issues applicable to both stationary and dynamic charging EVs are explained here. The issues are compensation, electric and magnetic circuit analyses, EMF cancel, and segmentation.

34.4.1 Compensation Circuit Design

Due to large inductive reactances of IPT, capacitors are preferably adopted to nullify the total reactance and to resonate to a certain frequency for filtering out harmonics. One of widely used compensation circuits is two-capacitor type, called basic compensation circuit, as shown Fig. 34.31. There are eight possible circuit topologies for compensation depending on current (I) or voltage (V) source types and serial (S) or parallel (P) configurations. In case the magnetic coupling factor k between Tx and Rx coils varies a lot, the three conditions should be met for practical applications: (1) load-independent output voltage or output current, (2) k-independent compensation, and (3) allowance of no magnetic coupling ($k=0$).

It is identified that only I-SS and I-SP can satisfy all of the three criteria simultaneously among the eight compensation schemes [37]. I-SS has the voltage-source-type output characteristics, which enable large load current; whereas, I-SP has the current-source-type output characteristics, which enable high load voltage. Of course, other schemes may be also used if the three conditions are not needed.

Substantial equivalence and duality between I-SS and I-SP are found in the aspect of efficiency, power transfer characteristics, and voltage and current ratings of reactive components, as shown in Fig. 34.32. This means that there is no privilege between I-SS and I-SP, so we can freely choose compensation scheme according to large-current or high-voltage applications.

One of the ways to implement the current source of IPT is to make the current of a primary coil constant by feedback, as shown in Fig. 34.20. Another way of getting the current source is to use an LC filter for a given voltage source so that the Norton equivalent circuit has infinite output impedance when the source frequency is tuned to the resonance frequency, as shown in Fig. 34.33. This is known to be LCC topology of IPT [27,37], which has the current source input and voltage source output characteristics.

34.4.2 Gyrator Based Circuit Analysis

The electric analysis of IPT including compensation circuits is quite challenging because there are at least five energy storage circuit elements. Therefore, a powerful circuit analysis tool is recently invented, called gyrator-based circuit analysis by the author [38]. This method drastically simplifies the analysis process and makes it possible to get analytic results without cumbersome manipulation of equations. Applying Kirchhoff's voltage law on V_1 and V_2 in Fig. 34.34A gives us the following equations in the steady state of sinusoidal AC circuits:

$$V_1 = (-jX_0) \times (I_1 - I_2) + jX_0 \times I_1 = jX_0 \times I_2 \tag{34.5a}$$

$$V_2 = (-jX_0) \times (I_1 - I_2) + jX_0 \times (-I_2) = -jX_0 \times I_1 = (jX_0)^* \times I_1. \tag{34.5b}$$

As shown in Fig. 34.34B, Eq. (34.5) describes the imaginary gyrator, first introduced in the literature [38].

As shown in Fig. 34.35, the T model of IPT can be decomposed into the imaginary gyrator and the primary and secondary inductances. This gyrator equivalent circuit is applied to the analysis of an example V-SS circuit of Fig. 34.36, where the series-series resonant circuits L_1-C_1 and L_2-C_2 are tuned to the source frequency, respectively.

From the gyrator characteristics, the load current of V-SS is solely determined by the source voltage and independent of load resistance and load voltage as follows:

$$A_G \equiv \frac{I_L}{V_s} = -\frac{1}{j\omega_0 M}, \tag{34.6}$$

$$\frac{\partial I_L}{\partial R_L} = 0. \tag{34.7}$$

In this way, other features of the V-SS in Fig. 34.36 such as input power factor, voltage and current stresses of each component, and input and output impedances can be deduced from the equivalent gyrator circuit without using high-order matrix manipulation.

34.4.3 Magnetic Mirror Based Coil Design

In the coil design, we are quite often encountered to calculation of magnetic flux density, but you will readily see that there is nearly no available theoretical tool to finish your job. The difficulties of magnetic field calculation come from the complex interaction between current and magnetic material, which denies the application of Ampere's law that gives us the result only when appropriate current is given.

Fortunately, the magnetic flux density of an open magnetic circuit can be simply calculated by the magnetic mirror model [15], as shown in Fig. 34.37, where a reflected current at the

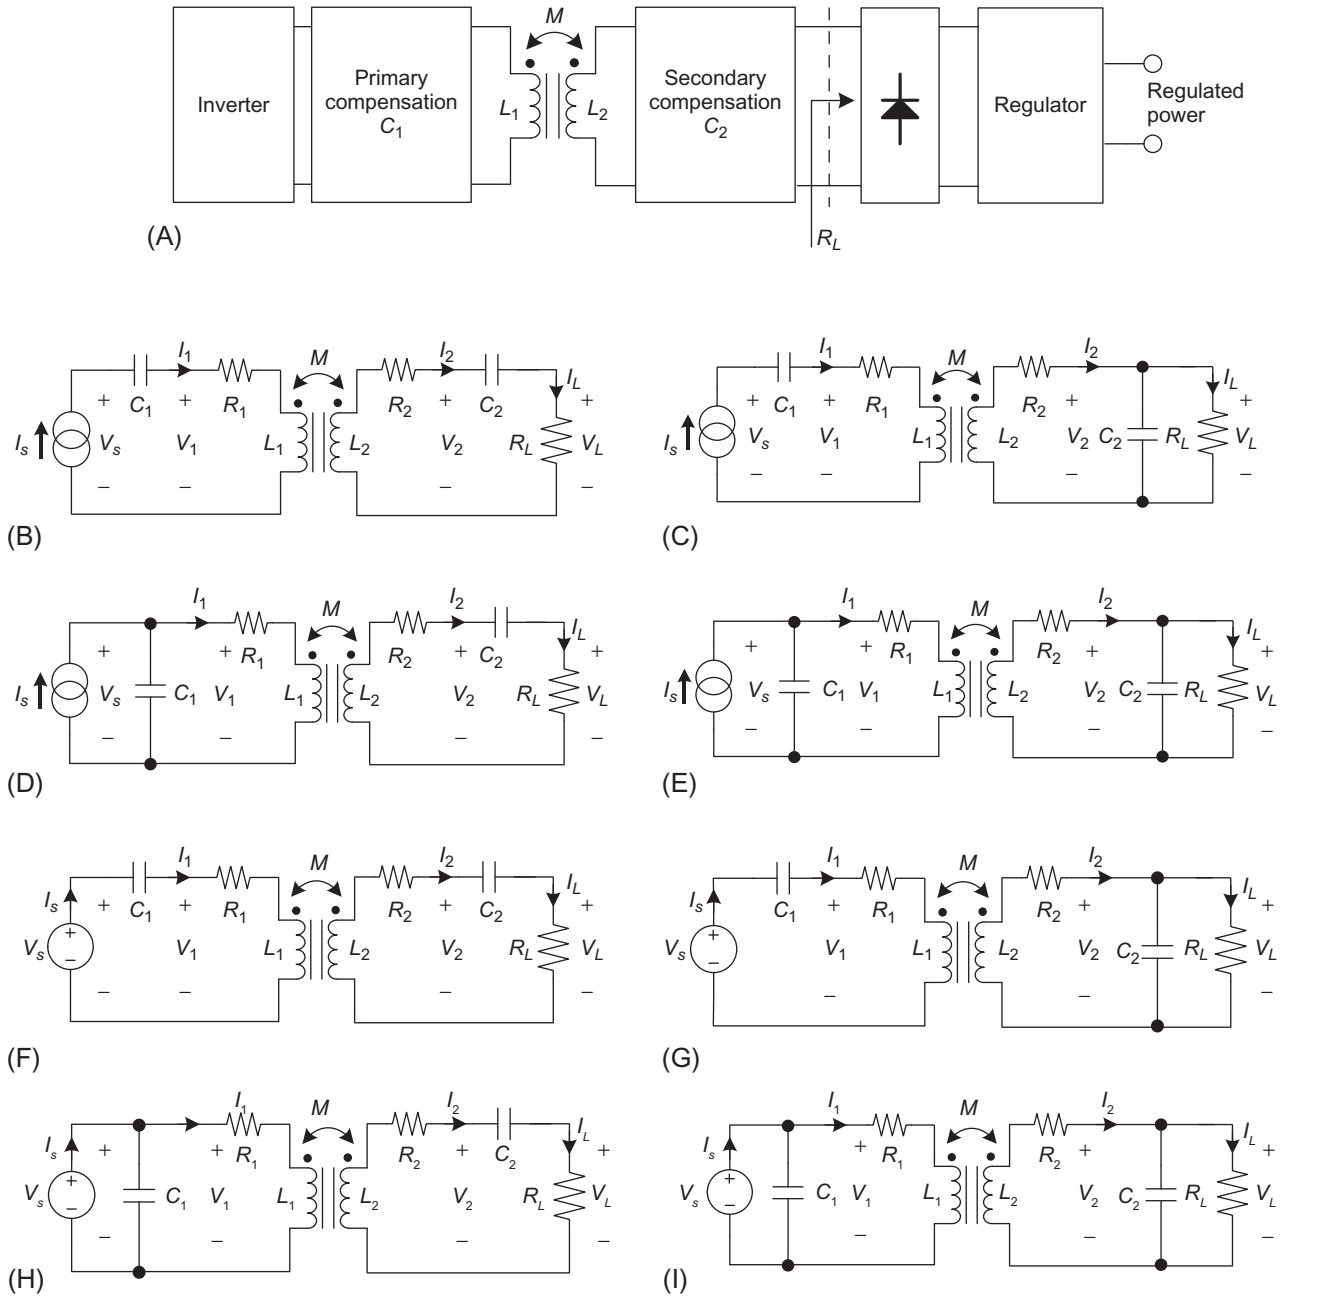

FIG. 34.31 The eight basic compensation circuits of IPT. (A) General configuration of an IPT system, (B) current-source-type primary series-secondary series (I-SS), (C) current-source-type primary series-secondary parallel (I-SP), (D) current-source-type primary parallel-secondary series (I-PS), (E) current-source-type primary parallel-secondary parallel (I-PP), (F) voltage-source-type primary series-secondary series (V-SS), (G) voltage-source-type primary series-secondary parallel (V-SP), (H) voltage-source-type primary parallel-secondary series (V-PS), (I) voltage-source-type primary parallel-secondary parallel (V-PP).

same distance from the surface of a magnetic plate exists with a reduced amplitude as follows:

$$d_m = d_s = d,\ \ \gamma_1 \equiv \frac{I_m}{I_s} \cong \left(1 - e^{-\frac{w_o}{\alpha_1 y}}\right)\ \ \because \alpha_1 \cong 1.7. \tag{34.8}$$

Then, the magnetic flux density of a mono coil B_1 for a mirror current I_m and a source current I_s at an arbitrary measurement point (x, y) are obtained as follows:

$$B_1 \equiv |\boldsymbol{B}_1| = |\mu_0 \boldsymbol{H}_1| = \left|\frac{\mu_0 I_s}{2\pi}\frac{\boldsymbol{\alpha}_x(y-d_s)-\boldsymbol{\alpha}_y x}{r_s^2} + \frac{\mu_0 I_m}{2\pi}\frac{\boldsymbol{\alpha}_x(y+d_m)-\boldsymbol{\alpha}_y x}{r_m^2}\right|$$

$$= \frac{\mu_o I_s}{2\pi}\sqrt{\left\{\frac{y-d_s}{r_s^2} + \gamma_1\frac{y+d_m}{r_m^2}\right\}^2 + \left\{\frac{x}{r_s^2} + \gamma_1\frac{x}{r_m^2}\right\}^2}\ \ for\ |x| < \frac{w_o}{2}, 0 \le y \tag{34.9a}$$

$$r_s = \sqrt{x^2 + (y-d_s)^2},\ r_m = \sqrt{x^2 + (y+d_m)^2}. \tag{34.9b}$$

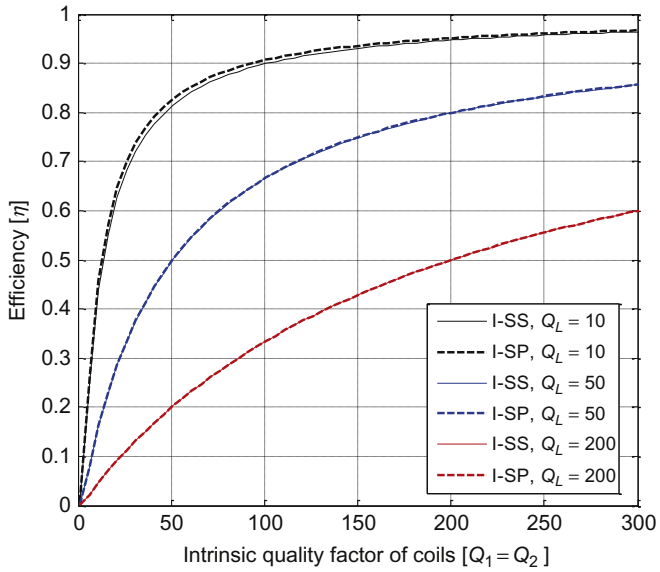

FIG. 34.32 Efficiencies η versus quality factor Q_1 for I-SS and I-SP when $\omega = \omega_2$ and $k = 0.3$.

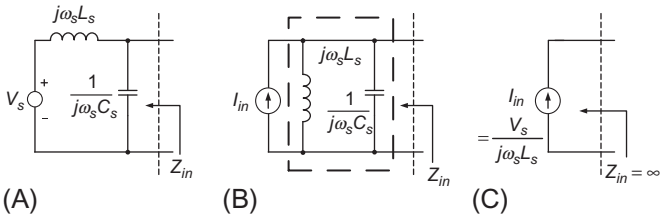

FIG. 34.33 An LC-tuned filter with a voltage source becomes an ideal current source. (A) Original LC input filter, (B) Norton equivalent circuit, (C) final equivalent circuit for tuned case.

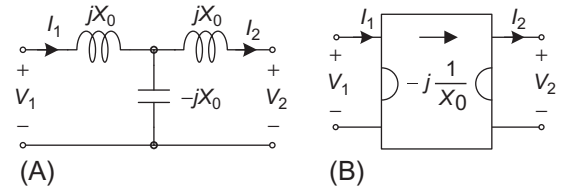

FIG. 34.34 A T-network consists of all equal reactance and its equivalent gyrator circuit. (A) Gyratorin a T-network, (B) A Gyrator circuit model.

As identified from Fig. 34.37 and Eqs. (34.8)–(34.9), the magnetic flux density is at best doubled by the magnetic core for an open magnetic circuit. This is one of the backgrounds on no core use for some applications.

34.4.4 Generalized Active EMF Cancellation Methods

In the IPTS of OLEV, the total EMF, which is the summation of EMF generated by the power supply rail and the pickup coil, should be lower than the ICNIRP guideline for the safety of pedestrians. Among EMF cancellation methods [35,36,39–44], passive methods rely on the use of ferromagnetic materials, conductive materials, and selective surfaces for protecting against radio-frequency interference [39–41], which is found to be inadequate for OLEV. An active EMF cancellation design was applied to the RPEV of PATH team [1], where a canceling coil mitigates the EMF without RPEV. Note that the EMF is generated from both the power supply rail and pickup coil of the IPTS, as shown in Fig. 34.38; therefore, they must be canceled together without the need for accurate sensing of EMF and complicated control circuits, which is requisite for practical use.

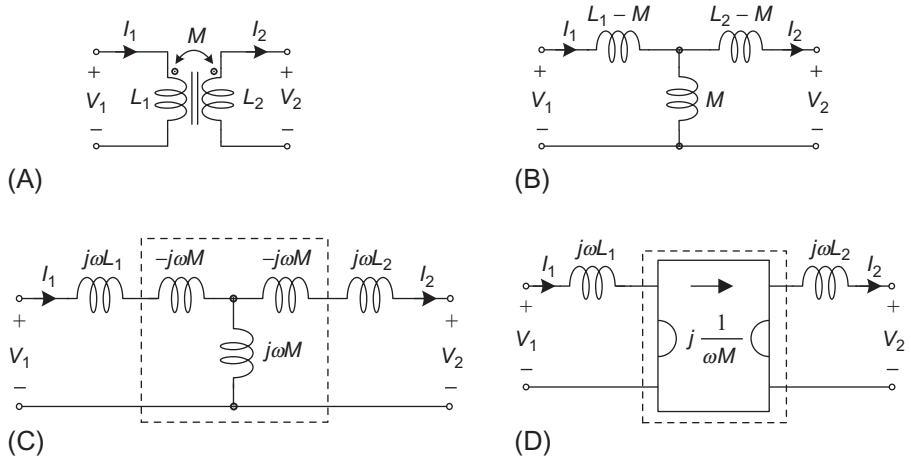

FIG. 34.35 Representation of coupled inductors with a gyrator. (A) Circuit model of coupled inductors, (B) equivalent T-model of coupled inductors, (C) equivalent circuit of (B), (D) Representation of (C) with a gyrator model.

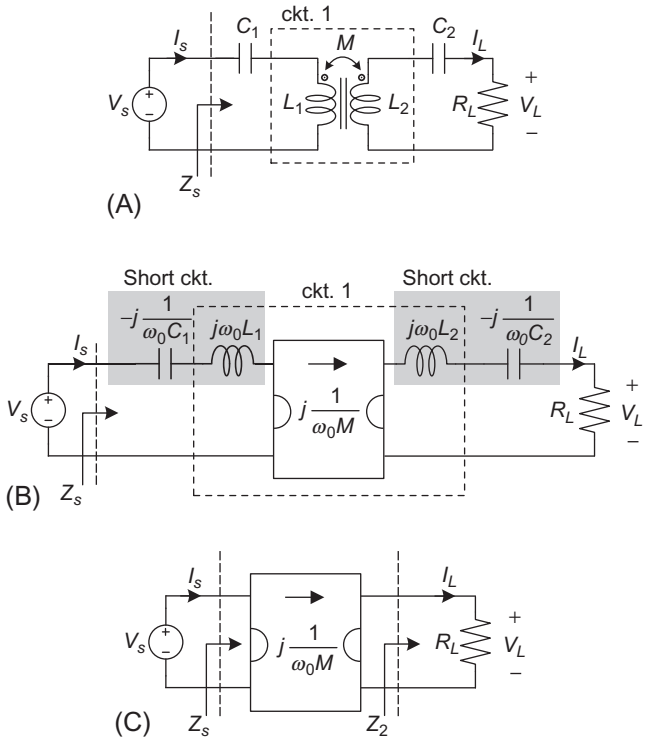

FIG. 34.36 V-SS and the equivalent gyrator-based models. (A) V-SS circuit model, (B) equivalent V-SS circuit of (A) with a gyrator, (C) equivalent V-SS circuit of (B) with a gyrator,when primary and secondary LC's are tuned.

A generalized active EMF design principle, which can be extended to any IPTS, has been developed [44], where there are three design methods: independent self EMF cancellation (ISEC), 3 dB dominant EMF cancellation (3DEC), and

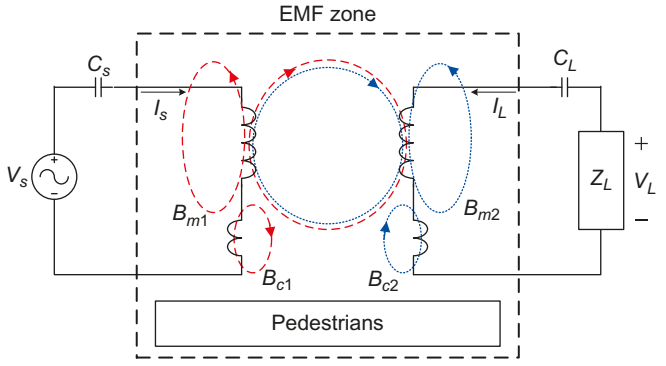

FIG. 34.38 Independent self EMF cancellation (ISEC) method for primary and secondary sides, fetching its cancellation current from each main coil.

leakage-free EMF cancellation (LFEC). By adding an active EMF cancellation coil to each power supply rail and pickup coil without EMF sensing and control circuits, the EMF generated from each main coil can be independently canceled by their corresponding cancellation coils. Because the current of each cancellation coil is fetched from its corresponding main coil, the magnetic flux of a cancellation coil is in the phase of that of a main coil; hence, the EMF $\boldsymbol{B}_t$ becomes independent of both phase and load conditions as follows:

$$\boldsymbol{B}_t = (\boldsymbol{B}_{m1} + \boldsymbol{B}_{c1}) + (\boldsymbol{B}_{m2} + \boldsymbol{B}_{c2}) \cong 0, \quad \because \ \boldsymbol{B}_{c1} \cong -\boldsymbol{B}_{m1}, \quad \boldsymbol{B}_{c2} \cong -\boldsymbol{B}_{m2} \quad \text{and} \quad \boldsymbol{B}_k \equiv B_{kx}\boldsymbol{x}_0 + B_{ky}\boldsymbol{y}_0 + B_{kz}\boldsymbol{z}_0. \tag{34.10}$$

Together with ISEC, the 3DEC method is quite useful in practice for designing IPTS because it makes it possible to completely isolate the primary and secondary cancellation designs from each other.

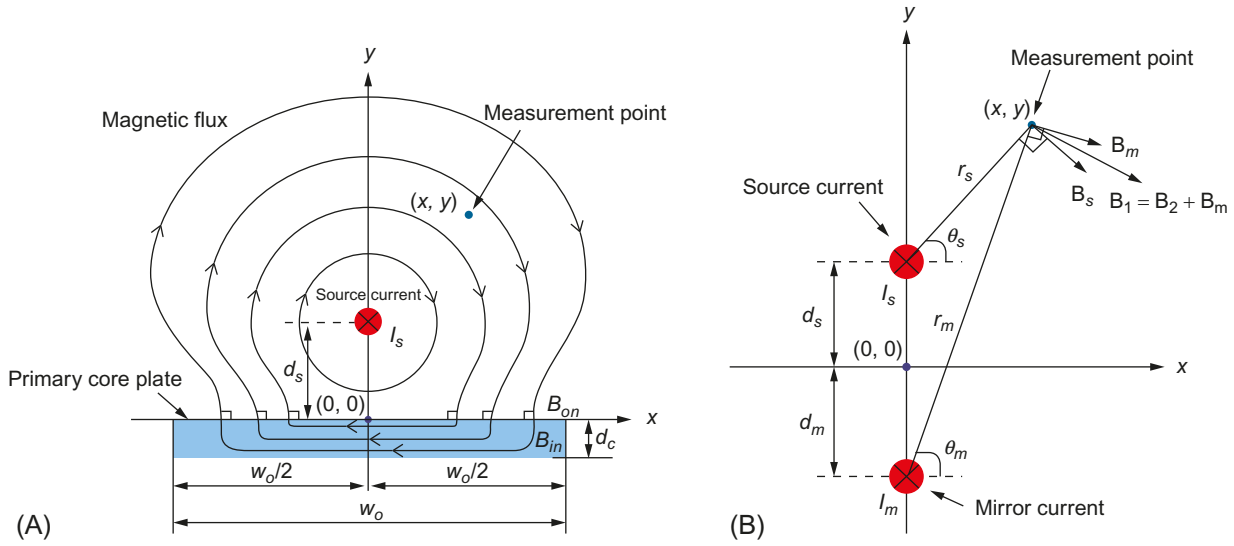

FIG. 34.37 The magnetic mirror model. (A) Mono coil consists of a source current and a core plate with finite width and infinite permeability, (B) the magnetic mirror current of the mono coil.

For the full resonant IPTS that is very common in practice, the primary and secondary currents are in quadrature, that is, $B_{1x} \perp B_{2x}$, $B_{1y} \perp B_{2y}$, and $B_{1z} \perp B_{2z}$. Then, the total magnetic field B_t can be constrained to the ICNIRP guidelines so far as the dominating magnetic field B_1 is less than 3 dB below the guideline as follows:

$$B_t \equiv |\boldsymbol{B}_t| = \sqrt{|\boldsymbol{B}_1|^2 + |\boldsymbol{B}_2|^2} = \sqrt{B_1^2 + B_2^2} \le \sqrt{B_1^2 + B_1^2} = \sqrt{2}B_1 \le B_{ref} \quad \because B_1 \equiv |\boldsymbol{B}_1|, B_2 \equiv |\boldsymbol{B}_2|, \quad B_2 \le B_1. \tag{34.11}$$

A design example for the 4G I-type IPTS based on the ISEC and 3DEC is shown in Fig. 34.39, where no cancellation coil was used for the power supply rail due to the low EMF generated from itself.

In case the EMF cancellation coils are involved in an unwanted magnetic linkage, as shown in Fig. 34.40, the induced load voltage drops; therefore, it is highly recommended to design the cancellation coils based on the LFEC method so that the magnetic linkage does not intersect them. The LFEC method can improve the load voltage as much as 21% [44].

34.4.5 Segmentation of Power rails

Unlike stationary charging EV, the RPEV needs its own roadway, where power supply rails should be activated when RPEVs are on the roadway, but they should be deactivated not to waste electric power and generate unwanted EMF for pedestrians; this is why the power supply rail is sometimes segmented into a few subrails. Each subrail can be activated by providing it with high-frequency current through a switch box from an inverter, as shown in Fig. 34.41.

The first segmented power supply rail developed for OLEV, as shown in Fig. 34.41A, was the centralized switching type composed of a few subrails, a bundle of supply cables, and a centralized switch box, where an inverter is connected to one of several pairs of supply cables through the switch box at a time. One of the demerits of the centralized one is that too many bundles of power cables are needed.

This is why the distributed switching power rail, as shown in Fig. 34.41B, was proposed, which is composed of a few subrails, a pair of common power supply cables, and multiple switch boxes located between two subrails.

Thus, the total length of the cable could be reduced compared with the centralized one, especially for a larger number

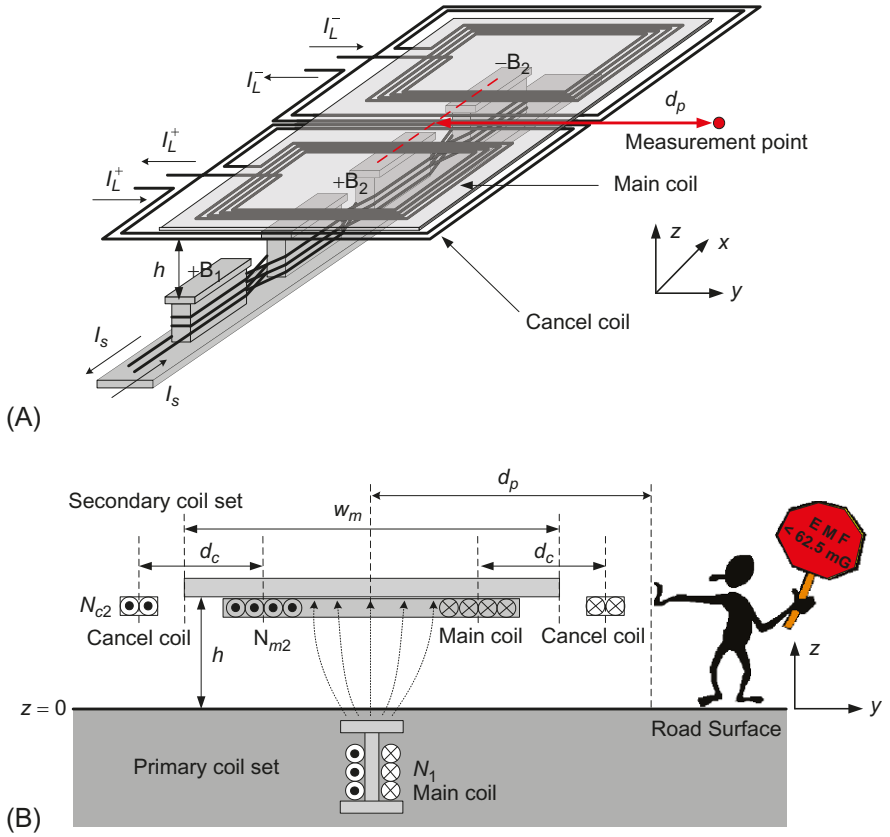

FIG. 34.39 An active EMF cancellation design example for the I-type IPTS. (A) Bird's eye view, (B) front view.

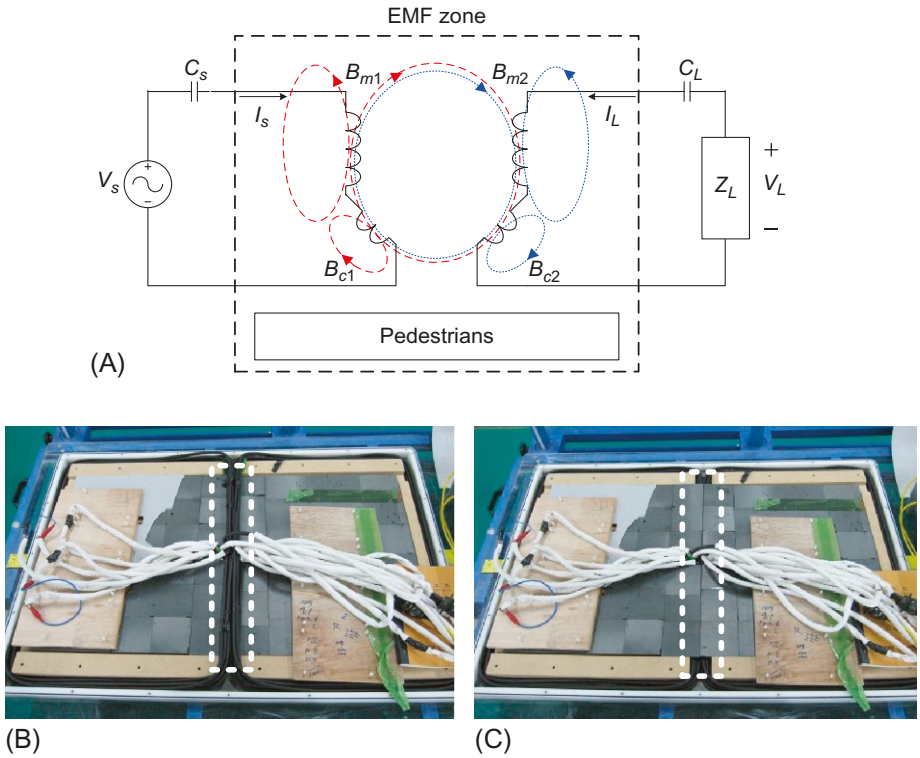

FIG. 34.40 Leakage-free EMF cancellation (LFEC). (A) A bad design case for cancellation coils, which are strongly coupled with main magnetic linkage, (B) the application of the LFEC design to a pick-up set, (C) the case where not applied.

of the cables. The distributed one, however, requires the common power supply cables, which increases the power rail construction cost and conductive power loss.

A recently proposed cross segmented power supply rail (X-rail) [16], consisting of segmented subrails, autocompensation switch boxes, control signal lines, and roadway harnesses, as shown in Fig. 34.41C, has the shortest length of power cable among the segmentations developed so far, and the inverter can drive multiple RPEVs, unlike the previous segmentations that activate only one subrail at a time.

As shown in Fig. 34.42, the cable cost of the X-rail is nearly halved compared with the distributed switching, and the cable length reduction effect becomes dominant as the number of segmented subrails increases.

If applicable, nonsegmented power rail would be better than the segmented one, considering increased cost and complexities. One of the possible candidates is the autotuned IPTS, where power is delivered only when EVs are on the power supply coils.

34.5 Summary

The concepts of WPT and its practical applications to EVs are explained throughout the chapter. IPT for stationary and dynamic charging EVs is explained. The development of IPTS for RPEV including state-of-the-art technologies is explained in detail. RPEV is becoming a viable solution for future transportation as the first commercialized online EV has demonstrated its validity.

35.1 Introduction

Switching power converters must be suitably designed and controlled in order to supply the voltages, currents, or frequency ranges needed for the load and to guarantee the requested dynamics [1–4]. Furthermore, they can be designed to serve as "clean" interfaces between most loads and the electric utility system. Thereafter, the set switching power converter plus load behaves as an almost pure electric utility resistive load.

This chapter provides basic and advanced skills to control electronic power converters, taking into account that the control of switching power converters is a vast and interdisciplinary subject. Control designers for switching power converters should know the static and dynamic behavior of the electronic power converter and how to design its elements for the intended operating modes. Designers must be experts on control techniques, especially the nonlinear ones, since switching converters are nonlinear, time-variant, discrete systems, and designers must be capable of analog or digital implementation of the derived modulators, regulators, or compensators. Powerful modeling methodologies and sophisticated control processes must be used to obtain stable-controlled switching power converters, not only with satisfactory static and dynamic performance but also with low sensitivity against load or line disturbances or, preferably, robustness.

In Section 35.2, the techniques to obtain suitable nonlinear and linear state-space models, for most switching converters, are presented and illustrated through examples. The derived linear models are used to create equivalent circuits and to design linear feedback controllers for converters operating in the continuous or discontinuous mode. The classical linear time-invariant system control theory, based on Laplace transform, transfer function concepts, Bode plots, or root locus, is best used with state-space averaged models or derived circuits and well-known triangular wave modulators for generating the switching variables or the trigger signals for the power semiconductors.

Nonlinear state-space models and sliding-mode controllers, presented in Section 35.3, provide a more consistent way of handling the control problem of switching converters, since sliding mode is aimed at variable structure systems, as are switching power converters. Chattering, a characteristic of sliding mode, is inherent to switching power converters, even if they are controlled with linear methods. Chattering is very hard to remove and is acceptable in certain converter variables. The described sliding-mode methodology defines exactly the variables that need to be measured, while providing the necessary equations (control law and switching law) whose implementation gives the robust modulator and compensator low-level hardware (or software). Therefore, the sliding-mode control integrates the design of the switching converter modulator and controller electronics, reducing the needed designer expertise. This approach requires measurement of the state variables but eliminates conventional modulators and linear feedback compensators, enabling better performance and robustness. It also reduces the converter cost, control complexity, volume, and weight (increasing power density). The so-called main drawback of sliding mode, variable switching frequency, is also addressed, providing fixed-frequency auxiliary functions and suitable augmented control laws to null steady-state errors due to the use of constant switching frequency.

Predictive control (Section 35.4) uses a detailed nonlinear dynamic model (including system bounds, saturations, and hysteresis) of the switching power converter to forecast the converter future behavior upon application of every possible switching state or vector. For all possible switching states (vectors), the control errors are evaluated and weighted, and the vector that leads to the minimum value of a suitable cost function is selected and applied to the converter. Predictive controllers also integrate the design of the switching converter modulator and controller electronics using fast microprocessors or fast algorithms. The steps in designing a predictive optimum controller for switching power converters with finite small number of switching states are explained in Section 35.4. Upon choosing a suitable cost function, obtained converter performances are usually better than obtained using linear or even sliding-mode controllers. This arises as sliding mode tries to go as fast as possible toward the sliding regime but chatters along the sliding surface, while predictive control aims to zero the error at the next sampling step.

In contrast, fuzzy control of switching converters (Section 35.5) is a control technique that needs no converter models, parameters, or operating conditions, but only an expert qualitative knowledge of the converter dynamics. Fuzzy controllers can be used in a diverse array of switching converters with only small adaptations, since the controllers, based on fuzzy sets, are obtained simply from the knowledge of the system dynamics, using a model reference adaptive control philosophy. Obtained fuzzy control rules can be built into a decision-lookup table, in which the control processor simply picks up the control input corresponding to the sampled measurements. Fuzzy controllers are almost resistant to system parameter fluctuations, since they do not take into account their values. The steps to obtain a fuzzy controller are described, and the example provided compares the fuzzy controller performance to the current-mode control.

Backstepping control (Section 35.6) is presented as a recursive method for stabilizing the origin of a converter modeled in a strict-feedback form. The procedure interconnects the choice of a candidate Lyapunov function with the design of the feedback control loop using Lyapunov's second method. Backstepping offers stability, tracking, and robust control under conditions less restrictive than other methods. Integral action is included to ensure the convergence, in steady state, of the tracking error to zero, regardless of nonmodeled disturbances and parameter uncertainty. Backstepping control is a nonlinear method that can be used with conventional fixed-frequency duty-cycle modulators for power converters to prevent chattering at variable frequency.

35.2 Switching Power Converter Control Using State-Space Averaged Models

35.2.1 Introduction

State-space models provide a general and strong basis for dynamic modeling of various systems including switching converters. State-space models are useful to design the needed linear control loops and can also be used to computer simulate the steady state and the dynamic behavior, of the switching converter, fitted with the designed feedback control loops and subjected to external perturbations. Furthermore, state-space models are the basis for applying powerful nonlinear control methods such as sliding mode. State-space averaging and linearization provide an elegant solution for the application of widely known linear control techniques to most switching power converters.

35.2.2 State-Space Modeling

Consider a switching power converter with sets of power semiconductor structures, each one with two different circuit configurations, according to the state of the respective semiconductors, and operating in the continuous mode of conduction. Supposing the power semiconductors as controlled ideal switches

(zero on-state voltage drops, zero off-state currents, and instantaneous commutation between the on- and off-states), the time (t) behavior of the circuit, over period T, can be represented by the general form of the state-space model Eq. (35.1):

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}\\ \mathbf{y} &= \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u}\end{aligned} \tag{35.1}$$

where $\mathbf{x}$ is the state vector; $\dot{\mathbf{x}} = \mathbf{dx/dt}$; $\mathbf{u}$ is the input or control vector; $\mathbf{y}$ is the output vector; and $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, and $\mathbf{D}$ are, respectively, the dynamics (or state), the input, the output, and the direct transmission (or feedforward) matrices.

Since the power semiconductors will be either conducting or blocking, a time-dependent switching variable $\delta(t)$ can be used to describe the allowed switch states of each structure (i.e., $\delta(t)=1$ for the on-state circuit and $\delta(t)=0$ for the off-state circuit). Then, two subintervals must be considered: subinterval 1 for $0 \le t \le \delta_1 T$, when $\delta(t)=1$, where δ_1 is the duty ratio between the on-state and the off-state, and subinterval 2 for $\delta_1 T \le t \le T$ when $\delta(t)=0$. The state equations of the circuit, in each of the circuit configurations, can be written as

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{A}_1\mathbf{x} + \mathbf{B}_1\mathbf{u}\\ \mathbf{y} &= \mathbf{C}_1\mathbf{x} + \mathbf{D}_1\mathbf{u}\end{aligned} \quad \text{for} \quad 0 \le t \le \delta_1 T \quad \text{where } \delta(t)=1 \tag{35.2}$$

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{A}_2\mathbf{x} + \mathbf{B}_2\mathbf{u}\\ \mathbf{y} &= \mathbf{C}_2\mathbf{x} + \mathbf{D}_2\mathbf{u}\end{aligned} \quad \text{for} \quad \delta_1 T \le t \le T \quad \text{where } \delta(t)=0 \tag{35.3}$$

35.2.2.1 Switched State-Space Model

Given the two binary values of the switching variable $\delta(t)$, Eqs. (35.2) and (35.3) can be combined to obtain the nonlinear and time-variant switched state-space model of the switching converter circuit, Eq. (35.4) or (35.5):

$$\begin{aligned}\dot{\mathbf{x}} &= [\mathbf{A}_1\delta(t) + \mathbf{A}_2(1-\delta(t))]\mathbf{x} + [\mathbf{B}_1\delta(t) + \mathbf{B}_2(1-\delta(t))]\mathbf{u}\\ \mathbf{y} &= [\mathbf{C}_1\delta(t) + \mathbf{C}_2(1-\delta(t))]\mathbf{x} + [\mathbf{D}_1\delta(t) + \mathbf{D}_2(1-\delta(t))]\mathbf{u}\end{aligned} \tag{35.4}$$

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{A}_S\mathbf{x} + \mathbf{B}_S\mathbf{u}\\ \mathbf{y} &= \mathbf{C}_S\mathbf{x} + \mathbf{D}_S\mathbf{u}\end{aligned} \tag{35.5}$$

where $\mathbf{A}_S = [\mathbf{A}_1\delta(t) + \mathbf{A}_2(1-\delta(t))]$, $\mathbf{B}_S = [\mathbf{B}_1\delta(t) + \mathbf{B}_2(1-\delta(t))]$, $\mathbf{C}_S = [\mathbf{C}_1\delta(t) + \mathbf{C}_2(1-\delta(t))]$, and $\mathbf{D}_S = [\mathbf{D}_1\delta(t) + \mathbf{D}_2(1-\delta(t))]$.

35.2.2.2 State-Space Averaged Model

Since the state variables of the $\mathbf{x}$ vector are continuous, using Eq. (35.4), with the initial conditions $\mathbf{x}_1(0) = \mathbf{x}_2(T)$ and $\mathbf{x}_2(\delta_1 T) = \mathbf{x}_1(\delta_1 T)$, and considering the duty cycle δ_1 as the average value of $\delta(t)$, the time evolution of the converter state variables can be obtained, integrating Eq. (35.4) over the intervals $0 \le t \le \delta_1 T$ and $\delta_1 T \le t \le T$, although it often requires excessive calculation effort. However, a convenient approximation can be devised, considering λ_{max}, the maximum of the absolute values of all eigenvalues of $\mathbf{A}$ (usually, λ_{max} is related to the cut-off frequency f_c of an equivalent low-pass filter with $f_c \ll 1/T$). For $\lambda_{max} T \ll 1$, the exponential matrix (or state transition matrix) $e^{\mathbf{A}t} = \mathbf{I} + \mathbf{A}t + \mathbf{A}^2 t^2/2 + \ldots + \mathbf{A}^n t^n/n!$, where $\mathbf{I}$ is the identity or unity matrix, can be approximated by $e^{\mathbf{A}t} \approx \mathbf{I} + \mathbf{A}t$. Therefore, $e^{\mathbf{A}_1\delta_1 t} \cdot e^{\mathbf{A}_2(1-\delta_1)t} \approx \mathbf{I} + [\mathbf{A}_1\delta_1 + \mathbf{A}_2(1-\delta_1)]t$. Hence, the solution over the period T, for the system represented by Eq. (35.4), is found to be

$$\begin{aligned}\mathbf{x}(T) \cong\ & e^{[\mathbf{A}_1\delta_1 + \mathbf{A}_2(1-\delta_1)]T}\mathbf{x}_1(0)\\ &+ \int_0^T e^{[\mathbf{A}_1\delta_1 + \mathbf{A}_2(1-\delta_1)](T-\tau)}[\mathbf{B}_1\delta_1 + \mathbf{B}_2(1-\delta_1)]\mathbf{u}\,d\tau\end{aligned} \tag{35.6}$$

This approximate response of Eq. (35.4) is identical to the exact response obtained from the nonlinear continuous time-invariant state-space model (35.7), supposing that the average values of $\mathbf{x}$, denoted $\overline{\mathbf{x}}$, are the new state variables and considering $\delta_2 = 1 - \delta_1$. Moreover, if $\mathbf{A}_1\,\mathbf{A}_2 = \mathbf{A}_2\,\mathbf{A}_1$, the approximation is exact:

$$\begin{aligned}\dot{\overline{\mathbf{x}}} &= [\mathbf{A}_1\delta_1 + \mathbf{A}_2\delta_2]\,\overline{\mathbf{x}} + [\mathbf{B}_1\delta_1 + \mathbf{B}_2\delta_2]\,\overline{\mathbf{u}}\\ \overline{\mathbf{y}} &= [\mathbf{C}_1\delta_1 + \mathbf{C}_2\delta_2]\,\overline{\mathbf{x}} + [\mathbf{D}_1\delta_1 + \mathbf{D}_2\delta_2]\,\overline{\mathbf{u}}\end{aligned} \tag{35.7}$$

For $\lambda_{max} T \ll 1$, the model (35.7), often referred to as the state-space averaged model, is also said to be obtained by "averaging" Eq. (35.4) over one period, under small ripple and slow variations, as the average of products is approximated by products of the averages. Comparing Eq. (35.7) with Eq. (35.1), the relations (35.8), defining the state-space averaged model, are obtained:

$$\begin{aligned}&\mathbf{A} = [\mathbf{A}_1\delta_1 + \mathbf{A}_2\delta_2]; \quad \mathbf{B} = [\mathbf{B}_1\delta_1 + \mathbf{B}_2\delta_2];\\ &\mathbf{C} = [\mathbf{C}_1\delta_1 + \mathbf{C}_2\delta_2]; \quad \mathbf{D} = [\mathbf{D}_1\delta_1 + \mathbf{D}_2\delta_2]\end{aligned} \tag{35.8}$$

Example 35.1 State-space models for the buck–boost dc/dc converter

Consider the simplified circuitry of the buck-boost converter of Fig. 35.1 switching at $f_s = 20$ kHz ($T = 50$ µs) with $V_{DCmax} = 28$ V, $V_{DCmin} = 22$ V, $V_o = 24$ V, $L_i = 400$ µH, $C_o = 2700$ µF, and $R_o = 2\ \Omega$.

The differential equations governing the dynamics of the state vector $\mathbf{x} = [i_L,\ v_o]^T$ (^{T} denotes the transpose of vectors or matrices) are

$$\begin{aligned}L_i\frac{di_L}{dt} &= V_{DC}\\ C_o\frac{dv_o}{dt} &= -\frac{v_o}{R_o}\end{aligned} \quad \text{for } 0 \le t \le \delta_1 T \quad (\delta(t)=1,\ Q_1 \text{ is on and } D_1 \text{ is off}) \tag{35.9}$$

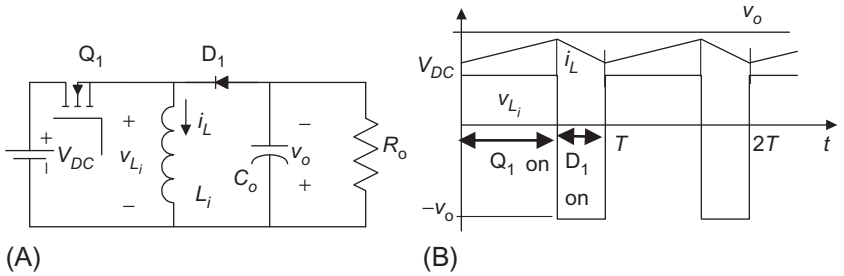

FIG. 35.1 (A) Basic circuit of the buck-boost dc/dc converter and (B) ideal waveforms.

$$\begin{aligned} L_i\frac{di_L}{dt} &= -v_o \\ C_o\frac{dv_o}{dt} &= i_L - \frac{v_o}{R_o} \end{aligned} \quad \text{for } \delta_1 T \le t \le T \quad (\delta(t)=0;\ Q_1 \text{ is off and } D_1 \text{ is on}) \tag{35.10}$$

Comparing Eqs. (35.9) and (35.10) with Eqs. (35.2) and (35.3) and considering $\mathbf{y}=[v_o,\ i_L]^T$, the following matrices can be identified:

$$\mathbf{A}_1=\begin{bmatrix}0 & 0\\ 0 & -1/(R_oC_o)\end{bmatrix};\ \mathbf{A}_2=\begin{bmatrix}0 & -1/L_i\\ -1/C_o & -1/(R_oC_o)\end{bmatrix};$$

$$\mathbf{B}_1=[1/L_i,0]^T;\ \mathbf{B}_2=[0,0]^T;\ \mathbf{u}=[V_{DC}];$$

$$\mathbf{C}_1=\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix};\ \mathbf{C}_2=\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix};$$

$$\mathbf{D}_1=[0,0]^T;\ \mathbf{D}_2=[0,0]^T$$

From Eqs. (35.4) and (35.5), the switched state-space model of this switching converter is

$$\begin{aligned} \begin{bmatrix}\dot{i}_L\\ \dot{v}_o\end{bmatrix} &= \begin{bmatrix}0 & -(1-\delta(t))/L_i\\ (1-\delta(t))/C_o & -1/(R_oC_o)\end{bmatrix}\begin{bmatrix}i_L\\ v_o\end{bmatrix}+\begin{bmatrix}\delta(t)/L_i\\ 0\end{bmatrix}V_{DC}\\ \begin{bmatrix}v_o\\ i_L\end{bmatrix} &= \begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\begin{bmatrix}i_L\\ v_o\end{bmatrix}+\begin{bmatrix}0\\ 0\end{bmatrix}[V_{DC}] \end{aligned} \tag{35.11}$$

Now, applying Eq. (35.7), Eqs. (35.12) and (35.13) can be obtained:

$$\begin{aligned} \begin{bmatrix}\dot{\bar{i}}_L\\ \dot{\bar{v}}_o\end{bmatrix} &= \left(\begin{bmatrix}0 & 0\\ 0 & -1/(R_oC_o)\end{bmatrix}\delta_1+\begin{bmatrix}0 & -1/L_i\\ 1/C_o & -1/R_oC_o\end{bmatrix}\delta_2\right)\\ &\quad\times\begin{bmatrix}\bar{i}_L\\ \bar{v}_o\end{bmatrix}+\left(\begin{bmatrix}1/L_i\\ 0\end{bmatrix}\delta_1+\begin{bmatrix}0\\ 0\end{bmatrix}\delta_2\right)[\overline{V}_{DC}] \end{aligned} \tag{35.12}$$

$$\begin{aligned} \begin{bmatrix}\bar{v}_o\\ \bar{i}_L\end{bmatrix} &= \left(\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\delta_1+\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\delta_2\right)\begin{bmatrix}\bar{i}_L\\ \bar{v}_o\end{bmatrix}\\ &\quad+\left(\begin{bmatrix}0\\ 0\end{bmatrix}\delta_1+\begin{bmatrix}0\\ 0\end{bmatrix}\delta_2\right)[\overline{V}_{DC}] \end{aligned} \tag{35.13}$$

From Eqs. (35.12) and (35.13), the state-space averaged model, written as a function of δ_1, is

$$\begin{bmatrix}\dot{\bar{i}}_L\\ \dot{\bar{v}}_o\end{bmatrix}=\begin{bmatrix}0 & -(1-\delta_1)/L_i\\ (1-\delta_1)/C_o & -1/(R_oC_o)\end{bmatrix}\begin{bmatrix}\bar{i}_L\\ \bar{v}_o\end{bmatrix}+\begin{bmatrix}\delta_1/L_i\\ 0\end{bmatrix}[\overline{V}_{DC}] \tag{35.14}$$

$$\begin{bmatrix}\bar{v}_o\\ \bar{i}_L\end{bmatrix}=\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\begin{bmatrix}\bar{i}_L\\ \bar{v}_o\end{bmatrix}+\begin{bmatrix}0\\ 0\end{bmatrix}[\overline{V}_{DC}] \tag{35.15}$$

The eigenvalues $s_{bb_{1,2}}$ or characteristic roots of $\mathbf{A}$ are the roots of $|s\mathbf{I}-\mathbf{A}|$. Therefore,

$$s_{bb_{1,2}}=\frac{-1}{2R_oC_o}\pm\sqrt{\frac{1}{4(R_oC_o)^2}-\frac{(1-\delta_1)^2}{L_iC_o}} \tag{35.16}$$

Since λ_{max} is the maximum of the absolute values of all the eigenvalues of $\mathbf{A}$, the model (35.14) and (35.15) is valid for switching frequencies f_s ($f_s=1/T$) that verify $\lambda_{max}T\ll 1$. Therefore, as $T\ll 1/\lambda_{max}$, the values of T that approximately verify this restriction are $T\ll 1/\max(|s_{bb1,2}|)$. Given these buck-boost converter data, $T\ll 2$ ms is obtained. Therefore, the converter switching frequency must obey $f_s\gg\max(|s_{bb1,2}|)$, implying switching frequencies above, say, 5 kHz. Consequently, the buck-boost switching frequency, the inductor value, and the capacitor value were chosen accordingly.

This restriction can be further used to discuss the maximum frequency ω_{max} for which the state-space averaged model is still valid, given a certain switching frequency. As λ_{max} can be regarded as a frequency, the preceding constraint brings $\omega_{max}\ll 2\pi f_s$, say $\omega_{max}<2\pi f_s/10$, which means that the state-space averaged model is a good approximation at frequencies under one-tenth of the power converter switching frequency.

The state-space averaged model (35.14) and (35.15) is also the state-space model of the circuit represented in Fig. 35.2. Hence, this circuit is often named "the averaged equivalent circuit" of the buck-boost converter and allows the determination, under small ripple and slow variations, of the average equivalent circuit of the converter switching cell (power transistor plus diode).

The average equivalent circuit of the switching cell (Fig. 35.3A) is represented in Fig. 35.3B and emerges directly from the state-space averaged model (35.14) and (35.15). This equivalent circuit can be viewed as the model of an "ideal transformer" (Fig. 35.3C), whose primary to secondary

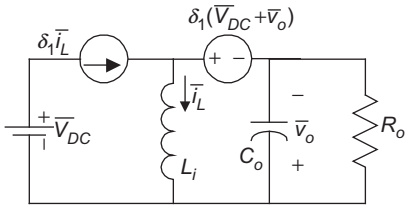

FIG. 35.2 Equivalent circuit of the averaged state-space model of the buck-boost converter.

ratio (v_1/v_2) can be calculated applying Kirchhoff's voltage law to obtain $-v_1+v_s-v_2=0$. As $v_2=\delta_1 v_s$, it follows that $v_1=v_s(1-\delta_1)$, giving $(v_1/v_2)=(1-\delta_1)/\delta_1$. The same ratio could be obtained beginning with $i_L=i_1+i_2$ and $i_1=\delta_1 i_L$ (Fig. 35.3B), which gives $i_2=i_L(1-\delta_1)$ and $(i_2/i_1)=\delta_2/\delta_1$.

The average equivalent circuit concept, obtained from Eq. (35.7) or Eqs. (35.14) and (35.15), can be applied to other switching converters, with or without a similar switching cell, to obtain transfer functions or to simulate the converter average behavior. The average equivalent circuit of the switching cell can be applied to converters with the same switching cell operating in the continuous conduction mode. However, note that the state variables of Eq. (35.7) or Eqs. (35.14) and (35.15) are the mean values of the converter instantaneous variables and, therefore, do not represent their ripple components. The inputs of the state-space averaged model are the mean values of the converter inputs over one switching period.

35.2.2.3 Linearized State-Space Averaged Model

The converter outputs $\overline{\mathbf{y}}$ must be regulated actuating on the duty cycle $\delta(t)$, and the converter inputs $\bar{\mathbf{u}}$ usually present perturbations due to the load and power supply variations. State variables are decomposed in small ac perturbations (denoted by "~") and dc steady-state quantities (represented by uppercase letters). Therefore,

$$\begin{aligned}\overline{\mathbf{x}}&=\mathbf{X}+\widetilde{\mathbf{x}}\\ \overline{\mathbf{y}}&=\mathbf{Y}+\widetilde{\mathbf{y}}\\ \overline{\mathbf{u}}&=\mathbf{U}+\widetilde{\mathbf{u}}\\ \delta_1&=\Delta_1+\widetilde{\delta}\\ \delta_2&=\Delta_2-\widetilde{\delta}\end{aligned}\tag{35.17}$$

Using Eq. (35.17) in Eq. (35.7) and rearranging terms, it is obtained:

$$\begin{aligned}\dot{\widetilde{\mathbf{x}}}=&[\mathbf{A}_1\Delta_1+\mathbf{A}_2\Delta_2]\mathbf{X}+[\mathbf{B}_1\Delta_1+\mathbf{B}_2\Delta_2]\mathbf{U}\\&+[\mathbf{A}_1\Delta_1+\mathbf{A}_2\Delta_2]\widetilde{\mathbf{x}}+[(\mathbf{A}_1-\mathbf{A}_2)\mathbf{X}+(\mathbf{B}_1-\mathbf{B}_2)\mathbf{U}]\widetilde{\delta}\\&+[\mathbf{B}_1\Delta_1+\mathbf{B}_2\Delta_2]\widetilde{\mathbf{u}}+[(\mathbf{A}_1-\mathbf{A}_2)]\widetilde{\mathbf{x}}+(\mathbf{B}_1-\mathbf{B}_2)\widetilde{\mathbf{u}}]\widetilde{\delta}\end{aligned}\tag{35.18}$$

$$\begin{aligned}\mathbf{Y}+\widetilde{\mathbf{y}}=&[\mathbf{C}_1\Delta_1+\mathbf{C}_2\Delta_2]\mathbf{X}+[\mathbf{D}_1\Delta_1+\mathbf{D}_2\Delta_2]\mathbf{U}\\&+[\mathbf{C}_1\Delta_1+\mathbf{C}_2\Delta_2]\widetilde{\mathbf{x}}+[(\mathbf{C}_1-\mathbf{C}_2)\mathbf{X}+(\mathbf{D}_1-\mathbf{D}_2)\mathbf{U}]\widetilde{\delta}\\&+[\mathbf{D}_1\Delta_1+\mathbf{D}_2\Delta_2]\widetilde{\mathbf{u}}+[(\mathbf{C}_1-\mathbf{C}_2)]\widetilde{\mathbf{x}}+(\mathbf{D}_1-\mathbf{D}_2)\widetilde{\mathbf{u}}]\widetilde{\delta}\end{aligned}\tag{35.19}$$

The terms $[\mathbf{A}_1\Delta_1+\mathbf{A}_2\ \Delta_2]\ \mathbf{X}+[\mathbf{B}_1\ \Delta_1+\mathbf{B}_2\ \Delta_2]\ \mathbf{U}$ and $[\mathbf{C}_1\ \Delta_1+\mathbf{C}_2\ \Delta_2]\ \mathbf{X}+[\mathbf{D}_1\ \Delta_1+\mathbf{D}_2\ \Delta_2]\ \mathbf{U}$, respectively, from Eqs. (35.18) and (35.19) represent the steady-state behavior of the system. As in steady-state $\dot{\mathrm{X}}=0$, the following relationships hold:

$$\mathbf{0}=[\mathbf{A}_1\Delta_1+\mathbf{A}_2\Delta_2]\mathbf{X}+[\mathbf{B}_1\Delta_1+\mathbf{B}_2\Delta_2]\mathbf{U}\tag{35.20}$$

$$\mathbf{Y}=[\mathrm{C}_1\Delta_1+\mathbf{C}_2\Delta_2]\mathbf{X}+[\mathbf{D}_1\Delta_1+\mathbf{D}_2\Delta_2]\mathbf{U}\tag{35.21}$$

Neglecting higher-order terms $([(\mathbf{A}_1-\mathbf{A}_2)\widetilde{\mathbf{x}}+(\mathbf{B}_1-\mathbf{B}_2)\widetilde{\mathbf{u}}])\widetilde{\delta}\approx 0$ of Eqs. (35.18) and (35.19), the linearized small-signal state-space averaged model is

$$\begin{aligned}\dot{\widetilde{\mathbf{x}}}=&[\mathbf{A}_1\Delta_1+\mathbf{A}_2\Delta_2]\widetilde{\mathbf{x}}+[(\mathbf{A}_1-\mathbf{A}_2)\mathbf{X}+(\mathbf{B}_1-\mathbf{B}_2)\mathbf{U}]\widetilde{\delta}\\&+[\mathbf{B}_1\Delta_1+\mathbf{B}_2\Delta_2]\widetilde{\mathbf{u}}\\\widetilde{\mathbf{y}}=&[\mathbf{C}_1\Delta_1+\mathbf{C}_2\Delta_2]\widetilde{\mathbf{x}}+[(\mathbf{C}_1-\mathbf{C}_2)\mathbf{X}+(\mathbf{D}_1-\mathbf{D}_2)\mathbf{U}]\widetilde{\delta}\\&+[\mathbf{D}_1\Delta_1+\mathbf{D}_2\Delta_2]\widetilde{\mathbf{u}}\end{aligned}\tag{35.22}$$

or

$$\begin{aligned}\dot{\widetilde{\mathbf{x}}}&=\mathbf{A}_{av}\widetilde{\mathbf{x}}+\mathbf{B}_{av}\widetilde{\mathbf{u}}+[(\mathbf{A}_1-\mathbf{A}_2)\mathbf{X}+(\mathbf{B}_1-\mathbf{B}_2)\mathbf{U}]\widetilde{\delta}\\\widetilde{\mathbf{y}}&=\mathbf{C}_{av}\widetilde{\mathbf{x}}+\mathbf{D}_{av}\widetilde{\mathbf{u}}+[(\mathbf{C}_1-\mathbf{C}_2)\mathbf{X}+(\mathbf{D}_1-\mathbf{D}_2)\mathbf{U}]\widetilde{\delta}\end{aligned}\tag{35.23}$$

with

$$\begin{aligned}\mathbf{A}_{av}&=[\mathbf{A}_1\Delta_1+\mathbf{A}_2\Delta_2]\\\mathbf{B}_{av}&=[\mathbf{B}_1\Delta_1+\mathbf{B}_2\Delta_2]\\\mathbf{C}_{av}&=[\mathbf{C}_1\Delta_1+\mathbf{C}_2\Delta_2]\\\mathbf{D}_{av}&=[\mathbf{D}_1\Delta_1+\mathbf{D}_2\Delta_2]\end{aligned}\tag{35.24}$$

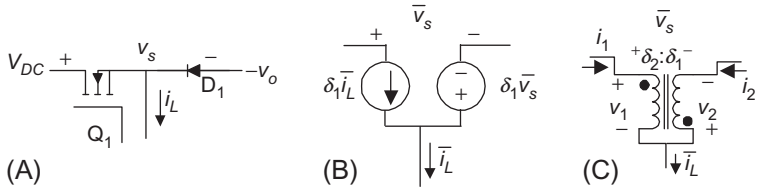

FIG. 35.3 Average equivalent circuit of the switching cell: (A) switching cell, (B) average equivalent circuit, and (C) average equivalent circuit using an ideal transformer.

35.2.3 Converter Transfer Functions

Using Eq. (35.20) in Eq. (35.21), the input **U** to output **Y** steady-state relations (35.25), needed for open-loop and feedforward control, can be obtained:

$$\frac{\mathbf{Y}}{\mathbf{U}} = -\mathbf{C}_{av}\mathbf{A}_{av}^{-1}\mathbf{B}_{av} + \mathbf{D}_{av} \tag{35.25}$$

Applying Laplace transforms to Eq. (35.23) with zero initial conditions and using the superposition theorem, the small-signal duty-cycle $\widetilde{\delta}$ -to-output $\tilde{y}$ transfer functions (35.26) can be obtained considering zero line perturbations ($\tilde{u}=0$):

$$\begin{aligned}\frac{\widetilde{\mathbf{y}}(s)}{\widetilde{\delta}(s)} = {} & \mathbf{C}_{av}[s\mathbf{I}-\mathbf{A}_{av}]^{-1}[(\mathbf{A}_1-\mathbf{A}_2)\mathbf{X}+(\mathbf{B}_1-\mathbf{B}_2)\mathbf{U}] \\ & +[(\mathbf{C}_1-\mathbf{C}_2)\mathbf{X}+(\mathbf{D}_1-\mathbf{D}_2)\mathbf{U}]\end{aligned} \tag{35.26}$$

The line-to-output transfer function (or audio susceptibility transfer function) (35.27) is derived using the same method, considering now zero small-signal duty-cycle perturbations $\left(\widetilde{\delta}=0\right)$:

$$\frac{\widetilde{\mathbf{y}}(s)}{\widetilde{\mathbf{u}}(s)} = \mathbf{C}_{av}[s\mathbf{I}-\mathbf{A}_{av}]^{-1}\mathbf{B}_{av} + \mathbf{D}_{av} \tag{35.27}$$

Example 35.2 Buck–Boost dc/dc converter transfer functions

From Eqs. (35.14) and (35.15) of Example 35.1 and Eq. (35.23), making $\mathbf{X}=[I_L,\ V_o]^{\mathrm{T}}$, $\mathbf{Y}=[V_o,\ I_L]^{\mathrm{T}}$ and $\mathbf{U}=[V_{DC}]$, the linearized small-signal state-space model of the buck-boost converter is

$$\begin{aligned}\begin{bmatrix}\dot{\widetilde{i}}_L\\ \dot{\widetilde{v}}_o\end{bmatrix} &= \begin{bmatrix}0 & -(1-\Delta_1)/L_i\\ (1-\Delta_1)/C_o & -1/(R_oC_o)\end{bmatrix}\begin{bmatrix}\widetilde{i}_L\\ \widetilde{v}_o\end{bmatrix} + \begin{bmatrix}\Delta_1/L_i\\ 0\end{bmatrix}[\widetilde{v}_{DC}] \\ &+ \begin{bmatrix}0 & \widetilde{\delta}/L_i\\ -\widetilde{\delta}/C_o & 0\end{bmatrix}\begin{bmatrix}I_L\\ V_o\end{bmatrix} + \begin{bmatrix}V_{DC}/L_i\\ 0\end{bmatrix}[\widetilde{\delta}] \\ \begin{bmatrix}\widetilde{v}_o\\ \widetilde{i}_L\end{bmatrix} &= \begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\begin{bmatrix}\widetilde{i}_L\\ \widetilde{v}_o\end{bmatrix} + \begin{bmatrix}0\\ 0\end{bmatrix}[\widetilde{v}_{DC}]\end{aligned} \tag{35.28}$$

From Eqs. (35.24) and (35.28), the following matrices are identified:

$$\mathbf{A}_{av} = \begin{bmatrix}0 & -(1-\Delta_1)/L_i\\ (1-\Delta_1)/C_0 & -1/(R_oC_o)\end{bmatrix};\ \mathbf{B}_{av} = \begin{bmatrix}\Delta_1/L_i\\ 0\end{bmatrix};$$
$$\mathbf{C}_{av} = \begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix};\ \mathbf{D}_{av} = \begin{bmatrix}0\\ 0\end{bmatrix} \tag{35.29}$$

The averaged linear equivalent circuit, resulting from Eq. (35.28) or from the linearization of the averaged equivalent circuit (Fig. 35.2) derived from Eqs. (35.14) and (35.15), now includes the small-signal current source $\widetilde{\delta}I_L$ in parallel with the current source $\Delta_1\tilde{i}_L$ and the small-signal voltage source $\widetilde{\delta}(V_{DC}+V_o)$ in series with the voltage source $\Delta_1(\widetilde{v}_{dc}+\widetilde{v}_o)$. The supply voltage source $\overline{V}_{DC}$ is replaced by the voltage source $\widetilde{v}_{DC}$.

Using Eq. (35.29) in Eq. (35.25), the *input U to output Y steady-state relations* are

$$\frac{I_L}{V_{DC}} = \frac{\Delta_1}{R_o(\Delta_1-1)^2} \tag{35.30}$$

$$\frac{V_o}{V_{DC}} = \frac{\Delta_1}{1-\Delta_1} \tag{35.31}$$

These relations are the well-known steady-state transfer relationships of the buck-boost converter [2,5,6]. For open-loop control of the V_o output, knowing the nominal value of the power supply V_{DC} and the required V_o, the value of Δ_1 can be offline calculated from Eq. (35.31) ($\Delta_1 = V_o/(V_o+V_{DC})$). A modulator such as that described in Section 35.2.4, with the modulation signal proportional to Δ_1, would generate the signal $\delta(t)$. The open-loop control for fixed output voltages is possible, if the power supply V_{DC} is almost constant and the converter load does not change significantly. If the V_{DC} value presents disturbances, then the feedforward control can be used, calculating Δ_1 online, so that its value will always be in accordance with Eq. (35.31). The correct V_o value will be attained at steady state, despite input voltage variations. However, because of converter parasitic reactances, not modeled here (see Example 35.3), in practice, a steady-state error would appear. Moreover, the transient dynamics imposed by the converter would present overshoots, being often not suited for demanding applications.

From Eq. (35.27), the *line-to-output transfer functions* are

$$\frac{\widetilde{i}_L(s)}{\widetilde{v}_{DC}(s)} = \frac{\Delta_1(1+sC_oR_o)}{s^2L_iC_oR_o + sL_i + R_o(1-\Delta_1)^2} \tag{35.32}$$

$$\frac{\widetilde{v}_o(s)}{\widetilde{v}_{DC}(s)} = \frac{R_o\Delta_1(1-\Delta_1)}{s^2L_iC_oR_o + sL_i + R_o(1-\Delta_1)^2} \tag{35.33}$$

From Eq. (35.26), *the small-signal duty-cycle $\widetilde{\delta}$ -to-output $\tilde{y}$ transfer functions are*

$$\frac{\widetilde{i}_L(s)}{\widetilde{\delta}(s)} = \frac{V_{DC}(1+\Delta_1+sC_oR_o)/(1-\Delta_1)}{s^2L_iC_oR_o + sL_i + R_o(1-\Delta_1)^2} \tag{35.34}$$

$$\frac{\widetilde{v}_o(s)}{\widetilde{\delta}(s)} = \frac{V_{DC}(R_o-sL_i\Delta_1)/(1-\Delta_1)^2)}{s^2L_iC_oR_o + sL_i + R_o(1-\Delta_1)^2} \tag{35.35}$$

These transfer functions enable the choice and feedback loop design of the compensation network. Note the positive zero in $\widetilde{v}_o(s)/\widetilde{\delta}(s)$, pointing out a nonminimum-phase

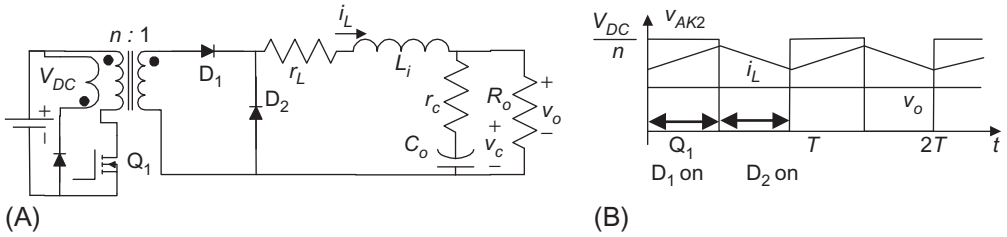

FIG. 35.4 (A) Basic circuit of the forward dc/dc converter and (B) circuit main waveforms.

system. These equations could also be obtained using the small-signal equivalent circuit derived from Eq. (35.28) or from the linearized model of the switching cell (Fig. 35.3B), substituting the current source $\delta_1 \bar{i}_L$ by the current sources $\Delta_1 \tilde{i}_L$ and $\tilde{\delta} I_L$ in parallel and the voltage source $\delta_1 \bar{v}_s$ by the voltage sources $\Delta_1(\tilde{v}_{DC} + \tilde{v}_o)$ and $\tilde{\delta}(V_{DC} + V_o)$ in series.

EXAMPLE 35.3 Transfer functions of the forward dc/dc converter

Consider the forward (buck-derived) converter of Fig. 35.4 switching at $f_s = 100$ kHz ($T = 10$ μs) with $V_{DC} = 300$ V, $n = 30$, $V_o = 5$ V, $L_i = 20$ μH, $r_L = 0.01\ \Omega$, $C_o = 2200$ μF, $r_C = 0.005\ \Omega$, and $R_o = 0.1\ \Omega$.

Assuming $\mathbf{x} = [i_L, v_C]^T$, $\delta(t) = 1$ when both Q_1 and D_1 are on and D_2 is off ($0 \le t \le \delta_1 T$), and $\delta(t) = 0$ when both Q_1 and D_1 are off and D_2 is on ($\delta_1 T \le t \le T$), the switched state-space model of the forward converter, considering as output vector $\mathbf{y} = [i_L, v_o]^T$, is

$$\begin{aligned}
\frac{di_L}{dt} &= -\frac{(R_o r_C + R_o r_L + r_L r_C)}{L_i(R_o + r_C)} i_L \\
&\quad - \frac{R_o}{L_i(R_o + r_C)} v_c + \frac{\delta(t)}{n} V_{DC} \\
\frac{dv_C}{dt} &= \frac{R_o}{(R_o + r_C)C_o} i_L - \frac{1}{(R_o + r_C)C_o} v_C \\
v_o &= \frac{r_C}{1 + r_C/R_o} i_L + \frac{1}{1 + r_C/R_o} v_C
\end{aligned} \tag{35.36}$$

Making $r_{cm} = r_C/(1 + r_C/R_o)$, $R_{oc} = R_o + r_C$, $k_{oc} = R_o/R_{oc}$, and $r_P = r_L + r_{cm}$ and comparing Eq. (35.36) with Eqs. (35.2) and (35.3), the following matrices can be identified:

$$\mathbf{A}_1 = \mathbf{A}_2 = \begin{bmatrix} -r_p/L_i & -k_{oc}/L_i \\ k_{oc}/C_o & -1/(R_{oc}C_o) \end{bmatrix};$$

$$\mathbf{B}_1 = [1/(nL_i), 0]^T;\ \mathbf{B}_2 = [0\ 0]^T;\ \mathbf{u} = [V_{DC}]$$

$$\mathbf{C}_1 = \mathbf{C}_2 = \begin{bmatrix} 1 & 0 \\ r_{cm} & k_{oc} \end{bmatrix};\ \mathbf{D}_1 = \mathbf{D}_2 = [00]^T$$

Now, applying Eq. (35.7), the exact (since $\mathbf{A}_1 = \mathbf{A}_2$) state-space averaged model (35.37) and (35.38) is obtained:

$$\begin{bmatrix} \dot{\bar{i}}_L \\ \dot{\bar{v}}_C \end{bmatrix} = \begin{bmatrix} -r_p/L_i & -k_{oc}/L_i \\ k_{oc}/C_o & -1/(R_{oc}C_o) \end{bmatrix} \begin{bmatrix} \bar{i}_L \\ \bar{v}_C \end{bmatrix} + \begin{bmatrix} \delta_1/(nL_i) \\ 0 \end{bmatrix} [\bar{V}_{DC}] \tag{35.37}$$

$$\begin{bmatrix} \bar{i}_L \\ \bar{v}_o \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ r_{cm} & k_{oc} \end{bmatrix} \begin{bmatrix} \bar{i}_L \\ \bar{v}_o \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \end{bmatrix} [\bar{V}_{DC}] \tag{35.38}$$

Since $\mathbf{A}_1 = \mathbf{A}_2$, this model is valid for $\omega_{max} < 2\pi f_s$. The converter eigenvalues $s_{f_{1,2}}$ are

$$s_{f_{1,2}} = -\frac{L_i + C_o R_{oc} r_p}{2R_{oc}L_i C_o} \pm \frac{\sqrt{-4R_{oc}L_i C_o\left(R_{oc}k_{oc}^2 + r_p\right) + \left(L_i + C_o R_{oc} r_p\right)^2}}{2R_{oc}L_i C_o} \tag{35.39}$$

The equivalent circuit arising from Eqs. (35.37) and (35.38) is represented in Fig. 35.5. It could also be obtained with the concept of the switching cell equivalent circuit Fig. 35.3 of Example (35.1).

Making $\mathbf{X} = [I_L, V_C]^T$, $\mathbf{Y} = [I_L, V_o]^T$ and $\mathbf{U} = [V_{DC}]$, from Eq. (35.23), the small-signal state-space averaged model is

$$\begin{bmatrix} \dot{\tilde{i}}_L \\ \dot{\tilde{v}}_C \end{bmatrix} = \begin{bmatrix} -r_p/L_i & -k_{oc}/L_i \\ k_{oc}/C_o & -1/(R_{oc}C_o) \end{bmatrix} \begin{bmatrix} \tilde{i}_L \\ \tilde{v}_C \end{bmatrix} + \begin{bmatrix} \Delta_1/(nL_i) \\ 0 \end{bmatrix} [\tilde{v}_{DC}] + \begin{bmatrix} V_{DC}/(nL_i) \\ 0 \end{bmatrix} [\tilde{\delta}] \tag{35.40}$$

$$\begin{bmatrix} \tilde{i}_L \\ \tilde{v}_o \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ r_{cm} & k_{oc} \end{bmatrix} \begin{bmatrix} \tilde{i}_L \\ \tilde{v}_C \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \end{bmatrix} [\tilde{v}_{DC}] \tag{35.41}$$

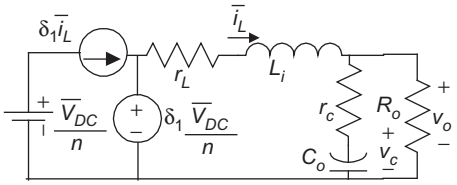

FIG. 35.5 Equivalent circuit of the averaged state-space model of the forward converter.

From Eq. (35.25), the input **U** to output **Y** steady-state relations are

$$\frac{I_L}{V_{DC}} = \frac{\Delta_1}{n\left(k_{oc}^2 R_{oc} + r_p\right)} \tag{35.42}$$

$$\frac{V_o}{V_{DC}} = \frac{\Delta_1\left(k_{oc}^2 R_{oc} + r_{cm}\right)}{n\left(k_{oc}^2 R_{oc} + r_p\right)} \tag{35.43}$$

Making $r_C = 0$, $r_L = 0$, and $n = 1$, the former relations give the well-known dc transfer relationships of the buck dc/dc converter. Relations (35.42) and (35.43) allow the open-loop and feedforward control of the converter, as discussed in Example 35.2, provided that all the modeled parameters are time-invariant and accurate enough.

From Eq. (35.27), the line-to-output transfer functions are derived:

$$\frac{\widetilde{i}_L(s)}{\widetilde{v}_{DC}(s)} = \frac{(\Delta_1/n)(1 + sC_oR_{oc})}{s^2L_iC_oR_{oc} + s\left(L_i + C_oR_{oc}r_p\right) + k_{oc}^2R_{oc} + r_p} \tag{35.44}$$

$$\frac{\widetilde{v}_o(s)}{\widetilde{v}_{DC}(s)} = \frac{(\Delta_1/n)\left(k_{oc}^2R_{oc} + r_{cm} + sC_oR_{oc}r_{cm}\right)}{s^2L_iC_oR_{oc} + s\left(L_i + C_oR_{oc}r_p\right) + k_{oc}^2R_{oc} + r_p} \tag{35.45}$$

Using Eq. (35.26), the small-signal duty-cycle $\widetilde{\delta}$-to-output $\tilde{y}$ transfer functions are

$$\frac{\widetilde{i}_L(s)}{\delta(s)} = \frac{(V_{DC}/n)(1 + sC_oR_{oc})}{s^2L_iC_oR_{oc} + s\left(L_i + C_oR_{oc}r_p\right) + k_{oc}^2R_{oc} + r_p} \tag{35.46}$$

$$\frac{\widetilde{v}_o(s)}{\delta(s)} = \frac{(V_{DC}/n)\left(k_{oc}^2R_{oc} + r_{cm} + sC_oR_{oc}r_{cm}\right)}{s^2L_iC_oR_{oc} + s\left(L_i + C_oR_{oc}r_p\right) + k_{oc}^2R_{oc} + r_p} \tag{35.47}$$

The real zero of Eq. (35.47) is due to r_C, the equivalent series resistance (ESR) of the output capacitor. A similar zero would occur in the buck-boost converter (Example 35.2), if the ESR of the output capacitor had been included in the modeling.

35.2.4 Pulse Width Modulator Transfer Functions

In what is often referred to as the pulse-width-modulation (PWM) voltage-mode control, the output voltage $u_c(t)$ of the error (between desired and actual output) amplifier plus regulator, processed if needed, is compared with a repetitive or carrier waveform $r(t)$, to obtain the switching variable $\delta(t)$ (Fig. 35.6A). This function controls the power switch, turning it on at the beginning of the period and turning it off when the ramp exceeds the $u_c(t)$ voltage. In Fig. 35.6B, the opposite occurs (turnoff at the end of the period and turn-on when the $u_c(t)$ voltage exceeds the ramp).

Considering $r(t)$ as represented in Fig. 35.6A ($r(t) = u_{cmax}t/T$), δ_k is obtained equating $r(t) = u_c$ giving $\delta_k = u_c\ (t)/u_{cmax}$ or $\delta_k/u_c\ (t) = G_M$ ($G_M = 1/u_{cmax}$). In Fig. 35.6B, the switching-on angle α_k is obtained from $r(t) = u_{cmax} - 2u_{cmax}\omega t/\pi$ and $u_c\ (t) = u_{cmax} - 2u_{cmax}\ \alpha_k/\pi$, giving $\alpha_k = (\pi/2) \times (1 - u_c/u_{cmax})$ and $G_M = \partial\alpha_k/\partial u_c = -\pi/(2u_{cmax})$.

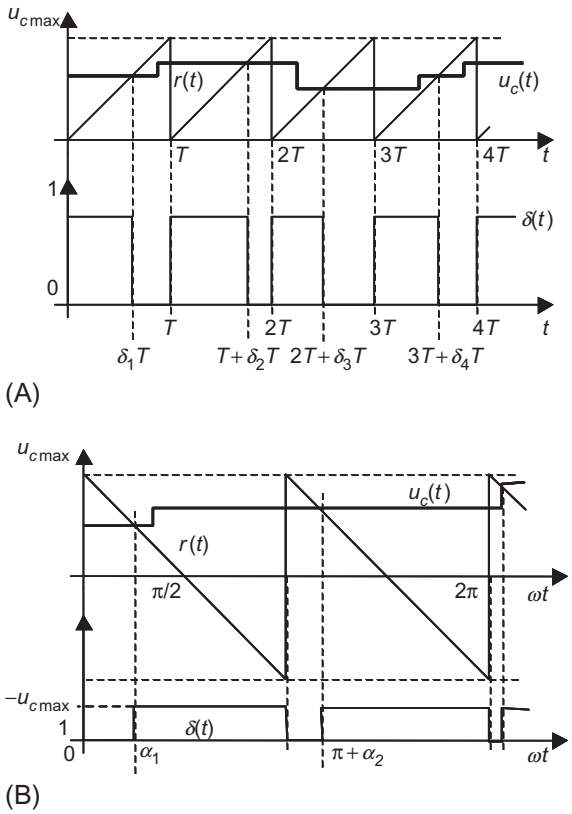

FIG. 35.6 Waveforms of pulse-width modulators showing the variable time delays of the modulator response: (A) $r(t) = u_{cmax}\ t/T$ and (B) $r(t) = u_{cmax} - 2u_{cmax}\ \omega t/\pi$.

Since, after turnoff or turn-on, any control action variation of $u_c(t)$ will only affect the converter duty cycle in the next period (or sample for digital hardware), a time delay is introduced in the control loop. For simplicity, with small-signal perturbations around the operating point, this delay is assumed almost constant and equal to its mean value ($T/2$). Then, the transfer function of the PWM modulator is

$$\frac{\widetilde{\delta}(s)}{\widetilde{u}_c(s)} = G_M e^{-sT/2} = \frac{G_M}{e^{s(T/2)}} = \frac{G_M}{1 + s\frac{T}{2} + \frac{s^2}{2!}\left(\frac{T}{2}\right)^2 + \ldots + \frac{s^j}{j!}\left(\frac{T}{2}\right)^j + \ldots} \approx \frac{G_M}{1 + s\frac{T}{2}} \tag{35.48}$$

The final approximation of Eq. (35.48), valid for $\omega T/2 < \sqrt{2}/2$, [7] suggests that the PWM modulator can be considered as an amplifier with gain G_M and a dominant pole. Notice that this pole occurs at a frequency doubling the switching frequency, and most state-space averaged models are valid only for frequencies below one-tenth of the switching frequency.

Therefore, in most situations, this modulator pole can be neglected, being simply $\delta(s) = G_M u_c(s)$, as the dominant pole of Eq. (35.48) stays at least one decade to the left of the dominant poles of the converter.

35.2.5 Linear Feedback Design Ensuring Stability

In the application of classical linear feedback control to switching power converters, Bode plots and root locus are, usually, suitable methods to assess system performance and stability. General rules for the design of the compensated open-loop transfer function are as follows:

The low-frequency gain should be high enough to minimize output steady-state errors.

The frequency of 0 dB gain (unity gain), ω_{0dB}, should be placed close to the maximum allowed by the modeling approximations ($\lambda_{max} T \ll 1$), to allow fast response to transients. In practice, this frequency should be almost an order of magnitude lower than the switching frequency.

To ensure stability, the phase margin, defined as the additional phase shift needed to render the system unstable without gain changes (or the difference between the open-loop system phase at ω_{0dB} and $-180°$), must be positive and in general greater than 30° (45 − 70° is desirable). In the root locus, no poles should enter the right half of the complex plane.

To increase stability, the gain should be less than −30 dB at the frequency where the phase reaches −180° (gain margin greater than 30 dB).

Transient behavior and stability margins are related: The obtained damping factor is generally 0.01 times the phase margin (in degrees), and overshoot (in percent) is given approximately by 75° minus the phase margin. The product of the rise time (in seconds) and the closed-loop bandwidth (in rad/s) is close to 2.8.

To guarantee gain and phase margins, the following series compensation transfer functions (usually implemented with operational amplifiers) are often used [8]:

35.2.5.1 Types of Compensation

Lag and lead compensation

Lag compensation should be used in converters with good stability margin but poor steady-state accuracy. If the frequencies $1/T_p$ and $1/T_z$ of Eq. (35.49) with $1/T_p < 1/T_z$ are chosen sufficiently below the unity gain frequency, lag-lead compensation lowers the loop gain at high frequency but maintains the phase unchanged for frequencies $f \gg 1/T_z$. Then, the dc gain can be increased to reduce the steady-state error without significantly decreasing the phase margin:

$$C_{LL}(s) = k_{LL}\frac{1+sT_z}{1+sT_p} = k_{LL}\frac{T_z}{T_p}\frac{s+1/T_z}{s+1/T_p} \tag{35.49}$$

Lead compensation can be used in converters with good steady-state accuracy but poor stability margin. If the frequencies $1/T_p$ and $1/T_z$ of Eq. (35.49) with $1/T_p > 1/T_z$ are chosen below the unity gain frequency, lead-lag compensation increases the phase margin without significantly affecting the steady-state error. The T_p and T_z values are chosen to increase the phase margin, fastening the transient response and increasing the bandwidth.

Proportional–Integral compensation

Proportional-integral (PI) compensators (35.50) are used to guarantee null steady-state error with acceptable rise times. The PI compensators are a particular case of lag-lead compensators, therefore suitable for converters with good stability margin but poor steady-state accuracy:

$$\begin{aligned} C_{PI}(s) &= \frac{1+sTz}{sT_p} = \frac{T_z}{T_p} + \frac{1}{sT_p} = K_p + \frac{K_i}{s} = K_p\left(1+\frac{K_i}{K_p s}\right) \\ &= K_p\left(1+\frac{1}{sT_z}\right) = \frac{1+sT_z}{sT_z/K_p} \end{aligned} \tag{35.50}$$

Proportional–integral plus high-frequency pole compensation

This integral plus zero-pole compensation (35.51) combines the advantages of a PI with lead or lag compensation. It can be used in converters with good stability margin but poor steady-state accuracy. If the frequencies $1/T_M$ and $1/T_z$ ($1/T_z < 1/T_M$) are carefully chosen, compensation lowers the loop gain at high frequency while only slightly lowering the phase to achieve the desired phase margin:

$$\begin{aligned} C_{ILD}(s) &= \frac{1+sT_z}{sT_p(1+sT_M)} = \frac{T_z}{T_p T_M}\frac{s+1/T_z}{s(s+1/T_M)} \\ &= W_{cp}\frac{s+\omega_z}{s(s+\omega_M)} \end{aligned} \tag{35.51}$$

Proportional-integral derivative (PID), plus high-frequency poles

The PID notch filter type (35.52) scheme is used in converters with two lightly damped complex poles, to increase the response speed, while ensuring zero steady-state error. In most switching power converters, the two complex zeros are selected to have a damping factor greater than the converter complex poles and slightly smaller oscillating frequency. The high-frequency pole is placed to achieve the needed phase margin [9]. The design is correct if the complex pole loci, heading to the complex zeros in the system root locus, never enter the right half plane:

$$\begin{aligned} C_{PIDnf}(s) &= T_{cp}\frac{s^2 + 2\xi_{cp}\omega_{0cp}s + \omega_0^2 cp}{s\left(1+s/\omega_{p1}\right)} \\ &= \frac{T_{cp}s}{1+s/\omega_{p1}} + \frac{2T_{cp}\xi_{cp}\omega_{0cp}}{1+s/\omega_{p1}} + \frac{T_{cp}\omega_0^2 cp}{s\left(1+s/\omega_{p1}\right)} \\ &= \frac{T_{cp}s}{1+s/\omega_{p1}} + \frac{T_{cp}\omega_{0pc}^2\left(1+2s\xi_{cp}/\omega_{0cp}\right)}{s\left(1+s/\omega_{p1}\right)} \end{aligned} \tag{35.52}$$

For systems with a high-frequency zero placed at least one decade above the two lightly damped complex poles, the compensator (35.53), with $\omega_{z1} \approx \omega_{z2} < \omega_p$, can be used. Usually, the two real zeros present frequencies slightly lower than the frequency of the converter complex poles. The two high-frequency poles are placed to obtain the desired phase margin [9]. The obtained overall performance will often be inferior to that of the PID type notch filter:

$$C_{PID}(s) = W_{cp} \frac{(1 + s/\omega_{z1})(1 + s/\omega_{z2})}{s(1 + s/\omega_p)^2} \tag{35.53}$$

35.2.5.2 Compensator Selection and Design

The procedure to select the compensator and to design its parameters can be outlined as follows:

1. Compensator selection: In general, since V_{DC} perturbations exist, null steady-state error guarantee is needed. High-frequency poles are usually necessary, if the transfer function shows a −6 dB/octave roll-off due to high-frequency left plane zeros. Therefore, in general, two types of compensation schemes with integral action (35.51) or (35.50) and (35.52) or (35.53) can be tried. Compensator (35.52) is usually convenient for systems with lightly damped complex poles.
2. Unity gain frequency ω_{0dB} choice:
   - If the selected compensator has no complex zeros, it is better to be conservative, choosing ω_{0dB} sufficiently below the frequency of the lightly damped poles of the converter (or the frequency of the right half-plane zeros if lower). However, because of the resonant peak of most converter transfer functions, the phase margin can be obtained at a frequency near the resonance. If the phase margin is not enough, the compensator gain must be lowered.
   - If the selected compensator has complex zeros, ω_{0dB} can be chosen slightly above the frequency of the lightly damped poles.
3. Desired phase margin (φ_M) specification $\varphi_M \geq 30°$ (preferably between 45 and 70°).
4. Compensator zero-pole placement to achieve the desired phase margin:
   - With the integral plus zero-pole compensation type (35.51), the compensator phase φ_{cp}, at the maximum frequency of unity gain (often ω_{0dB}), equals the phase margin (φ_M) minus 180° and minus the converter phase φ_{cv},($\varphi_{cp} = \varphi_M - 180° - \varphi_{cv}$). The zero-pole position can be obtained calculating the factor $f_{ct} = tg\,(\pi/2 + \varphi_{cp}/2)$ being $\omega_z = \omega_{0dB}/f_{ct}$ and $\omega_M = \omega_{0dB} f_{ct}$.
   - With the PID notch filter type (35.52) controller, the two complex zeros are placed to have a damping factor ξ_p roughly equal to two times the damping ξ_z of the converter complex poles and oscillating frequency ω_{0cp} 30% smaller than the complex poles frequency ω_p. The high-frequency pole ω_{p1} is placed to achieve the needed phase margin ($\omega_{p1} \approx (\omega_{0cp} \cdot \omega_{0dB})^{1/2} f_{ct}^2$ with $f_{ct} = \text{tg}\ (\pi/2 + \varphi_{cp}/2)$ and $\varphi_{cp} = \varphi_M - 180° - \varphi_{cv}$ [5]). Alternatively, since for stability $\xi_z\ \omega_{0cp} > \xi_p\ \omega_p$ and $\omega_p \sqrt{1 - \xi_p^2} > \omega_{0cp} \sqrt{1 - \xi_z^2}$, it is obtained $1 > \xi_z > \xi_p$ and using the geometric mean, $\omega_{0cp} = \omega_p \sqrt{\frac{\xi_p}{\xi_z} \sqrt{\frac{1 - \xi_p^2}{1 - \xi_z^2}}}$.
5. Compensator gain calculation (the product of the converter and compensator gains at the ω_{0dB} frequency must be one).
6. Stability margin verification using Bode plots and root locus.
7. Result evaluation. Restarting the compensator selection and design, if the attained results are still not good enough.

Note that several modern computer programs, such as MATLAB, provide very easy and efficient tools (such as SISOTOOL) to design these controllers, even considering that switching power converters are discrete systems. Optimum controllers such as linear-quadratic-Gaussian (LQG, LQR) controllers, whose performances might be much better than linear controllers, can also be designed using the same tools. However, in evaluating optimum controller results, care must be taken in order to guarantee that the controlled converter frequency bandwidth and gain are not beyond the validity limits of the used models.

35.2.6 Examples: Buck–Boost DC/DC Converter, Forward DC/DC Converter, 12 Pulse Rectifiers, Buck–Boost DC/DC Converter in the Discontinuous Mode (Voltage and Current Mode), Three-phase PWM Inverters

EXAMPLE 35.4 Feedback design for the buck–boost dc/dc converter

Consider the converter output voltage v_o (Fig. 35.1) to be the controlled output. From Example 35.2 and Eqs. (35.33) and (35.35), the block diagram of Fig. 35.7 is obtained. The modulator transfer function is considered a pure gain ($G_M = 0.1$). The magnitude and phase of the open-loop transfer function v_o/u_c (Fig. 35.8A trace 1) shows a resonant peak due to the two lightly damped complex poles and the associated −12 dB/octave roll-off. The right half-plane zero changes the roll-off to −6 dB/octave and adds −90° to the converter phase (nonminimum-phase converter).

Compensator selection. As V_{DC} perturbations exist, null steady-state error guarantee is needed.

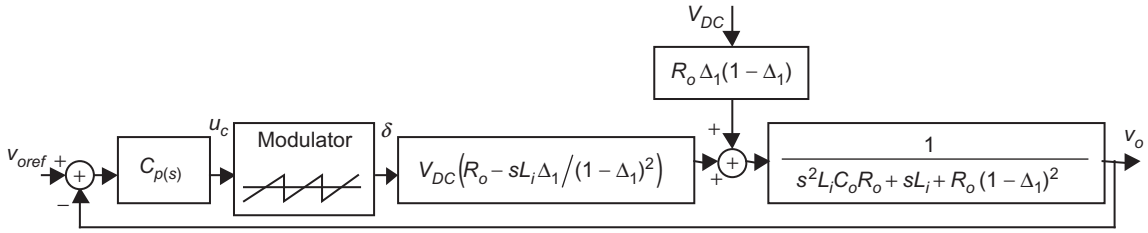

FIG. 35.7 Block diagram of the linearized model of the closed-loop buck-boost converter.

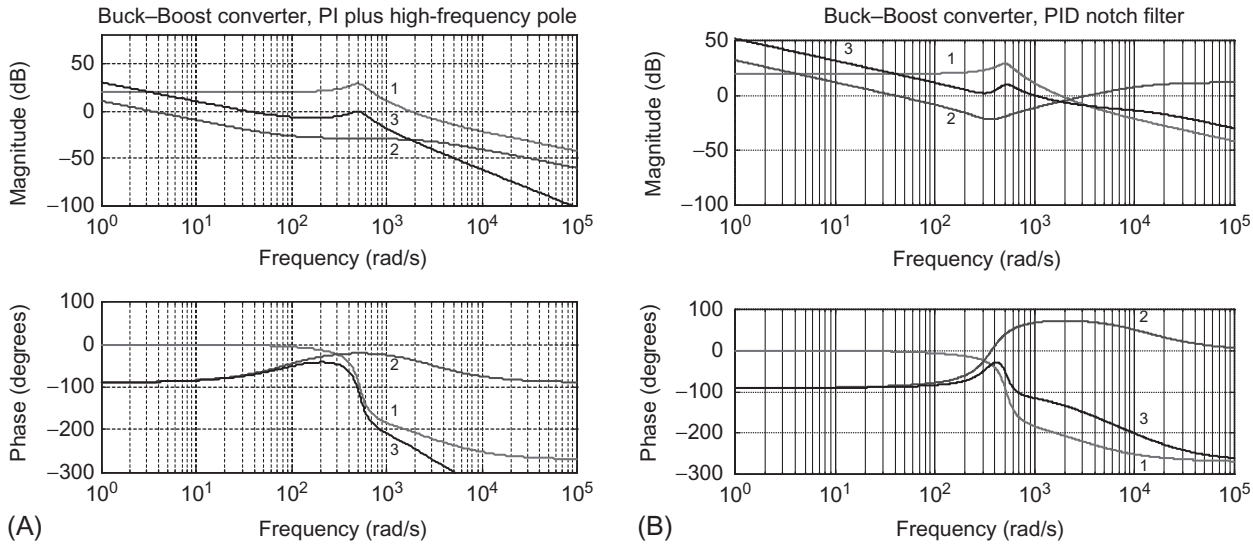

FIG. 35.8 Bode plots for the buck-boost converter. Trace 1, switching power converter magnitude and phase; trace 2, compensator magnitude and phase; and trace 3, resulting magnitude and phase of the compensated converter: (A) PI plus high-frequency pole compensation with 60° phase margin, $\omega_{0dB} = 500$ rad/s, and (B) PID notch filter compensation with 65° phase margin, $\omega_{0dB} = 1000$ rad/s.

High-frequency poles are needed given the −6 dB/octave final slope of the transfer function. Therefore, two compensation schemes (35.51) and (35.52) with integral action are tried here. The buck-boost converter controlled with integral plus zero-pole compensation presents, in closed-loop, two complex poles closer to the imaginary axes than in open loop. These poles should not dominate the converter dynamics. Instead, the real pole resulting from the open-loop pole placed at the origin should be almost the dominant one, thus slightly lowering the calculated compensator gain. If the ω_{0dB} frequency is chosen too low, the integral plus zero-pole compensation turns into a pure integral compensator ($\omega_z = \omega_M = \omega_{0dB}$). However, the obtained gains are too low, leading to very slow transient responses.

Results showing the transient responses to v_{oref} and V_{DC} step changes, using the selected compensators and converter Bode plots (Fig. 35.8), are shown (Fig. 35.9). The compensated real converter transient behavior occurs in the buck and in the boost regions. Notice the nonminimum-phase behavior of the converter (mainly in Fig. 35.9B), the superior performance of the PID notch filter compensator, and the unacceptable behavior of the PI with high-frequency pole. Care should be taken with load changes, when using this compensator, since instability can easily occur.

The compensator critical values, obtained with the root-locus studies, are $W_{cpcrit} = 700\ \text{s}^{-1}$ for the integral plus zero-pole compensator, $T_{cpcrit} = 0.0012$ s for the PID notch filter, and $W_{Icpcrit} = 18\ \text{s}^{-1}$ for the integral compensation derived from the integral plus zero-pole compensator ($\omega_z = \omega_M$). This confirms the Bode-plot design and allows stability estimation with changing loads and power supply.

Example 35.5 Feedback design for the forward dc/dc converter

Consider the output voltage v_o of the forward converter (Fig. 35.4A) to be the controlled output. From Example 35.3 and Eqs. (35.45) and (35.47), the block diagram of Fig. 35.10 is obtained. As in Example 35.4, the modulator transfer function is considered as a pure gain

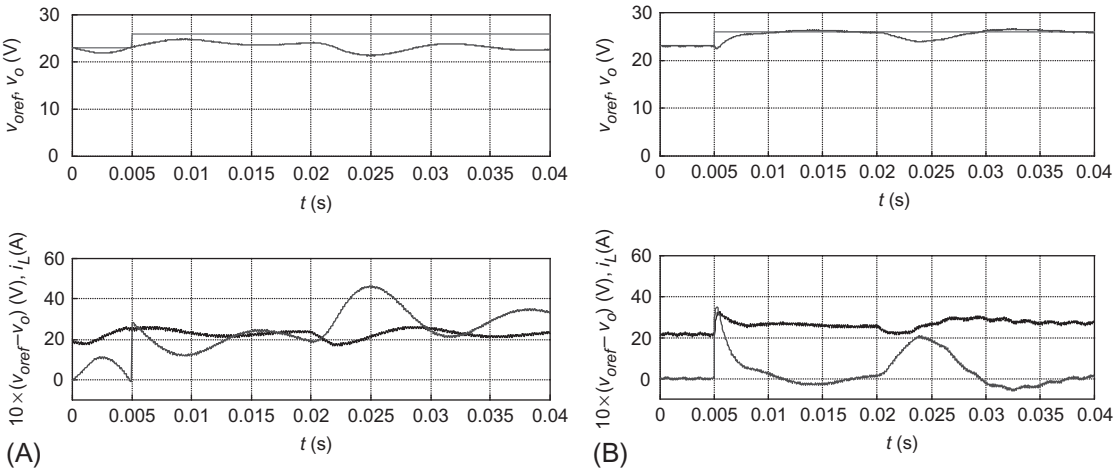

FIG. 35.9 Transient responses of the compensated buck-boost converter. At $t=0.00$ s, v_{oref} step from 23 to 26 V. At $t=0.02$ s, V_{DC} step from 26 to 23 V. Top graphs, step reference v_{oref} and output voltage v_o. Bottom graphs, trace starting at 20 is i_L current; trace starting at zero is $10\times(v_{oref}-v_o)$: (A) PI plus high-frequency pole compensation with 60° phase margin and $\omega_{0dB}=500$ rad/s and (B) PID notch filter compensation with 64° phase margin and $\omega_{0dB}=1000$ rad/s.

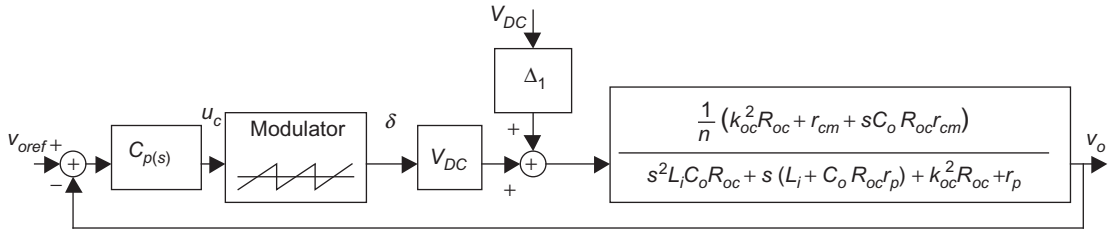

FIG. 35.10 Block diagram of the linearized model of the closed-loop controlled forward converter.

($G_M=0.1$). The magnitude and phase of the open-loop transfer function v_o/u_c (Fig. 35.11A trace 1) shows an open-loop stable system. Since integral action is needed to have some disturbance rejection of the voltage source V_{DC}, the compensation schemes used in Example 35.4, obtained using the same procedure (Fig. 35.11), were also tested.

Results, showing the transient responses to v_{oref} and V_{DC} step changes, are shown (Fig. 35.12). Both compensators (35.51) and (35.52) are easier to design than the ones for the buck-boost converter, and both have acceptable performances. Moreover, the PID notch filter presents a much faster response.

Alternatively, a PID feedback controller such as Eq. (35.53) can be easily hand-adjusted, starting with the proportional, integral, and derivative gains all set to zero. In the first step, the proportional gain is increased until the output presents an oscillatory response with nearly 50% overshoot. Next, the derivative gain is slowly increased until the overshoot is eliminated. Finally, the integral gain is increased to eliminate the steady-state error as quickly as possible.

EXAMPLE 35.6 Feedback design for phase controlled rectifiers in the continuous mode

Phase-controlled, p pulse ($p>1$), thyristor rectifiers (Fig. 35.13A), operating in the continuous mode, present an output voltage with p identical segments within the mains period T. Given this cyclic waveform, the **A**, **B**, **C**, and **D** matrices for all these p intervals can be written with the same form, in spite of the topological variation. Hence, the state-space averaged model is obtained simply by averaging all the variables within the period T/p. Assuming small variations, the mean value of the rectifier output voltage U_{DC} can be written as [4]:

$$U_{DC}=U_p\frac{p}{\pi}\sin\left(\frac{\pi}{p}\right)\cos\alpha \tag{35.54}$$

where α is the triggering angle of the thyristors and U_p the maximum peak value of the rectifier output voltage, determined by the rectifier topology and the ac supply voltage. The α value can be obtained ($\alpha=(\pi/2)\times(1-u_c/u_{cmax})$) using the modulator of Fig. 35.6B, where $\omega=2\pi/T$ is the mains frequency. From Eq. (35.54), the incremental gain K_R of the modulator plus rectifier yields

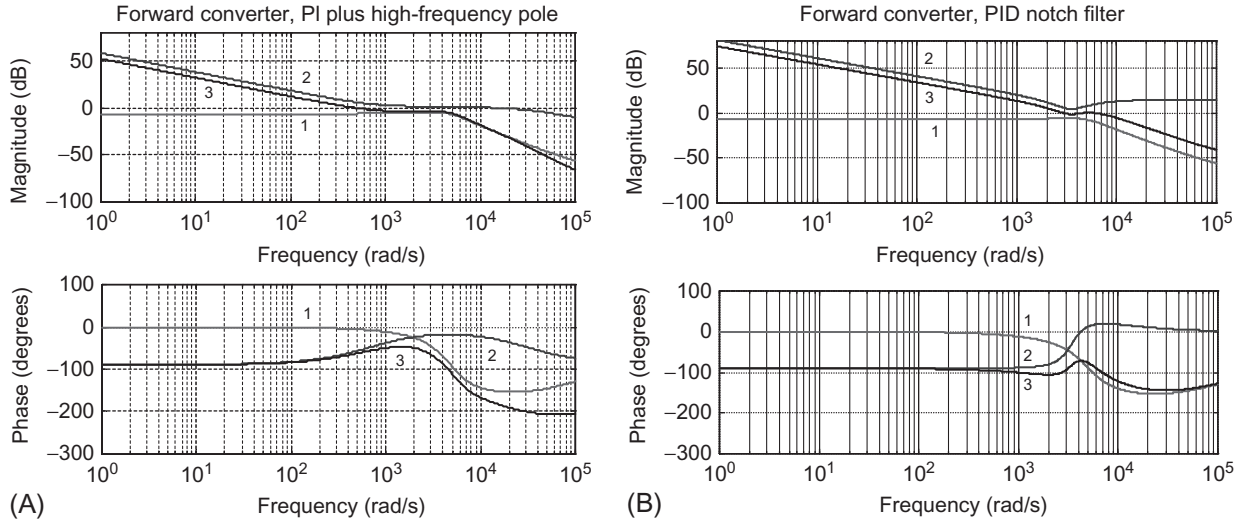

FIG. 35.11 Bode plots for the forward converter. Trace 1, switching power converter magnitude and phase; trace 2, compensator magnitude and phase; trace 3, resulting magnitude and phase of the compensated converter: (A) PI plus high-frequency pole compensation with 115° phase margin, $\omega_{0dB} = 500$ rad/s, and (B) PID notch filter compensation with 85° phase margin, $\omega_{0dB} = 6000$ rad/s.

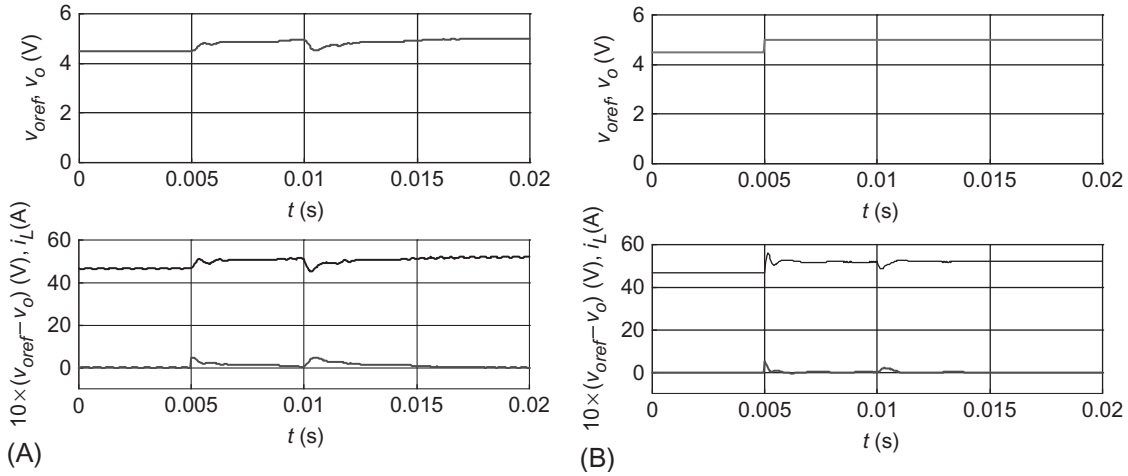

FIG. 35.12 Transient responses of the compensated forward converter. At $t = 0.005$ s, v_{oref} step from 4.5 to 5 V. At $t = 0.01$ s, V_{DC} step from 300 to 260 V. Top graphs: step reference v_{oref} and output voltage v_o. Bottom graphs: top traces i_L current and bottom traces $10 \times (v_{oref} - v_o)$; (A) PI plus high-frequency pole compensation with 115° phase margin and $\omega_{0dB} = 500$ rad/s and (B) PID notch filter compensation with 85° phase margin and $\omega_{0dB} = 6000$ rad/s.

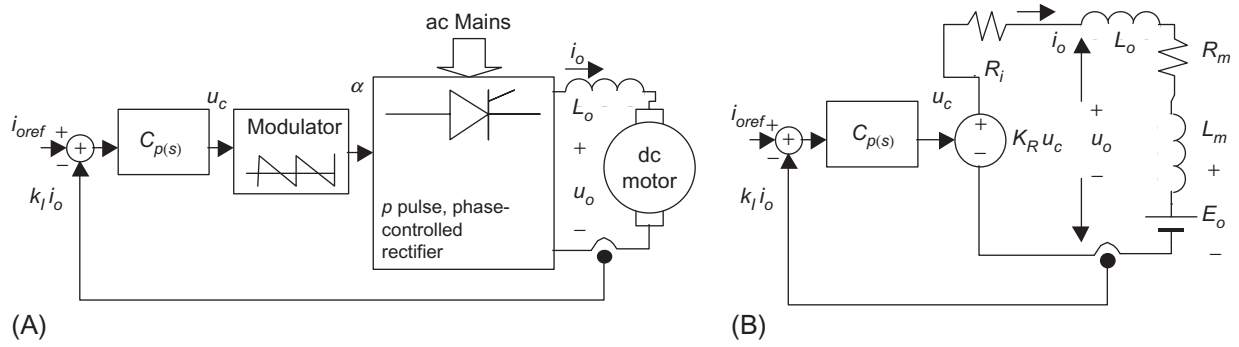

FIG. 35.13 (A) Block diagram of a p pulse phase-controlled rectifier feeding a separately excited dc motor and (B) equivalent averaged circuit.

$$K_R = \frac{\partial U_{DC}}{\partial u_c} = U_p \frac{p}{2u_{cmax}} \sin\left(\frac{\pi}{p}\right) \cos\left(\frac{\pi u_c}{2u_{cmax}}\right) \tag{35.55}$$

For a given rectifier, this gain depends on u_c and should be calculated for a certain quiescent point. However, for feedback design purposes, keeping in mind that the rectifier could be required to be stable in all operating points, the maximum value of K_R, denoted K_{RM}, can be used:

$$K_{RM} = U_p \frac{p}{2u_{cmax}} \sin\left(\frac{\pi}{p}\right) \tag{35.56}$$

The operation of the modulator, coupled to the rectifier thyristors, introduces a nonnegligible time delay, with mean value $T/2p$. Therefore, from Eq. (35.48), the modulator-rectifier transfer function $G_R(s)$ is

$$G_R(s) = \frac{U_{DC}(s)}{u_c(s)} = K_{RM} e^{-s(T/2p)} \approx \frac{K_{RM}}{1 + s(T/2p)} \tag{35.57}$$

Considering zero U_p perturbations, the rectifier equivalent averaged circuit (Fig. 35.13B) includes the loss-free rectifier output resistance R_i, due to the overlap in the commutation phenomenon caused by the mains inductance. Usually, $R_i \approx p\omega l/\pi$ where l is the equivalent inductance of the lines paralleled during the overlap, half of the line inductance for most rectifiers, except for single-phase bridge rectifiers where l is the line inductance. Here, L_o is the smoothing reactor, and R_m, L_m, and E_o are, respectively, the armature internal resistance, inductance, and back electromotive force of a separately excited dc motor (typical load). Assuming the mean value of the output current as the controlled output, making $L_t = L_o + L_m$, $R_t = R_i + R_m$, and $T_t = L_t/R_t$, and applying Laplace transforms to the differential equation obtained from the circuit of Fig. 35.13B, the output current transfer function is

$$\frac{i_o(s)}{U_{DC}(s) - E_o(s)} = \frac{1}{R_t(1 + sT_t)} \tag{35.58}$$

The rectifier and load are now represented by a perturbed (E_o) second-order system (Fig. 35.14). To achieve zero steady-state error, which ensures steady-state insensitivity to the perturbations, and to obtain closed-loop second-order dynamics, a PI controller (35.50) was selected for $C_p(s)$ (Fig. 35.14). Canceling the load pole $(-1/T_t)$ with the PI zero $(-1/T_z)$ yields

$$T_z = L_t/R_t \tag{35.59}$$

The rectifier closed-loop transfer function $i_o(s)/i_{oref}(s)$, with zero E_o perturbations, is

$$\frac{i_o(s)}{i_{oref}(s)} = \frac{2pK_{RM}k_I/(R_t T_p T)}{s^2 + (2p/T)s + 2pK_{RM}k_I/(R_t T_p T)} \tag{35.60}$$

The final value theorem enables the verification of the zero steady-state error. Comparing the denominator of Eq. (35.60) with the second-order polynomial $s^2 + 2\varsigma\omega_n s + \omega_n^2$ yields

$$\omega_n^2 = 2pK_{RM}k_I/(R_t T_p T) \qquad 4\zeta^2\omega_n^2 = (2p/T)^2 \tag{35.61}$$

Since only one degree of freedom is available (T_p), the damping factor ζ is imposed. Usually, $\zeta = \sqrt{2}/2$ is selected, since it often gives the best compromise between response speed and overshoot. Therefore, from Eq. (35.61), Eq. (35.62) arises:

$$T_p = 4\zeta^2 K_{RM}k_I T/(2pR_t) = K_{RM}k_I T/(pR_t) \tag{35.62}$$

Note that both T_z (35.59) and T_p (35.62) are dependent upon circuit parameters. They will have the correct values only for dc motors with parameters closed to the nominal load value. Using Eq. (35.62) in Eq. (35.60) yields Eq. (35.63), the second-order closed-loop transfer function of the rectifier, showing that, with loads close to the nominal value, the rectifier dynamics depend only on the mean delay time $T/2p$:

$$\frac{i_o(s)}{i_{oref}(s)} = \frac{1}{2(T/2p)^2 s^2 + sT/p + 1} \tag{35.63}$$

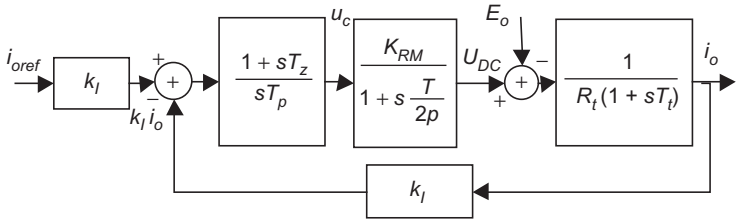

FIG. 35.14 Block diagram of a PI-controlled p pulse rectifier.

From Eq. (35.63), $\omega_n = \sqrt{2}p/T$ results, which is the maximum frequency allowed by $\omega T/2p < \sqrt{2}/2$, the validity limit of Eq. (35.48). This implies that $\zeta \geq \sqrt{2}/2$, which confirms the preceding choice. For $U_p = 300$ V, $p = 6$, $T = 20$ ms, $l = 0.8$ mH, $R_m = 0.5\ \Omega$, $L_t = 50$ mH, $E_o = -150$ V, $u_{cmax} = 10$ V, and $k_I = 0.1$, Fig. 35.15A shows the rectifier output voltage u_{oN} ($u_{oN} = u_o/U_p$) and the step response of the output current i_{oN} ($i_{oN} = i_o/40$) in accordance with Eq. (35.63). Notice that the rectifier is operating in the inverter mode. Fig. 35.15B shows the effect, in the i_o current, of a 50% reduction in the E_o value. The output current is initially disturbed, but the error vanishes rapidly with time.

These modeling and compensator design are valid for small perturbations. For large perturbations, the rectifier firing angles will either saturate at the zero value or originate large current overshoots. For large signals, antiwindup schemes (Fig. 35.16A) or error ramp limiters (or soft starters) and limiters of the PI integral component (Fig. 35.16B) must be used. These solutions will also work with other switching power converters.

To use this rectifier current controller as the inner control loop of a cascaded controller for the dc motor speed regulation, a useful first-order approximation of Eq. (35.63) is $i_o(s)/i_{oref}(s) \approx 1/(sT/p + 1)$.

Although allowing a straightforward compensator selection and precise calculation of its parameters, the rectifier modeling presented here is not suited for stability studies. The rectifier root locus will contain two complex conjugate poles in branches parallel to the imaginary axis. To study the current controller stability, at least the second-order term of Eq. (35.48) in Eq. (35.57) is needed. Alternative ways include the first-order Padé approximation of $e^{-sT/2p}$, $e^{-sT/2p} \approx (1 - sT/4p)/(1 + sT/4p)$, or the second-order approximation, $e^{-sT/2p} \approx (1 - sT/4p + (sT/2p)^2/12)/(1 + sT/4p + (sT/2p)^2/12)$. These approaches introduce zeros in the right half-plane (nonminimum-phase systems) and/or extra poles, giving more realistic results. Taking a first-order approximation and root-locus techniques, it is found that the rectifier is stable for $T_p > K_{RM}\, k_I\, T/(4pR_t)$ ($\zeta > 0.25$). Another approach uses the conditions of magnitude and angle of the delay function $e^{-sT/2p}$ to obtain the system root locus. Also, the switching power converter can be considered as a sampled data system, at frequency p/T, and Z transform can be used to determine the critical gain and first frequency of instability $p/(2\ T)$, usually half the switching frequency of the rectifier.

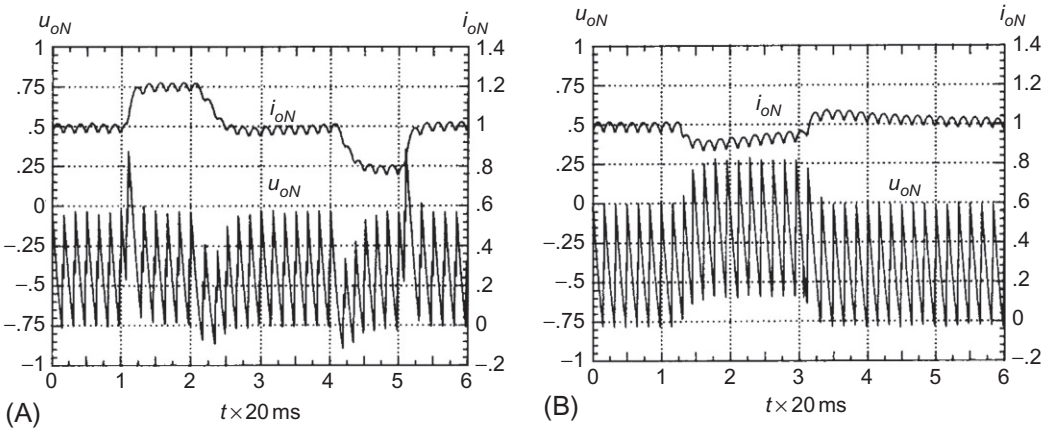

FIG. 35.15 Transient response of the compensated rectifier: (A) step response of the controlled current i_o and (B) the current i_o response to a step chance to 50% of the E_o nominal value during 1.5 T.

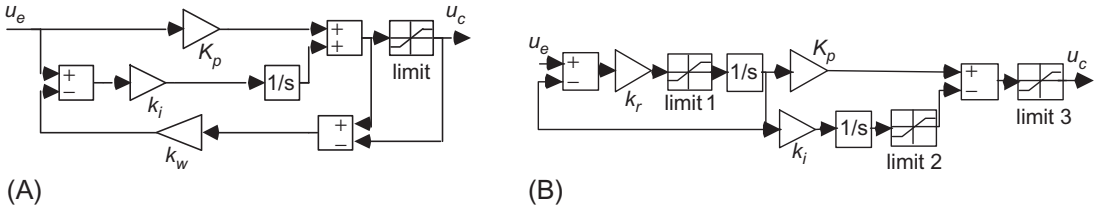

FIG. 35.16 (A) PI implementation with antiwindup (usually $1/K_p \leq k_w \leq K_i/K_p$) to deal with rectifier saturation and (B) PI with ramp limiter/soft starter ($k_r \gg K_p$) and integral component limiter to deal with large perturbations.

EXAMPLE 35.7 Buck–Boost dc/dc converter feedback design in the discontinuous mode

The methodologies just described do not apply to switching power converters operating in the discontinuous mode. However, the derived equivalent averaged circuit approach can be used, calculating the mean value of the discontinuous current supplied to the load, to obtain the equivalent circuit. Consider the buck-boost converter of Example 35.1 (Fig. 35.1) with the new values $L_i = 40\ \mu H$, $C_o = 1000\ \mu F$, and $R_o = 15\ \Omega$. The mean value of the current i_{Lo}, supplied to the output capacitor and resistor of the circuit operating in the discontinuous mode, can be calculated noting that, if the input V_{DC} and output v_o voltages are essentially constant (low ripple), the inductor current rises linearly from zero, peaking at $I_P = (V_{DC}/L_i)\delta_1\, T$ (Fig. 35.17A). As the mean value of i_{Lo}, supposed linear, is $I_{Lo} = (I_P\delta_2 T)/(2\ T)$, using the steady-state input-output relation $V_{DC}\delta_1 = V_o\delta_2$ and the above I_P value, I_{Lo} can be written as

$$I_{Lo} = \frac{\delta_1^2 V_{DC}^2 T}{2 L_i V_o} \tag{35.64}$$

This is a nonlinear relation that could be linearized around an operating point. However, switching power converters in the discontinuous mode seldom operate just around an operating point. Therefore, using a quadratic modulator (Fig. 35.18), obtained integrating the ramp $r(t)$ (Fig. 35.6A) and comparing the quadratic curve to the term $u_{cPI}v_o/V_{DC}^2$ (which is easily implemented using the Unitrode UC3854 integrated circuit), the duty cycle δ_1 is $\delta_1 = \sqrt{u_{cPI}V_o/\left(u_{cmax}V_{DC}^2\right)}$, and a constant incremental factor K_{CV} can be obtained:

$$K_{CV} = \frac{\partial I_{Lo}}{\partial u_{cPI}} = \frac{T}{2 u_{cmax} L_i} \tag{35.65}$$

Considering zero-voltage perturbations and neglecting the modulator delay, the equivalent averaged circuit (Fig. 35.17B) can be used to derive the output voltage to input current transfer function $v_o(s)/i_{Lo}(s) = R_o/(sC_oR_o + 1)$. Using a PI controller (35.50), the closed-loop transfer function is

$$\frac{v_o(s)}{v_{oref}(s)} = \frac{K_{CV}(1 + sT_z)/(C_oT_p)}{s^2 + s\left(T_p + T_zK_{CV}k_vR_o\right)/(C_oR_oT_p) + K_{CV}k_V/(C_oT_p)} \tag{35.66}$$

Since two degrees of freedom exist, the PI constants are derived imposing ζ and ω_n for the second-order denominator of Eq. (35.66), usually $\zeta \geq \sqrt{2}/2$ and $\omega_n \leq 2\pi f_s/10$. Therefore,

$$\begin{aligned} T_p &= K_{CV}k_v/\left(\omega_n^2 C_o\right) \\ T_z &= T_p(2\zeta\omega_n C_oR_o - 1)/(K_{CV}k_vR_o) \end{aligned} \tag{35.67}$$

The transient behavior of this converter, with $\zeta = 1$ and $\omega_n \approx \pi f_s/10$, is shown in Fig. 35.19A. Compared with

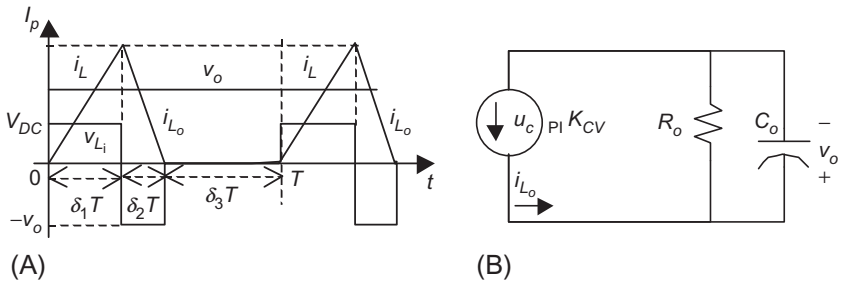

FIG. 35.17 (A) Waveforms of the buck-boost converter in the discontinuous mode and (B) equivalent averaged circuit.

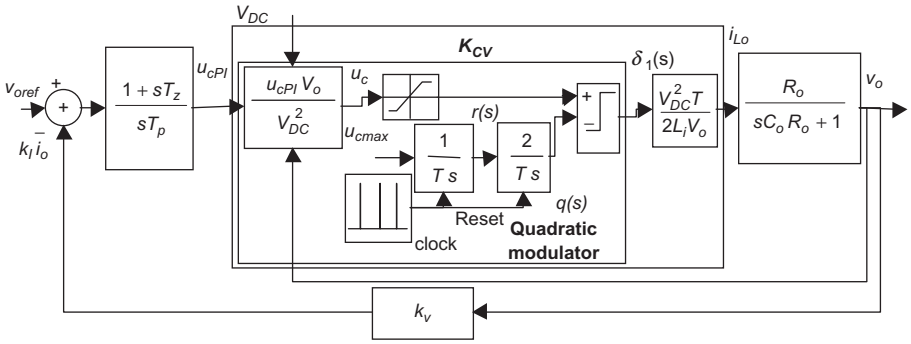

FIG. 35.18 Block diagram of a PI-controlled (feedforward linearized) buck-boost converter operating in the discontinuous mode.

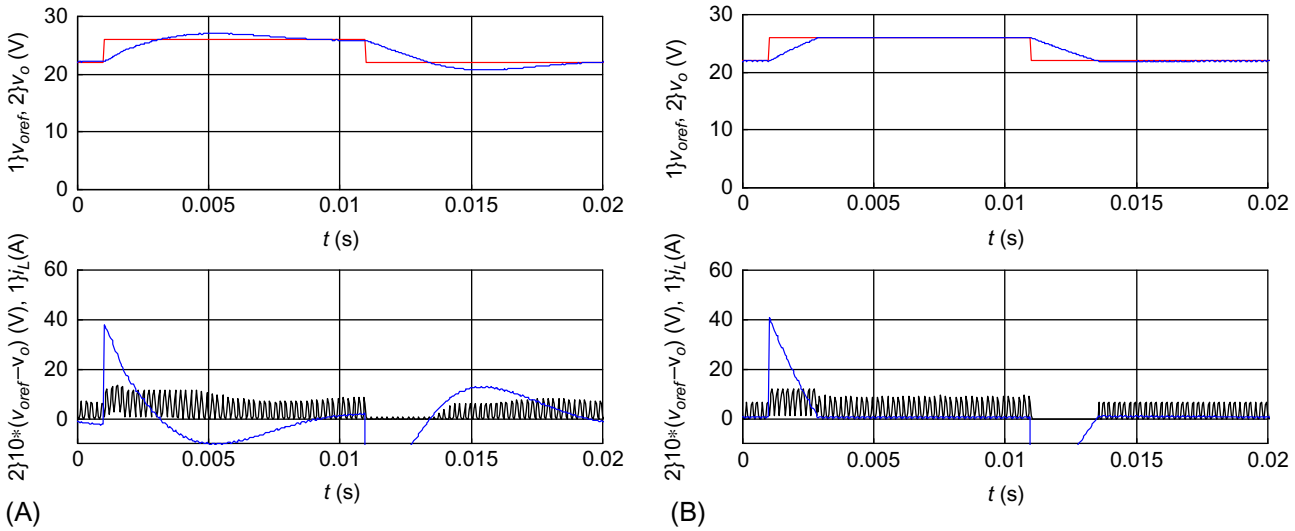

FIG. 35.19 Transient response of the compensated buck-boost converter in the discontinuous mode. At $t=0.001$ s, v_{oref} step from 23 to 26 V. At $t=0.011$ s, v_{oref} step from 26 to 23 V. Top graphs: step reference v_{oref} and output voltage v_o. Bottom graphs: pulses and i_L current; trace peaking at 40, $10\times(v_{oref}-v_o)$: (A) PI-controlled and feedforward linearized buck-boost converter with $\zeta=1$ and $\omega_n\approx\pi f_s/10$ and (B) current-mode-controlled buck-boost with $\zeta=1$ and maximum value $I_{pmax}=15$ A.

Example 35.2, the operation in the discontinuous conduction mode reduces, by 1, the order of the state-space averaged model and eliminates the zero in the right half of the complex plane. The inductor current does not behave as a true state variable, since during the interval $\delta_3 T$ this current is zero, and this value is always the i_{Lo} current initial condition. Given the differences between these two examples, care should be taken to avoid the operation in the continuous mode of converters designed and compensated for the discontinuous mode. This can happen during turn-on or step load changes, and if not prevented, the feedback design should guarantee stability in both modes (Example 35.8 and Fig. 35.20).

EXAMPLE 35.8 Feedback design for the buck–boost dc/dc converter operating in the discontinuous mode and using current-mode control

The performances of the buck-boost converter operating in the discontinuous mode can be greatly enhanced if a *current-mode control* scheme is used, instead of the voltage-mode controller designed in Example 35.7. Current-mode control in switching power converters is the simplest form of state feedback. Current mode needs the measurement of the current i_L (Fig. 35.1) but greatly simplifies the modulator design (compare Fig. 35.18 with Fig. 35.20), since no modulator linearization is used. The measured value, proportional to the current i_L, is

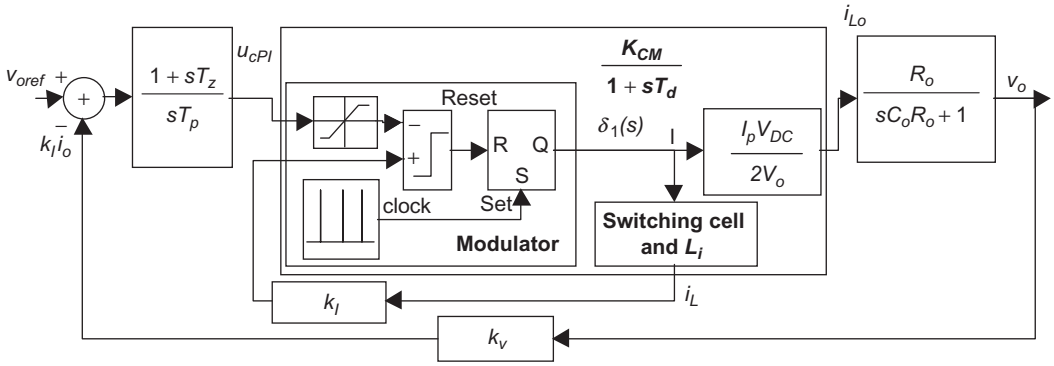

FIG. 35.20 Block diagram of a current-mode controlled buck-boost converter operating in the discontinuous mode.

compared with the value u_{cPI} given by the output voltage controller (Fig. 35.20). The modulator switches off the power semiconductor when $k_I I_P = u_{cPI}$.

Expressed as a function of the peak i_L current I_P, I_{Lo} becomes (Example 35.7) $I_{Lo} = I_P \delta_1 V_{DC}/(2V_o)$, or considering the modulator task $I_{Lo} = u_{cPI}\delta_1 V_{DC}/(2k_I V_o)$. For small perturbations, the incremental gain is $K_{CM} = \partial I_{Lo}/\partial u_{cPI} = \delta_1 V_{DC}/(2k_I V_o)$. An I_{Lo} current delay $T_d = 1/(2f_s)$, related to the switching frequency f_s, can be assumed. The current-mode control transfer function $G_{CM}(s)$ is

$$G_{CM}(s) = \frac{I_{Lo}(s)}{u_{cPI}(s)} \approx \frac{K_{CM}}{1 + sT_d} \approx \frac{\delta_1 V_{DC}}{2k_I V_o(1 + sT_d)} \tag{35.68}$$

Using the approach of Example 35.6, the values for T_z and T_p are given by Eq. (35.69).

$$\begin{aligned} T_z &= R_o C_o \\ T_p &= 4\zeta^2 K_{CM} k_v R_o T_d \end{aligned} \tag{35.69}$$

The transient behavior of this converter, with $\zeta = 1$ and maximum value for I_p, $I_{pmax} = 15$ A, is shown in Fig. 35.19B. The output voltage step response presents no overshoot, no steady-state error, and better dynamics, compared with the response (Fig. 35.19A) obtained using the quadratic modulator (Fig. 35.18). Notice that, with current-mode control, the converter behaves like a reduced-order system and the right half-plane zero is not present.

The current-mode control scheme can be advantageously applied to converters operating in the continuous mode, guarantying short-circuit protection, system order reduction, and better performances. However, for converters operating in the step-up (boost) regime, a stabilizing ramp with negative slope is required, to ensure stability. The stabilizing ramp will transform the signal u_{cPI} in a new signal $u_{cPI} - \text{rem}(k_{sr}t/T)$ where k_{sr} is the needed amplitude for the compensation ramp and the function rem is the remainder of the division of $k_{sr}t$ by T. In the next section, current control of switching power converters will be detailed.

Closed-loop control of resonant converters can be achieved using the outlined approaches, if the resonant phases of operation last for small intervals compared with the fundamental period. Otherwise, the equivalent averaged circuit concept can often be used and linearized, now considering the resonant converter input-output relations, normally functions of the driving frequency and input or output voltages, to replace the δ_1 variable.

EXAMPLE 35.9 Output voltage control in three-phase voltage-source inverters using sinusoidal wave PWM (SPWM) and space-vector modulation (SVM)

Sinusoidal wave PWM

Voltage-source three-phase inverters (Fig. 35.21) are often used to drive squirrel cage induction motors (IM) in variable speed applications.

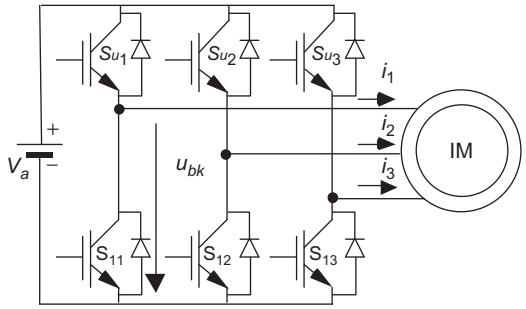

FIG. 35.21 IGBT-based voltage-sourced three-phase inverter with induction motor.

Considering almost ideal power semiconductors, the output voltage $u_{bk}(k \in \{1, 2, 3\})$ dynamics of the inverter is negligible as the output voltage can hardly be considered a state variable in the time scale describing the motor behavior. Therefore, the best known method to create sinusoidal output voltages uses an open-loop modulator with low-frequency sinusoidal waveforms $\sin(\omega t)$, with the amplitude defined by the modulation index m_i ($m_i \in [0, 1]$), modulating high-frequency triangular waveforms $r(t)$ (carriers) (Fig. 35.22), a process similar to the one described in Section 35.2.4. The frequency and phase of the triangular carriers should guarantee half-wave and quarter-wave symmetry for minimum harmonic distortion.

This sinusoidal wave PWM (SPWM) modulator generates the variable γ_k, represented in Fig. 35.22 by the rectangular waveform, which describes the inverter k leg state:

$$\gamma_k = \begin{cases} 1 \rightarrow \text{when } m_i \sin(\omega t) > r(t) \\ 0 \rightarrow \text{when } m_i \sin(\omega t) < r(t) \end{cases} \tag{35.70}$$

The turn-on and turn-off signals for the k leg inverter switches are related with the variable γ_k as follows:

$$\gamma_k = \begin{cases} 1 \rightarrow \text{when } Su_k \text{ is on and } Sl_k \text{ is off} \\ 0 \rightarrow \text{when } Su_k \text{ is off and } Sl_k \text{ is on} \end{cases} \tag{35.71}$$

This applies constant-frequency sinusoidally weighted PWM signals to the gates of each insulated-gate bipolar transistor (IGBT). The PWM signals for all the upper IGBTs (Su_k, $k \in \{1, 2, 3\}$) must be 120° out of phase, and the PWM signal for the lower IGBT Sl_k must be the complement of the Su_k signal. Since transistor turn-on times are usually shorter than turn-off times, some dead time must be included between the Su_k and Sl_k pulses to prevent internal short circuits.

Sinusoidal PWM can be easily implemented using a microprocessor or two digital counters/timers generating the addresses for two lookup tables (one for the triangular function and another for supplying the per unit basis of the sine, whose frequency can vary). Tables can be

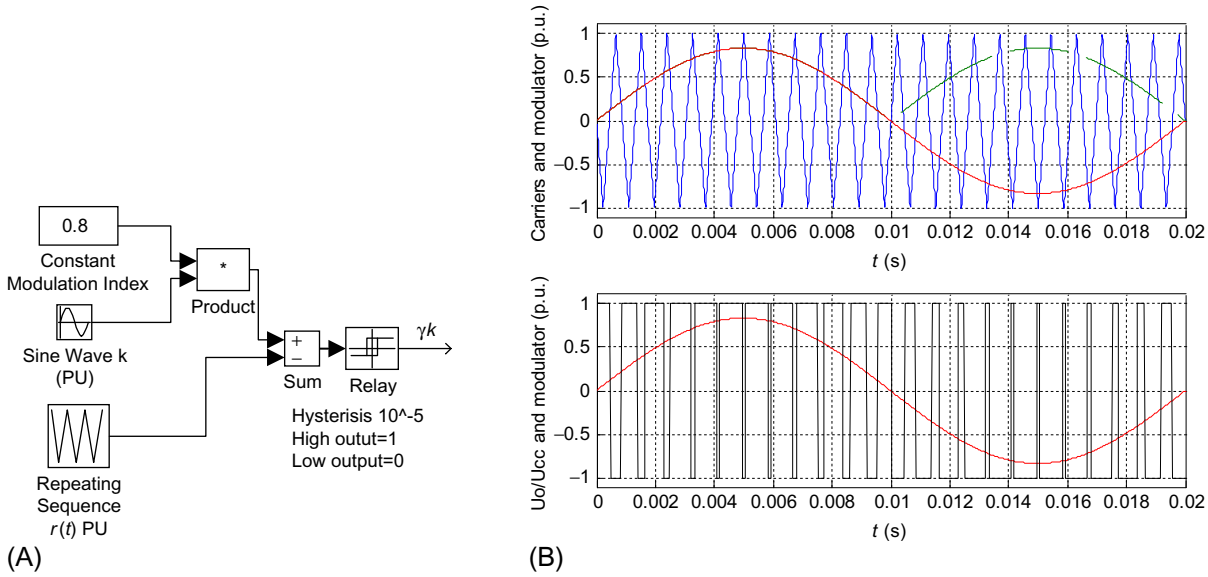

FIG. 35.22 (A) SPWM modulator schematic and (B) main SPWM signals.

stored in read-only memories, ROM, or erasable programmable ROM, EPROM. One multiplier for the modulation index (perhaps into the digital-to-analog (D/A) converter for the sine ROM output) and one hysteresis comparator must also be included.

With SPWM, the first harmonic maximum amplitude of the obtained line-to-line voltage is only about 86% of the inverter dc supply voltage V_a. Since it is expectable that this amplitude should be closer to V_a, different modulating voltages (e.g., adding a third-order harmonic with one-fourth of the fundamental sine amplitude) can be used as long as the fundamental harmonic of the line-to-line voltage is kept sinusoidal. Another way is to leave SPWM and consider the eight possible inverter output voltages trying to directly use then. This will lead to space-vector modulation.

Space vector modulation

Space vector modulation (SVM) is based on the polar representation (Fig. 35.23) of the eight possible base output voltages of the three-phase inverter (Table 35.1, where v_α and v_β are the vector components of vector $\vec{V}_g$, $g \in \{0, 1, 2, 3, 4, 5, 6, 7\}$, obtained with Eq. (35.72)). Therefore, as all the available voltages can be used, SVM does not present the voltage limitation of SPWM.

Furthermore, being a vector technique, SVM fits nicely with the vector control methods often used in IM drives:

$$\begin{bmatrix} v_\alpha \\ v_\beta \end{bmatrix} = \sqrt{\frac{2}{3}} \begin{bmatrix} 1 & -1/2 & -1/2 \\ 0 & \frac{\sqrt{3}}{2} & -\frac{\sqrt{3}}{2} \end{bmatrix} \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} V_a \qquad (35.72)$$

Consider that the vector $\vec{V}_s$ (magnitude V_s and angle [Fcy]) must be applied to the IM. Since there is no such

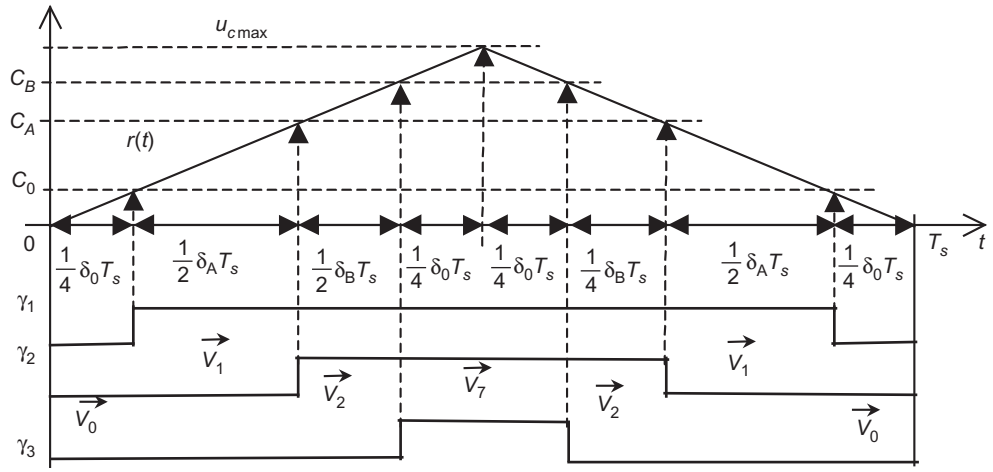

FIG. 35.24 Symmetrical SVM.

vector available directly, SVM uses an averaging technique to apply the two vectors, $\vec{V}_1$ and $\vec{V}_2$, closest to $\vec{V}_s$. The vector $\vec{V}_1$ will be applied during $\delta_A T_s$, while vector $\vec{V}_2$ will last $\delta_B T_s$ (where $1/T_s$ is the inverter switching frequency and δ_A and δ_B are duty cycles, δ_A and $\delta_B \in [0, 1]$). If there is any leftover time in the PWM period T_s, then the zero vector is applied during time $\delta_0 T_s = T_s - \delta_A T_s - \delta_B T_s$. Since there are two zero vectors ($\vec{V}_0$ and $\vec{V}_7$), a symmetrical PWM can be devised, which uses both $\vec{V}_0$ and $\vec{V}_7$, as shown in Fig. 35.24. Such a PWM arrangement minimizes the power semiconductor switching frequency and IM torque ripples

The input to the SVM algorithm is the space vector $\vec{V}_s$, into the sector s_n, with magnitude V_s and angle Φ_s. This vector can be rotated to fit into sector 0 (Fig. 35.23) reducing Φ_s to the first sector, $\Phi = \Phi_s - s_n\pi/3$. For any $\vec{V}_s$ that is not exactly along one of the six nonnull inverter base vectors (Fig. 35.23), SVM must generate an approximation by applying the two adjacent vectors during an appropriate amount of time. The algorithm can be devised considering that the projections of $\vec{V}_s$, onto the two closest base vectors, are values proportional to δ_A and δ_B duty cycles. Using simple trigonometric relations in sector 0 ($0 < \Phi < \pi/3$) (Fig. 35.23) and considering K_T the proportional ratio, δ_A and δ_B are, respectively, $\delta_A = K_T \overline{\mathrm{OA}}$ and $\delta_B = K_T \overline{\mathrm{OA}}$, yielding

$$\begin{aligned} \delta_A &= K_T \frac{2V_s}{\sqrt{3}} \sin\left(\frac{\pi}{3} - \Phi\right) \\ \delta_B &= K_T \frac{2V_s}{\sqrt{3}} \sin\Phi \end{aligned} \tag{35.73}$$

The K_T value can be found if we notice that when $\vec{V}_s = \vec{V}_1$, $\delta_A = 1$, and $\delta_B = 0$ (or when $\vec{V}_s = \vec{V}_2$, $\delta_A = 0$, and $\delta_B = 1$). Therefore, since when $\vec{V}_s = \vec{V}_1$, $V_s = \sqrt{v_\alpha^2 + v_\beta^2} = \sqrt{2/3}V_a$, $\Phi = 0$, or when $\vec{V}_s = \vec{V}_2$, $V_s = \sqrt{2/3}V_a$, $\Phi = \pi/3$, the K_T constant is $K_T = \sqrt{3}/\left(\sqrt{2}V_a\right)$. Hence,

$$\begin{aligned} \delta_A &= \frac{\sqrt{2}V_s}{V_a} \sin\left(\frac{\pi}{3} - \Phi\right) \\ \delta_B &= \frac{\sqrt{2}V_s}{V_a} \sin\Phi \\ \delta_0 &= 1 - \delta_A - \delta_B \end{aligned} \tag{35.74}$$

The obtained resulting vector $\vec{V}_s$ cannot extend beyond the hexagon of Fig. 35.23. This can be understood if the maximum magnitude V_{sm} of a vector with $\Phi = \pi/6$ is calculated. For $\Phi = \pi/6$, the maximum duty cycles are $\delta_A = 1/2$ and $\delta_B = 1/2$. Then, from Eq. (35.74,) $V_{sm} = V_a/\sqrt{2}$ is obtained. This magnitude is lower than that of the vector $\vec{V}_1$ since the ratio between these magnitudes is $\sqrt{3/2}$. To generate sinusoidal voltages, the vector $\vec{V}_s$ must be inside the inner circle of Fig. 35.23, so that it can be rotated without crossing the hexagon boundary. Vectors with tips between this circle and the hexagon are reachable but produce nonsinusoidal line-to-line voltages.

For sector 0 (Fig. 35.23), SVM symmetrical PWM switching variables (γ_1, γ_2, and γ_3) and intervals (Fig. 35.24) can be obtained by comparing a triangular wave with amplitude u_{cmax} (Fig. 35.24, where $r(t) = 2u_{cmax}t/T_s$ and $t \in [0, T_s/2]$), with the following values:

$$\begin{aligned} C_0 &= \frac{u_{c\max}}{2}\delta_0 = \frac{u_{c\max}}{2}(1 - \delta_A - \delta_B) \\ C_A &= \frac{u_{c\max}}{2}\left(\frac{\delta_0}{2} + \delta_A\right) = \frac{u_{c\max}}{2}(1 + \delta_A - \delta_B) \\ C_B &= \frac{u_{c\max}}{2}\left(\frac{\delta_0}{2} + \delta_A + \delta_B\right) = \frac{u_{c\max}}{2}(1 + \delta_A + \delta_B) \end{aligned} \tag{35.75}$$

Extension of Eq. (35.75) to all six sectors can be done if the sector number s_n is considered, together with the auxiliary matrix $\boldsymbol{\Xi}$:

$$\Xi^T = \begin{bmatrix} -1 & -1 & 1 & 1 & 1 & -1 \\ -1 & 1 & 1 & 1 & -1 & -1 \end{bmatrix} \tag{35.76}$$

Generalization of the values C_0, C_A, and C_B, denoted C_{0sn}, C_{Asn}, and C_{Bsn}, is written in Eq. (35.77), knowing that, for example, $\Xi_{\left((sn+4)_{\text{mod }6}+1\right)}$ is the $\boldsymbol{\Xi}$ matrix row with number $(s_n+4)_{\text{mod }6}+1$:

$$\begin{aligned} C_{0sn} &= \frac{u_{c\max}}{2}\left(1+\Xi_{\left((Sn)_{\text{mod}6}+1\right)}\begin{bmatrix}\delta_A\\ \delta_B\end{bmatrix}\right) \\ C_{Asn} &= \frac{u_{c\max}}{2}\left(1+\Xi_{\left((Sn+4)_{\text{mod}6}+1\right)}\begin{bmatrix}\delta_A\\ \delta_B\end{bmatrix}\right) \\ C_{Bsn} &= \frac{u_{c\max}}{2}\left(1+\Xi_{\left((Sn+2)_{\text{mod}6}+1\right)}\begin{bmatrix}\delta_A\\ \delta_B\end{bmatrix}\right) \end{aligned} \tag{35.77}$$

Therefore, γ_1, γ_2, and γ_3 are

$$\begin{aligned} \gamma_1 &= \begin{cases} 0 \rightarrow \text{when } r(t) < C_{0sn} \\ 1 \rightarrow \text{when } r(t) > C_{0sn} \end{cases} \\ \gamma_2 &= \begin{cases} 0 \rightarrow \text{when } r(t) < C_{Asn} \\ 1 \rightarrow \text{when } r(t) > C_{Asn} \end{cases} \\ \gamma_3 &= \begin{cases} 0 \rightarrow \text{when } r(t) < C_{Bsn} \\ 1 \rightarrow \text{when } r(t) > C_{Bsn} \end{cases} \end{aligned} \tag{35.78}$$

Supposing that the space vector $\vec{V}_s$ is now specified in the orthogonal coordinates $\alpha,\beta\left(\vec{V}_\alpha, \vec{V}_\beta\right)$, instead of magnitude V_s and angle Φ_s, the duty cycles δ_A and δ_B can be easily calculated knowing that $v_\alpha = V_s \cos \Phi$ and $v_\beta = V_s \sin \Phi$ and using Eq. (35.74):

$$\begin{aligned} \delta_A &= \frac{\sqrt{2}}{2V_a}\left(\sqrt{3}v_\alpha - v_\beta\right) \\ \delta_B &= \frac{\sqrt{2}}{V_a}v_\beta \end{aligned} \tag{35.79}$$

This equation enables the use of Eqs. (35.77) and (35.78) to obtain SVM in orthogonal coordinates.

Using SVM or SPWM, the closed-loop control of the inverter output currents (induction motor stator currents) can be performed using an approach similar to that outlined in Example 35.6 and decoupling the currents expressed in a d and q rotating frame.

35.3 Sliding-Mode Control of Switching Power Converters

35.3.1 Introduction

All the designed controllers for switching power converters are in fact variable structure controllers, in the sense that the control action changes rapidly from one to another of, usually, two possible $\delta(t)$ values, cyclically changing the converter topology. This is accomplished by the modulator (Fig. 35.6), which creates the switching variable $\delta(t)$ imposing $\delta(t)=1$ or $\delta(t)=0$, to turn on or off the power semiconductors. As a consequence of this discontinuous control action, indispensable for efficiency reasons, state trajectories move back and forth around a certain average surface in the state-space, and variables present some ripple. To avoid the effects of this ripple in the modeling and to apply linear control methodologies to time-variant systems, average values of state variables and state-space averaged models or circuits were presented (Section 35.2). However, a nonlinear approach to the modeling and control problem, taking advantage of the inherent ripple and variable structure behavior of switching power converters, instead of just trying to live with them, would be desirable, especially if enhanced performances could be attained.

In this approach, switching power converter topologies, as discrete nonlinear time-variant systems, are controlled to switch from one dynamics to another when just needed. If this switching occurs at a very high frequency (theoretically infinite), the state dynamics described as in Eq. (35.4) can be enforced to slide along a certain prescribed state-space trajectory. The converter is said to be in sliding mode, the allowed deviations from the trajectory (the ripple) imposing the practical switching frequency.

Sliding-mode control of variable structure systems, such as switching power converters, is particularly interesting because of the inherent robustness [10,11], capability of system order reduction, and appropriateness to the on/off switching of power semiconductors. The control action, being the control equivalent of the management paradigm "just in time" (JIT), provides timely and precise control actions, determined by the control law and the allowed ripple. Therefore, the switching frequency is not constant over all operating regions of the converter.

This section treats the derivation of the control (sliding surface) and switching laws, robustness, stability, constant-frequency operation, and steady-state error elimination necessary for sliding-mode control of switching power converters, also giving some examples.

35.3.2 Principles of Sliding-mode Control

Consider the state-space switched model Eq. (35.4) of a switching converter subsystem and input-output linearization or another technique, to obtain, from state-space equations, one

Eq. (35.80), for each controllable subsystem output $\mathbf{y}=\mathbf{x}$. In the controllability canonical form [12] (also known as input-output decoupled or companion form), Eq. (35.80) is

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[x_h,\ldots x_{j-1},x_j\right]^T=\left[x_{h+1},\ldots,x_j,-f_h(\mathbf{x})-p_h(t)+b_h(\mathbf{x})u_h(t)\right]^{\mathrm{T}} \tag{35.80}$$

where $\mathbf{x}=[x_h,\ldots,x_{j-1},x_j]^{\mathrm{T}}$ is the subsystem state vector, $f_h(\mathbf{x})$ and $b_h(\mathbf{x})$ are functions of $\mathbf{x}$, $p_h(t)$ represents the external disturbances, and $u_h(t)$ is the control input. In this special form of state-space modeling, the state variables are chosen so that the x_{i+1} variable ($i\in\{h,\ldots,j-1\}$) is the time derivative of x_i, that is, $\mathbf{x}=\left[x_h,\dot{x}_h,x_h,\ldots,\overset{m}{x}_h\right]^{\mathrm{T}}$, where $m=j-h$ [13].

35.3.2.1 Control Law (Sliding Surface)

The required closed-loop dynamics for the subsystem output vector $\mathbf{y}=\mathbf{x}$ can be chosen to verify Eq. (35.81) with selected k_i values. This is a model reference adaptive control approach to impose a state trajectory that advantageously reduces the system order ($j-h+1$):

$$\frac{\mathrm{d}x_j}{\mathrm{d}t}=-\sum_{i=h}^{j-1}\frac{k_i}{k_j}x_{i+1} \tag{35.81}$$

Effectively, in a single-input single-output (SISO) subsystem, the order is reduced by unity, applying the restriction Eq. (35.81). In a multiple-input multiple-output (MIMO) system, in which ν-independent restrictions could be imposed (usually with ν degrees of freedom), the order could often be reduced in ν units. Indeed, from Eq. (35.81), the dynamics of the jth term of $\mathbf{x}$ is linearly dependent from the $j-h$ first terms:

$$\frac{\mathrm{d}x_j}{\mathrm{d}t}=-\sum_{i=h}^{j-1}\frac{k_i}{k_j}x_{i+1}=-\sum_{i=h}^{j-1}\frac{k_i}{k_j}\frac{\mathrm{d}x_i}{\mathrm{d}t} \tag{35.82}$$

The controllability canonical model allows the direct calculation of the needed control input to achieve the desired dynamics Eq. (35.81). In fact, as the control action should enforce the state vector $\mathbf{x}$, to follow the reference vector $\mathbf{x}_r=\left[x_{h_r},\dot{x}_{h_r},\ddot{x}_{h_r},\ldots,x_{h_r}^m\right]^T$, the tracking error vector will be $\mathbf{e}=\left[x_{h_r}-x_h,\ldots,x_{j-1r}-x_{j-1},x_{jr}-x_j\right]^T$ or $\mathbf{e}=\left[e_{x_h},\ldots,e_{xj-1},e_{x_j}\right]^T$. Thus, equating the subexpressions for $\mathrm{d}x_j/\mathrm{d}t$ of Eqs. (35.80) and (35.81), the necessary control input $u_h(t)$ is

$$u_h(t)=\frac{p_h(t)+f_h(x)+\dfrac{\mathrm{d}x_j}{\mathrm{d}t}}{b_h(x)}=\frac{p_h(t)+f_h(x)-\displaystyle\sum_{i=h}^{j-1}\frac{k_i}{k_j}x_{i+1_r}+\sum_{i=h}^{j-1}\frac{k_i}{k_j}e_{x_{i+1}}}{b_h(x)} \tag{35.83}$$

This expression is the required closed-loop control law, but unfortunately, it depends on the system parameters and on external perturbations and is difficult to compute. Moreover, for some output requirements, Eq. (35.83) would give extremely high values for the control input $u_h(t)$, which would be impractical or almost impossible.

In most switching power converters, $u_h(t)$ is discontinuous. Yet, if we assume one or more discontinuity borders dividing the state-space into subspaces, the existence and uniqueness of the solution are guaranteed out of the discontinuity borders, since in each subspace the input is continuous. The discontinuity borders are subspace switching hypersurfaces, whose order is the space order minus one, along which the subsystem state slides, since its intersections with the auxiliary equations defining the discontinuity surfaces can give the needed control input.

Within the sliding-mode control (SMC) theory, assuming a certain dynamic error driven to zero, one auxiliary equation (sliding surface) and the equivalent control input $u_h(t)$ can be obtained, integrating both sides of Eq. (35.82) with null initial conditions:

$$k_jx_j+\sum_{i=h}^{j-1}k_ix_i=\sum_{i=h}^{j}k_ix_i=0 \tag{35.84}$$

This equation represents the discontinuity surface (hyperplane) and just defines the necessary sliding surface $S(x_i,\,t)$ to obtain the prescribed dynamics of Eq. (35.81):

$$S(x_i,t)=\sum_{i=h}^{j}k_ix_i=0 \tag{35.85}$$

In fact, by taking the first time derivative of $S(x_i,\,t)$, $\dot{S}(x_i,t)=0$; solving it for $\mathrm{d}x_j/\mathrm{d}t$; and substituting the result in Eq. (35.83), the dynamics specified by Eq. (35.81) is obtained. This means that the control problem is reduced to a first-order problem, since it is only necessary to calculate the time derivative of Eq. (35.85) to obtain the dynamics (35.81) and the needed control input $u_h(t)$.

The sliding surface Eq. (35.85), as the dynamics of the converter subsystem, must be a Routh-Hurwitz polynomial and verify the sliding manifold invariance conditions, $S(x_i,\,t)=0$ and $\dot{S}(x_i,t)=0$. Consequently, the closed-loop controlled system behaves as a stable system of order $j-h$, whose dynamics is imposed by the coefficients k_i, which can be chosen by pole placement of the poles of the order $m=j-h$ polynomial. Alternatively, certain kinds of polynomials can be advantageously used [14]: Butterworth, Bessel, Chebyshev, elliptic (or Cauer), binomial, and minimum integral of time absolute error product (ITAE). Most useful are Bessel polynomials $B_E(s)$ (Eq. (35.88)), which minimize the system response time t_r, providing no overshoot; the polynomials $I_{TAE}(s)$ (Eq. (35.87)) that minimize the ITAE criterion for a system with desired natural oscillating frequency ω_o; and binomial

polynomials $B_I(s)$ (Eq. (35.86)). For $m>1$, ITAE polynomials give faster responses than binomial polynomials:

$$B_I(s)_m=(s+\omega_o)^m = \begin{cases} m=0\Rightarrow B_I(s)=1 \\ m=1\Rightarrow B_I(s)=s+\omega_o \\ m=2\Rightarrow B_I(s)=s^2+2\omega_o s+\omega_0^2 \\ m=3\Rightarrow B_I(s)=s^3+3\omega_o s^2+3\omega_0^2 s+\omega_0^3 \\ m=4\Rightarrow B_I(s)=s^4+4\omega_o s^3+6\omega_0^2 s^2+4\omega_0^3 s+\omega_0^4 \\ \dots \end{cases} \tag{35.86}$$

$$I_{TAE}(s)_m = \begin{cases} m=0\Rightarrow I_{TAE}(s)=1 \\ m=1\Rightarrow I_{TAE}(s)=s+\omega_o \\ m=2\Rightarrow I_{TAE}(s)=s^2+1.4\omega_o s+\omega_0^2 \\ m=3\Rightarrow I_{TAE}(s)=s^3+1.75\omega_o s^2+2.15\omega_0^2 s+\omega_0^3 \\ m=4\Rightarrow I_{TAE}(s)=s^4+2.1\omega_o s^3+3.4\omega_0^2 s^2 \\ \qquad\qquad +2.7\omega_0^3 s+\omega_0^4 \\ \dots \end{cases} \tag{35.87}$$

$$B_E(s)_m = \begin{cases} m=0\Rightarrow B_E(s) = 1 \\ m=1\Rightarrow B_E(s) = st_r+1 \\ m=2\Rightarrow B_E(s) = \dfrac{(st_r)^2+3st_r+3}{3} \\ m=3\Rightarrow B_E(s) = \dfrac{\left((st_r)^2+3.678st_r+6.459\right)(st_r+2.322)}{15} \\ \qquad\qquad = \dfrac{(st_t)^3+6(st_r)^2+15st_r+15}{15} \\ m=4\Rightarrow B_E(s) = \dfrac{(st_r)^4+10(st_r)^3+45(st_r)^2+105(st_r)+105}{105} \\ \dots \end{cases} \tag{35.88}$$

These polynomials can be the reference model for this model reference adaptive control method.

35.3.2.2 Closed-Loop Control Input–Output Decoupled Form

For closed-loop control applications, instead of the state variables x_i, it is worthy to consider, as new state variables, the errors e_{x_i}, components of the error vector $\mathbf{e}=\left[e_{x_h}, \dot{e}_{x_h}, e_{x_h}, \dots, \overset{m}{e}_{x_h}\right]^{\mathrm{T}}$ of the state-space variables x_i, relative to a given reference x_{i_r} Eq. (35.90). The new controllability canonical model of the system is

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[e_{x_h}, \dots, e_{x_{j-1}}, e_{x_j}\right]^{\mathrm{T}} = \left[e_{x_{h+1}}, \dots, e_{x_j}, -f_e(\mathbf{e})+p_e(t)-b_e(\mathbf{e})u_h(t)\right]^{\mathrm{T}} \tag{35.89}$$

where $f_e(\mathbf{e})$, $p_e(t)$, and $b_e(\mathbf{e})$ are functions of the error vector $\mathbf{e}$.

As the transformation of variables

$$e_{x_i}=x_{i_r}-x_i \quad \text{with} \quad i=h,\dots,j \tag{35.90}$$

is linear, the Routh-Hurwitz polynomial for the new sliding surface $S(e_{x_i},t)$ is

$$S(e_{x_i},t)=\sum_{i=h}^{j} k_i e_{x_i}=0 \tag{35.91}$$

Since $e_{x_{i+1}}(s)=se_{x_i}(s)$, this *control law*, from Eqs. (35.86) to (35.88), can be written as $S(\mathbf{e},s)=e_{x_i}(s+\omega_o)^m$ and is robust as it does not depend on circuit parameters, disturbances, or operating conditions, but only on the imposed k_i parameters and on the state variable errors e_{x_i}, which can usually be measured or estimated. The control law Eq. (35.91) enables the desired dynamics of the output variable(s), if the semiconductor switching strategy is designed to guarantee the system stability. In practice, the finite switching frequency of the semiconductors will impose a certain dynamic error ε steered to zero. The control law Eq. (35.91) is the required controller for the closed-loop SISO subsystem with output $\mathbf{y}$.

35.3.2.3 Stability

Existence condition. The existence of the operation in sliding mode implies $S(e_{x_i},t)=0$. Also, to stay in this regime, the control system should guarantee $\dot{S}(e_{x_i},t)=0$. Therefore, the semiconductor switching law must ensure the stability condition for the system in sliding mode, written as

$$S(e_{x_i},t)\dot{S}(e_{x_i},t)<0 \tag{35.92}$$

The fulfillment of this inequality ensures the convergence of the system state trajectories to the sliding surface $S(e_{x_i},t)=0$, since

- if $S(e_{x_i},t)>0$ and $\dot{S}(e_{x_i},t)<0$, then $S(e_{x_i},t)$ will decrease to zero,
- if $S(e_{x_i},t)<0$ and $\dot{S}(e_{x_i},t)>0$, then $S(e_{x_i}t)$ will increase toward zero.

Hence, if Eq. (35.92) is verified, then $S(e_{x_i},t)$ will converge to zero. The condition (35.92) is the manifold $S(e_{x_i},t)$ invariance condition or the sliding-mode existence condition.

Given the state-space model Eq. (35.89) as a function of the error vector $\mathbf{e}$ and, from $\dot{S}(e_{x_i},t)=0$, the equivalent average control input $U_{eq}(t)$ that must be applied to the system in order that the system state slides along the surface, Eq. (35.91) is given by

$$U_{eq}(t)=\frac{k_h\dfrac{\mathrm{d}e_{x_h}}{\mathrm{d}t}+k_{h+1}\dfrac{\mathrm{d}e_{x_{h+1}}}{\mathrm{d}t}+\dots+k_{j-1}+\dfrac{\mathrm{d}e_{x_{j-1}}}{\mathrm{d}t}+k_j(-f_e(\mathbf{e})+p_e(t))}{k_j b_e(\mathbf{e})} \tag{35.93}$$

This control input $U_{eq}(t)$ ensures the converter subsystem operation in the sliding mode.

Reaching condition. The fulfillment of $S(e_{x_i},t)\dot{S}(e_{x_i},t)<0$ as $S(e_{x_i},t)\dot{S}(e_{x_i},t)=(1/2)\dot{S}^2(e_{x_i},t)$ implies that the distance between the system state and the sliding surface will tend to zero, since $S^2(e_{x_i},t)$ can be considered as a measure for this distance. This means that the system will reach sliding mode. Additionally, from Eq. (35.89), it can be written as

$$\frac{de_{x_j}}{dt}=-f_e(\mathbf{e})+p_e(t)-b_e(\mathbf{e})u_h(t) \tag{35.94}$$

From Eq. (35.91), Eq. (35.95) is obtained:

$$S(e_{x_i}t)=\sum_{i=h}^{j}k_ie_{x_i}=k_he_{x_h}+k_{h+1}\frac{\mathrm{d}e_{x_h}}{\mathrm{d}t}+k_{h+2}\frac{\mathrm{d}^2e_{x_h}}{\mathrm{d}t^2}+\ldots+k_j\frac{\mathrm{d}^me_{x_h}}{\mathrm{d}t^m} \tag{35.95}$$

If $S(e_{x_i},t)>0$, from the Routh-Hurwitz property of Eq. (35.91), then $e_{x_j}>0$. In this case, to reach $S(e_{x_i},t)=0$, it is necessary to impose $-b_e(\mathbf{e})u_h(t)=-U$ in Eq. (35.94), with U chosen to guarantee $\mathrm{d}e_{x_j}/\mathrm{d}t<0$. After a certain time, e_{x_j} will be $e_{x_j}=\mathrm{d}^me_{x_h}/\mathrm{d}t^m<0$, implying along with Eq. (35.95) that $\dot{S}(e_{x_i},t)<0$, thus verifying Eq. (35.92). Therefore, every term of $S(e_{x_i},t)$ will be negative, which implies, after a certain time, an error $e_{x_h}<0$ and $S(e_{x_i},t)<0$. Hence, the system will reach sliding mode, staying there if $U=U_{eq}(t)$. This same reasoning can be made for $S(e_{x_i},t)<0$; it is now being necessary to impose $-b_e(\mathbf{e})u_h(t)=+U$, with U high enough to guarantee $\mathrm{d}e_{x_j}/\mathrm{d}t>0$.

To ensure that the system always reaches sliding-mode operation, it is necessary to calculate the maximum value of $U_{eq}(t)$ and U_{eqmax} and also impose the reaching condition:

$$U>U_{eqmax} \tag{35.96}$$

This means that the power supply voltage values U should be chosen high enough to additionally account for the maximum effects of the perturbations. With step inputs, even with $U>U_{eqmax}$, the converter usually loses sliding mode, but it will reach it again, even if the U_{eqmax} is calculated considering only the maximum steady-state values for the perturbations.

35.3.2.4 Switching Law

From the foregoing considerations, supposing a system with two possible structures, the semiconductor switching strategy must ensure $S(e_{x_i},t)\dot{S}(e_{x_i},t)<0$. Therefore, if $S(e_{x_i},t)>0$, then $\dot{S}(e_{x_i},t)<0$, which implies, as seen, $-b_e(\mathbf{e})u_h(t)=-U$ (the sign of $b_e(\mathbf{e})$ must be known). Also, if $S(e_{x_i},t)<0$, then $\dot{S}(e_{x_i},t)>0$, which implies $-b_e(\mathbf{e})u_h(t)=+U$. This imposes the switching between two structures at infinite frequency. Since power semiconductors can only switch at finite frequency, in practice, a small enough error for $S(e_{x_i},t)$ must be allowed $(-\varepsilon<S(e_{x_i},t)<+\varepsilon)$. Hence, the switching law between the two possible system structures might be

$$u_h(t)=\begin{cases}U/b_e(\mathbf{e}) \text{ for } S(e_{x_i}t)>+\varepsilon\\ -U/b_e(\mathbf{e}) \text{ for } S(e_{x_i}t)<-\varepsilon\end{cases} \tag{35.97}$$

The condition Eq. (35.97) determines the control input to be applied and therefore represents the semiconductor switching strategy or switching function. This law determines a two-level pulse-width modulator with JIT switching (variable frequency).

35.3.2.5 Robustness

The dynamics of a system, with closed-loop control using the control law Eq. (35.91) and the switching law Eq. (35.97), does not depend on the system operating point, load, circuit parameters, power supply, or bounded disturbances, as long as the control input $u_h(t)$ is large enough to maintain the converter subsystem in sliding mode. Therefore, it is said that the switching power converter dynamics, operating in sliding mode, is robust against changing operating conditions, variations of circuit parameters, and external disturbances. The desired dynamics for the output variable(s) is determined only by the k_i coefficients of the control law Eq. (35.91), as long as the switching law (35.97) maintains the converter in sliding mode.

35.3.3 Constant-Frequency Operation

Prefixed switching frequency can be achieved, even with the sliding-mode controllers, at the cost of losing the JIT action. As the sliding-mode controller changes the control input when needed and not at a certain prefixed rhythm, applications needing constant switching frequency (such as thyristor rectifiers or resonant converters) must compare $S(e_{xi}, t)$ (hysteresis width 2ι much narrower than 2ε) with auxiliary triangular waveforms (Fig. 35.25A), auxiliary sawtooth functions (Fig. 35.25B), three-level clocks (Fig. 35.25C), or phase-locked loop control of the comparator hysteresis variable width 2ε [15]. However, as illustrated in Fig. 35.25D, steady-state errors do appear. Often, they should be eliminated as described in Section 35.3.4.

35.3.4 Steady-State Error Elimination in Converters with Continuous Control Inputs

In the ideal sliding mode, state trajectories are directed toward the sliding surface (35.91) and move exactly along the discontinuity surface, switching between the possible system structures at infinite frequency. Practical sliding modes cannot switch at infinite frequency and therefore exhibit phase-plane trajectory oscillations inside a hysteresis band of width 2ε, centered in the discontinuity surface.

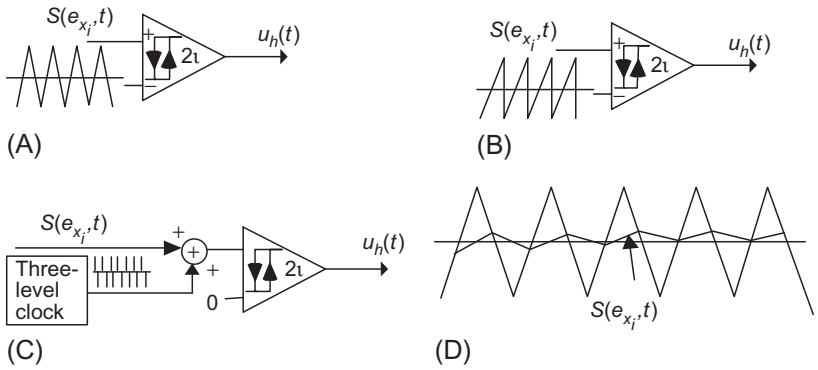

FIG. 35.25 Auxiliary functions and methods to obtain constant switching frequency with sliding-mode controllers. (A) Using a triangular carrier; (B) using a sawtooth carrier; (C) using a three-level clock; (D) generation of steady-state error.

The switching law Eq. (35.91) permits no steady-state errors as long as $S(e_{x_i}, t)$ tends to zero, which implies no restrictions on the commutation frequency. Control circuits operating at constant frequency or needed continuous inputs or particular limitations of the power semiconductors, such as minimum on or off times, can originate $S(e_{x_i}, t) = \varepsilon_1 \neq 0$. The steady-state error (e_{x_h}) of the x_h variable $x_{h_r} - x_h = \varepsilon_1 / k_h$ can be eliminated, increasing the system order by 1. The new state-space controllability canonical form, considering the error e_{x_j}, between the variables and their references, as the state vector, is

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int e_{x_h}dt, e_{x_h}, \ldots, e_{x_{j-1}}, e_{x_j}\right]^{\mathrm{T}} = \left[e_{x_h}, e_{x_{h+1}}, \ldots, e_{x_j}, -f_e(\mathbf{e}) - p_e(t) - b_e(\mathbf{e})u_h(t)\right]^{\mathrm{T}} \tag{35.98}$$

The new sliding surface $S(e_{x_i}, t)$ written from Eq. (35.91), considering the new system in Eq. (35.98), is

$$S(e_{x_i}t) = k_0 \int e_{x_h}\mathrm{d}t + \sum_{i=h}^{j} k_i e_{x_i} = 0 \tag{35.99}$$

This sliding surface offers zero-state error, even if $S(e_{x_i}, t) = \varepsilon_1$ due to the hardware errors or fixed (or limited) frequency switching. Indeed, at the steady state, the only nonzero term is $k_0 \int e_{x_h}\mathrm{d}t = \varepsilon_1$. Also, like Eq. (35.91), this closed-loop control law does not depend on system parameters or perturbations to ensure a prescribed closed-loop dynamics similar to Eq. (35.81) with an error approaching zero.

The approach outlined herein precisely defines the control law (sliding surface (35.91) or (35.99)) needed to obtain the selected dynamics and the switching law Eq. (35.97). As the control law allows the implementation of the system controller and the switching law gives the PWM modulator, there is no need to design linear or nonlinear controllers, based on linear converter models, or devise offline PWM modulators. Therefore, sliding-mode control theory, applied to switching power converters, provides a systematic method to generate both the controller(s) (usually nonlinear) and the modulator(s) that will ensure a model reference robust dynamics, solving the control problem of switching power converters.

In the next examples, it is shown that the sliding-mode controllers use (nonlinear) state feedback, therefore, needing to measure the state variables and often other variables, since they use more system information. This is a disadvantage since more sensors are needed. However, the straightforward control design and obtained performances are much better than those obtained with the averaged models, the use of more sensors being really valued. Alternatively to the extra sensors, state observers can be used [12,13].

35.3.5 Examples: Buck–Boost DC/DC Converter, Half-bridge Inverter, 12-Pulse Parallel Rectifiers, Audio Power Amplifiers, Near Unity Power Factor Rectifiers, Multilevel Inverters, Matrix Converters

EXAMPLE 35.10 Sliding-mode control of the buck–boost dc/dc converter

Consider again the buck-boost converter of Fig. 35.1 and assume the converter output voltage v_o to be the controlled output. From Section 35.2, using the switched state-space model of Eq. (35.11), making $\mathrm{d}v_o/\mathrm{d}t = \theta$, and calculating the first time derivative of θ, the controllability canonical model (35.100), where $i_o = v_o/R_o$, is obtained:

$$\begin{aligned}\frac{\mathrm{d}v_o}{\mathrm{d}t} &= \theta = \frac{1-\delta(t)}{C_o}i_L - \frac{i_o}{C_o}\\ \frac{\mathrm{d}\theta}{\mathrm{d}t} &= -\frac{(1-\delta(t))^2}{L_i C_o}v_o - \frac{C_o\theta + i_o}{C_o(1-\delta(t))}\frac{\mathrm{d}\delta(t)}{\mathrm{d}t}\\ &\quad -\frac{1}{C_o}\frac{\mathrm{d}i_o}{\mathrm{d}t} + \frac{\delta(t)(1-\delta(t))}{C_o L_i}V_{DC}\end{aligned} \tag{35.100}$$

This model, written in the form of Eq. (35.80), contains two state variables, v_o and θ. Therefore, from Eq. (35.91) and considering $e_{v_o} = v_{o_r} - v_o, e_\theta = \theta_r - \theta$, the control law (sliding surface) is

$$S(e_{x_i}t)=\sum_{i=h}^{2}k_i e_{x_i}=k_1(v_{o_r}-v_o)+k_2\frac{\mathrm{d}v_{o_r}}{\mathrm{d}t}-k_2\frac{\mathrm{d}v_o}{\mathrm{d}t}$$
$$=k_1(v_{o_r}-v_o)+k_2\frac{\mathrm{d}v_{or}}{\mathrm{d}t}-\frac{k_2}{C_o}(1-\delta(t))i_L$$
$$+\frac{k_2}{C_o}i_o=0 \tag{35.101}$$

This sliding surface depends on the variable $\delta(t)$, which should be precisely the result of the application, in Eq. (35.101), of a switching law similar to Eq. (35.97). Assuming an ideal up-down converter and slow variations, from Eq. (35.31), the variable $\delta(t)$ can be averaged to $\delta_1=v_o/(v_o+V_{DC})$. Substituting this relation in Eq. (35.101) and rearranging, Eq. (35.102) is derived:

$$S(e_{x_i}t)=\frac{C_o k_1}{k_2}\left(\frac{v_o+V_{DC}}{v_o}\right)$$
$$\times\left((v_{or}-v_0)+\frac{k_2}{k_1}\frac{\mathrm{d}v_{o_r}}{\mathrm{d}t}+\frac{k_2}{k_1}\frac{1}{C_o}i_o\right)-i_L=0 \tag{35.102}$$

This control law shows that the power supply voltage V_{DC} must be measured, as well as the output voltage v_o and the currents i_o and i_L.

To obtain the switching law from stability considerations (35.92), the time derivative of $S(e_{x_i},t)$, supposing $(v_o+V_{DC})/v_o$ almost constant, is

$$\dot{S}(e_{x_i},t)=\frac{C_o k_1}{k_2}\left(\frac{v_o+V_{DC}}{v_o}\right)$$
$$\times\left(\frac{\mathrm{d}e_{v_o}}{\mathrm{d}t}+\frac{k_2}{k_1}\frac{\mathrm{d}^2v_{o_r}}{\mathrm{d}t^2}+\frac{k_2}{k_1C_o}\frac{\mathrm{d}i_o}{\mathrm{d}t}\right)-\frac{\mathrm{d}i_L}{\mathrm{d}t} \tag{35.103}$$

If $S(e_{x_i},t)>0$, then, from Eq. (35.92), $\dot{S}(e_{x_i},t)<0$ must hold. Analyzing Eq. (35.103), we can conclude that, if $S(e_{x_i},t)>0$, $\dot{S}(e_{x_i},t)$ is negative if, and only if, $\mathrm{d}i_L/\mathrm{d}t>0$. Therefore, for positive errors $e_{v_o}>0$, the current i_L must be increased, which implies $\delta(t)=1$. Similarly, for $S(e_{x_i},t)<0$, $\mathrm{d}i_L/\mathrm{d}t<0$, and $\delta(t)=0$. Thus, a switching law similar to Eq. (35.97) is obtained:

$$\delta(t)=\begin{cases}1 & \text{for } S(e_{x_i},t)>+e\\ 0 & \text{for } S(e_{x_i},t)<-e\end{cases} \tag{35.104}$$

The same switching law could be obtained from knowing the dynamic behavior of this nonminimum-phase up-down converter: to increase (decrease) the output voltage, a previous increase (decrease) of the i_L current is mandatory.

Eq. (35.101) shows that, if the buck-boost converter is into the sliding mode ($S(e_{x_i},t)=0$), the dynamics of the output voltage error tends exponentially to zero with time constant k_2/k_1 ($k_2/k_1>0$). Since during step transients, the converter is in the reaching mode, the time constant k_2/k_1 cannot be designed to originate error variations larger than the one allowed by the self-dynamics of the converter excited by a certain maximum permissible i_L current. Given the polynomials (35.86–35.88) with $m=1$, $k_1/k_2=\omega_o$ should be much lower than the finite switching frequency ($1/T$) of the converter. Therefore, the time constant must obey $k_2/k_1\gg T$. Then, knowing that k_2 and k_1 are both imposed, the control designer can tailor the time constant as needed, provided that the above restrictions are observed.

Short-circuit-proof operation for the sliding-mode-controlled buck-boost converter can be derived from Eq. (35.102), noting that all the terms to the left of i_L represent the set point for this current. Therefore, limiting these terms (Fig. 35.26, saturation block, with $i_{Lmax}=40$ A), the switching law (35.104) ensures that the output current will not rise above the maximum imposed limit. Given the converter nonminimum-phase behavior, this i_L current limit is fundamental to reach the sliding mode of operation with step disturbances.

The block diagram (Fig. 35.26A) of the implemented control law Eq. (35.102) (with $C_o k_1/k_2=4$) and switching law (35.103) (with $\varepsilon=0.3$) does not include the time derivative of the reference ($\mathrm{d}v_{o_r}/\mathrm{d}t$) since, in a dc/dc converter, its value is considered zero. The controller hardware (or software), derived using just the sliding-mode approach, operates only in a closed-loop.

The resulting performance (Fig. 35.26B) is much better than that obtained with the PID notch filter (compare with Example 35.4 and Fig. 35.9B), with a higher response speed and robustness against power supply variations.

35.3.5.1 Example 35.11: Sliding Mode Control of the Single-Phase Half-Bridge Converter

Consider the half-bridge four-quadrant converter of Fig. 35.27 with the output filter and the inductive load ($V_{DCmax}=300$ V, $V_{DCmin}=230$ V, $R_i=0.1\ \Omega$, $L_o=4$ mH, $C_o=470\ \mu$F, inductive load with nominal values $R_o=7\ \Omega$, and $L_o=1$ mH).

Assuming that power switches, output filter capacitor, and power supply are all ideal and a generic load with allowed slow variations, the switched state-space model of the converter, with state variables v_o and i_L, is

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix}v_o\\ i_L\end{bmatrix}=\begin{bmatrix}0 & 1/C_o\\ -1/L_o & -R_i/L_o\end{bmatrix}\begin{bmatrix}v_o\\ i_L\end{bmatrix}$$
$$+\begin{bmatrix}-1/C_o & 0\\ 0 & 1/L_o\end{bmatrix}\begin{bmatrix}i_o\\ \delta(t)V_{DC}\end{bmatrix} \tag{35.105}$$

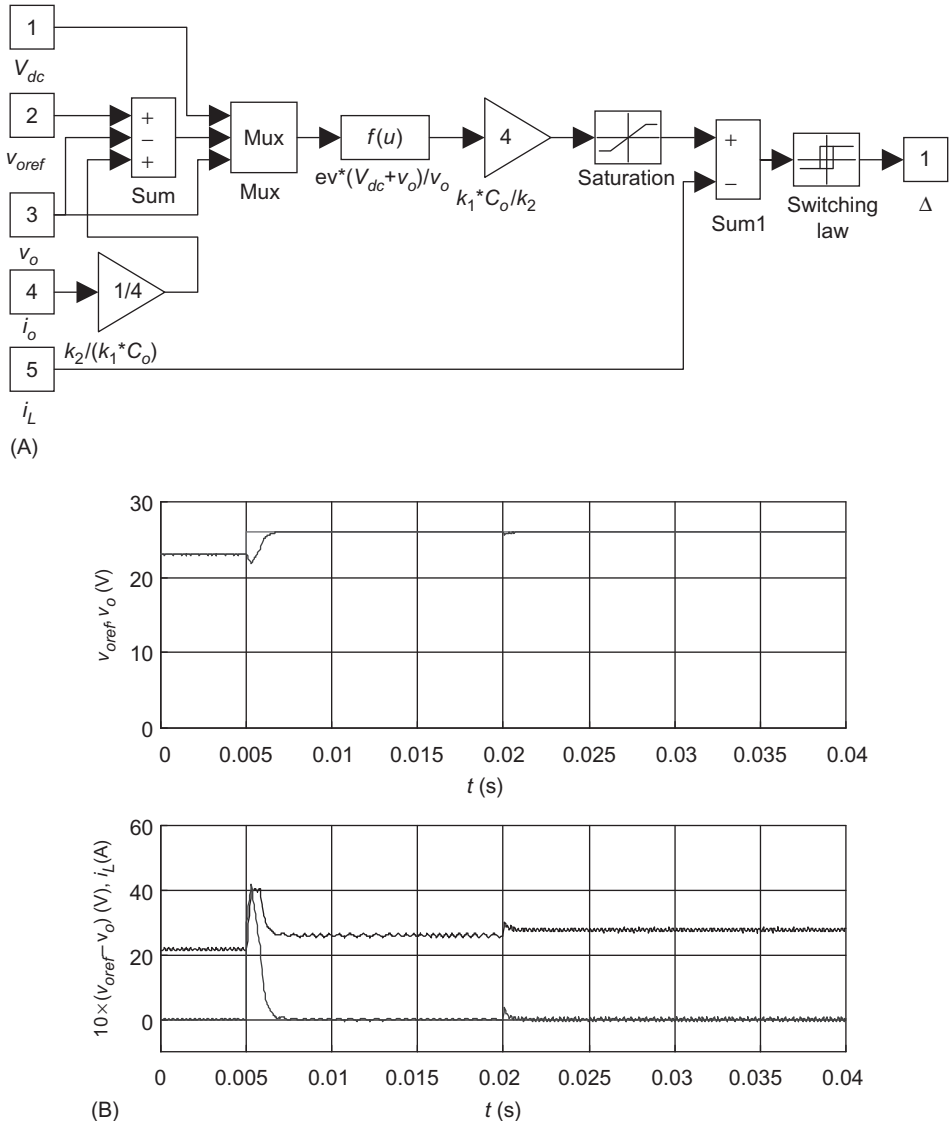

FIG. 35.26 (A) Block diagram of the sliding-mode nonlinear controller for the buck-boost converter and (B) transient responses of the sliding-mode-controlled buck-boost converter. At $t=0.005$ s, v_{oref} step from 23 to 26 V. At $t=0.02$ s, V_{DC} step from 26 to 23 V. Top graph: step reference v_{oref} and output voltage v_o. Bottom graph: trace starting at 20 is i_L current; trace starting at zero is $10\times(v_{oref}-v_o)$.

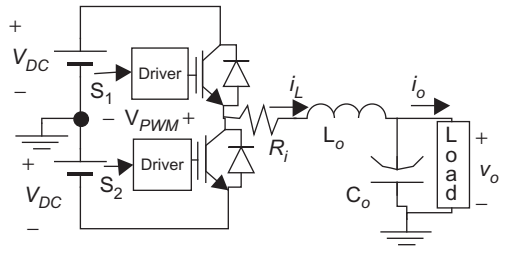

FIG. 35.27 Half-bridge power inverter with insulated-gate bipolar transistors, output filter, and load.

where i_o is the generic load current and $v_{PWM}=\delta(t)V_{DC}$ is the extended PWM output voltage ($\delta(t)=+1$ when one of the upper main semiconductors of Fig. 35.27 is conducting and $\delta(t)=-1$ when one of the lower semiconductors is on).

Output current control (current-mode control)

To perform as a v_{i_L} voltage-controlled i_L current source (or sink) with transconductance g_m ($g_m=i_L/v_{i_L}$), this converter must supply a current i_L to the output inductor, obeying $i_L=g_m v_{i_L}$. Using a bounded v_{i_L} voltage to provide output short-circuit protection, the reference current for a sliding-mode controller must be $i_{L_r}=g_m v_{iL}$. Therefore, the controlled output is the i_L current, and the controllability canonical model (35.106) is obtained from the second equation of (35.105), since the dynamics of this

subsystem, being governed by $\delta(t)V_{DC}$, is already in the controllability canonical form for this chosen output:

$$\frac{di_L}{dt} = -\frac{R_i}{L_o}i_L - \frac{1}{L_o}v_o + \frac{\delta(t)V_{DC}}{L_o} \tag{35.106}$$

A suitable sliding surface (35.107) is obtained from Eq. (35.91), making $e_{i_L} = i_{L_r} - i_L$:

$$S(e_{i_L}, t) = k_p e_{i_L} = k_p(i_{L_r} - i_L) = k_p(g_m v_{i_L} - i_L) = 0 \tag{35.107}$$

The switching law Eq. (35.108) can be devised calculating the time derivative of Eq. (35.107) $\dot{S}(e_{i_L}, t)$ and applying Eq. (35.92). If $S(e_{i_L}, t) > 0$, then $di_L/dt > 0$ must hold to obtain $S(e_{i_L}, t) < 0$, implying $\delta(t) = 1$:

$$\delta(t) = \begin{cases} 1 & \text{for } S(e_{i_L}t) > +\varepsilon \\ -1 & \text{for } S(e_{i_L}t) < -\varepsilon \end{cases} \tag{35.108}$$

The k_p value and the allowed ripple ε define the instantaneous value of the variable switching frequency. The sliding-mode controller is represented in Fig. 35.28A. Step response (Fig. 35.29A) shows the variable-frequency operation, a very short rise time (limited only by the available power supply), and confirms the expected robustness against supply variations.

For systems where fixed-frequency operation is needed, a triangular wave, with frequency (10 kHz) slightly greater than the maximum variable frequency, can be added (Fig. 35.28B) to the sliding-mode controller, as explained in Section 35.3.3. Performances (Fig. 35.29B) are comparable with those of the variable-frequency sliding-mode controller (Fig. 35.29A). Fig. 35.29B shows not only the constant switching frequency but also a steady-state error dependent on the operating point.

To eliminate this error, a new sliding surface Eq. (35.109), based on Eq. (35.99), should be used. The constants k_p and k_0 can be calculated, as discussed in Example 35.10:

$$S(e_{i_L}t) = k_0 \int e_{i_L} dt + k_p e_{i_L} = 0 \tag{35.109}$$

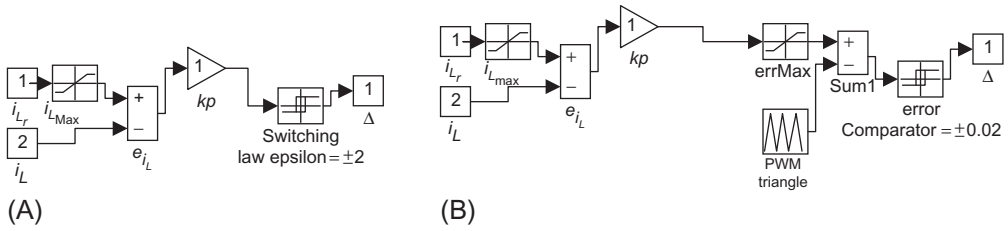

FIG. 35.28 (A) Implementation of short-circuit-proof sliding-mode current controller (variable frequency) and (B) implementation of fixed-frequency, short-circuit-proof sliding-mode current controller using a triangular waveform.

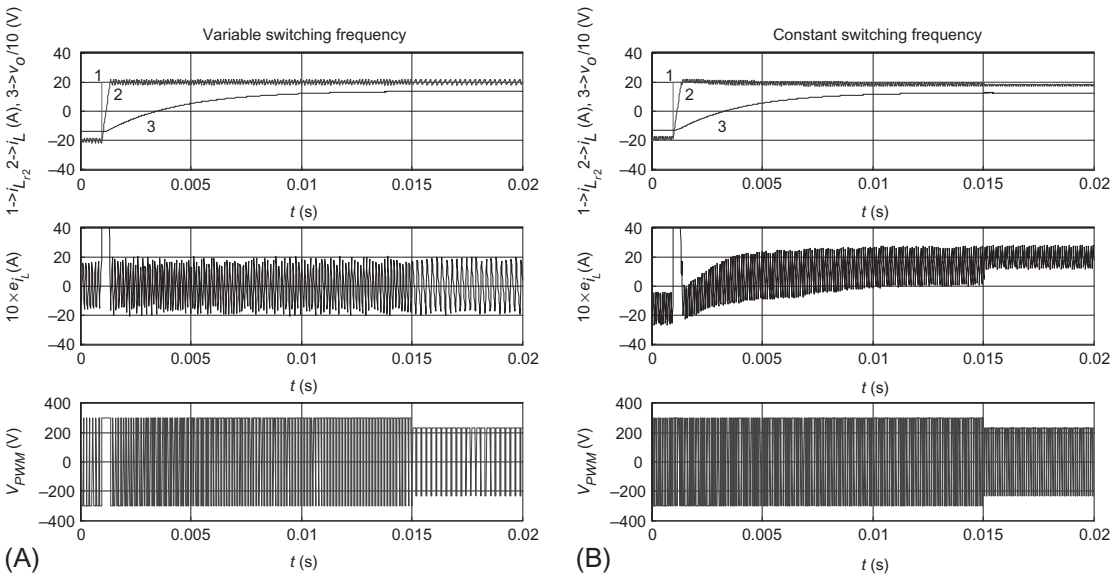

FIG. 35.29 Performance of the transconductance amplifier; response to an i_{Lr} step from −20 to 20 A at $t = 0.001$ s and to a V_{DC} step from 300 to 230 V at $t = 0.015$ s: (A) variable-frequency sliding-mode controller and (B) fixed-frequency sliding-mode controller.

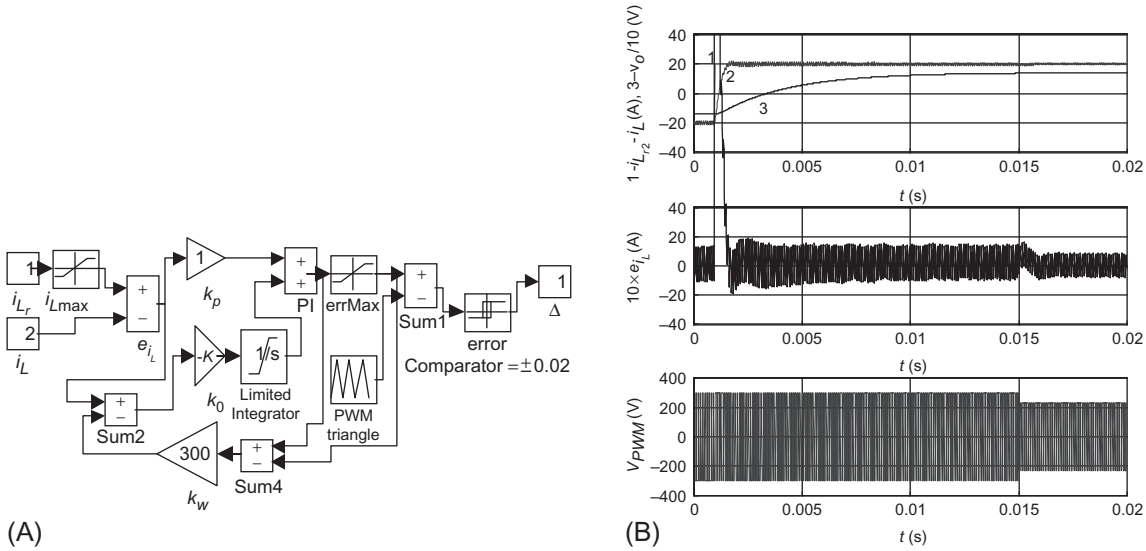

FIG. 35.30 (A) Block diagram of the average current-mode controller (sliding mode) and (B) performance of the fixed-frequency sliding-mode controller with removed steady-state error: response to an i_{L_r} step from −20 to 20 A at $t=0.001$ s and to a V_{DC} step from 300 to 230 V at $t=0.015$ s.

The new constant-frequency sliding-mode current controller (Fig. 35.30A), with added antiwindup techniques (Example 35.6), since a saturation (errMax) is needed to keep the frequency constant, now presents no steady-state error (Fig. 35.30B). Performances are comparable with those of the variable-frequency controller, and no robustness loss is visible. The applied sliding-mode approach led to the derivation of the known average current-mode controller.

Output voltage control

To obtain a power operational amplifier suitable for building uninterruptible power supplies, power filters, power gyrators, inductance simulators, or power factor active compensators, v_o must be the controlled converter output. Therefore, using the input-output linearization technique, it is seen that the first time derivative of the output $(\mathrm{d}v_o/\mathrm{d}t)=(i_L-i_o)/C_o=\theta$ does not explicitly contain the control input $\delta(t)V_{DC}$. Then, the second derivative must be calculated. Taking into account Eq. (35.105), as $\theta=(i_L-i_o)/C_o$, Eq. (35.110) is derived

$$\frac{\mathrm{d}^2 v_o}{\mathrm{d}t^2}=\frac{\mathrm{d}}{\mathrm{d}t}\theta=\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{i_L-i_o}{C_o}\right)=-\frac{R_i}{L_o}\theta-\frac{1}{L_oC_o}v_o-\frac{R_i}{L_oC_o}i_o-\frac{1}{C_o}\frac{\mathrm{d}i_o}{\mathrm{d}t}+\frac{1}{L_oC_o}\delta(t)V_{DC} \tag{35.110}$$

This expression shows that the second derivative of the output depends on the control input $\delta(t)V_{DC}$. No further time derivative is needed, and the state-space equations of the equivalent circuit, written in the phase canonical form, are

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} v_o \\ \theta \end{bmatrix}=\begin{bmatrix} \theta \\ -\frac{R_i}{L_o}\theta-\frac{1}{L_oC_o}v_o-\frac{R_i}{L_oC_o}i_o-\frac{1}{C_o}\frac{\mathrm{d}i_o}{\mathrm{d}t}+\frac{1}{L_oC_o}\delta(t)V_{DC} \end{bmatrix} \tag{35.111}$$

According to Eqs. (35.91), (35.111), and (35.105), considering that e_{v_o} is the feedback error $e_{v_o}=v_{o_r}-v_o$, a sliding surface $S(e_{v_o},t)$ can be chosen:

$$S(e_{v_o}t)=k_1e_{v_o}+k_2\frac{\mathrm{d}e_{v_o}}{\mathrm{d}t}=e_{v_o}+\frac{k_2}{k_1}\frac{\mathrm{d}e_{v_o}}{\mathrm{d}t}=e_{v_o}+\beta\frac{\mathrm{d}e_{v_o}}{\mathrm{d}t}=\frac{C_o}{\beta}(v_{o_r}-v_o)+C_o\frac{\mathrm{d}v_{o_r}}{\mathrm{d}t}+i_o-i_L=0 \tag{35.112}$$

where β is the time constant of the desired first-order response of output voltage ($\beta\gg T>0$), as the strong relative degree [13] of this system is 2, and the sliding-mode operation reduces by one, the order of this system (the strong relative degree of a system is the least positive integer r for which the rth derivative of the output $\mathrm{d}^r v_o/\mathrm{d}t^r$ is an explicit function of the control input u, being $\mathrm{d}^i v_o/\mathrm{d}u=0$ for $0\le i\le r-1$ and $\mathrm{d}^r v_o/\mathrm{d}u\neq 0$).

Calculating $\dot{S}(e_{v_o},t)$, the control strategy (switching law) Eq. (35.113) can be devised since, if $S(e_{v_o},t)>0$, then $\mathrm{d}i_L/\mathrm{d}t$ must be positive to obtain $\dot{S}(e_{i_L},t)<0$, implying $\delta(t)=1$. Otherwise, $\delta(t)=-1$:

$$\delta(t)=\begin{cases} 1 & \text{for } S(e_{v_o},t)>0 \,(v_{PWM}=+V_{DC}) \\ -1 & \text{for } S(e_{v_o},t)<0 \,(v_{PWM}=-V_{DC}) \end{cases} \tag{35.113}$$

In the ideal sliding-mode dynamics, the filter input voltage v_{PWM} switches between V_{DC} and $-V_{DC}$ with the infinite frequency. This switching generates the equivalent control voltage V_{eq} that must satisfy the sliding manifold invariance conditions, $S(e_{v_o},t)=0$ and $\dot{S}(e_{v_o},t)=0$. Therefore, from $\dot{S}(e_{v_o},t)=0$, using Eqs. (35.112) and (35.105) (or from Eq. (35.110)), V_{eq} is

$$V_{eq} = L_o C_o \left[\frac{d^2 v_{o_r}}{dt^2} + \frac{1}{\beta} \frac{dv_{o_r}}{dt} + \frac{v_o}{L_o C_o} + \frac{(\beta R_i - L_o) i_L}{\beta L_o C_o} \frac{i_o}{\beta C_o} + \frac{1}{C_o} \frac{di_o}{dt} \right] \tag{35.114}$$

This equation shows that only smooth input v_{o_r} signals ("smooth" functions) can be accurately reproduced at the inverter output, as it contains derivatives of the v_{o_r} signal. This fact is a consequence of the stored electromagnetic energy. The existence of the sliding-mode operation implies the following necessary and sufficient condition:

$$-V_{DC} < V_{eq} < V_{DC} \tag{35.115}$$

Eq. (35.115) enables the determination of the minimum input voltage V_{DC} needed to enforce the sliding-mode operation. Moreover, even in the case of $|V_{eq}| > |V_{DC}|$, the system experiences only a saturation transient and eventually reaches the region of sliding-mode operation, except if the operating point and disturbances enforce $|V_{eq}| > |V_{DC}|$ in steady state.

In the ideal sliding mode, at infinite switching frequency, state trajectories are directed toward the sliding surface and move exactly along the discontinuity surface. Practical switching power converters cannot switch at infinite frequency, so a typical implementation of Eq. (35.112) (Fig. 35.31A) with neglected $\dot{v}_{o_r}$ features a comparator with hysteresis 2ε, switching occurring at $|S(e_{v_o}, t)| > \varepsilon$ with frequency depending on the slopes of i_L. This hysteresis causes phase-plane trajectory oscillations of width 2ε around the discontinuity surface $S(e_{v_o}, t) = 0$, but the V_{eq} voltage is still correctly generated, since the resulting duty cycle is a continuous variable (except for error limitations in the hardware or software, which can be corrected using the approach pointed out by Eq. (35.98)).

The design of the compensator and the modulator is integrated with the same theoretical approach, since the signal $S(e_{v_o}, t)$ applied to a comparator generates the pulses for the power semiconductors drives. If the short-circuit-proof operation is built into the power semiconductor drives, there is the possibility to measure only the capacitor current $(i_L - i_o)$.

Short-circuit protection and fixed-frequency operation of the power operational amplifier

If we note that all the terms to the left of i_L in Eq. (35.112) represent the value of i_{L_r}, a simple way to provide short-circuit protection is to bound the sum of all these terms (Fig. 35.31A with $i_{L_{rmax}} = 100$A). Alternatively, the output current controllers of Fig. 35.28 can be used, comparing Eq. (35.107) with Eq. (35.112), to obtain $i_{L_r} = S(e_{v_o}, t)/k_p + i_L$. Therefore, the block diagram of Fig. 35.31A provides the i_{L_r} output (for $k_p = 1$) to be the input of the current controllers (Figs. 35.28 and 35.31A). As seen, the controllers of Figs. 35.28B and 35.30A also ensure fixed-frequency operation.

For comparison purposes, a proportional-integral (PI) controller, with antiwindup (Fig. 35.31B) for output voltage control, was designed, supposing the current-mode control of the half bridge ($i_{L_r} = g_m v_{i_L}/(1 + sT_d)$ considering a small delay T_d) and a pure resistive load R_o and using the approach outlined in Examples 35.6 and 35.8 ($k_v = 1$, $g_m = 1$, $\zeta^2 = 0.5$, and $T_d = 600$ μs). The obtained PI (35.50) parameters are

$$\begin{aligned} T_z &= R_o C_o \\ T_p &= 4\zeta^2 g_m k_v R_o T_d \end{aligned} \tag{35.116}$$

Both variable frequency (Fig. 35.32) and constant frequency (Fig. 35.33) sliding-mode output voltage controllers present excellent performance and robustness with nominal loads. With loads much higher than the nominal value (Figs. 35.32B and 35.33B), the performance and robustness are also excellent. The sliding-mode constant-frequency PWM controller presents the additional advantage of injecting lower ripple in the load.

As expected, the PI regulator presents lower performance (Fig. 35.34). The response speed is lower, and the insensitivity to power supply and load variations (Fig. 35.34B) is not as high as with the sliding mode. Nevertheless, the PI performances are acceptable, since its design was carried considering a slow and fast manifold sliding-mode approach: the fixed-frequency sliding-mode current controller (35.109) for the fast manifold (the i_L current dynamics) and the antiwindup PI for the slow manifold (the v_o voltage dynamics, usually much slower than the current dynamics).

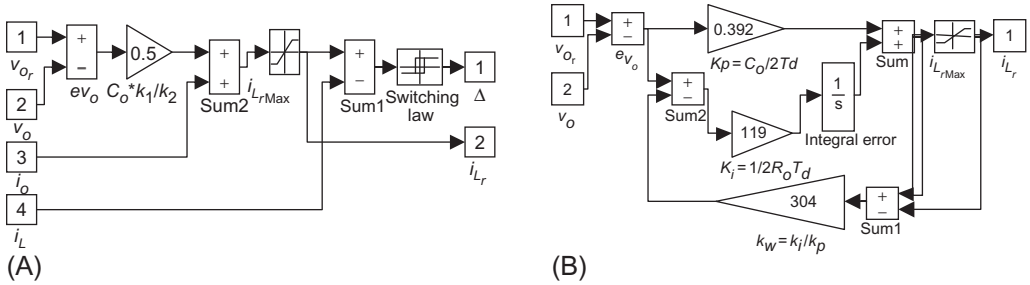

FIG. 35.31 (A) Implementation of short-circuit-proof, sliding-mode output voltage controller (variable frequency) and (B) implementation of antiwindup PI current-mode (fixed frequency) controller.

35.3.5.2 Example 35.12: Constant-Frequency Sliding-Mode Control of *p* Pulse Parallel Rectifiers

This example presents a new paradigm to the control of thyristor rectifiers. Since p pulse rectifiers are variable-structure systems, sliding-mode control is applied here to 12-pulse rectifiers, still useful for very high-power applications [3]. The design determines the variables to be measured, and the controlled rectifier presents robustness and much shorter response times, even with the parameter uncertainty, perturbations, noise, and nonmodeled dynamics. These performances are not feasible using linear controllers, obtained here for comparison purposes.

Modeling the 12-pulse parallel rectifier

The 12-pulse rectifier (Fig. 35.35A) is built with four three-phase half-wave rectifiers, connected in parallel with current-sharing inductances l and l' merged with capacitors C' and C_2, to obtain a second-order LC filter. This allows low-ripple output voltage and continuous mode of operation (laboratory model with $l=44$ mH, $l'=13$ mH, $C'=C_2=10$ mF, star-delta-connected ac sources with $E_{RMS}\approx 65$ V, and power rating 2.2 kW, load approximately resistive $R_o\approx 3$–5 Ω).

To control the output voltage v_{c2}, given the complexity of the whole system, the best approach is to derive a low-order model. By averaging the four half-wave rectifiers, neglecting the rectifier

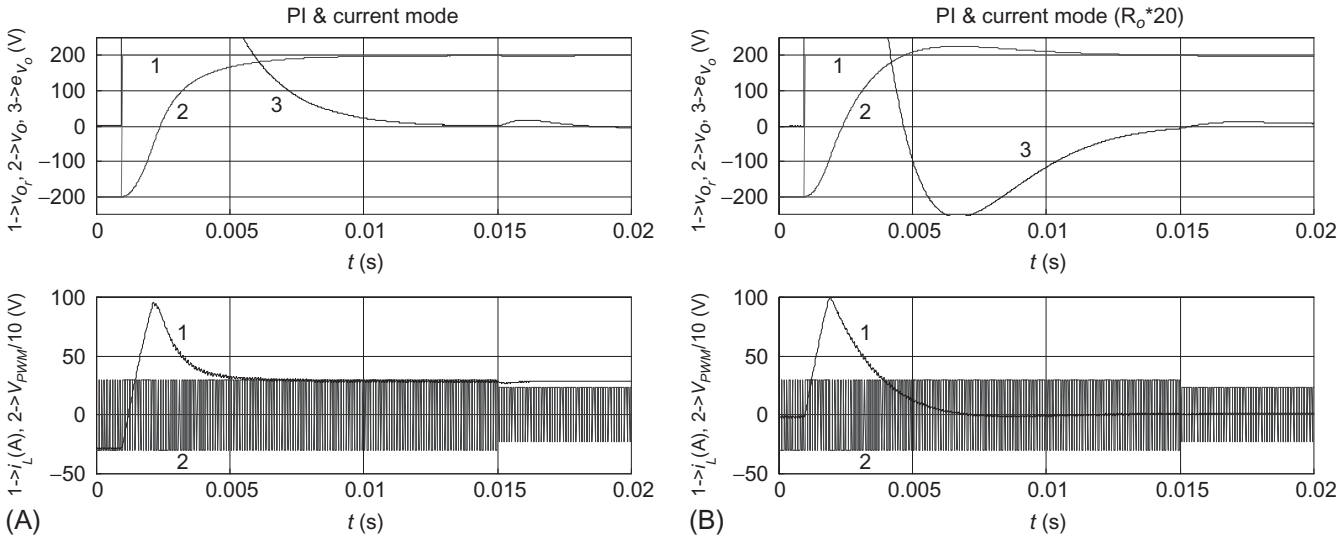

FIG. 35.34 Performance of the PI-controlled power operational amplifier; response to a v_{o_r} step from −200 to 200 V at $t=0.001$ s and to a V_{DC} step from 300 to 230 V at $t=0.015$ s: (A) PI current-mode controller (nominal load) and (B) PI current-mode controller ($R_o \times 20$).

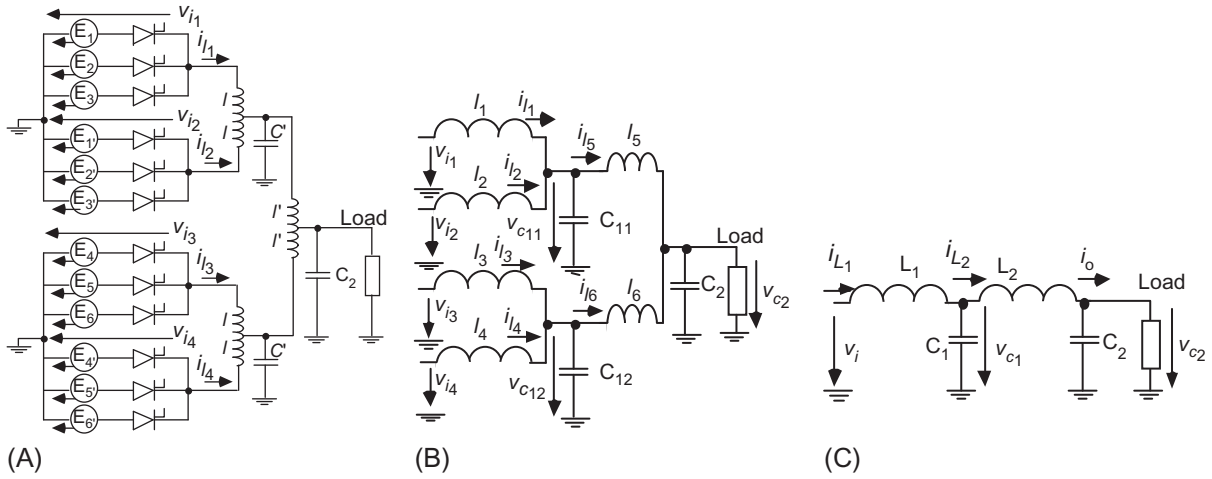

FIG. 35.35 (A) Twelve-pulse rectifier with interphase reactors and intermediate capacitors, (B) rectifier model neglecting the half-wave rectifier dynamics, and (C) low-order averaged equivalent circuit for the 12-pulse rectifier with the resulting output double LC filter.

dynamics and mutual couplings, the equivalent circuit of Fig. 35.35B is obtained ($l_1=l_2=l_3=l_4=l$, $l_5=l_6=l'$, and $C_{11}=C_{12}=C'$). Since the rectifiers are identical, the equivalent 12-pulse rectifier model of Fig. 35.35C is derived, simplifying the resulting parallel associations ($L_1=l/4$, $L_2=l/2$, and $C_1=2C'$).

Considering the load current i_o as an external perturbation and v_i the control input, the state-space model of the equivalent circuit of Fig. 35.35C is

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} i_{L_1} \\ i_{L2} \\ v_{c_1} \\ v_{c_2} \end{bmatrix} = \begin{bmatrix} 0 & 0 & -1/L_1 & 0 \\ 0 & 0 & 1/L_2 & -1/L_2 \\ 1/C_1 & -1/C_1 & 0 & 0 \\ 0 & 1/C_2 & 0 & 0 \end{bmatrix} \begin{bmatrix} i_{L_1} \\ i_{L2} \\ v_{c_1} \\ v_{c_2} \end{bmatrix} + \begin{bmatrix} 1/L_1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & -1/C_2 \end{bmatrix} \begin{bmatrix} v_i \\ i_o \end{bmatrix} \tag{35.117}$$

Sliding-mode control of the 12-pulse parallel rectifier

Since the output voltage v_{c_2} of the system must follow the reference $v_{c_{2r}}$, the system equations in the phase canonical (or controllability) form must be written, using the error $e_{v_2}=v_{c_{2r}}-v_{c_2}$ and its time derivatives as new state error variables, as done in Example 35.11:

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} e_{v_{c_2}} \\ e_\theta \\ e_\gamma \\ e_\beta \end{bmatrix} = \begin{bmatrix} e_\theta \\ e_\gamma \\ e_\beta \\ -\left(\dfrac{1}{C_1L_1}+\dfrac{1}{C_1L_2}+\dfrac{1}{C_2L_2}\right)e_\gamma - \dfrac{e_{v_{c_2}}}{C_1L_1C_2L_2} - \left(\dfrac{1}{C_1L_1C_2}+\dfrac{1}{C_1C_2L_2}\right)\dfrac{\mathrm{d}i_o}{\mathrm{d}t} - \dfrac{1}{C_2}\dfrac{\mathrm{d}^3 i_o}{\mathrm{d}t^3} - \dfrac{v_i}{C_1L_1C_2L_2} \end{bmatrix} \tag{35.118}$$

The sliding surface $S(e_{x_i}, t)$, designed to reduce the system order, is a linear combination of all the phase canonical state variables. Considering Eqs. (35.118) and (35.117) and the

errors $e_{v_{c_2}}$, e_θ, e_γ, and e_β, the sliding surface can be expressed as a combination of the rectifier currents, voltages, and their time derivatives:

$$\begin{aligned} S(e_{x_i}t) &= e_{v_{c_2}} + k_\theta e_\theta + k_\gamma e_\gamma + k_\beta e_\beta \\ &= v_{c_{2r}} + k_\theta\theta_r + k_\gamma\gamma_r + k_\beta\beta_r - \left(1 - \frac{k_\gamma}{C_2L_2}\right)v_{c_2} \\ &\quad - \frac{k_\gamma}{C_2L_2}v_{c_1} + \left(\frac{k_\theta}{C_2} - \frac{k_\beta}{C_2^2L_2}\right)i_o + \frac{k_\gamma}{C_2}\frac{\mathrm{d}i_o}{\mathrm{d}t} + \frac{k_\beta}{C_2}\frac{\mathrm{d}^2i_o}{\mathrm{d}t^2} \\ &\quad - \frac{k_\beta}{C_1C_2L_2}i_{L_1} - \left(\frac{k_\theta}{C_2} - \frac{k_\beta}{C_1C_2L_2} - \frac{k_\beta}{C_2^2L_2}\right)i_{L_2} = 0 \end{aligned} \tag{35.119}$$

Eq. (35.119) shows the variables to be measured ($v_{c_2}, v_{c_1}, i_o, i_{L_1}$, and i_{L_2}). Therefore, it can be concluded that the output current of each three-phase half-wave rectifier must be measured.

The existence of the sliding mode implies $S(e_{x_i}, t) = 0$ and $\dot{S}(e_{x_i}, t) = 0$. Given the state models (35.117) and (35.118) and from $\dot{S}(e_{x_i}, t) = 0$, the available voltage of the power supply v_i must exceed the equivalent average dc input voltage V_{eq} (35.120), which should be applied at the filter input, in order that the system state slides along the sliding surface (35.119):

$$\begin{aligned} V_{eq} &= \frac{C_1L_1C_2L_2}{k_\beta}\left(\theta_r + k_\theta\gamma_r + k_\gamma\beta_r + k_\beta\dot{\beta}_r\right) + v_{c_2} - \frac{C_1L_1C_2L_2}{k_\beta} \\ &\quad \times \left(\theta + k_\gamma\beta\right) + \left(C_2L_2 + C_2L_1 + C_1L_1 - C_1L_1C_2L_2\frac{k_\theta}{k_\beta}\right)\gamma \\ &\quad + (L_1 + L_2)\frac{\mathrm{d}i_o}{\mathrm{d}t} + C_1L_1L_2\frac{\mathrm{d}^3i_o}{\mathrm{d}t^3} \end{aligned} \tag{35.120}$$

This means that the power supply root mean square (RMS) voltage values should be chosen high enough to account for the maximum effects of the perturbations. This is almost the same criterion adopted when calculating the RMS voltage values needed with linear controllers. However, as the V_{eq} voltage contains the derivatives of the reference voltage, the system will not be able to stay in sliding mode with a step as the reference.

The switching law would be derived, considering that, from Eq. (35.97), $b_e(\mathbf{e}) > 0$. Therefore, from Eq. (35.119), if $S(e_{x_i}, t) > +\varepsilon$, then $v_i(t) = V_{eq_{max}}$, else if $S(e_{x_i}, t) < -\varepsilon$, then $v_i(t) = -V_{eq_{max}}$. However, because of the lack of gate turn-off capability of the rectifier thyristors, power rectifiers cannot generate the high-frequency switching voltage $v_i(t)$, since the statistical mean delay time is $T/2p$ ($T = 20$ ms) and reaches $T/2$ when switching from $+V_{eq_{max}}$ to $-V_{eq_{max}}$. To control mains switched rectifiers, the described constant-frequency sliding-mode operation method is used, in which the sliding surface $S(e_{x_i}, t)$ instead of being compared with zero is compared with an auxiliary constant-frequency function $r(t)$ (Fig. 35.6B) synchronized with the mains frequency. The new switching law is

$$\left.\begin{array}{l} \text{if } k_pS(e_{x_i}, t) > r(t) + \iota \Rightarrow \text{Trigger the next thyristor} \\ \text{if } k_pS(e_{x_i}, t) < r(t) - \iota \Rightarrow \text{Do not trigger any thyristor} \end{array}\right\} \Rightarrow v_i(t) \tag{35.121}$$

Since now $S(e_{x_i}, t)$ is not near zero, but around some value of $r(t)$, a steady-state error $e_{v_{c_{2av}}}$ appears $\left(\min[r(t)]/k_p < e_{v_{c_{2av}}} < \max[r(t)]/k_p\right)$, as seen in Example 35.11. Increasing the value of k_p (toward the ideal saturation control) does not overcome this drawback, since oscillations would appear even for moderate k_p gains, because of the rectifier dynamics. Instead, the sliding surface (35.122), based on Eq. (35.99), should be used. It contains an integral term, which, given the canonical controllability form and the Routh-Hurwitz property, is the only nonzero term at steady state, enabling the complete elimination of the steady-state error:

$$S_i(e_{x_i}, t) = \int e_{v_{c_2}}dt + k_{1v}e_{v_{c_2}} + k_{1\theta}e_\theta + k_{1\gamma}e_\gamma + k_{1\beta}e_\beta \tag{35.122}$$

To determine the k constants of Eq. (35.122), a pole-placement technique is selected, according to a fourth-order Bessel polynomial $B_E(s)_m$, $m = 4$, from Eq. (35.88), in order to obtain the smallest possible response time with almost no overshoot. For a delay characteristic as flat as possible, the delay t_r is taken inversely proportional to a frequency f_{ci} just below the lowest cutoff frequency ($f_{ci} < 8.44$ Hz) of the double LC filter. For this fourth-order filter, the delay is $t_r = 2.8/(2\pi f_{ci})$. By choosing $f_{ci} = 7$ Hz ($t_r \approx 64$ ms) and dividing all the Bessel polynomial terms by st_r, the characteristic polynomial (35.123) is obtained:

$$S_i(e_{x_i}, s) = \frac{1}{st_r} + 1 + \frac{45}{105}st_r + \frac{10}{105}s^2t_r^2 + \frac{1}{105}s^3t_r^3 \tag{35.123}$$

This polynomial must be applied to Eq. (35.122) to obtain the four sliding functions needed to derive the thyristor trigger pulses of the four three-phase half-wave rectifiers. These sliding functions will enable the control of the output current ($i_{l_1}, i_{l_2}, i_{l_3}$ and i_{l_4}) of each half-wave rectifier, improving the current sharing among them (Fig. 35.35B). Supposing equal current share, the relation between the i_{L_1} current and the output currents of each three-phase rectifier is $i_{L_1} = 4i_{l_1} = 4i_{l_2} = 4i_{l_3} = 4i_{l_4}$. Therefore, for the nth half-wave three-phase rectifier, since, for $n = 1$ and $n = 2$, $v_{c_1} = v_{c_{11}}$ and $i_{L_2} = 2i_{l_5}$ and, for $n = 3$ and $n = 4$, $v_{c_1} = v_{c_{12}}$ and $i_{L_2} = 2i_{l_6}$, the four sliding surfaces are ($k_{1v} = 1$)

$$S_i(e_{x_i}t)_n = \Bigg[k_{1v}v_{c_{2r}} + \frac{45t_r}{105}\theta_r + \frac{10t_r^2}{105}\gamma_r + \frac{t_r^3}{105}\beta_r + \frac{1}{t_r}\int (v_{c_{2r}} - v_{c_2})dt - \left(\frac{k_{1v}}{C_2L_2} - \frac{10t_r^2}{105C_2L_2}\right)v_{c_2} - \frac{10t_r^2}{105C_2L_2}v_{c_{1,2}} + \left(\frac{45t_r}{105C_2} - \frac{t_r^3}{105C_2^2L_2}\right)i_o + \left(\frac{10t_r^2}{105C_2}\right)\frac{di_o}{dt} + \left(\frac{t_r^3}{105C_2}\right)\frac{d^2i_o}{dt^2}\Bigg]/4 - \left[\left(\frac{45t_r}{105C_2} - \frac{t_r^3}{105C_2^2L_2} - \frac{t_r^3}{105C_1L_2C_2}\right)i_{l_{5,6}}\right]/2 - \left(\frac{t_r^3}{105C_1L_2C_2}\right)i_{l_n} \tag{35.124}$$

If an inexpensive analog controller is desired, the successive time derivatives of the reference voltage and the output current of Eq. (35.124) can be neglected (furthermore, their calculation is noise prone). Nonzero errors on the first-, second-, and third-order derivatives of the controlled variable will appear, worsening the response speed. However, the steady-state error is not affected.

To implement the four equations (35.124), the variables $v_{c_2}, v_{c11}, v_{c12}, i_o, i_{l_5}, i_{l_6}, i_{l_1}, i_{l_2}, i_{l_3}$ and i_{l_4} must be measured. Although this could be done easily, it is very convenient to further simplify the practical controller, keeping its complexity and cost at the level of linear controllers, while maintaining the advantages of sliding mode. Therefore, the voltages $v_{c_{11}}$ and $v_{c_{12}}$ are assumed almost constant over one period of the filter input current, and $v_{c_{11}} = v_{c_{12}} = v_{c_2}$, meaning that $i_{l_5} = i_{l_6} = i_o/2$. With these assumptions, valid as the values of C' and C_2 are designed to provide an output voltage with very low ripple, the new sliding-mode functions are

$$S_i(e_{x_i}t)_n \approx \frac{\frac{1}{t_r}\int (v_{c2r} - v_{c2})dt + k_{1v}(v_{c_{2r}} - v_{c_2}) + \frac{t_r^3}{105}\frac{1}{C_1C_2L_2}i_o}{4} - \left(\frac{t_r^3}{105C_1L_2C_2}\right)i_{ln} \tag{35.125}$$

These approximations disregard only the high-frequency content of v_{c11}, v_{c12}, i_{l_5}, and i_{l_6} and do not affect the rectifier steady-state response, but the step response will be a little slower, although still much faster (150 ms, Fig. 35.39) than that obtained with linear controllers (280 ms, Fig. 35.38). Regardless of all the approximations, the low switching frequency of the rectifier would not allow the elimination of the dynamic errors. As a benefit of these approximations, the sliding-mode controller (Fig. 35.36A) will need only an extra current sensor (or a current observer) and an extra operational amplifier in comparison with linear controllers derived hereafter (which need four current sensors and six operational amplifiers). Compared with the total cost of the 12-pulse rectifier plus output filter, the control hardware cost is negligible in both cases, even for medium-power applications.

Average current-mode control of the 12-pulse rectifier

For comparison purposes, a PI-based controller structure is designed (Fig. 35.36B), taking into account that small mismatches of the line voltages or of the trigger angles can completely destroy the current share of the four paralleled rectifiers, in spite of the current equalizing inductances (l and l'). Output voltage control sensing only the output voltage is, therefore, not feasible. Instead, the slow and fast manifold approach is selected. For the fast manifold, four internal current control loops guarantee the same dc current level in each three-phase rectifier and limit the short-circuit currents. For

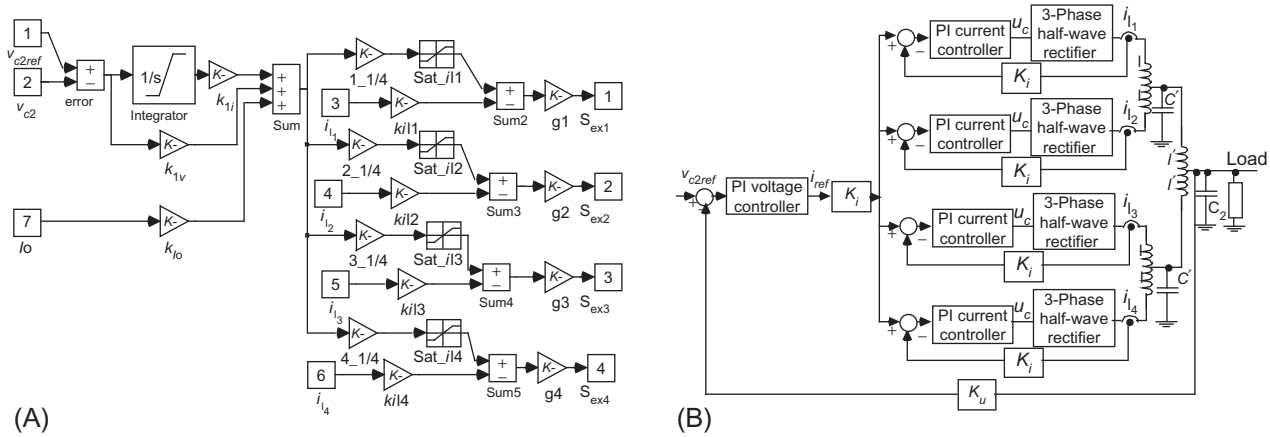

FIG. 35.36 (A) Sliding-mode controller block diagram and (B) linear control hierarchy for the 12-pulse rectifier.

the output slow dynamics, an external cascaded output voltage control loop (Fig. 35.36B), measuring the voltage applied to the load, is the minimum.

For a straightforward design, given the much slower dynamics of the capacitor voltages compared with the input current, the PI current controllers are calculated as shown in Example 35.6, considering the capacitor voltage constant during a switching period and $r_t \approx 1\ \Omega$ the intrinsic resistance of the transformer windings, thyristor overlap, and inductor l. From Eq. (35.59), $T_z = l/r_t \approx 0.044$ s. From Eq. (35.62), with the common assumptions, $T_p \approx 0.16\, k_I$ s ($p=3$). These values guarantee a small overshoot ($\approx 5\%$) and a current rise time of approximately $T/3$.

To design the external output voltage control loop, each current-controlled rectifier can be considered a voltage-controlled current source $i_{L_1}(s)/4$, since each half-wave rectifier current response will be much faster than the filter output voltage response. Therefore, in the equivalent circuit of Fig. 35.35B, the current source $i_{L_1}(s)$ substitutes the input inductor, yielding the transfer function $v_{c_2}(s)/i_{L_1}(s)$:

$$\frac{V_{c_2}(s)}{i_{L_1}(s)} = \frac{R_o}{C_2C_1L_2R_os^3 + C_1L_2s^2 + (C_2R_o + C_1R_o)s + 1} \tag{35.126}$$

Given the real pole ($p_1 = -6.7$) and two complex poles ($p_{2,3} = -6.65 \pm j140.9$) of Eq. (35.126), the PI voltage controller zero ($1/T_{zv} = p_1$) can be chosen with a value equal to the transfer function real pole. The integral gain T_{pv} can be determined using a root-locus analysis to determine the maximum gain that still guarantees the stability of the closed-loop controlled system. The critical gain for the PI was found to be $T_{zv}/T_{pv} \approx 0.4$ and then $T_{pv} > 0.37$. The value $T_{pv} \approx 2$ was selected to obtain weak oscillations, together with almost no overshoot.

The dynamic and steady-state responses of the output currents of the four rectifiers ($i_{l_1}, i_{l_2}, i_{l_3}, i_{l_4}$) and the output voltage V_{c_2} were analyzed using a step input from 2 to 2.5 A applied at $t = 1.1$ s, for the currents, and from 40 to 50 V for the V_{c_2} voltage. The PI current controllers (Fig. 35.37) show good sharing of the total current, slight overshoot ($\zeta = 0.7$), and response time 6.6 ms (T/p).

The open-loop voltage V_{c_2} presents a rise time of 0.38 s. The PI voltage controller (Fig. 35.38) shows a response time of 0.4 s,

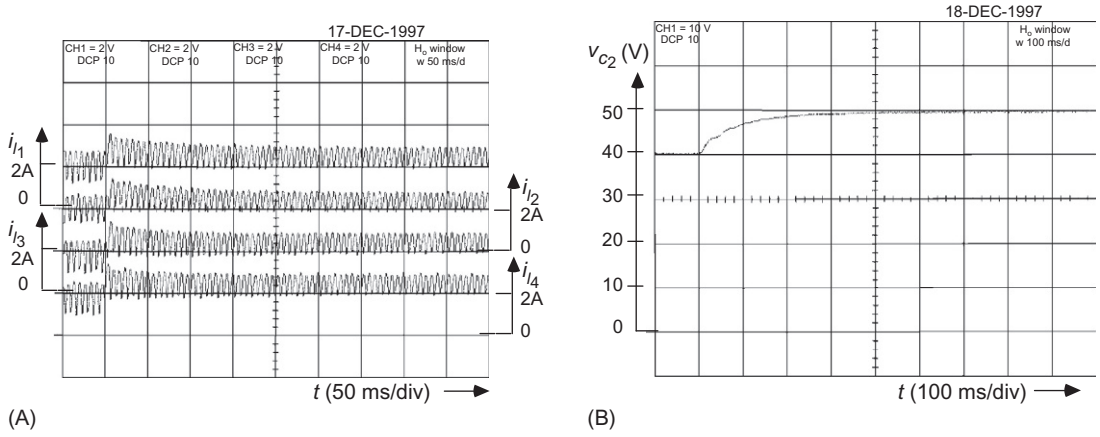

FIG. 35.37 PI current controller performance: (A) $i_{l_1}, i_{l_2}, i_{l_3}, i_{l_4}$ closed-loop currents and (B) open-loop output voltage V_{c_2}.

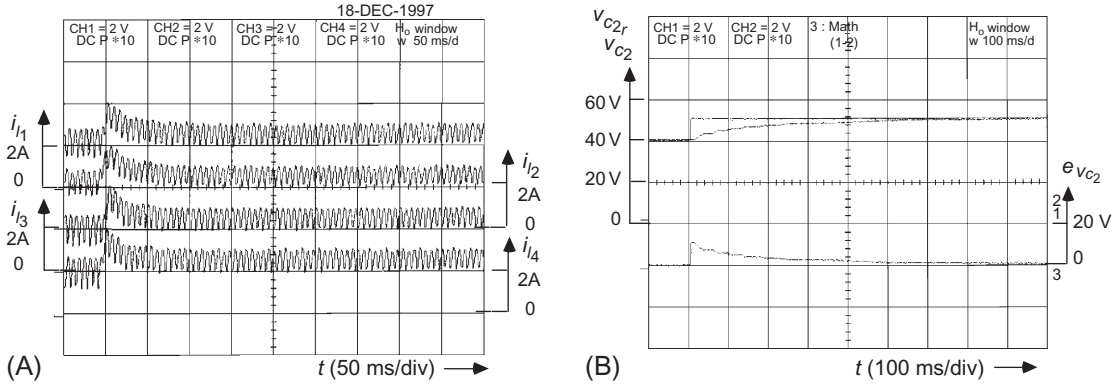

FIG. 35.38 PI voltage controller performance: (A) $i_{l_1}, i_{l_2}, i_{l_3}, i_{l_4}$ closed-loop currents and (B) closed output voltage V_{c_2} and $l_{v_{c_2}}$ output voltage error.

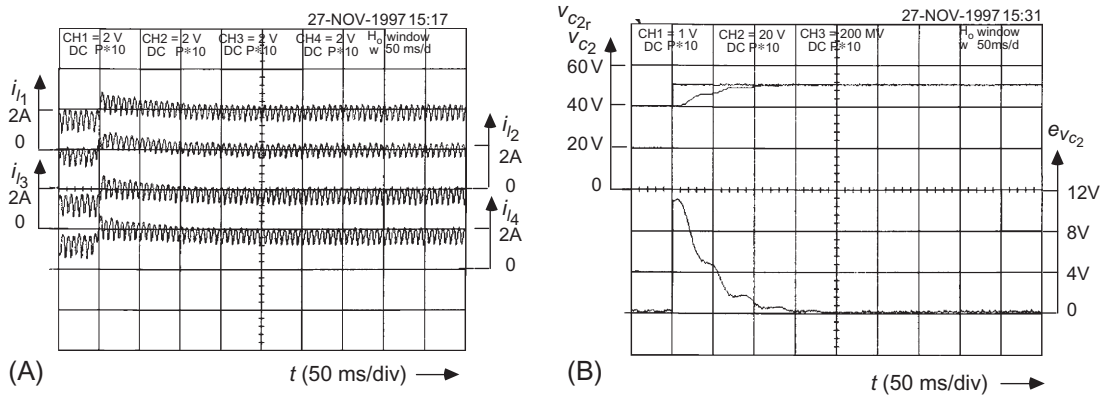

FIG. 35.39 Closed-loop constant-frequency sliding-mode controller performance: (A) $i_{l_1}, i_{l_2}, i_{l_3}, i_{l_4}$ closed-loop currents and (B) closed output voltage V_{c_2} and $e_{v_{c_2}}$ output voltage error.

no overshoot. The four three-phase half-wave rectifier output currents $(i_{l_1}, i_{l_2}, i_{l_3}, \text{and } i_{l_4})$ present nearly the same transient and steady-state values, with no very high current peaks. These results validate the assumptions made in the PI design.

The closed-loop performance of the fixed-frequency sliding-mode controller (Fig. 35.39) shows that all the $i_{l_1}, i_{l_2}, i_{l_3}, \text{and } i_{l_4}$ currents are almost equal and have peak values only slightly higher than those obtained with the PI linear controllers. The output voltage presents a much faster response time (150 ms) than the PI linear controllers, negligible or no steady-state error, and no overshoot. From these waveforms, it can be concluded that the sliding-mode controller provides a much more effective control of the rectifier, as the output voltage response time is much lower than the obtained with PI linear controllers, without significantly increasing the thyristor currents, overshoots, or costs. Furthermore, sliding mode is an elegant way to know the variables to be measured and to design all the controller and the modulator electronics.

35.3.5.3 Example 35.13: Sliding-Mode Control of Pulse Width Modulation Audio Power Amplifiers

Linear audio power amplifiers can be astonishing but have efficiencies as low as 15%–20% with speech or music signals. To improve the efficiency of audio systems while preserving the quality, PWM switching power amplifiers, enabling the reduction of the power supply cost, volume, and weight and compensating the efficiency loss of modern loudspeakers, are needed. Moreover, PWM amplifiers can provide a complete digital solution for audio power processing.

For high-fidelity systems, PWM audio amplifiers must present flat passbands of at least 16–20 kHz (±0.5 dB), distortions less than 0.1% at the rated output power, fast dynamic response, and signal-to-noise ratios above 90 dB. This requires fast power semiconductors (usually metal-oxide-semiconductor field-effect transistor (MOSFET) transistors), capable of switching at frequencies near 500 kHz, and fast nonlinear controllers to provide the precise and timely control actions needed to accomplish the mentioned requirements and to eliminate the phase delays in the LC output filter and loudspeakers.

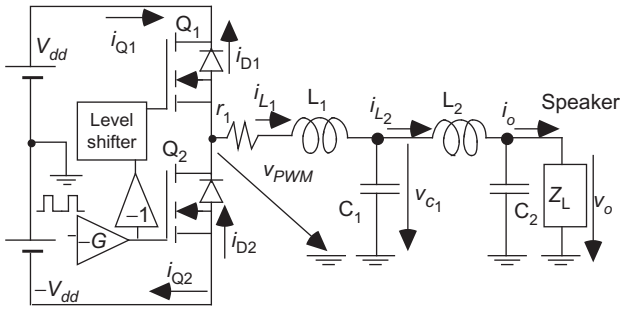

FIG. 35.40 PWM audio amplifier with fourth-order Chebyshev low-pass output filter and loudspeaker load.

A low-cost PWM audio power amplifier, able to provide over 80 W to 8 Ω loads (V_{dd} = 50 V), can be obtained using a half-bridge power inverter (switching at $f_{PWM} \approx 450$ kHz), coupled to an output filter for high-frequency attenuation (Fig. 35.40). A low-sensitivity, doubly terminated passive ladder (double LC), low-pass filter using fourth-order Chebyshev approximation polynomials is selected, given its ability to meet, while minimizing the number of inductors, the following requirements: passband edge frequency 21 kHz, passband ripple 0.5 dB, stopband edge frequency 300 kHz, and 90 dB minimum attenuation in the stopband ($L_1 = 80$ μH, $L_2 = 85$ μH, $C_1 = 1.7$ μF, $C_2 = 820$ nF, $R_2 = 8$ Ω, and $r_1 = 0.47$ Ω).

Modeling the PWM audio amplifier

The two half-bridge switches must always be in complementary states, to avoid power supply internal short circuits. Their state can be represented by the time-dependent variable γ, which is $\gamma = 1$ when Q1 is on and Q2 is off, and is $\gamma = -1$ when Q1 is off and Q2 is on.

Neglecting switch delays, on-state semiconductor voltage drops, and auxiliary networks and supposing small dead times, the half-bridge output voltage (v_{PWM}) is $v_{PWM}=\gamma V_{dd}$. Considering the state variables and circuit components of Fig. 35.40 and modeling the loudspeaker load as a disturbance represented by the current i_o (ensuring robustness to the frequency -dependent impedance of the speaker), the switched state-space model of the PWM audio amplifier is

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} i_{L_1} \\ v_{c_1} \\ i_{L_2} \\ v_o \end{bmatrix} = \begin{bmatrix} -r_1/L_1 & -1/L_1 & 0 & 0 \\ 1/C_1 & 0 & -1/C_1 & 0 \\ 0 & 1/L_2 & 0 & -1/L_2 \\ 0 & 0 & 1/C_2 & 0 \end{bmatrix}\begin{bmatrix} i_{L_1} \\ v_{c_1} \\ i_{L_2} \\ v_o \end{bmatrix} + \begin{bmatrix} 1/L_1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & -1/C_2 \end{bmatrix}\begin{bmatrix} \gamma V_{dd} \\ i_o \end{bmatrix} \tag{35.127}$$

This model will be used to define the output voltage v_o controller.

Sliding-mode control of the PWM audio amplifier

The filter output voltage v_o, divided by the amplifier gain ($1/k_v$), must follow a reference v_{o_r}. Defining the output error as $e_{v_o}=v_{o_r}-k_v v_o$ and also using its time derivatives (e_θ, e_γ, and e_β) as a new state vector $\mathbf{e}=\left[e_{v_o}, e_\theta, e_\gamma, e_\beta\right]^{\mathrm{T}}$, the system equations, in the phase canonical (or controllability) form, can be written in the form

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[e_{v_o}, e_\theta, e_\gamma, e_\beta\right]^{\mathrm{T}} = \left[e_\theta, e_\gamma, e_\beta - f\left(e_{v_o}, e_\theta, e_\gamma, e_\beta\right) + p_e(t) - \gamma V_{dd}/C_1L_1C_2L_2\right]^{\mathrm{T}} \tag{35.128}$$

Sliding-mode control of the output voltage will enable a robust and reduced-order dynamics, independent of semiconductors, power supply, filter, and load parameters. According to Eqs. (35.91) and (35.128), the sliding surface is

$$\begin{aligned} S\left(e_{v_o}, e_\theta, e_\gamma, e_\beta, t\right) &= e_{v_o} + k_\theta e_\theta + k_\gamma e_\gamma + k_\beta e_\beta \\ &= v_{o_r} - k_v v_o + k_\theta \frac{\mathrm{d}(v_{o_r} - k_v v_o)}{\mathrm{d}t} \\ &\quad + k_\gamma \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\mathrm{d}(v_{o_r} - k_v v_o)}{\mathrm{d}t}\right) \\ &\quad + k_\beta \frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\mathrm{d}(v_{o_r} - k_v v_o)}{\mathrm{d}t}\right)\right] = 0 \end{aligned} \tag{35.129}$$

In sliding mode, Eq. (35.129) confirms the amplifier gain ($v_o/v_{o_r}=1/kv$). To obtain a stable system and the smallest possible response time t_r, a pole placement according to a third-order Bessel polynomial is used. Taking t_r inversely proportional to a frequency just below the lowest cutoff frequency (ω_1) of the double LC filter ($t_r \approx 2.8/\omega_1 \approx 2.8/(2\pi \times 21\ \mathrm{kHz}) \approx 20\ \mu\mathrm{s}$) and using Eq. (35.88) with $m=3$, the characteristic polynomial Eq. (35.130), verifying the Routh-Hurwitz criterion, is obtained:

$$S(\mathbf{e}, s) = 1 + st_r + \frac{6}{15}(st_r)^2 + \frac{1}{15}(st_r)^3 \tag{35.130}$$

From Eq. (35.97), the switching law for the control input at time t_k, $\gamma(t_k)$, must be

$$\gamma(t_k) = \mathrm{sgn}\{S(\mathrm{e}, t_k) + \varepsilon\,\mathrm{sgn}[S(\mathrm{e}, t_{k-1})]\} \tag{35.131}$$

To ensure reaching and existence conditions, the power supply voltage V_{dd} must be greater than the maximum required mean value of the output voltage in a switching period $V_{dd} > (\overline{v_{PWMmax}})$. The sliding-mode controller (Fig. 35.41) is obtained from Eqs. (35.129)–(35.131) with $k_\theta = t_r$, $k_\gamma = 6t_r^2/15$, $k_\beta = t_r^3/15$. The derivatives can be approximated by the block diagram of Fig. 35.41B, where h is the oversampling period.

Fig. 35.42A shows the v_{PWM}, v_{o_r}, $v_o/10$, and error $10\times(v_{o_r}-v_o/10)$ waveforms for a 20 kHz sine input. The overall behavior is much better than the obtained with the sigma-delta controllers (Figs. 35.43 and 35.44) explained below for comparison purposes. There is no 0.5 dB loss or phase delay over the entire audio band; the Chebyshev filter behaves as a maximally flat filter, with higher stopband attenuation. Fig. 35.42B shows v_{PWM}, v_{o_r}, and $10\times(v_{o_r}-v_o/10)$ with a

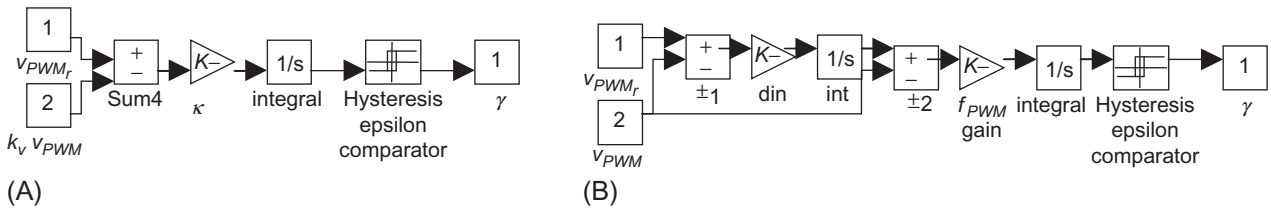

FIG. 35.43 (A) First-order sigma-delta modulator and (B) second-order sigma-delta modulator.

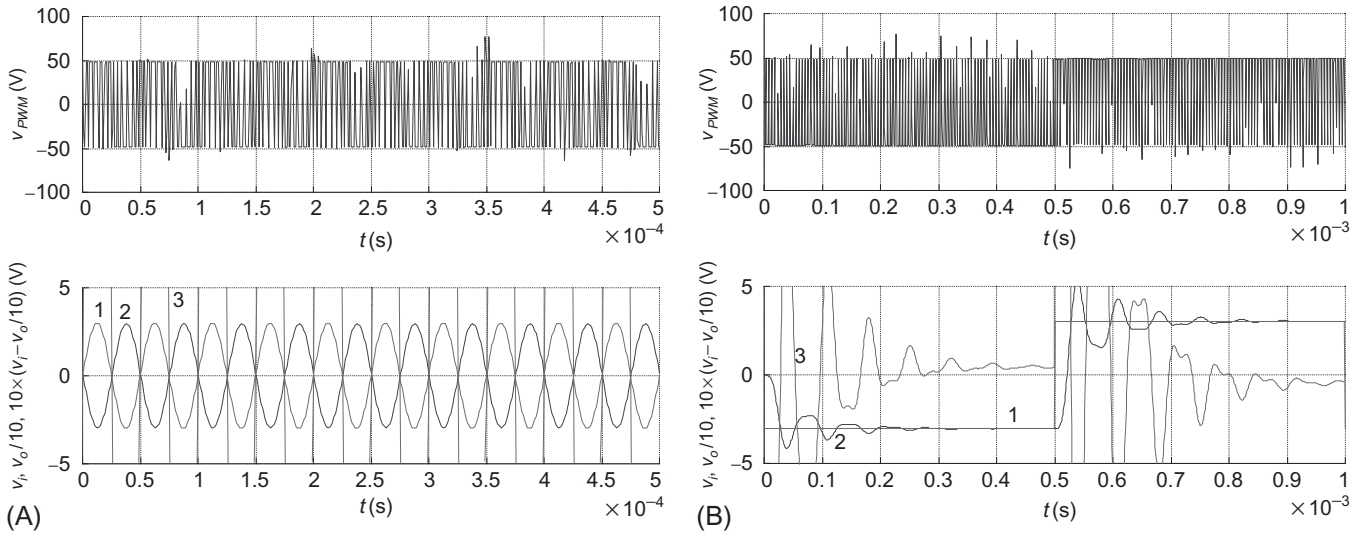

FIG. 35.44 First-order sigma-delta audio amplifier performance (upper graphs show v_{PWM}, lower graphs trace 1 show $v_{o_r}(v_{o_r} \equiv v_i)$, lower graphs trace 2 shows $v_o/10$, and lower graphs trace 3 show $10 \times (v_{o_r} - v_o/10)$): (A) response to a 20 kHz sine input, at 55 W output power, and (B) response to 1 kHz square wave input, at 100 W output power.

1 kHz square input. There is almost no steady-state error and almost no overshoot on the speaker voltage v_o, attesting to the speed of response ($t \approx 20$ μs as designed, since, in contrast to Example 35.12, no derivatives were neglected). The stability, the system order reduction, and the sliding-mode controller usefulness for the PWM audio amplifier are also shown.

Sigma delta controlled PWM audio amplifier

Assume now the fourth-order Chebyshev low-pass filter, as an ideal filter removing the high-frequency content of the v_{PWM} voltage. Then, the v_{PWM} voltage can be considered as the amplifier output. However, the discontinuous voltage $v_{PWM} = \gamma V_{dd}$ is not a state variable and cannot follow the almost continuous reference v_{PWM_r}. The new error variable $e_{vPWM} = v_{PWM_r} - k_v \gamma V_{dd}$ is always far from the zero value. Given this nonzero error, the approach outlined in Section 35.3.4 can be used. The switching law remains Eq. (35.131), but the new control law Eq. (35.132) is

$$S(e_{vPVM}, t) = k \int (v_{PWM_r} - k_v \gamma V_{dd}) dt = 0 \qquad (35.132)$$

The κ parameter is calculated to impose the maximum switching frequency f_{PWM}. Since $\kappa \int_0^{1/2f_{PWM}} \left(v_{PWM_{r\,max}} + k_v V_{dd}\right) \mathrm{d}t = 2\varepsilon$, we obtain

$$f_{PWM} = \kappa (v_{PWM_{rmax}} + k_v V_{dd})/4\varepsilon \qquad (35.133)$$

Assuming that v_{PWM_r} is nearly constant over the switching period $1/f_{PWM}$, Eq. (35.132) confirms the amplifier gain, since $\overline{v_{PWM}} = v_{PWM_r}/k_v$.

Practical implementation of this control strategy can be done using an integrator with gain κ ($\kappa \approx 1800$) and a comparator with hysteresis ε ($\varepsilon \approx 6$ mV) (Fig. 35.43A). Such an arrangement is called a first-order sigma-delta ($\Sigma\Delta$) modulator.

Fig. 35.44A shows the v_{PWM}, v_{or}, and $v_o/10$ waveforms for a 20 kHz sine input. The overall behavior is as expected, because the practical filter and loudspeaker are not ideal, but notice the 0.5 dB loss and phase delay of the speaker voltage v_o, mainly due to the output filter and speaker inductance. In Fig. 35.44B, the v_{PWM}, v_{o_r}, $v_o/10$, and error $10 \times (v_{o_r} - v_o/10)$ for a 1 kHz square input are shown. Note the oscillations and steady-state error of the speaker voltage v_o, due to the filter dynamics and double termination.

A second-order sigma-delta modulator is a better compromise between circuit complexity and signal-to-quantization noise ratio. As the switching frequency of the two power MOSFET (Fig. 35.40) cannot be further increased, the second-order structure named "cascaded integrators with feedback" (Fig. 35.43B) was selected and designed to eliminate the step response overshoot found in Fig. 35.44B.

Fig. 35.45A, for 1 kHz square input, shows much less overshoot and oscillations than Fig. 35.44B. However, the v_{PWM}, v_{o_r}, and $v_o/10$ waveforms, for a 20 kHz sine input presented in Fig. 35.45B, show increased output voltage loss, compared to the first-order sigma-delta modulator, since the second-order modulator was designed to eliminate the v_o output voltage ringing (therefore reducing the amplifier bandwidth). The obtained performances with these and other sigma-delta structures are inferior to the sliding-mode performances (Fig. 35.42). Sliding mode brings definite advantages as the system order is reduced, flatter passbands are obtained, power supply rejection ratio is

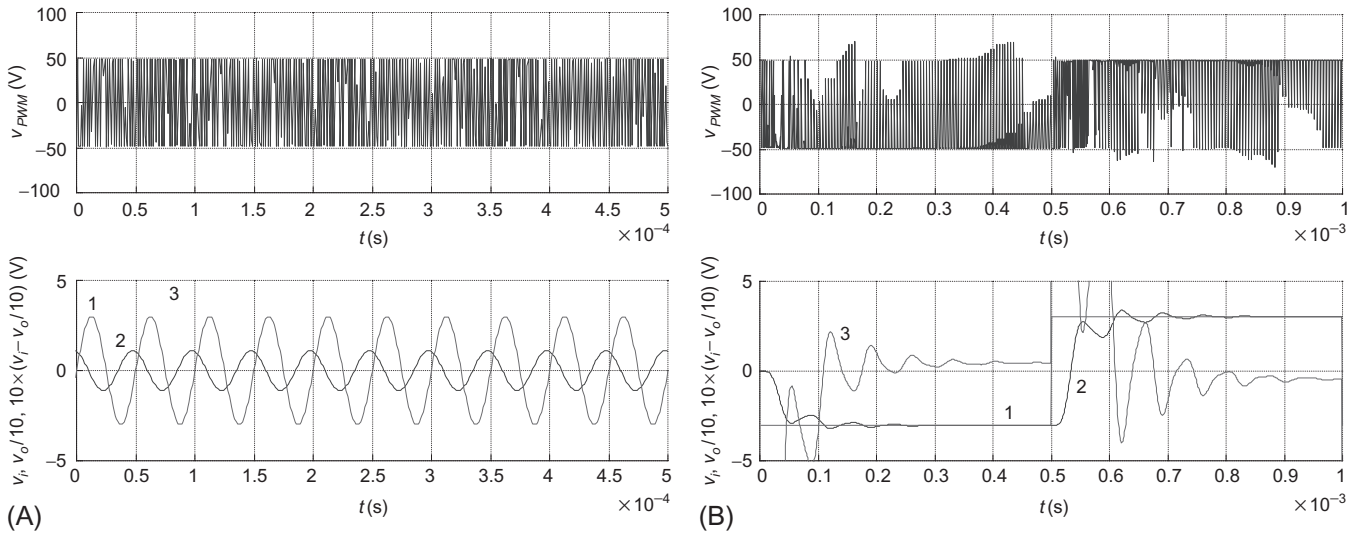

FIG. 35.45 Second-order sigma-delta audio amplifier performance (upper graphs show v_{PWM}, lower graphs trace 1 show $v_{o_r} \equiv v_i$, lower graphs trace 2 show $v_o/10$, and lower graphs trace 3 show $10 \times (v_{o_r} - v_o/10)$): (A) response to 1 kHz square wave input, at 100 W output power, and (B) response to a 20 kHz sine input, at 55 W output power.

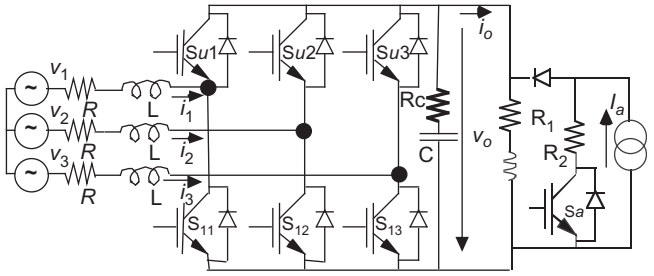

FIG. 35.46 Voltage-sourced three-phase PWM rectifier with IGBTs and test load.

increased, and the nonlinear effects, together with the frequency-dependent phase delays, are canceled out.

35.3.5.4 Example 35.14: Sliding-Mode Control of Near Unity Power Factor PWM Three Phase Rectifiers

Boost-type voltage-sourced three-phase rectifiers (Fig. 35.46) are multiple-input multiple-output (MIMO) systems capable of bidirectional power flow, near unity power factor operation, and almost sinusoidal input currents and can behave as ac/dc power supplies or power factor compensators.

The fast power semiconductors used (usually MOSFETs or IGBTs) can switch at frequencies much higher than the mains frequency, enabling the voltage controller to provide an output voltage with fast dynamic response.

Modeling the three phase PWM boost rectifier

Neglecting switch delays and dead times, the states of the switches of the kth inverter leg (Fig. 35.46) can be represented by the time-dependent nonlinear variables γ_k, defined as

$$\gamma_k = \begin{cases} 1 > \text{if } Su_k \text{ is on and } Sl_k \text{ is off} \\ 0 > \text{if } Su_k \text{ is off and } Sl_k \text{ is on} \end{cases} \tag{35.134}$$

Consider the displayed variables of the circuit (Fig. 35.46), where L is the value of the boost inductors, R their resistance, C the value of the output capacitor, and R_c its equivalent series resistance (ESR). Neglecting semiconductor voltage drops, leakage currents, and auxiliary networks, the application of Kirchhoff laws (taking the load current i_o as a time-dependent perturbation) yields the following switched state-space model of the boost rectifier:

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} i_1 \\ i_2 \\ i_3 \\ v_o \end{bmatrix} = \begin{bmatrix} -R/L & 0 & 0 & (-2\gamma_1+\gamma_2+\gamma_3)/(3L) \\ 0 & -R/L & 0 & (-2\gamma_2+\gamma_3+\gamma_1)/(3L) \\ 0 & 0 & -R/L & (-2\gamma_3+\gamma_1+\gamma_2)/(3L) \\ A_{41} & A_{42} & A_{43} & A_{44} \end{bmatrix}\begin{bmatrix} i_1 \\ i_2 \\ i_3 \\ v_o \end{bmatrix} + \begin{bmatrix} 1/L & 0 & 0 & 0 & 0 \\ 0 & 1/L & 0 & 0 & 0 \\ 0 & 0 & 1/L & 0 & 0 \\ \gamma_1 R_c/L & \gamma_2 R_c/L & \gamma_3 R_c/L & -1/C & -R_c \end{bmatrix}\begin{bmatrix} v_1 \\ v_2 \\ v_3 \\ i_o \\ \mathrm{d}i_o/\mathrm{d}t \end{bmatrix} \tag{35.135}$$

where $A_{41} = \gamma_1\left(\frac{1}{C} - \frac{RR_c}{L}\right)$, $A_{42} = \gamma_2\left(\frac{1}{C} - \frac{RR_c}{L}\right)$, $A_{43} = \gamma_3\left(\frac{1}{C} - \frac{RR_c}{L}\right)$, $A_{44} = \frac{-2R_c(\gamma_1(\gamma_1-\gamma_2)+\gamma_2(\gamma_2-\gamma_3)+\gamma_3(\gamma_3-\gamma_1))}{3L}$

Since the input voltage sources have no neutral connection, the preceding model can be simplified, eliminating one equation. Using the relationship (35.136) between the fixed frames x_1, 2, 3, and $x_{\alpha,\beta}$, in Eq. (35.135), the state-space model (35.137), in the α,β frame, is obtained:

$$\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} \sqrt{2/3} & 0 \\ -\sqrt{1/6} & \sqrt{1/2} \end{bmatrix}\begin{bmatrix} x_\alpha \\ x_\beta \end{bmatrix} \tag{35.136}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} i_\alpha \\ i_\beta \\ v_o \end{bmatrix} = \begin{bmatrix} -R/L & \omega & -\gamma_\alpha/L \\ 0 & -R/L & -\gamma_\alpha/L \\ A^\alpha_{31} & A^\alpha_{32} & A^\alpha_{33} \end{bmatrix}\begin{bmatrix} i_\alpha \\ i_\beta \\ v_o \end{bmatrix} + \begin{bmatrix} 1/L & 0 & 0 & 0 \\ 0 & 1/L & 0 & 0 \\ \gamma_\alpha R_c/L & \gamma_\beta R_c/L & -1/C & -R_c \end{bmatrix}\begin{bmatrix} v_\alpha \\ v_\beta \\ i_o \\ \mathrm{d}i_o/\mathrm{d}t \end{bmatrix} \tag{35.137}$$

where $A^\alpha_{31} = \gamma_\alpha\left(\frac{1}{C} - \frac{RR_c}{L}\right)$, $A^\alpha_{32} = \gamma_\beta\left(\frac{1}{C} - \frac{RR_c}{L}\right)$, $A^\alpha_{33} = \frac{-R_c\left(\gamma_\alpha^2+\gamma_\beta^2\right)}{L}$

Sliding-mode control of the PWM rectifier

The model (35.137) is nonlinear and time-variant. Applying the Park transformation (35.138), using a frequency ω rotating reference frame synchronized with the mains (with the q component of the supply voltages equal to zero), the nonlinear, time-invariant model (35.139) is written as

$$\begin{bmatrix} i_\alpha \\ i_\beta \end{bmatrix} = \begin{bmatrix} \cos(\omega t) & -\sin(\omega t) \\ \sin(\omega t) & \cos(\omega t) \end{bmatrix}\begin{bmatrix} i_d \\ i_q \end{bmatrix} \tag{35.138}$$

$$\frac{d}{dt}\begin{bmatrix} i_d \\ i_q \\ v_o \end{bmatrix} = \begin{bmatrix} -R/L & \omega & -\gamma_d/L \\ -\omega & -R/L & -\gamma_q/L \\ A^d_{31} & A^d_{32} & A^d_{33} \end{bmatrix}\begin{bmatrix} i_d \\ i_q \\ v_o \end{bmatrix} + \begin{bmatrix} 1/L & 0 & 0 & 0 \\ 0 & 1/L & 0 & 0 \\ \gamma_d R_c/L & \gamma_q R_c/L & -1/C & -R_c \end{bmatrix}\begin{bmatrix} v_d \\ v_q \\ i_o \\ di_o dt \end{bmatrix} \tag{35.139}$$

where $A^d_{31} = \gamma_d\left(\frac{1}{C} - \frac{RR_c}{L}\right)$, $A^d_{32} = \gamma_q\left(\frac{1}{C} - \frac{RR_c}{L}\right)$, $A^d_{33} = \frac{-R_c\left(\gamma_d^2+\gamma_q^2\right)}{L}$

This state-space model can be used to obtain the feedback controllers for the PWM boost rectifier. Considering the output voltage v_o and the i_q current as the controlled outputs and γ_d and γ_q the control inputs (MIMO system), the input-output linearization of Eq. (35.72) gives the state-space equations in the controllability canonical form (35.140):

$$\frac{di_q}{dt} = -\omega i_d - \frac{R}{L} i_q - \frac{\gamma_q}{L} v_o + \frac{1}{L} v_q$$

$$\frac{dv_o}{dt} = \theta$$

$$\frac{d\theta}{dt} = \frac{R + R_c\left(\gamma_d^2 + \gamma_q^2\right)}{L}\theta - \frac{\gamma_d^2 + \gamma_q^2}{LC} v_o + \frac{\gamma_d v_d + \gamma_q v_q}{LC} - \frac{R i_o}{LC} - \left(\frac{1}{C} + \frac{RR_c}{L}\right)\frac{di_o}{dt} + \omega\left(\frac{1}{C} - \frac{RR_c}{L}\right)\left(\gamma_d i_q - \gamma_d i_q\right) - R_c \frac{d^2 i_o}{dt^2} \tag{35.140}$$

where

$$\theta = \left(\frac{1}{C} - \frac{RR_c}{L}\right)\left(\gamma_d i_d + \gamma_q i_q\right) - \frac{R_c\left(\gamma_d^2 + \gamma_q^2\right)}{L} v_o + \frac{R_c}{L}\left(\gamma_d v_d + \gamma_q v_q\right) - \frac{i_o}{C} - R_c \frac{di_o}{dt}$$

Using the rectifier overall power balance (from Tellegen's theorem, the converter is conservative, i.e., the power delivered to the load or dissipated in the converter intrinsic devices equals the input power) and neglecting the switching and output capacitor losses, $v_d i_d + v_q i_q = v_o i_o + R i_d^2$. Supposing unity power factor ($i_{qr} \approx 0$) and the output v_o at steady state, $\gamma_d i_d + \gamma_q i_q \approx i_o$, $v_d = \sqrt{3} V_{RMS}$, $v_q = 0, \gamma_q \approx v_q / v_o, \gamma_d \approx (v_d - R i_d)/v_o$. Then, from Eqs. (35.140) and (35.91), the following two sliding surfaces can be derived:

$$S_q\left(e_{i_q}, t\right) = k_{e_{i_q}}\left(i_{qr} - i_q\right) = 0 \tag{35.141}$$

$$S_d(e_{v_o}, e_\theta, t) \approx \left[\beta^{-1}(v_{o_r} - v_o) + \frac{dv_{o_r}}{dt} + \frac{1}{C} i_o + R_c \frac{di_o}{dt}\right] \times \frac{LC}{L - CRR_c} \frac{v_o}{\sqrt{3} V_{RMS} - R i_d} - i_d = i_{d_r} - i_d = 0 \tag{35.142}$$

where β^{-1} is the time constant of the desired first-order response of output voltage v_o ($\beta \gg T > 0$). For the synthesis of the closed-loop control system, notice that the terms of Eq. (35.142) inside the square brackets can be assumed as the i_d reference current i_{d_r}. Furthermore, from Eqs. (35.141) and (35.142), it is seen that the current control loops for i_d and i_q are needed. Considering Eqs. (35.138) and (35.136), the two sliding surfaces can be written as

$$S_\alpha\left(e_{i_\alpha}, t\right) = i_{\alpha_r} - i_\alpha = 0 \tag{35.143}$$

$$S_\beta\left(e_{i_\beta}, t\right) = i_{\beta_r} - i_\beta = 0 \tag{35.144}$$

The switching laws relating the sliding surfaces (35.143) and (35.144) with the switching variables γ_k are

$$\begin{cases} \text{if } S_{\alpha\beta}\left(e_{i_{\alpha\beta}}, t\right) > \varepsilon \text{ then } i_{\alpha\beta_r} > i_{\alpha\beta} \text{ hence choose } \gamma_k \text{ to increase the } i_{\alpha\beta} \text{ current} \\ \text{if } S_{\alpha\beta}\left(e_{i_{\alpha\beta}}, t\right) < -\varepsilon \text{ then } i_{\alpha\beta_r} > i_{\alpha\beta} \text{ hence choose } \gamma_k \text{ to decrease the } i_{\alpha\beta} \text{ current} \end{cases} \tag{35.145}$$

The practical implementation of this switching strategy could be accomplished using three independent two-level hysteresis comparators. However, this might introduce limit cycles as only two line currents are independent. Therefore, the control laws (35.143) and (35.144) can be implemented using the block diagram of Fig. 35.47A, with d, q/α, and β (from Eq. (35.138)) and 1,2,3/α, and β (from Eq. (35.136)) transformations and two

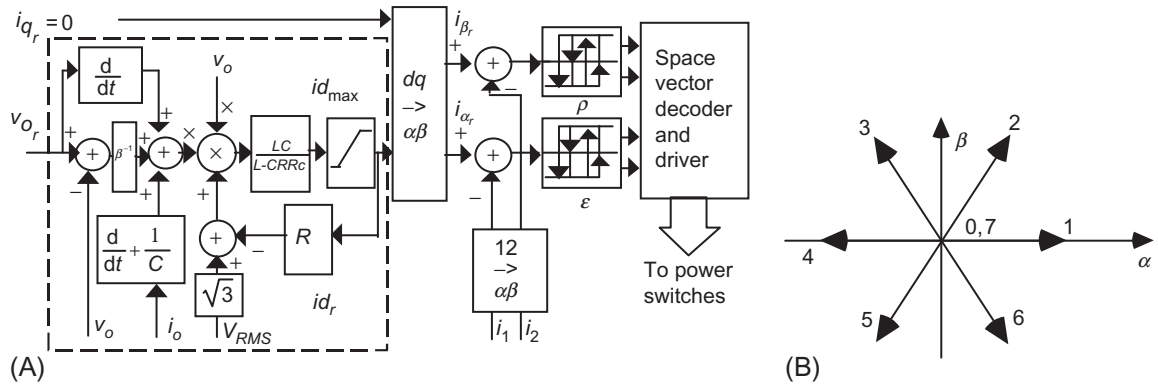

FIG. 35.47 (A) Sliding-mode PWM controller modulator for the unity power factor three-phase PWM rectifier and (B) α and β space-vector representation of the PWM bridge rectifier leg voltages.

three-level hysteretic comparators with equivalent hysteresis ε and ρ to limit the maximum switching frequency. A limiter is included to bound the i_d reference current to i_{dmax}, keeping the input line currents within a safe value. This helps to eliminate the nonminimum-phase behavior (outside sliding mode) when large transients are present while providing short-circuit proof operation.

α, β space vector current modulator

Depending on the values of γ_k, the bridge rectifier leg output voltages can assume only eight possible distinct states represented as voltage vectors in the α and β reference frame (Fig. 35.47B), for sources with isolated neutral.

With only two independent currents, two three-level hysteresis comparators, for the current errors, must be used in order to accurately select all eight available voltage vectors. Each three-level comparator [16] can be obtained by summing the outputs of two comparators with two levels each. One of these two comparators ($\delta_{L\alpha}$ and $\delta_{L\beta}$) has a wide hysteresis width, and the other ($\delta_{N\alpha}$ and $\delta_{N\beta}$) has a narrower hysteresis width. The hysteresis bands are represented by ε and ρ. Table 35.1 represents all possible output combinations of the resulting four two-level comparators, their sums giving the two three-level comparators (δ_α and δ_β), plus the voltage vector needed to accomplish the current tracking strategy $\left(i_{\alpha,\beta_r} - i_{\alpha,\beta}\right) = 0$ (ensuring $\left(i_{\alpha,\beta_r} - i_{\alpha,\beta}\right) \times d\left(i_{\alpha,\beta_r} - i_{\alpha,\beta}\right)/dt < 0$, plus the γ_k variables and the α and β voltage components).

From the analysis of the PWM boost rectifier, it is concluded that, if, for example, the voltage vector 2 is applied ($\gamma_1 = 1$, $\gamma_2 = 1$, and $\gamma_3 = 0$), in boost operation, the currents i_α and i_β will both decrease. Oppositely, if the voltage vector 5 ($\gamma_1 = 0$, $\gamma_2 = 0$, and $\gamma_3 = 1$) is applied, the currents i_α and i_β will both increase. Therefore, vector 2 should be selected when both i_α and i_β currents are above their respective references, that is, for $\delta_\alpha = -1$, $\delta_\beta = -1$, whereas vector 5 must be chosen when both i_α and i_β currents are under their respective references or, for $\delta_\alpha = 1$, $\delta_\beta = 1$. Nearly all the outputs of Table 35.2 can be filled using this kind of reasoning.

In the cases where $\delta_\alpha = 0$ and $\delta_\beta = -1$, the vector is selected upon the value of the i_α current error (if $\delta_{L\alpha} > 0$ and $\delta_{N\alpha} < 0$, then vector 2 and if $\delta_{L\alpha} < 0$ and $\delta_{N\alpha} > 0$, then vector 3). When $\delta_\alpha = 0$ and $\delta_\beta = 1$, if $\delta_{L\alpha} > 0$ and $\delta_{N\alpha} < 0$, then vector 6, else if $\delta_{L\alpha} < 0$ and $\delta_{N\alpha} > 0$, then vector 5. The vectors 0 and 7 are selected in order to minimize the switching frequency (if two of the three upper switches are on, then vector 7, otherwise vector 0). The space-vector decoder can be stored in a lookup table (or in an EPROM) whose inputs are the four two-level comparator outputs and the logic result of the operations needed to select between vectors 0 and 7.

PI output voltage control of the current-mode PWM rectifier

Using the α and β current-mode hysteresis modulators to enforce the i_d and i_q currents to follow their reference values, i_{d_r}, i_{q_r} (the values of L and C are such that the i_d and i_q currents usually exhibit a very fast dynamics compared with the slow dynamics of v_o), a first-order model (35.146) of the rectifier output voltage can be obtained from Eq. (35.73):

$$\frac{dv_o}{dt} = \left(\frac{1}{C} - \frac{RR_c}{L}\right)\left(\gamma_d i_{d_r} + \gamma_q i_{q_r}\right) - \frac{R_c\left(\gamma_d^2 + \gamma_q^2\right)}{L} v_o + \frac{R_c}{L}\left(\gamma_d v_d + \gamma_q v_q\right) - \frac{i_o}{C} - R_c \frac{di_o}{dt} \tag{35.146}$$

Assuming now a pure resistor load $R_1 = v_o/i_o$ and a mean delay T_d between the i_d current and the reference i_{d_r}, continuous

transfer functions result for the i_d current ($i_d = i_{dr}(1+sTd)^{-1}$) and for the v_o voltage ($v_o = k_A i_d/(1+sk_B)$ with k_A and k_B obtained from Eq. (35.146)). Therefore, using the same approach as Examples 35.6, 35.8, and 35.11, a linear PI regulator, with gains K_p and K_i (35.147), sampling the error between the output voltage reference v_{o_r} and the output v_o, can be designed to provide a voltage proportional (k_I) to the reference current $i_{d_r}\left(i_{d_r} = \left(K_p + K_i/s\right)K_I(v_{o_r} - v_o)\right)$:

$$K_p = \frac{R_1 + R_c}{4\zeta^2 T_d R_1 K_1 \gamma_d (1/C - RR_c/L)}$$
$$K_i = \frac{R_c\left(\gamma_d^2 + \gamma_q^2\right)/L + 1/(R_1 C)}{4\zeta^2 T_d K_1 \gamma_d (1/C - RR_c/L)} \quad (35.147)$$

These PI regulator parameters depend on the load resistance R_1, on the rectifier parameters (C, R_c, L, and R), on the rectifier operating point γ_d, on the mean delay time T_d, and on the required damping factor ζ. Therefore, the expected response can only be obtained with the nominal load and input voltages, the line current dynamics depending on the K_p and K_i gains.

Results (Fig. 35.48) obtained with the values $V_{RMS} \approx 70$ V, $L \approx 1.1$ mH, $R \approx 0.1\ \Omega$, $C \approx 2000\ \mu$F with equivalent series resistance ESR $\approx 0.1\ \Omega$ ($R_c \approx 0.1\ \Omega$), $R_1 \approx 25\ \Omega$, $R_2 \approx 12\ \Omega$, $\beta = 0.0012$, $K_p = 1.2$, $K_i = 100$, and $k_I = 1$ show that the α and β space-vector current modulator ensures the current tracking needed (Fig. 35.48) [17–19]. The v_o step response reveals a faster sliding-mode controller and the correct design of the current-mode/PI controller parameters. The robustness property of the sliding-mode-controlled output v_o, compared with the current mode/PI, is shown in Fig. 35.49.

35.3.5.5 Example 35.15: Sliding-Mode Controllers for Multilevel Inverters

Diode-clamped multilevel inverters (Fig. 35.50) are the converters of choice for high-voltage high-power dc/ac or ac/ac (with dc link) applications, as the active semiconductors (usually gate turn-off thyristors (GTO) or IGBT transistors) of n-level power conversion systems, must withstand only a fraction (normally $U_{cc}/(n-1)$) of the total supply voltage U_{cc}. Moreover, the output voltage of multilevel converters, being staircase-like waveforms with n steps, features lower harmonic

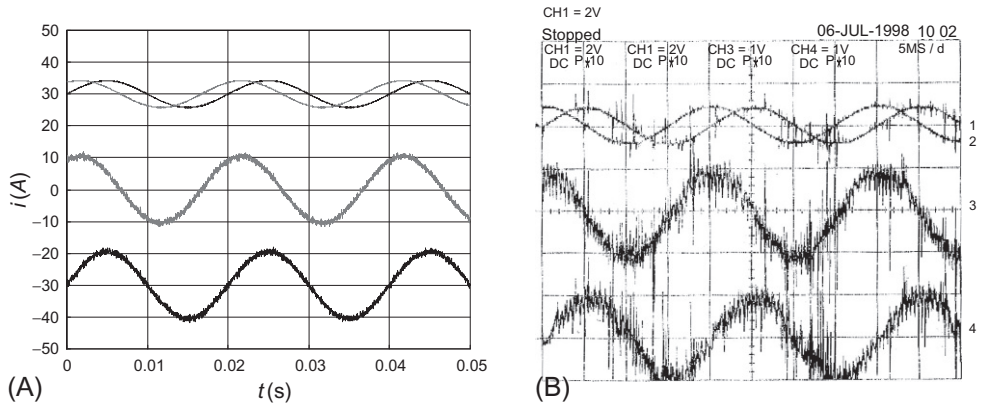

FIG. 35.48 α and β space-vector current modulator operation at near unity power factor: (A) simulation result ($i_{1r} + 30; i_{2_r} + 30; 2 \times i_1; 2 \times i_2 - 30$) and (B) experimental result ($1 \rightarrow i_{1r}, 2 \rightarrow i_{2r}$ (10 A/div); $3 \rightarrow i_1, 4 \rightarrow i_2$ (5 A/div)).

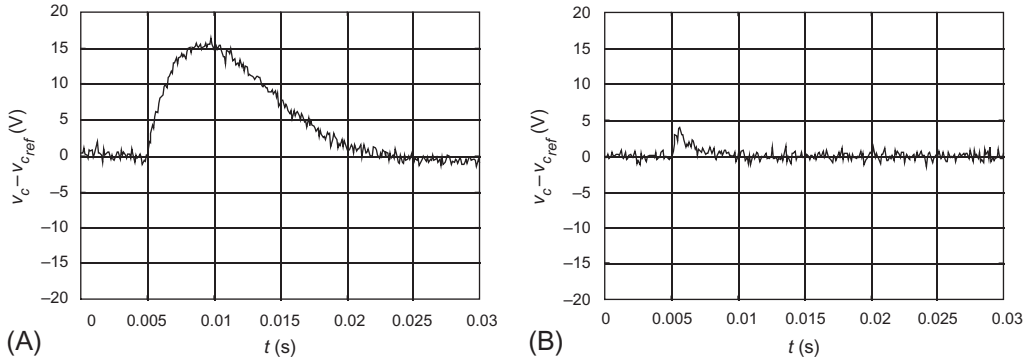

FIG. 35.49 Transition from rectifier to inverter operation (i_o from 8 to −8 A) obtained by switching off IGBT S_a (Fig. 35.46) and using $I_a = 16$ A: (A) $v_o - v_{or}$ (v) with sliding-mode control and (B) $v_o - v_{or}$ (v) with current-mode/PI control.

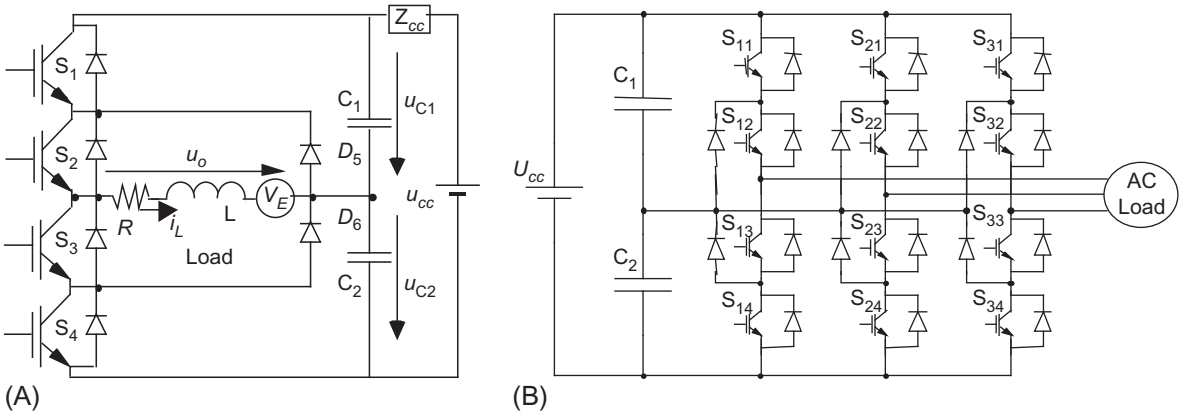

FIG. 35.50 (A) Single-phase, neutral-point-clamped, three-level inverter with IGBTs and (B) three-phase, neutral-clamped, three-level inverter.

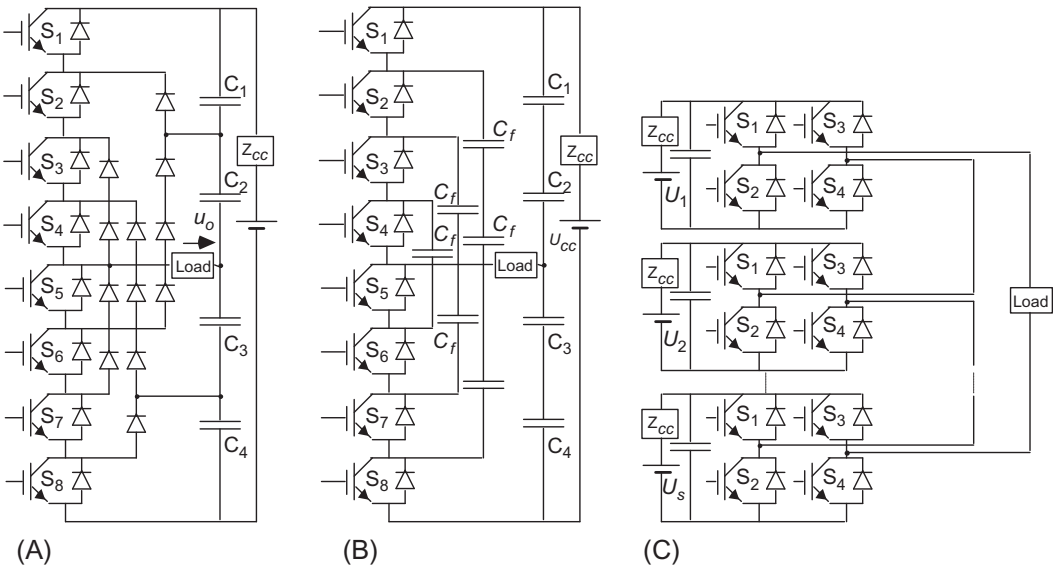

FIG. 35.51 (A) Five-level ($n=5$) diode-clamped inverter with IGBTs, (B) five-level ($n=5$) flying capacitor converter, and (C) multilevel converter based on cascaded full-bridge inverters.

distortion compared with the two-level waveforms with the same switching frequency.

The advantages of multilevel converters are paid into the price of the capacitor supply voltage dividers (Fig. 35.51) and voltage equalization circuits, into the cost of extra power supply arrangements (Fig. 35.51C) and into increased control complexity. This example shows how to extend the two-level switching law (35.97) to n-level converters and how to equalize the voltage of the capacitive dividers.

Considering single-phase three-level inverters (Fig. 35.50A), the open-loop control of the output voltage can be made using three-level SPWM. The two-level modulator, seen in Example 35.9, can be easily extended (Fig. 35.52A) to generate the γ_{III} command (Fig. 35.52B) to three-level inverter legs, from the two-level γ_{II} signal, either with a dedicated modulator or using the following relation:

$$\gamma_{III} = \gamma_{II}(m_i sin(\omega t) - \text{sgn}(m_i \sin(\omega t))/2 - r(t)/2) - 1/2 + \text{sgn}(m_i \sin(\omega t))/2 \quad (35.148)$$

The required three-level SPWM modulators for the output voltage synthesis seldom take into account the semiconductors and the capacitor voltage divider nonideal characteristics. Consequently, the capacitor voltage divider tends to drift, one capacitor being overcharged and the other discharged, and an asymmetry appears in the currents of the power supply. A steady-state error in the output voltage can also be present. Sliding-mode control can provide the optimum switching

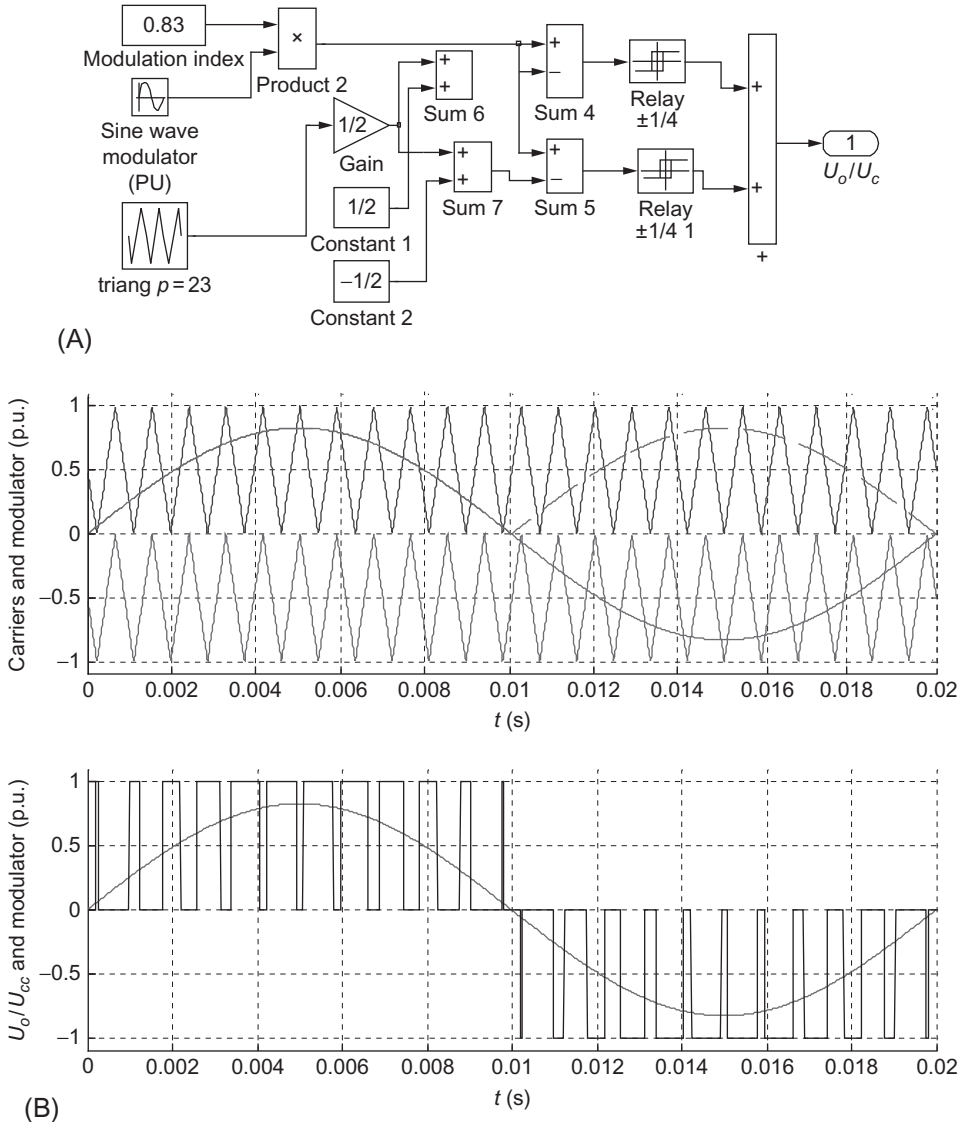

FIG. 35.52 (A) Three-level SPWM modulator schematic and (B) main three-level SPWM signals.

timing between all the converter levels, together with robustness to supply voltage disturbances, semiconductor nonidealities, and load parameters.

Sliding-mode surface and switching law

For a variable-structure system where the control input $u_i(t)$ can present n levels, consider the n values of the integer variable γ, being $-(n-1)/2 \leq \gamma \leq (n-1)/2$ and $u_i(t) = \gamma U_{cc}/(n-1)$, dependent on the topology and on the conducting semiconductors. To ensure the sliding-mode manifold invariance condition (35.92) and the reaching mode behavior, the switching strategy $\gamma(t_{k+1})$ for the time instant t_{k+1}, considering the value of $\gamma(t_k)$, must be

$$\gamma(t_{k+1}) = \begin{cases} \gamma(t_k) + 1 \text{ if } S(e_{x_i}, t) > \varepsilon \wedge \dot{S}(e_{x_i}, t) \\ \qquad > \varepsilon \wedge \gamma(t_k) < (n-1)/2 \\ \gamma(t_k) - 1 \text{ if } S(e_{x_i}, t) < -\varepsilon \wedge \dot{S}(e_{x_i}, t) \\ \qquad < -\varepsilon \wedge \gamma(t_k) > -(n-1)/2 \end{cases} \tag{35.149}$$

This switching law can be implemented as depicted in Fig. 35.53A and for five levels in B. An alternative is shown in Fig. 35.53C and named stability condition-based modulator [20], where the switching law (35.149) is directly used, calculating the sliding-mode surface and its time derivative, implemented as a discrete time variation. They are two-level quantized, and upon their values (obtained by half of their sum), the

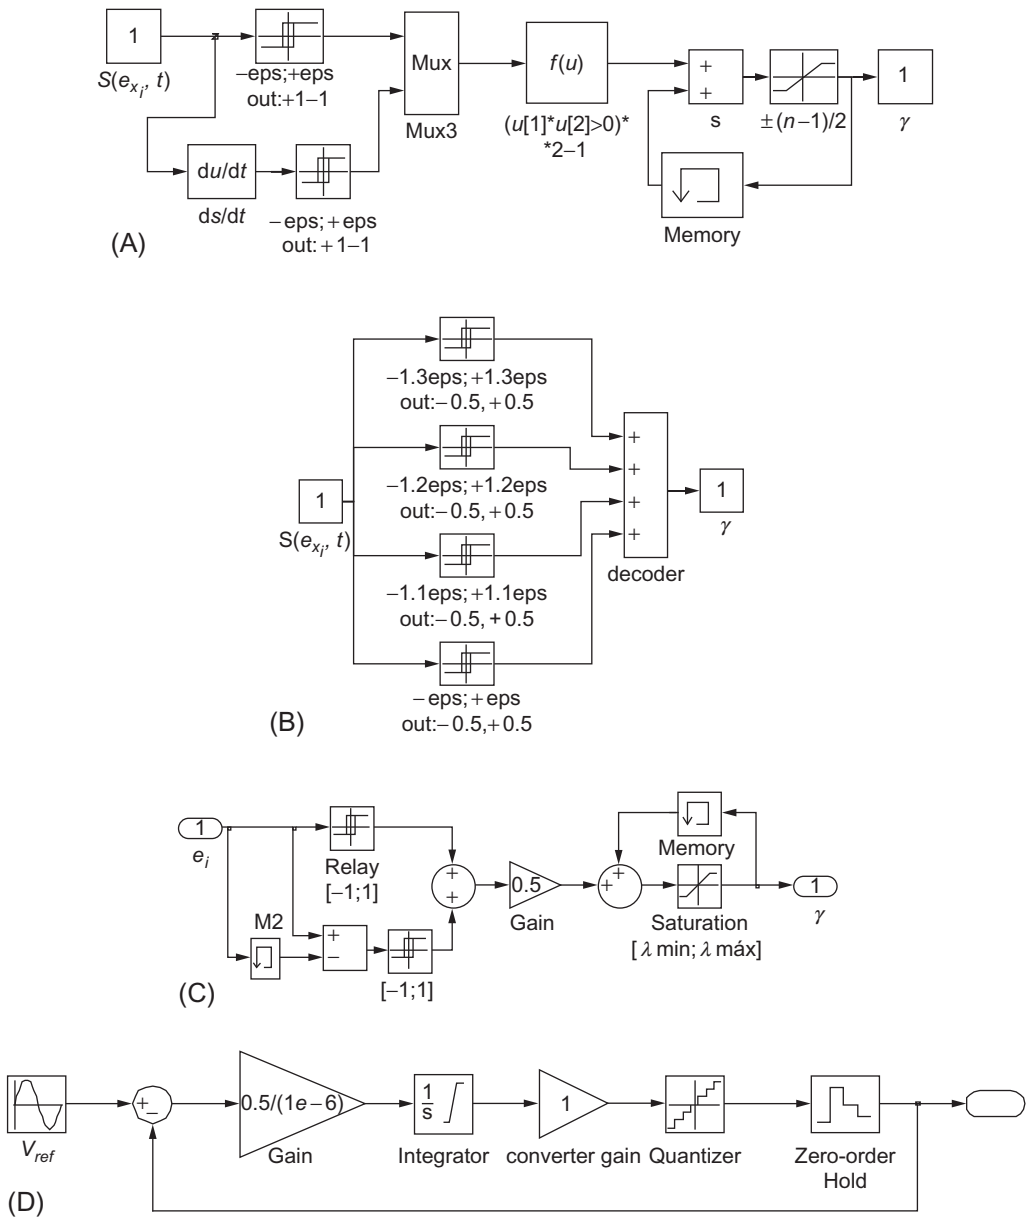

FIG. 35.53 (A) Multilevel sliding-mode PWM modulator with n-level hysteresis comparator with quantization interval ε, (B) four hysteresis comparator implementation of a five-level switching law, (C) stability condition-based multilevel modulator (one phase), (D) generalized sigma-delta n-level modulator.

voltage level is increased (or decreased), until it reaches the maximum (or the minimum). Therefore, the output level is increased (or decreased) if the error and its derivative are both positive (or negative), with the upper limit $\lambda_{máx} = (n-1)/2$ and lower limit $\lambda_{min} = -(n-1)/2$.

Other implementations are possible (Fig. 35.53D), since in every modulation method the generated pulse levels must have the same volt-second average of the fundamental sinusoidal (i.e., the integral over time of the n-level voltage waveform minus the value of the fundamental should be zero).

Control of the output voltage in single-phase multilevel converters

To control the inverter output voltage, in closed-loop and in diode-clamped multilevel inverters with n levels and supply voltage U_{cc}, a control law similar to Eq. (35.132), $S(e_{uo}, t) = \kappa \int (u_{o_r} - k_v \gamma(t_k) U_{cc}/(n-1))dt = 0$, is suitable.

Fig. 35.54A shows the waveforms of a five-level sliding-mode-controlled inverter, namely, the input sinus voltage, the generated output staircase wave, and the sliding-surface

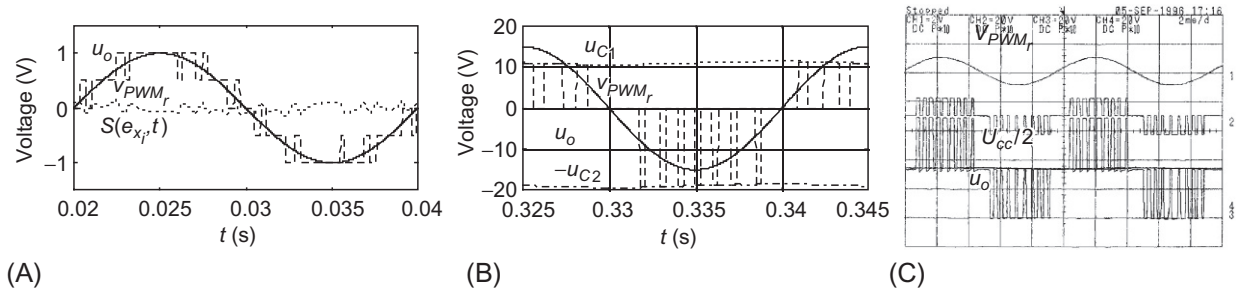

FIG. 35.54 (A) Scaled waveforms of a five-level sliding-mode-controlled single-phase converter, showing the input sinus voltage v_{PWM_r}, the generated output staircase wave u_o, and the value of the sliding surface $S(e_{x_i}, t)$; (B) scaled waveforms of a three-level neutral-point-clamped inverter showing the capacitor voltage unbalance (shown as two near-flat lines touching the tips of the PWM pulses); and (C) experimental results from a laboratory prototype of a three-level single-phase power inverter with the capacitor voltage equalization described.

instantaneous error. This error is always within a band centered around the zero value and presents zero mean value, which is not the case of sigma-delta modulators followed by n-level quantizers, where the error presents an offset mean value in each half period.

Experimental multilevel converters always show capacitor voltage unbalances (Fig. 35.54B) due to small differences between semiconductor voltage drops and circuitry offsets. To obtain capacitor voltage equalization, the voltage error $(v_{c_2} - U_{cc}/2)$ is fed back to the controller (Fig. 35.55A) to counteract the circuitry offsets. Experimental results (Fig. 35.54C) clearly show the effectiveness of the correction made. The small steady-state error, between the voltages of the two capacitors, still present, could be eliminated using an integral regulator (Fig. 35.55B).

Fig. 35.56 confirms the robustness of the sliding-mode controller to power supply disturbances.

Output current control in single-phase multilevel converters
Considering an inductive load with current i_L, the control law (35.107) and the switching law of (35.149) should be used for single-phase multilevel inverters. Results obtained using the capacitor voltage equalization principle just described are shown in Fig. 35.57.

35.3.5.6 Example 35.16: Sliding-Mode Controllers for Three-Phase Multilevel Inverters

Three-phase n-level inverters (Fig. 35.58) are suitable for high-voltage, high-power dc/ac applications, such as modern high-speed railway traction drives, as the controlled turn-off

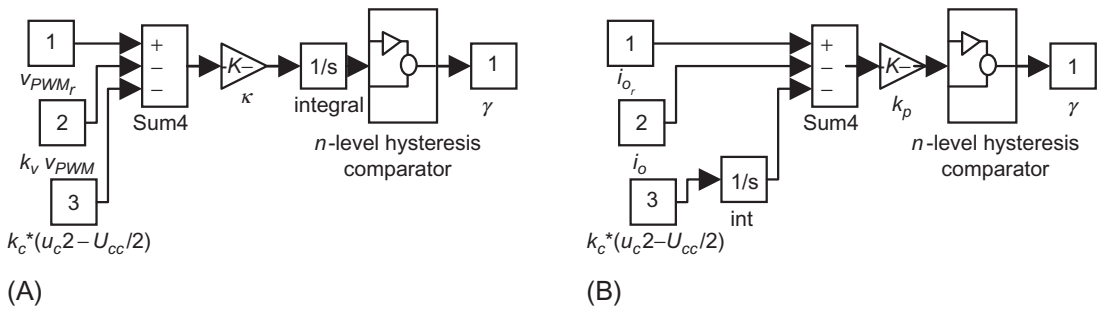

FIG. 35.55 (A) Multilevel sliding-mode output voltage controller and PWM modulator with capacitor voltage equalization and (B) sliding-mode output current controller with capacitor voltage equalization.

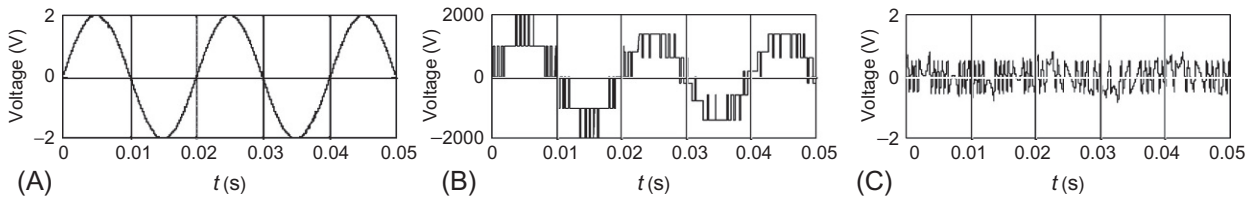

FIG. 35.56 Simulated performance of a five-level power inverter, with a U_{cc} voltage dip (from 2 to 1.5 kV). Response to a sinusoidal wave of frequency 50 Hz: (A) v_{PWM_r} input, (B) PWM output voltage u_o, and (C) the integral of the error voltage, which is maintained close to zero.

semiconductors must block only a fraction (normally $U_{dc}/(n-1)$) of the total supply voltage U_{dc}.

This example presents a real-time modulator for the control of the three output voltages and capacitor voltage equalization, based on the use of sliding mode and space vectors represented in the α and β frame. Capacitor voltage equalization is done with the proper selection of redundant space vectors.

Output voltage control in multilevel converters

To guarantee the topological constraints of this converter and the correct sharing of the U_{dc} voltage by the semiconductors, the switching strategy for the k leg ($k \in \{1, 2, 3\}$) must ensure complementary states to switches S_{k1} and S_{k3}.

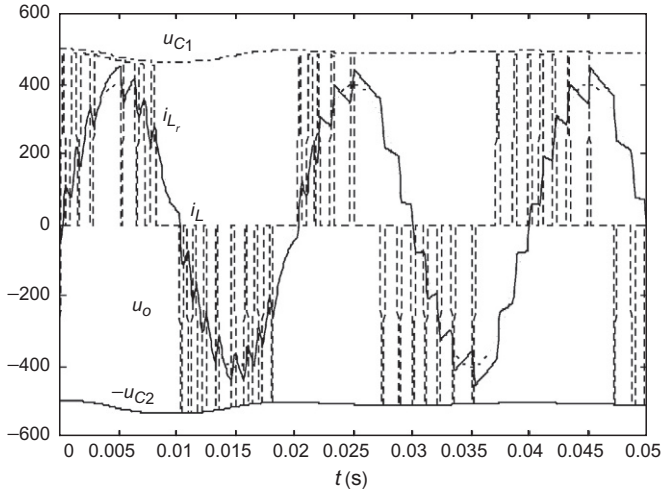

FIG. 35.57 Operation of a three-level neutral-point-clamped inverter as a sinusoidal current source: Scaled waveforms of the output current sine wave reference i_{Lr}, the output current i_L, showing ripple, together with the PWM-generated voltage u_o, with nearly equal pulse heights, corresponding to the equalized dc capacitor voltages u_{C1} and u_{C2}.

The same restriction applies for S_{k2} and S_{k4}. Neglecting switching delays, dead times, on-state semiconductor voltage drops, snubber networks, and power supply variations; supposing small dead times and equal capacitor voltages $U_{C1} = U_{C2} = U_{dc}/2$; and using the time-dependent switching variable $\gamma_k(t)$, the leg output voltage U_k (Fig. 35.58) will be $U_k = \gamma_k(t) U_{dc}/2$, with

$$\gamma_k(t) = \begin{cases} 1 & \text{if } S_{k1} \wedge S_{k2} \text{ are ON} \wedge S_{k3} \wedge S_{k4} \text{ are OFF} \\ 0 & \text{if } S_{k2} \wedge S_{k3} \text{ are ON} \wedge S_{k1} \wedge S_{k4} \text{ are OFF} \\ -1 & \text{if } S_{k3} \wedge S_{k4} \text{ are ON} \wedge S_{k1} \wedge S_{k2} \text{ are OFF} \end{cases} \tag{35.150}$$

The converter output voltages U_{Sk} of vector $\mathbf{U}_S$ can be expressed as

$$\mathrm{U}_S = \begin{bmatrix} 2/3 & -1/3 & -1/3 \\ -1/3 & 2/3 & -1/3 \\ -1/3 & -1/3 & 2/3 \end{bmatrix} \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} \frac{U_{dc}}{2} \tag{35.151}$$

The application of the Concordia transformation $U_{S1,2,3} = [\mathbf{C}]\, U_{S\alpha,\,\beta,\,o}$ (Eq. (35.152) to (35.151))

$$\begin{bmatrix} U_{S1} \\ U_{S2} \\ U_{S3} \end{bmatrix} = \sqrt{\frac{2}{3}} \begin{bmatrix} 1 & 0 & 1/\sqrt{2} \\ -1/2 & \sqrt{3}/2 & 1/\sqrt{2} \\ -1/2 & -\sqrt{3}/2 & 1/\sqrt{2} \end{bmatrix} \begin{bmatrix} U_{S\alpha} \\ U_{S\beta} \\ U_{So} \end{bmatrix} \tag{35.152}$$

gives the output voltage vector in the α and β coordinates $\mathbf{U}_{S_{\alpha,\beta}}$:

$$\mathbf{U}_{S_{\alpha,\beta}} = \begin{bmatrix} U_{s\alpha} \\ U_{s\beta} \end{bmatrix} = \sqrt{\frac{2}{3}} \begin{bmatrix} 1 & -\frac{1}{2} & -\frac{1}{2} \\ 0 & \frac{\sqrt{3}}{2} & -\frac{\sqrt{3}}{2} \end{bmatrix} \begin{bmatrix} \Gamma_1 \\ \Gamma_2 \\ \Gamma_3 \end{bmatrix} \frac{U_{dc}}{2} = \begin{bmatrix} \Gamma_\alpha \\ \Gamma_\beta \end{bmatrix} \frac{U_{dc}}{2} \tag{35.153}$$

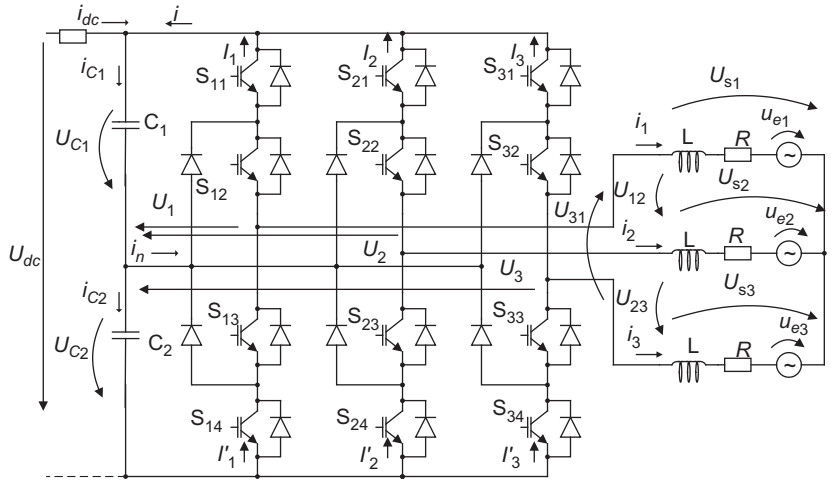

FIG. 35.58 Three-phase, neutral-point-clamped, three-level inverter with IGBTs.

where

$$\Gamma_1=\frac{2}{3}\gamma_1-\frac{1}{3}\gamma_2-\frac{1}{3}\gamma_3;\ \ \Gamma_2=\frac{2}{3}\gamma_2-\frac{1}{3}\gamma_3-\frac{1}{3}\gamma_1;$$
$$\Gamma_3=\frac{2}{3}\gamma_3-\frac{1}{3}\gamma_1-\frac{1}{3}\gamma_2 \tag{35.154}$$

The output voltage vector in the α and β coordinates $\mathbf{U}_{S_{\alpha,\beta}}$ is discontinuous. A suitable state variable for this output can be its average value $\overline{\mathbf{U}}_{S_{\alpha,\beta}}$ during one switching period:

$$\overline{\mathbf{U}}_{S_{\alpha,\beta}}=\frac{1}{T}\int_0^T \mathbf{U}_{S_{\alpha,\beta}}\mathrm{d}t=\frac{1}{T}\int_0^T \Gamma_{\alpha,\beta}\frac{U_{dc}}{2}\mathrm{d}t \tag{35.155}$$

The controllable canonical form is

$$\frac{\mathrm{d}}{\mathrm{d}t}\overline{\mathbf{U}}_{S_{\alpha,\beta}}=\frac{\mathbf{U}_{S_{\alpha,\beta}}}{T}=\frac{\Gamma_{\alpha,\beta}}{T}\frac{U_{dc}}{2} \tag{35.156}$$

Considering the control goal $\overline{\mathbf{U}}_{S_{\alpha,\beta}}=\overline{\mathbf{U}}_{S_{\alpha,\beta_{ref}}}$ and Eq. (35.91), the sliding surface is

$$\mathbf{S}(\mathbf{e}_{\alpha,\beta},t)=\sum_{o=1}^{\varphi}\mathbf{k}_{\alpha\beta_o}\mathbf{e}_{\alpha,\beta_o}=\mathbf{k}_{\alpha,\beta_1}\mathbf{e}_{\alpha,\beta_1}=\mathbf{k}_{\alpha,\beta_1}\left(\overline{\mathbf{U}}_{S_{\alpha,\beta_{ref}}}-\overline{\mathbf{U}}_{S_{\alpha,\beta}}\right)$$
$$=\frac{\mathbf{k}_{\alpha,\beta}}{T}\int_0^T\left(\mathbf{U}_{S_{\alpha,\beta ref}}-\mathbf{U}_{S_{\alpha,\beta}}\right)dt=0 \tag{35.157}$$

To ensure reaching mode behavior and sliding-mode stability (35.92), as the first derivative of Eq. (35.157), $\dot{\mathbf{S}}(\mathbf{e}_{\alpha,\beta},t)$ is

$$\dot{\mathbf{S}}(\mathbf{e}_{\alpha,\beta},t)=\frac{\mathbf{k}_{\alpha,\beta}}{T}\left(\mathbf{U}_{S_{\alpha,\beta ref}}-\mathbf{U}_{S_{\alpha,\beta}}\right) \tag{35.158}$$

The switching law is

$$\begin{aligned}&\mathbf{S}(\mathbf{e}_{\alpha,\beta},t)>0\Rightarrow\dot{\mathbf{S}}(\mathbf{e}_{\alpha,\beta},t)<0\Rightarrow\mathbf{U}_{S_{\alpha,\beta}}>\mathbf{U}_{S_{\alpha,\beta ref}}\\&\mathbf{S}(\mathbf{e}_{\alpha,\beta},t)<0\Rightarrow\dot{\mathbf{S}}(\mathbf{e}_{\alpha,\beta},t)>0\Rightarrow\mathbf{U}_{S_{\alpha,\beta}}<\mathbf{U}_{S_{\alpha,\beta ref}}\end{aligned} \tag{35.159}$$

This switching strategy must select the proper values of $\mathbf{U}_{S_{\alpha,\beta}}$ from the available outputs. As each inverter leg (Fig. 35.58) can deliver one of the three possible output voltages ($U_{dc}/2$, 0, and $-U_{dc}/2$), all the 27 possible output voltage vectors listed in Table 35.3 can be represented in the α and β frame of

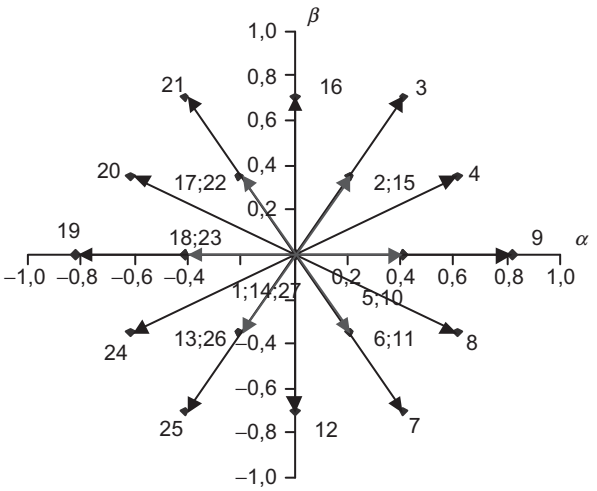

FIG. 35.59 Output voltage vectors (1–27) of three-phase, neutral-clamped three-level inverters, in the α and β frame.

Fig. 35.59 (in per units, 1 p.u. $= U_{dc}$). There are nine different levels for the α space vector component and only five for the β component. However, considering any particular value of α (or β) component, there are at most five levels available in the remaining orthogonal component. From the load viewpoint, the 27 space vectors of Table 35.3 define only 19 distinct space positions (Fig. 35.59).

To select one of these 19 positions from the control law (35.157) and the switching law of Eq. (35.159), two five-level hysteretic comparators (Fig. 35.53B) must be used ($5^2 = 25$). Their outputs are the integer variables λ_α and λ_β, denoted $\lambda_{\alpha,\beta}$ ($\lambda_\alpha, \lambda_\beta \in \{-2; -1; 0; 1; 2\}$) corresponding to the five selectable levels of Γ_α and Γ_β. Considering the sliding-mode stability, $\lambda_{\alpha,\beta}$, at time step $j+1$, is given by Eq. (35.160), knowing their previous values at step j. This means that the output level is increased (decreased) if the error and its derivative are both positive (negative), provided the maximum (minimum) output level is not exceeded:

$$\begin{cases} \left(\lambda_{\alpha,\beta}\right)_{j+1} = \left(\lambda_{\alpha,\beta}\right)_j + 1 \quad \text{if } \mathbf{S}\left(\mathbf{e}_{\alpha,\beta}, t\right) > \varepsilon \wedge \dot{\mathbf{S}}\left(\mathbf{e}_{\alpha,\beta}, t\right) \\ \qquad\qquad > \varepsilon \wedge \left(\lambda_{\alpha,\beta}\right)_j < 2 \\ \left(\lambda_{\alpha,\beta}\right)_{j+1} = \left(\lambda_{\alpha,\beta}\right)_j - 1 \quad \text{if } \mathbf{S}\left(\mathbf{e}_{\alpha,\beta}, t\right) < -\varepsilon \wedge \dot{\mathbf{S}}\left(\mathbf{e}_{\alpha,\beta}, t\right) \\ \qquad\qquad < -\varepsilon \wedge \left(\lambda_{\alpha,\beta}\right)_j > -2 \end{cases} \tag{35.160}$$

The available space vectors must be chosen not only to reduce the mean output voltage errors but also to guarantee transitions only between the adjacent levels, to minimize the capacitor voltage unbalance, to minimize the switching frequency, to observe minimum on or off times if applicable, and to equally stress all the semiconductors.

Using Eq. (35.160) and the control laws $S(\mathbf{e}_{\alpha,\beta,t})$ Eq. (35.157), Tables 35.4 and 35.5 can be used to choose the correct voltage vector in order to ensure stability, output voltage tracking, and DC capacitor voltage equalization. The vector with α and β components corresponding to the levels of the pair λ_β and λ_α is selected, provided that the adjacent transitions on inverter legs are obtained. If there is no directly corresponding vector, then the nearest vector guaranteeing adjacent transitions is selected. If a zero vector must be applied, then one of the three zero vectors (1, 14, and 27) is selected, to minimize the switching frequency. If more than one vector is the nearest, then one of them is selected to equalize the capacitor voltages, as shown next.

DC capacitor voltage equalization

The discrete values of $\lambda_{\alpha,\beta}$ allow 25 different combinations. As only 19 are distinct from the load viewpoint, the extra ones can be used to select vectors that are able to equalize the capacitor voltages ($U_{C1} = U_{C2} = U_{dc/2}$).

Considering the control goal $U_{C1} = U_{C2}$, since the first derivatives of U_{C1} and U_{C2} Eq. (35.161) directly depend on the $\gamma_k(t)$ control inputs, from Eq. (35.91), the sliding surface is given by Eq. (35.162), where k_U is a positive gain:

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} U_{C1} \\ U_{C2} \end{bmatrix} = \begin{bmatrix} -\dfrac{\gamma_1(1+\gamma_1)}{2C_1} & -\dfrac{\gamma_2(1+\gamma_2)}{2C_1} & -\dfrac{\gamma_3(1+\gamma_3)}{2C_1} & \dfrac{1}{C_1} \\ -\dfrac{\gamma_1(1-\gamma_1)}{2C_2} & -\dfrac{\gamma_2(1-\gamma_2)}{2C_2} & -\dfrac{\gamma_3(1-\gamma_3)}{2C_2} & \dfrac{1}{C_2} \end{bmatrix} \begin{bmatrix} i_1 \\ i_2 \\ i_3 \\ i_{dc} \end{bmatrix} \tag{35.161}$$

$$S(e_{Uc}, t) = k_U e_{Uc}(t) = k_U (U_{C1} - U_{C2}) = 0 \tag{35.162}$$

The first derivative of $U_{C1} - U_{C2}$ (the sliding surface) is (Fig. 35.58 with $C_1 = C_2 = C$)

$$\frac{\mathrm{d}}{\mathrm{d}t}e_{Uc}=\frac{i_{C1}}{C_1}-\frac{i_{C2}}{C_2}=\frac{i_n}{C}=\frac{\left(\gamma_3^2-\gamma_1^2\right)i_1+\left(\gamma_3^2-\gamma_2^2\right)i_2}{C} \tag{35.163}$$

To ensure reaching mode behavior and sliding-mode stability, from Eq. (35.92), considering a small enough $e_{Uc}(t)$ error, ε_{eU}, the switching law is

$$\begin{aligned} S(e_{Uc},t)>\varepsilon_{eU}\Rightarrow\dot{S}(e_{Uc},t)<0\Rightarrow i_n<0\\ S(e_{Uc},t)<-\varepsilon_{eU}\Rightarrow\dot{S}(e_{Uc},t)>0\Rightarrow i_n>0 \end{aligned} \tag{35.164}$$

From circuit analysis, it can be seen that vectors (2, 5, 6, 13, 17, and 18) result in the discharge of capacitor C_1, if the converter operates in inverter mode, or in the charge of C_1, if the converter operates in boost rectifier (regenerative) mode. Similar reasoning can be applied for vectors (10, 11, 15, 22, 23, and 26) and capacitor C_2, since this vector set gives i_n currents with opposite sign relatively to the set (2, 5, 6, 13, 17, and 18). Therefore, considering the vector $[\Upsilon_1,\Upsilon_2]=\left[\left(\gamma_1^2-\gamma_3^2\right),\left(\gamma_2^2-\gamma_3^2\right)\right]$, the switching law is the following:

If $(U_{C1}-U_{C2})>\varepsilon_{eU}$,

THEN { IF the candidate vector from {2, 5, 6, 13, 17, 18} gives $(\Upsilon_1 i_1+\Upsilon_2 i_2)>0$, THEN choose the vector according to $\lambda_{\alpha,\beta}$ on Table 34.4; ELSE, the candidate vector of {10, 11, 15, 22, 23, 26} gives $(\Upsilon_1 i_1+\Upsilon_2 i_2)>0$, the vector being chosen according to $\lambda_{\alpha,\beta}$ from (table 34.5)

If $(U_{C1}-U_{C2})<\varepsilon_{eU}$,

THEN { IF the candidate vector from {2, 5, 6, 13, 17, 18} gives $(\Upsilon_1 i_1+\Upsilon_2 i_2)<0$, THEN choose the vector according to $\lambda_{\alpha,\beta}$ on Table 34.4; ELSE, the candidate vector of {10, 11, 15, 22, 23, 26} gives $(\Upsilon_1 i_1+\Upsilon_2 i_2)<0$, the vector being chosen according to $\lambda_{\alpha,\beta}$ from (table 34.5)

For example, consider the case where $U_{C1}>U_{C2}+\varepsilon_{eU}$. Then, the capacitor C_2 must be charged, and Table 35.4 must be used if the multilevel inverter is operating in the inverter mode or Table 35.5 for the regenerative mode. Additionally, when using Table 35.4, if $\lambda_\alpha=-1$ and $\lambda_\beta=-1$, then vector 13 should be used.

Experimental results shown in Fig. 35.61 were obtained with a low-power, scaled-down laboratory prototype (150 V and 3 kW) of a three-level inverter (Fig. 35.60), controlled by two four-level comparators, and described capacitor voltage equalizing procedures and EPROM-based lookup Tables 35.3–35.5. Transistors IGBT (MG25Q2YS40) were switched at frequencies

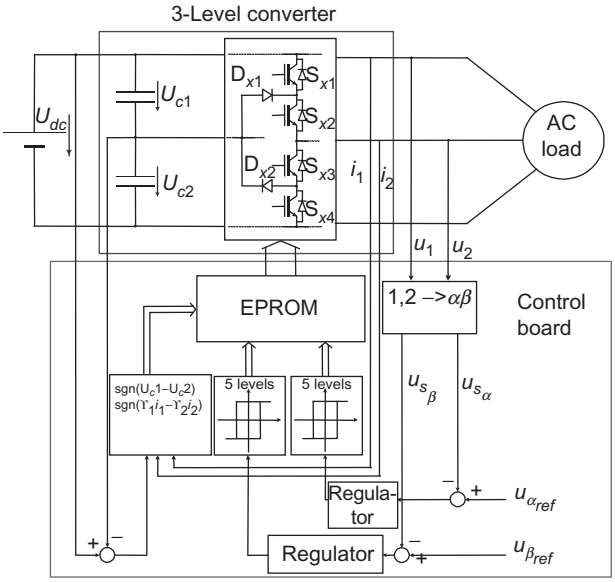

FIG. 35.60 Block diagram of the multilevel converter and control board.

near 4 kHz, with neutral clamp diodes 40HFL, $C_1\approx C_2\approx 20$ mF. The load was mainly inductive (3×10 mH and 2 Ω).

The inverter number of levels (three for the phase voltage and five for the line voltage), together with the adjacent transitions of inverter legs between levels, is shown in Fig. 35.61A and, in detail, in Fig. 35.62A.

The performance of the capacitor voltage equalizing strategy is shown in Fig. 35.62B, where the reference current of phase 1 and the output current of phase 3, together with the power supply voltage ($U_{dc}\approx 100$ V) and the voltage of capacitor $C_2(U_{C2})$, can be seen. It can be noted that the U_{C2} voltage is nearly half of the supply voltage. Therefore, the capacitor voltages are nearly equal. Furthermore, it can be stated that without this voltage equalization procedure, the three-level inverter operates only during a brief transient, during which one of the capacitor voltages vanishes to nearly 0 V and the other is overcharged to the supply voltage. Fig. 35.61B shows the harmonic spectrum of the output voltages, where the harmonics due to the switching frequency (≈4.5 kHz) and the fundamental harmonic can be seen.

On-line output current control in multilevel inverters

Considering a standard inductive balanced load (R and L) with electromotive force (u) and isolated neutral, the converter output currents i_k can be expressed:

$$U_{Sk}=Ri_k+L\frac{\mathrm{d}i_k}{\mathrm{d}t}+u_{ek} \tag{35.165}$$

Now analyzing the circuit of Fig. 35.58, the multilevel converter switched state-space model can be obtained:

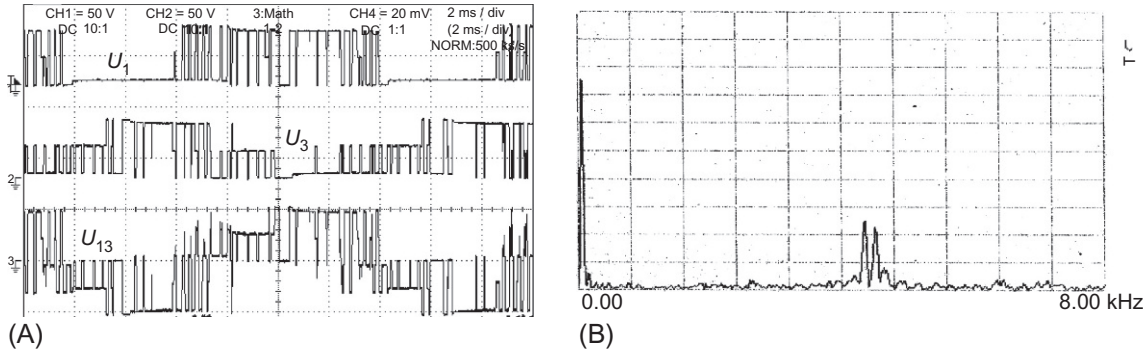

FIG. 35.61 (A) Experimental results showing phase and line voltages and (B) harmonic spectrum of output voltages.

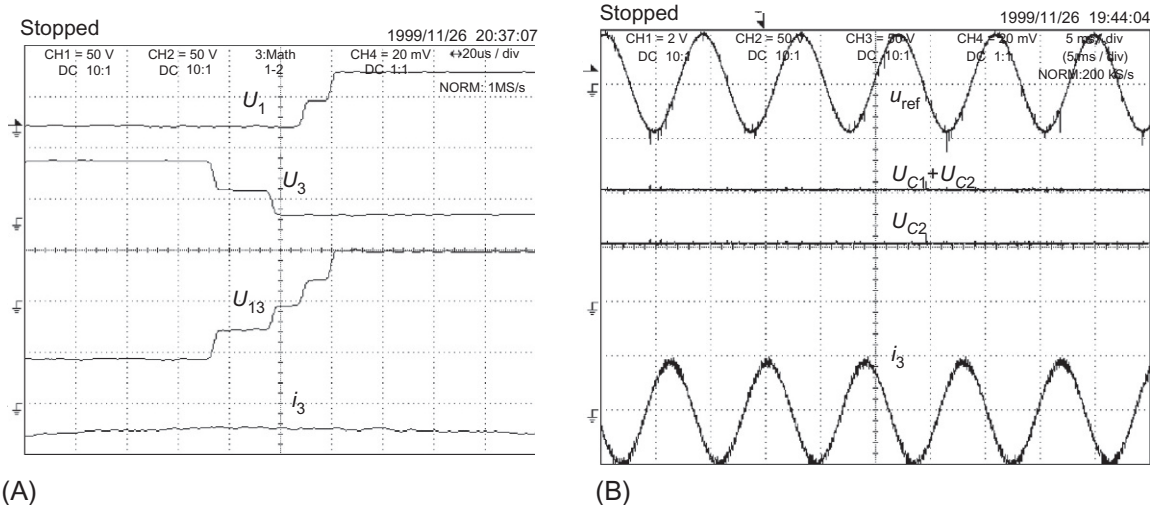

FIG. 35.62 Experimental results showing (A) the transitions between adjacent voltage levels (50 V/div and time 20 μs/div) and (B) performance of the capacitor voltage equalizing strategy; from top trace to bottom, 1 is the voltage reference input; 2 is the power supply voltage; 3 is the midpoint capacitor voltage, which is maintained close to $U_{dc}/2$; and 4 is the output current of phase 3 (2 A/div, 50 V/div, and 5 ms/div).

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} i_1 \\ i_2 \\ i_3 \end{bmatrix} = -\begin{bmatrix} \frac{R}{L} & 0 & 0 \\ 0 & \frac{R}{L} & 0 \\ 0 & 0 & \frac{R}{L} \end{bmatrix}\begin{bmatrix} i_1 \\ i_2 \\ i_3 \end{bmatrix} - \begin{bmatrix} \frac{1}{L} & 0 & 0 \\ 0 & \frac{1}{L} & 0 \\ 0 & 0 & \frac{1}{L} \end{bmatrix}\begin{bmatrix} u_{e1} \\ u_{e2} \\ u_{e3} \end{bmatrix} + \begin{bmatrix} \frac{\Gamma_1}{L} \\ \frac{\Gamma_2}{L} \\ \frac{\Gamma_3}{L} \end{bmatrix}\frac{U_{dc}}{2} \tag{35.166}$$

The application of the Concordia matrix Eqs. (35.152)–(35.166) reduces the number of the new model equations (Eq. (35.167)) to two, since an isolated neutral is assumed:

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} i_\alpha \\ i_\beta \end{bmatrix} = -\begin{bmatrix} \frac{R}{L} & 0 \\ 0 & \frac{R}{L} \end{bmatrix}\begin{bmatrix} i_\alpha \\ i_\beta \end{bmatrix} - \begin{bmatrix} \frac{1}{L} & 0 \\ 0 & \frac{1}{L} \end{bmatrix}\begin{bmatrix} u_{e\alpha} \\ u_{e\beta} \end{bmatrix} + \begin{bmatrix} \frac{1}{L} & 0 \\ 0 & \frac{1}{L} \end{bmatrix}\begin{bmatrix} U_{S\alpha} \\ U_{S\beta} \end{bmatrix} \tag{35.167}$$

The model Eq. (35.167) of this multiple-input multiple-output system (MIMO) with outputs i_α and i_β reveals the control inputs $U_{S\alpha}$ and $U_{S\beta}$, dependent on the control variables $\gamma_k(t)$.

From Eqs. (35.167) and (35.91), the two sliding surfaces $\mathbf{S}(\mathbf{e}_{\alpha,\,\beta,}\,t)$ are

$$\mathbf{S}\left(\mathbf{e}_{\alpha,\beta,}t\right) = \mathbf{k}_{\alpha,\beta}\left(\mathbf{i}_{\alpha,\beta ref} - \mathbf{i}_{\alpha,\beta}\right) = \mathbf{k}_{\alpha,\beta}\mathbf{e}_{\alpha,\beta} = 0 \tag{35.168}$$

The first derivatives of Eq. (35.167), denoted $\dot{\mathbf{S}}\left(\mathbf{e}_{\alpha,\beta},t\right)$, are

$$\begin{aligned}\dot{\mathbf{S}}\left(\mathbf{e}_{\alpha,\beta},t\right) &= \mathbf{k}_{\alpha,\beta}\left(\dot{\mathbf{i}}_{\alpha,\beta ref} - \dot{\mathbf{i}}_{\alpha,\beta}\right) \\ &= \mathbf{k}_{\alpha,\beta}\left[\dot{\mathbf{i}}_{\alpha,\beta ref} + \mathbf{R}\mathbf{L}^{-1}\mathbf{i}_{\alpha,\beta} + \mathbf{u}_{e\alpha,\beta}\mathbf{L}^{-1} - \mathbf{U}_{S\alpha,\beta}\mathbf{L}^{-1}\right]\end{aligned} \tag{35.169}$$

Therefore, the switching law is

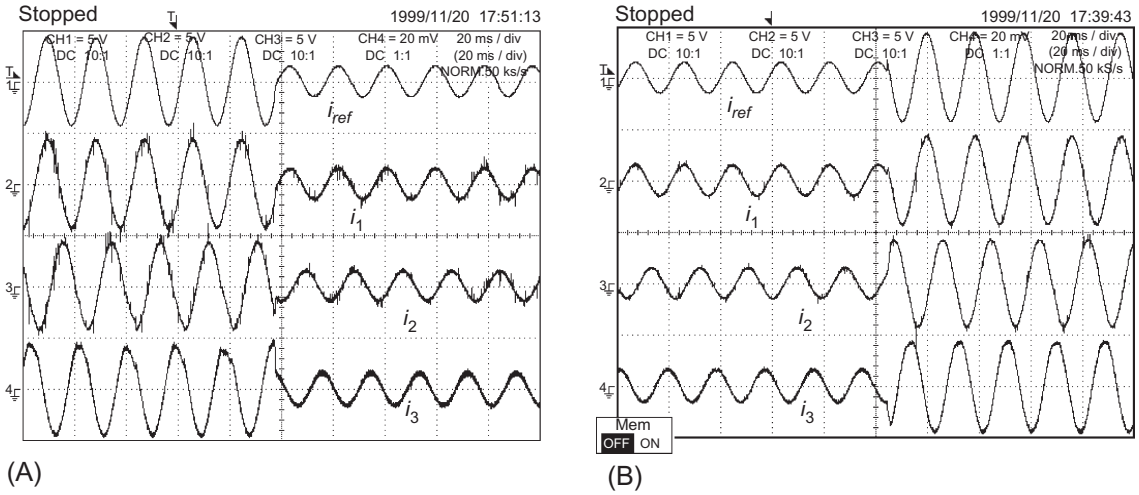

FIG. 35.63 Step response of the current control method: (A) step from 4 to 2 A. Traces show the reference current for phase 1 and the three output currents with 150 V power supply (5 A/div and time scale 20 ms/div) and (B) step from 2 to 4 A in the reference amplitude at 52 Hz. Traces show the reference current for phase 1 and the three output currents with 50 V power supply.

$$\mathbf{S}(\mathbf{e}_{\alpha,\beta},t)>0\Rightarrow\dot{\mathbf{S}}(\mathbf{e}_{\alpha,\beta},t)<0\Rightarrow\mathbf{U}_{\mathbf{S}\alpha,\beta}>\mathbf{L}\dot{\mathbf{i}}_{\alpha,\beta ref}+\mathbf{R}\mathbf{i}_{\alpha,\beta}+\mathbf{u}_{e\alpha,\beta}$$
$$\mathbf{S}(\mathbf{e}_{\alpha,\beta},t)<0\Rightarrow\dot{\mathbf{S}}(\mathbf{e}_{\alpha,\beta},t)>0\Rightarrow\mathbf{U}_{\mathbf{S}\alpha,\beta}>\mathbf{L}\dot{\mathbf{i}}_{\alpha,\beta ref}+\mathbf{R}\mathbf{i}_{\alpha,\beta}+\mathbf{u}_{e\alpha,\beta} \quad (35.170)$$

These switching laws are implemented using the same α and β vector modulator described above in this example.

Fig. 35.63A shows the experimental results. The multilevel converter and proposed control behavior are obtained for step inputs (4–2 A) in the amplitude of the sinus references with frequency near 52 Hz ($U_{dc}\approx 150$ V). Observe the tracking ability, the fast transient response, and the balanced three-phase currents. Fig. 35.63B shows almost the same test (step response from 2 to 4 A at the same frequency), but now, the power supply is set at 50 V, and the inductive load was unbalanced (±30% on resistor value). The response remains virtually the same, with tracking ability, almost no current distortions due to dead times or semiconductor voltage drops. These results and other works [21,51] confirm experimentally that the designed controllers are robust concerning these nonidealities.

35.3.5.7 Example 35.17: Sliding-Mode Vector Controllers for Matrix Converters

Matrix converters are all silicon ac/ac switching power converters, able to provide almost sinusoidal output voltages with adjustable amplitude and frequency, almost sinusoidal input currents, and controllable input power factor [22]. They have been used in ac drive speed control and are well suited for applications related to power-quality enhancement. The lack of an intermediate energy storage link results in high power density, their main advantage, but implies an input/output coupling that increases the control complexity.

This example presents the design of sliding-mode controllers considering the switched state-space model of the matrix converter (nine bidirectional power switches), including the three-phase input filter and the output load (Fig. 35.64).

Output voltage control

Ideal three-phase matrix converters are obtained by assembling nine bidirectional switches, with the turn-off capability, to allow the connection of each one of the input phases to any one of the output phases (Fig. 35.64). The states of these switches are usually represented as a nine-element matrix **S** (Eq. (35.171)), in which each matrix element, S_{kj} $k, j\in\{1, 2, 3\}$, has two possible states: $S_{kj}=1$ if the switch is closed (ON) and $S_{kj}=0$ if it is open (OFF). Only 27 switching combinations are possible (Table 35.6), as a result of the topological constraints (the input phases should never be short-circuited, and the output inductive currents should never be interrupted), which implies that the sum of all the S_{kj} of each one of the matrix, k rows, must always equal to 1 (Eq. (35.171)):

$$\mathbf{S}=\begin{bmatrix}S_{11} & S_{12} & S_{13}\\ S_{21} & S_{22} & S_{23}\\ S_{31} & S_{32} & S_{33}\end{bmatrix} \quad \sum_{j=1}^{3}S_{kj}=1 \quad k,j\in\{1,2,3\} \quad (35.171)$$

Based on matrix **S**, output voltages related to input neutral v_{on_1}, v_{on_2}, and v_{on_3} and line voltages $v_{o_{12}}$, $v_{o_{23}}$, and $v_{o_{31}}$ can be expressed in terms of matrix converter input phase voltages v_{i_1}, v_{i_2}, and v_{i_3}. Input currents i_{i_1}, i_{i_2}, and i_{i_3} can be expressed as a function of output currents i_{o_1}, i_{o_2}, and i_{o_3}:

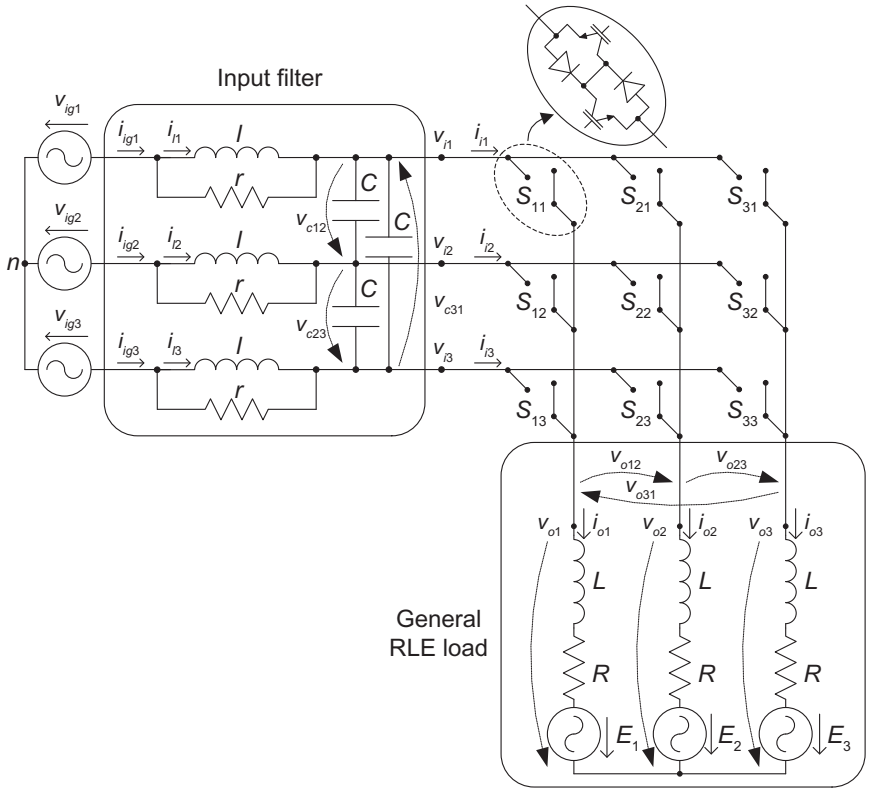

FIG. 35.64 AC/AC matrix converter with input *lCr* filter.

$$\begin{bmatrix} v_{on_1} \\ v_{on_2} \\ v_{on_3} \end{bmatrix} = \mathbf{S} \begin{bmatrix} v_{i_1} \\ v_{i_2} \\ v_{i_3} \end{bmatrix}$$
$$\begin{bmatrix} v_{o_{12}} \\ v_{o_{23}} \\ v_{o_{31}} \end{bmatrix} = \begin{bmatrix} S_{11}-S_{21} & S_{12}-S_{22} & S_{13}-S_{23} \\ S_{21}-S_{31} & S_{22}-S_{32} & S_{23}-S_{33} \\ S_{31}-S_{11} & S_{32}-S_{12} & S_{33}-S_{13} \end{bmatrix} \begin{bmatrix} v_{i_1} \\ v_{i_2} \\ v_{i_3} \end{bmatrix} \quad (35.172)$$
$$\begin{bmatrix} i_{i_1} \\ i_{i_2} \\ i_{i_3} \end{bmatrix} = \mathbf{S}^T \begin{bmatrix} i_{o_1} \\ i_{o_2} \\ i_{o_3} \end{bmatrix}$$

The application of Concordia transformation $[X_{\alpha,\beta,0}]^{\mathrm{T}} = \mathbf{C}^{\mathrm{T}} [X_{1,2,3}]^{\mathrm{T}}$ to the output line-to-line voltages of Eq. (35.172) results in the output voltage vector:

$$\mathbf{v_{ol_{\alpha\beta}}} = \begin{bmatrix} v_{ol_\alpha} \\ v_{ol_\beta} \end{bmatrix} = \sqrt{\frac{2}{3}} \begin{bmatrix} 1 & -\frac{1}{2} & -\frac{1}{2} \\ 0 & \frac{\sqrt{3}}{2} & -\frac{\sqrt{3}}{2} \end{bmatrix} \begin{bmatrix} S_{11}-S_{21} & S_{12}-S_{22} & S_{13}-S_{23} \\ S_{21}-S_{31} & S_{22}-S_{32} & S_{23}-S_{33} \\ S_{31}-S_{11} & S_{32}-S_{12} & S_{33}-S_{13} \end{bmatrix} \begin{bmatrix} v_{i_1} \\ v_{i_2} \\ v_{i_3} \end{bmatrix}$$
$$= \begin{bmatrix} \rho_{v_{\alpha\alpha}} & \rho_{v_{\alpha\beta}} \\ \rho_{v_{\beta\alpha}} & \rho_{v_{\beta\beta}} \end{bmatrix} \begin{bmatrix} v_{ic_\alpha} \\ v_{ic_\beta} \end{bmatrix} \quad (35.173)$$

where $v_{ic\alpha\beta}$ is the input filter capacitor voltage and $\rho_{v_{\alpha\alpha}}$, $\rho_{v_{\alpha\beta}}$, $\rho_{v_{\beta\alpha}}$, and $\rho_{v_{\beta\beta}}$ are functions of the ON/OFF state of the nine S_{kj} switches:

$$\begin{bmatrix} \rho_{v_{\alpha\alpha}} & \rho_{v_{\alpha\beta}} \\ \rho_{v_{\beta\alpha}} & \rho_{v_{\beta\beta}} \end{bmatrix} = \frac{1}{2} \begin{bmatrix} (S_{11}-S_{21}-S_{12}+S_{22}) \\ \sqrt{3}(S_{11}+S_{21}-2S_{31}-S_{12}-S_{22}+2S_{32}) \\ \sqrt{3}(S_{11}-S_{21}+S_{12}-S_{22}) \\ (S_{11}+S_{21}-2S_{31}+S_{12}+S_{22}+2S_{32}) \end{bmatrix} \quad (35.174)$$

The average value $\overline{v_{ol_{\alpha\beta}}}$ of the output line-to-line voltages, in $\alpha\beta$ coordinates, during one switching period, is the output variable to be controlled (since $v_{ol\alpha\beta}$ is discontinuous) [23,50]:

$$\overline{v_{ol_{\alpha\beta}}} = \frac{1}{T_s} \int_{nT_s}^{(n+1)T_s} v_{ol_{\alpha\beta}} \mathrm{d}t \quad (35.175)$$

Considering the control goal $\overline{v_{ol_{\alpha\beta}}} = \overline{v_{ol_{\alpha\beta\,ref}}}$, the sliding surface $S(e_{\alpha\beta}, t)(k_{\alpha\beta} > 0)$ is

$$S(e_{\alpha\beta}, t) = \frac{k_{\alpha\beta}}{T} \int_0^T \left(v_{ol_{\alpha\beta_{ref}}} - v_{ol_{\alpha\beta}} \right) \mathrm{d}t = 0 \quad (35.176)$$

The first derivative of Eq. (35.176) is

$$\dot{S}(e_{\alpha\beta}, t) = k_\alpha \left(v_{ol_{\alpha\beta ref}} - v_{ol_{\alpha\beta}} \right) \quad (35.177)$$

As the sliding-mode stability is guaranteed if $S_{\alpha\beta}(e_{\alpha\beta}, t)\, \dot{S}_{\alpha\beta}(e_{\alpha\beta}, t) < 0$, the criterion to choose the output line voltages state-space vectors is

$$\begin{aligned} S_{\alpha\beta}(e_{\alpha\beta}, t) < 0 \;\Rightarrow\; \dot{S}_{\alpha\beta}(e_{\alpha\beta}, t) > 0 \;\Rightarrow\; v_{ol_{\alpha\beta}} < v_{ol_{\alpha\beta\,ref}} \\ S_{\alpha\beta}(e_{\alpha\beta}, t) > 0 \;\Rightarrow\; \dot{S}_{\alpha\beta}(e_{\alpha\beta}, t) < 0 \;\Rightarrow\; v_{ol_{\alpha\beta}} > v_{ol_{\alpha\beta\,ref}} \end{aligned} \quad (35.178)$$

This implies that the sliding mode is reached only when the vector applied to the converter has the desired amplitude and phase.

According to Table 35.6, the six vectors of group I have fixed amplitude but time-varying phase, the 18 vectors of group II have variable amplitude, and the vectors of group III are null. Therefore, from the load viewpoint, the 18 highest amplitude vectors (6 vectors from group I and 12 vectors from group II) and one null vector are suitable to guarantee the sliding-mode stability.

Therefore, if two three-level comparators ($C_{\alpha\beta} \in \{-1, 0, 1\}$) are used to quantize the deviations of Eq. (35.178) from zero, the nine output voltage error combinations (3^3) are not enough to guarantee the choice of all the 19 available vectors. The extra vectors may be used to control the input power factor. As an example, if the output voltage error is quantized as $C_\alpha = 1$ and $C_\beta = 1$, at sector V_i1 (Fig. 35.65), the vectors −3, +1, or 1 g might be used to control the output voltage. The final choice would depend on the input current error.

Output current control

For some applications, it is more useful to control the output currents, which implies some changes on the previously designed controllers. From Fig. 35.64, the output currents can be obtained as a function of the phase voltages applied to the load:

$$\begin{cases} \dfrac{di_{o_\alpha}}{dt} = -\dfrac{R}{L} i_{o_\alpha} + \dfrac{1}{L} v_{o_\alpha} + \dfrac{1}{L} E_\alpha \\ \dfrac{di_{o_\beta}}{dt} = -\dfrac{R}{L} i_{o_\beta} + \dfrac{1}{L} v_{o_\beta} + \dfrac{1}{L} E_\beta \end{cases} \quad (35.179)$$

As the output currents are state variables, with a strong relative degree of 1, the sliding surfaces should depend directly on their errors:

$$S_{io_{\alpha\beta}}(e_{io_{\alpha\beta}}, t) = k_{i_o} \left(i_{o_{\alpha\beta ref}} - i_{o_{\alpha\beta}} \right) \quad (35.180)$$

The state-space vectors should be chosen to guarantee the stability criterion $S_{io_{\alpha\beta}}(e_{io_{\alpha\beta}}, t)\ \dot{S}_{io_{\alpha\beta}}(e_{io_{\alpha\beta}}, t) < 0$, according to the following:

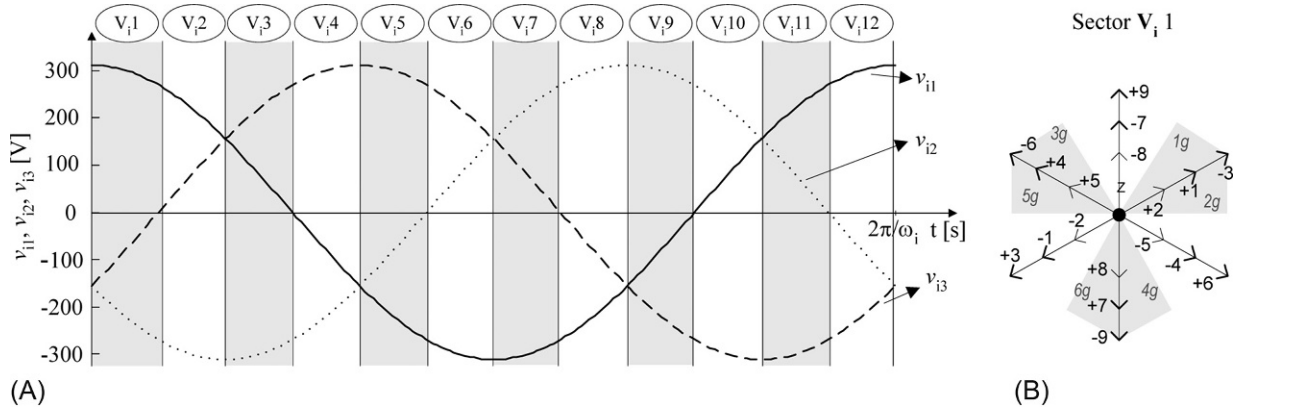

FIG. 35.65 (A) Input voltages and their corresponding sector and (B) representation of the output voltage state-space vectors when the input voltages are located at sector V_i1.

(a) If $S_{io_{\alpha\beta}}\left(e_{io_{\alpha\beta}}, t\right) < 0$, then $i_{o_{\alpha\beta}} > i_{o_{\alpha\beta ref}}$ and the output current must decrease $i_{o_{\alpha\beta}} \downarrow$. This means that the chosen output voltage $v_{o_{\alpha\beta}}$ phase vector should be low enough to guarantee $\mathrm{d}i_{o_{\alpha\beta}}/\mathrm{d}t < 0$.

(b) If $S_{io_{\alpha\beta}}\left(e_{io_{\alpha\beta}}, t\right) > 0$, then $i_{o_{\alpha\beta}} < i_{o_{\alpha\beta ref}}$ and the output current must increase $i_{o_{\alpha\beta}} \uparrow$. This means that the chosen output voltage $v_{o_{\alpha\beta}}$ phase vector should be high enough to guarantee $\mathrm{d}i_{o_{\alpha\beta}}/\mathrm{d}t > 0$.

The output voltage phase vectors can be obtained from the output voltage line vectors of Table 35.6, using the well-known relations between three-phase line and phase voltages:

$$\mathbf{V_o} = \begin{bmatrix} v_{o_1} & v_{o_2} & v_{o_3} \end{bmatrix}^T = \left[\frac{2v_{o_{12}} + v_{o_{23}}}{3} \quad \frac{2v_{o_{23}} + v_{o_{31}}}{3} \quad \frac{2v_{o_{31}} + v_{o_{12}}}{3} \right]^T \tag{35.181}$$

As expected, the resultant output voltage phase vectors will have an amplitude $\sqrt{3}$ lower than the voltage line vectors of Table 35.6 and a lagging phase of $\pi/6$. As an example, from Fig. 35.65B, this will result in a $-\pi/6$ rotation of all the voltage vectors represented.

Therefore, if two three-level comparators ($C_{\alpha\beta} \in \{-1,0,1\}$) are used to quantize the deviations of Eq. (35.180) from zero and if the output current error is quantized as $C_\alpha = 1$ and $C_\beta = 1$, at sector V_i1 (Fig. 35.65), the vectors +9 or −7 might be used to control the output current. The final choice would depend on the input current error.

Input power factor control

Assuming that the source is a balanced sinusoidal three-phase voltage supply with frequency ω_i, the switched state-space model equations of the converter input filter are obtained in 123 coordinates:

$$\begin{cases} \dfrac{\mathrm{d}i_{l_1}}{\mathrm{d}t} = \dfrac{1}{3l}v_{c23} + \dfrac{2}{3l}v_{c31} + \dfrac{1}{l}v_{ig_1} \\ \dfrac{\mathrm{d}i_{l_2}}{\mathrm{d}t} = -\dfrac{2}{3l}v_{c23} - \dfrac{1}{3l}v_{c31} + \dfrac{1}{l}v_{ig_2} \\ \dfrac{\mathrm{d}v_{c23}}{\mathrm{d}t} = \dfrac{1}{3C}i_{l_1} + \dfrac{2}{3C}i_{l_2} - \dfrac{1}{3Cr}v_{c23} + \dfrac{1}{3Cr}v_{ig_1} + \dfrac{2}{3Cr}v_{ig_2} \\ \qquad - \dfrac{1}{3C}(S_{11} - S_{31} + 2S_{12} - 2S_{32})\, i_{o_1} \\ \qquad - \dfrac{1}{3C}(S_{21} - S_{31} + 2S_{22} - 2S_{32})\, i_{o_2} \\ \dfrac{\mathrm{d}v_{c31}}{\mathrm{d}t} = -\dfrac{2}{3C}i_{l_1} - \dfrac{1}{3C}i_{l_2} - \dfrac{1}{3Cr}v_{c31} - \dfrac{2}{3Cr}v_{ig_1} - \dfrac{1}{3Cr}v_{ig_2} \\ \qquad + \dfrac{1}{3C}(2S_{11} - 2S_{31} + S_{12} - S_{32})\, i_{o_1} \\ \qquad + \dfrac{1}{3C}(2S_{21} - 2S_{31} + S_{22} - S_{32})\, i_{o_2} \end{cases} \tag{35.182}$$

To control the input power factor, a reference frame synchronous with input voltage v_{ig1} may be used applying the Blondel-Park transformation to the matrix converter switched state-space model (Eq. (35.183)), where $\rho_{i_{dd}}$, $\rho_{i_{dq}}$, $\rho_{i_{qd}}$, and $\rho_{i_{qq}}$ are functions of the on/off states of the nine S_{kj} switches:

$$\begin{cases} \dfrac{\mathrm{d}i_{l_d}}{\mathrm{d}t} = \omega_i i_{lq} - \dfrac{1}{2l}v_{c_d} - \dfrac{1}{2\sqrt{3}l}v_{c_q} + \dfrac{1}{l}v_{ig_d} \\ \dfrac{\mathrm{d}i_{l_q}}{\mathrm{d}t} = -\omega_i i_{l_d} + \dfrac{1}{2\sqrt{3}l}v_{c_d} - \dfrac{1}{2l}v_{c_q} + \dfrac{1}{l}v_{ig_q} \\ \dfrac{\mathrm{d}v_{c_d}}{\mathrm{d}t} = \dfrac{1}{2C}i_{l_d} - \dfrac{1}{2\sqrt{3}C}i_{l_q} - \dfrac{1}{3Cr}v_{c_d} + \omega_i v_{c_q} + \dfrac{-\rho_{i_{dd}} + \left(\rho_{i_{qd}}/\sqrt{3}\right)}{2C}i_{o_d} \\ \qquad + \dfrac{-\rho_{i_{dq}} + \left(\rho_{i_{qq}}/\sqrt{3}\right)}{2C}i_{o_q} + \dfrac{1}{2Cr}v_{ig_d} - \dfrac{1}{2\sqrt{3}Cr}v_{ig_q} \\ \dfrac{\mathrm{d}v_{c_q}}{\mathrm{d}t} = \dfrac{1}{2\sqrt{3}C}i_{l_d} + \dfrac{1}{2C}i_{l_q} - \omega_i v_{c_d} - \dfrac{1}{3Cr}v_{c_q} + \dfrac{-\left(\rho_{i_{dd}}/\sqrt{3}\right) - \rho_{i_{qd}}}{2C}i_{o_d} \\ \qquad + \dfrac{-\left(\rho_{i_{dq}}/\sqrt{3}\right) - \rho_{i_{qq}}}{2C}i_{o_q} + \dfrac{1}{2\sqrt{3}Cr}v_{ig_d} + \dfrac{1}{2Cr}v_{ig_q} \end{cases} \tag{35.183}$$

As a consequence, neglecting ripples, all the input variables become time invariant, allowing a better understanding of the sliding-mode controller design, and the choice of the most adequate state-space vector. Using this state-space model, the input i_{igd} and i_{igq} currents are

$$\begin{cases} i_{ig_d} = i_{l_d} + \dfrac{l}{r}\left(\dfrac{di_{l_d}}{dt} - \omega_i i_{l_q}\right) \\ i_{ig_q} = i_{l_q} + \dfrac{l}{r}\left(\dfrac{di_{l_q}}{dt} + \omega_i i_{l_d}\right) \end{cases} \Leftrightarrow \begin{cases} i_{ig_d} = i_{l_d} - \dfrac{1}{2r}v_{c_d} - \dfrac{1}{2\sqrt{3}r}v_{c_q} + \dfrac{1}{r}v_{ig_d} \\ i_{ig_q} = i_{l_q} + \dfrac{1}{2\sqrt{3}r}v_{c_d} - \dfrac{1}{2r}v_{c_q} + \dfrac{1}{r}v_{ig_q} \end{cases} \tag{35.184}$$

The input power factor controller should consider the input-output power constraint (Eq. (35.185)) (the converter losses and ripples are neglected), obtained as a function of the input and output voltages and currents (the input voltage v_{igq} is equal to zero in the chosen dq rotating frame). The choice of one output voltage vector automatically defines the instantaneous value of the input $i_{igd}(t)$ current:

$$v_{ig_d} i_{ig_d} \approx \frac{1}{3}\left(\frac{\sqrt{3}}{2}v_{ol_d} + \frac{1}{2}v_{ol_q}\right) i_{o_d} + \frac{1}{3}\left(-\frac{1}{2}v_{ol_d} + \frac{\sqrt{3}}{2}v_{ol_q}\right) i_{o_q} \tag{35.185}$$

Therefore, only the sliding surface associated to the i_{igq} current is needed, expressed as a function of the system state variables and based on the state-space model determined in Eq. (35.183):

$$\begin{aligned} \frac{di_{ig_q}}{dt} = &-\omega_i i_{l_d} - \frac{1}{3Cr} i_{l_q} + \left(-\frac{1}{6\sqrt{3}Cr^2} + \frac{\omega_i}{2r} + \frac{1}{2\sqrt{3}l}\right) v_{c_d} \\ &+ \left(\frac{\omega_i}{2\sqrt{3}r} + \frac{1}{6Cr^2} - \frac{1}{2l}\right) v_{c_q} + \frac{1}{3Cr}\left(\rho_{i_{qd}} i_{o_d} + \rho_{i_{qq}} i_{o_q}\right) \\ &+ \left(-\frac{1}{3Cr^2} + \frac{1}{l}\right) v_{ig_q} + \frac{1}{r}\frac{dv_{ig_q}}{dt} \end{aligned} \tag{35.186}$$

As the derivative of the input $i_{igq}(t)$ current depends directly on the control variables $\rho_{i_{qd}}$ and $\rho_{i_{qq}}$, the sliding function $S_{i_q}(e_{i_q}, t)$ will depend only on the input current error $e_{i_q} = i_{ig_{qref}} - i_{ig_q}$:

$$S_{i_q}(e_{i_q}, t) = k_{i_q}\left(i_{ig_{qref}} - i_{ig_q}\right) \tag{35.187}$$

As the sliding-mode stability is guaranteed if $S_{i_q}(e_{i_q}, t)\,\dot{S}_{i_q}(e_{i_q}, t) < 0$, the criterion to choose the state-space vectors is [23]

$$\begin{aligned} &S_{i_q}(e_{i_q}t) > 0 \;\Rightarrow\; \dot{S}_{i_q}(e_{i_q}t) < 0 \;\Rightarrow\; \frac{di_{ig_q}}{dt} > \frac{di_{ig_{qref}}}{dt} \;\Rightarrow\; i_{ig_q}\uparrow \\ &S_{i_q}(e_{i_q}t) < 0 \;\Rightarrow\; \dot{S}_{i_q}(e_{i_q}t) > 0 \;\Rightarrow\; \frac{di_{ig_q}}{dt} < \frac{di_{ig_{qref}}}{dt} \;\Rightarrow\; i_{ig_q}\downarrow \end{aligned} \tag{35.188}$$

Also, to choose the adequate input current vector, it is necessary (a) to know the location of the output currents, as the input currents depend on the output currents location (Table 35.6), and (b) to know the dq frame location. As in the chosen frame (synchronous with the v_{ig1} input voltage), the dq-axis location depends on the v_{ig1} input voltage location; the sign of the input current vector i_{igq} component can be determined knowing the location of the input voltages and the location of the output currents (Fig. 35.66).

Considering the previous example, at sector V_i1 (Fig. 35.65), for an error of $C_\alpha = 1$ and $C_\beta = 1$, vector −3, +1, or 1 g might be used to control the output voltage. When compared, at sector I_o1 (Fig. 35.66B), these three vectors have positive i_d components and, as a result, will have a similar effect on the input i_{igd} current. However, they have a different effect on the i_{igq} current: Vector −3 has a positive i_{iq} component, vector +1 has a negative i_{iq} component, and vector 1 g has a nearly zero i_{iq} component. As a result, if the output voltage errors are $C_\alpha = 1$ and $C_\beta = 1$, at sectors V_i1 and I_o1, vector −3 should be chosen if the input current error is quantized as $C_{iq} = 1$ (Fig. 35.66B), vector +1 should be chosen if the input current error is quantized as $C_{iq} = -1$, and if the input current error is $C_{iq} = 0$, vector 1 g or −3 might be used.

When the output voltage errors are quantized as zero $C_{\alpha\beta} = 0$, the null vectors of group III should be used only if the input current error is $C_{iq} = 0$. Otherwise (being $C_{i_q} \neq 0$),

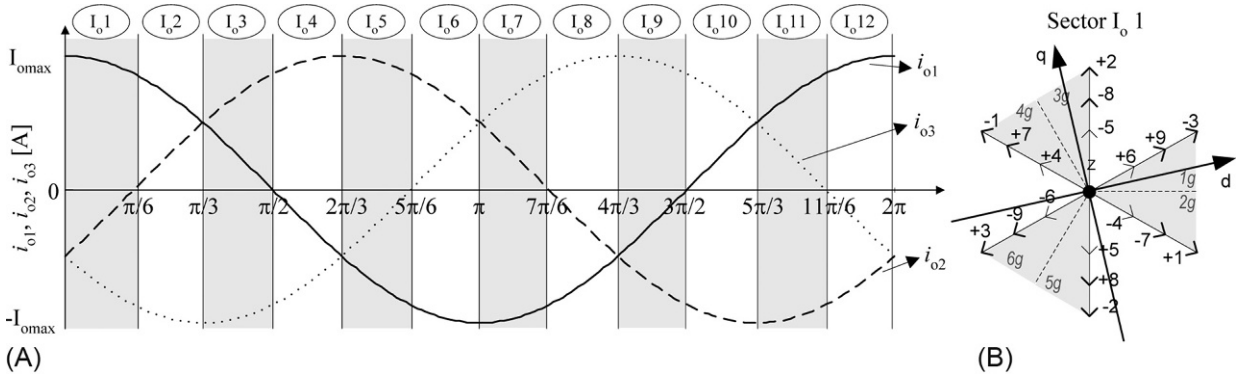

FIG. 35.66 (A) Output currents and their corresponding sector and (B) representation of input current state-space vectors, when the output currents are located at sector I_o1. The dq-axis is represented considering that the input voltages are located in zone V_i1.

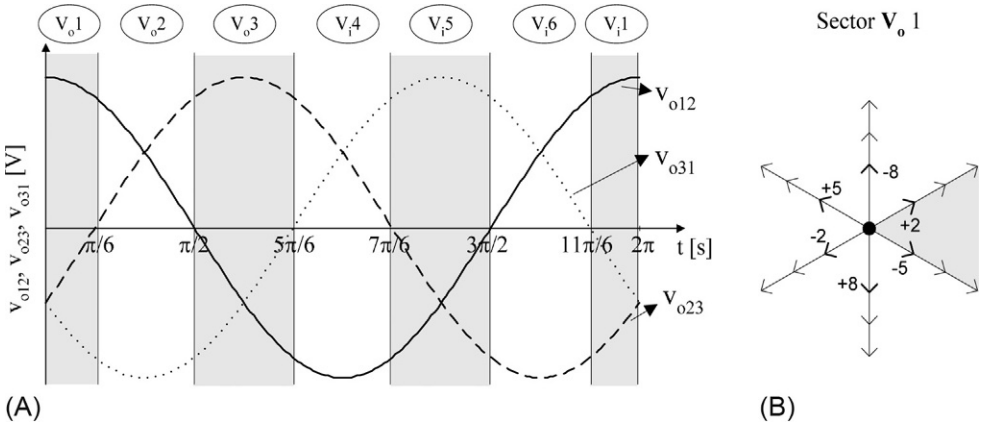

FIG. 35.67 (A) Output voltages and their corresponding sector and (B) representation of the lowest amplitude output voltage vectors, when the input voltages are located at sector V_o1.

the lowest amplitude voltage vectors ({+2, −8, +5, −2, +8, −5} at sector V_i1 of Fig. 35.65B) that were not used to control the output voltages might be chosen to control the input i_{igq} current as these vectors may have a strong influence on the input i_{igq} current component (Fig. 35.66B).

To choose one of these six vectors, only the vectors located as near as possible to the output voltages sector (Fig. 35.67) are chosen (to minimize the output voltage ripple), and a five-level comparator is enough. As a result, there will be $9 \times 5 = 45$ error combinations to select 27 space vectors. Therefore, the same vector may have to be used for more than one error combination.

With this reasoning, it is possible to obtain Table 35.7 for sector V_i1, I_o1, and V_o1 and generalize it for all the other sectors.

The experimental results shown in (Fig. 35.68) were obtained with a low-power prototype (1 kW), with two three-level comparators and one five-level comparator. The transistors IGBT were switched at frequencies near 10 kHz.

The results show the response to a step on the output voltage reference (Fig. 35.68A) and on the input reference current (Fig. 35.68B), for a three-phase output load (R = 7 Ω and $L = 15$ mH), with $k_{\alpha\beta} = 100$ and $k_{iq} = 2$. It can be seen that the matrix converter may operate with a near unity input power factor (Fig. 35.68A – $f_o = 20$ Hz) or with lead/lag power factor (Fig. 35.68B), guaranteeing very low ripple on the output currents, a good tracking capability and fast transient response times.

Also, some simulation results were obtained for the output current-controlled matrix converter. The results (Fig. 35.69A) show the response to a step on the output current reference at $t = 0.22$ s, a step of the output current frequency at $t = 0.28$ s, and a step at the input i_{ig_q} current at $t = 0.34$ s, for a three-phase output load ($R = 3\ \Omega$ and $L = 30$ mH), with $k_{io\alpha\beta} = 10$ and $k_{iq} = 2$. Again, these results show that matrix converter may operate with lead/lag power factor, guaranteeing very low ripple on the output currents, a good tracking capability and fast transient response times for both input and output currents.

35.3.5.8 Example 35.18: PI Linear Controllers for Matrix Converters

For comparison purposes, a PI-based controller using a pulse-width-modulation (PWM) technique is designed. From Eq (35.171), the modulation indexes m_{ij} associated to the matrix converter with nine switches are represented as a nine-element matrix $\mathbf{M}(t)$ (Eq. (35.189)) [24]:

$$\mathbf{M}(t) = \begin{bmatrix} m_{11}(t) & m_{12}(t) & m_{13}(t) \\ m_{21}(t) & m_{22}(t) & m_{23}(t) \\ m_{31}(t) & m_{32}(t) & m_{33}(t) \end{bmatrix} \quad \begin{array}{l} \sum_{j=1}^{3} m_{kj}(t) = 1 \\ 0 \le m_{kj}(t) \le 1 \quad k, j \in [1,\ 2,\ 3] \end{array} \tag{35.189}$$

These modulation indexes are used to synthesize the output voltages $\mathbf{V_{on}}(t) = [v_{on_1}(t)\ \ v_{on_2}(t)\ \ v_{on_3}(t)]^T$ as a function of input voltages $\mathbf{V_i}(t) = [v_{i_1}(t)\ \ v_{i_2}(t)\ \ v_{i_3}(t)]^T$ Eq. (35.190) and input currents $\mathbf{I_i}(t) = [i_{i_1}(t)\ \ i_{i_2}(t)\ \ i_{i_3}(t)]^T$ as a function of output load currents $\mathbf{I_o}(t) = [i_{o_1}(t)\ \ i_{o_2}(t)\ \ i_{o_3}(t)]^T$ Eq. (35.190):

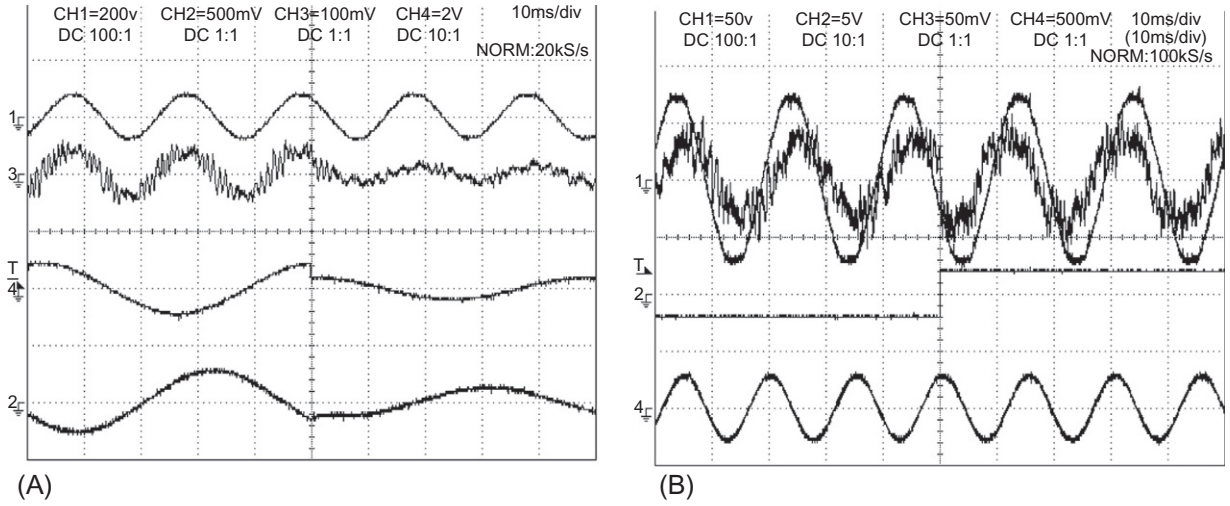

FIG. 35.68 Dynamic responses obtained with a three-phase load: (A) output reference voltage step ($R=7\ \Omega$, $L=15$ mH, and $f_o=20$ Hz): input voltage $v_{ig1}(t)$ (CH1), input current $i_{ig1}(t)$ (CH3), output reference voltage $v_{o23ref}(t)$ (CH4), and output current $i_{o1}(t)$ (CH2) and (B) input reference current $i_{igqref}(t)$ step: input voltage $v_{ig1}(t)$ (CH1), input current $i_{ig1}(t)$ (CH3), input reference current $i_{igqref}(t)$ (CH2), and output current $i_{o1}(t)$ (CH4).

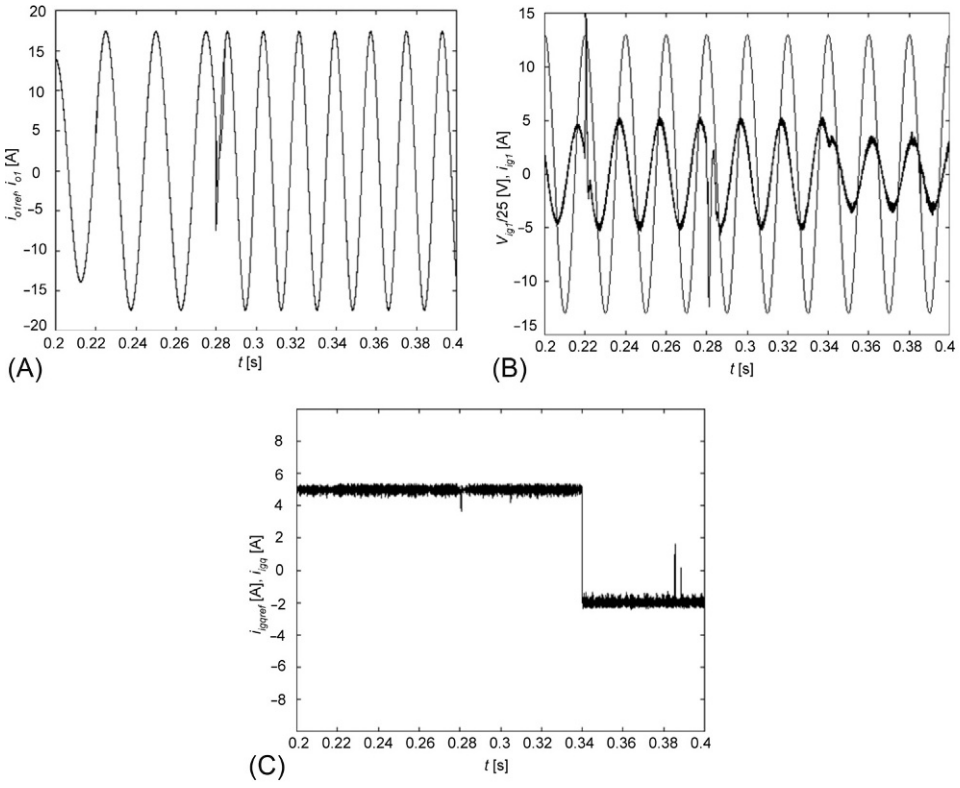

FIG. 35.69 Dynamic responses obtained with a three-phase load ($R=3\ \Omega$ and $L=30$ mH) for a step in the output reference current amplitude at $t=0.22$ s, in the output reference current frequency at $t=0.28$ s and in the input $i_{igq}(t)$ current at $t=0.34$ s, (A) output reference current $i_{o1ref}(t)$ and output current $i_{o1}(t)$, (B) input grid voltage $v_{ig1}(t)$ and input grid current $i_{ig1}(t)$, and (C) input reference current $i_{igqref}(t)$ and input grid current $i_{igq}(t)$.

$$\begin{aligned}\mathbf{V_{on}}(t) &= \mathbf{M}(t)\ \mathbf{V_i}(t)\\ \mathbf{I_i}(t) &= \mathbf{M}(t)^T\ \mathbf{I_o}(t)\end{aligned} \tag{35.190}$$

However, assuming a balanced source system $\sum_{k=1}^{3} v_{i_k}(t) = 0$ with input and output neutral wires not connected $\sum_{k=1}^{3} i_{i_k}(t) = 0$, $\sum_{k=1}^{3} i_{o_k}(t) = 0$, and restriction (35.189), the modulation index matrix may be reduced to a four element $a_{kj}(t)$ (k, $j = \{1, 2\}$) matrix Eq. (35.191) [25]:

$$\mathbf{M_a} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} = \begin{bmatrix} m_{11} - m_{31} & m_{21} - m_{31} \\ m_{12} - m_{32} & m_{22} - m_{32} \end{bmatrix} \tag{35.191}$$

Based on Eq. (35.189), Eq. (35.190), and Eq. (35.191), input currents are obtained as a function of output currents:

$$\begin{bmatrix} i_{i_1} & i_{i_2} \end{bmatrix}^{\mathrm{T}} = \mathbf{M_a} \begin{bmatrix} i_{o_1} & i_{o_2} \end{bmatrix}^{\mathrm{T}} \tag{35.192}$$

From Eq. (35.189) and Eq. (35.190), output load phase voltages Eq. (35.193) can be directly obtained from input phase voltages using a four modulation index matrix Eq. (35.194) based on Eq. (35.191):

$$\begin{bmatrix} v_{o_1} & v_{o_2} \end{bmatrix}^{\mathrm{T}} = \mathbf{M_v} \begin{bmatrix} v_{i_1} & v_{i_2} \end{bmatrix}^{\mathrm{T}} \tag{35.193}$$

$$\mathbf{M_v} = \frac{1}{3} \begin{bmatrix} 4a_{11} - 2a_{12} + 2a_{21} - a_{22} & 2a_{11} - a_{12} + 4a_{21} - 2a_{22} \\ -2a_{11} + 4a_{12} - a_{21} + 2a_{22} & -a_{11} + 2a_{12} - 2a_{21} + 4a_{22} \end{bmatrix} \tag{35.194}$$

Assuming ideal input filtering, phase voltages Eq. (35.195) applied to matrix converter should be approximately equal to grid voltages:

$$v_{i_k}(t) \approx v_{ig_k}(t) = \sqrt{2}\, V_i \cos\left(\omega_i t - 2(k-1)\pi/3\right) \quad k \in [1, 2, 3] \tag{35.195}$$

Also, assuming ideal output filtering, output currents Eq. (35.196) should be nearly equal to their fundamental harmonics (with frequency ω_o and displacement factor ϕ_o):

$$i_{o_k}(t) = \sqrt{2} I_o \cos\left(\omega_o t - \varphi_o - 2(k-1)\pi/3\right) \quad k \in [1, 2, 3] \tag{35.196}$$

If switching frequencies are much higher than input and output frequencies ($f_s \gg f_i$ and $f_s \gg f_o$), then input currents Eq. (35.197) and output load voltages Eq. (35.198) should be approximately equal to their references:

$$i_{i_k}(t) = \sqrt{2} I_i \cos\left(\omega_i t - \varphi_i - 2(k-1)\pi/3\right) \quad k \in [1, 2, 3] \tag{35.197}$$

$$v_{o_k}(t) = \sqrt{2} V_o \cos\left(\omega_o t - 2(k-1)\pi/3\right) \quad k, j \in [1, 2, 3] \tag{35.198}$$

Applying Concordia and Park transformation [26] to Eq. (35.192) and Eq. (35.193) and choosing a reference frame synchronous with input phase voltages ($\Theta_i = \omega_i t$) for all the input variables and a reference frame synchronous with output phase voltages ($\Theta_o = \omega_o t$) for all the output variables, then, three-phase input and output variables (Eq. (35.199) and Eq. (35.200)) may become time invariant:

$$\begin{aligned}\mathbf{T}_{\Theta_o}{}^T\ \mathbf{V}_{\mathbf{o}_{123}} &= \left(\mathbf{T}_{\Theta_o}{}^T \mathbf{M_v}\ \mathbf{T}_{\Theta_i}\right)\ \mathbf{T}_{\Theta_i}{}^T \mathbf{V}_{\mathbf{i}_{123}}\\ \mathbf{V}_{\mathbf{o}_{dq}} &= \mathbf{M_{dq}} \mathbf{V}_{\mathbf{i}_{dq}}\end{aligned} \tag{35.199}$$

$$\begin{aligned}\mathbf{T}_{\Theta_i}{}^T\ \mathbf{I}_{\mathbf{i}_{123}} &= \left(\mathbf{T}_{\Theta_i}{}^T \mathbf{M_a}\ \mathbf{T}_{\Theta_o}\right)\ \mathbf{T}_{\Theta_o}{}^T \mathbf{I}_{o_{123}}\\ \mathbf{I}_{\mathbf{i}_{dq}} &= \mathbf{M}_{\mathbf{dq}}^{\mathbf{T}} \mathbf{I}_{\mathbf{o}_{dq}}\end{aligned} \tag{35.200}$$

From Eqs. (35.199) and (35.200), in the new coordinate frame, input phase voltages should be given by Eq. (35.201), and target input currents should be equal to Eq. (35.202):

$$\begin{bmatrix} v_{i_d} & v_{i_q} \end{bmatrix}^{\mathrm{T}} = \mathbf{T}_{\Theta_i}{}^T \mathbf{V}_{\mathbf{i}_{abc}} = \begin{bmatrix} \sqrt{3} V_i & 0 \end{bmatrix}^{\mathrm{T}} \tag{35.201}$$

$$\begin{bmatrix} i_{i_d} & i_{i_q} \end{bmatrix}^{\mathrm{T}} = \mathbf{T}_{\Theta_i}{}^T\ \mathbf{I}_{\mathbf{i}_{abc}} = \sqrt{3} I_i \begin{bmatrix} \cos(\varphi_i) & -\sin(\varphi_i) \end{bmatrix}^{\mathrm{T}} \tag{35.202}$$

Target output load phase voltages Eq. (35.203) and output currents Eq. (35.204) should be

$$\begin{bmatrix} v_{o_d} & v_{o_q} \end{bmatrix}^{\mathrm{T}} = \mathbf{T}_{\Theta_o}{}^T\ \mathbf{V}_{\mathbf{o}_{abc}} = \begin{bmatrix} \sqrt{3} V_o & 0 \end{bmatrix}^{\mathrm{T}} \tag{35.203}$$

$$\begin{bmatrix} i_{o_d} & i_{o_q} \end{bmatrix}^{\mathrm{T}} = \mathbf{T}_{\Theta_o}{}^T \mathbf{I}_{o_{abc}} = \sqrt{3} I_o \begin{bmatrix} \cos(\varphi_o) & -\sin(\varphi_o) \end{bmatrix}^{\mathrm{T}} \tag{35.204}$$

From Eq. (35.199), in the new coordinate frame, matrix converter modulation indexes are given by Eq. (35.205):

$$\mathbf{M_{dq}} = \mathbf{T}_{\Theta_o}{}^T \mathbf{M_v}\ \mathbf{T}_{\Theta_i} = \begin{bmatrix} \gamma_{dd} & \gamma_{dq} \\ \gamma_{qd} & \gamma_{qq} \end{bmatrix} \tag{35.205}$$

From Eq. (35.199), using input voltages Eq. (35.201), two independent control actions based on different modulation indexes, allowing the independent control of each output voltage component, are obtained:

$$\begin{bmatrix} v_{o_d} & v_{o_q} \end{bmatrix}^{\mathrm{T}} = \sqrt{3} V_i \begin{bmatrix} \gamma_{dd} & \gamma_{qd} \end{bmatrix}^{\mathrm{T}} \tag{35.206}$$

Solving Eq. (35.206) using target output voltages Eq. (35.203), it is possible to calculate γ_{dd} Eq. (35.207) and γ_{qd} Eq. (35.208) modulation indexes:

$$\gamma_{dd} = \frac{V_o}{V_i} \tag{35.207}$$

$$\gamma_{qd} = 0 \tag{35.208}$$

Input/output power constraint can be verified Eq. (35.209) by calculating current $i_{i_d} = \gamma_{dd} i_{o_d} + \gamma_{qd} i_{o_q}$ from Eq. (35.200) and Eq. (35.205), assuming an ideal matrix converter without losses and input/output ideal filtering, using the previously calculated modulation indexes γ_{dd} Eq. (35.207) and γ_{qd} Eq. (35.208), input target currents Eq. (35.202) and output currents Eq. (35.204):

$$V_i I_i \cos(\varphi_i) = V_o I_o \cos(\varphi_o) \tag{35.209}$$

From Eqs. (35.209) and (35.206), it is possible to conclude the following:

(a) Output voltages (Eq. (35.206)) and input i_{i_d} current control depend only on γ_{dd} and γ_{qd} modulation indexes. This shows the well-known nonlinear coupling between output voltages and input currents that results from the input/output active power constraint.
(b) Output voltages and input i_{i_d} current are independent from input i_{i_q} current, which depends only on γ_{dq} and γ_{qq} modulation indexes. This shows that the input power factor is controllable and independent from output voltages control.

From Eqs. (35.200) and (35.205), to guarantee decoupled i_{i_d} and i_{i_q} current components, then, γ_{dq} and γ_{qq} modulation indexes should be given by Eqs. (35.210) and (35.211):

$$\gamma_{dq} = 0 \tag{35.210}$$

$$\gamma_{qq} = k\gamma_{dd} \tag{35.211}$$

From the previously defined modulation indexes and Eq. (35.200), input i_{i_q} current component can be determined by Eq. (35.212):

$$i_{i_q} = \gamma_{qq}\, i_{o_q} = k\gamma_{dd}\, i_{o_q} \tag{35.212}$$

Constant k (Eq. (35.213)) is calculated from Eq. (35.212) using output currents (Eq. (35.204)), target input currents (Eq. (35.202)), and input/output power constraint (Eq. (35.209)):

$$k = \frac{\tan(\varphi_i)}{\tan(\varphi_o)} \tag{35.213}$$

In the previously defined reference frame, the modulation index matrix (Eq. (35.214)) is time invariant and can be obtained from Eqs. (35.207), (35.208), (35.210), (35.211), and (35.213):

$$\mathbf{M_{dq}} = \begin{bmatrix} \gamma_{dd} & \gamma_{dq} \\ \gamma_{qd} & \gamma_{qq} \end{bmatrix} = \begin{bmatrix} \frac{V_o}{V_i} & 0 \\ 0 & \frac{\tan(\varphi_i)}{\tan(\varphi_o)} \frac{V_o}{V_i} \end{bmatrix} \tag{35.214}$$

As a conclusion, from Eqs. (35.206) and (35.212), there are three possible control actions:

(a) γ_{dd} and γ_{qd} to control output currents dq components
(b) k to control input currents power factor

Output current controllers

In order to design the output current controllers, it is assumed that matrix converter is feeding a three-phase general RLE load (Fig. 35.64). In the synchronized dq coordinate frame, output currents are given by Eq. (35.215):

$$\begin{cases} \frac{di_{o_d}}{dt} = -\frac{R}{L} i_{o_d} + \omega_o i_{o_q} + \frac{1}{L} v_{o_d} + \frac{1}{L} E_d \\ \frac{di_{o_q}}{dt} = -\frac{R}{L} i_{o_q} - \omega_o i_{o_d} + \frac{1}{L} v_{o_q} + \frac{1}{L} E_q \end{cases} \tag{35.215}$$

From Eq. (35.215), assuming nearly constant E_d and E_q voltages, H_{dq} (Eq. (35.216)) command voltages will guarantee that i_{o_d} and i_{o_q} output currents follow their references:

$$\begin{cases} H_d = \omega_o L i_{o_q} + v_{o_d} \\ H_q = -\omega_o L i_{o_d} + v_{o_q} \end{cases} \tag{35.216}$$

From Eq. (35.206) and H_{dq} command variables (Eq. (35.216)), matrix converter γ_{dd} and γ_{qd} modulation indexes (Eq. (35.217)) are calculated as functions of H_{dq} command voltages, allowing d and q control action decoupling (Fig. 35.70):

$$\begin{cases} \gamma_{dd} = \frac{H_d - \omega L i_{o_q}}{\sqrt{3} V_i} \\ \gamma_{qd} = \frac{H_q + \omega L i_{o_d}}{\sqrt{3} V_i} \end{cases} \tag{35.217}$$

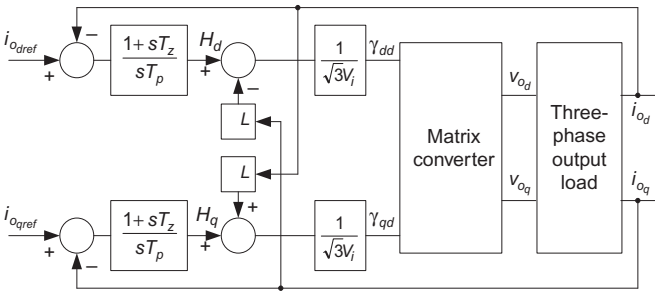

FIG. 35.70 Decoupled block diagram of the current controllers.

Often, the crossed terms $\omega L i_{o_d}$ and $\omega L i_{o_q}$ do not have a significant weight and can be neglected.

Matrix converter should be defined as having a unitary gain and a dominant pole dependent on the average delay time T_d (usually one half of the switching period) [24–27]

$$G_M(s) = \frac{v_{o_{dq}}(s)}{H_{dq}(s)} = \frac{1}{sT_d + 1} \tag{35.218}$$

The first-order dynamics load may be represented as in Eq. (35.219), where R is the load resistance and τ is the load time constant:

$$G_L(s) = \frac{v_{o_{dq}}(s)}{i_{o_{dq}}(s)} = \frac{1}{R(1 + s\tau)} \tag{35.219}$$

Usually, the zero of the compensator is chosen to cancel the pole introduced by the load.

$$T_z = \tau \tag{35.220}$$

From Eqs. (35.218) and (35.219) and Fig. 35.70, the closed-loop transfer function is given by

$$G_{cl}(s) = \frac{\dfrac{K_i}{T_p R T_d}}{s^2 + s\dfrac{1}{T_d} + \dfrac{K_i}{T_p R T_d}} \tag{35.221}$$

Comparing this transfer function with a second-order system in the canonical form, then, $\omega_n^2 = K_i/(T_p R T_d)$, where ω_n is the natural frequency, and $2\xi\omega_n = 1/T_d$, where ξ is the damping factor. Choosing $\xi = \sqrt{2}/2$ to minimize the closed-loop response overshoot and rise time, it is possible to calculate T_p (Eq. (35.222)):

$$T_p = \frac{2K_i T_d}{R} \tag{35.222}$$

Input current controller

Due to the input/output power constraint (Eq. (35.209)), input i_{i_d} current depends on the same modulation indexes as output voltages. On the contrary, i_{i_q} is linearly independent from output voltages and i_{i_d} input current and depends on variable k (Eq. (35.212)):

$$i_{i_q} = \gamma_{qd} i_{o_d} + \gamma_{qq} i_{o_q} \tag{35.223}$$

Using the expected values of γ_{qd} (Eq. (35.208)) and γ_{dd} (Eq. (35.207)) modulation indexes and the target output currents (Eq. (35.204)) in Eq. (35.223), input i_{i_q} current is shown to depend linearly on variable k:

$$i_{i_q} = k\sqrt{3} I_o \frac{V_o}{V_i} \sin\varphi_o \tag{35.224}$$

Neglecting the input filter dynamics, a nearly unitary matrix converter input power factor is obtained for $k = 0$ and, from Eq. (35.211), for $\gamma_{qq} = 0$. However, as the input filter is not ideal, this will usually result in leading power factor on the grid side connection. To control matrix converter input power factor, a simple integral controller would be enough, as the matrix converter input currents have no associated dynamics, depending directly on the switches states. However, due to the input filter capacitive characteristic, in general, and depending on the operating power conditions, the input power factor on the grid connection will be leading when compared with the controlled matrix converter input power factor.

To consider the input filter dynamics in the controller design, it is necessary to relate the grid current i_{ig_q} to the matrix converter input current i_{i_q}. The resultant second-order transfer function can be further used to design an adequate higher order input current linear controller.

Results

Considering an output three-phase RL load $R = 3\ \Omega$ and $L = 30$ mH, some results were obtained for a step of the output current amplitude at $t = 0.22$ s, a step of the output current frequency at $t = 0.28$ s, and a step of matrix converter input i_{i_q} current at $t = 0.34$ s (Fig. 35.71). The input filter dynamics was not considered, and an integral controller was used to control matrix converter input power factor.

These results were obtained using the block diagram of Fig. 35.70, assuming that matrix converter model is characterized by $T_d = 1/(2\ f_m)$, where f_m, the triangular modulator frequency, is $f_m = 10$ kHz. They show that the designed controllers guarantee a good response to step changes in the references: The output current i_{o1} and its reference i_{o1ref} are almost coincident (Fig. 35.71A), and the matrix converter input current i_{iq} follows its reference value i_{iqref}. As expected, due to the input filter, the grid current is slightly in advance when compared with the i_{iqref} reference current or when compared with matrix converter input current i_{iq}.

35.4 Predictive Optimum Control of Switching Power Converters

35.4.1 Introduction

Predictive optimum controllers are based on linear optimum control systems theory and aim to solve the minimization problem of a cost functional [13,28]. Predictive optimum controllers automatically ensure closed-loop stability and some degree of robustness concerning parameter variation and system disturbances while being easy to numerically implement [13,28].

Predictive controllers can be designed to minimize switching power converter state output errors, together with the switching frequency, being useful to control converter state variables,

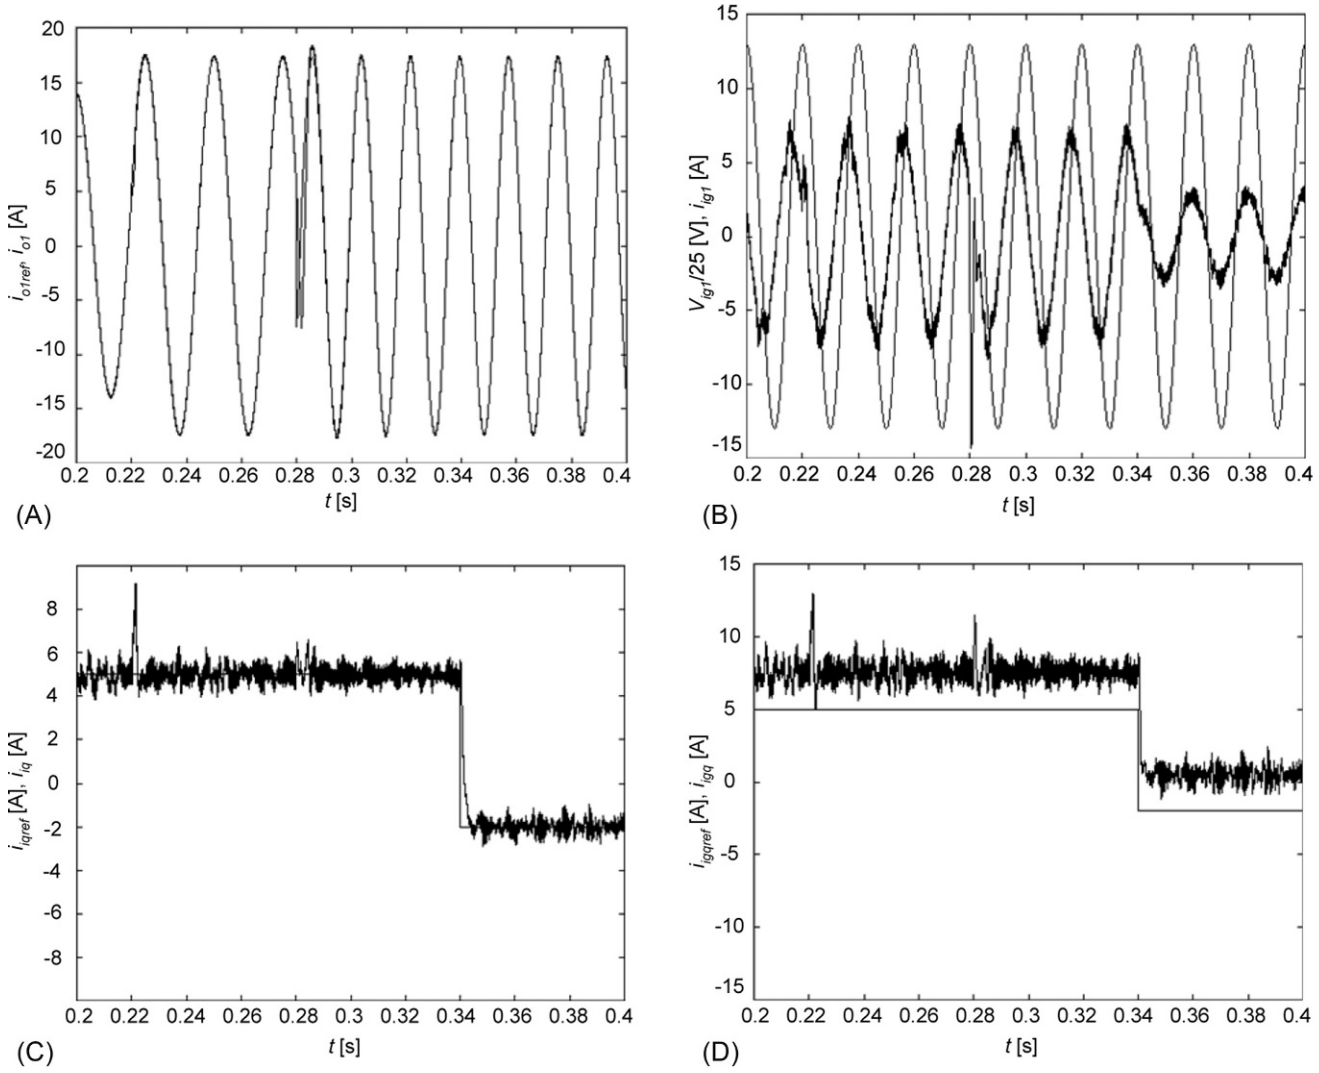

FIG. 35.71 Dynamic responses obtained with a three-phase load ($R=3\ \Omega$ and $L=30$ mH) for a step in the output reference current amplitude at $t=0.22$ s, in the output reference current frequency at $t=0.28$ s, and in the input $i_{iq}(t)$ current at $t=0.34$ s: (A) output reference current $i_{o1ref}(t)$ and output current $i_{o1}(t)$, (B) input grid voltage $v_{ig1}(t)$ and input grid current $i_{ig1}(t)$, (C) matrix converter input reference current $i_{iqref}(t)$ and matrix converter input filtered current $i_{iq}(t)$, and (D) input reference current $i_{igqref}(t)$ and input grid current $i_{igq}(t)$.

such as currents, voltages, or powers, even with coupled dynamics. Several approaches to the predictive control of switching power converters are being developed, and obtained results show improvements comparatively to standard modulation techniques or to sliding-mode control [29–38].

35.4.2 Principles of Non-Linear Predictive Optimum Control

The first step in designing a predictive controller is to obtain a detailed nonlinear direct dynamic model (including bounds, saturations, hysteresis, or other effects) of the switching power converter. This model must contain just enough detail for the converter dynamics to allow the model to forecast, in real time and with negligible error, from initial conditions the future behavior of the converter state-space variables and load, over the next sampling steps, with the converter subjected to each possible switching state (or vector).

The next step is to define a cost functional to evaluate the error cost of the application of every vector to the converter. The cost functional contains the weighted control errors and usually is defined as a norm of the error vector and/or weight control efforts, such as the switching frequency.

Known, measured (sampled), or estimated the initial conditions of the state variables, the predictive control algorithm executes by applying every possible control vector to the model. The predicted values of the state-space variables are used to evaluate the controlled output errors corresponding to each

one of the available vectors. The errors are weighted, and the value of the cost functional is calculated and stored as a vector.

After applying all the vectors to the model, the minimum of the cost functional vector indicates which switching vector must be applied to the converter in order to nearly zero the output errors in the next sampling step, that is, the next control action of the switching power converter is the vector that obtained the least value of the cost functional. Then, the algorithm is executed again in the next sampling step.

This procedure needs a powerful microprocessor to execute all the predictions in real time using fixed sampling steps (usually within 10–30 ms).

This control technology, here called nonlinear predictive optimum control, is feasible in switching power converters, as they have a reduced set of control actions: from just two in simple dc-dc converters to eight vectors in three-phase PWM inverters or 27 in three-level, three-phase multilevel or matrix converters. Therefore, for these converters, the optimization problem is reduced to the calculation and selection of the vector that generates the minimum value of the cost functional vector. However, for multilevel converters with higher number of levels, the number of vectors steeply increases (125 in five-level three-phase converters). This greatly increases the cost of the control system, since the microprocessor must execute the 125 predictions using a nonlinear model roughly within the same 10–30 ms sampling time. A faster alternative to the predictive optimum controller is also proposed.

35.4.2.1 State and Output Prediction

Consider again the state-space model (35.1), where the input vector has been separated in control vector $\mathbf{u}$ and disturbance vector $\mathbf{v}$, being $\mathbf{E}$ the disturbance matrix:

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} + \mathbf{E}\mathbf{v}\\ \mathbf{y} &= \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u}\end{aligned} \tag{35.225}$$

We want to predict the operation of the switching power converter output vector at a future time $t+h$, $\mathbf{y}_{t+h}$, where h is the predictive controller sampling step. We assume to know both the system state at step t and the system switching vector at step $t+h$ (i.e., we measure the state variables at step t, $\mathbf{x}_t$, and know the system matrices at step $t+h$, $\mathbf{A}_{t+h}$, $\mathbf{B}_{t+h}$, $\mathbf{C}_{t+h}$, $\mathbf{D}_{t+h}$, and $\mathbf{E}_{t+h}$, since they depend on a known way from the converter switching vector or they are time invariant). To predict $\mathbf{y}_{t+h}$, we could use the system response obtained from (35.6), substituting the switching period T, by the time difference h between step $t+h$ and step t. For practical converters, Eq. (35.6) must be simplified to minimize calculation time, for example, making $e^{\mathbf{A}h} \approx \mathbf{I} + \mathbf{A}h$ for $\mathbf{A}h \ll \mathbf{I}$, which gives the explicit Euler forward method of integration:

$$\begin{aligned}\mathbf{x}_{t+h} &= \mathbf{x}_t + h\dot{\mathbf{x}}_t\\ \mathbf{y}_{t+h} &= \mathbf{C}_{t+h}\mathbf{x}_{t+h} + \mathbf{D}_{t+h}\mathbf{u}_{t+h}\end{aligned} \tag{35.226}$$

Looking carefully, this prediction method is only a rough approximation, since the switching vector to be applied at $t+h$ is included only in $\mathbf{C}_{t+h}$ and $\mathbf{D}_{t+h}$, but not in $\mathbf{A}_{t+h}$, $\mathbf{B}_{t+h}$, and $\mathbf{E}_{t+h}$, which are usually strongly dependent on the switching vector applied to the converters. The Euler forward method of integration can be devised to be a first-order truncation of the $\mathbf{x}_t$ Taylor series expansion in the neighborhood of t:

$$\mathbf{x}_{t+h} = \mathbf{x}_t + h\dot{\mathbf{x}}_t + \frac{h^2}{2!}\ddot{\mathbf{x}}_t + \frac{h^3}{3!}\dddot{\mathbf{x}}_t + \ldots \tag{35.227}$$

For prediction, the Euler forward is not formally adequate since the future converter switching configuration (vector) is not included explicitly in the predictive equations. Nevertheless, it has been used in predictive control, by using some equation replacement to include the needed converter matrices. Furthermore, the Euler forward method is stable only if the step h obeys $h < 2/\lambda_{max}$, where λ_{max} is the maximum of the absolute values of all eigenvalues of $\mathbf{A}$. This means that the sampling step must often be too small, which helps to reduce the relative step error (close to $h^2/4$), but increases the needed computing power [29].

The Euler backward is an implicit method derived by backward rewriting a truncated Taylor series as

$$\mathbf{x}_t = \mathbf{x}_{t+h} - h\dot{\mathbf{x}}_{t+h} - \ldots \tag{35.228}$$

The unconditionally stable Euler backward algorithm can converge even with long sampling steps, although they are bounded by a relative step error close to $-h^2/4$ [29]:

$$\mathbf{x}_{t+h} = \mathbf{x}_t + h\dot{\mathbf{x}}_{t+h} \tag{35.229}$$

Stable and lower relative step error methods could be used, like the trapezoidal integration method (35.230), but as it needs to calculate both $\dot{\mathbf{x}}_t$ and $\dot{\mathbf{x}}_{t+h}$, it loses the relative step error $h^3/12$ advantage [29] to longer computing times:

$$\mathbf{x}_{t+h} = \mathbf{x}_t + \frac{h}{2}(\dot{\mathbf{x}}_t + \dot{\mathbf{x}}_{t+h}) \tag{35.230}$$

Since we must predict the result of the application of the switching vector at $t+h$, we should use $\mathbf{A}_{t+h}$, $\mathbf{B}_{t+h}$, and $\mathbf{E}_{t+h}$, for prediction, by selecting the Euler backward method, which gives the system time derivatives at $t+h$:

$$\dot{\mathbf{x}}_{t+h} = \mathbf{A}_{t+h}\mathbf{x}_{t+h} + \mathbf{B}_{t+h}\mathbf{u}_{t+h} + \mathbf{E}_{t+h}\mathbf{v}_{t+h} \tag{35.231}$$

Therefore, the converter state variables and outputs at $t+h$ will be

$$\begin{aligned}\mathbf{x}_{t+h} &= [\mathbf{I} - h\mathbf{A}_{t+h}]^{-1}[\mathbf{x}_t + h(\mathbf{B}_{t+h}\mathbf{u}_{t+h} + \mathbf{E}_{t+h}\mathbf{v}_{t+n})]\\ \mathbf{y}_{t+h} &= \mathbf{C}_{t+h}\mathbf{x}_{t+h} + \mathbf{D}_{t+h}\mathbf{u}_{t+h}\end{aligned} \tag{35.232}$$

This equation means that to predict the converter behavior, the switching vector must define the matrices $\mathbf{A}_{t+h}$, $\mathbf{B}_{t+h}$, $\mathbf{C}_{t+h}$, $\mathbf{D}_{t+h}$, and $\mathbf{E}_{t+h}$ (or they must be time invariant) and we must measure (or estimate) the state $\mathbf{x}_t$, the inputs $\mathbf{u}_t$, and disturbances $\mathbf{v}_t$ to estimate $\mathbf{u}_{t+h}$ and $\mathbf{v}_{t+h}$. If $\mathbf{u}_{t+h}$ values are based on the switching

vectors times dc quantities $\mathbf{U}$, then it might be $\mathbf{U}_{t+h} \approx \mathbf{U}_t$, or $\mathbf{U}_{t+h}$ can be estimated using linear extrapolations, such as Euler backward or at least the Euler forward. If $\mathbf{v}_t$ contains ac sinusoidal voltages, then it should be for $\omega h \ll 1$:

$$\begin{aligned}\sin(\omega(t+h)) &= \sin(\omega t)\cos(\omega h) + \sin(\omega h)\cos(\omega t)\\ &\approx \sin(\omega t) + \omega h \cos(\omega t)\\ \cos(\omega(t+h)) &= \cos(\omega t)\cos(\omega h) - \sin(\omega t)\sin(\omega h)\\ &\approx \cos(\omega t) - \omega h \sin(\omega t)\end{aligned} \tag{35.233}$$

The above equations can also be used to predict the future values of the output vector reference values $\mathbf{y}_{ref}$ at $t+h$, if sinusoidal references are being in use and tracking control is sought.

In predictive control, the direct dynamics equations (35.232) are used to predict all the possible future values of the converter outputs, assuming open-loop stability, observability, and all state variables are accessible for measuring or estimation.

35.4.2.2 Minimization of the Cost Functional in Converters with a Reduced Set of Vectors

To solve the minimization problem of the cost functional in a system with a reduced set of m control vectors, consider the errors $\mathbf{e}_j$ ($j \in \{1,m\}$) between the output vector reference values $\mathbf{y}_{ref}$ and the output at $t+h$ corresponding to the vector j of the control vector set, $\mathbf{y}_{jt+h}$, defined as

$$\mathbf{e}_j = \mathbf{y}_{ref} - \mathbf{y}_{j_{t+h}} \tag{35.234}$$

Define also $\mathbf{J}_{t+h}$ (35.235) as an m components vector, the quadratic cost functional of the weighted errors $\mathbf{e}_j$, and the weighted control action $\mathbf{u}_j$, for each control vector j, with weighting matrices $\boldsymbol{\rho}_e$ and $\boldsymbol{\rho}_u$, respectively, for the errors and control actions:

$$\mathbf{J}_{t+h} = \int_0^\infty \left(\mathbf{e}_j^{\mathrm{T}} \boldsymbol{\rho}_e \mathbf{e}_j + \mathbf{u}_j^{\mathrm{T}} \boldsymbol{\rho}_u \mathbf{u}_j\right) \mathrm{d}t \tag{35.235}$$

The weighting matrices $\boldsymbol{\rho}_e$ and $\boldsymbol{\rho}_u$ are the predictive optimum controller degrees of freedom to penalize excessively high errors or high control efforts, such as high switching frequencies.

After calculating all the m components of the quadratic cost functional $\mathbf{J}_{t+h}$, the last step in the design of predictive optimum controller is to select the control vector $\mathbf{u}_j$ to be applied to the converter, as the control vector j for which the quadratic cost functional is minimum:

$$\mathbf{u}_j \Leftrightarrow \min_j \left[J_{1t+h}, J_{2t+h}, \ldots, J_{j_{t+h}}, \ldots, J_{mt+h}\right] \tag{35.236}$$

It is worth to note that the control vector $\mathbf{u}_j$ just minimizes the defined quadratic cost functional, subjected to the constraints imposed in the converter direct dynamics (35.225). The usual system performance indexes (overshoot, stability margin, disturbance rejection, and robustness) can have little relation with the minimization of the defined quadratic cost functional. This must be considered when defining the cost functional and the weighting matrices of predictive optimum controllers. The designed predictive controller will only perform correctly if, while minimizing the cost functional, it also guarantees adequate steady-state and dynamic behavior. Nevertheless, predictive optimum controllers use state feedback of all the state variables to be controlled and therefore can be tailored to present optimum or near optimum dynamics, considering the physical bounds.

35.4.3 Principles of Non-Linear Fast Predictive Optimum Control

The above algorithm needs to evaluate Eqs (35.232)–(35.235) m times, which can be time-consuming for three-phase multilevel converters with five or more levels.

To reduce the microprocessor computational task, the use of a subset of either adjacent vectors (for minimum switching frequency) or vectors that can zero one or several harmonics, is an alternative to reduce the number of candidate vectors to be analyzed in real time.

Another possibility is to use the converter inverse dynamics to obtain a fast predictive optimum controller, which is here introduced.

From the output equation of the state-space model (35.225), it can be written as

$$\mathbf{x}_{ref} = \mathbf{C}^{-1}\left[\mathbf{y}_{ref} - \mathbf{D}\,\mathbf{u}_{t+h}\right] \tag{35.237}$$

Note also that if we suppose that the control objective is attained at sampling time $t+h$, then $\mathbf{x}_{t+h} = \mathbf{x}_{ref}$, and from (35.229),

$$\dot{\mathbf{x}}_{t+h} = h^{-1}\left[\mathbf{x}_{t+h} - \mathbf{x}_t\right] = h^{-1}\left[\mathbf{x}_{ref} - \mathbf{x}_t\right] \tag{35.238}$$

Using (35.237) in (35.238) and the result in the state equation of (35.225), the converter inverse dynamics, needed to estimate the necessary control vector $\mathbf{u}_{t+h}$, can be obtained:

$$\begin{aligned}\mathbf{u}_{t+h} = &\left[\mathbf{A}\mathbf{C}^{-1}\mathbf{D} - \mathbf{B} - \left[h^{-1}\mathbf{C}^{-1}\right]\mathbf{D}\right]^{-1}\left[\left[\mathbf{A}\mathbf{C}^{-1} - \left[h^{-1}\mathbf{C}^{-1}\right]\right]\mathbf{y}_{ref}\right.\\ &\left. + \mathbf{E}\mathbf{v} + \left[h^{-1}\mathbf{x}_t\right]\right]\end{aligned} \tag{35.239}$$

This equation defines the needed components of the control vector $\mathbf{u}_{t+h}$. An alternative way to generate the needed control vector $\mathbf{u}_{t+h}$ is to use the controllability canonical form of the converter dynamics to compute the equivalent control, similar to (35.83).

Seldom, the converter will be able to replicate the vector in (35.239), since it is a continuously variable equivalent control vector and the converter only outputs a reduced set of control vectors. Therefore, the control vector $\mathbf{u}_{t+h}$ might be either

obtained as a kind of space-vector modulation or found by minimization of a quadratic cost functional, based on the norm of the difference vector between the needed $\mathbf{u}_{t+h}$ and the available set of vectors $\mathbf{u}_j$:

$$J_{j_{t+h}} = \left\|\mathbf{u}_{t+h} - \mathbf{u}_j\right\| = \sqrt{\left(u_{1t+h} - u_{1j}\right)^2 + \ldots + \left(u_{mt+h} - u_{mj}\right)^2} \tag{35.240}$$

Then, this functional is computed for all $\mathbf{u}_j$, to find the vector that leads to the minimum value of the cost functional (35.240) accordingly to (35.236).

The fast predictive optimum control needs much less computational time, as it only evaluates 35.239 one time per step and (35.240) m times. However, preliminary inspection of Eq. (35.239) indicates that it can only be directly applied to converters with input and output circuits that have time-invariant dynamic matrices.

35.4.4 Examples: Predictive Control of Multilevel Inverters and Matrix Converters

35.4.4.1 Example 35.19: Non-linear Predictive Optimum Control of Multilevel Inverters

Consider the multilevel inverter of Fig. 35.58, with three-phase ac current direct dynamics in the αβ plane given by (35.167) and 35.161, which can be rewritten as

$$\begin{bmatrix} \frac{di_\alpha}{dt} \\ \frac{di_\beta}{dt} \\ \frac{dU_{C1}}{dt} \\ \frac{dU_{C2}}{dt} \end{bmatrix} = \begin{bmatrix} -\frac{R}{L} & 0 & \frac{\Gamma_{1\alpha}}{L} & \frac{\Gamma_{2\alpha}}{L} \\ 0 & -\frac{R}{L} & \frac{\Gamma_{1\beta}}{L} & \frac{\Gamma_{2\beta}}{L} \\ -\frac{\Gamma_{1\alpha}}{C_1} & -\frac{\Gamma_{1\beta}}{C_1} & 0 & 0 \\ -\frac{\Gamma_{2\alpha}}{C_2} & -\frac{\Gamma_{2\beta}}{C_2} & 0 & 0 \end{bmatrix} \begin{bmatrix} i_\alpha \\ i_\beta \\ U_{C1} \\ U_{C2} \end{bmatrix} + \begin{bmatrix} -\frac{1}{L} & 0 & 0 \\ 0 & -\frac{1}{L} & 0 \\ 0 & 0 & \frac{1}{C_1} \\ 0 & 0 & \frac{1}{C_2} \end{bmatrix} \begin{bmatrix} U_{e\alpha} \\ U_{e\beta} \\ i_{dc} \end{bmatrix}. \tag{35.241}$$

where $\Gamma_{i\alpha} = \sqrt{\frac{2}{3}}\left(\Gamma_{i1} - \frac{\Gamma_{i2}}{2} - \frac{\Gamma_{i3}}{2}\right)$, $\Gamma_{i\beta} = \sqrt{\frac{2}{3}}\left(\frac{\sqrt{3}}{2}\Gamma_{i2} - \frac{\sqrt{3}}{2}\Gamma_{i3}\right)$, and $i \in \{1,2\}$.

The optimal controller is designed to choose the best output voltage vector able to minimize both the ac current, i_α and i_β, errors and the input dc capacitor U_{C1} and U_{C2} voltage unbalance.

Predictive equations for ac αβ currents

To design a real-time optimal predictive controller, the obtained αβ converter model (35.167) will be solved to predict the state variable values at the next sampling period, for all the 27 available vectors, assuming a sampling time h small enough, so that U_{C1}, U_{C2}, and u_{ep}, $p \in \{\alpha,\beta\}$, can be considered nearly constant during step time h. Therefore, the simplified model is decoupled and, using (35.229) in (35.167), the αβ current i_{pt+h} ($p \in \{\alpha,\beta\}$) prediction is obtained:

$$i_{p_{t+h}} \approx \frac{i_{p_t} + \frac{h}{L}\left(U_{Sp_{t+h_j}} - u_{ep_{t+h}}\right)}{\left(1 + \frac{hR}{L}\right)} \tag{35.242}$$

where the perturbations u_{ep} can be estimated using (35.233).

Predictive equations for dc capacitor voltage unbalance

To predict the capacitor voltage difference or unbalance, $U_{C1} - U_{C2}$, the corresponding dynamic equations (35.241) must be solved. Assuming h small enough, $C_1 = C_2 = C$, and small control errors, it can be assumed that the ac currents follow their references, for example, $i_{pt+h} = i_{pref}$. Then, from (35.241) and (35.229),

$$\left(U_{C1} - U_{C2}\right)_{t+h} = \left(U_{C1} - U_{C2}\right)_t + \frac{h}{C}\left[\left(\Gamma_{2\alpha} - \Gamma_{1\alpha}\right)_j i_{\alpha ref} + \left(\Gamma_{2\beta} - \Gamma_{1\beta}\right)_j i_{\beta ref}\right] \tag{35.243}$$

Quadratic cost functional

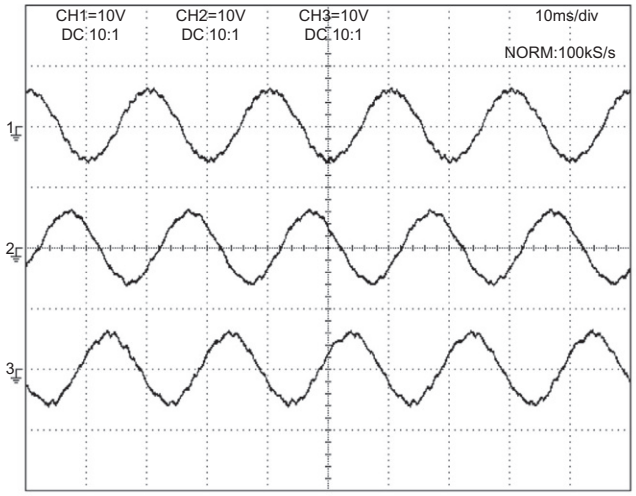
In NPC multilevel converters operated as ac current sources, three independent variables can be controlled, such as two ac currents $i_\alpha(t)$ and $i_\beta(t)$, and the dc capacitor voltage unbalance U_{C1}-U_{C2}. Therefore, the tracking error vector is defined as

$$\left[e_{i\alpha}, e_{i\beta}, e_{UC}\right]_j = \left[i_{\alpha ref} - i_{\alpha t+h}, i_{\beta ref} - i_{\beta t+h}, \left(U_{C1} - U_{C2}\right)_{t+h}\right]_j \tag{35.244}$$

The ac current references $i_{\alpha ref}$ and $i_{\beta ref}$ are obtained one sample step forward (using (35.233)) to avoid the delay time due to processor calculation time.

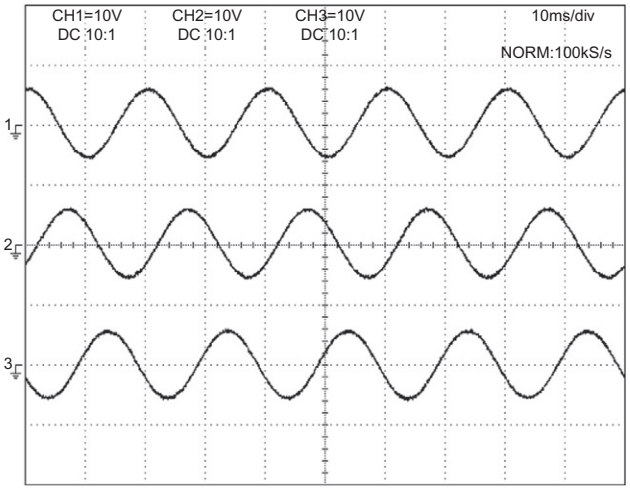
The main objective of the predictive optimum controller is the minimization of both the ac currents errors and the capacitor voltage difference using the following quadratic cost functional:

$$J_{j_{t+h}} = \sqrt{\rho_\alpha e_{i\alpha_j}^2 + \rho_\beta e_{i\beta_j}^2 + \rho_U e_{UC_j}^2} \tag{35.245}$$



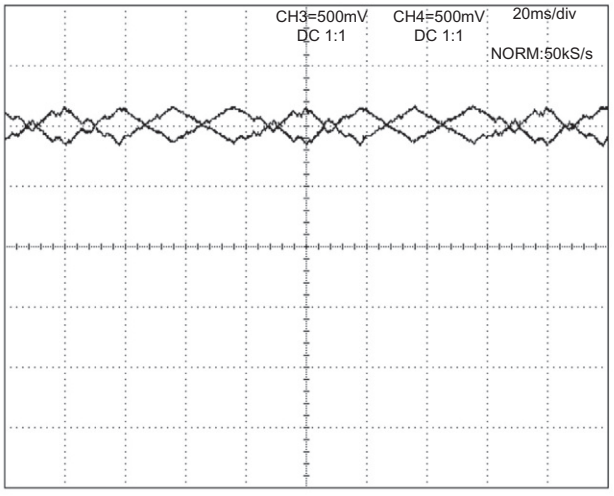
This functional is calculated for all the multilevel 27 available vectors and the resultant value stored (Eqs 35.242–35.245 are calculated 27 times). Using the procedure outlined in

(35.236), the vector leading to the minimum value of the cost functional is selected to be applied to the multilevel converter.



Results

The above procedure was implemented in a PowerPC-based board (DS1103) to execute in $h = 25$ ms. The following parameters were used: $U_{dc} = 300$ V, $C_1 = 4.4$ mF, $C_2 = 4.4$ mF, $L = 15.1$ mH, $R = 0.1\ \Omega$, $i_{ac} = 7$ A, U_e obtained from 230/400 V, 50 Hz through a 400/230 V transformer, and $\rho_\alpha = \rho_\beta = 11$ and $\rho_U = 25$. The ac-controlled currents and dc capacitor voltage balance are compared with the results of a sliding-mode controller. Fig. 35.72 shows that the predictive optimum controller performance is better than the sliding-mode controller. The predictive optimum controller presents some robustness to industrial component tolerances. Results showed a tolerance from −50% to +100%.



Further experiments [37,38] revealed that harmonics of ac currents were 46 dB below the 50 Hz fundamental level, improving by 14 dB the sliding-mode controller result. The switching frequency of the predictive optimum controller spreads over the frequency spectrum below 2.5 kHz, reducing and softening the audible noise. The average switching frequency of the predictive optimum controlled multilevel converter is reduced to half of the value of a sliding-mode-controlled multilevel at the same

current ripple. Further reduction could be obtained by weighting the switching frequency in the quadratic cost functional [39].

35.4.4.2 Example 35.20: Fast Predictive Optimum Control of Matrix Converters

Consider the three-phase ac/ac matrix converter with input *lCr* filter of Fig. 35.64, and suppose we want to control the output currents i_{o_1}, i_{o_2}, and i_{o_3} while guaranteeing an almost unity input power factor and near sinusoidal input currents i_{ig1}, i_{ig2}, and i_{ig3}.

The converter direct dynamics of the output currents in dq frame at frequency ω_o, i_{od}, i_{oq} is

$$\begin{cases} \dfrac{di_{o_d}}{dt} = -\dfrac{R}{L} i_{o_d} + \dfrac{1}{L} v_{o_d} + \dfrac{1}{L} E_d + \omega_o i_{o_q} \\ \dfrac{di_{o_q}}{dt} = -\dfrac{R}{L} i_{o_q} + \dfrac{1}{L} v_{o_q} + \dfrac{1}{L} E_q - \omega_o i_{o_d} \end{cases} \tag{35.246}$$

The converter direct dynamics of the input currents in dq frame at frequency ω_i, i_{igd}, i_{igq} is given in (35.183) and (35.184). To control the matrix input power factor, the dynamics of the input dq currents, neglecting the effects of the matrix input filter damping resistor ($r \to \infty$), can be simplified to be

$$\begin{cases} \dfrac{di_{igd}}{dt} = \omega_i i_{igq} - \dfrac{1}{2l} v_{cd} - \dfrac{1}{2\sqrt{3}l} v_{cq} + \dfrac{1}{l} V_{igd} \\ \dfrac{di_{igq}}{dt} = -\omega_i i_{igd} + \dfrac{1}{2\sqrt{3}l} v_{cd} - \dfrac{1}{2l} v_{cq} + \dfrac{1}{l} V_{igq} \\ \dfrac{dv_{cd}}{dt} = \omega_i v_{cq} - \dfrac{1}{2\sqrt{3}C} i_{igq} + \dfrac{1}{2C} i_{igd} - \dfrac{1}{2C} i_{id} + \dfrac{1}{2\sqrt{3}C} i_{iq} \\ \dfrac{dv_{cq}}{dt} = -\omega_i v_{cd} + \dfrac{1}{2\sqrt{3}C} i_{igd} + \dfrac{1}{2C} i_{igq} - \dfrac{1}{2\sqrt{3}C} i_{id} - \dfrac{1}{2C} i_{iq} \end{cases} \tag{35.247}$$

The control vector $\mathbf{u}_{t+h}$ are defined by v_{odt+h}, v_{oqt+h}, and i_{iqt+h}. From the input and output dynamics of the matrix converter, Eq. (35.248) computes the necessary vector components to ensure convergence to the reference values within one sampling step h. Most terms of the i_{iqt+h} current can be neglected for simplicity, the essential ones being the difference $i_{igqref} - i_{igqt}$ with associated gain and the feedforward value of i_{igqref}:

$$\begin{aligned} v_{o_{d_{t+h}}} &= \frac{L}{h}\left(i_{o_{d_{ref}}} - i_{o_{d_t}}\right) + R i_{o_{d_{ref}}} - E_d - \omega_o l i_{o_{q_{ref}}} \\ v_{o_{q_{t+h}}} &= \frac{L}{h}\left(i_{o_{q_{ref}}} - i_{o_{q_t}}\right) + R i_{o_{q_{ref}}} - E_q + \omega_o l i_{o_{d_{ref}}} \\ i_{i_{q_{t+h}}} &= \frac{6Cl}{h^2}\left(i_{igq_{ref}} - 2i_{igq_t} + i_{igq_{t-h}}\right) + \left(3Cl\omega_i^2 + 1\right) i_{igq_{ref}} \\ &\quad -3\omega_i C v_{cd} - \sqrt{3}\omega_i C v_{cq} + 3\omega_i C V_{gd} \approx \\ &\approx \frac{6Cl}{h^2}\left(i_{igq_{ref}} - 2i_{igq_t} + i_{igq_{t-h}}\right) + \left(3Cl\omega_i^2 + 1\right) i_{igq_{ref}} \end{aligned} \tag{35.248}$$

Only one calculation for the optimum vector with components (35.247) is needed, avoiding the currents and the respective errors computation for all the 27 possible converter vectors, speeding the predictive method. Since the discrete time derivative and damping terms are calculated using the current future values, the Euler backward algorithm is used, ensuring convergence.

In practice, none of the available converter vectors will present exactly the necessary components. Therefore, the distance from each vector to the optimum vector (the vector error norm) must be computed, using the cost functional:

$$J_{j_{t+h}} = \sqrt{\rho_{vd}\left(v_{o_{d_{t+h}}} - v_{o_{d_j}}\right)^2 + \rho_{vq}\left(v_{o_{q_{t+h}}} - v_{o_{q_j}}\right)^2 + \rho_{iq}\left(i_{i_{q_{t+h}}} - i_{i_{q_j}}\right)^2} \tag{35.249}$$

Results using $\rho_{vd} = \rho_{vq} = \rho_{iq} = 1$ show that fast predictive optimum controllers, using the converter inverse dynamics, present better performances than state-of-art sliding-mode controllers (Fig. 35.73). Stability and robustness of fast predictive optimum controllers, concerning parameter variation, disturbances, and nonmodeled dynamics, must be investigated. The fast predictive methodology was successful applied to other converters [40]:

35.5 Fuzzy Logic Control of Switching power converters

35.5.1 Introduction

Fuzzy logic control is a heuristic approach that easily embeds the knowledge and key elements of human thinking in the design of nonlinear controllers [41–43]. Qualitative and heuristic considerations, which cannot be handled by conventional control theory, can be used for control purposes in a systematic form, applying fuzzy control concepts [44]. Fuzzy logic control does not need an accurate mathematical model, can work with imprecise inputs, can handle nonlinearity, and can present disturbance insensitivity greater than the most nonlinear controllers. Fuzzy logic controllers usually outperform other controllers in complex, nonlinear, or undefined systems for which a good practical knowledge exists.

Fuzzy logic controllers are based on fuzzy sets, that is, classes of objects in which the transition from membership to nonmembership is smooth rather than abrupt. Therefore, boundaries of fuzzy sets can be vague and ambiguous, making them useful for approximation models.

The first step in the fuzzy controller synthesis procedure is to define the input and output variables of the fuzzy controller. This is done accordingly with the expected function of the controller. There are no general rules to select those variables, although typically the variables chosen are the states of the

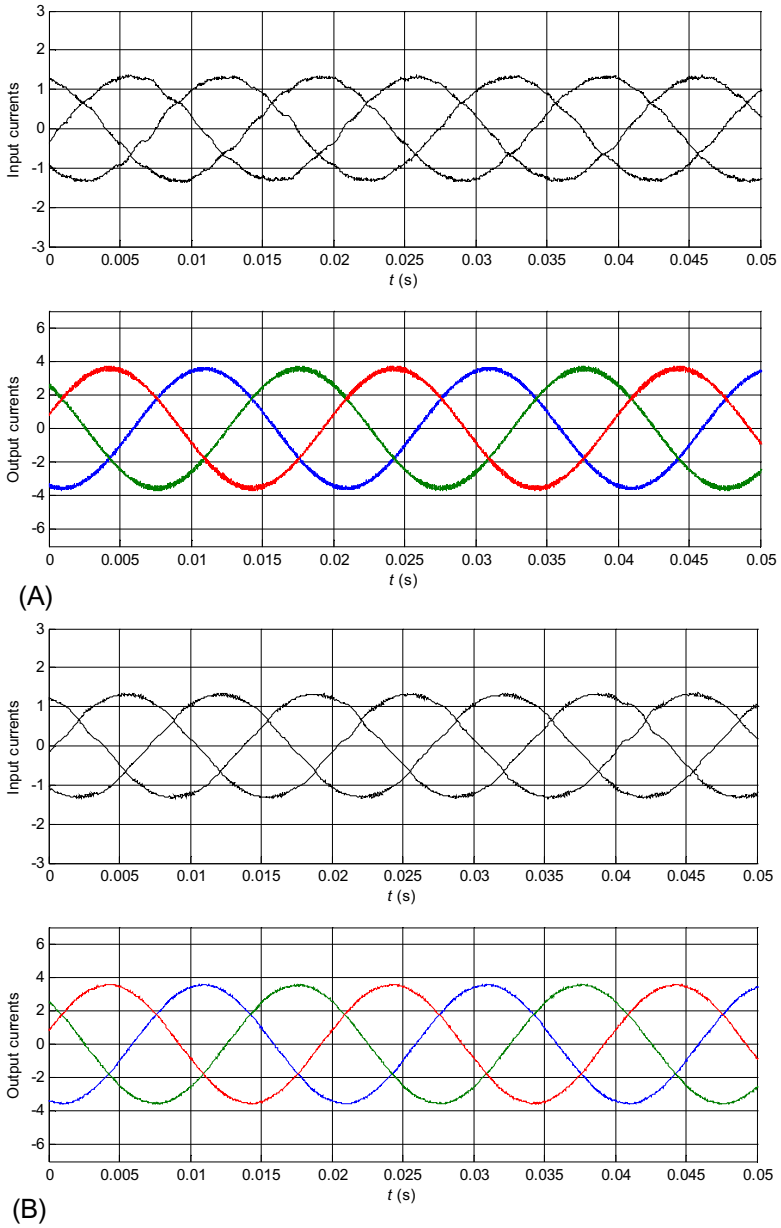

FIG. 35.73 Matrix converter sinusoidal ac input and output currents, i_1, i_2, and i_3, in steady-state operation, using sliding-mode controllers (A) and fast predictive optimum controllers (B).

controlled system, their errors, error variation, and/or error accumulation. In switching power converters, the fuzzy controller input variables are commonly the output voltage or current error and/or the variation or accumulation of this error. The output variables $u(k)$ of the fuzzy controller can define the converter duty cycle (Fig. 35.74) or a reference current to be applied in an inner current-mode PI or a sliding-mode controller.

The fuzzy controller rules are usually formulated in linguistic terms. Thus, the use of linguistic variables and fuzzy sets implies the fuzzification procedure, that is, the mapping of the input variables into suitable linguistics values.

Rule evaluation or decision-making infers, using an inference engine, the fuzzy control action from the knowledge of the fuzzy rules and the linguistic variable definition.

The output of a fuzzy controller is a fuzzy set, and thus, it is necessary to perform a defuzzification procedure, that is, the conversion of the inferred fuzzy result to a nonfuzzy (crisp) control action, that better represents the fuzzy one. This last step obtains the crisp value for the controller output $u(k)$ (Fig. 35.74).

These steps can be implemented online or offline. Online implementation, useful if an adaptive controller is intended, performs real-time inference to obtain the controller output

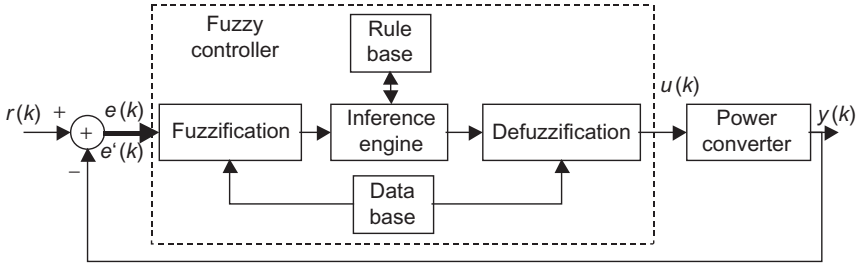

FIG. 35.74 Structure of a fuzzy logic controller.

and needs a fast enough processor. Off-line implementation employs a lookup table built according to the set of all possible combinations of input variables. To obtain this lookup table, the input values in a quantified range are converted (fuzzification) into fuzzy variables (linguistic). The fuzzy set output, obtained by the inference or decision-making engine according to linguistic control rules (designed by the knowledge expert), is then, converted into numeric controller output values (defuzzification). The table contains the output for all the combinations of quantified input entries. Off-line process can actually reduce the controller actuation time since the only effort is limited to consulting the table at each iteration.

This section presents the main steps for the implementation of a fuzzy controller suitable for switching power converter control. A meaningful example is provided.

35.5.2 Fuzzy Logic Controller Synthesis

Fuzzy logic controllers consider neither the parameters of the switching power converter or their fluctuations nor the operating conditions, but only the experimental knowledge of the switching power converter dynamics. In this way, such a controller can be used with a wide diversity of switching power converters implying only small modifications. The necessary fuzzy rules are simply obtained considering roughly the knowledge of the switching power converter dynamic behavior.

35.5.2.1 Fuzzification

Assume, as fuzzy controller input variables, an output voltage (or current) error and the variation of this error. For the output, assume a signal $u(k)$, the control input of the converter.

A. Quantization Levels

Consider the reference $r(k)$ of the converter output kth sample, $y(k)$. The tracking error $e(k)$ is $e(k)=r(k)-y(k)$, and the output error change $\Delta_e(k)$, between the samples k and $k-1$, is determined by $\Delta_e(k)=e(k)-e(k-1)$.

These variables and the fuzzy controller output $u(k)$, usually ranging from -10 to 10 V, can be quantified in m levels $\{-(m-1)/2, +(m-1)/2\}$. For offline implementation, m sets a compromise between the finite length of a lookup table and the required precision.

B. Linguistic Variables and Fuzzy Sets

The fuzzy sets for x_e, the linguistic variable corresponding to the error $e(k)$; for $x_{\Delta e}$, the linguistic variable corresponding to the error variation $\Delta_e(k)$; and for x_u, the linguistic variable of the fuzzy controller output $u(k)$ are usually defined as positive big (*PB*), positive medium (*PM*), positive small (*PS*), zero (*ZE*), negative small (*NS*), negative medium (*NM*), and negative big (*NB*), instead of having numerical values.

In most cases, the use of these seven fuzzy sets is the best compromise between accuracy and computational task.

C. Membership Functions

A fuzzy subset, for example, $\mathbf{S}_i$ ($\mathbf{S}_i=$(NB, NM, NS, ZE, PS, PM, or PB)) of a universe E, collection of $e(k)$ values denoted generically by $\{e\}$, is characterized by a membership function μ_{Si}: $E\rightarrow[0,1]$, associating with each element e of universe E, a number $\mu_{Si}(e)$ in the interval [0,1], which represents the grade of membership of e to E. Therefore, each variable is assigned a membership grade to each fuzzy set, based on a corresponding membership function (Fig. 35.75). Considering the m quantization levels, the membership function $\mu_{Si}(e)$ of the element e in the universe of discourse E, may take one of the discrete values included in $\mu_{Si}(e)\in\{0; 0.2; 0.4; 0.6; 0.8; 1; 0.8; 0.6; 0.4; 0.2; 0\}$. Membership functions are stored in the database (Fig. 35.74).

Considering $e(k)=2$ and $\Delta_e(k)=-3$, taking into account the staircase-like membership functions shown in Fig. 35.75, it can be said that x_e is *PS* and also *ZE*, being equally *PS* and *ZE*. Also, $x_{\Delta e}$ is *NS* and *ZE*, being less *ZE* than *NS*.

D. Linguistic Control Rules

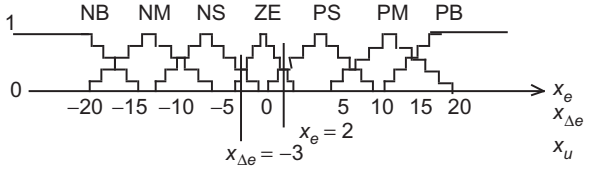

FIG. 35.75 Membership functions in the universe of discourse.

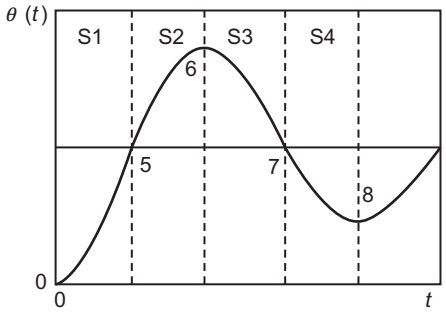

FIG. 35.76 Reference dynamic model of switching power converters: second-order damped oscillating error response.

The generic linguistic control rule has the following form: "IF $x_e(k)$ is membership of the set $\mathbf{S}_i$ = (NB, NM, NS, ZE, PS, PM, or PB) AND $x_{\Delta e}(k)$ is membership of the set $\mathbf{S}_j$ = (NB, NM, NS, ZE, PS, PM, or PB), THEN the output control variable $x_u(k+1)$ is membership of the set $\mathbf{S}_u$ = (NB, NM, NS, ZE, PS, PM, or PB)."

Usually, the rules are obtained considering the most common dynamic behavior of switching power converters, the second-order system with damped oscillating response (Fig. 35.76). Analyzing the error and its variation, together with the rough linguistic knowledge of the needed control input, an expert can obtain linguistic control rules such as the ones displayed in Table 35.8. For example, at point six of Fig. 35.76, the rule is "if $x_e(k)$ is NM AND $x_{\Delta e}(k)$ is ZE, THEN $x_u(k+1)$ should be NM."

Table 35.8, for example, states that

IF $x_e(k)$ is NB AND $x_{\Delta e}(k)$ is NB, THEN $x_u(k+1)$ must be NB, or
IF $x_e(k)$ is PS AND $x_{\Delta e}(k)$ is NS, THEN $x_u(k+1)$ must be NS, or
IF $x_e(k)$is PS AND $x_{\Delta e}(k)$ is ZE, THEN $x_u(k+1)$ must be PS, or

These rules (rule base) alone do not allow the definition of the control output, as several of them may apply at the same time.

35.5.2.2 Inference Engine

The result of a fuzzy control algorithm can be obtained using the control rules of Table 35.8, the membership functions, and an inference engine. In fact, any quantified value for $e(k)$ and $\Delta_e(k)$ is often included into two linguistic variables. With the membership functions used and knowing that the controller considers $e(k)$ and $\Delta_e(k)$, the control decision generically must be taken according to four linguistic control rules.

To obtain the corresponding fuzzy set, the min-max inference method can be used. The minimum operator describes the "AND" present in each of the four rules, that is, it calculates the minimum between the discrete value of the membership function $\mu_{Si}(x_e(k))$ and the discrete value of the membership function $\mu_{Sj}(x_{\Delta e}(k))$. The "THEN" statement links this minimum to the membership function of the output variable. The membership function of the output variable will therefore include trapezoids limited by the segment $\min(\mu_{Si}(x_e(k))$ and $\mu_{Sj}(x_{\Delta e}(k)))$.

The OR operator linking the different rules is implemented by calculating the maximum of all the (usually four) rules. This mechanism to obtain the resulting membership function of the output variable is represented in Fig. 35.77.

35.5.2.3 Defuzzification

As shown, the inference method provides a resulting membership function $\mu_{Sr}(x_u(k))$, for the output fuzzy variable x_u (Fig. 35.77). Using a defuzzification process, this final membership function, obtained by combining all the membership functions, as a consequence of each rule, is then converted into a numerical value, called $u(k)$. The defuzzification strategy can be the center of area (COA) method. This method generates one output value $u(k)$, which is the abscissa of the gravity center of the resulting membership function area, given by the following relation:

$$u(k) = \left(\sum_{i=1}^{m} \mu_{Sr}(x_u(k))x_u(k)\right) \Big/ \sum_{i=1}^{m} \mu_{Sr}(x_u(k)) \qquad (35.250)$$

This method provides good results for output control. Indeed, for a weak variation of $e(k)$ and $\Delta_e(k)$, the center of the area will move just a little and so does the controller output value. By comparison, the alternative defuzzification method, mean of maximum strategy (MOM) is advantageous for fast response, but it causes a greater steady-state error and overshoot (considering no perturbations).

35.5.2.4 Lookup Table Construction

Using the rules given in Table 35.8, the min-max inference procedure and COA defuzzification, all the controller output

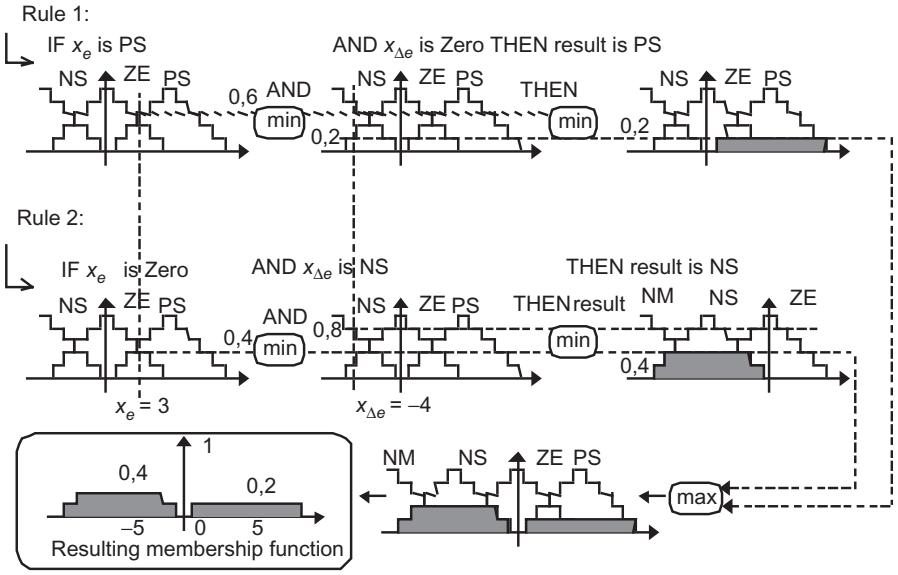

FIG. 35.77 Application of the min-max operator to obtain the output membership function.

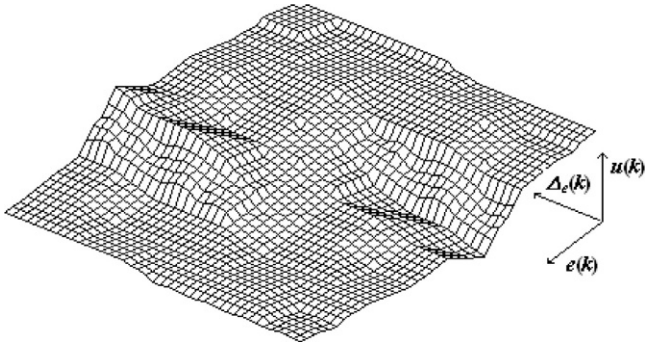

FIG. 35.78 Three-dimensional view of the lookup table.

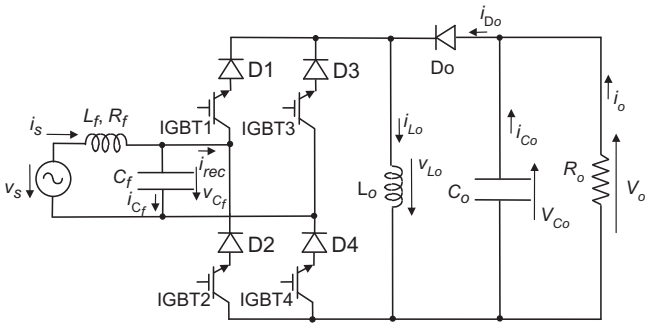

FIG. 35.79 Power factor buck-boost rectifier with four IGBTs.

values for all quantified $e(k)$ and $\Delta_e(k)$, can be stored in an array to serve as the decision-lookup table. This lookup table usually has a three-dimensional representation similar to Fig. 35.78. A microprocessor-based control algorithm just picks up output values from the lookup table.

35.5.3 Near Unity Power Factor Buck–Boost PWM Rectifier

35.5.3.1 Example 35.21: Fuzzy Logic Control of Unity Power Factor Buck–Boost Rectifiers

Consider the near unity power factor buck-boost rectifier of Fig. 35.79, where the diodes in series with the transistors enable them to withstand negative voltages.

The switched state-space model of this converter can be written as

$$\begin{cases} \dfrac{di_s}{dt} = -\dfrac{R_f}{L_f} i_s - \dfrac{1}{L_f} v_{C_f} + \dfrac{1}{L_f} v_s \\ \dfrac{dv_{C_f}}{dt} = \dfrac{1}{C_f} i_s - \dfrac{\gamma_p}{C_f} i_{L_o} \\ \dfrac{di_{L_o}}{dt} = \dfrac{\gamma_p}{L_o} v_{C_f} - \dfrac{\gamma\left(1 - \left|\gamma_p\right|\right)}{L_o} V_{C_o} \\ \dfrac{dV_{C_o}}{dt} = \dfrac{1 - \left|\gamma_p\right|}{C_o} i_{L_o} - \dfrac{1}{R_o C_o} V_o \end{cases} \tag{35.251}$$

where $\gamma_p = \begin{cases} 1, & (\textit{switch 1 and 4 are ON}) \ \textit{and} \ (\textit{switch 2 and 3 are OFF}) \\ 0, & \textit{all the switches are OFF} \\ -1, & (\textit{switch 2 and 3 are ON}) \ \textit{and} \ (\textit{switch 1 and 4 are OFF}) \end{cases}$

and $\gamma = \begin{cases} 1, & i_{L_o} > 0 \\ 0, & i_{L_o} \leq 0 \end{cases}$.

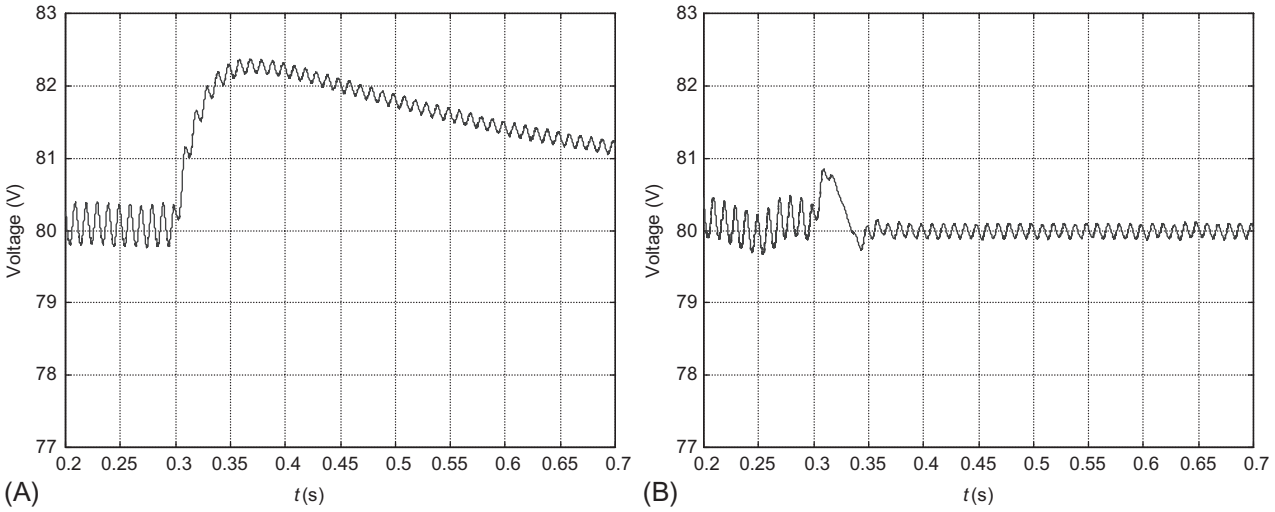

FIG. 35.80 Simulated result of the output voltage response to load disturbances ($R_o = 50$–$150\ \Omega$ at time 0.3 s): (A) PI control and (B) fuzzy logic control.

For comparison purposes, a PI output voltage controller is designed considering that a current-mode PWM modulator enforces the reference value for the i_s current (which usually exhibits a fast dynamics compared with the dynamics of V_{Co}). A first-order model, similar to Eq. (35.146), is obtained. The PI gains are similar to Eq. (35.116) and load-dependent ($K_p = C_o/(2T_d)$ and $K_i = 1/(2T_dR_o)$).

A fuzzy controller is obtained considering the approach outlined, with seven membership functions for the output voltage error, five for its change, and three membership functions for the output. The linguistic control rules are obtained as the ones depicted in Table 35.8, and the lookup table gives a mapping similar to Fig. 35.78. Performances obtained for the step response show a fuzzy controlled rectifier behavior close to the PI behavior. The advantages of the fuzzy controller emerge for perturbed loads or power supplies, where the low sensitivity of the fuzzy controller to system parameters is clearly seen (Fig. 35.80). Therefore, the fuzzy controllers can be advantageous for switching power converters with changing loads, power supply voltages, and other external disturbances.

35.6 Backstepping Control of Switching Power Converters

35.6.1 Principles of Backstepping Control

The backstepping control methodology [45,46] may be implemented using a recursive procedure interconnecting the choice of a candidate Lyapunov function with the design of the feedback control loop using the second method of Lyapunov stability (direct method). Backstepping offers tracking ability, stability, and robust control under conditions less restrictive than other methods [47]. Backstepping uses a strict-feedback form of the system model:

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} x \\ z_1 \\ \cdots \\ z_m \end{bmatrix} = \begin{bmatrix} f_0(x) + g_0(x)z_1 \\ f_1(xz_1) + g_1(xz_1)z_2 \\ \cdots \\ f_m(x, z_1, \ldots, z_m) + g_m(x, z_1, \ldots, z_m)u \end{bmatrix} \tag{35.252}$$

where $x \in \Re^n$, z_1–z_m are scalar state variables, f_0–f_m are nonlinearities dependent only on the state variables that are fed back [x, z_1,…, z_m] (strict feedback), and $g_i \neq 0$ is dependent on $(x, z_1, \ldots, z_i)$ for $1 \leq i \leq m$.

To apply the backstepping method [47] and stabilize the system to the origin (zero error), the following steps can be used:

(1) The recursive procedure starts with the subsystem of (35.252):

$$\frac{\mathrm{d}x}{\mathrm{d}t} = f_0(x) + g_0(x)z_1 \tag{35.253}$$

where z_1 is a state variable, whose dynamics can be enforced, called a stabilizing control input (or virtual control input).

(2) Proceed to obtain z_1 by defining the control objective $x = x_{ref}$, and considering the tracking error e_x,

$$e_x = x - x_{ref} \tag{35.254}$$

Select a Lyapunov function $V_1(x,t)$ globally positive definite, continuously differentiable, and radially

unbounded for all e_x. Denoting $V_1(x,t)$ by V_1 for simplicity, a candidate function for this case can be written as

$$V_1 = \frac{e_x^2}{2} \tag{35.255}$$

To guarantee the control solution is globally asymptotically stable, from Lyapunov's second method of stability, the time derivative of the positive-definite Lyapunov function V_1 must be globally negative definite for all (x,t), so that $V_1\dot{V}_1 < 0$ [47], as in the sliding-mode stability condition (35.92):

$$\frac{dV_1}{dt} = e_x\frac{de_x}{dt} < 0 \Rightarrow e_x\frac{de_x}{dt} = -k_1e_x^2 \Rightarrow \frac{de_x}{dt} = -k_1e_x \tag{35.256}$$

The constant k_1 must be positive definite (for stability). The last relation implies that the tracking error will converge to zero asymptotically with time constant $1/k_1$. Eq. (35.256) will be satisfied if $z_1 = z_{1ref}$. Using (35.254) and (35.253) in (35.256), then,

$$\frac{de_x}{dt} = -k_1e_x \Rightarrow \frac{dx}{dt} - \frac{dx_{ref}}{dt} = -k_1e_x \Rightarrow f_0(x) + g_0(x)z_{1ref} - \frac{dx_{ref}}{dt} = -k_1e_x \tag{35.257}$$

Solving for z_{1ref}, $(g_0(x) \neq 0)$, it results

$$z_{1ref} = \frac{-k_1\left(x - x_{ref}\right) - f_0(x) + \dfrac{dx_{ref}}{dt}}{g_0(x)} \tag{35.258}$$

(3) Proceed to the second recursion to obtain z_{2ref} by considering the tracking error

$$e_{z1} = z_1 - z_{1ref} \tag{35.259}$$

and select a recursively defined composite Lyapunov function V_2 positive definite:

$$V_2 = \frac{e_x^2}{2} + \frac{e_{z1}^2}{2} \tag{35.260}$$

The stability condition is $dV_2/dt < 0$:

$$\frac{dV_2}{dt} = e_x\frac{de_x}{dt} + e_{z1}\frac{de_{z1}}{dt} = -k_1e_x^2 - k_2e_{z1}^2 \tag{35.261}$$

where k_1 and k_2 must be positive (k_1 and $k_2 > 0$) for asymptotic stability.

From (35.261) using (35.254), (35.253), (35.259), and the second equation of (35.252), replacing $z_1 = e_{z1} + z_{1ref}$ in (35.257), and using the result of (35.257), it is written as

$$\begin{aligned} &e_x\left(f_0(x) + g_0(x)\left(e_{z1} + z_{1ref}\right) - \frac{dx_{ref}}{dt}\right) \\ &+ e_{z1}\left(f_1(xz_1) + g_1(xz_1)z_{2ref} - \frac{dz_{1ref}}{dt}\right) = \\ &= -k_1e_x^2 - k_2e_{z1}^2 \Rightarrow e_{z1}\left(g_0(x)e_x + f_1(xz_1) + g_1(xz_1)z_{2ref} - \frac{dz_{1ref}}{dt}\right) \\ &= -k_2e_{z1}^2 \end{aligned} \tag{35.262}$$

If dz_{1ref}/dt is independent of z_2, solving for z_{2ref} returns,

$$z_{2ref} = \frac{-k_2e_{z1} - g_0(x)e_x - f_1(xz_1) + \dfrac{dz_{1ref}}{dt}}{g_1(xz_1)} \tag{35.263}$$

(4) Proceed recursively (return to step 1) up to the definition of the control law of z_m, by selecting a recursively defined composite positive-definite Lyapunov function.

Alternatively, the integral action backstepping approach can be used in the first recursion.

Define a control objective $x = x_{ref}$ and consider the tracking error $e_x = x - x_{ref}$ as in (35.254). Now, add the integral of the tracking error e_I to the control action. The integral term is useful to ensure the convergence, in steady state, of the tracking error to zero regardless of nonmodeled disturbances and parameter uncertainty:

$$e_I = \int_0^t e_x d\tau \tag{35.264}$$

Use a positive-definite Lyapunov function V_I that weights (with k_0) the integral action to be added to the state feedback control law:

$$V_I = \frac{1}{2}k_0e_I^2 + \frac{e_x^2}{2} \tag{35.265}$$

Compute the time derivative of the Lyapunov function V_I and enforce it to be negative definite ($\dot{V}_I = -k_1e_x^2$, $k_1 > 0$):

$$\frac{dV_I}{dt} = k_0e_I\frac{de_I}{dt} + e_x\frac{de_x}{dt} = e_x\left(k_0e_I + \frac{de_x}{dt}\right) = -k_1e_x^2 \tag{35.266}$$

Eq. (35.266) will be satisfied if $z_1 = z_{1ref}$. Using (35.266), (35.254), and (35.253), then,

$$\begin{aligned} &k_0e_I + \frac{de_x}{dt} = -k_1e_x \Rightarrow k_0e_I + \frac{dx}{dt} - \frac{dx_{ref}}{dt} = -k_1e_x \Rightarrow \\ &\Rightarrow k_0e_I + f_0(x) + g_0(x)z_{1ref} - \frac{dx_{ref}}{dt} = -k_1e_x \end{aligned} \tag{35.267}$$

Solving for z_{1ref}, being $g_0(x) \neq 0$, and using (35.264), then,

$$z_{1ref} = \frac{-k_1 e_x - k_0 \int_0^t e_x d\tau - f_0(x) + \frac{dx_{ref}}{dt}}{g_0(x)} \tag{35.268}$$

This is the backstepping equivalent of a proportional-integral (PI) linear controller. Besides the proportional k_1 and integral k_0 gains, it adds the influence of the plant characteristics $f_0(x)$ and $g_0(x)$ and the derivative of the reference dx_{ref}/dt, by including the correspondent feed-forward terms, which are not in the linear PI.

35.6.2 Example 35.22: Backstepping Control of the Buck–Boost Converter

Consider the buck-boost converter (Fig. 35.81) strict-feedback averaged subsystem model (35.269), where D is the average value of the transistor duty-cycle $\delta(t)$:

$$\begin{aligned} \frac{dv_{PV}}{dt} &= \frac{i_{PV}}{C_1} - \frac{i_{L1}}{C_1} D \\ \frac{di_{L1}}{dt} &= \frac{v_{PV}}{L_1} D - \frac{v_p}{L_1}(1-D) \end{aligned} \tag{35.269}$$

In this example, the current source I_{PV} is a simple model of a photovoltaic panel and depends on v_{PV}. To obtain the maximum power from the panel, the v_{PV} voltage must be regulated to track the maximum power point (MPPT), defined by an MPPT algorithm [48,49], so that the control objective is $v_{PV} = v_{PVref}$, the control input is the averaged duty-cycle D, and the stabilizing virtual control input is i_{L1}:

(1) Consider the strict-feedback subsystem:

$$\frac{dv_{PV}}{dt} = \frac{i_{PV}}{C_1} - \frac{i_{L1}}{C_1} D \tag{35.270}$$

(2) Define the control objective $v_{PV} = v_{PVref}$ and the tracking error:

$$e_{PV} = v_{PV} - v_{PVref} \tag{35.271}$$

Define a positive-definite Lyapunov function V_{1b}:

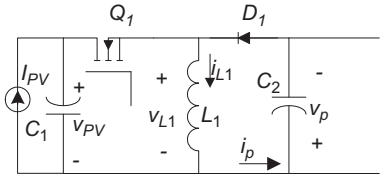

FIG. 35.81 Buck-boost dc/dc converter feed from a current source I_{PV}.

$$V_{1b} = \frac{e_{PV}^2}{2} \tag{35.272}$$

The time derivative of V_{1b} must be negative definite for asymptotic stability. Similarly to (35.256) and considering (35.270),

$$\begin{aligned} \frac{de_{PV}}{dt} &= \frac{dv_{PV}}{dt} - \frac{dv_{PVref}}{dt} = -k_{PV} e_{PV} \Rightarrow \frac{i_{PV}}{C_1} - \frac{i_{L1ref}}{C_1} D - \frac{dv_{PVref}}{dt} \\ &= -k_{PV} e_{PV} \end{aligned} \tag{35.273}$$

where k_{PV} is a positive constant, selected to impose the time constant of the tracking error vanishing asymptotically to zero. Then, the virtual control law (stabilizing function) reference value i_{L1ref} for the i_{L1} current ($i_{L1} = i_{L1ref}$) if ($D \neq 0$) is

$$i_{L1ref} = \frac{C_1 k_{PV} e_{PV}}{D} + \frac{i_{PV}}{D} - \frac{C_1}{D} \frac{dv_{PVref}}{dt} \tag{35.274}$$

Note that this reference current might be enforced using a sliding-mode controller and $D = V_P/(V_{PV} + V_P)$. To consider parameter uncertainty and disturbances, the integral action backstepping could be used.

(3) Start the second recursion to obtain the control input averaged duty-cycle D, by defining the inductor current i_{L1} error e_{iL1}:

$$e_{iL1} = i_{iL1} - i_{iL1ref} \tag{35.275}$$

Select a suitable composite positive-definite Lyapunov function V_{2b}:

$$V_{2b} = \frac{e_{PV}^2}{2} + \frac{e_{iL1}^2}{2} \tag{35.276}$$

Apply the asymptotic stability condition, where k_{PV} and k_{iL} are positive constants:

$$\frac{dV_{2b}}{dt} = e_{PV} \frac{de_{PV}}{dt} + e_{iL1} \frac{de_{iL1}}{dt} = -k_{PV} e_{PV}^2 - k_{iL} e_{iL1}^2 \tag{35.277}$$

As this converter is a nonminimum-phase system, the stabilizing function reference value i_{L1ref} in (35.274) depends on the control input D. To evaluate de_{iL1}/dt in (35.277), first compute di_{L1ref}/dt using (35.273), (35.274) and (35.275):

$$\begin{aligned} \frac{di_{L1ref}}{dt} &= -k_{PV} e_{iL1} - \frac{C_1 k_{PV}^2}{D} e_{PV} + \frac{1}{D} \frac{di_{PV}}{dt} - \frac{C_1}{D} \frac{d^2 v_{PVref}}{dt^2} \\ &\quad - \frac{i_{L_1 ref}}{D} \frac{dD}{dt} \end{aligned} \tag{35.278}$$

Substitute (35.270) in (35.277), and use the second equation of (35.269) for di_{L1}/dt, replacing $iL1$ by $e_{iL1}+i_{L1ref}$, and use (35.278) to obtain

$$\frac{dV_{2b}}{dt}=e_{PV}\frac{de_{PV}}{dt}+e_{iL1}\frac{de_{iL1}}{dt}=e_{PV}\left(\frac{i_{PV}}{C_1}-\frac{e_{iL1}+i_{L_1ref}}{C_1}D-\frac{dv_{PVref}}{dt}\right)+$$

$$+e_{iL1}\left(\frac{v_{PV}}{L_1}D-\frac{v_p}{L_1}(1-D)+k_{PV}e_{iL1}+\frac{C_1k_{PV}^2}{D}e_{PV}-\frac{1}{D}\frac{di_{PV}}{dt}\right.$$

$$\left.+\frac{C_1}{D}\frac{d^2v_{PVref}}{dt^2}+\frac{i_{L_1ref}}{D}\frac{dD}{dt}\right)=$$

$$=-k_{PV}e_{PV}^2-k_{iL}e_{iL1}^2 \tag{35.279}$$

Remember (35.273) to receive

$$-e_{PV}^2k_{PV}-e_{PV}\frac{e_{iL1}}{C_1}D$$

$$+e_{iL1}\left(\begin{array}{l}\frac{-v_p}{L_1}+\frac{v_{PV}+v_p}{L_1}D+k_{PV}e_{iL1}+\\+\frac{C_1k_{PV}^2}{D}e_{PV}-\frac{1}{D}\frac{di_{PV}}{dt}+\frac{C_1}{D}\frac{d^2v_{PVref}}{dt^2}+\frac{i_{L_1ref}}{D}\frac{dD}{dt}\end{array}\right)=$$

$$=-k_{PV}e_{PV}^2-k_{iL}e_{iL1}^2 \tag{35.280}$$

Simplify and group terms relative to e_{iL1}:

$$e_{iL1}\left(\begin{array}{l}\frac{-v_p}{L_1}+\frac{v_{PV}+v_p}{L_1}D+k_{PV}e_{iL1}+\\+\left(\frac{C_1k_{PV}^2}{D}-\frac{D}{C_1}\right)e_{PV}-\frac{1}{D}\frac{di_{PV}}{dt}+\frac{C_1}{D}\frac{d^2v_{PVref}}{dt^2}+\frac{i_{L_1ref}}{D}\frac{dD}{dt}\end{array}\right)$$

$$=-k_{iL}e_{iL1}^2 \tag{35.281}$$

Solve for dD/dt and integrate to obtain the duty-cycle D controller ($i_{L1ref}\neq 0$):

$$D=\int_0^\tau\left[\frac{1}{i_{L_1ref}}\left(-e_{iL1}(k_{iL}+k_{PV})D+\frac{v_p}{L_1}D-\frac{v_{PV}+v_p}{L_1}D^2\right.\right.$$

$$\left.\left.-\left(C_1k_{PV}^2-\frac{D^2}{C_1}\right)e_{PV}+\frac{di_{PV}}{dt}-C_1\frac{d^2v_{PVref}}{dt^2}\right)\right]d\tau \tag{35.282}$$

This result shows that the duty-cycle controller D has to go back to the input through an integrator.

Using this procedure, backstepping can stabilize nonminimum-phase systems, provided it is known how to obtain the origin stabilizing virtual control input.

Fig. 35.82 shows the buck-boost backstepping controller (35.282) transient response to a step change in v_{PVref} from 18–15 V at t = 0.3 s. The buck-boost switching frequency is

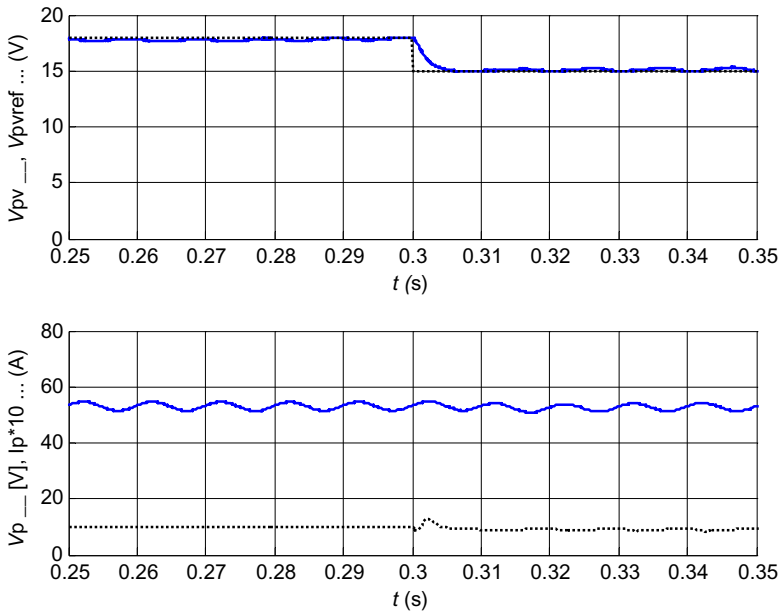

FIG. 35.82 Upper graph, the v_{PV} controlled voltage (solid gray line) and its reference (dotted line) and bottom graph, the buck-boost v_p output voltage (solid line) and the average value of the i_p (× 10) current (dotted line).

15 kHz, and controller gains are $k_{PV}=150$ and $k_{iL}=1500$ ($C_1=1$ mF, $C_2=1$ mF, $L_1=3$ mH, and $I_{PV}\approx 3$ A). The buck-boost load is a single-phase inverter connected to a 50 Hz grid. Voltage dynamics is nearly a first-order system response, even with a nonlinear load, whose dynamics was not included in the controller design. A small steady-state error is visible due to nonmodeled switch and inductor resistors and modulator delay. Response time is less than 5 ms.

35.6.3 Example 35.23: Backstepping Control of a Single Phase Inverter

Consider a single-phase dc-ac inverter (Fig. 35.83) that enforces a dc voltage v_p at the output capacitor of the previous buck-boost (Fig. 35.81), using a fixed-frequency PWM modulator to inject a sinusoidal i_{L2} current into the grid, so that the power received from the buck-boost is injected in the grid v_R.

Assuming unity power factor, unity efficiency, and the output capacitor of the buck-boost converter, the strict-feedback averaged model can be written as

$$\begin{aligned}\frac{dv_p^2}{dt}&=\frac{2}{C_2}i_p v_p-\frac{2}{C_2}v_R i_{L2}\\ \frac{di_{L2}}{dt}&=\frac{\beta v_p}{L_2}-\frac{v_R}{L_2}\end{aligned}\tag{35.283}$$

where the voltage v_{pwm} is obtained from v_p using the sinusoidal modulating waveform β, such as $v_{pwm}=\beta\ v_p$. The stabilizing virtual control input will be the root mean square value I_{L2RMS} of the i_{L2} current. The control input is the modulation waveform β:

(1) Consider the strict-feedback subsystem:

$$\frac{dv_p^2}{dt}=\frac{2}{C_2}i_p v_p-\frac{2}{C_2}v_R i_{L2}\tag{35.284}$$

(2) Define the control objective $v_p^2=v_{pref}^2$ and the tracking error:

$$e_{vp2}=v_p^2-v_{pref}^2\tag{35.285}$$

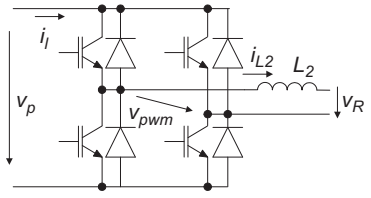

FIG. 35.83 Single-phase inverter fed from the buck-boost.

Select a suitable positive-definite Lyapunov function:

$$V_{vp2}=\frac{e_{vp2}^2}{2}\tag{35.286}$$

To ensure asymptotic stability, the time derivative of this Lyapunov function must be negative, which is true if

$$\frac{de_{vp2}}{dt}=-k_{vp2}e_{vp2}\tag{35.287}$$

where k_{vp2} is a positive constant. The stability condition will be satisfied if the root mean square value of i_{L2} is I_{L2RMS} in (35.284), giving

$$\frac{2\left(i_p v_p-I_{L2RMS}\ v_R\right)}{C_2}-\frac{dv_{pref}^2}{dt}=-k_{vp2}e_{vp2}\tag{35.288}$$

The virtual control law (stabilizing function) is I_{L2RMS} (with $v_R\neq 0$):

$$I_{L2RMS}=\frac{C_2 k_{vp2}e_{vp2}}{2v_R}+i_p\frac{v_p}{v_R}-\frac{C_2}{2v_R}\frac{dv_{pref}^2}{dt}\tag{35.289}$$

This I_{L2RMS} value is "constant" regarding the switching period of the inverter semiconductors.

(3) Knowing that the inverter input power is a constant at the scale of the switching period whereas the inverter output power varies along the v_R grid period (the mean value is the active power), the converter fast dynamics (i_{L2} current) and slow dynamics (DC v_p voltage) must be separated. Otherwise, the backstepping controller would impose the energy balance during the semiconductor switching period, distorting the i_{L2} current. This sinusoidal current may be written as $i_{L2ref}=I_{L2RMS}\ v_{Rpu}$, being the tracking error:

$$e_{iL2}=i_{L2ref}-i_{L2}\tag{35.290}$$

Select a positive-definite Lyapunov function:

$$V_{iL2}=\frac{e_{iL2}^2}{2}\tag{35.291}$$

Use the stability condition, with a positive constant k_{iL2}, and the second equation of (35.283) to write

$$\frac{de_{iL2}}{dt}=-k_{iL2}e_{iL2}\Rightarrow\frac{di_{L2ref}}{dt}-\frac{\beta v_p-v_R}{L_2}=-k_{iL2}e_{iL2}\tag{35.292}$$

Solve to obtain the modulation waveform β ($v_p\neq 0$):

$$\beta=\frac{L_2\dfrac{di_{L2ref}}{dt}+v_R+k_{iL2}L_2e_{iL2}}{v_p}\tag{35.293}$$

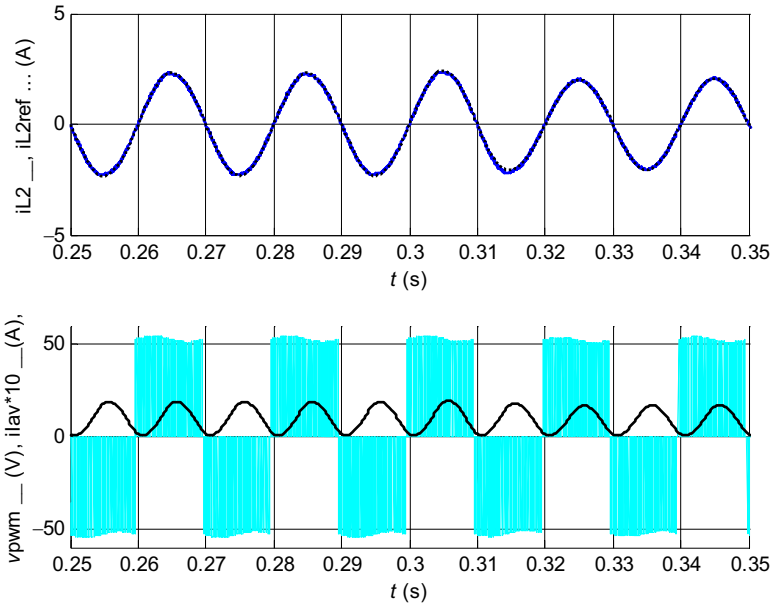

FIG. 35.84 Upper graph, the i_{L2} ac grid current (solid line) and its reference (dotted line) and bottom graph, the inverter v_{pwm} output voltage (gray line) and the average value of the i_I ($\times$ 10) inverter input current (black solid line).

Fig. 35.84 shows the buck-boost-fed single-phase inverter backstepping controller ((35.293) and (35.289)) response to the step change in v_{PVref} of the buck-boost from 18–15 V at $t = 0.3$ s. The PWM modulator frequency is 15 kHz, and controller gains are $k_{vp2} = 0.05$ and $k_{iL2} = 0.025$ ($L_2 = 10$ mH, $v_R \approx 45$ V and 50 Hz). The ac current is almost not distorted by v_{PVref} step change, and its total harmonic distortion is less than 2%.

35.7 Conclusions

Control techniques for switching power converters were reviewed. Linear controllers based on state-space averaged models or circuits are well established and suitable for the application of linear systems control theory. Obtained linear controllers are useful, if the converter operating point is almost constant and the disturbances are not relevant. For changing operating points and strong disturbances, linear controllers can be enhanced with nonlinear, antiwindup, soft-start, or saturation techniques. Current-mode control will also help to overcome the main drawbacks of linear controllers.

Sliding mode is a nonlinear approach well adapted for the variable structure of the switching power converters. The critical problem of obtaining the correct sliding surface was highlighted, and examples were given. The sliding-mode control law allows the implementation of the switching power converter controller, and the switching law gives the PWM modulator. The system variables to be measured and fed back are identified. The obtained reduced-order dynamics is not dependent on system parameters or power supply (as long as it is high enough), presents no steady-state errors, and has a faster response speed (compared with linear controllers), as the system order is reduced and nonidealities are eliminated. Should the measure of the state variables be difficult, state observers may be used, with steady-state errors easily corrected. Sliding-mode controllers provide robustness against bounded disturbances and an elegant way to obtain the controller and modulator, using just the same theoretical approach. Fixed-frequency operation was addressed and solved, together with the short-circuit-proof operation. Presently, fixed-frequency techniques were applied to converters that can only operate with fixed frequency. Sliding-mode techniques were successfully applied to MIMO switching power converters and to multilevel converters, solving the capacitor voltage divider equalization. Sliding-mode control needs more information from the controlled system than do the linear controllers but is probably the most adequate tool to solve the control problem of switching power converters.

Predictive optimum control of power converters is based on a detailed nonlinear direct dynamics model that includes converter bounds. The predictive optimum algorithm uses the model to forecast in real time the converter future behavior, which is dependent on the applied control vector. The minimization of a suitable cost functional gives the optimum vector. Predictive optimum controllers designed to minimize converter output errors, together with the switching frequency, present better performances than sliding-mode controllers, even when controlling nonlinear outputs with cross coupled dynamics. Fast predictive controllers, using the converter inverse dynamics, designed to save computation power, also show promising results.

Fuzzy logic controller synthesis was briefly presented. Fuzzy logic controllers are based on human experience and intuition and do not depend on system parameters or operating points. Fuzzy logic controllers can be easily applied to various types of power converters having the same qualitative dynamics. Fuzzy logic controllers, like sliding-mode controllers, show robustness to load and power supply perturbations, semiconductor nonidealities (such as switch delays or uneven conduction voltage drops), and dead times. The controller implementation is simple, if based on the offline concept. Online implementation requires a fast microprocessor but can include adaptive techniques to optimize the rule base and/or the database.

Backstepping control was explained using a strict-feedback form of the converter dynamic model and a recursive approach. The procedure correctly selects positive-definite Lyapunov functions and designs the feedback control loop to ensure stability using Lyapunov's second method. Integral action control may be included to overcome nonmodeled disturbances and parameter uncertainty, ensuring convergence, in steady state, of the tracking error to zero. Backstepping control is a robust method to be used with conventional fixed-frequency duty-cycle modulators, being ideal for nonminimum-phase converters, while needing less computing power compared with predictive controllers.

Acknowledgments

Authors thank all the researchers whose works contributed to this chapter, namely, professors V. Pires, D. Barros, J. Quadrado, T. Amaral, M. Crisóstomo, L. Encarnação, and Aranzazu D. Martin; engineers J. Costa and N. Rodrigues; and the suggestions of Professor M. P. Kazmierkowski. 36.1 Introduction

Improving the popular proportional-integral-derivative (PID) controller using fuzzy logic (FL) is currently an important research topic. Years of various applications have shown different techniques for customizing the PID controller [1–7]. Recent work by Sant [1] employs an FL controller combined with a classical PID controller with a switching function between them for speed control of a motor drive. The switching algorithm allows each controller type to perform better under different operations. In another recent example, Hohan [2] has developed a fuzzy-PID controller based upon the error, the difference in error, and the difference to create a delta change in the control signal at each time step. Hohan includes analytic stability analysis for bounded inputs, important for fuzzy systems to gain acceptance among control engineers. The

application of fuzzy reasoning to improve the PID controller is evident in the research community today to build state-of-the-art control systems. Recent work on self-tuning PID controllers demonstrates adaptive control of motor drive systems. Typically, an engineer might retune the gains of a nominal PID controller during operation, but an adaptive PID system autonomously tunes gains as performance diminishes. The work of Rubaai [3] employs a genetic algorithm to evolve optimal scale factors of fuzzy-based PID gains for improved control of a motor drive. This genetic-based scale factor in conjunction with FL gain selection enhances the sensitivity of the PID control to error. Another class of fuzzy-PID control design mimics PID control via blending FL networks with absolute and incremental control values at a given control time step. The work of Kuo [4] employs two FL structures to formulate a control of a suspension system. One FL mimics PD control, while the other FL generates a change in control to mimic a PI control signal. These FL structures adapt using a genetic algorithm as well. The work of Hu [5] also employs fuzzy-PD and fuzzy-PI elements as part of a control strategy. Li [6] designs an FL based on error and error derivative to generate an initial control estimate that then feeds a PI logic and a PD logic. This work demonstrates robustness of the control algorithm through simulations of a dynamic model. The recent work of Masiala [7] demonstrates incremental fuzzy-PI control of an induction motor drive. For Masiala, the FL decision at each time step modifies the control current based on the error and a change in error. All these controllers use FL to generate absolute and incremental control signals to mimic control techniques seen in PID control. Kalman filter (KF) is another research topic that has been applied to a wide range of engineering disciplines. For a linear system, the KF is an established control design feature, but the improved application of variants of the KF to account for nonlinearity in systems inspires research today. Barut [8] employs an extended Kalman filter (EKF) for a speed sensorless control of an induction motor. This work depends on high-fidelity equations of motion model and noise characteristics. Szabat [9] demonstrates an adaptively tuned EKF for control of an industrial drive. Ahn [10] designs an EKF algorithm to update parameters of parallel FL systems, which generate a PID gain set for control of a motor drive system. Treating the controller as a process and deriving appropriate derivatives allow for adaptive update to the FL components. So, while PID control is a commonly known algorithm, current research applications of adaptive tuning are yielding better tuned PID systems. The artificial neural network (ANN) is a computational data structure modeled after the firing of neurons in the brain. Training exercises may adjust the parameters within the ANN to improve modeling capabilities. The work of Lary [11] details an EKF algorithm for training an ANN to model correlations between chemical compounds. Singhal [12] shows that the EKF training algorithm treats all ANN parameters as a state vector, and thus, the ANN becomes a nonlinear stationary process. Research experience demonstrates that the EKF training compares favorably to the BP update method in terms of iterations of training epochs, but with higher computational cost per time step. The ANN is an important contribution to the control field. The fuzzy neural network (FNN) combines aspects of FL and the ANN and is at the state of the art in control research today. For example, recent work of Ho [13] simulates PID control using an FNN structure that updates time constants in the dynamic models that generate the PID gains online. Ho compares the orthogonal simulated annealing learning technique to a genetic technique to improve performance of the FNN portion of the controller. Campo [14] designs an embedded hardware FNN updated by the Takagi-Sugeno training method for performance improvement. Such a chip enables for a fuzzy system embedded into a hardware control loop. Uddin [15] also developed a hybrid neuro-fuzzy-PI controller adapted by a real-coded genetic algorithm to control an IPMSM. In this case, a fuzzy basis function network similar to an FNN output PI gains sensitive to error conditions. The cutting-edge work of many researchers today relies on the FNN to improve the performance of fuzzy control systems in electric applications.

36.2 PI/PD-Like Fuzzy Control Structure

The FNN PI/PD-like fuzzy controller using EKF control structure presented in this chapter is an instantiation of a feedback control loop. The FNN PI/PD-like fuzzy consists of two independent fuzzy structures, namely, fuzzy-PD controller and fuzzy-PI controller. EKF technique is used to modify the weights and the membership functions of the FNN PI/PD controller to adaptively control the rotor speed of the drive system. The summation of the outputs of the two FNNs forms the control signal. Fig. 36.1 shows the architecture of the neural-fuzzy PI-/PD-based EKF learning scheme. The control structure is anticipated to accommodate the robust stabilization and disturbance rejection problems. The fuzzy controller generates a control signal based upon two FL structures. The first structure is a fuzzy PD that generates a fuzzy-PD control signal. The second structure is a fuzzy PI that generates an incremental fuzzy-PI control signal.

$$\mathrm{UPD} = \mathrm{FLPD}(e_{\mathrm{filt}}, \Delta e_{\mathrm{filt}})$$

$$\Delta\mathrm{UPI} = \mathrm{FLPI}(e_{\mathrm{filt}}, \Delta e_{\mathrm{filt}})$$

The incremental fuzzy-PI signal sums with the previous fuzzy-PI signal to generate the fuzzy-PI signal for the time step at hand. The fuzzy-PI/fuzzy-PD controller generates a control signal with the summation of the fuzzy-PI/fuzzy-PD control signals:

$$U = \mathrm{UPD} + \mathrm{UPI}$$

The control signal is limited by a discontinuous range-limiting saturation element. The saturation equation caps the signal between a maximum and minimum value:

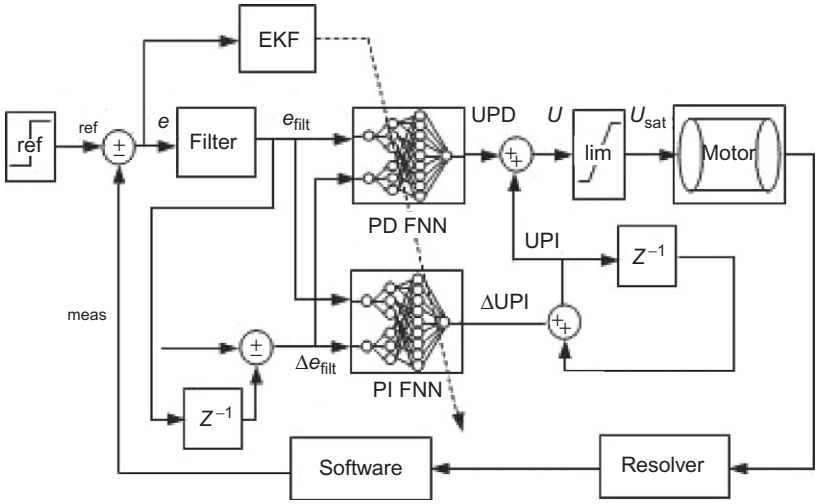

FIG. 36.1 FNN PI/PD-like fuzzy control structure.

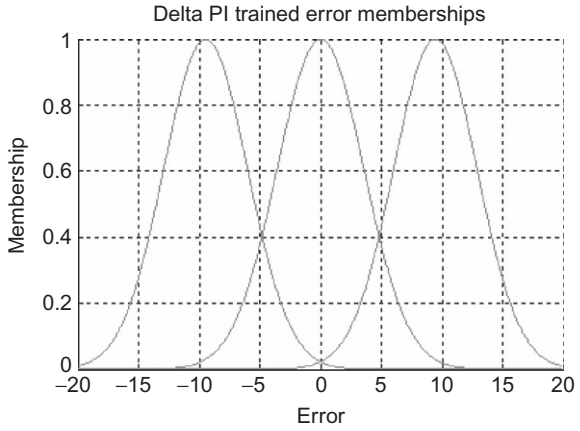

FIG. 36.2 Trained membership function for speed error.

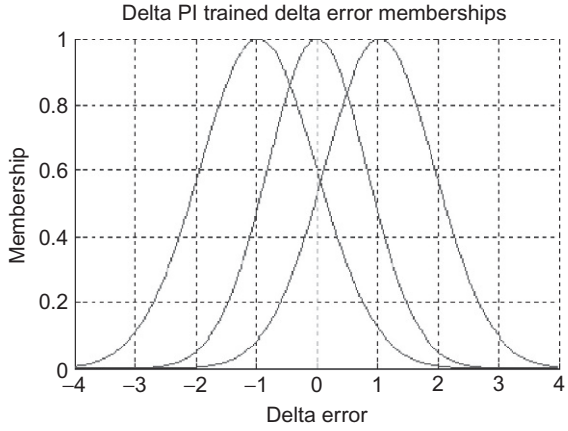

FIG. 36.3 Trained membership functions for the delta speed error.

$$u_{sat} = \begin{cases} u_{max} & \text{if } U > u_{max} \\ u_{min} & \text{if } U < u_{min} \\ U & \text{otherwise} \end{cases}$$

36.2.1 Fuzzy-Based PI Controller

The fuzzy-PI system implements an FL for the PI control signals e_{filt} and Δe_{filt}, the error and the delta error, respectively, the linguistic inputs to the system. The FL output is the PI control ΔUPI signal. The error signal has three fuzzy variables: positive (P), zero (Z), and negative (N). The delta error signal has three fuzzy variables: positive (P), zero (Z), and negative (N). The membership function for each fuzzy variable is a Gaussian function. Figs. 36.2 and 36.3 display the trained membership functions for the fuzzy inputs.

The linguistic control rules are established considering the dynamic behavior of the BLDC drive system and analyzing the error and its variation. The fuzzy inference system has nine rules.

Rule 1: IF speed error is negative (N) AND delta speed error is negative (N), THEN the fuzzy-PI control voltage (output of FL) is negative large (NL). This rule pertains to the condition that $w_{ref} < w_{meas}$ and that the difference between them is increasing. Thus, the control action must act to change the error momentum and bring the motor rate back down to the reference rate. Therefore, a large negative change in control voltage is necessary.

Rule 2: IF speed error is negative (N) AND delta speed error is zero (Z), THEN the fuzzy-PI control voltage (output of FL) is negative medium (NM). This rule pertains to the condition that $w_{ref} < w_{meas}$ and that the difference between them is steady. Thus, the control action need not change the error momentum but still bring the motor rate back down to the reference rate. Therefore, a medium negative change in control voltage is necessary.

Rule 3: IF speed error is zero (Z) AND delta speed error is negative (N), THEN the fuzzy-PI control voltage (output of FL) is negative small (NS). This rule pertains to the condition that $w_{ref} = w_{meas}$ but tending toward $w_{ref} < w_{meas}$ as the error

trends more negative. Thus, the control action must act to halt the error momentum but maintain the motor rate being close to the reference rate. Therefore, a small negative change in control voltage is necessary.

Rule 4: IF speed error is negative (N) AND delta speed error is positive (P), THEN the fuzzy-PI control voltage (output of FL) is zero (ZE). This rule pertains to the condition that $w_{ref} < w_{meas}$ and that the difference between them is decreasing. Thus, the control action of nothing allows the error momentum to bring the motor rate back down to the reference rate. Therefore, no change in control voltage is necessary.

Rule 5: IF speed error is zero (Z) AND delta speed error is zero (Z), THEN the fuzzy-PI control voltage (output of FL) is zero (ZE). This rule pertains to the condition that $w_{ref} = w_{meas}$ and that the difference between them is steady. Thus, the control action of nothing allows the error momentum to remain negligible to leave the motor rate at the reference rate. Therefore, no change in control voltage is necessary.

Rule 6: IF speed error is positive (P) AND delta speed error is positive (P), THEN the fuzzy-PI control voltage (output of FL) is positive large (PL). This rule pertains to the condition that $w_{ref} > w_{meas}$ and that the difference between them is increasing. Thus, the control action must act to change the error momentum and bring the motor rate back up to the reference rate. Therefore, a large positive change in control voltage is necessary.

Rule 7: IF speed error is positive (P) AND delta speed error is zero (Z), THEN the fuzzy-PI control voltage (output of FL) is negative medium (NM). This rule pertains to the condition that $w_{ref} > w_{meas}$ and that the difference between them is steady. Thus, the control action need not change the error momentum but still bring the motor rate back down to the reference rate. Therefore, a medium positive change in control voltage is necessary.

Rule 8: IF speed error is zero (Z) AND delta speed error is positive (P), THEN the fuzzy-PI control voltage (output of FL) is positive small (PS). This rule pertains to the condition that $w_{ref} = w_{meas}$ but tending toward $w_{ref} > w_{meas}$ as the error trends more positive. Thus, the control action must act to halt the error momentum but maintain the motor rate being close to the reference rate. Therefore, a small positive change in control voltage is necessary.

Rule 9: IF speed error is positive (P) AND delta speed error is negative (N), THEN the fuzzy-PI control voltage (output of FL) is zero (ZE). This rule pertains to the condition that $w_{ref} > w_{meas}$ and that the difference between them is decreasing. Thus, the control action of nothing allows the error momentum to bring the motor rate back down to the reference rate. Therefore, no change in control voltage is necessary.

Each rule is implemented via a weighted product of the membership variables. The fuzzy centroid method generates a crisp output from the nine-dimensional fuzzy rule vector. This scaled output corresponds to the control signal, ΔUPI. Figs. 36.4 and 36.5 illustrate the initial and trained fuzzy control output ΔUPI as a function of the error and the change of error.

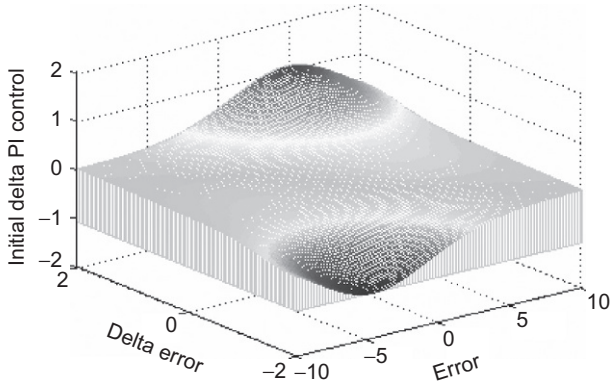

FIG. 36.4 Initial fuzzy delta PI control surface.

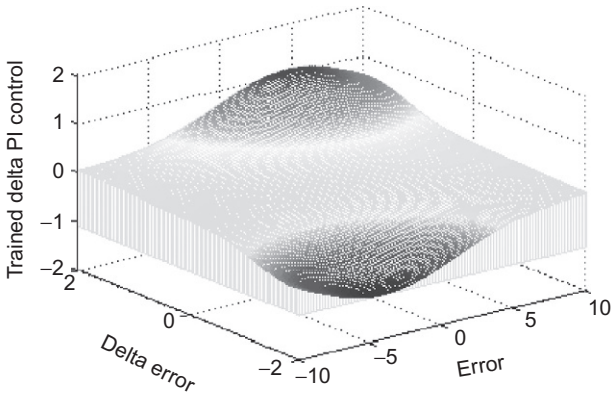

FIG. 36.5 Trained fuzzy delta PI control surface.

36.2.2 Fuzzy-Based PD Controller

The same technique applied to the fuzzy-PI controller is applied to the fuzzy-PD controller. The controller has two inputs and one output. The fuzzy-PD system implements an FL for the PD control signal. The signals e_{filt} and Δe_{filt}, the error and the delta error, respectively, are the linguistic inputs to the system. The FL output is the PD control signal *UPD*. The error signal has three fuzzy variables: positive (P), zero (Z), and negative (N). The delta error signal has three fuzzy variables: positive (P), zero (Z), and negative (N). The membership function for each fuzzy variable is a Gaussian function. Figs. 36.6 and 36.7 show the trained membership functions for the PD fuzzy inputs.

Similarly, the number of fuzzy rules that are required is equal to the product of the number of fuzzy sets that make up each of the two fuzzy input variables. Therefore, a total of nine fuzzy rules are instituted. The nine fuzzy rules are composed of the same fuzzy rules generated for the fuzzy-PI controller and are not repeated here. Each rule is implemented via a weighted product of the membership variables. The fuzzy centroid method generates a crisp output from the nine-dimensional fuzzy rule vector. This scaled output corresponds to the control

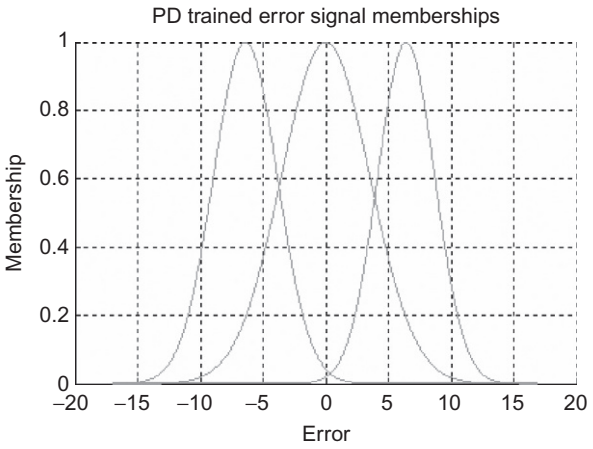

FIG. 36.6 Trained membership functions for speed error.

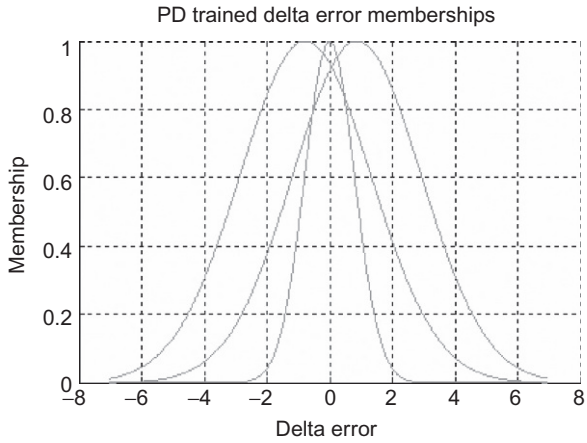

FIG. 36.7 Trained membership functions for delta speed error.

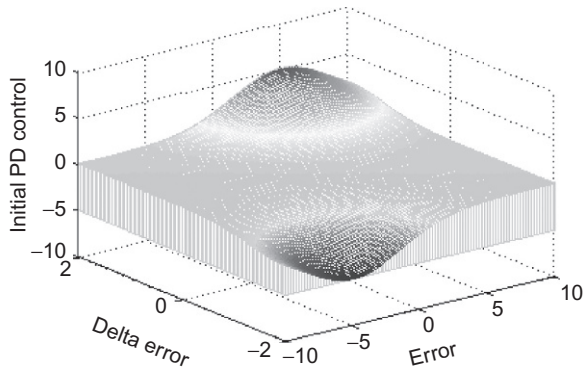

FIG. 36.8 Initial fuzzy-PD control surface.

signal, UPD. Figs. 36.8 and 36.9 demonstrate the initial and trained fuzzy control output, UPD, as a function of the error and the change of error.

Figs. 36.8 and 36.9 provide an indication of how well the EKF learning algorithm succeeds in training the output fuzzy-PD

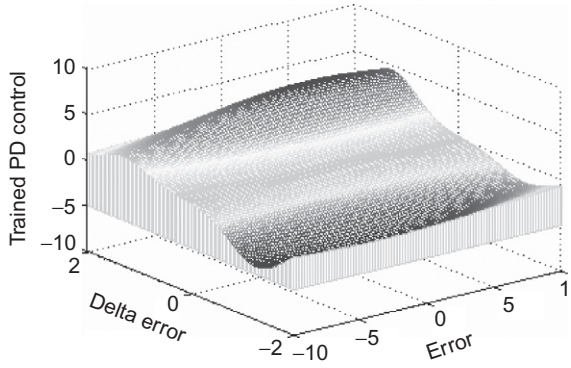

FIG. 36.9 Trained fuzzy-PD control surface.

control signal. This is an indication of how well the control process is proceeding during the experimental implementation.

36.3 FNN PI/PD-Like Fuzzy Control Architecture

The proposed FNN has four layers: an input layer, a membership layer, a rule layer, and an output layer. The input layer is a pass-through capture of each input signal. The membership layer creates a fuzzy set for each input using Gaussian membership functions. The rule layer consists of a truth table like evaluation of the fuzzy membership sets by product pairing. The output layer consists of a weighted summation of the rules. Three numbers define the size of an FNN: the number of inputs to the logic, the number of memberships per input, and the number of outputs, respectively, that is, $2 \times 3 \times 1$. The PI/PD demands two $2 \times M \times 1$ FNNs, where M, the number of memberships, is customizable. A larger number of memberships enhance accuracy of the FNN for modeling; however, a smaller number of memberships yields a smaller training calculation time period per step (there are less calculations to perform) enabling a faster system rate on real-time hardware. The membership number of 3 is selected. The parameters of the FNN are the means and sigmas of the Gaussian memberships and the weights of the output layer. For a $2 \times 3 \times 1$ FNN, there are (six means + six sigmas + nine weights) 21 parameters. Figs. 36.10 and 36.11 display the structure of FNN-based PI and FNN-based PD. Below is the definition of the function of each layer.

36.3.1 Input Layer

The input layer passes the input value, assigned for each FNN as follows (let be the feedback error).

Network\input	u_1	u_2
PI FNN	e_{filt}	Δe_{filt}
PD FNN	e_{filt}	Δe_{filt}

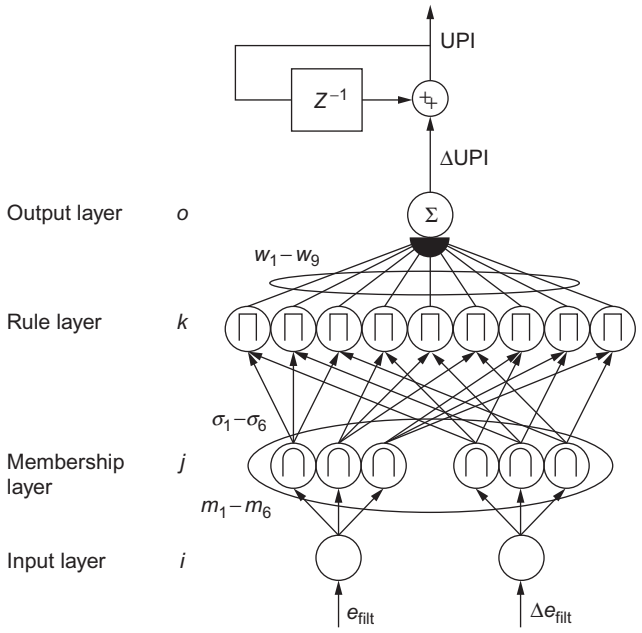

FIG. 36.10 Proposed $2 \times 3 \times 1$ FNN PI structure.

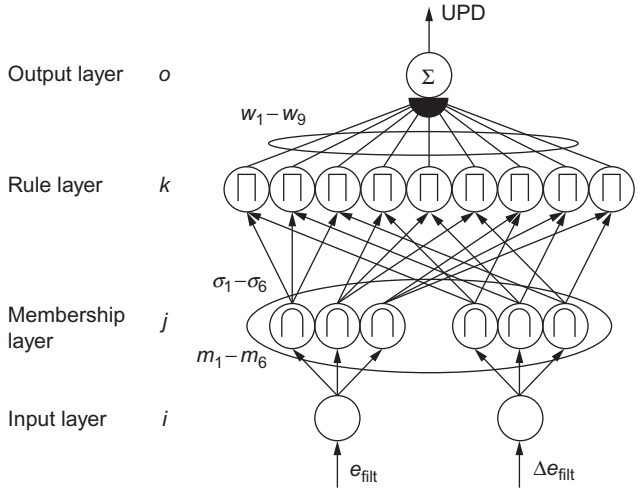

FIG. 36.11 Proposed $2 \times 3 \times 1$ FNN PD structure.

36.3.2 The Membership Layer

Each membership function into the fuzzy set is a Gaussian; the following evaluation occurs (note that m_{ij} and σ_{ij} are parameters): $y_{ij}^{\text{mem}} = \exp \dfrac{\left(u_i - m_{ij}\right)^2}{\sigma_{ij}^2}$ for input $i = 1,2$ and member $j = 1,2,3$ of that input.

For further derivations, allow the matrix y^{mem} to be vectorized as follows:

$$y_1^{\text{mem}} = y_{11}^{\text{mem}}, y_2^{\text{mem}} = y_{12}^{\text{mem}}, y_3^{\text{mem}} = y_{13}^{\text{mem}}, y_4^{\text{mem}} = y_{21}^{\text{mem}},$$
$$y_5^{\text{mem}} = y_{22}^{\text{mem}}, y_6^{\text{mem}} = y_{23}^{\text{mem}}$$

and allow the same vectorization for the means m matrix into a vector and sigmas σ matrix into a vector.

36.3.3 The Rule Layer

Each rule function is a product of two membership outputs. Refer to the table: each table cell is a rule layer output calculated by the product of the row and column label values.

Row\column	y_{21}^{mem}	y_{22}^{mem}	y_{23}^{mem}
y_{11}^{mem}	y_1^{rule}	y_4^{rule}	y_7^{rule}
y_{12}^{mem}	y_2^{rule}	y_5^{rule}	y_8^{rule}
y_{13}^{mem}	y_3^{rule}	y_6^{rule}	y_9^{rule}

36.3.4 The Output Layer

The weighted summation of the rules composes the output layer (note parameters W_k): $y = \Sigma_{k=1}^{9} y_k^{\text{rule}} W_k$ where $k = 1,9$.

36.4 Learning Algorithm-Based EKF

At each time step, for each $2 \times 3 \times 1$ FNN, there is a state vector comprised of 21 elements: $x = [W_1 \cdots W_9, m_1 \cdots m_6, \sigma_1 \cdots \sigma_6]$ (noting vector form of m, σ).

Furthermore, define the following: the reference model output ω_{ref}, measured output ω_{meas}, control signal U, PI FNN output control signal ΔUPI, and PD FNN output control signal UPD. Also, allow for the matrix notation of the membership outputs to be vectorized as follows:

The EKF innovation process is the difference from a reference signal to the measured output of the system $\widetilde{Z} = \omega_{\text{ref}} - \omega_{\text{meas}}$. A state gradient vector h must be created, such that $h_i = d(\omega_{\text{meas}})/dx_i$ using the chain rule backpropagation. The change in system output with respect to input $(\omega_{\text{meas}})/d(U)$ is assumed as unity. This is a dangerous assumption, and a more sophisticated control algorithm would attempt to model this scalar value, perhaps with an FNN identification structure.

The control signal is the summation $U = \text{UPI} + \text{UPD}$. Thus, to propagate into each FNN, the following are useful: $d(U)/d(\text{UPI}) = 1$ and $d(U)/d(\text{UPD}) = 1$ and $d(\text{UPI})/d(\Delta\text{UPI}) = 1$.

Within the FNN, the change in output layer calculation with respect to each weight is $d(y)/d(W_k) = y_k^{\text{rule}}$ for $k = [1, 9]$ and note $y = \Delta$UPI and $y =$ UPD for each FNN.

Within the FNN, to propagate to the membership layer, the vector $d(y)/d\left(y_k^{\text{rule}}\right) = W_k$ is the change in the FNN output with respect to each rule.

Each rule is a product of two fuzzy set elements from the membership layer. The following matrix defines the gradient of rules to a vector form of membership outputs.

$$\frac{d\left(y^{\text{rule}}\right)^T}{d\left(y^{\text{mem}}\right)}=\begin{bmatrix} y_4^{\text{mem}} & 0 & 0 & y_!^{\text{mem}} & 0 & 0 \\ y_5^{\text{mem}} & 0 & 0 & 0 & y_1^{\text{mem}} & 0 \\ y_6^{\text{mem}} & 0 & 0 & 0 & 0 & y_1^{\text{mem}} \\ 0 & y_4^{\text{mem}} & 0 & y_2^{\text{mem}} & 0 & 0 \\ 0 & y_5^{\text{mem}} & 0 & 0 & y_2^{\text{mem}} & 0 \\ 0 & y_6^{\text{mem}} & 0 & 0 & 0 & y_2^{\text{mem}} \\ 0 & 0 & y_4^{\text{mem}} & y_3^{\text{mem}} & 0 & 0 \\ 0 & 0 & y_5^{\text{mem}} & 0 & y_3^{\text{mem}} & 0 \\ 0 & 0 & y_6^{\text{mem}} & 0 & 0 & y_3^{\text{mem}} \end{bmatrix}$$

Each membership is Gaussian. The partial with respect to the mean and sigma are necessary:

$$d\left(y_{ij}^{\text{mem}}\right)/d\left(m_{ij}\right)=y_{ij}^{\text{mem}}2\left(u_i-m_{ij}\right)/\sigma_{ij}^2$$

and

$$d\left(y_{ij}^{\text{mem}}\right)/d\left(\sigma_{ij}\right)=y_{ij}^{\text{mem}}2\left(u_i-m_{ij}\right)^2/\sigma_{ij}^3$$

Note that the resulting matrix may be vectorized as seen previously for y^{mem}.

Applying the chain rule, the following gradients for each FNN are (where $y=\Delta\text{UPI}$ and $y=\text{UPD}$ for each respective calculation) and * represents element-wise multiplication:

$$d(\omega_{\text{meas}})/d(w)=\frac{d(\omega_{\text{meas}})}{d(U)}\frac{d(U)}{d(y)}\frac{d(y)}{d(W)}$$

$$d(\omega_{\text{meas}})/d(m)=\frac{d(\omega_{\text{meas}})}{d(U)}\frac{d(U)}{d(y)}\frac{d(y)^T}{d(y^{\text{rule}})}\frac{d\left(y^{\text{rule}}\right)^{T^T}}{d(y^{\text{mem}})}*\frac{d(y^{\text{mem}})}{d(m)}$$

$$d(\omega_{\text{meas}})/d(\sigma)=\frac{d(\omega_{\text{meas}})}{d(U)}\frac{d(U)}{d(y)}\frac{d(y)^T}{d(y^{\text{rule}})}\frac{d\left(y^{\text{rule}}\right)^{T^T}}{d(y^{\text{mem}})}*\frac{d(y^{\text{mem}})}{d(\sigma)}$$

The gradient state vector is then a concatenation:

$$h=\left[\frac{d(\omega_{\text{meas}})}{d(w)}\lambda_w,\frac{d(\omega_{\text{meas}})}{d(m)}\lambda_m,\frac{d(\omega_{\text{meas}})}{d(\sigma)}\lambda_\sigma\right]$$

where λ_w,λ_m, and λ_σ are learning rate constants for the weights, means, and sigmas.

The EKF algorithm consists of the following recursive equations built on the state vector x and gradient state vector h (both 21×1 below) and a state covariance matrix P and measurement noise scalar r and state noise vector q:

$$k=(Ph)/\left(r+h^TPh\right)$$

$$x^{\text{next}}=x+k\tilde{z}$$

$$P^{\text{next}}=P-kh^TP+q$$

36.5 Fuzzy PID Control Design-Based Genetic Optimization

A genetic-based hybrid fuzzy-PID controller, which employs a fuzzy-PID controller integrating a classical PID controller, is presented in this section. The fuzzy-PID controller consists of three parallel fuzzy subcontrollers, namely, fuzzy-based proportional controller, fuzzy-based integral controller, and fuzzy-based derivative controller. A genetic optimization technique is used to determine the optimal values of the scaling factors of the output variables of these subcontrollers. These independent controllers are grouped together and integrated with an industrial PID controller to form a hybrid fuzzy-PID controller. Fig. 36.12 shows the architecture of the proposed genetic-based hybrid fuzzy-PID controller. The hybrid fuzzy-PID controller is anticipated to accommodate the robust stabilization and disturbance rejection problems.

36.5.1 Fuzzy-Based Proportional Controller

The first step in designing the controller is to decide which state variables of the drive system can be taken as the input signals to the controller. Both the speed error, $e(k)$, and the delayed feedback control signal, $u_{\text{FP}}(k-1)$, are used as the inputs to the speed controller. The output of the fuzzy-based proportional controllers is the gain, FK_{P}. The linguistic fuzzy variable "$e(k)$" has three sets: positive large (PL), zero (ZE), and negative large (NL), with each set having its own membership function. Furthermore, the linguistic fuzzy variable "$u_{\text{FP}}(k-1)$" also has three sets: positive large (PL), zero (ZE), and negative large (NL), with each set having its own membership function. After specifying the fuzzy sets, it is required to determine the membership functions for these sets. Typical triangular membership functions are utilized for the $e(k)$ and $u_{\text{FP}}(k-1)$. The three fuzzy sets can be symbolized by

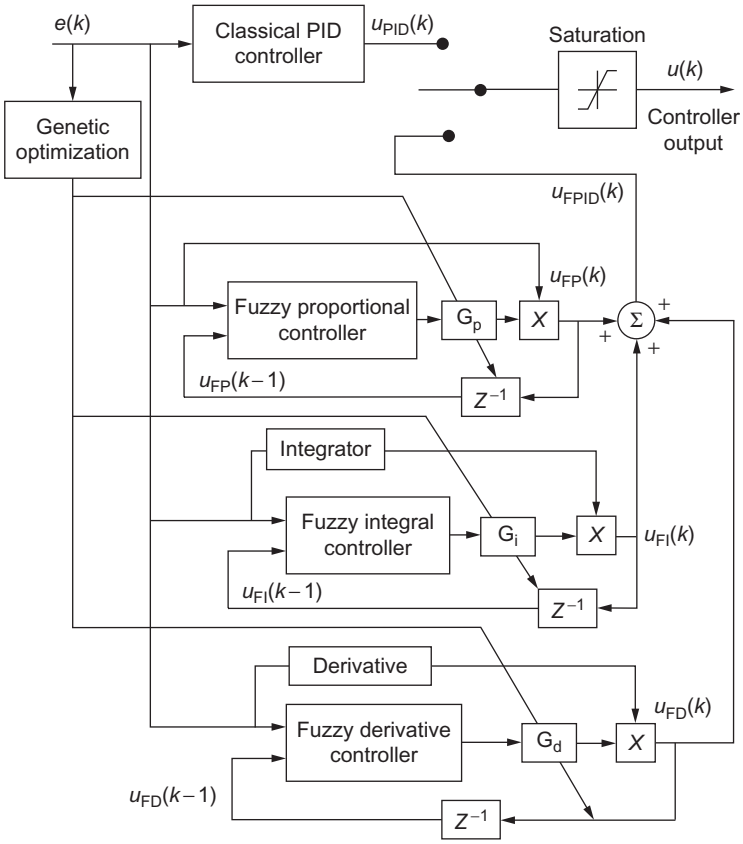

FIG. 36.12 Block diagram of the proposed hybrid fuzzy-PID controller.

$F_i^j, i = 1,2$ and $j = 1,2,3$. Their corresponding membership functions can be symbolized by $\mu F^j(e, u_{\mathrm{FP}}(k-1)), j = 1,2,3$.

The next step in the design of the fuzzy subcontroller is the determination of the fuzzy IF-THEN inference rules. The number of fuzzy rules that are required is equal to the product of the number of fuzzy sets that make up each of the two fuzzy input variables. Thus, a total of nine fuzzy rules are required to relate each possible combination of the two fuzzy input variables to the output membership fuzzy sets. The fuzzy rules ensure that the output of each fuzzy controller enhances the overall speed-tracking performance. Examples of such rules are the following:

IF $e(k)$ is positive large AND $u_{\mathrm{FP}}(k-1)$ is negative large, THEN FK_{P} is positive medium (PM).

IF $e(k)$ is zero AND $u_{\mathrm{FP}}(k-1)$ is zero, THEN FK_{P} is positive small (PS).

IF $e(k)$ is positive large AND $u_{\mathrm{FP}}(k-1)$ is zero, THEN FK_{P} is positive very large (PVL).

In general, a typical fuzzy rule is of the form:

$R^{(k)}$: IF $e(k)$ is F_1^j, and $u_{\mathrm{FP}}(k-1)$ is F_2^l, THEN f_{P} is C_{k}^l for $j = 1\ldots3, l = 1\ldots3, k = 1\ldots9$.

The conjunction of the rule antecedents is evaluated by the fuzzy operation intersection, which is implemented by the min operator. The rule strength represents the degree of membership of the output variable for a particular rule. Defining the rule strength, $\xi_{i,j}$ of a particular rule as $\xi_{i,j} = \min\left(\mu_{F_i}, \mu_{F_j}\right)$ where $i \in [PL, ZE, NL]$ is associated with the fuzzy variable, $e(k)$, and $j \in [PL, ZE, NL]$ is associated with the fuzzy variable, $u_{\mathrm{FP}}(k-1)$. The fuzzy inference engine uses the appropriately designed knowledge base to evaluate the fuzzy rules and produce an output for each rule. Subsequently, the multiple outputs are transformed to a crisp output by the defuzzification interface. Once the aggregated fuzzy set representing the fuzzy output variable has been determined, an actual crisp control decision must be made. The process of decoding the output to produce an actual value for the controller gain FK_{P} is referred to as defuzzification. Thus, a fuzzy-logic controller-based center-average defuzzifier is implemented. The output of fuzzy-based proportional controller is given by $FK_{\mathrm{P}} = f_{\mathrm{P}}(e(k), u_{\mathrm{FP}}(k-1))$, where

$$f_{\mathrm{P}}(e(k), u_{\mathrm{FP}}(k-1)) = \frac{\sum_{1=1}^{9} \mu_{\mathrm{O}^l}\left(\min_{i=1,2}\left(\mu_{\mathrm{F}_i^l}(e(k), u_{\mathrm{FP}}(k-1))\right)\right)}{\sum_{1=1}^{9}\left(\min_{i=1,2}\left(\mu_{\mathrm{F}_i^l}(e(k), u_{\mathrm{FP}}(k-1))\right)\right)}$$

The linguistic fuzzy output variable "FK_{P}" has nine sets: negative very large (NVL), negative large (NL), negative medium (NM), and negative small (NS), zero (ZE), positive small (PS), positive medium (PM), positive large (PL), and positive

very large (PVL). The two fuzzy sets, namely, negative very large (NVL) and positive very large (PVL), are added to enhance the tracking performance. After specifying the fuzzy sets, it is required to determine the membership functions for these sets μ_{O}^{l} for $l=1\ldots9$. The membership function for the fuzzy set-representing zero is a fuzzy singleton. Additionally, the other membership functions are composed of fuzzy singletons within the region defined for the fuzzy output variable. Consequently, the control signal generated by the fuzzy-proportional controller can be written as $u_{\mathrm{FP}}(k)=G_{\mathrm{P}}\{f_{\mathrm{P}}(e(k),u_{\mathrm{FP}}(k-1))\}e(k)$, where G_{P} is the scaling factor that is tuned experimentally using genetic optimization.

36.5.2 Fuzzy-Based Integral Controller

The same technique applied to the fuzzy-based proportional controller is applied to the fuzzy-based integral controller. The controller has two inputs and one output. The inputs to the fuzzy-based controller are (1) the angular speed error, $e(k)$, and (2) the delayed feedback control signal, $u_{\mathrm{FI}}(k-1)$. The controller output is the gain, FK_{I}, of the controller. Three fuzzy sets are defined for the fuzzy linguistic variable "$e(k)$" and three fuzzy sets for the fuzzy linguistic variable "$u_{\mathrm{FI}}(k-1)$." After specifying the fuzzy sets of the two fuzzy variables, the membership functions for these sets are derived. The membership functions are composed of the same fuzzy triangular membership functions allocated for the fuzzy-based proportional controller. Similarly, the number of fuzzy rules that are required is equal to the product of the number of fuzzy sets that make up each of the two fuzzy input variables. Therefore, a total of nine fuzzy rules are introduced. Some of these rules and their significance are explained as follows:

Rule 1: IF $e(k)$ is positive large (PL) AND $u_{\mathrm{FI}}(k-1)$ is positive large (PL), THEN FK_{I} is positive large (PL). This rule implies a general condition when both input signals are positive. Consequently, the output membership function assigned to this rule is a positive value to keep the controller gain within a stable range.

Rule 2: IF $e(k)$ is zero (ZE) AND $u_{\mathrm{FI}}(k-1)$ is positive large (PL), THEN FK_{I} is positive very small (PVS). This rule implies a general condition when the speed error is close to zero and $u_{\mathrm{FI}}(k-1)$ is positive. Therefore, the output membership function assigned to this rule is a small positive value to reduce the control signal variations.

Rule 3: IF $e(k)$ is negative large (NL) AND $u_{\mathrm{FI}}(k-1)$ is positive large (PL), THEN FK_{I} is positive medium (PM). This rule usually deals with the case in which overshoots occur. A medium positive value is assigned in this case to ensure that the overshoot is decreased and prevent oscillations at the same time.

The rule strength represents the degree of membership of the output variable for a particular rule. Similarly, the rule strength, $\xi_{n,m}$ of a particular rule is defined as

$$\xi_{n,m}=\min\left(\mu_{F_n},\mu_{F_m}\right)$$

where $n\in[PL,ZE,NL]$ is associated with the fuzzy variable, $e(k)$, and $m\in[PL,ZE,NL]$ is associated with the fuzzy variable, $u_{\mathrm{FI}}(k-1)$.

The fuzzy inference engine uses the appropriately designed knowledge base to evaluate the fuzzy rules and produce an output for each rule. Subsequently, the multiple outputs are transformed to a crisp output, by the defuzzification interface. A center-average defuzzifier method is used. Thus, the output of fuzzy-based integral controller is given by $FK_{\mathrm{I}}=f_{\mathrm{I}}(e(k),u_{\mathrm{FI}}(k-1)$ where

$$f_{\mathrm{I}}(e(k),u_{\mathrm{FI}}(k-1))=\frac{\sum_{1=1}^{9}\mu_{\mathrm{O}^l}\left(\min_{i=1,2}\left(\mu_{\mathrm{F}_i^l}(e(k),u_{\mathrm{FI}}(k-1))\right)\right)}{\sum_{\mathrm{l}=1}^{9}\left(\min_{i=1,2}\left(\mu_{\mathrm{F}_i^l}(e(k),u_{\mathrm{FI}}(k-1))\right)\right)}$$

After specifying the fuzzy sets for the fuzzy output variable, FK_{I}, the membership functions for these sets are derived. It is important to note that the same fuzzy singleton membership functions are used here. The control signal of the fuzzy-based integral controller is given by

$$u_{\mathrm{FI}}(k)=G_{\mathrm{I}}\{f_{\mathrm{I}}(e,u_{\mathrm{FI}}(k-1))\}\sum_{i=0}^{k}e(i)\Delta t,k=0,1,2,\ldots,$$

where G_{I} is the scaling factor that is tuned experimentally using genetic optimization.

36.5.3 Fuzzy-Based Derivative Controller

The same process applied to fuzzy-based proportional controller and fuzzy-based integral controller is applied to the fuzzy-based derivative controller. The input signals (state variables) to the controller are $e(k)$ and $u_{\mathrm{FD}}(k-1)$. The output of the controller is the gain FK_{D}. After specifying the fuzzy sets and the membership functions for these sets, the triangle membership functions are also used to define the degree of membership. Figs. 36.2 and 36.3 show the membership functions for the fuzzy sets. Similarly, the linguistic fuzzy output variable "FK_{D}" has nine sets: negative very large (NVL), negative large (NL), negative medium (NM), and negative small (NS), zero (ZE), positive small (PS), positive medium (PM), positive large (PL), and positive very large (PVL). Now, it is necessary to find the final controller output. Consequently, the output of fuzzy-based derivative controller is given by $FK_{\mathrm{D}}=f_{\mathrm{D}}(e(k),u_{\mathrm{FD}}(k-1))$, where

$$f_{\mathrm{D}}(e(k),u_{\mathrm{FD}}(k-1))=\frac{\sum_{1=1}^{9}\mu_{\mathrm{O}^l}\left(\min_{i=1,2}\left(\mu_{\mathrm{F}_i^l}(e(k),u_{\mathrm{FD}}(k-1))\right)\right)}{\sum_{\mathrm{l}=1}^{9}\left(\min_{i=1,2}\left(\mu_{\mathrm{F}_i^l}(e(k),u_{\mathrm{FD}}(k-1))\right)\right)}$$

The control signal of the fuzzy-based derivative controller:

$$u_{\mathrm{FD}}(k) = G_{\mathrm{D}} f_{\mathrm{D}}(e(k), u_{\mathrm{FD}}(k-1))\Delta e(k)/\Delta t$$

where G_{D} is a scaling factor that tuned experimentally using genetic optimization.

Finally, the overall output of fuzzy PID was derived as follows:

$$u_{\mathrm{FPID}}(k) = u_{\mathrm{FP}}(k) + u_{\mathrm{FI}}(k) + u_{\mathrm{FD}}(k)$$

Saturation is also incorporated in the hybrid fuzzy-PID controller structure. As such, the final output of proposed controller is

$$\begin{aligned} &u_{\max}(k), u_{\mathrm{FPID}}(k) > u_{\max}(k), \\ &u(k) = u_{\mathrm{FPID}}(k) u_{\min}(k) \le u_{\mathrm{FPID}}(k) \le u_{\max}(k) \\ &u_{\min}(k) u_{\mathrm{FPID}}(k) < u_{\min}(k) \quad (10) \end{aligned}$$

where $u_{\min}$ and $u_{\max}$ are the permitted minimum and maximum inputs to the brushless drive system.

36.6 Classical PID Versus Fuzzy-PID Controller

The classical linear PID controller in its discrete form can be characterized as

$$u_{\mathrm{PID}} = K_{\mathrm{P}} e(k) + K_{\mathrm{I}} \sum_{\mathrm{i}=0}^{k} e(i)\Delta t + K_{\mathrm{D}} \Delta e(k)/\Delta t \quad k = 0, 1, \ldots,$$

where $K_{\mathrm{P}}, K_{\mathrm{I}}$, and K_{D} are constant gains.

This discrete form characterization equation provides a closed-form solution to the proposed fuzzy-PID controller. It can be rewritten as

$$\begin{aligned} u_{\mathrm{FPID}}(k) &= f_{\mathrm{P}}(e, Du_{\mathrm{P}}) G_{\mathrm{P}} e(k) + f_{\mathrm{I}}(e, Du_{\mathrm{I}}) G_{\mathrm{I}} \sum_{i=0}^{k} e(i)\Delta t \\ &\quad + f_{\mathrm{D}}(e, Du_{\mathrm{D}}) G_{\mathrm{D}} \Delta e(k)/\Delta t k = 0, 1, 2, \ldots \\ &= (FK_{\mathrm{P}})_{\mathrm{eq}} e(k) + (FK_{\mathrm{I}})_{\mathrm{eq}} \sum_{i=0}^{k} e(i)\Delta t \\ &\quad + (FK_{\mathrm{D}})_{\mathrm{eq}} \Delta e(k)/\Delta t \quad k = 0, 1, 2, \ldots, \end{aligned}$$

where $(FK_{\mathrm{P}})_{\mathrm{eq}}, (FK_{\mathrm{I}})_{\mathrm{eq}}$, and $(FK_{\mathrm{D}})_{\mathrm{eq}}$ are defined to be the equivalent proportional, integral, and derivative gains to a classical linear PID controller, respectively.

36.7 Genetic-Based Autotuning of Fuzzy-PID Controller

Genetic optimization-based approach is used to ensure the best performance of the proposed fuzzy-PID controller. The genetic optimization imitates the natural evolution process in which the fittest survive and the best genes are propagated to the next generation. A population of chromosomes is evaluated and a fitness value is assigned to each. Each chromosome represents a possible solution for a given problem, and the ones with the higher fitness have a better chance to reproduce. One of the main features is that it could work well for nondeterministic systems, ill-defined systems, and systems that are hard to model. Furthermore, the final performance outcome of the algorithm does not depend highly on the initial choice of chromosomes. When the genetic optimization is applied to control applications, each chromosome represents the set of controller's adjustable parameters, and the fitness value is a quantitative measure of the controller performance. The autotuning consists of the automatic adjustment of these parameters to optimize the controller performance. The genetic optimization combines a stochastic exploratory search with a well-defined cost function to find the solution that fit the problem the best. The cost function that represents the fuzzy-PID controller is defined as follows:

$$J = F(G_{\mathrm{P}}, G_{\mathrm{I}}, G_{\mathrm{D}}),$$

where $G_{\mathrm{P}}, G_{\mathrm{I}}, G_{\mathrm{D}}$ are the output scaling factors of the fuzzy-PID subcontrollers. The function F represents the relationship between the overall performance and the design parameters.

The optimization problem for the fuzzy-PID controller is described as

$$\max(F(G_{\mathrm{P}}, G_{\mathrm{I}}, G_{\mathrm{D}})) = \max(1/J)$$

where F is the fitness function. There are various ways to calculate the overall performance J of the controller, but for simplicity reasons, the mean square error (MSE) performance index was selected.

$$J = \frac{1}{N} \sum_{k=1}^{N} (e(k))^2$$

where N is the length of the evaluation window and $e(k)$ is the error between the reference speed and the actual speed. The fitness of each parameter set or chromosome can be determined as follows:

$$F(G_{\mathrm{P}}, G_{\mathrm{I}}, G_{\mathrm{D}}) = 1 \Big/ \left(\frac{1}{N} \sum_{k=1}^{N} (e(k))^2 \right)$$

Once the fitness function is established, the genetic operators and parameters are defined. The genetic optimization consists

of three basic operators: the crossover, mutation, and reproduction. The parameters are the number of generations, the population size, the probability of crossover, and mutation. In general, an initial population size is defined and evaluated with the fitness function. Once each chromosome has a fitness assigned to it, the reproduction process takes place with those that are more fit having a greater chance to be selected. Then, each of the two operators of crossover and mutation is applied to create the new pool of chromosomes to be evaluated. Crossover occurs when the chromosomes partially exchange their information by interchanging some of their genes. Mutation is the random alteration of a particular section of the chromosome by occasionally changing one or more of the genes that are part of the chromosome. For this optimization task, a crossover factor of 0.3 and a mutation factor of 0.7 were used. Another important aspect of the genetic optimization is the coding of the parameters. Binary coding has been used widely for decades; however, real-coded algorithms are proving useful for a number of applications, and it was chosen to implement the genetic optimization algorithm. One of the difficulties of the real-time implementation is in the simultaneous evaluation of the fitness for all the chromosomes in one generation as a batch data. This problem was overcome by reducing the population size to one and evaluating the fitness function of each chromosome sequentially. The mutation function is applied by increasing or decreasing the value proportional to a uniformly distributed random number between −0.9 and 1. The crossover is implemented with the chromosome that had the higher value for the fitness function and the chromosome being tested in the current generation. A Bernoulli binary set of numbers with probability of 0.5 is used to select the resulting offspring chromosome with a mix of genes from both parent chromosomes. The overall genetic-based autotuning procedure of the fuzzy-PID controller consists of the following steps:

Step 1: Select the control topology of the fuzzy-PID controller in which the outputs of the subcontrollers are used as the FPID gains.

Step 2: Define the characteristics of the fuzzy-PID subcontrollers such as the number of fuzzy sets, membership functions, fuzzy rules, and defuzzification method.

Step 3: Set the genetic optimization parameters, such as the number of generations, the population size, the probability of crossover, and mutation.

Step 4: The last step is the tuning of the parameters, G_P, G_I, and G_D of the fuzzy-PID controller using the genetic optimization procedure.

36.8 Fuzzy and *H*∞ Control Design

36.8.1 Brushless Servo-Motor Drive System

The brushless DC motor used in the section is excited by a three-phase sinusoidal supply and driven from a six-step inverter, which converts a constant voltage to a three-phase voltage with a frequency corresponding instantaneously to the rotor speed. The model of the drive system is used to design the $H\infty$ tracking controller and to simulate its dynamic behavior. However, fuzzy-logic controller does not require mathematical models and has the ability to approximate nonlinear systems. The reader is referred to [16] for details of the dynamic model of the brushless dc motor drive system. For the purpose of discussion, the dynamics of the brushless servomotor drive system can be written in state space form as follows:

$$x^{(n)} = f(x) + Bu + d$$

where $x = \left(x, \dot{x}, \ldots, x^{(n-1)}\right)^T \in R^n$, d is the external disturbance, and $B \neq 0$. Since $B \neq 0$ for $x \in R^n$, the system is controllable in the whole space R^n.

36.8.2 The Fuzzy *H*∞ Control Structure

A hybrid adaptive fuzzy controller is implemented, which employs a fuzzy-logic controller integrating an $H\infty$ tracking controller. The $H\infty$ tracking controller is capable of taking care of the robust stabilization and disturbance rejection problems, while fuzzy-logic controller is used as principle components of the adaptive fuzzy controller. Actually, it is outfitted with an adaptive control law that modifies the parameters of the controller based on a Lyapunov synthesis approach. Fig. 36.13 shows the block diagram of the proposed control structure.

36.8.3 *H*∞ Control Design

The controller objective is to obtain high-performance servo tracking; therefore, the control problem is to force the actual output to follow a predetermined bounded reference trajectory. The tracking performance indicates how closely the servomotor follows a desired position trajectory, velocity trajectory, or acceleration trajectory. For the purpose of discussion, we define the tracking error to be $\overline{\varepsilon} = [\varepsilon, \dot{\varepsilon}]^T$, where ε is the rotor speed error and $\dot{\varepsilon}$ is the acceleration error. Consequently, the motor speed error $\varepsilon = \omega_{ref} - \omega_{act}$ and the acceleration error $\dot{\varepsilon} = \alpha_{ref} - \alpha_{act}$ are used as input variables to the $H\infty$ controller. Here, ω_{act} is the actual speed in rev/s, ω_{ref} is the desired reference speed, α_{ref} is the desired acceleration in rev/s^2, and α_{act} is the calculated acceleration. The acceleration is calculated as the difference in the speed over two successive sampling periods. A block diagram of the $H\infty$ tracking controller is shown in Fig. 36.14. The $H\infty$ control law is defined as [17]

$$u_\infty = -\frac{1}{r_r} B^T P \varepsilon$$

where r_r is a weighting factor and P is the solution of the simplified Riccati-like equation for $P = P^T \geq 0$

$$PA + A^T P = -Q$$

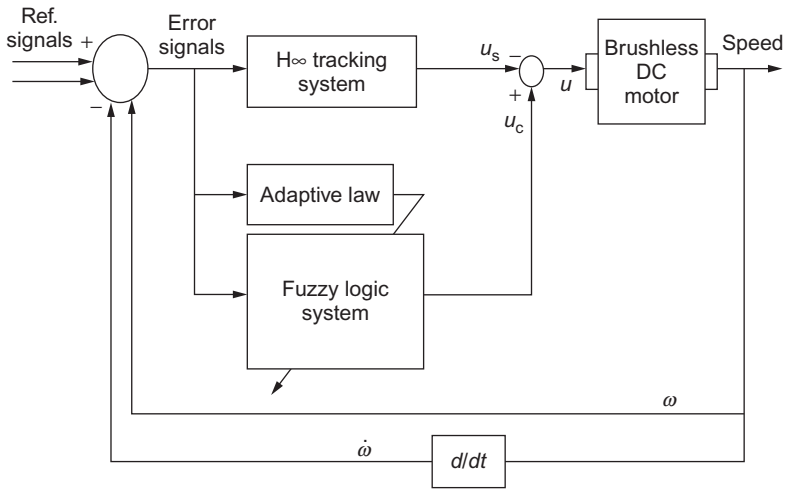

FIG. 36.13 Block diagram of the overall control structure.

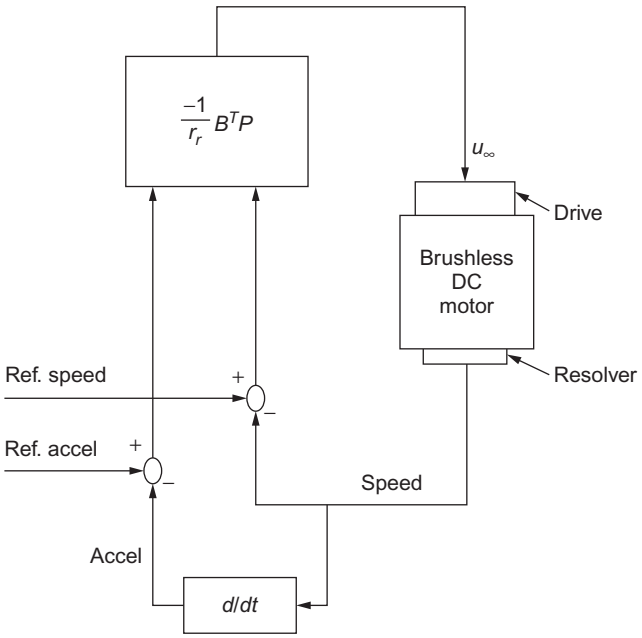

FIG. 36.14 Block diagram of $H\infty$ tracking controller.

The matrices A and B are given by

$$A = \begin{bmatrix} 0 & 1 \\ -k_2 & -k_1 \end{bmatrix} \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

where $k = [k_1, k_2]$ is chosen such that all roots of the polynomial $p^{(S)} = S^n + K_n S^{n-1} + \cdots + k_1$ are in the open left-hand plane.

36.8.4 Fuzzy Logic Control Design

The fuzzy-logic principles with center-average defuzzifier, product inference, and singleton fuzzifier are used as building blocks for the fuzzy controller. A block diagram of the fuzzy control structure is shown in Fig. 36.15. The fuzzy-logic-based controller implemented in this work has two inputs and one output. The inputs are the rotor speed error and the feedback acceleration error, with each of these inputs corresponding to a fuzzy variable.

The output is the fuzzy control decision. The fuzzy variable associated with the rotor speed error signal consists of five fuzzy sets: positive large (PL), positive medium (PM), zero (ZE), negative large (NL), and negative medium (NM). Typical example of the fuzzy membership functions used for the speed is shown in Fig. 36.16. In this way, for any given value of the rotor angle, the degree of membership μ, to which it belongs to each of these sets, can be determined, and a control decision based on this information can be obtained.

Similarly, the acceleration error can be described by a group of partially overlapping fuzzy sets as positive large (PL), positive medium (PM), zero (ZE), negative large (NL), and negative medium (NM), with each set having its own membership function. An example of typical membership functions that make up the fuzzy variable acceleration is shown in Fig. 36.17.

The five fuzzy sets can be symbolized by $F_1^j, i = 1,2$ and $j = 1,2,3\ldots5$. Their membership functions can be symbolized by $\mu F_1^j(x_1), i = 1,2$ and $j = 1,2,3\ldots5$.

36.8.5 Fuzzy Logic Rules

The next step in the design of the fuzzy-logic-based controller is the determination of the fuzzy IF-THEN inference rules. The number of fuzzy rules that are required is equal to the product of the number of fuzzy sets that make up each of the two fuzzy input variables. For the fuzzy controller described here, the input variables representing the rotor speed and its acceleration consist of five fuzzy sets each. Thus, a total of 25 fuzzy rules are required. During each sampling interval that a controller is

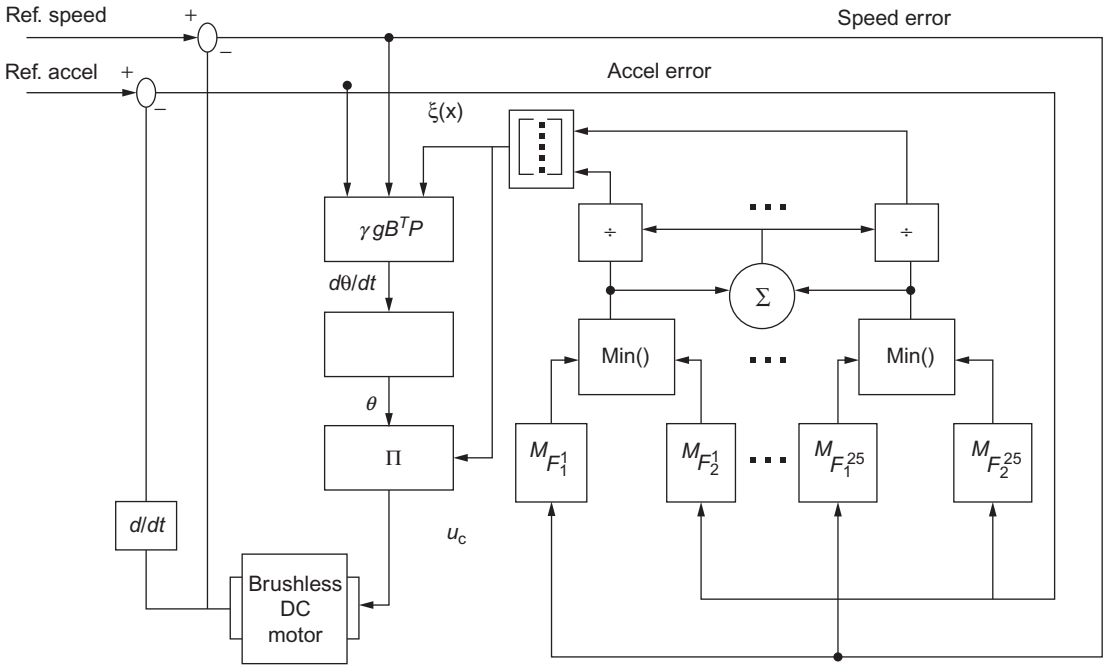

FIG. 36.15 Block diagram of the fuzzy-logic control structure.

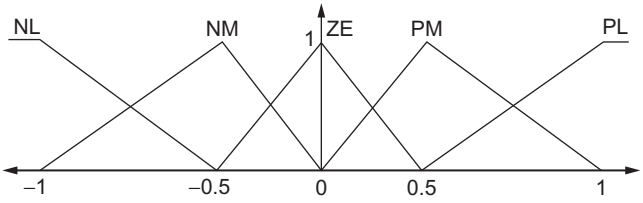

FIG. 36.16 Fuzzy membership functions for the rotor speed error.

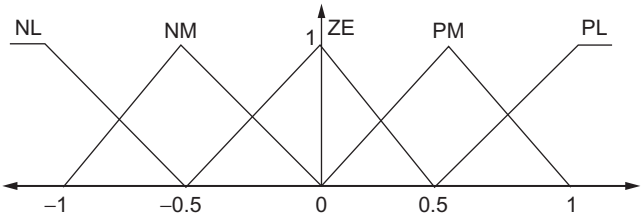

FIG. 36.17 Fuzzy membership functions representing the acceleration error.

calculated, the present value of the degree of membership of the motor speed and its acceleration is calculated for each of the fuzzy sets that make up their respective fuzzy variables. This process is one of the largest computational burdens of the fuzzy-logic control algorithm if each fuzzy set is expected to have some degree of membership for the present input value of the motor speed and its acceleration. This will in addition affect the computational speed at which the fuzzy rules are processed since all the rules have to be evaluated.

Using a triangular membership function for the input variables was very desirable to reduce this computational burden and speed up the process. This ensures that only two fuzzy sets, which are overlapping, will actually have a nonzero degree of membership (Figs. 36.16 and 36.17). With this advantage, the evaluation of the degree of membership in each set is accelerated. This also speeds up the evaluation of the fuzzy rules since only those rules that correspond to nonzero values of membership function need to be evaluated. Hence, for this controller, only four fuzzy rules need to be evaluated during any sampling interval. The fuzzy inference rules have been determined experimentally using the measured responses of the brushless drive servo system. A typical fuzzy rule is of the form:

$[R^{(1)}:]$ IF x_1 is F_1^j, and x_2 is F_2^j, THEN O is G_1^l for $j = 1\ldots5, l = 1\ldots5$.

In general,

$[R^{(k)}:]$ IF x_1 is F_1^j, and x_2 is F_2^j, THEN O is G_k^l for $j = 1\ldots5, l = 1\ldots5, k = 1\ldots25$.

The conjunction of the rule antecedents is evaluated by the fuzzy operation *intersection,* which is implemented by the *min* operator. The rule strength represents the degree of membership of the output variable for a particular rule. Defining the rule strength, $\xi_{i,j}$, of a particular rule as

$$\xi_{i,j} = \min\left(\mu_{F_i^{\text{speed}}}, \mu_{F_j^{\text{accel}}}\right)$$

where $i \in [PL, PM, ZE, NM, NL]$ is associated with the fuzzy variable, *speed*, and $j \in [PL, PM, ZE, NM, NL]$ is associated with

the fuzzy variable, *acceleration*. From above, it is clear that for all the rules where at least one of the degrees of membership in the corresponding fuzzy sets is zero, the output of the *min* operator will be zero, and hence, these rules do not have to be analyzed. The fuzzy inference engine uses the appropriately designed knowledge base to evaluate the fuzzy rules and produce an output for each rule. Subsequently, the multiple outputs are transformed to a crisp output by the defuzzification interface.

36.8.6 Defuzzification

Once the aggregated fuzzy set representing the fuzzy output variable has been determined, an actual crisp control decision must be made. The process of decoding the output to produce an actual value for the control signal is referred to as defuzzification. Thus, a fuzzy-logic controller-based center-average defuzzifier is implemented. The control output can be written in general form:

$$O(x) = \sum_{l=1}^{25} \mu_{O^l} \left(\min_{i=1,2} \left(\mu_{F_i^l}(x) \right) \right) / \sum_{l=1}^{25} \left(\min_{i=1,2} \left(\mu_{F_i^l}(x) \right) \right)$$

which can be written in the form

$$O(x) = \theta^T \xi(x) = \xi^T(x)\theta$$

where

$$\xi^l(x) = \min_{i=1,2} \left(\mu_{F_i^l}(x) \right) / \sum_{l=1}^{25} \left(\min_{i=1,2} \left(\mu_{F_i^l}(x) \right) \right)$$

$\theta = (\mu_{O^1}, \ldots \mu_{O^{25}},)$ is a parameter vector representing the degree of membership of the output, which is tuned online using an adaptation law.

36.8.7 On-Line Adaptation

By using an adaptive law, the fuzzy parameters, θ, can be tuned online based on the Lyapunov synthesis approach. The feedback control law can be expressed as follows [17]:

$$u = \xi^T(x)\theta - u_\infty / g$$

where θ is a vector denoting the parameter estimate of fuzzy-logic controller. The parameter θ is adjusted using the following adaptive law:

$$\dot{\theta} = \gamma \xi(x) g B^T P \varepsilon$$

where γ is an adaptation gain and g is a constant that depends on machine parameters. A block diagram of the hybrid adaptive fuzzy controller is shown in Fig. 36.18.

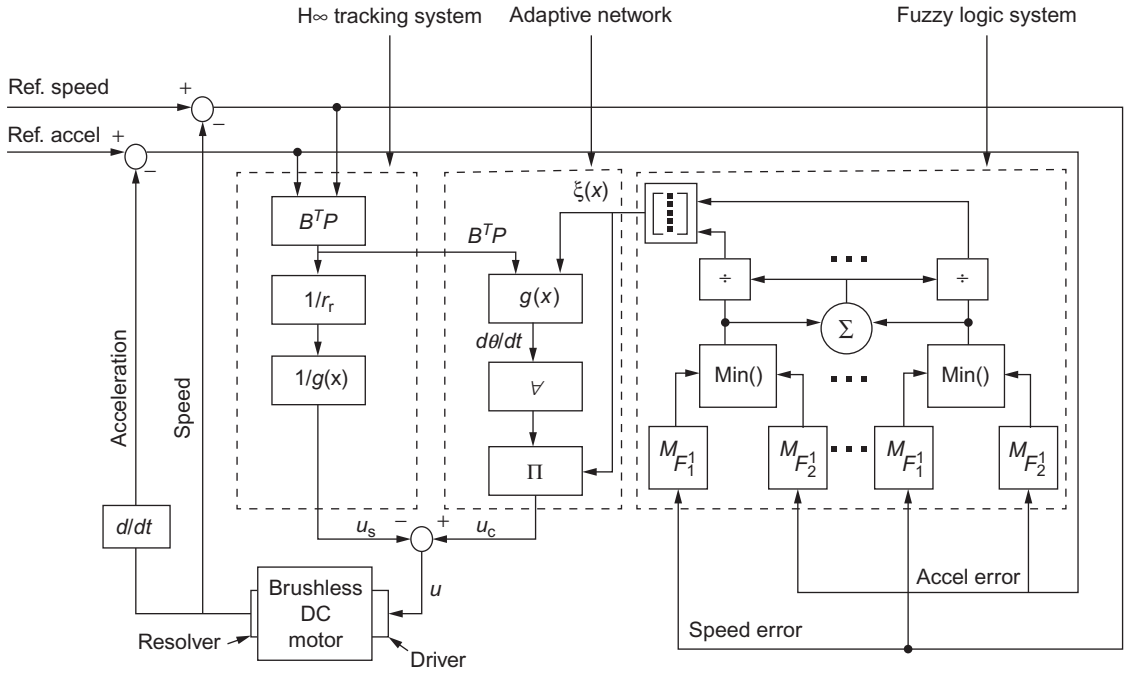

FIG. 36.18 Block diagram of the overall fuzzy- $H\infty$ control structure.

36.9 Fuzzy Control for DC-DC Converters

36.9.1 Background

The DC-DC converters are generally divided into two groups: hard-switching converters and soft-switching converters. In hard-switching converters, the power switches cut off the load current within the turn-on and turn-off times under the hard-switching conditions. The output voltage is controlled by adjusting the on-time of the power switch, which in turn adjusts the width of a voltage pulse at the output. This is known as PWM control. In soft-switching converters, resonant components are used to create oscillatory voltage or current waveforms so that the zero-voltage switching or zero-current switching conditions could be created for the power switches. For many years, control design for converters has been carried out through analog circuits, which limited them to mostly PI controller structure. The PI controllers generally give overshoot in output voltage and high initial current when rise time of response is reduced. Feed-forward types of controllers have also been designed by sensing the input voltage to improve line regulation in applications with a wide range of input voltages and load currents. However, direct sensing of the input voltage through a feed-forward loop may induce large-signal disturbances that could upset the normal duty cycle of the converter. Using human linguistic terms and common sense, several fuzzy-logic controllers have been developed and implemented for the DC-DC converters [18–20]. These controllers have shown promise in dealing with nonlinear systems and achieving voltage regulation in buck converters. Fuzzy-logic control uses humanlike linguistic terms in the form of IF-THEN rules to capture the nonlinear system dynamics. Once in place, the fuzzy rules will not be able to adapt themselves to adequately capture the dynamics and external disturbances of the converter. Although achieving many practical successes, fuzzy control has not been viewed as a rigorous science due to a lack of formal analysis and synthesis techniques. As a result of this, a lot of work has been done to develop adaptive fuzzy controllers and automate the modeling process as much as possible. Recently, the resurgence of interest in ANN has injected a new driving force into fuzzy literature. One of the major features of ANNs is their learning capability. A learning algorithm is usually used to update the nonlinear parameters of the network architecture. A drawback in using an ANN for control is that there is so much freedom in structural implementation choice that it is often difficult to decide how complex a structure is actually necessary for the desired control. Besides, the implementation is not at all intuitive, and the inner workings of the network are very much invisible to the designer. The integration of neural network architectures with fuzzy inference system has resulted in a very powerful strategy known as adaptive network-based fuzzy inference system. Some researchers suggest that neural networks and fuzzy control are in fact special instances of adaptive networks [21,22]. The suggested fuzzy inference system has the advantage that it can not only take linguistic information from human experts but also adapt itself using numerical data to achieve better performance.

36.10 Fuzzy Control Design for Switch-Mode Power Converters

The structure built-up here is a two-input single-output controller. The inputs are the variable voltage error, $e(k)$, and the change in voltage error, $\Delta e(k)$. Consequently, the input to the DC-DC converter would be the duty cycle that is actually the output of the fuzzy controller. The operational structure of the proposed fuzzy controller is shown in Fig. 36.19. It consists of three building blocks: (1) a fuzzification block that expresses quantitative action to qualitative action, (2) fuzzy inference engine that generates the fuzzy rules, and (3) a defuzzification block that articulates qualitative action to quantitative action. Fuzzification translates a numeric value for the error $e(k)$ or change in error $\Delta e(k)$ into a linguistic value such as big or small with a membership grade. Defuzzification takes the fuzzy output of the rules and generates a "crisp" numeric value used as the control input to the DC-DC converter. The controller qualitatively captures the dynamics of the DC-DC converter and executes this qualitative idea in a real-time situation. The DC-DC converter is equipped with a feedback network that provides the error value at the output. The overall architecture of a DC-DC converter topology with the fuzzy controller structure is given in Fig. 36.20. The feedback network consists of a *precision voltage reference* with a nominal voltage of 2.5 V. The 5 and 15 V output potentials are combined in a resistive sampling network in such a way that the output voltage of the network is 2.5 V when the potentials are closed to their nominal magnitudes. This output voltage is then compared internally with the reference of the *precision voltage reference*, and any error difference detected is amplified and fed back. The converter is represented by a "black box" from which we only extract the terminals corresponding to input voltage (V_I), output voltage (V_o), and controlled switch (S). From these measurements, the controller provides a percentage duty-cycle

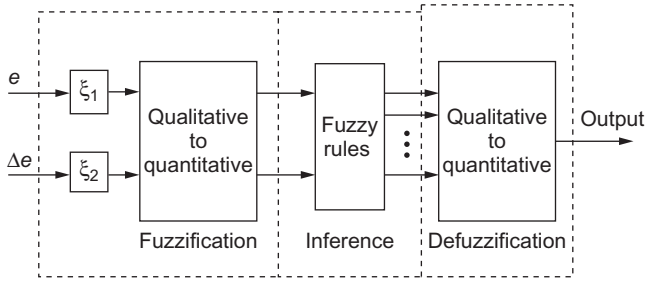

FIG. 36.19 Fuzzy control structure.

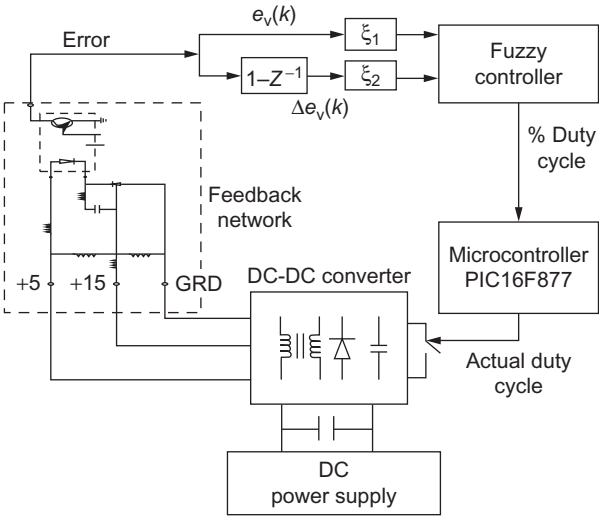

FIG. 36.20 Fuzzy control-based DC-DC converter topology.

signal for a peripheral interface microcontroller PIC16F877, which generates the converters' actual duty cycle.

36.10.1 DC-DC Switch-Mode Power Converter

The DC-DC switch-mode power converter consists of six distinct circuit networks as shown in Fig. 36.21, working together to form a complete DC-to-DC dual-output switch-mode power regulator [23]. The six distinct circuit networks are (1) the bias voltage regulator network, (2) the 100 KHZ clock, (3) the pulse-width modulator (PWM), (4) the power switch driver interface, (5) the feedback error amplifier, and (6) the integrated-magnetic (IM) power stage. In order to implement the proposed adaptive fuzzy-neural-network controller, the converter system shown in Fig. 36.21 was modified by removing the *bias voltage regulator network*, the *100 KHz clock*, and the *pulse-width modulator (PWM)*, which is the core of the control system. The power-stage concept is based on that of a "dual-output forward" configuration operating in a continuous mode of energy storage. When the power MOSFET switch Q1 is turned ON, energy is transferred from the input power source (V_{IN}) to the two secondary sides of the transformer. The voltage potential across the terminals of C1 will be that of the reflected line voltage, namely, $N_{S1} \times V_{IN}/N_P$. The ON time is a fraction of the clock period, and it has to be short and long enough to bring the output to a level above the desired voltage (5 and 15 V). Diodes D1 and D4 conduct allowing the energy transfer to be used to supply 5 and 15 V load power, respectively, and to replenish the energy lost in the "output" inductors during the previous OFF period of Q1. Diodes D2 and D3 do not conduct during this time, since they are reverse-biased.

When Q1 turns OFF, the 5 and 15 V load power is sustained by the energies of the two "inductors" (L1 and L2). The output stored energy, located in two inductors, will then start discharging causing the voltages to drop. Diodes D2 and D3 conduct

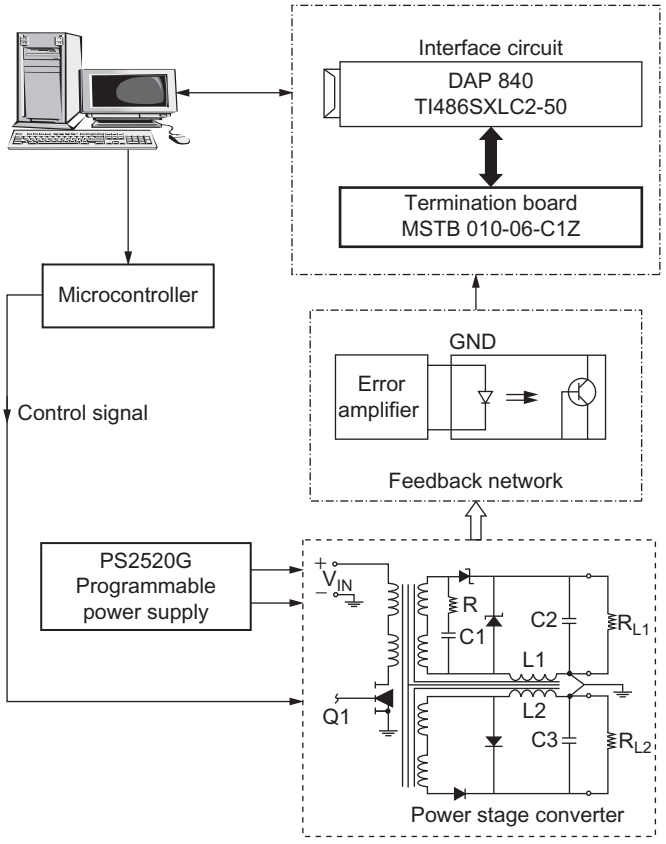

FIG. 36.21 Block diagram of switch-mode DC-DC power converter.

during this time with diodes D1 and D4 forced off. As soon as the voltages go below the desired values, another impulse will be applied on Q1 (Q1 ON), to bring the voltage back upward. Capacitors C2 (0.001 μf) and C3 (100 μf) serve to prevent the dynamic ripple currents in the "inductors" from appearing at the 5 and 15 V load terminals, respectively.

36.11 Optimum Topology of the Fuzzy Controller

The main problem with fuzzy controller generation is related to the definition of its optimum topology such as scaling factors, number of fuzzy sets, shape of the fuzzy sets, and decision-making. This section is devoted to the topology determination of the proposed fuzzy controller structure. Various test cases were performed on the DC-DC converter in order to determine the ranges of membership functions and other system-specific responses of the converter that will help in the design of the linguistic control rules of the proposed controller. The experimental tests were focused on the responses of the DC-DC converter with and without the action of the controller. One other point was to observe how the changes of the control signal and the variations of the error signal with respect to the variations of

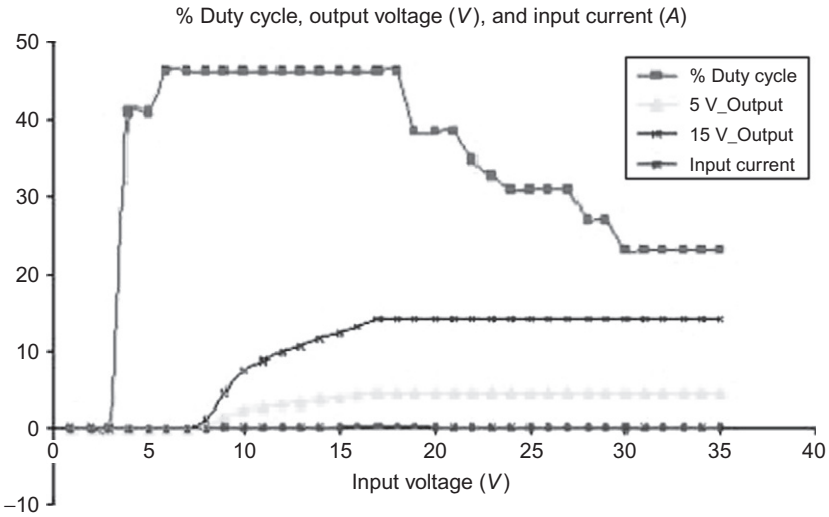

FIG. 36.22 Optimum trajectories of the percentage duty cycle, the output voltage, and the input current with variations in the input voltage.

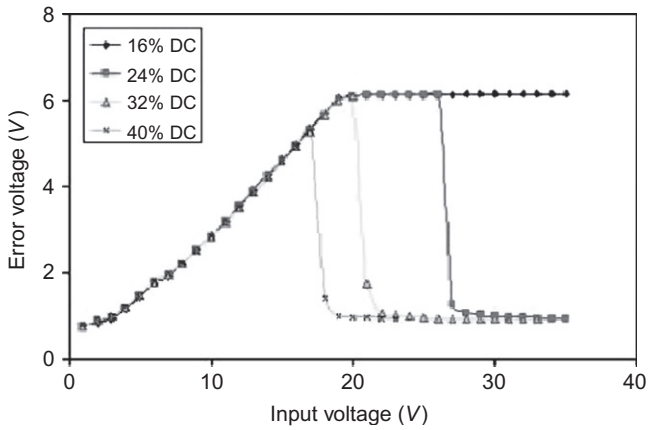

FIG. 36.23 Variations of the error voltage with the control signal at 16%, 24%, 32%, and 40% duty cycle.

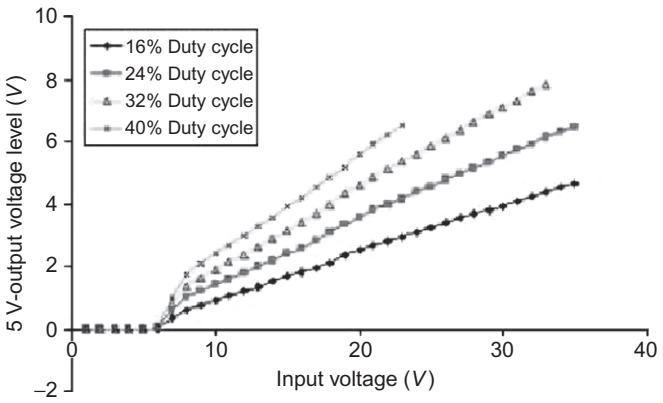

FIG. 36.24 5 V output voltage level tested for different constant control signals.

the input voltage. The various voltage ranges observed in the test cases assisted in choosing the ranges for the input and output membership set. A summary of some of these tests is shown in Figs. 36.22–36.24. Fig. 36.22 shows the optimum trajectories of the duty cycle, the output voltage, and the input current with variations in the input voltage. From Fig. 36.22, when the input voltage increases, the control signal pulses get reduced to maintain the output voltages at their required level. The other information gives the range of the control signal (i.e., 16%–50%) required for the working range of the DC-DC converter. A similar test case was conducted while the error of the system was observed. Fig. 36.23 shows four different test cases of variations of the error voltage and duty cycle with increase in the input voltage plotted together. The figure shows four variations of the error voltage with the control signal at 16%, 24%, 32%, and 40% duty cycle. For the 40% duty-cycle test case, the feedback network becomes active at an input voltage of 18 V. When the duty cycle was reduced to 32%, the feedback network becomes active at around 21 V of the input voltage. At 16% duty cycle, it was realized that the feedback network was not yet active at 36 V of the input voltage. This test case shows that when the feedback network is active, the error voltages are all below 2 V. Fig. 36.23 also gives the actual values of the error voltage and the control signals needed at each stage of the input voltage variations. A general rule from Fig. 36.23 will be "if the error voltage is high (i.e., max 6 V) and the change in error is zero (i.e., very small), then increase the control signal (i.e., duty cycle)." In Fig. 36.24, a 5 V output voltage level was tested for different constant control signals while increasing the input voltage. Four different test cases were conducted for duty-cycle values of 16%, 24%, 32%, and 40%. From the figure, it shows the various voltage levels at which the output voltage gets to the 5 V mark for the different duty cycles. It also shows that without any control, the output voltage will continue to increase without any bound. These experimental observations were in general very helpful in the design of the fuzzy-logic controller.

36.11.1 Membership Functions and Rules Generation

The chief problem of the construction of the fuzzy controller is related to the choice of the regulator parameters. Certainly, there is no systematic procedure for the design of a fuzzy controller (membership functions and rules generation), and this section is devoted to the determination of the fuzzy sets and the linguistic rules. The number of the linguistic sets of the proposed controller has been determined using laboratory experimentation and the responses of the DC-DC converter that have been compared with different numbers of the fuzzy sets. The actual responses have been compared with three, four, five, and seven fuzzy sets. It has been found that the use of more than five linguistic sets does not improve the tracking accuracy of the DC-DC converters but in fact increases the computation time. Consequently, four linguistic sets, positive large (PL), positive small (PS), negative large (NL), and negative small (NS), have been chosen for the input variable voltage error, $e(k)$, and three linguistic sets, positive medium (PM), zero (ZE), and negative medium (NM), have been chosen for that of the change in voltage error, $\Delta e(k)$. Additionally, five linguistic sets, positive large (PL), positive small (PS), zero, negative large (NL), and negative small (NL), have been chosen for the output variable of the fuzzy controller structure. The fuzzy controller utilizes triangular membership functions on the controller input. The triangular membership function is chosen owing to its simplicity. For the change in voltage error, $\Delta e(k)$, the initial values of the premise parameters (the corner coordinates of the triangle) are chosen so that the membership functions are equally spaced along the operating range of each input variable. The scaled input and output membership functions sets are shown in Figs. 36.25 through 36.27. The actual error measured from the feedback network ranges from 0.8 to about 6.0 V, while the control signal ranges from 16% to 50% duty cycle.

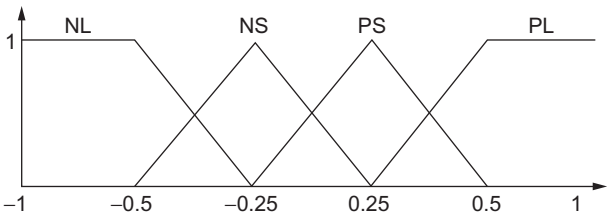

FIG. 36.25 Input membership functions for the error, $e(k)$.

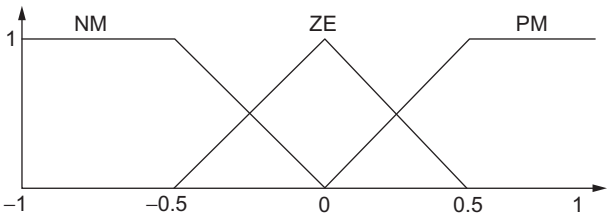

FIG. 36.26 Input membership functions for the change in error, $\Delta e(k)$.

The scaling factors $\xi_1 = 0.167$ and $\xi_2 = 0.01$ were determined using experimental tests in such a way that the normalized inputs $e(k)$ and $\Delta e(k)$ are well adapted to the universe of discourse $[-1,1]$ for any operating point. The linguistic control rules are established considering the dynamic behavior of the DC-DC converter and analyzing the error and its variation. To obtain control decision, the max-min inference method is used. It is based on the minimum function to describe the "AND" operator present in each control rule and the maximum function to describe the "OR" operator.

The output of the fuzzy controller structure is crisp, and thus a combined output fuzzy set must be defuzzified. To express the qualitative action in a quantitative action, the sum-product composition method was used. It calculates the crisp output as the weighted average of the centroids of all output membership functions. The output of the controller can be expressed as

$$O_o = \frac{\left(\sum_m O_m^* a_{Cm} \times b_{Cm}\right)}{\sum_m (O_m^* b_{Cm})}$$

where a_{Cm} and b_{Cm} are the centers and widths of the output fuzzy sets, respectively, for $m = 1,\ldots,5$. The values of the b_{Cm} s were chosen to be unity. This scaled output corresponds to the control signal (percent duty cycle) to be applied to maintain the output voltage at a constant value. Fig. 36.28 represents the normalized output O_o of the proposed fuzzy controller

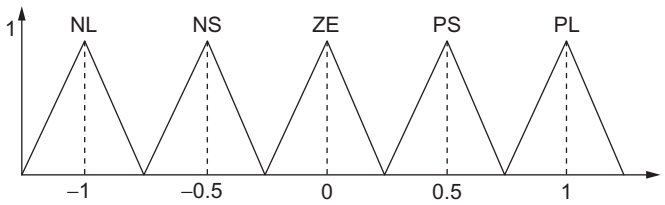

FIG. 36.27 Output membership functions for the control signal.

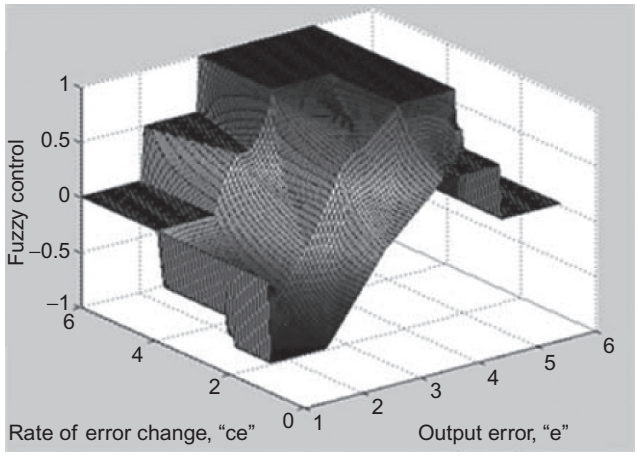

FIG. 36.28 Fuzzy control surface.

structure as a function of the error $e(k)$ and the change of error $\Delta e(k)$. It clearly illustrates the nonlinear characteristics of the proposed fuzzy controller structure.

36.12 Adaptive Network-Based Fuzzy Control System for DC-DC Converters

Adaptive network architecture, ANFIS, and a learning algorithm by which the ANFIS could construct a desired input-output mapping are proposed. The basic structure of a converter topology with adaptive network architecture is given in Fig. 36.29. Both fuzzy-logic principles and learning functions of neural networks are employed together to construct the adaptive fuzzy-network inference system for the control topology. Initially, a basic fuzzy-logic controller is set up utilizing linguistic rules, and then numerical data is used for training the controller. The number of membership functions is chosen so as to cover the entire input space. The converter is represented by a "black box" from which we only extract the terminals corresponding to input voltage (V_i), output voltage (V_o), and controlled switch (S). From these measurements, the ANFIS provides a signal proportional to a percentage duty-cycle signal for a peripheral interface microcontroller, PIC16F877, which generates the converters' actual duty cycle.

36.12.1 Topology of the Neural-Fuzzy Controller (NFC)

The proposed ANFIS is a multilayer neural network-based fuzzy-logic controller. The network architecture is built, such

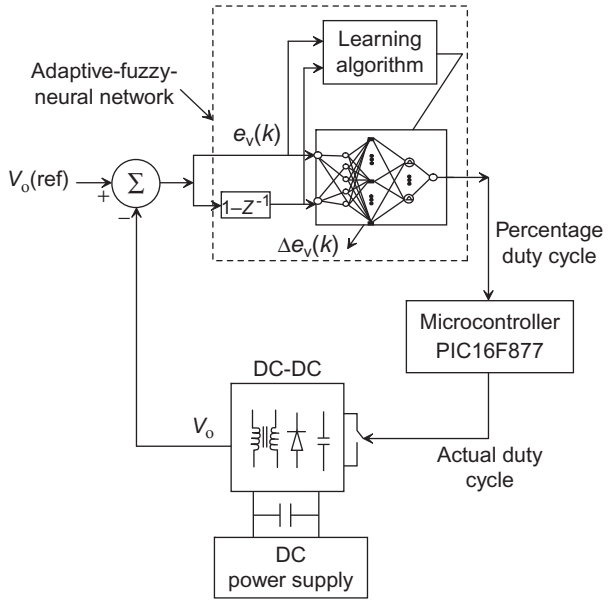

FIG. 36.29 Structure of a converter topology with adaptive network architecture.

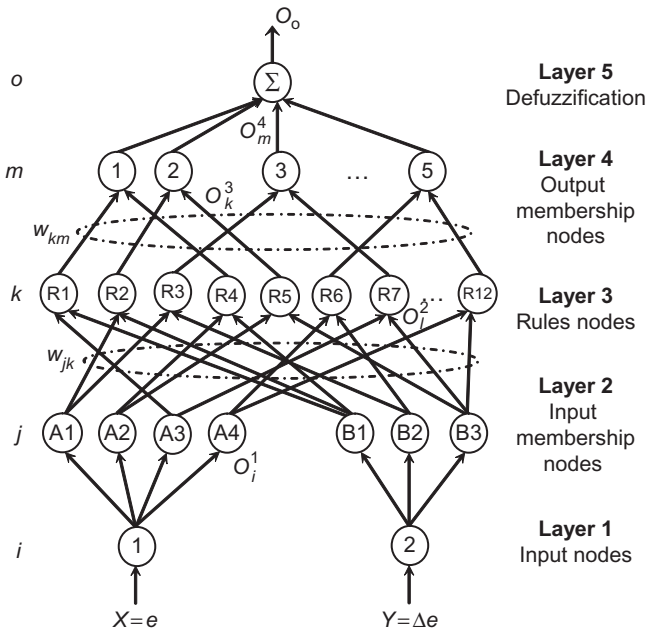

FIG. 36.30 Network architecture-based topology.

that the designer recognizes the internal nodes as they relate to the components of fuzzy controller. The system has a total of five layers. The architecture of the network is shown in Fig. 36.30. The scaled input and output membership functions sets are shown in Figs. 36.3–36.5. The actual error measured from the feedback network ranges from 0.8 to about 6.0 V, while the control signal ranges from 16% to 50% duty cycle.

36.12.1.1 Layer 1: Input Layer

Each node in this layer is an input node, which corresponds to one input variable. These nodes only bypass input signals to the next layer. The input variables are the output voltage error $e(k) = V_o(k) - V_{oref}(k)$ and change in voltage error $\Delta e(k) = [e(k) - e(k-1)]$, respectively. The fuzzy sets proposed for the input variable voltage error, $e(k)$, are positive large (PL), positive medium (PM), positive small (PS), and small (S) and that for the change in voltage error, $\Delta e(k)$, are positive medium (PM), zero (ZE), and negative medium (NM). The output of the neuron i in layer 1 is obtained as

$$O_i^1 = f_i^1\left(\text{net}_i^1\right) = \text{net}_i^1$$

where net_I^1 is the ith input to the node of layer 1, namely, the error and the change in the error.

36.12.1.2 Layer 2: Input Membership Layer

Each node in this layer acts as a linguistic label of one of the input variables in layer 1, that is, the membership value specifying the degree to which an input value belongs to a fuzzy set is determined in this layer. The triangular membership function is chosen owing to its simplicity. For the change in voltage

error, $\Delta e(k)$, the initial values of the premise parameters (the corner coordinates of the triangle) are chosen so that the membership functions are equally spaced along the operating range of each input variable. Due to the nonlinearity in the converter, the triangular membership for the error, $e(k)$, was slightly modified. The weights between the input and membership level are assumed to be unity. The output of neuron j in the second layer can be obtained as follows:

when $(X_i \geq a_j)$ and $(X_i \leq b_j)$

$$O_j^2 = f_j^2\left(\text{net}_j^2\right) = (X_i - a_j)/(b_j - a_j)$$

else when $(X_i \geq b_j)$ and $(X_i \leq c_j)$

$$O_j^2 = f_j^2\left(\text{net}_j^2\right) = (X_i - c_j)/(b_j - c_j)$$

where a_j, b_j, and c_j are the corners of the jth membership function in layer 2 shown in Fig. 36.31 and X_i is the ith input variable to the node of layer 2, which could be either the value of the error or the change in error.

36.12.1.3 Layer 3: Rule Layer

Each node in layer 3 multiplies the incoming signal and outputs the result of the product. The conjunction of the rule antecedents is evaluated by the fuzzy operation *intersection*, which is implemented by the product operator. Consequently, each node of this layer is a rule node that represents one fuzzy control rule. Each node takes two inputs: one from nodes A1–A4 and the other from nodes B1–B3 of layer 2. Nodes A1–A4 define the membership values for the voltage error, and nodes B1–B3 define the membership values for the change in voltage error. Accordingly, there are 12 nodes in layer 3 to form a fuzzy rule base for two input variables, with four linguistic variables for the input *voltage error*, $e(k)$, and three linguistic variables for the input *change in voltage error*, $\Delta e(k)$. The input/output links of layer 3 define the preconditions and the outcome of the rule nodes, respectively. The outcome is the strength applied to the evaluation of the effect defined for each particular rule. The output of neuron k in layer 3 is obtained as

$$O_k^3 = f_k^3\left(\text{net}_k^3\right) = \text{net}_k^3, \text{ where } \text{net}_k^3 = \prod_j w_{jk}^3 y_j^3$$

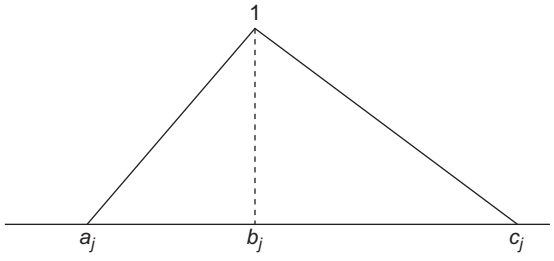

FIG. 36.31 A single membership function.

y_j^3 represents the j th input to the node of layer 3, and w_{jk}^3 is assumed to be unity.

36.12.1.4 Layer 4: Output Membership Layer

Neurons in this layer represent fuzzy sets used in the consequent of fuzzy rules. An output membership neuron receives inputs from the corresponding fuzzy rule neurons and combines them by using the fuzzy operation *union*. This was implemented by the *maximum* function. Layer 4 acts upon the output of layer 3 multiplied by the connecting weights. These link weights represent the output action of the rule nodes evaluated by layer 3. That output is given by

$$O_m^4 = f_m^4\left(\text{net}_{km}^4\right) = \max\left(\text{net}_{km}^4\right)$$

and

$$\text{net}_{km}^4 = O_k^3 w_{km}$$

where the count of k depends on the links from layer 3 to the particular mth output in layer 4 and the link weight w_{km} is the output action of the mth output associate with the kth rule. This level is essential in ensuring the system's stability and allowing a smooth control action.

36.12.1.5 Layer 5: Defuzzification Layer

Layer 5 is the output layer and acts as a defuzzifier. The single node in this layer takes the output fuzzy sets clipped by the respective integrated firing strengths and combines them into a single fuzzy set. The output of the neurofuzzy system is crisp, and thus a combined output fuzzy set must be defuzzified. The sum-product composition method was used. It calculates the crisp output as the weighted average of the centroids of all output membership functions.

$$O_o = f_o^5\left(\text{net}_o^5\right) = \text{net}_o^5$$

and

$$\text{net}_o^5 = \frac{\left(\sum_m O_m^4 \times a_{Cm} \times b_{Cm}\right)}{\sum_m \left(O_m^4 \times b_{Cm}\right)}$$

where a_{Cm} and b_{Cm} for $m = 1, \ldots, 5$ are the centers and widths of the output fuzzy sets, respectively. The values for the b_{Cm}'s were chosen to be unity. This scaled output corresponds to the control signal (percent duty cycle) to be applied to maintain the output voltage at a constant value.

36.12.2 Learning Algorithm

The only weights that are trained are those between layer 3 and layer 4 of Fig. 36.30. The back-propagation network is used to train the weights of this layer. The weights of the neural

network were trained offline before they were used in the experimental setup. The learning algorithm used can be described in the following steps:

Step 1: Calculate the error for the change in the control signal (duty cycle) based on the type of the converter.

$$E_o = T_o - O_o^5$$

where E_o, T_o, and O_o^5 are the output error, the target control signal, and the actual control signal, respectively.

Step 2: Calculate the error gradient.

$$\delta_m = E_o \times f'\left(O_1^4, \ldots, O_m^4\right)$$
$$\Rightarrow \delta_m = \left(T_o - O_o^5\right) \times f'\left(O_1^4, \ldots, O_m^4\right)$$

where

$$f\left(O_1^4, \ldots, O_m^4\right) = \frac{\sum_{j=1}^{m} O_j^4 \times a_{Cj}}{\sum_{j=1}^{m} O_j^4}$$

and the partial derivative of f with respect to O_m^4 is given by

$$f_{O_m^4}{}'\left(O_1^4, \ldots, O_m^4\right) = \frac{\sum_{\substack{j=1 \\ j \neq m}}^{m-1} O_j^4 \times \left(a_{Cm} - a_{Cj}\right)}{\left(\sum_{j=1}^{m} O_j^4\right)^2}$$

where a_{Ci} for $i = 1, \ldots, 5$ are the centers of the output fuzzy sets and O_j^4 is the firing strength from node j in layer 4.

Step 3: Calculate the weight correction

$$\Delta w_{km} = \eta \times \delta_m \times O_k^3$$

to increase the learning rate, the Sejnowski-Rosenberg updating mechanism was used, which takes into account the effect of past weight changes on the current direction of the movement in the weight space. This is given by

$$\Delta w_{km}(t) = \eta \times (1 - \alpha) \times \delta_m \times O_m^3 + \alpha \times \Delta w_{km}(t-1)$$

where α is a smoothing coefficient in the range of 0–1.0 and η is the learning rate.

Step 4: Update the weights.

$$w_{km}(t+1) = w_{km}(t) + \Delta w_{km}(t)$$

where t is the iteration number

The weights linking the rule layer (layer 3) and the output membership layer (layer 4) are trained to capture the system dynamics and therefore minimize the ripples around the operating point. The training results of the link weights are shown in Figs. 36.32 and 36.33.

In the initialization of the weights, wt5 and wt6 in Fig. 36.32 were set to a very small number of 0.001 with the initial assumption that those weights are almost redundant before the training begins. However, the neurofuzzy system was capable of correcting those assumptions. Weight wt5 finally converges to a positive value

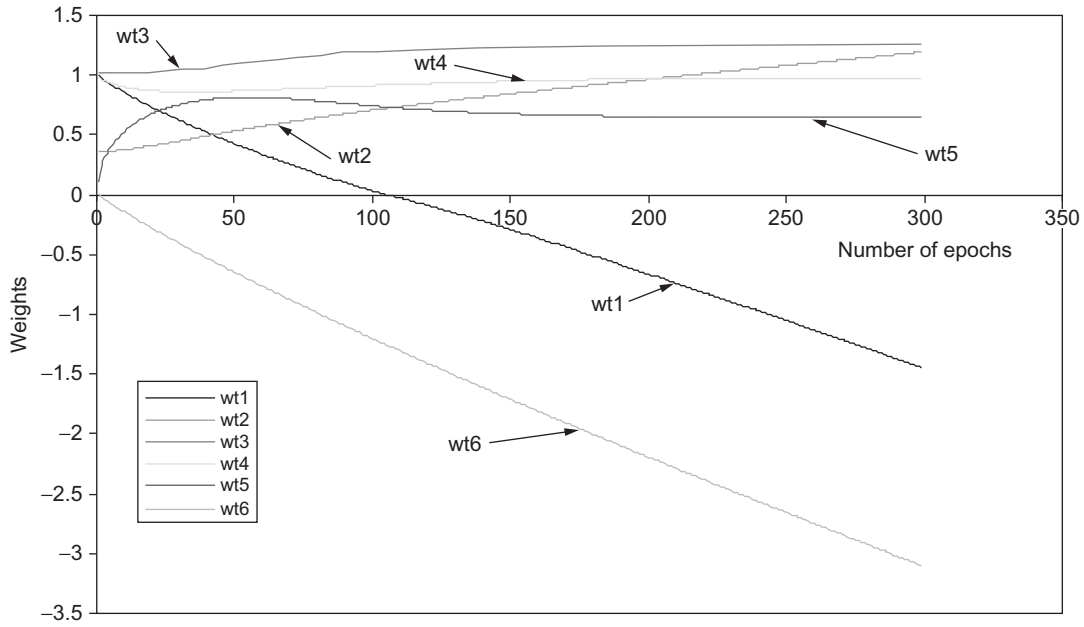

FIG. 36.32 Weight adaptations for the first set of six weights.

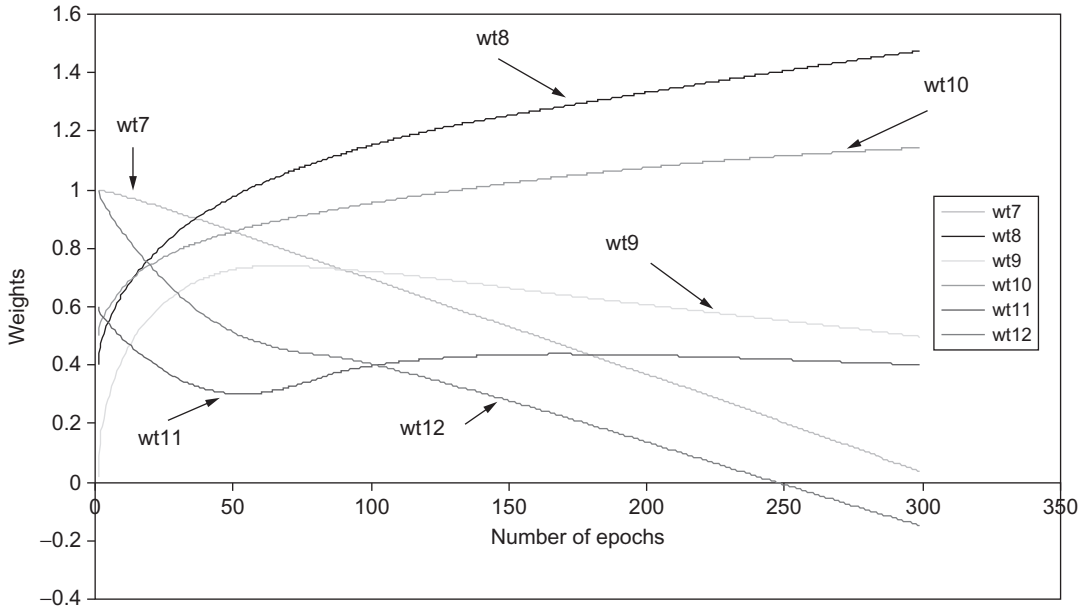

FIG. 36.33 Weight adaptations for the second set of six weights.

that indicates an excitatory rule weight, while wt6 converges to a negative number that is an inhibitory rule weight. Some of the weights change sign during the training process. Weight wt1 was initially set at a positive value but converges to a negative value that makes that rule weight inhibitory.

36.13 Summary

The presence of adaptive control via the EKF learning of the FNN control laws marks an improvement over the FL design. The motor drive over time is subject to experience degradation of mechanical parts or even electric characteristics, and the ability to automatically adapt the control laws to these changes is a feature that a nonadaptive fuzzy controller does not have. A genetic-based FPID controller and its integration with a classical PID in a global control scheme have been developed. Experimental results have shown excellent tracking performance of the proposed hybrid FPID controller and have convincingly demonstrated the usefulness of the FPID controller in high-performance drives with uncertainties. For the H-infinity-based controller, test results have shown that the proposed hybrid controller achieved good tracking performance and stable control, under loading conditions for a number of desired reference trajectories. The ability of the hybrid controller to achieve the tracking process with a high degree of accuracy, even in the presence of random disturbance, was also demonstrated, while the fuzzy application to the DC-DC converter topology showed considerable control performance over a wide range of operating conditions.

Acknowledgments

We will like to acknowledge Dr. Ahmed Rubaai at Howard University, Dr. Paul Young of *RadiantBlue Technologies* and Dr. Marcel J. Castro-Sitiriche at the *Electrical and Computer Engineering Department,* of the *University of Puerto Rico at Mayagüez,* for their contribution to the third edition of this chapter.

37.1 Introduction

In classical control systems, knowledge of the controlled system (plant) is required in the form of a set of algebraic and differential equations, which analytically relate inputs and outputs. However, these models can become complex, rely on many assumptions, may contain parameters that are difficult to measure, or may change significantly during operation as in the case of the rotor-flux-oriented control (RFOC) induction motor drive. Classical control theory suffers from some limitations due to the assumptions made for the control system such as linearity and time invariance. These problems can be overcome by using artificial intelligence-based control techniques, and these techniques can be used, even when the analytic models are not known. Such control systems can also be less sensitive to parameter variation than classical control systems.

The main advantages of using artificial intelligence-based controllers and estimators are the following:

- Their design does not require a mathematical model of the plant.
- They can lead to improved performance, when properly tuned.
- They can be designed exclusively on the basis of linguistic information available from experts or by using clustering or other techniques.
- They may require less tuning effort than conventional controllers.
- They may be designed on the basis of data from a real system or a plant in the absence of necessary expert knowledge.
- They can be designed using a combination of linguistic- and response-based information.

Generally, the following two types of intelligence-based systems are used for estimation and control of drives, namely:

(a) Artificial neural networks (ANNs)
(b) Fuzzy-logic systems (FLSs)

In different applications in power electronics and electric drives, there are occasions where an output y has to be estimated for an input x. This is generally accomplished with the help of mathematical equations of the system under consideration. Sometimes, it may not be possible to have an accurate mathematical model, or there is no conventional model at all that can be used. In these circumstances, model-free estimators

Copyright © 2018 Elsevier Inc. All rights reserved.
http://dx.doi.org/10.1016/B978-0-12-811407-0.00041-6

are required that can be used either ANNs or fuzzy-logic systems. A mathematical model-based system can operate smoothly when there is no noise in the inputs, but they might fail when the input has noise or if the inputs themselves are uncertain. Also, depending on the complexity of the mathematical model, the computation times can be excessive leading to difficulties for practical implementation.

A conventional function approximator, a neural function estimator, and how these estimators are arrived at are discussed briefly in Section 37.2. It will be shown how neural estimators are used in the estimation of speed, flux, torque, etc. for an induction motor. Some of these estimators are briefly reviewed in Section 37.3. Also, the ANNs have been used for identification and control of stator current in induction motor drives, and these are briefly described in Section 37.4. In addition to their applications to motor drives, they are also used in control of power converters. Some of these applications are discussed in Section 37.5.

37.2 Conventional and Neural Function Approximators

37.2.1 Conventional Approximator

A conventional function approximator should give a good prediction of output data, when a system is presented with a new input data. A conventional function approximator uses a mathematical model of the system as shown in Fig. 37.1A. Sometimes, it is not possible to have an accurate mathematical model of the system, in such a case; mathematical model-free approximators are required, as shown in Fig. 37.1B. A conventional function approximator can easily be replaced by a neural-network-based function approximator.

37.2.2 Neural Function Approximator

The function $y = f(x_1, x_2, \ldots, x_n)$ is the function to be approximated, and $x_1, x_2, x_3, \ldots x_n$ are the n variables (n inputs), and the approximator uses the sum of nonlinear functions $g_1, g_2, g_3, g_4, \ldots, g_i$, where each of the g is nonlinear function of a single variable. Thus,

$$y = f(x_1, x_2, \ldots, x_n) = g_1 + g_2 + g_3 + \cdots + g_{2n+1} = \sum_{i=1}^{2n+1} g_i \tag{37.1}$$

where g_i is a real and continuous nonlinear function that depends only on a single-variable z_i. The output y can also be represented as

$$y = \sum_{j=1}^{n} w_{Mj} x_j = w_{M1} x_1 + w_{M2} x_2 + \cdots w_{Mn} x_n \tag{37.2}$$

These equations can be represented by a network shown in Fig. 37.2. There are n input nodes in the input layer and M hidden nodes in the hidden layer.

Fig. 37.3 shows the schematic diagram of a neural approximation, and Fig. 37.4 shows the technique of its training. The error (e) between the desired nonlinear function (y) and the nonlinear function ($\hat{y}$) obtained by the neural estimator is the input to the learning algorithm for the artificial neural estimator. This type of learning is known as back propagation.

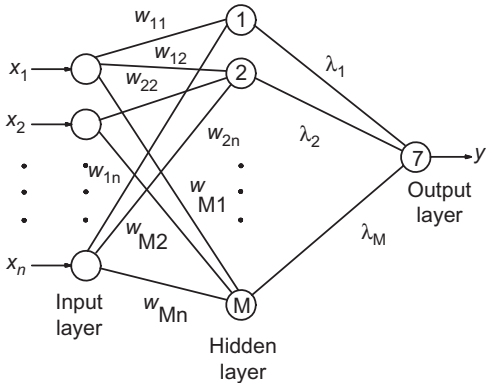

FIG. 37.2 Artificial neural network to generate the required function.

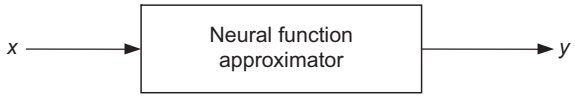

FIG. 37.3 Schematic of a neural function approximator.

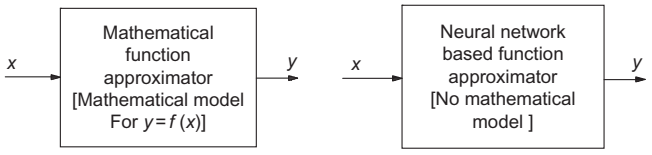

FIG. 37.1 Conventional and neural-network-based function approximators.

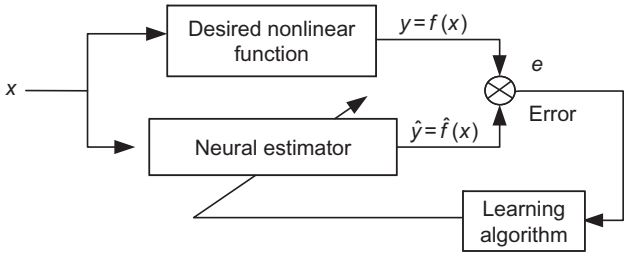

FIG. 37.4 Training of a neural function approximator.

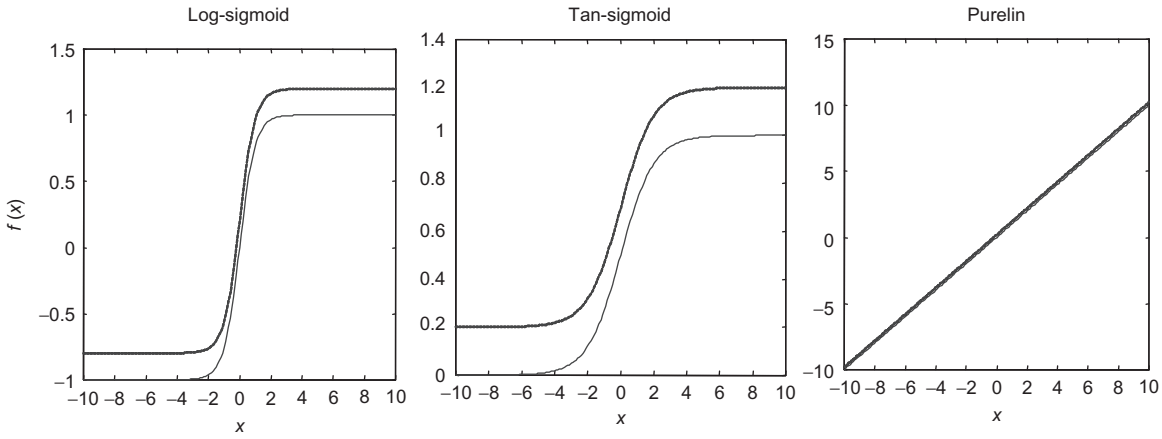

FIG. 37.5 Log-sigmoid, tan-sigmoid, and purelin activation functions.

The output of a single neuron can be represented as

$$a_i = f_i\left\{\sum_{j=1}^{n} w_{ij}x_j(t) + b_i\right\} \tag{37.3}$$

where f_i is the activation function and b_i is the bias. Fig. 37.5 shows a number of possible activation functions in a neuron. The simplest of all is the linear activation function, where the output varies linearly with the input but saturates at ± 1 as shown with a large magnitude of the input. The most commonly used activation functions are nonlinear, continuously varying types between two asymptotic values 0 and 1 or -1 and $+1$. These are, respectively, the sigmoidal function also called log-sigmoid and the hyperbolic tan function also called tan-sigmoid.

The learning process of an ANN is based on the training process. One of the most widely used training techniques is the error back-propagation technique, a scheme that is illustrated in Fig. 37.4. When this technique is employed, the ANN is provided with input and output training data, and the ANN configures its weights. The training process is then followed by supplying with the real input data, and the ANN then produces the required output data.

The total network error (sum of squared errors) can be expressed as

$$E = \frac{1}{2}\sum_{k=1}^{P}\sum_{j=1}^{K}\left(d_{kj} - o_{kj}\right)^2 \tag{37.4}$$

where E is the total error, P is the number of patterns in the training data, k is the number of outputs in the network, d_{kj} is the target (desired) output for the pattern K, and $o_{kj}\left(=y_{kj}\right)$ is the jth output of the kth pattern. The minimization of the error can be arranged with different algorithms such as the gradient descent with momentum, Levenberg-Marquardt, reduced memory Levenberg-Marquardt, and Bayesian regularization.

37.3 ANN-Based Estimation in Induction Motor Drives

Artificial neural networks have found widespread use in function approximation. It has been shown that, theoretically, a three-layer ANN can approximate arbitrarily closely, any nonlinear function, provided that it is nonsingular. Some of the ANN-based estimators reported in the literature for rotor flux, torque, and rotor speed of induction motor drive are discussed in the following section.

37.3.1 Speed Estimation

In general, steady-state and transient analysis of induction motors is done using space-vector theory, with the mathematical model having the parameters of the motor. To estimate the various machine quantities such as stator- and rotor-flux linkages, rotor speed, and electromagnetic torque, the above mathematical model is normally used. However, these machine quantities could be estimated without the mathematical model by using an ANN. Here, no assumptions have to be made about any type of nonlinearity.

As an example, the rotor speed of an induction motor can be estimated from the direct and quadrature-axis stator voltages and currents in the stationary reference frame, as shown in Fig. 37.6. A three-layer feedforward neural network structure with $8 \times 7 \times 1$ (eight input, seven hidden, and one output) is used in this case. The input nodes were selected as equal to the number of input signals and the output nodes as equal to the number of output signals. The number of hidden layer neurons is generally taken as the mean of the input and output nodes. In this speed estimator ANN, seven hidden neurons were selected.

The results of an experiment conducted on a 1.1 kW, 415 V, 3 phase, 4 pole, 50 Hz induction motor is explained in this section. In order to investigate the case of speed estimation using ANN, a rotor-flux-oriented induction motor drive was set up in

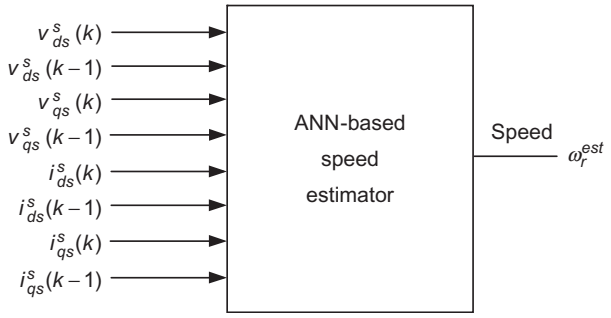

FIG. 37.6 ANN-based speed estimator for induction motor.

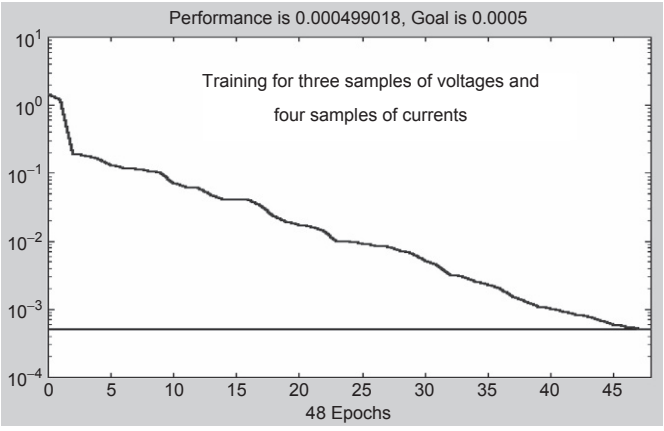

FIG. 37.7 The error plot of $8 \times 7 \times 1$ network training for speed estimation.

the laboratory, where the speed reference was changed in steps of 100 rpm and reversed every time the speed reached 1000 rpm. The load torque on the motor was kept constant at its full load rating. The stator voltages, stator currents, and rotor speed were measured for 5 s, and a data file was generated. The neural network was then trained using the *trainlm* algorithm with this data file. The training of the neural network converged after 48 epochs, and the error plot for this network training is shown in Fig. 37.7. The estimated speed was predicted with the trained neural network, and the result is shown in Fig. 37.8.

The noisy data in the plot are the estimated speed, and the continuous line is the speed measured with the encoder. The speed estimation was found to fail for speeds <100 rpm. If the trained neural network has to predict the speed under the complete range of operation of the drive, the data for training the neural network also have to be taken for the whole range. From this example investigated, it was found that the off-line training of the neural network could not produce satisfactory results, and it can be concluded that these off-line methods are not most suitable for these applications.

Artificial neural networks were also used for the estimation of the rotor speed of an induction motor together with the help of induction motor dynamic model. Though the technique gives a fairly good estimate of the speed, this technique lies more in the adaptive control area than in neural networks. The speed is not obtained at the output of a neural network; instead, the magnitude of one of the weights corresponds to the speed. The four quadrant operation of the drive was not possible for speeds <500 rpm. The motor was not able to follow the speed reference during the reversal for speeds <500 rpm. The drive worked satisfactorily for speeds above 500 rpm. Even though this method does not fall into a true neural network estimator, the results achieved with this type of implementation were very good except for lower speeds.

Alternately, the estimated speed can be made available at the output of a neural network as shown in Fig. 37.9. This speed estimator used a three-layer neural network with five input nodes, one hidden layer, and one output layer to give the estimated speed $\hat{\omega}_r(k)$ as shown in Fig. 37.9. The three inputs to the ANN are a reference model flux λ_r^*, an adjustable model flux $\hat{\lambda}_r$, and $\hat{\omega}_r(k-1)$, the time delayed estimated speed. The multilayer and recurrent structure of the network makes it robust to parameter variations and system noise. The main advantage of their ANN structure lies in the fact that they have used a recurrent structure that is robust to parameter variations and system noise. These authors were able to achieve a speed control error of 0.6% for a reference speed of 10 rpm. The speed control error dropped to 0.584% for a reference speed of 1000 rpm.

37.3.2 Flux and Torque Estimation

The same principle as described in Section 37.3.1 can also be extended for simultaneous estimation of more quantities such as torque and stator flux. When more quantities or variables have to be estimated, the complex ANN has to implement a complex nonlinear mapping.

The four feedback signals required for a direct field-oriented induction motor drive can be estimated using ANNs. A $4 \times 20 \times 4$ multilayer network has been used for the estimation of the rotor-flux magnitude, the electromagnetic torque, and the sine/cosine of the rotor-flux angle. It has been demonstrated both by modeling and experimental results that the above estimated quantities were almost equal to the same quantities computed by a DSP-based estimator. Both the estimated torque and rotor-flux signals using neural network were found to have higher ripple content compared with the DSP-based estimated quantities. It could be concluded that a properly trained ANN could totally eliminate the machine model equations as evident from the results reported.

In another application, an ANN with $5 \times 8 \times 8 \times 2$ structure has been used to estimate the stator flux using the measured induction motor stator variable quantities. After successful training, the ANN was used in a direct field-oriented controlled drive. The rotor flux is computed from the stator flux estimate provided by the ANN and the stator current. This particular

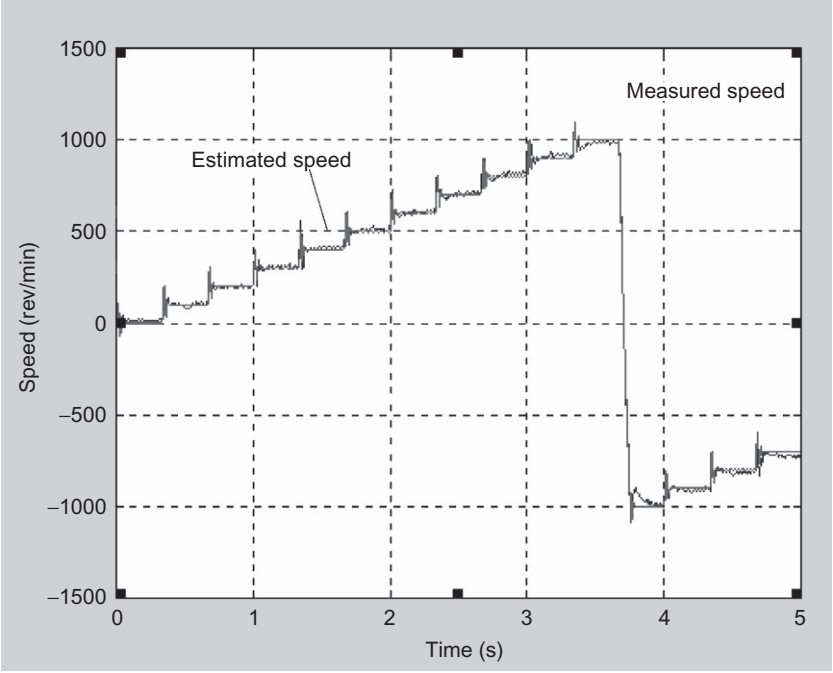

FIG. 37.8 Measured speed versus estimated speed with ANN for induction motor.

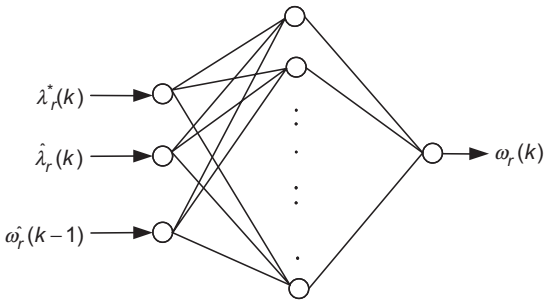

FIG. 37.9 Structure of the neural network for the induction motor speed estimation.

implementation also included an ANN-based decoupler which was used for the indirect field-oriented (IFO) drive. An ANN with a structure of $2 \times 8 \times 8 \times 1$ was used for implementing the mapping between the flux and torque references and the stator current references. The estimated rotor flux using an ANN and a conventional FOC controller was shown to be equal. These authors have used experimental data for the ANN training, and thus, the effect of motor parameters was reduced. The authors were unable to use these estimated fluxes for controlling the induction motor in the experiment. The structure of the ANN used for this estimation is only that of a static ANN. It is preferable to have a dynamic neural network for this purpose.

37.3.3 Rotor Resistance Identification Using ANN

37.3.3.1 Off-Line Trained ANN

The artificial neural network can also be used for the rotor time constant adaptation in indirect field-oriented controlled drives. One of the implementation reported in the literature is shown in Fig. 37.10. There are five inputs to the T_r estimator, namely $v_{ds}^s, v_{qs}^s, i_{ds}^s, i_{qs}^s, \omega_r$. The training signals are generated with step variations in rotor resistance for different torque reference T_e^* and flux command λ_r^*, and the final network is connected in the IFO controller as shown in Fig. 37.10. The rotor time constant was tracked by a proportional integral (PI) regulator that corrects any errors in the slip calculator. The output of this regulator is summed with that of the slip calculator, and the result constitutes the new slip command that is required to compensate for the rotor time constant variation. The major drawback of this scheme is that the final neural network is only an off-line trained neural network with a limited data file obtained from the modeling.

37.3.3.2 On-Line Trained ANN

The limitations of off-line trained ANN are overcome by using an online trained ANN configuration. The method discussed in this section has used an online trained ANN for adaptation of R_r of an induction motor in the RFOC induction motor drive. The error between the desired state variable of an induction

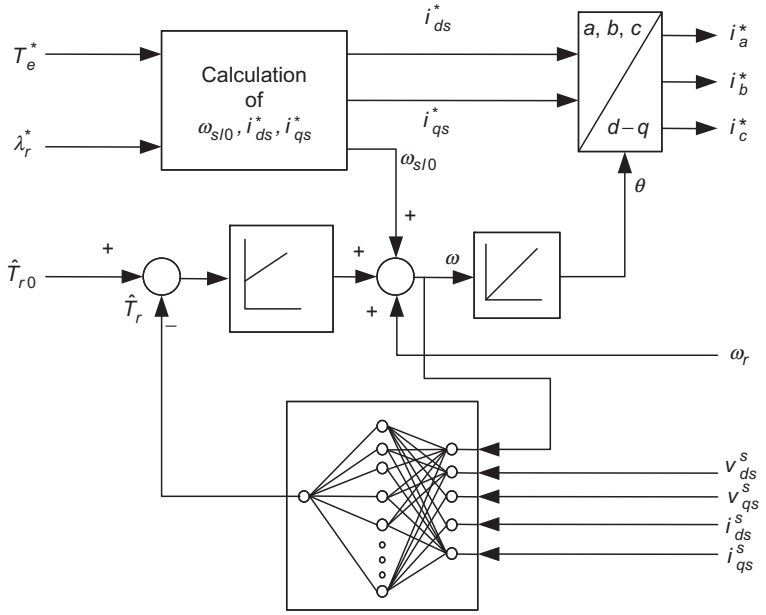

FIG. 37.10 Principle of rotor time constant adaptation.

motor and the actual state variable of a neural model is back propagated to adjust the weights of the neural model, so that the actual state variable tracks the desired value.

The principle of online estimation of rotor resistance (R_r) with multilayer feedforward artificial neural networks using online training has been described in "Multilayer feedforward ANN" section. This technique was then investigated with the help of modeling studies with a 1.1 kW squirrel-cage induction motor (SCIM), described in "Rotor resistance estimation for RFOC using ANN" section. The modeling results are presented in "Modeling results" section. In order to validate the modeling studies, modeling results were compared with those from an experimental setup with a SCIM under RFOC. These experimental results are presented in "Experimental results" section.

Multilayer feedforward ANN

Multilayer feedforward neural networks are regarded as universal approximations and have the capability to acquire nonlinear input-output relationships of a system by learning via the back-propagation algorithm. It should be possible that a simple two-layer feedforward neural network trained by the back-propagation technique can be employed in the rotor resistance identification. The modified technique using ANN proposed in this section can be implemented in real time so that the resistance updates are available instantaneously, and there is no convergence issues related to the learning algorithm. The two-layered neural network based on a back-propagation technique is used to estimate the rotor resistance. Two models of the state variable estimation are used; one provides the actual induction motor output, and the other one gives the neural model output. The total error between the desired and actual state variables is then back propagated as shown in Fig. 37.11, to adjust the weights of the neural model, so that the output of this model coincides with the actual output. When the training is completed, the weights of the neural network should correspond to the parameters in the actual motor.

Rotor resistance estimation for RFOC using ANN

The basic structure of an adaptive scheme described by Fig. 37.11 is extended for rotor resistance estimation of an induction motor as illustrated in Fig. 37.12. Two independent observers are used to estimate the rotor-flux vectors of the induction motor. If the rotor-flux linkages are estimated using the stator voltages and stator currents, they are referred to as *voltage model*, and if the rotor-flux linkages are estimated using the stator currents and rotor speed, they are referred to as *current model*.

The stator flux linkages based on the neural network model in Fig. 37.12 can be represented using Eq. (37.5), which is derived from the sample data models of the combined voltage and current model equations of the induction motor:

$$\overleftarrow{\lambda_r^{s^{nm}}}(k) = W_1X_1 + W_2X_2 + W_3X_3 \tag{37.5}$$

The neural network model represented by Eq. (37.5) is shown in Fig. 37.13, where W_1, W_2, and W_3 represent the weights of the networks and X_1, X_2, and X_3 are the three inputs to the network. If the network shown in Fig. 37.13 has to be used to estimate R_r, where W_2 is already known, then W_1 and W_3 need to be updated.

The weights of the network, W_1 and W_3, are found from training, so as to minimize the cumulative error function E_1:

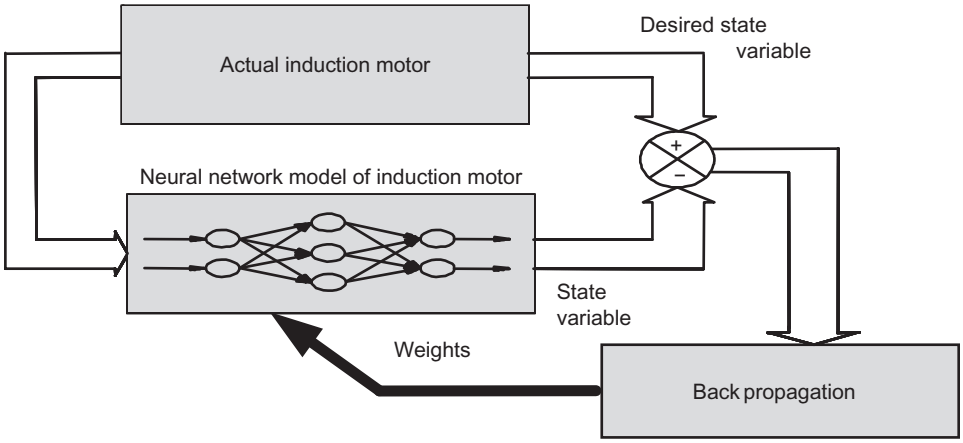

FIG. 37.11 Block diagram of rotor resistance identification using neural networks.

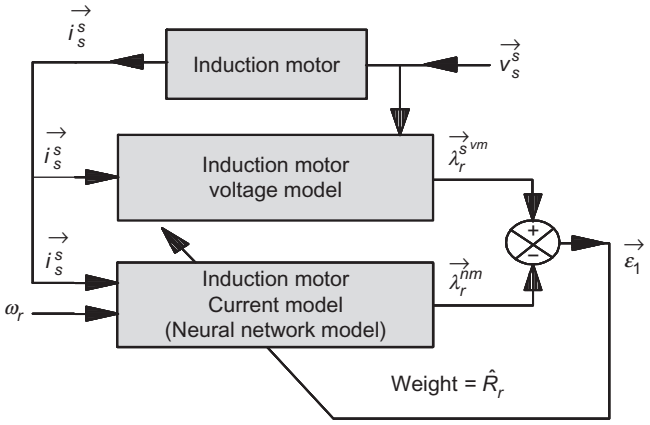

FIG. 37.12 Structure of the neural network system for R_r estimation.

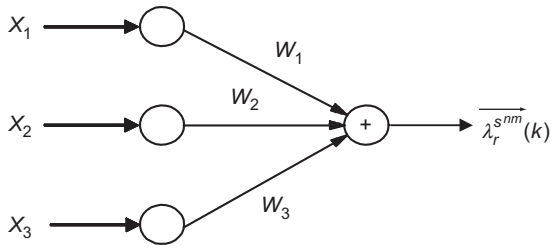

FIG. 37.13 Two-layered neural network model for rotor-flux linkage estimation.

$$E_1 = \frac{1}{2}\vec{\varepsilon}_1^{\,2}(k) = \frac{1}{2}\left\{\overleftarrow{\lambda_r^{s^{vm}}}(k) - \overleftarrow{\lambda_r^{s^{im}}}(k)\right\}^2 \tag{37.6}$$

The weight of the neural network W_1 has to be adjusted using generalized delta rule.

To accelerate the convergence of the error back-propagation learning algorithm, the current weight adjustment has to be supplemented with a fraction of the most recent weight adjustment, as indicated in Eq. (37.7):

$$W_1(k) = W_1(k-1) - \eta_1 \vec{\delta} X_2 + \alpha_1 \Delta W_1(k-1) \tag{37.7}$$

where α_1 is a user-selected positive momentum constant and η_1 is the training coefficient.

The rotor resistance R_r can now be calculated from W_3 from Eq. (37.8) as follows:

$$\hat{R}_r = \frac{L_r W_3}{L_m T_s} \tag{37.8}$$

Modeling results

A schematic diagram showing the implementation of a rotor resistance estimator in RFOC controller for induction motor is shown in Fig. 37.14. The stator voltages and currents are measured to estimate the rotor-flux linkages using the voltage model as shown in this figure. The inputs to the rotor resistance estimator (RRE) are the stator currents, the rotor-flux linkages $\lambda_{dr}^{s^{vm}}$, $\lambda_{qr}^{s^{vm}}$, and the rotor speed ω_r. The estimated rotor resistance $\hat{R}_r$ will then be used in the RFOC controllers for the flux model. The response of the drive together with the rotor resistance estimator OFF is shown in Fig. 37.15 for an abrupt change in R_r of motor, from 6.03 to 8.5 Ω at 0.8 s. The possible changes in the estimated motor torque T_e, the rotor-flux linkage λ_{rd} with this estimator were noted.

Subsequently, the results of the drive were looked at with RRE ON, so that the rotor resistance in the controller R_r' was updated with the estimated rotor resistance $\hat{R}_r$ as shown in Fig. 37.16. The estimated rotor resistance $\hat{R}_r$ has converged to the rotor resistance of the motor R_r within 50 ms.

The response of the drive system with the RRE using ANN is also shown for a practical profile in load torque, speed, and change in R_r. The R_r was increased from 6.03 to 8.5 Ω over a period of 8 s, and the torque and rotor-flux linkage are shown in Fig. 37.17 when the RRE is OFF. For rapid reversals of the drive and variations in load torque, there are significant errors in rotor-flux linkages and thus errors in estimated torques.

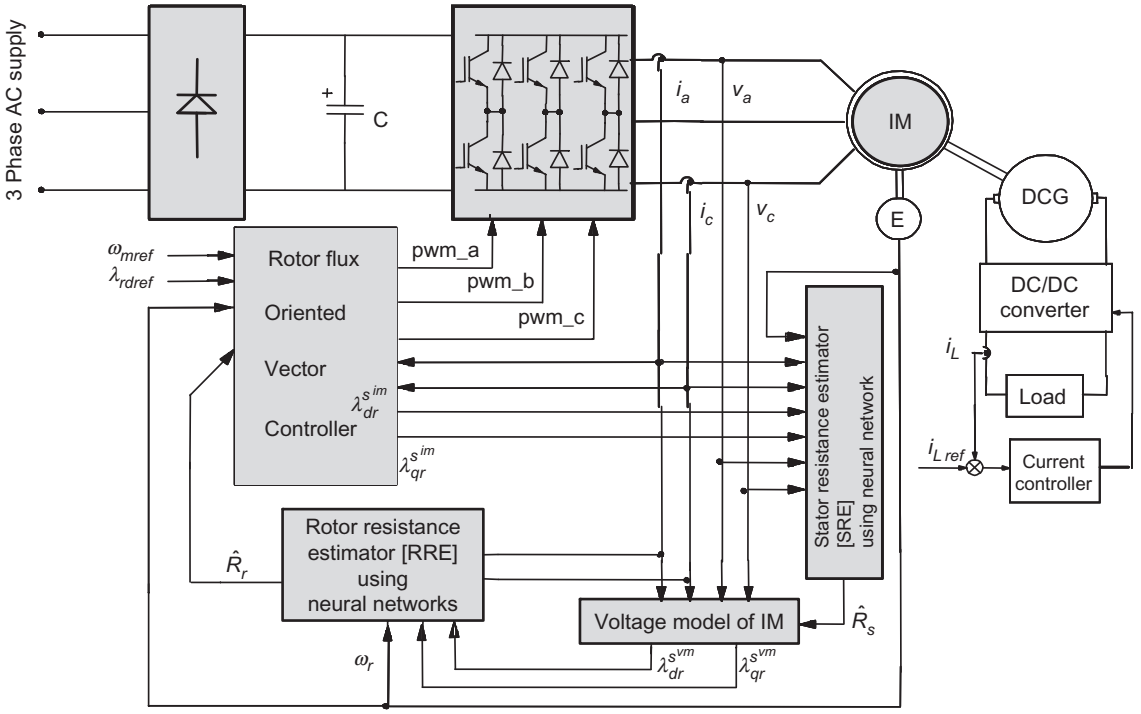

FIG. 37.14 Block diagram of the RFOC induction motor drive with online rotor and stator resistance tracking using ANN.

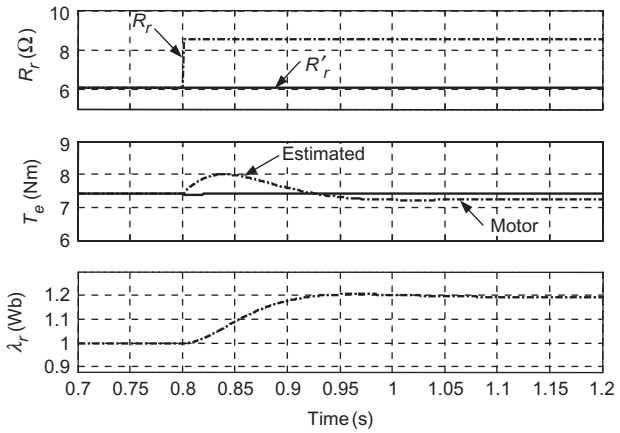

FIG. 37.15 Effect of rotor resistance variation without rotor resistance estimator for 40% step change in R_r —modeling results.

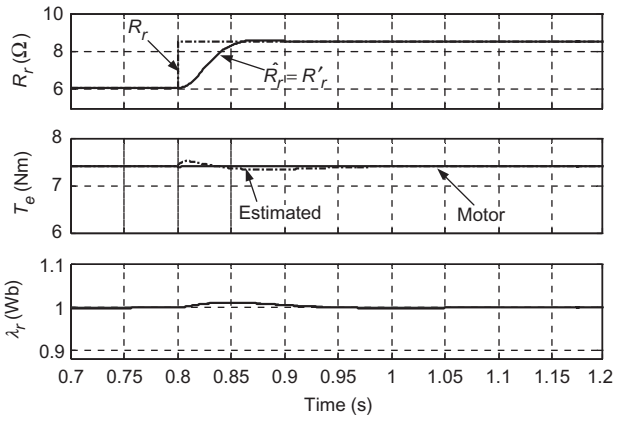

FIG. 37.16 Effect of rotor resistance variation with rotor resistance estimator using ANN for 40% step change in R_r —modeling results.

Subsequently, the RRE block was switched ON, and it can be observed that the rotor resistance estimator was tracking very well even during the worst dynamics in the motor speed and load torques as shown in Fig. 37.18. The estimated rotor resistance $\hat{R}_r$ tracked the actual rotor resistance of the motor R_r throughout except that there was some small error during the reversal of the motor. The rotor-flux linkage λ_{rd} was found to remain constant at 1.0 Wb during this transient condition. The current i_{qs} also remained constant as the torque is now perfectly decoupled.

Experimental results

The practical implementation of the above rotor resistance estimation was found functioning very well in the experimental drive setup. The results of the R_r estimation obtained from the experiment is shown in Fig. 37.19 taken from a heat-run test conducted on an induction motor. As the RRE calculated, the rotor resistance using variables in stationary reference frame, the d-axis rotor-flux linkages of the current model (λ_{dr}^{im}), the voltage model (λ_{dr}^{vm}), and the neural model (λ_{dr}^{nm}), taken at the end of heat run, is also recorded as shown in Fig. 37.20.

37.3.4 Stator Resistance Estimation Using ANN

In this section, the capability of a neural network has been deployed to have online estimator for stator resistance in an RFOC induction motor drive. The stator resistance observer was realized with a recurrent neural network with feedback loops trained using the standard back-propagation learning algorithm. Such architecture with recurrent neural network is known to be a more desirable approach, and the implementation reported in this section confirms this.

The d-axis stator current in the stationary reference frame in the discrete form can be represented using the voltage and current model equations of the induction motor:

$$i_{ds}^{s*}(k) = W_4 i_{ds}^{s*}(k-1) + W_5 \lambda_{dr}^{s\,im}(k-1) + W_6 \omega_r \lambda_{qr}^{s\,im}(k-1) + W_7 v_{ds}^{s}(k-1) \tag{37.9}$$

where, $W_4 = 1 - \frac{T_s}{\sigma L_s}\frac{L_m^2}{L_r T_r} - \frac{T_s}{\sigma L_s} R_s$; $W_5 = \frac{T_s}{\sigma L_s}\frac{L_m}{L_r T_r}$

$W_6 = \frac{T_s}{\sigma L_s}\frac{L_m}{L_r}$; $W_7 = \frac{T_s}{\sigma L_s}$

The weights W_5, W_6, and W_7 are calculated using the induction motor parameters, the rotor speed ω_r, and the sampling interval used in the estimator T_s.

The relationship between stator current and stator resistance is nonlinear that could be easily mapped using a neural network.

When this Eq. (37.9) is represented graphically, it resembles a recurrent neural network as shown in Fig. 37.21. The standard back-propagation learning rule can then be employed for training this neural network. The weight W_4 is the result of training so as to minimize the cumulative error function E_2:

$$E_2 = \frac{1}{2}\vec{e}_2^{\,2}(k) = \frac{1}{2}\left\{ i_{ds}^{s}(k) - i_{ds}^{s*}(k) \right\}^2 \tag{37.10}$$

To accelerate the convergence of the error back-propagation learning algorithm, the current weight adjustment is supplemented with a fraction of the most recent weight adjustment, as indicated in Eq. (37.11):

$$W_4(k) = W_4(k-1) + \eta_2 \Delta W_4(k) + \alpha_2 \Delta W_4(k-1) \tag{37.11}$$

where η_2 is the training coefficient and α_2 is a user-selected positive momentum constant.

Following a similar procedure, the q-axis stator current of the induction motor can be estimated using the discrete form as shown in Eq. (37.12):

$$i_{qs}^{s*}(k) = W_4 i_{qs}^{s*}(k-1) + W_5 \lambda_{qr}^{s\,im}(k-1) - \omega_r W_6 \lambda_{dr}^{s\,im}(k-1) + W_7 v_{qs}^{s}(k-1) \tag{37.12}$$

Equation (37.12) can be represented by a neural network as shown in Fig. 37.22. The weight W_4 is updated with the training based on Eq. (37.12).

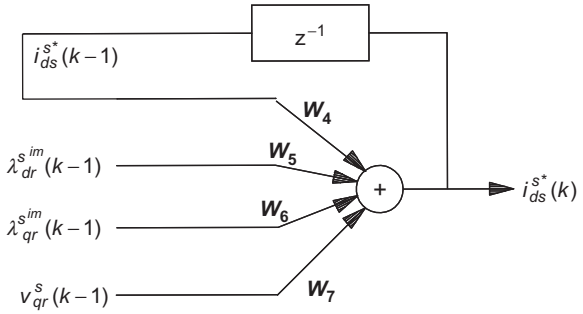

FIG. 37.21 d-Axis stator current estimation using recurrent neural network based on Eq. (37.9).

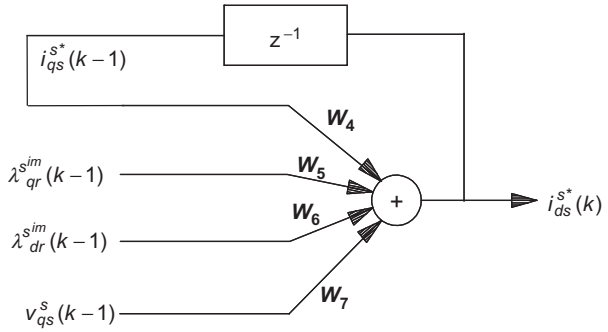

FIG. 37.22 q-Axis stator current estimation using recurrent neural network based on Eq. (37.12).

The stator resistance $\hat{R}_s$ of the induction motor can now be calculated using Eq. (37.13) as follows:

$$\hat{R}_s = \left\{1 - W_4 - \frac{T_s}{\sigma L_s}\frac{L_m^2 \hat{R}_r}{L_r^2}\right\}\frac{\sigma L_s}{T_s} \tag{37.13}$$

The stator resistance of an induction motor can be thus estimated from the stator current using the neural network system as indicated in Fig. 37.23.

37.3.4.1 Modeling Results of Stator Resistance Estimation Using ANN

The block diagram of a rotor-flux-oriented induction motor drive together with stator resistance identification is already shown in Fig. 37.14, where the stator resistance estimation is implemented by the stator resistance estimator (SRE) block.

The stator resistance estimation results are as shown in Fig. 37.24. It has three results (1) without both rotor and stator resistance estimators, (2) with only rotor resistance estimation, and (3) with both rotor and stator resistance estimations. As shown in the figure, both R_r and R_s were increased abruptly by 40% at 1.5 s. It can be seen that the estimated stator resistance $\hat{R}_s$ converges to $\hat{R}_s$ within 200 ms. It can be noted from this figure that the convergence of the stator resistance estimation is not affected by the convergence of the rotor resistance estimator.

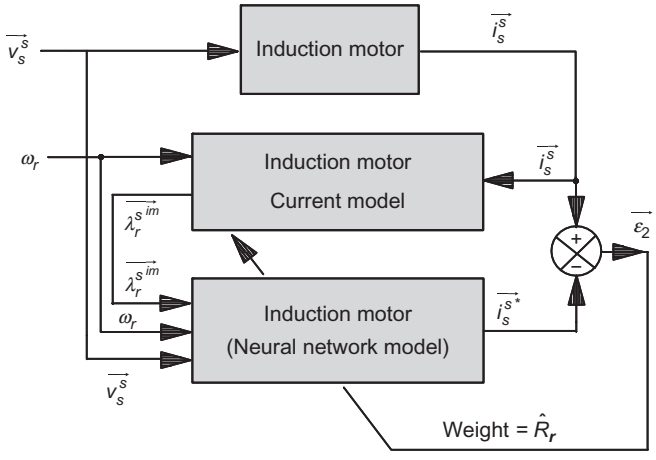

FIG. 37.23 Block diagram of R_s estimation using artificial neural network.

37.3.4.2 Experimental Results of Stator Resistance Estimation Using ANN

The stator resistance estimation algorithm was tested together with the rotor-flux-oriented induction motor drive of Fig. 37.14 implemented in the laboratory. To test the stator resistance estimation, an additional 3.4 Ω per phase was added in series with the induction motor stator, with the motor running at 1000 rev/min and with a load torque of 7.4 Nm.

The estimated stator resistance together with the actual stator resistance is shown in Fig. 37.25. The estimated stator resistance converges to 9.4 Ω within <200 ms.

Fig. 37.26 shows both the measured d-axis stator current and the one estimated by the neural network model. The neural network model output $i_{ds}^{s*}(k)$ follows the measured values $i_{ds}^{s}(k)$, due to the online training of the neural network.

37.4 ANN-Based Controls in Motor Drives

37.4.1 Induction Motor Current Control

Another application of ANN is to identify and control the stator current of an induction motor. In one study, Burton et al. have used a current control strategy outlined by Wishart and Harley to train an ANN to control the induction motor stator currents. They have used a training algorithm named random weight change (RWC) that is reported to be slightly faster than back propagation. In RWC algorithm, the weights are perturbed by a fixed step size and a random sign. This is done for fixed number of trials, and after each trial, the error with the desired output is computed. Finally, the set of weight changes that result in the least error are chosen, and the whole process is repeated until convergence is reached. The modeling results reported in this scheme was excellent. Later, Burton *et al.* presented their practical implementation of this proposed stator current controller with a transputer controller card.

37.4.2 Induction Motor Control

Narendra and Parthasarathy proposed methods for identification and control of dynamic systems using ANNs. Wishart and Harley used the above basic principles to identify and control induction machines. A block diagram of the control scheme is shown in Fig. 37.27. For the induction motor, the nonlinear autoregressive moving average with exogenous input (NARMAX) model for the stationary frame stator current is derived and used for the identification of electromagnetic model. In its

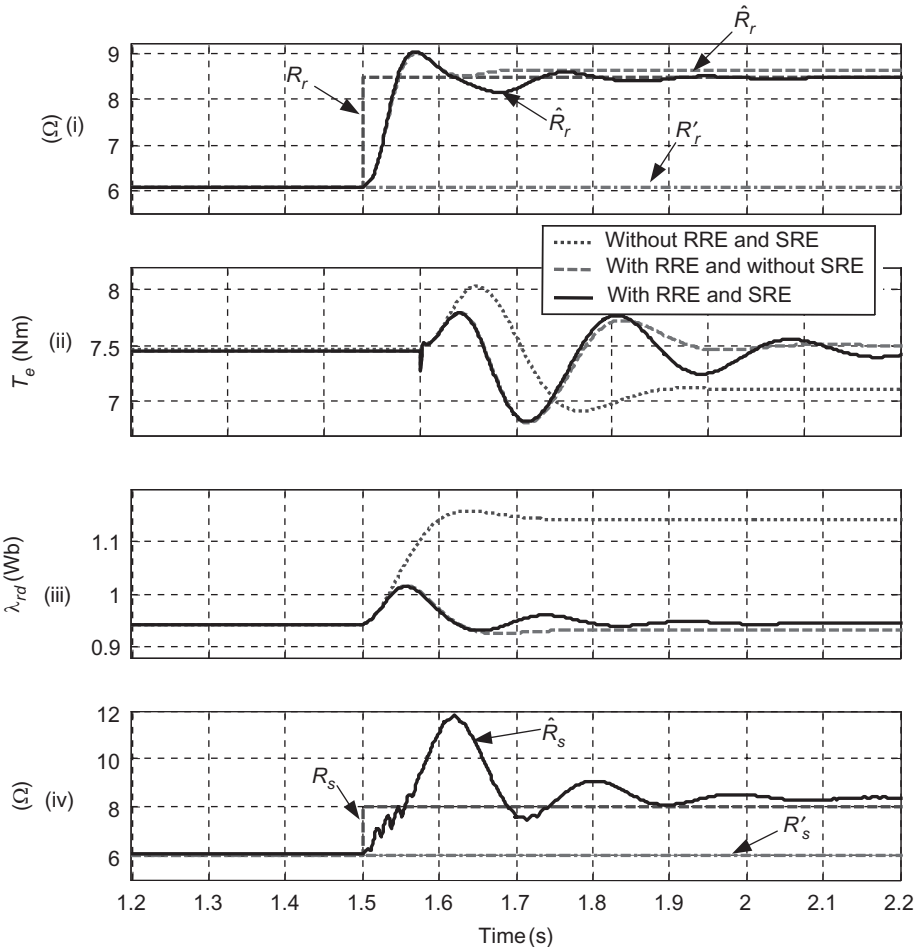

FIG. 37.24 Performance of the drive with and without RRE and SRE using ANN for 40% step change in R_r and R_s, R_r', and R_s' compensated—modeling results.

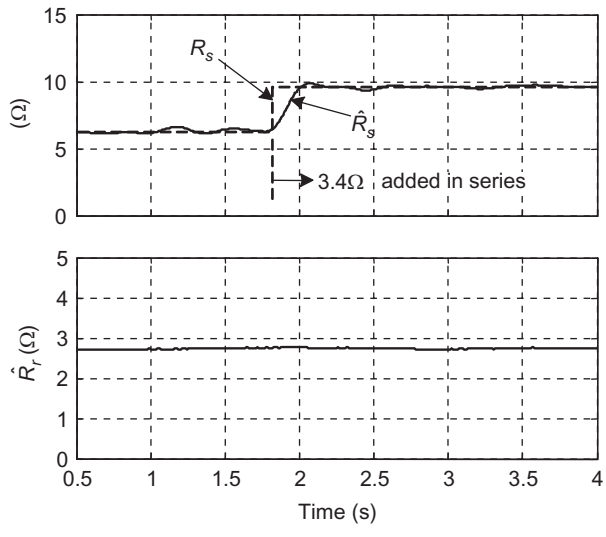

FIG. 37.25 Estimated stator resistance R_s using ANN—experimental results.

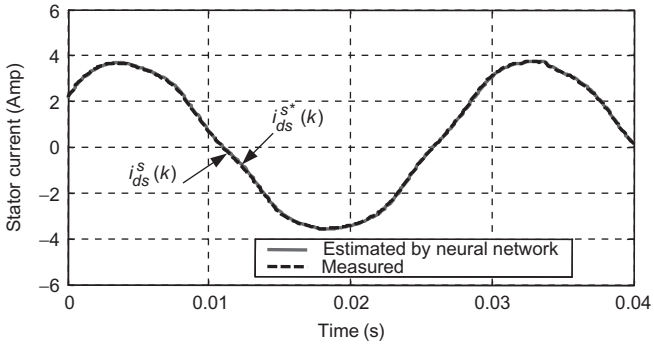

FIG. 37.26 Stator currents in R_s estimation—experimental results.

general form, the NARMAX model represents a system in terms of its delayed inputs and outputs. Random steps in the stator voltage are given for the purpose of identification. The neural network used is of the multilayer back-propagation type, and a quantity based on the rotor time constant is also

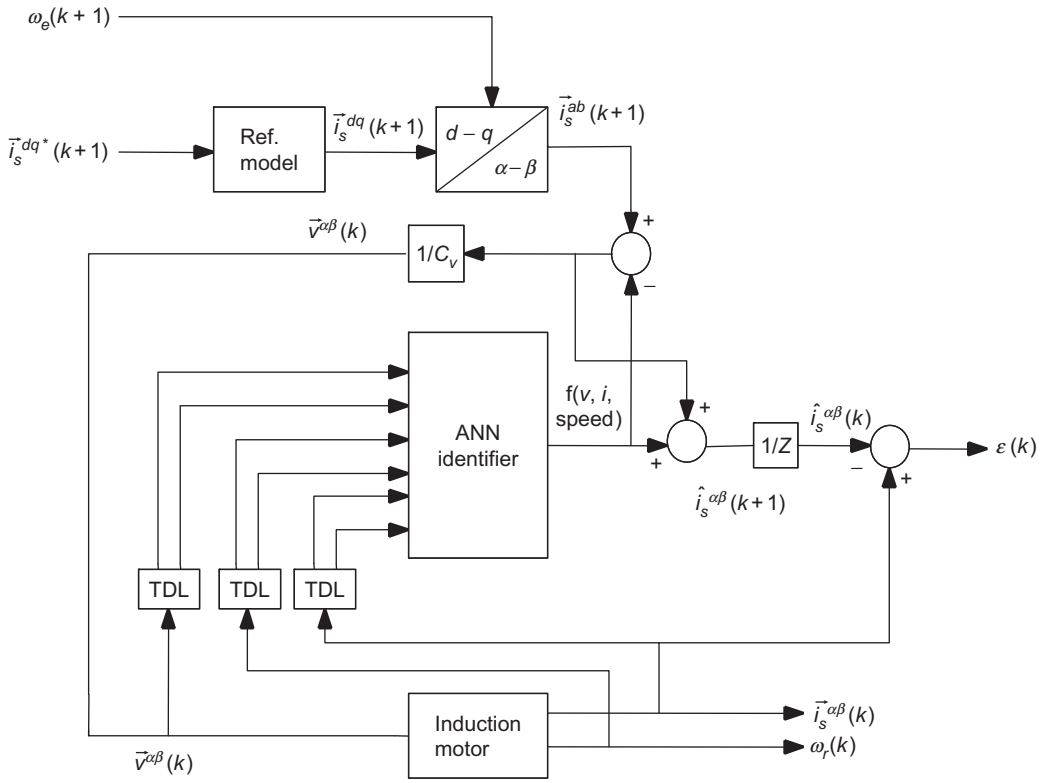

FIG. 37.27 Adaptive current control using ANN proposed by Harley.

computed as an extra weight. As opposed to the regular ANN architecture, this ANN has nonlinearity in the output layer, and the weighted sum of the inputs is used as the output. This gives an estimate of the rotor time constant and makes the system robust against variation of the parameters. Once, the identification is over, the ANN is used for current control. The stator currents predicted by the ANN are used to compute the input voltage for the induction motor, and the ANN output is made to track the reference currents by back propagating the error.

The rotor speed is also controlled in this system by identifying a NARMAX model for the speed increment rather than the absolute value of speed. To simplify the NARMAX model, the load torque is assumed to be a function of the motor speed, as is the case in a fan or pump type of load. For the current control case, the relationship between the control variable (voltage) and the controlled quantity (current) was linear. In the speed control case, this relationship is nonlinear, thus necessitating two ANNs, one for identification of speed and the other for control.

The identification ANN (N_i) predicts the value for the speed increment, which is compared with the actual speed increment, and the error (ε_i) is back propagated through the ANN. A PI controller is used for basic speed control, and the control ANN (N_c) produces the slip frequency, and the difference between the desired speed increment and actual speed increment (ε_c) is back propagated through the ANN. The induction motor drive therefore employs three ANNs as shown in Fig. 37.28.

37.4.3 Efficiency Optimization in Electric Drives

The efficiency improvement of induction motor drives via flux control can be classified into three groups: precomputed flux programs, real-time computation of losses, and online input-output efficiency optimization control. All of these methods target choosing a value of the motor excitation that optimizes the motor-converter losses. The main requirement of an input-output optimization is to achieve the flux optimization in a minimum number of search steps. A constant search step may take too long if the step is too small, or it may bypass the minimum power input if the step is too large. For each mechanical operating point of the motor, it is possible to find a combination of rotor-flux linkage and torque producing current i_q at which the dc-link power P_{dc} to the drive system is minimum.

One of the possible ANN efficiency optimizers reported is shown in Fig. 37.29. An ANN-based search algorithm is employed to operate as an efficiency optimizer. The inputs to the system are the dc power fed into the drive system at instant k and the change in the control variable at the previous instant $\Delta c(k-1)$. The only output is the actual change in control variable $\Delta c(k)$. Appropriate scaling from engineering units to the normalized interval $[-1, 1]$ are implemented by the input and output interfaces, input scaling (IS), and output scaling (OS). The speed signal is used to generate the reference flux $C(k)_0$ corresponding to each speed. The mechanical steady state is

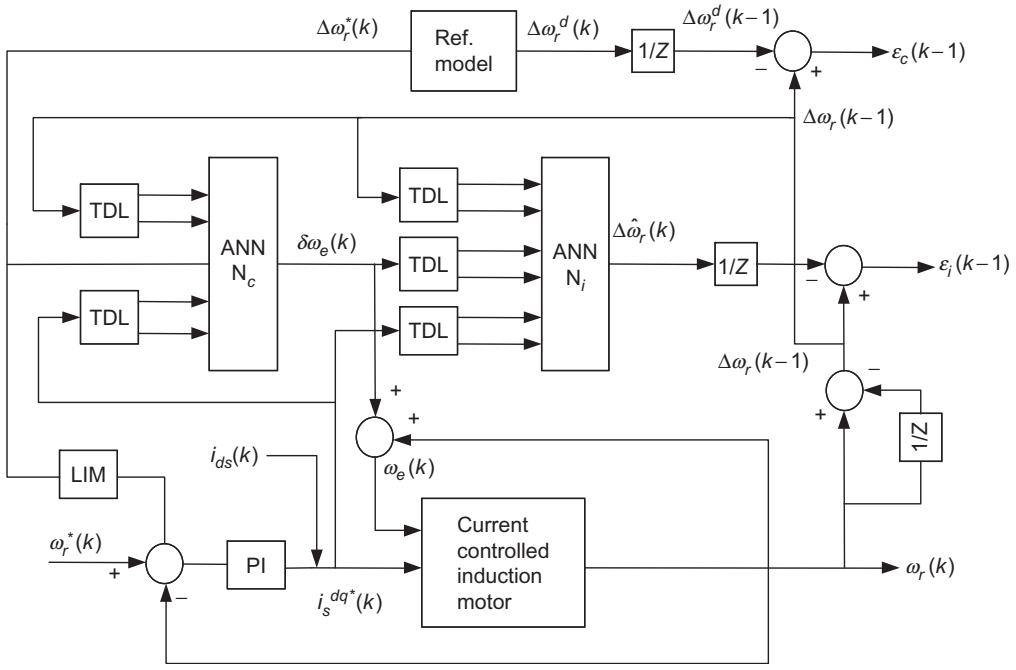

FIG. 37.28 Adaptive speed control of the induction motor using ANN.

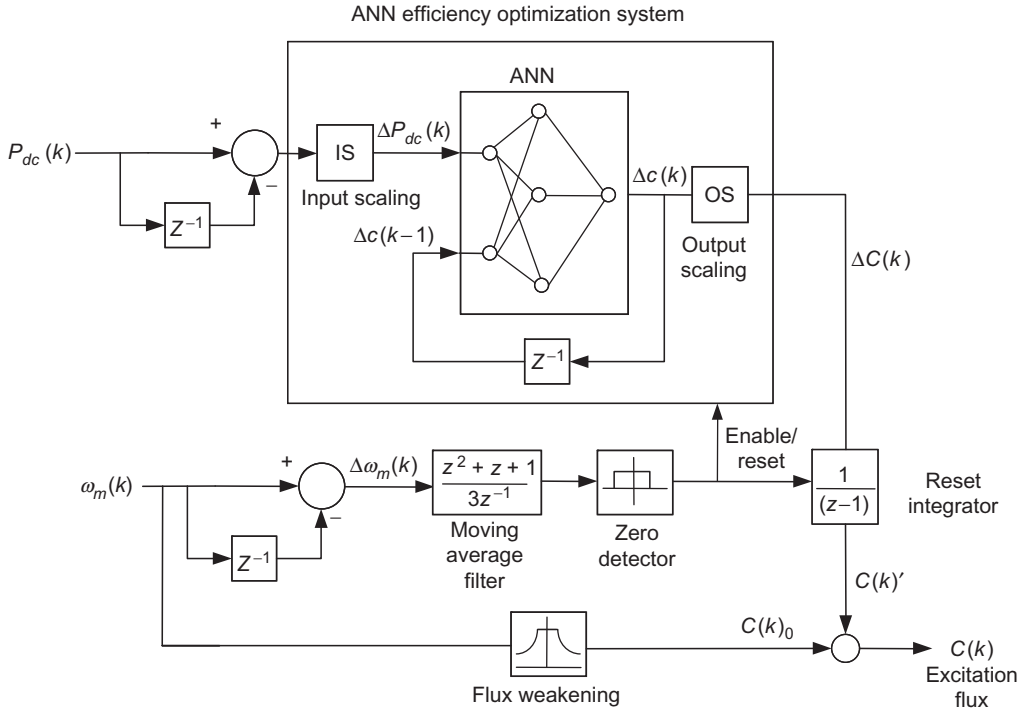

FIG. 37.29 Induction motor efficiency optimizer using ANN.

detected by applying a moving average filtering to the speed variation $\Delta\omega_m$. The ANN efficiency optimizer is enabled only during the mechanical steady state.

37.5 ANN-Based Controls in Power Converters

A feedforward ANN can implement a nonlinear input-output mapping. A feedforward carrier-based pulse-width modulation (PWM) technique, such as space-vector modulator (SVM), can be looked at as a nonlinear mapping where the command phase voltages are sampled at the input and the corresponding pulse-width patterns are established at the output. Fig. 37.30 shows the block diagram of an open-loop V/f-controlled induction motor drive incorporating the proposed ANN-based SVM controller. The command voltage $V_{qs}^*(=V^*)$ is generated from the frequency or speed command, and the angle command θ_e^* is obtained by integrating the frequency, as shown. The output of the modulator generates the PWM patterns for the inverter switches.

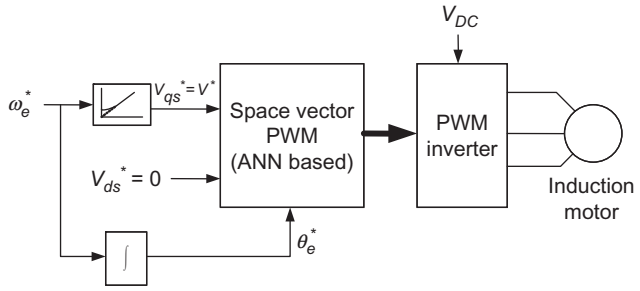

FIG. 37.30 V/f control of induction motor using ANN-based SVM.

The ANN can be conveniently trained off-line with the data generated by calculation of the SVM algorithm. The ANN has inherent learning capability that can give improved precision by interpolation unlike the standard lookup table method. Fig. 37.31 shows such an SVM that can operate during both undermodulation and overmodulation regions linearly extending smoothly up to a square wave. The SVM is implemented using two subnets: angle subnet and amplitude subnet. The subnets use a multiplayer perceptron-type network with sigmoidal-type transfer function. The bias is not shown in the figure. The composite network uses two neurons at the input, 20 neurons in the hidden layer, and four output neurons. The input signal to the angle subnet is θ_e angle that is normalized, and then pulse-width functions at unit amplitude are solved (or mapped) at the output for three phases, as indicated. The amplitude subnet implements the $f(V^*)$ function. The digital words corresponding to the turn-on time are generated by multiplying the angle subnet output with that of the amplitude subnet and then adding the $T_s/4$ bias signal, as shown. The PWM signals are then generated using a single timer. The angle subnet is trained with an angle interval of 2.16 degrees in the range of 0–360 degrees. Due to learning or interpolation

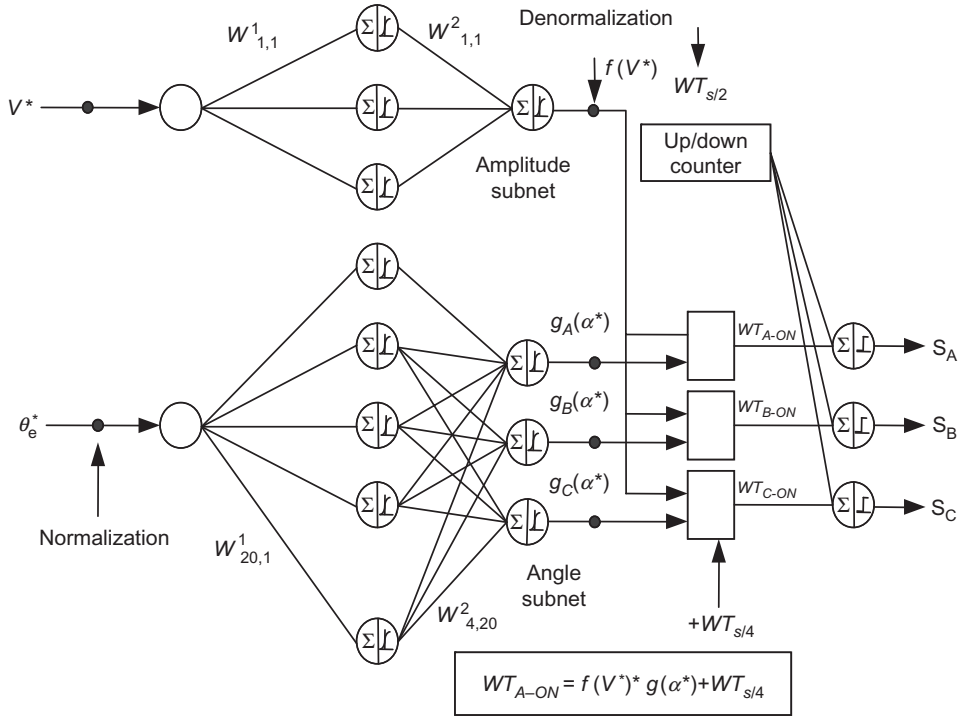

FIG. 37.31 Neural network topology $(2\times20\times4)$ for PWM wave synthesis.

capability, both the subnets will operate higher signal resolution. A sampling interval T_s of 50 µs corresponds to a switching frequency of 20 kHz and a 100 µs that corresponds to 10 kHz.

38.1 Introduction

Solving an optimization problem is one of the common scenarios that occur in most engineering applications. Classical optimization techniques such as linear programming (LP) and nonlinear programming (NLP) are efficient approaches that can be used to solve special cases of optimization problem in power system and motor drive applications. As the complexities of the problem increase, especially with the introduction of parameter uncertainties, more complicated optimization techniques, such as stochastic programming, have to be used. However, these analytic methods are not easy to implement for most of the real-world problems. As a highly nonlinear, nonstationary motor drive system with nonlinear inertia, load, noise, and uncertainties, motor drives can have a large number of operating condition states and parameters. Implementing any of the classical analytic optimization search methods may not be feasible in most of the cases. On the other hand, GA and particle swarm optimization (PSO) search techniques can be an attractive alternative and effective solutions. GA and PSO are stochastically based search techniques that have its roots in artificial life and social psychology and in engineering and computer science. In general, there are two possible optimization techniques based on GA and PSO. These two techniques are the following:

(1) Single-objective optimization (SOO)
(2) Multiobjective optimization (MOO)

The main procedure of the SOO is based on deriving a single-objective function for the optimization search problem. The single-objective function may be combined from several objective functions using weighting factors. The objective function is optimized (either minimized or maximized) using GA or PSO to obtain a single solution. On the other hand, the main objective of the multiobjective (MO) problem is finding the set of acceptable trade-off optimal solutions. This set of

http://dx.doi.org/10.1016/B978-0-12-811407-0.00042-8

accepted solutions is called Pareto front. These acceptable solutions give more ability to the user to make an informed decision by seeing a wide range of solutions that are optimum from an "overall" standpoint. Single-objective (SO) optimization may ignore this trade-off viewpoint. This chapter has described the basic concepts of GA and PSO and presents a review of some of the applications of GA and PSO in motor drive-based optimization problems to give the reader some insights of how GA and PSO can serve as acceptable near-optimal solutions to some of the most complicated engineering optimization problems.

38.2 Differences Between GA and PSO and Other Evolutionary Computation Techniques

A comparison between conventional optimization techniques and evolutionary algorithms (like GA and PSO) is presented in Table 38.1 [1]:

- Unlike other random search algorithms, each potential solution (called a particle) is also assigned a randomized velocity and then flown through the problem hyperspace.
- The most striking difference between the PSO and the other evolutionary soft computing algorithms is that PSO chooses the path of cooperation over competition. The other algorithms commonly use some form of decimation, survival of the fittest. In contrast, the PSO population is stable and individuals are not destroyed or created. Individuals are influenced by the best performance of their neighbors. Individuals eventually converge on optimal points in the problem domain.
- The PSO traditionally does not have any genetic operators like crossover between individuals and mutation, and other individuals never substitute particles during the run. Instead, the PSO refines its search by attracting the particles to positions with good solutions.
- Particles update themselves with the internal velocity.
- They also have memory, which is important to the algorithm.
- Compared with GA, the information sharing mechanism in PSO is significantly different. In GAs, chromosomes share information with each other. So the whole population moves like one group toward an optimal area. In PSO, only $\mathbf{g}_{\mathbf{best}}$ or $\mathbf{p}_{\mathbf{best}}$ gives out the information to others. It is a one-way information sharing mechanism. The evolution only looks for the best solution.
- Compared with the GA, the advantages of PSO are that PSO is easy to implement and there are few parameters to adjust.

38.3 Single Objective Genetic Optimization Search Algorithm (SOGA)

GAs are an evolutionary optimization approach that is an alternative to traditional optimization methods. GA is most appropriate for complex nonlinear models where location of the global optimum is a difficult task. It may be possible to use GA techniques to consider problems that may not be modeled as accurately using other approaches.

Therefore, GA appears to be a potentially useful approach. GA is particularly applicable to problems that are large, nonlinear, and possibly discrete in nature, features that traditionally add to the degree of complexity of solution. Due to the probabilistic development of the solution, GA does not guarantee optimality even when it may be reached. However, they are likely to be close to the global optimum. This probabilistic nature of the solution is also the reason they are not contained by local optima. The GA procedure is based on the Darwinian principle of survival of the fittest. An initial population is created containing a predefined number of individuals (or solutions), each represented by a genetic string (incorporating the variable information). Each individual has an associated fitness measure, typically representing an objective value. The concept that fittest (or best) individuals in a population will produce fitter offspring

TABLE 38.1 Comparison between conventional optimization procedures and evolutionary algorithms

Property	Evolutionary	Traditional
Search space	Population of potential solutions	Trajectory by a single point
Motivation	Natural selection and social adaptation	Mathematical properties (gradient, Hessian)
Applicability	Domain independent, applicable to variety of problems	Applicable to a specific problem domain
Point transition	Probabilistic	Deterministic
Prerequisites	An objective function to be optimized	Auxiliary knowledge such as gradient vectors
Initial guess	Automatically generated by the algorithm	Provided by user
Flow of control	Mostly parallel	Mostly serial
CPU time	Large	Small
Results	Global optimum more probable	Local optimum, dependent of initial guess
Advantages	Global search, parallel, speed	Convergence proof
Drawbacks	No general formal convergence proof	Locality, computational cost

is then implemented in order to reproduce the next population. Selected individuals are chosen for reproduction (or crossover) at each generation, with an appropriate mutation factor to randomly modify the genes of an individual, in order to develop the new population. The result is another set of individuals based on the original subjects leading to subsequent populations with better (min or max) individual fitness. Therefore, the algorithm identifies the individuals with the optimizing fitness values, and those with lower fitness will naturally get discarded from the population [2]. Fig. 38.1 shows the general flowchart of the GA algorithm based on total error iterative minimum search. The steps of the GA are depicted as follows:

1. **[Start]** Generate random population of *n* chromosomes (suitable solutions for the problem).
2. **[Fitness]** Evaluate the fitness *f(x)* of each chromosome *x* in the population.
3. **[New population]** Create a new population by repeating following steps until the new population is complete:
   a. **[Selection]** Select two parent chromosomes from a population according to their fitness (the better fitness, the bigger chance to be selected).
   b. **[Crossover]** With a crossover probability cross over the parents to form a new offspring (children). If no crossover was performed, offspring is an exact copy of parents.
   c. **[Mutation]** With a mutation probability, mutate new offspring at each locus (position in chromosome).
   d. **[Accepting]** Place new offspring in a new population.
4. **[Replace]** Use new generated population for a further run of algorithm.
5. **[Test]** If the end condition is satisfied, **stop**, and return the best solution in current population.
   [Loop] Go to step **2**.

GAs can be applied to many scientific, engineering problems, once solutions of a given problem can be encoded to chromosomes in GA and compare the relative performance (fitness) of solutions. An effective GA representation and meaningful fitness evaluation are the keys of the success in GA applications. The appeal of GAs comes from their simplicity and elegance as robust search algorithms and from their power to discover good solutions rapidly for difficult high-dimensional problems. The main advantage of GA is that models that cannot be developed using other solution methods without some form of approximation can be considered in an unapproximated form. The size of the model, that is, number of probabilistic variables, has a significant effect on the speed of solution; therefore, model specification can be crucial. Unlike other solution methods, integer variables are easier to accommodate in GA than continuous variables. This is due to the resulting restricted search space. Further, variable bound values can be applied to achieve similar results. GAs can be used for problem-solving and for modeling when the search space is large, complex, or poorly understood. Domain knowledge is scarce or expert knowledge is difficult to encode to narrow the search space. No mathematical analysis is available and traditional search methods fail.

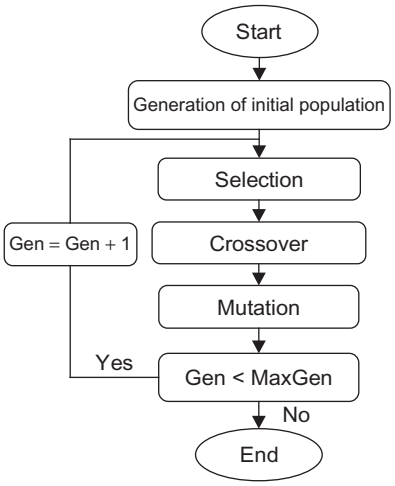

FIG. 38.1 Flowchart for the GA minimizing search algorithm.

38.4 Single Objective Particle Swarm Optimization Search Algorithm (SOPSO)

Particle swarm optimization (PSO) is an evolutionary computational technique (a search method based on a natural system), which was introduced by Kennedy and Eberhart in 1995 [3]. This optimization and search technique models the natural swarm behavior seen in many species of birds returning to roost, group of fish, and swarm of bees, etc. The particle swarm optimization (PSO) may be used to find optimal (or near-optimal) solutions to numerical and qualitative problems [4–8]. PSO methods are inspired by particles moving around in the defined search space. The individuals in a PSO have a position and a velocity. The PSO method remembers the best position found by any particle. Additionally, each particle remembers its own previously best-found position. A particle moves through the specified solution space along a trajectory defined by its velocity, the draw to return to a previous promising search area, and an attraction toward the best location discovered by its close neighbors. Particle swarm optimization has been used for a wide range of search applications and for specific optimization tasks. PSO can be easily implemented in most programming languages and has proved to be both effective and fast when applied to a diverse set of nonlinear optimization problems. PSO has been successfully applied in many areas:

- Function optimization
- Artificial neural network training
- Proportional and integral fuzzy system control
- Other near-optimal search and optimization areas where GA can be applied

38.4.1 Structure of the PSO Particle

The basic structure of any particle in a selected population consists of five components:

- $\vec{x}$ is a vector containing the current location in the solution space. The size of $\vec{x}$ is defined by the number of variables used by the problem that is being solved.
- Fitness is the quality of the solution represented by the vector $\vec{x}$, as computed by a problem-specific evaluation function.
- $\vec{V}$ is a vector containing the velocity for each dimension of $\vec{x}$. The velocity of a dimension is the step size that the corresponding $\vec{x}$ value will change into at the next iteration. Changing the $\vec{V}$ values changes the direction the particle will move through in the search space, causing the particle to make a turn. The velocity vector is used to control the range and resolution of the search.
- P_{best} is the fitness value of the best solution yet found by a particular particle.
- $\vec{P}$ is the copy of the $\vec{x}$ for the location that generated the particle's P_{best}. Jointly, P_{best} and $\vec{x}$ comprise the particle's memory, which is used to control the particle to go back toward a definite search region.
- Each particle is also aware of the current best fitness in the neighborhood for any given iteration. A neighborhood may consist of some small group of particles, in which case the neighborhoods overlap and every particle is in multiple neighborhoods. Particles in a swarm are related socially; that is, each particle is a member of one or more neighborhoods. Each individual tries to emulate the behavior of the best of its neighbors. Each individual can be thought of as moving through the feature space with a velocity vector that is influenced by its neighbors.

38.4.2 Basic Search Method

The position of each particle is represented by XY-axis position, and also, the velocity is expressed by V_{x} (the velocity of X-axis) and V_{y} (the velocity of Y-axis). Modification of the particle position is realized by the position and velocity information. Each particle knows its best value so far **($\mathbf{P_{best}}$)** and its XY position. This information represents the personal experiences of each particle. Moreover, each particle knows the best value so far in the group **($\mathbf{g_{best}}$)** among $\mathbf{P_{bests}}$. This information represents the knowledge of how the other particles around have performed. Namely, each particle tries to modify its position using the following information:

- The current positions (x, y)
- The current velocities (V_{x}, V_{y})
- The distance between the current position and $\mathbf{P_{best}}$
- The distance between the current position and $\mathbf{g_{best}}$

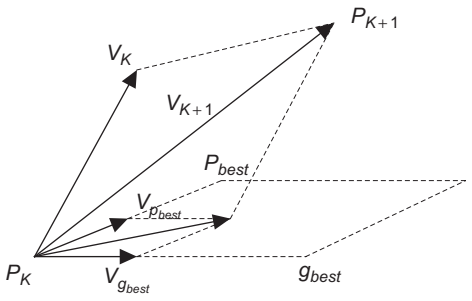

FIG. 38.2 Concept of modification of a searching point by PSO.

This modification can be represented by the concept of velocity. Velocity of each particle can be modified by the following equation:

$$V_{id} = W \times V_{id} + C_1 \times rand_1 \times (P_{id} - X_{id}) + C_2 \times rand_2 \times (P_{gd} - X_{id}) \quad (38.1)$$

where

- V_{id} is the value of dimension d in the velocity vector $\vec{v}$ for particle i.
- C_1 is the cognitive learning selected rate.
- C_2 is the social learning selected rate.
- rand_1 and rand_2 are random values on the range [0.1].
- X_{id} is the current position of particle i along dimension d.
- W is the selected weighting factor.
- P_{id} is the location along dimension d at which the particle previously had the best fitness measure.
- P_{gd} is the current location along dimension d of the neighborhood particle with the best fitness.

The basic concept of the PSO technique lies in accelerating each particle toward its $\mathbf{P_{best}}$ and $\mathbf{g_{best}}$ locations, with a random weighted acceleration at each step, and this is illustrated in Fig. 38.2.
where

P_K is the current position of a particle.
P_{K+1} is its modified position.
V_K is its initial velocity.
V_{K+1} is its modified velocity.
$V_{\text{p}_{\text{best}}}$ is the velocity considering its p_{best} location.
$V_{\text{g}_{\text{best}}}$ is the velocity considering its g_{best} location.

Using the above concept, a certain velocity, which gradually gets close to $\mathbf{P_{best}}$ and $\mathbf{g_{best}}$, can be calculated. The current position (searching point in the solution space) can be modified by the following equation:

$$X_{id} = X_{id} + V_{id} \quad (38.2)$$

38.4.3 PSO Search Algorithm

Fig. 38.3 shows the general flowchart of the PSO algorithm. The main steps in the particle swarm optimization process are described as follows:

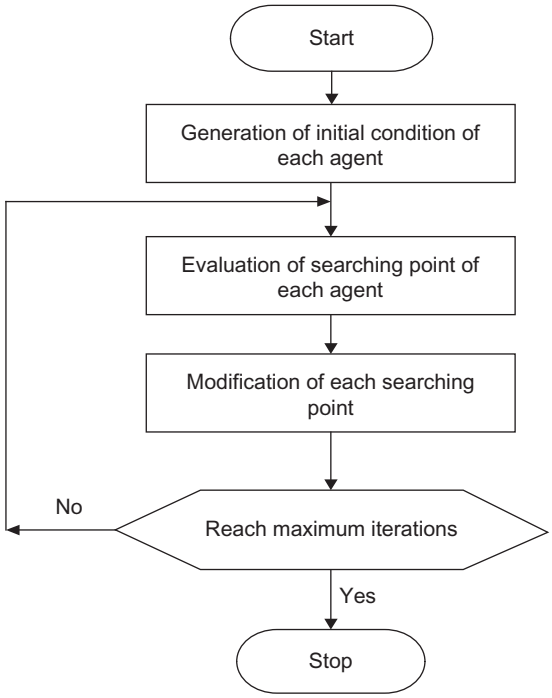

FIG. 38.3 The general flowchart of PSO search algorithm.

1. System initialized with a population of random potential solutions. Each potential solution is assigned a random "velocity" and is called a particle. (It has position in the space, i.e., it is a point in the solution space and it has velocity.) These particles are then "flown" through the search space of potential solutions.
2. Evaluate the fitness of each particle in the swarm.
3. For every iteration, compare each particle's fitness with its previous best fitness (P_{best}) obtained. If the current value is better than P_{best}, then set P_{best} equal to the current value and the P_{best} location equal to the current location in the d-dimensional space.
4. Compare P_{best} of particles with each other and update the swarm global best location with the greatest fitness (g_{best}).
5. The velocity of each particle is changed (accelerated) toward its P_{best} and g_{best}. This acceleration is weighted by a random term. A new position in the solution space is calculated for each particle by adding the new velocity value to each component of the particle's position vector.
6. Repeat steps (2)–(5) until convergence is reached based on some desired single- or multiple-objective criteria.

38.5 Multiobjective Optimization (MOO)

In many real-life applications, multiple and often conflicting objectives need to be satisfied. Satisfying these conflicting objective functions is called multiobjective optimization (MO). For example, to place more functional blocks on a chip while minimizing that chip's area and/or power dissipation is a conflicting objective that needs performing a trade-off analysis [9,10]. The objective of MO optimization is to find a set of acceptable solutions and present them to the user, who will then choose from them. Generally, there are two general approaches to solve multiobjective optimization. The first approach lies in combining the individual objective functions into a single composite function. Determination of a single objective is possible with methods, such as the weighted sum method, but the problem lies in the correct selection of the weights. In practice, it can be very difficult to accurately select these weights, even for someone very familiar with the problem domain. In addition, optimizing a particular solution with respect to a single objective can result in unacceptable results with respect to the other objectives [11,12]. The second general approach is to obtain the optimal solution. There will be a set of optimal trade-offs between the conflicting objectives, but this optimal solution is called Pareto-optimal solution set or Pareto front [13,14]. A Pareto-optimal set is a set of solutions that are nondominated with respect to one another. While moving from one Pareto solution to another, there is always a certain amount of importance in one objective to achieve a certain amount of gain in the other. Generating the Pareto set has several advantages. The Pareto set allows the user to make an informed decision by seeing a wide range of options. The Pareto set contains the solutions that are optimum from an "overall" standpoint. SO optimization may ignore this trade-off viewpoint. This feature is useful since it provides better understanding of this system in which all the consequences of a decision with respect to all the objectives can be explored [9].

The following definitions are used in the proposed multiobjective optimization (MO) search algorithm:

Definition 1 The general MO problem requiring the optimization of N objectives may be formulated as follows:

Minimize

$$\vec{y}=\vec{F}\left(\vec{x}\right)=\left[\vec{f}_1\left(\vec{x}\right),\vec{f}_2\left(\vec{x}\right),\vec{f}_3\left(\vec{x}\right),\ldots,\vec{f}_N\left(\vec{x}\right)\right]^T \quad (38.3)$$

$$\text{subject to } g_j\left(\vec{x}\right)\le 0 \quad j=1,2,\ldots,M \quad (38.4)$$

where

$$\vec{x}^*=\left[\vec{x}_1^*,\vec{x}_2^*,\ldots,\vec{x}_P^*\right]^T\in\Omega \quad (38.5)$$

$\vec{y}$ is the objective vector, the $\vec{g}_i\left(\vec{x}\right)$ represent the constraints, and $\vec{x}^*$ is a P-dimensional vector representing the decision variables within a parameter space Ω. The space spanned by the objective vectors is called the objective space. The subspace of the objective vectors satisfying the constraints is called the feasible space.

Definition 2 A decision vector $\vec{x}_1 \in \Omega$ is said to dominate the decision vector $\vec{x}_2 \in \Omega$ (denoted by $\vec{x}_1 \prec \vec{x}_1$), if the decision vector $\vec{x}_1$ is not worse than $\vec{x}_2$in all objectives and strictly better than $\vec{x}_2$ in at least one objective.

Definition 3 A decision vector $\vec{x}_1 \in \Omega$ is called Pareto-optimal, if there does not exist another $\vec{x}_2 \in \Omega$ that dominates it. An objective vector is called Pareto-optimal, if the corresponding decision vector is Pareto-optimal.

Definition 4 The nondominated set of the entire feasible search space Ω is the Pareto-optimal set. The Pareto-optimal set in the objective space is called Pareto-optimal front.

38.6 Multiobjective Genetic Optimization Search Algorithm (MOGA)

The nondominated sorting genetic algorithm (NSGA) is a multiobjective GA that was developed by Deb et al. [15]. This algorithm has been chosen over a conventional GA for three principal reasons: (a) no need to specify a sharing parameter, (b) a strong tendency to find a diverse set of solutions along the Pareto-optimal front, and (c) the ability to specify multiple objectives without the need to combine them using a weighted sum. The basic idea behind NSGA is the ranking process executed before the selection operation, as shown in Fig. 38.4. This process identifies nondominated solutions in the population, at each generation, to form nondominated fronts [16]; after this, the selection, crossover, and mutation usual operators are performed. In the ranking procedure, the nondominated individuals in the current population are first identified. Then, these individuals are assumed to constitute the first nondominated front with a large dummy fitness value [16]. The same fitness value is assigned to all of them. In order to maintain diversity in the population, a sharing method is then applied. Afterward, the individuals of the first front are ignored temporarily, and the rest of population is processed in the same way to identify individuals for the second nondominated front. A dummy fitness value that is kept smaller than the minimum shared dummy fitness of the previous front is assigned to all individuals belonging to the new front. This process continues until the whole population is classified into nondominated fronts. Since the nondominated fronts are defined, the population is then reproduced according to the dummy fitness values.

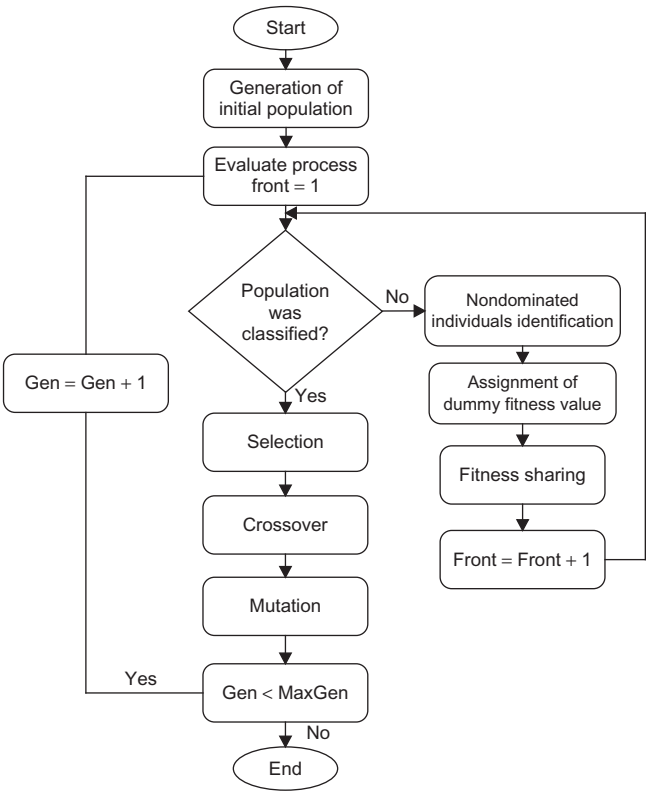

FIG. 38.4 Flowchart of NSGA.

38.7 Multiobjective Particle Swarm Optimization Search Algorithm (MOPSO)

In MOPSO [9–14], a set of particles are initialized in the decision space at random. For each particle i, a position x_i in the decision space and a velocity v_i are assigned. The particles change their positions and move toward the so-far best-found solutions. The nondominated solutions from the last generations are kept in the archive. The archive is an external population, in which the so-far found nondominated solutions are kept. Moving toward the optima (maximum or minimum) is done in the calculations of the velocities as follows:

$$V_{id} = \omega \times V_{id} + C_1 \times rand_1 \times \left(P_{pd} - X_{id}\right) + C_2 \times rand_2 \times \left(P_{rd} - X_{id}\right) \tag{38.6}$$

$$X_{id} = X_{id} + V_{id} \tag{38.7}$$

where $P_{r,d}$, $P_{p,d}$ are randomly chosen from a single global Pareto archive, ω is the inertia factor influencing the local and global abilities of the algorithm, $V_{i,d}$ is the velocity of the particle i in the d-th dimension, and c_1 and c_2 are weights affecting the cognitive and social factors, respectively. r_1 and r_2 are two uniform random functions in the range [0, 1]. According to Eq. (38.7), each particle has to change its position $\mathbf{X_{i,d}}$ toward the position of the two guides $\mathbf{P_{r,d}}$, $\mathbf{P_{p,d}}$ that must be selected from the updated set of nondominated solutions stored in the archive. The particles change their positions during generations until a termination criterion is met. Finding a relatively large set of Pareto-optimal trade-off solutions is possible by running the MOPSO for many generations. Fig. 38.5 shows the flowchart of

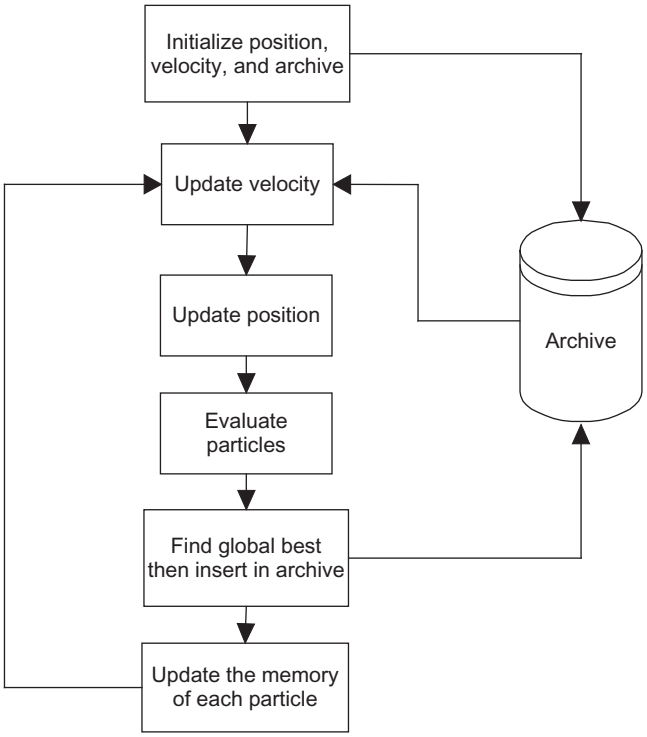

FIG. 38.5 Flowchart of the MOPSO algorithm.

the multiobjective particle swarm optimization (MOPSO). Also, Fig. 38.6 explains the procedure of the multiobjective particle swarm optimization (MOPSO) using pseudocode.

Init Pop(); The particle swarm is initialized with random values corresponding to the ranges of the decision variables. These values are dependent on the test functions.

Init Velocity(); The velocities are initialized with zero values.

Check the feasibility of each particle. If the particle does not satisfy the constraints, then regenerate it.

Evaluate Pop(); The swarm is evaluated using the corresponding objective functions.

Update Fbest(); The fitness vectors are updated (evaluate the multiobjective fitness value of each particle and save it in vector form). As we are dealing with multiobjective optimization, these vectors store the values of each decision variable, whereby the particles obtain the best values in a Pareto sense.

At this stage of the algorithm, these vectors are filled with the results of the initial particle evaluations.

Update Pbest(); Analogously, these values are copied in the pbest vectors.

Insert nodom(); Calculate the multiobjective fitness values of each particle and check its Pareto optimality. Store the nondominated particles in the Pareto archive. If the specific constraint does not exist for the archive, the size of the archive will be unlimited (all nondominated particles are inserted in the grid, i.e., in the external file).

Gbestpos = rnd (0,nodomfileSize); The global gbest particle is randomly selected.

//The flight cycle starts here //

24.         Print Statistics();
25.         Generate Outfile();
26. }
```

FIG. 38.6 Pseudocode of the MOPSO.

Update Velocity(); The velocity of each particle is updated, using Eq. (38.6). Two Pareto solutions are chosen randomly for $P_{r,d}$, $P_{i,d}$ from the Pareto archive.

Update Particle(); The position of each particle is also updated using Eq. (38.7).

Keeping(); The keeping operation is carried out to maintain the particles into the allowable range values. Then, the particles are mutated. If the particle does not remain within the feasible solution region, it is discarded and mutated again.

Evaluate Pop(); Update Fbest(); Update Pbest();

The particles are evaluated; the fitness and pbest vector are, if appropriate, updated.

Insert nodom(); As the particles move in the search space because they have changed positions, the dominance of each particle is verified, and, if appropriate, they are inserted in the grid.

(a) Check the Pareto optimality of each particle. If the fitness value of the particle is nondominated when compared with the Pareto-optimal set in the archive, save it into the Pareto archive.

(b) In the Pareto archive, if a particle is dominated by a new one, then discard it.

Gbestpos = rnd(0,nodomfileSize); Then, the new gbest is randomly selected. Two Pareto solutions are chosen randomly for $p_{p;d}$ and $p_{r;d}$ from the Pareto archive.

Repeat the cycle until the number of generations reaches a given n.

// the end of the cycles //

Print Statistics(); Generate Outfile(); Print the statistics and generate an output file, which contains the nondominated particles.

38.8 GA and PSO Applications in Speed Control of Motor Drives

Many areas in power systems require solving one or more nonlinear optimization problems. While analytic methods might suffer from slow convergence and the problem of dimensionality, GA and PSO are known to effectively solve large-scale nonlinear optimization problems [17]. This section provides some motor drives applications that have benefited from the powerful nature of GA and PSO as an optimization techniques. For each application, technical details that are required for applying GA and PSO and the most efficient fitness functions are also discussed. In this section, online energy optimization controllers are proposed for induction motor drives and PMDC motor drives using GA and PSO. In many applications, efficiency optimization of induction motors and PMDC motors represents an important factor of control especially for autonomous electric traction. This section will present some of the applications of GA and PSO in motor drive-based optimization problems to give some insight of how GA and PSO can serve as a solution to some of the most complicated engineering optimization problems [18–43].

38.8.1 Efficient Operation of Induction Motor Drives [18]

Induction motor is a high-efficiency electrical machine when working close to its rated torque and speed. However, at light loads, no balance in between copper and iron losses results considerable reduction in the efficiency. The part load efficiency and power factor can be improved by making the motor excitation adjustment in accordance with load and speed. To implement the above goal, the induction motor should either be fed through an inverter or redesigned with optimization algorithms [19]. This application presents an optimization technique for an efficient controller for the three-phase induction motors. Multiobjective particle swarm optimization (MOPSO) technique is implemented to tackle all the conflicting goals that define the search for the optimality problem. The PSO search deals with two main conflicting objective functions. These conflicting functions are maximizing the operating efficiency of the drive system for a given mechanical load and maximizing the equivalent power factor of the induction motor for start-up and steady-state operations. In addition, the optimization ensures that maximum allowable stator current constraints are not exceeded. The proposed technique are based on the principle that the flux level in a machine can be adjusted to give the required trade-off solution of maximum efficiency and maximum power factor for a given value of speed and load torque. The optimum flux levels are function of the machine load and speed requirements. Simulation results show that considerable efficiency and power factor improvements are achieved using MOPSO when compared with the field-oriented control (FOC) and constant voltage-to-frequency ratio-based control (CVFRC).

For optimal operation, three key objective functions that can affect the motor operation had been chosen. These three objective functions are based on motor efficiency, motor power factor, and motor stator current:

1. Efficiency (to maximize)
2. Power factor (to maximize)
3. Stator current (to minimize)

In addition, the optimization search ensures that all maximum stator current and inrush constraints are not exceeded. Fig. 38.7 is a plot of input power versus stator current. As illustrated in this figure, the stator current and the input power are minimized almost simultaneously. Therefore, in practice, the maximum efficiency (ME) and the minimum stator current (MSC) are not conflicting objective functions. So, when the efficiency is maximized, the stator current is minimized and the torque per ampere is maximized. So, the maximum efficiency and power factor will be considered as the main conflicting objective functions. However, a good operation should represent the right compromise among different objectives, but the problem consists in searching this "compromise." The best tool to optimally solve this problem is represented by the multiobjective approach. This approach allows us to investigate how each single-objective and multiobjective problem affects the

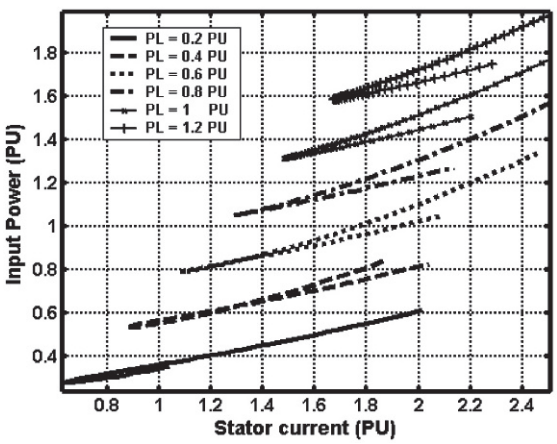

FIG. 38.7 Input power versus stator current at rated speed and various load powers.

results in terms of performance and independent variables and, above all, allows us to have a wide range of alternative solutions among which the operator can choose a better solution. The MOGA and MOPSO algorithms have been applied to optimize the operation of a three-phase, 380 V, 1 hp, 50 Hz, four-pole, squirrel cage induction motor. The block diagram of the optimization process based on PSO is shown in Fig. 38.8. In the proposed controller, the PSO algorithm receives the rotor speed and load torque, and then, the PSO controller determines the slip frequency at which the optimal fitness function occurs at that rotor speed and load torque. As stated before, this part of simulation will consider the maximum efficiency and the maximum power factor (ME and MPF) problem to be solved using multiobjective particle swarm optimization. Fig. 38.9 shows the solution to this problem and shows the Pareto fronts of the problem for different levels of rotor speed $\omega_r = 0.2$, 0.4, 0.8, 1 pu and different levels of load torque $T_L = 0.2$ and 1 pu. Tables 38.2 and 38.3 show the solution limits of the efficiency and the power factor for each operating point using MOGA and MOPSO. This range of solutions that is called the Pareto front enables the operator to choose the best compromise solution. Fig. 38.10 shows the comparison between the constant voltage-to-frequency ratio strategy (CVFRS), the field-oriented control strategy (FOCS), and the available solutions from MOPSO at different levels of load torque and rotor speed $\omega_r = 0.2$ and 1 pu, respectively. The solution that has maximum efficiency is selected from the Pareto front to achieve this comparison. Keep in mind that the operator can choose the compromised solution from the Pareto front depending on the desired efficiency and power factor. It is obvious from Fig. 38.7 that the stator current is minimized using MOPSO. In addition, there is a great improvement in efficiency and power factor using MOPSO when compared with other strategies especially at light loads. It is noted that there is a very poor PF obtained using conventional methods (field-oriented control strategy and constant voltage-to-frequency ratio) especially at light loads. It is obvious from Fig. 38.9 that the efficiency improvement has a noticeable value especially at light loads and rotor speed $\omega_r = 0.2$ pu that can be as high as 80% using CVFRS. This difference decreases to 65% at rotor speed $\omega_r = 1$ pu. On the other hand, the power factor improvement reaches 55% at light load and rotor speed $\omega_r = 0.2$ pu, whereas this improvement reaches to 160% at rotor speed $\omega_r = 1$ pu and light load. The performance difference between the field-oriented control (FOC) and the proposed control strategies MOPSO comes from the chosen value of the slip frequency and the air gap flux for each strategy. For example, at loading condition of rotor speed equal to 0.2 pu and load torques varying from 0.2 to 1 pu, the values of slip frequency based on FOCS vary from 0.01 to 0.042 pu. On the other hand, the values of slip frequency based on MOPSO vary from0.0301 to 0.0524 PU. This difference in slip frequency and air gap flux causes the difference in performance of each control strategy. The difference in the flux level of the (FOCS) controller comes from the choice of the level of the magnetization current command. The command of magnetization current is set to a constant value, which produces rated torque at rated stator flux. At light loads, the constant chosen value of magnetization current fails to choose the optimal flux level. On the other hand, this value yields the optimal flux level at rated loads. The proposed strategies overcome this problem and successfully choosing the optimal flux level especially at light loads.

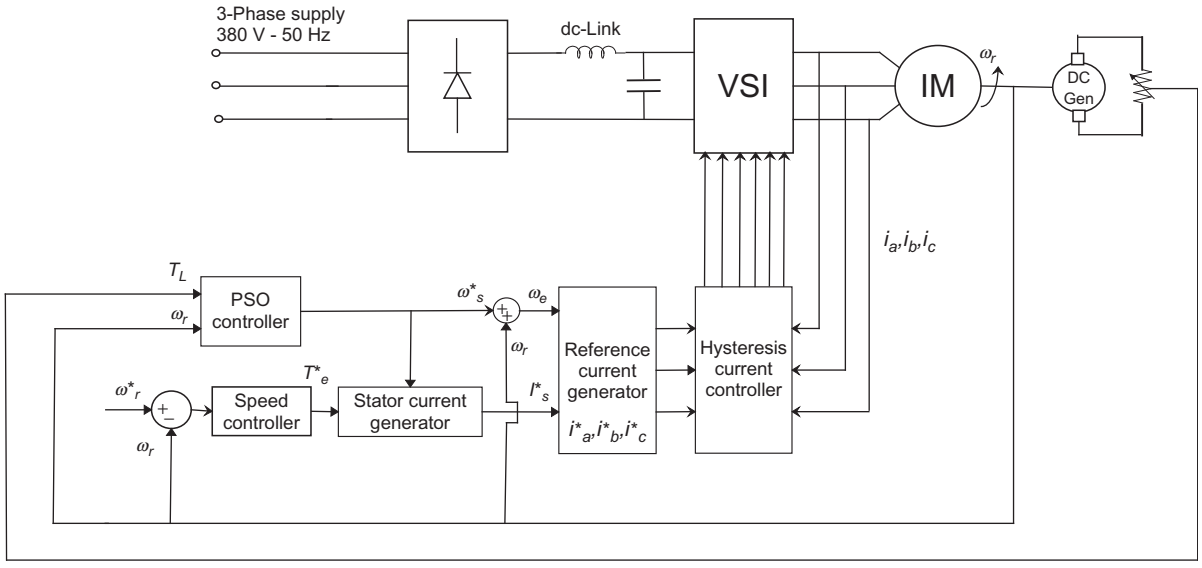

FIG. 38.8 The proposed drive system using PSO based on the loss model controller.

38.8.2 A Novel Self Regulating Hybrid (PV-FC-Diesel-Battery) Electric Vehicle-EV Drive System [20]

This application presents a number of novel self-regulating triloop error-driven controllers for a hybrid PV-FC-diesel-battery-powered all-wheel drive electric vehicle using four-wheel permanent magnet DC (PMDC) motors, which are modeled to include existing nonlinearities in motor plus load inertia (J) and viscous friction (B). A triloop dynamic error-driven scheme is proposed to regulate motor speed and current and avoid motor overloading/inrush conditions, in addition to motor speed dynamic reference tracking. The proposed triloop dynamic error-driven self-tuned control schemes are utilized to ensure dynamic energy efficiency, control loop decoupling, and grid interface stability while maintaining reference speed tracking capability. The integrated motor drive scheme is fully stabilized using novel FACTS-based green filter compensators that ensure stabilized DC bus voltage, minimal inrush current conditions, and damped load excursions. This application presents a novel comparison of multiobjective particle swarm optimization (MOPSO) and genetic search algorithms MOGA optimization and search

techniques for online dynamic tuning of the different controllers under varying renewable source conditions and load excursions.

The pressing need to utilize all abundant renewable green energy sources (wind, solar, PV, wave, tidal, fuel cell, biogas, and hybrid) is currently motivated by economic and environmental concerns. The increasing reliance on costly fossil fuels with increasing rate of resource depletion is causing a shift to energy alternatives, clean fuel replacement, and energy displacement of conventional sources to new green renewable, environmentally safe, and friendly counterparts [21,22]. Electric vehicle is one of the solutions for the reduction of the fossil fuel consumption and pollutant emissions of gas, responsible for the greenhouse effect. However, pure battery electric vehicles have shown their own range limitations; because of their size, the vehicle habitability is reduced so as its range. Adding different kinds of power supply in the same vehicle allow taking advantages from their different characteristics [23]. Several types of electric motors may be used for EV propulsion purposes. Earlier traction motors were exclusively dc motors, either series excited or separately excited. Recently, more advanced ac drive systems have found application in EV propulsion using induction motors, permanent magnet synchronous motors, and permanent magnet brushless dc motors [24,25]. The EV-DC motor speed or position control has been realized including conventional PI, PID, fuzzy logic based, nonlinear, adaptive variable structure, model reference adaptive control, artificial neural networks, and feedforward computed torque control strategies [26–28]. The need for an online gains adaptation or a "tunable" control mechanism is highly stressed in the control of any nonlinear systems with unmodeled dynamics. The PSO- and GA-based self-regulating algorithms are utilized to track any reference speed trajectory

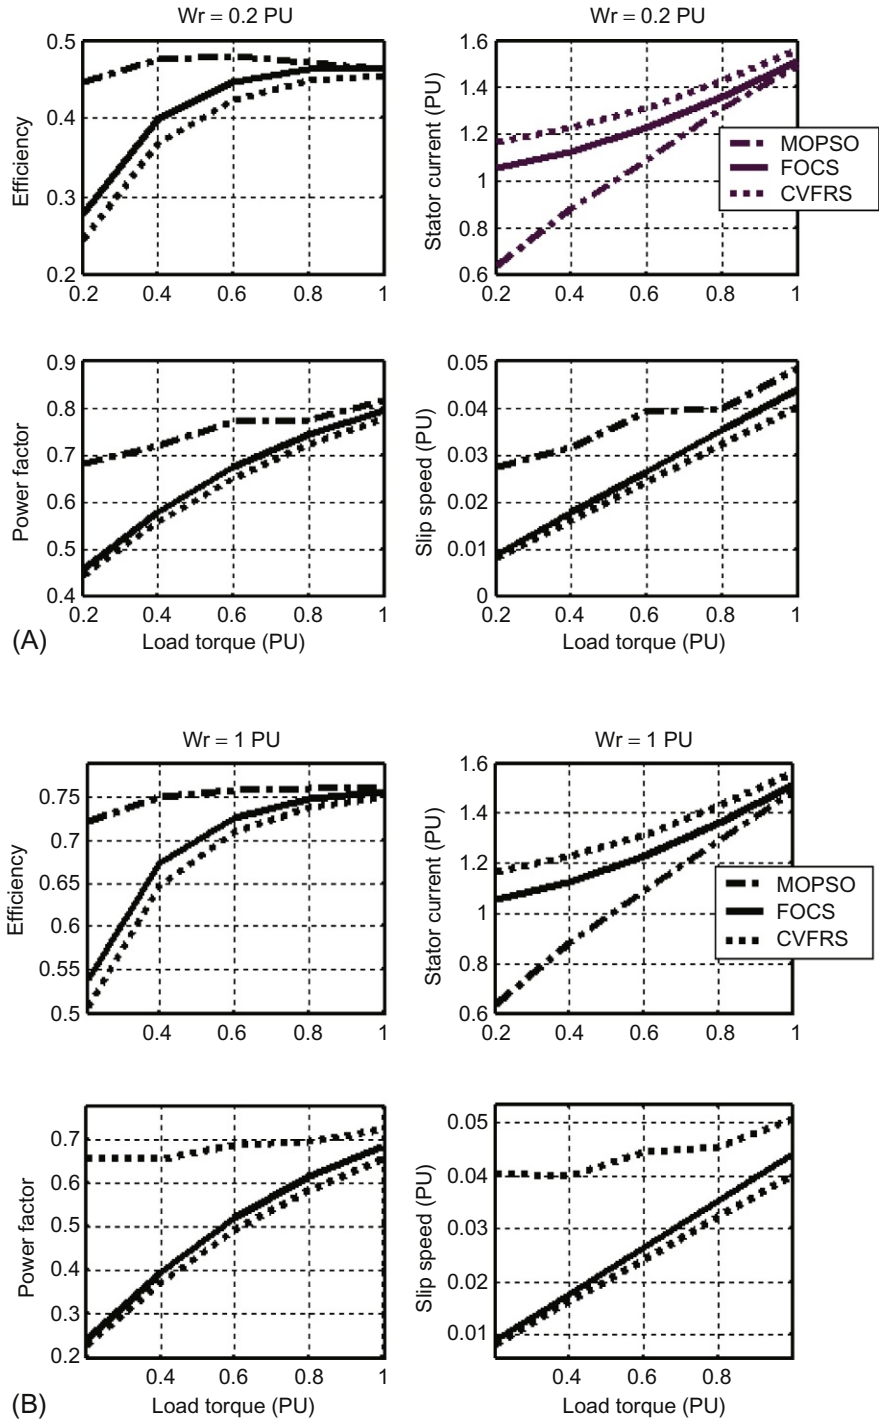

FIG. 38.10 The comparison between CVFRS, FOCS, and MOPSO for different levels of load torque T_L and different levels of rotor speed: (A) $\omega_r = 0.2$ pu and (B) $\omega_r = 1$ pu.

under varying parameter and load conditions. The control system comprises four different controllers used to track speed reference trajectory depicting the motor with minimum over-current, inrush, and ripple conditions. The proposed novel control scheme has been validated for effective dynamic speed reference trajectory tracking and enhanced power utilization.

38.8.2.1 Sample Study AC-DC System

Figs. 38.11 and 38.12 show the proposed the four-wheel electric vehicle drive system scheme with the PV, FC sources, the diesel generator, and the backup battery. The DC compensator scheme developed by the first author is used to ensure stable, efficient, and minimal inrush operation of the hybrid renewable energy

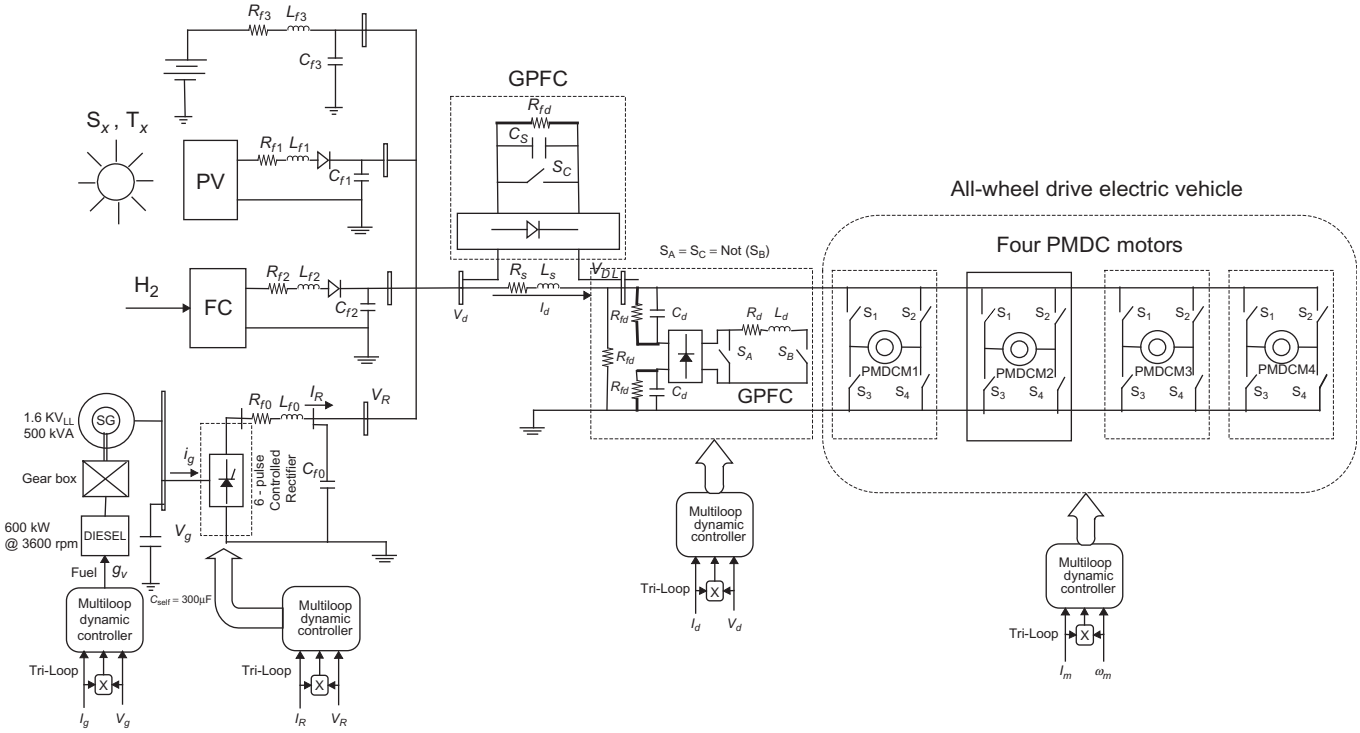

FIG. 38.11 The proposed all-wheel electric vehicle drive system with PV-FC-diesel-battery AC/DC generation.

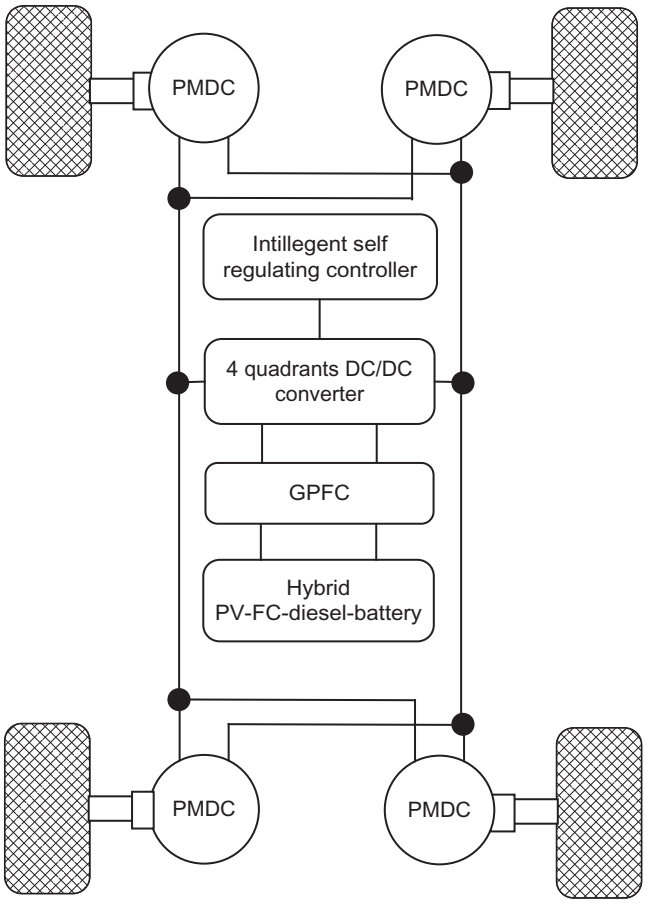

FIG. 38.12 Schematic diagram of a prototype all-wheel drive electric vehicle using four PMDC motors.

scheme. The novel PSO and GA self-tuned multiregulators and coordinated controller are used for the following purposes:

1. Diesel AC generator set with control regulator is based on excess generation and load dynamic matching and stabilization of the common DC collection bus using six-pulse-controlled rectifier.
2. AC/DC power converter regulator to regulate the DC voltage at the diesel engine AC/DC interface and ensure limited inrush conditions and dynamic power matching to reduce current transients and improve utilization at the diesel engine interface AC-DC bus.
3. The DC side green plug filter compensator GPFC-SPWM regulator for pulse-width switching scheme to regulate the DC bus voltage and minimize inrush current transients and load excursions and/or PV and FC nonlinear volt-ampere characteristics. The GPFC device acts as a matching DC-DC interface device between the DC load dynamic characteristics and that of the hybrid main PV, FC, and backup diesel generator set.
4. The permanent magnet DC motor drive with the speed regulator that ensures speed reference tracking with minimum inrush conditions and ensures reduced voltage transients and improved energy utilization.

The unified DC-AC utilization scheme is fully validated using the Matlab/Simulink software environment under normal conditions, DC load excursion, PMDC motor torque changes and the PV, and FC source output variations due to the inherent volt-ampere nonlinear relationship. Other excursion conditions in the diesel engine generator set are also introduced to assess

the control system robustness, effective energy utilization, and speed reference tracking.

Diesel generator set

From an electric system point of view, a diesel-driven AC generator can be represented as a prime mover and generator. Ideally, the prime mover has the capability to supply any power demand up to rated power at constant synchronous frequency. The synchronous generator connected to it must be able to keep the voltage constant at any load condition. The diesel engine kept the operating speed and frequency constant. When power demand fluctuates, the diesel generator could vary its power output via fuel valve regulation and governor control. The synchronous generator must control its output voltage by controlling its excitation current. Thus, the diesel generating system, as an auxiliary source, must be able to control its frequency and its output voltage. The ability of the diesel generator to respond to any frequency changes is affected by the inertia of the diesel gen set, the sensitivity of the governor, and the power capability of the diesel engine. The ability of the AC synchronous generator to control its terminal voltage can be affected by the field-winding time constant, the availability of DC excitation power to supply the field winding, and the time constant of the voltage control loop.

Photo voltaic PV

The equivalent circuit shown in Fig. 38.13 is used to model the PV cells used in the proposed PV array [29]. This model consists of a current source, a resistor, and a reverse parallel connected diode. The PVA model developed and used in Matlab/Simulink environment is based upon the circuit given in Fig. 38.13, in which the current produced by the solar cell is equal to that produced by the current source, minus that which flows through the diode, minus that which flows through the shunt resistor:

$$I = I_L - I_D - I_{SH} \tag{38.8}$$

where I = output current, I_L = photo-generated current, I_D = diode current, and I_{SH} = shunt current. The current through these elements is governed by the voltage across them:

$$V_j = V + IR_S \tag{38.9}$$

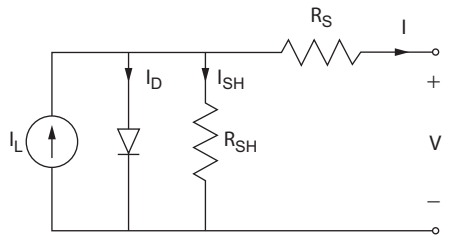

FIG. 38.13 The equivalent circuit of a solar cell.

where V_j = voltage across both diode and resistor R_{SH} (volts), V = voltage across the output terminals (volts), I = output current (amperes), and R_S = series resistance (Ω).

The current diverted through the diode is

$$I_D = I_o\left\{\exp\left[\frac{qV_j}{nkT}\right] - 1\right\} \tag{38.10}$$

where I_0 = reverse saturation current (amperes), n = diode ideality factor (1 for an ideal diode), q = elementary charge, k = Boltzmann's constant, and T = absolute temperature.

The characteristic equation of a solar cell, which relates solar cell parameters to the output current and voltage [30]:

$$I = I_L - I_o\left\{\exp\left[\frac{q(V+IR_s)}{nkT}\right] - 1\right\} - \frac{V+IR_s}{R_{SH}} \tag{38.11}$$

where R_{SH} = shunt resistance (Ω). The I-V curve of an illuminated PV cell has the shape shown in Fig. 38.14 as the voltage across the measuring load is swept from zero to V_{OC}, The power produced by the cell in watts can be easily calculated along the I-V sweep by the equation $P = IV$. At the I_{SC} and V_{OC} points, the power will be zero, and the maximum value for power will occur between the two.

Fuel cell energy system model

Fuel cell stacks were connected in series/parallel combination to achieve the rating desired. Fig. 38.15 shows a simplified diagram of the PEMFC system [31,32]. The FC model here is for a type of PEM, which uses the following electrochemical reaction:

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O + \text{Heat} + \text{Electrical Energy} \tag{38.12}$$

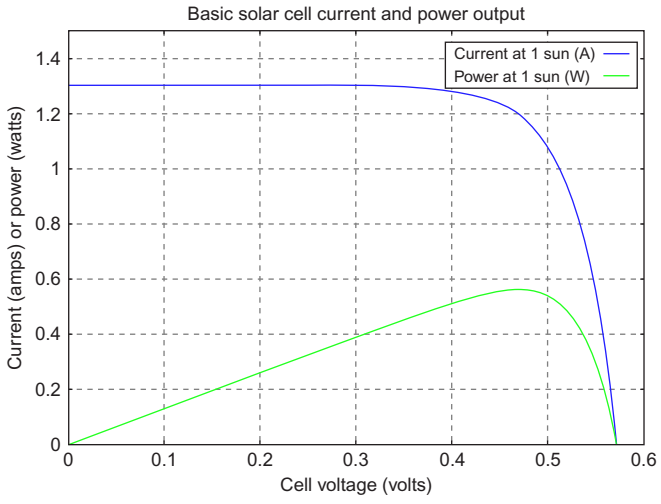

FIG. 38.14 The behavior of a solar cell at particular intensities of solar radiation.

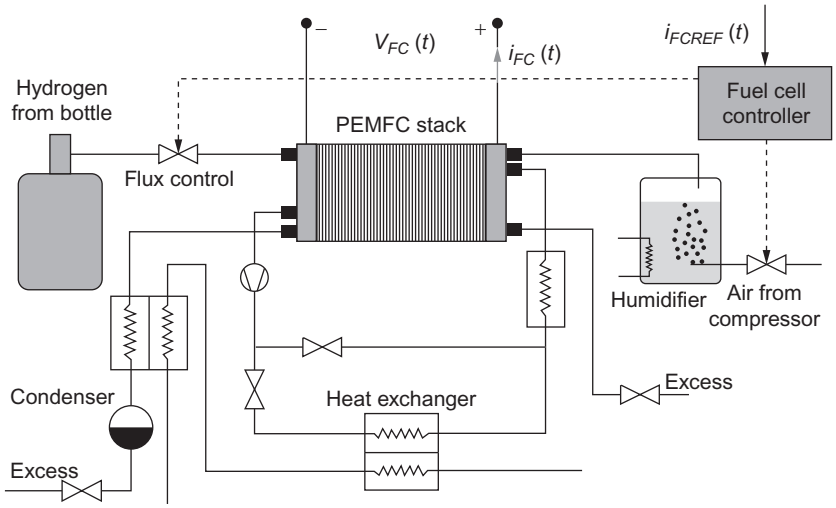

FIG. 38.15 Simplified diagram of the fuel cell PEMFC system.

Fig. 38.16 shows a simulated *V-I* (voltage versus current) polarization curve of a fuel cell [31,32]. As the cell current begins to increase from zero, a sudden drop of the output voltage of the fuel cell is seen. This drop of the cell voltage is due to activation voltage loss. Then, almost a linear decrease of the cell voltage is seen as the cell current increases beyond certain values, as shown in Fig. 38.17, which is a result of the ohmic loss. Finally, the cell voltage drops sharply to zero as the load current approaches the maximum current density that can be generated of the fuel cell. The sharp voltage drop is the effect of the concentration loss in the fuel cell. The fuel cell can be commonly modeled by simple equivalent first-order circuit shown in Fig. 38.10. The open circuit voltage is modified as follows:

$$E_{oc} = N(E_n - A \ln(i_o)) \tag{38.13}$$

where

$$A = \frac{RT}{Z\alpha F} \tag{38.14}$$

where $R = 8.3145$ J/(mol K); $F = 96{,}485$ As/mol; $z =$ number of moving electrons; $E_n =$ Nernst voltage, which is the thermodynamics voltage of the cells and depends on the temperatures and partial pressures of reactants and products inside the stack; and $i_0 =$ exchange current, which is the current resulting from the continual backward and forward flow of electrons from and to the electrolyte at no load. It depends also on the temperatures and partial pressures of reactants inside the stack. α is the

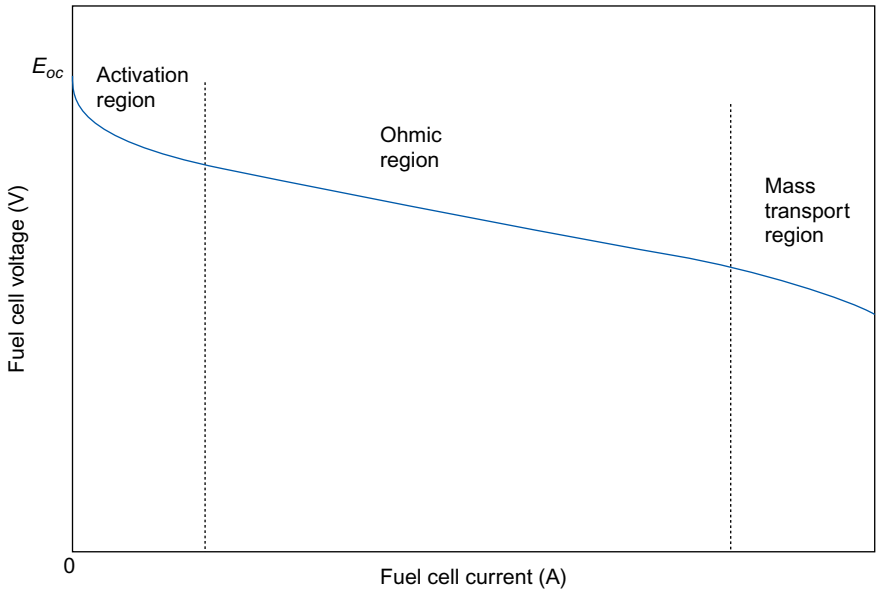

FIG. 38.16 (*V-I*) polarization curve of an SOFC.

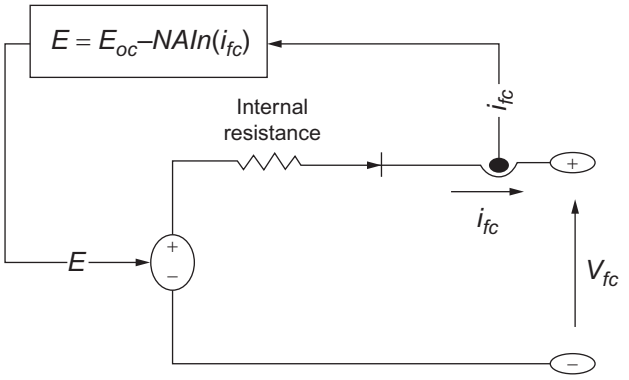

FIG. 38.17 DC-equivalent circuit of an electrochemical fuel cell.

charge transfer coefficient, which depends on the type of electrodes and catalysts used and T is the temperature of operation. The fuel cell voltage V_{FC} is modeled as [31,32]

$$V_{FC} = E_{oc} - V_{\text{Activation loss}} - V_{\text{Ohmic loss}} - V_{\text{Concentrion loss}} \quad (38.15)$$

where

$$V_{Activation\ Loss} = A\log\left(\frac{I_{FC}+i_n}{i_o}\right) \quad (38.16)$$

$$V_{Ohmic\ Loss} = R_m(I_{FC}+i_n) \quad (38.17)$$

$$V_{Concentration\ Loss} = B\log\left(1-\frac{I_{FC}+i_n}{i_L}\right) \quad (38.18)$$

Fuel cell stacks were connected in series/parallel combination to achieve the rating desired. The output of the fuel cell array was connected to a DC bus through a DC/DC converter. The DC bus voltage was kept constant via a DC bus voltage controller.

DC side green plug filter compensator GPFC

The common concerns of power quality are the long-duration voltage variations (overvoltage, undervoltage, and sustained interruptions), short-duration voltage variations (interruption, sags, and swells), voltage imbalance (voltage unbalance), waveform distortion (DC offset, harmonics, interharmonics, notching, and noise), voltage fluctuation (voltage flicker), and power frequency variations [33]. To prevent the undesirable states and to reduce the power consumption, a GPF scheme is used to stabilize the common DC bus.

Dynamic error driven control

The proposed control system developed by first author comprises four subregulators or controllers named as a diesel DC generator set value control regulator, DC side green plug filter compensator GPFC-SPWM regulator, the permanent magnet DC motor drive speed controller, and the AC/DC power converter regulator. Figs. 38.12–38.15 depict the proposed multiloop dynamic self-regulating controllers based on multiobjective optimization search and optimization technique based on soft computing PSO and GA. The global error is the summation of the three loop individual errors including voltage stability, current limiting, and synthesis dynamic power loops. Each multiloop dynamic control scheme is used to reduce a global error based on a triloop dynamic error summation signal and to mainly track a given speed reference trajectory loop error in addition to other supplementary motor current limiting, and dynamic power loops are used as auxiliary loops to generate a dynamic global total error signal that consists of not only the main loop speed error but also the current ripple, overcurrent limit, and dynamic overload power conditions.

The global error signal is input to the self-tuned controllers shown in Figs. 38.18–38.21. The (per unit) three-dimensional-error vector (e_{vg}, e_{Ig}, and e_{pg}) of the diesel engine controller scheme is governed by the following equations:

$$e_{vg}(k) = V_g(k)\left(\frac{1}{1+ST_g}\right)\left(\frac{1}{1+SD}\right) - V_g(k)\left(\frac{1}{1+ST_g}\right) \quad (38.19)$$

$$e_{Ig}(k) = I_g(k)\left(\frac{1}{1+ST_g}\right)\left(\frac{1}{1+SD}\right) - I_g(k)\left(\frac{1}{1+ST_g}\right) \quad (38.20)$$

$$e_{Pg}(k) = I_g(k)\times V_g(k)\left(\frac{1}{1+ST_g}\right)\left(\frac{1}{1+SD}\right) - I_g(k) \times V_g(k)\left(\frac{1}{1+ST_g}\right) \quad (38.21)$$

The total or global error $e_{tg}(k)$ at the AC side scheme at a time instant

$$e_{tg}(k) = \gamma_{vg}e_{vg}(k) + \gamma_{ig}e_{ig}(k) + \gamma_{pg}e_{pg}(k) \quad (38.22)$$

In the same manner, the (per unit) three-dimensional-error vector (e_{vd}, e_{Id}, and e_{pd}) of the GPFC scheme is governed by the following equations:

$$e_{vd}(k) = V_d(k)\left(\frac{1}{1+ST_d}\right)\left(\frac{1}{1+SD}\right) - V_d(k)\left(\frac{1}{1+ST_d}\right) \quad (38.23)$$

$$e_{Id}(k) = I_d(k)\left(\frac{1}{1+ST_d}\right)\left(\frac{1}{1+SD}\right) - I_d(k)\left(\frac{1}{1+ST_d}\right) \quad (38.24)$$

$$e_{Pd}(k) = I_d(k)\times V_d(k)\left(\frac{1}{1+ST_d}\right)\left(\frac{1}{1+SD}\right) - I_d(k) \times V_d(k)\left(\frac{1}{1+ST_d}\right) \quad (38.25)$$

and the total or global error $e_{td}(k)$ for the DC side green plug filter compensator GPFC scheme at a time instant

$$e_{td}(k) = \gamma_{vd}e_{vd}(k) + \gamma_{id}e_{id}(k) + \gamma_{pd}e_{pd}(k) \quad (38.26)$$

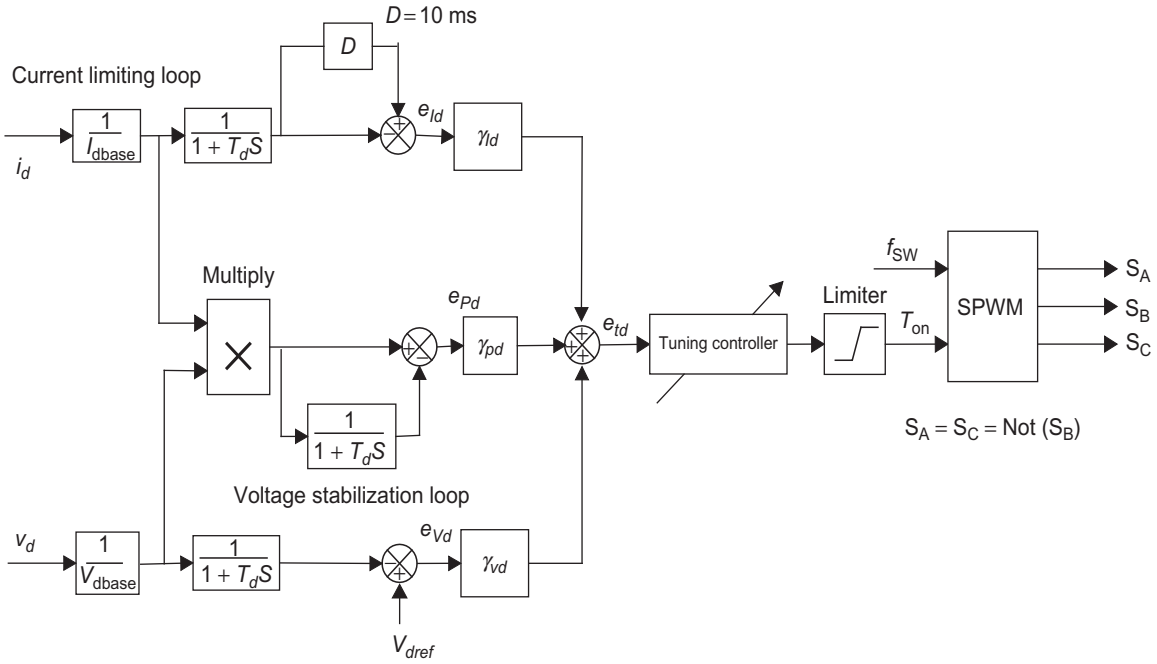

FIG. 38.18 Triloop error-driven self-regulating VSC/SMC/B-B controller for the common DC side GPFC scheme.

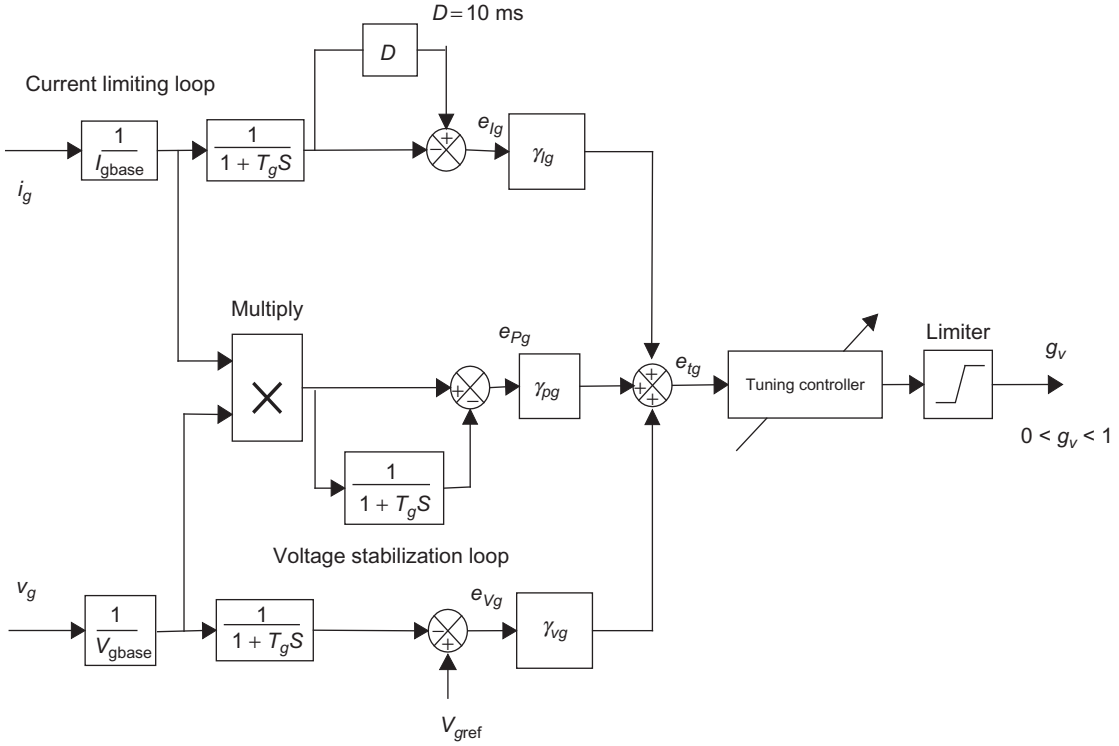

FIG. 38.19 Triloop error-driven self-regulating VSC/SMC/B-B controller for the diesel engine generator set.

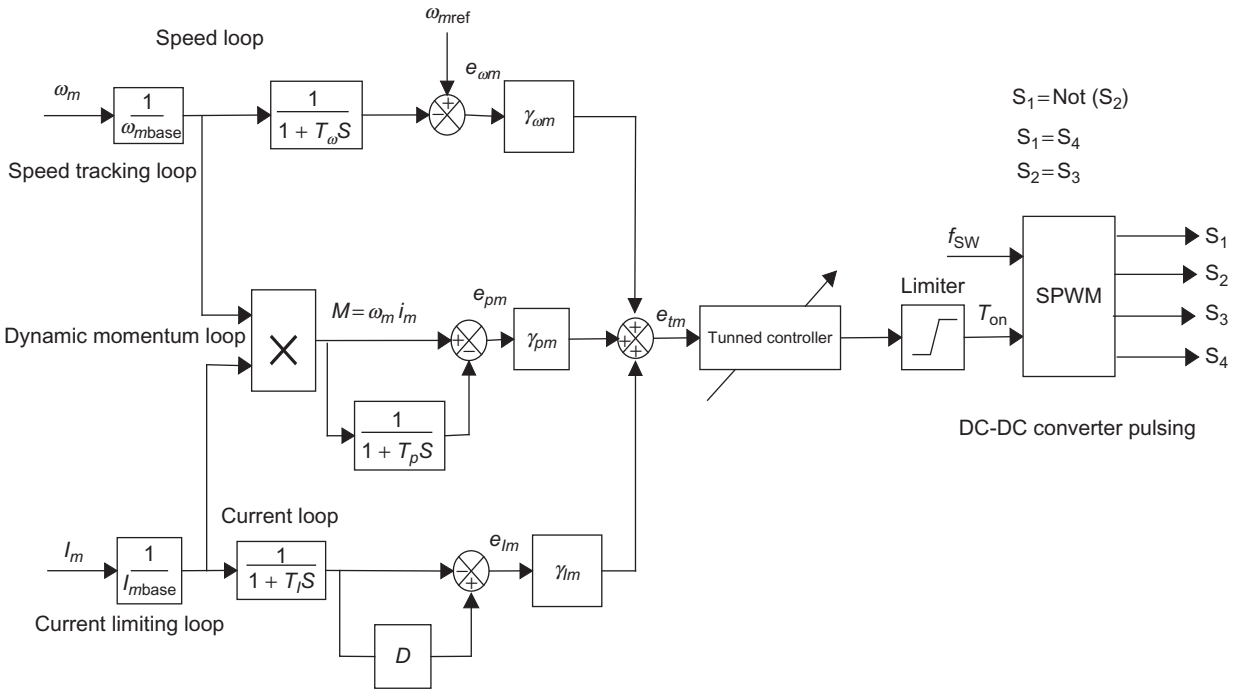

FIG. 38.20 Triloop error-driven self-regulating VSC/SMC/B-B controller for dynamic speed control PMDC motor drive.

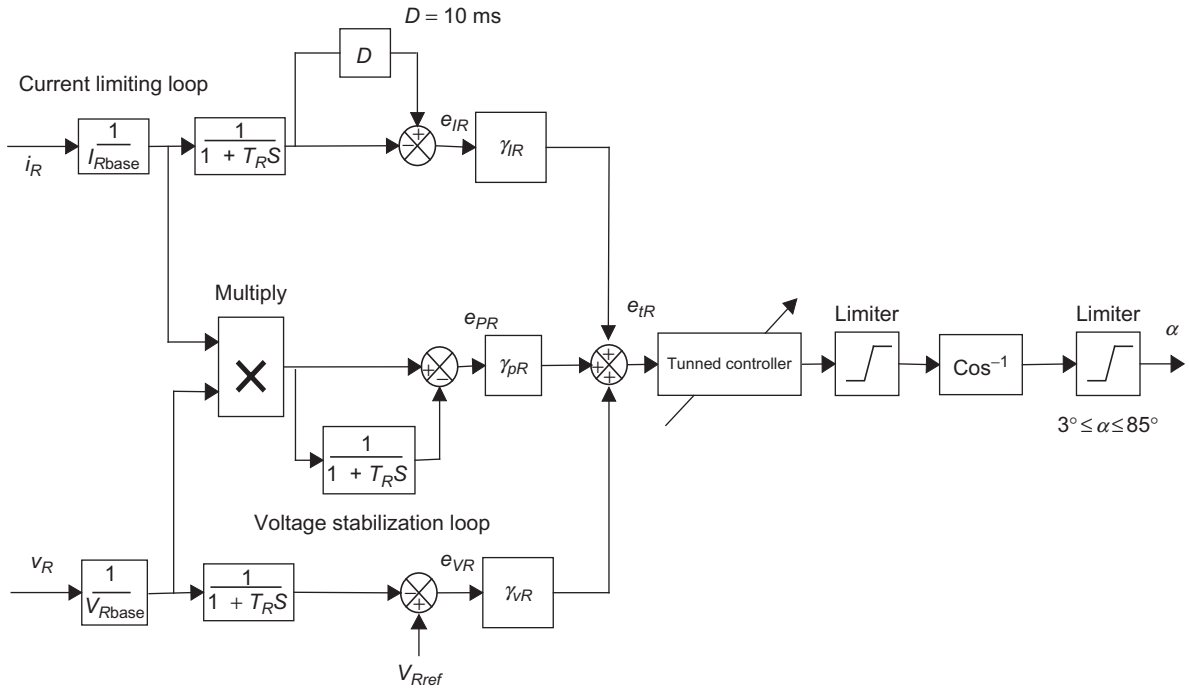

FIG. 38.21 Triloop error-driven self-regulating VSC/SMC/B-B controller firing angle α-controller for diesel AC/DC interface rectifier scheme.

In addition, The (per unit) three-dimensional-error vector (e_{vR}, e_{IR}, and e_{pR}) of the three-phase-controlled rectifier scheme is governed by the following equations:

$$e_{vR}(k) = V_R(k)\left(\frac{1}{1+ST_R}\right)\left(\frac{1}{1+SD}\right) - V_R(k)\left(\frac{1}{1+ST_R}\right) \tag{38.27}$$

$$e_{IR}(k) = I_R(k)\left(\frac{1}{1+ST_R}\right)\left(\frac{1}{1+SD}\right) - I_R(k)\left(\frac{1}{1+ST_R}\right) \tag{38.28}$$

$$e_{PR}(k) = I_R(k) \times V_R(k)\left(\frac{1}{1+ST_R}\right)\left(\frac{1}{1+SD}\right) - I_R(k) \times V_R(k)\left(\frac{1}{1+ST_R}\right) \tag{38.29}$$

The total or global error $e_{tR}(k)$ for the three-phase-controlled converter rectifier scheme at a time instant:

$$e_{tR}(k) = \gamma_{vR}e_{vR}(k) + \gamma_{iR}e_{iR}(k) + \gamma_{pR}e_{pR}(k) \tag{38.30}$$

Finally, the (per unit) three-dimensional-error vector ($e_{\omega m}$, e_{Im}, and e_{pm}) of the PMDC motor scheme is governed by the following equations:

$$e_{\omega m}(k) = \omega_m(k)\left(\frac{1}{1+ST_m}\right)\left(\frac{1}{1+SD}\right) - \omega_m(k)\left(\frac{1}{1+ST_m}\right) \tag{38.31}$$

$$e_{\mathrm{Im}}(k) = I_m(k)\left(\frac{1}{1+ST_m}\right)\left(\frac{1}{1+SD}\right) - I_m(k)\left(\frac{1}{1+ST_m}\right) \tag{38.32}$$

$$e_{Pm}(k) = I_m(k) \times \omega_m(k)\left(\frac{1}{1+ST_m}\right)\left(\frac{1}{1+SD}\right) - I_m(k) \times \omega_m(k)\left(\frac{1}{1+ST_m}\right) \tag{38.33}$$

and the total or global error $e_{tm}(k)$ for the MPFC scheme at a time instant

$$e_{tm}(k) = \gamma_{\omega m}e_{\omega m}(k) + \gamma_{im}e_{im}(k) + \gamma_{pm}e_{pm}(k) \tag{38.34}$$

A number of conflicting objective functions are selected to optimize using the PSO algorithm. These functions are defined by the following:

$$J_1 = \text{Minimize}\left\{\left|e_{tg}\right|, |e_{tR}|, |e_{td}|, |e_{tm}|\right\} \tag{38.35}$$

$$J_2 = \text{Steady state error} = |e_{\omega}(k)| = \left|\omega_{ref}(k) - \omega_m(k)\right| \tag{38.36}$$

$$J_3 = \text{Settling time} \tag{38.37}$$

$$J_4 = \text{Maximum over shoot} \tag{38.38}$$

$$J_5 = \text{Rise time} \tag{38.39}$$

In general, to solve this multiobjective complex optimality search problem, there are two possible optimization techniques based on particle swarm optimization (PSO): single aggregate selected objective optimization (SOO), which is explained, and multiobjective optimization (MOO). The main procedure of the SOO is based on selecting a single aggregate objective function with weighted single-objective parameters scaled by a number of weighting factors. The objective function is optimized (either minimized or maximized) using either GA or particle swarm optimization search algorithm (PSO) methods to obtain a single global or near-optimal solution. On the other hand, the main objective of the multiobjective (MO) problem is finding the set of acceptable (trade-off) optimal solutions. This set of accepted solutions is called Pareto front. These acceptable trade-off multilevel solutions give more ability to the user to make an informed decision by seeing a wide range of near-optimal selected solutions that are feasible and acceptable from an "overall" standpoint. Single-objective (SO) optimization may ignore this trade-off viewpoint, which is crucial. The main advantages of the proposed MOO method are the following: It doesn't require a priori knowledge of the relative importance of the objective functions, and it provides a set of acceptable trade-off near-optimal solutions. This set is called Pareto front or optimality trade-off surfaces. Both SOO and MOO searching algorithms are tested, validated, and compared. The dynamic error-driven controller regulates the controllers' gains using the particle swarm optimization (PSO) and GA to minimize the system total error, the settling time, the rising time, and the maximum overshoot. The proposed dynamic triloop error-driven controller, developed by the first author, is a novel advanced regulation concept that operates as an adaptive dynamic-type multipurpose controller capable of handling sudden parametric changes, load and/or DC source excursions. By using the triloop error-driven controller, it is expected to have a smoother, less dynamic overshoot and fast and more robust speed controller when compared with those of classical control schemes. The proposed general PMDC motor drive model with the novel triloop error-driven controller is fully validated in this application for effective reference speed trajectory tracking under different loading conditions and parametric variations, such as temperature changes, while driving a complex mechanical load with nonlinear parameters and/or torque-speed characteristics.

Self tuned variable structure sliding mode bang-bang VSC/SMC/B-B controller

In the variable structure sliding mode controller scheme, an optimally adaptive and self-tuned variable structure sliding

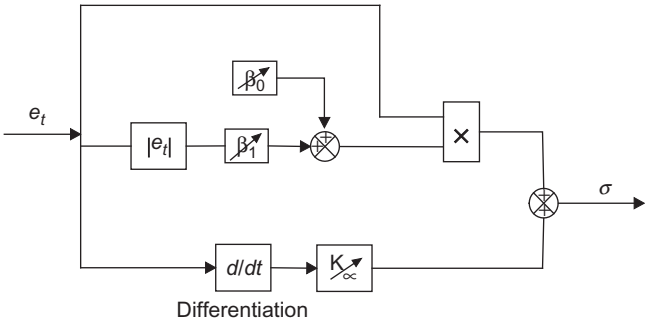

FIG. 38.22 VSC/SMC/B-B controller block diagram.

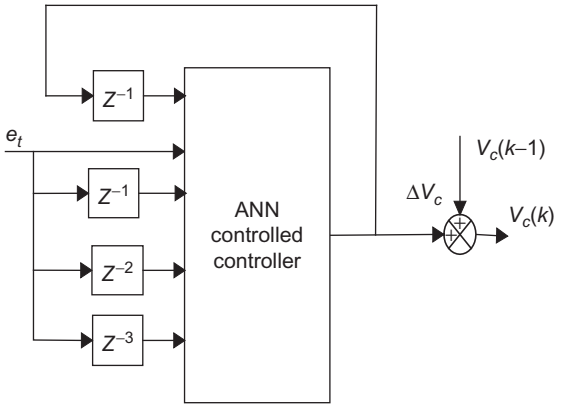

FIG. 38.23 ANN incremental controlled controller block diagram.

mode controller for PMDC motor drive systems using particle swarm optimization technique (PSO) and GA is shown in Fig. 38.22. The slope of the sliding surface is designed as

$$\sigma = \beta e_t + K_\alpha \frac{de_t}{dt} \tag{38.40}$$

With adaptive adjustable error scaling gain,

$$\beta = \beta_0 + \beta_1 |e_t| \tag{38.41}$$

where

$$|e_t| = \sqrt{(\gamma_I e_I)^2 + (\gamma_\omega e_\omega)^2 + (\gamma_V e_V)^2 + \left(\gamma_p e_p\right)^2} \tag{38.42}$$

The system control voltage has the following form in the time domain [33]: the control is an on-off logic; that is, when $\sigma > 0$, $V_c = 1$, and when $\sigma < 0$, $V_c = -1$

The PSO and GA search and optimization are implemented for tuning the various gains β_0, β_1, and α to minimize the selected five conflicting objective functions ($J_1 - J_5$). This test is to verify that the proposed VSC/B-B with adaptive β can maintain the motor speed with nonlinear $J(\omega_m)$ and $B(\omega_m)$ even if the load changes; accordingly, the robustness can be confirmed.

Self tuned artificial neural network controller ANN

The neural network used in this application is the simplest one that uses three layers, which is widely used in the control of the electric machines. Each layer is composed of neurons. Each neuron is connected via weights to the previous layer. The first layer is connected to the input variables. The second one is connected via weights to all the neurons of the previous layer, and the last one is composed of one neuron given the output value. The weights and the biases of the ANN network's are updated to provide that the global error of the system is minimized. The proposed ANN regulator is tuned online using the back-propagation algorithm. The online ANN rule-based algorithm is used to update the ANN network weights and biases to ensure continuous effective dynamic response while keeping the motor inrush current under specified tolerable limits. The input vector with three-layer ANN as shown in Fig. 38.23 is

$$\overline{X} = \{e_t(k), e_t(k-1), e_t(k-2), e_t(k-3), \Delta V_c(k-1)\} \tag{38.43}$$

Self tuned fuzzy logic controller (FLC)

As shown in Fig. 38.24, the FLC system consists of three subsystems, which are the fuzzification, rule base, and defuzzification. Fuzzification subsystem converts the exact inputs to fuzzy values using five membership functions: positive big (PB), positive small (PS), zero (ZZ), negative small (NS), and negative big (NB). The rule base unit processes these fuzzy values with fuzzy rules. The defuzzification unit converts the fuzzy results to exact values. The FLC input values are the global error, e_t, and change in global error, de_t. According to these variables, a rule table is produced in the FLC rule base unit as shown in Table 38.4.

38.8.2.2 Digital Simulation Results

The integrated microgrid for PMDC-driven electric vehicle scheme using the photovoltaic (PV), fuel cell (FC), and backup diesel generation with battery backup renewable generation system performance is compared for two cases, with fixed and self-tuned-type controllers using either GA or PSO. The second case is to compare the performance with artificial neural network (ANN) controller and fuzzy logic controller (FLC) with the self-tuned-type controllers using either GA or PSO. The tuned variable structure sliding mode controller VSC/SMC/B-B has been applied to the speed tracking control of the same EV for performance comparison. There are three different speed references. In the first speed track, the speed increases linearly and reaches the 1 pu at the end of the first 5 s, and then, the reference speed remains speed constant during 5 s. At tenth second, the reference speed decreases with same slope as at the first 5 s. After 15 s, the motor changes the direction and EV increases its speed through the reverse direction. At twentieth second, the reference speed reaches the −1 pu and remains constant speed at the end of twenty-fifth second, and then, the reference speed decreases and

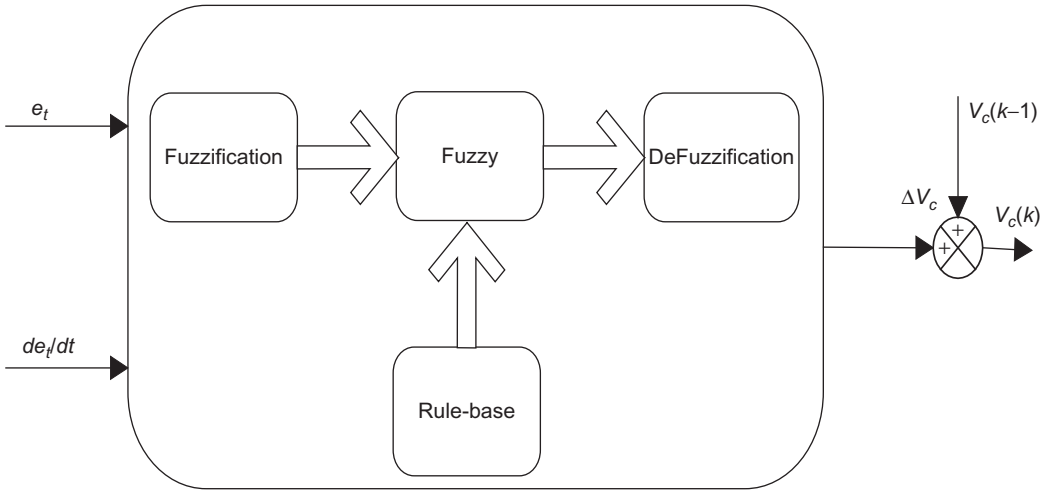

FIG. 38.24 Main structure of the FLC incremental scheme.

TABLE 38.4 Fuzzy rule decision table

	de_t

becomes zero at thirtieth second. The second reference speed waveform is sinusoidal, and its magnitude is 1 pu, and the period is 12 s. The third reference track is constant speed reference starting with an exponential track. In all references, the system responses have been observed. Matlab/Simulink software was used to design, test, and validate the effectiveness of the integrated microgrid for PMDC-driven electric vehicle scheme using photovoltaic (PV), fuel cell (FC), and backup diesel generation with battery backup renewable generation system with the FACTS devices. The digital dynamic simulation model using Matlab/Simulink software environment allows for low-cost assessment and prototyping, system parameter selection, and optimization of control settings. The use of PSO search algorithm is utilized in online gain adjusting to minimize controller absolute value of total error. This is required before full-scale prototyping that is both expensive and time-consuming. The effectiveness of dynamic simulators brings on detailed submodels selections and tested submodels Matlab library of power system components already tested and validated. The common DC bus voltage reference is set at 1 pu. Digital simulations are obtained with sampling interval Ts = 20 μs. Dynamic responses obtained with GA are compared with the ones resulting from the PSO for the seven proposed self-tuned controllers. The dynamic simulation conditions are identical for all tuned controllers. To compare the global performances of all controllers, the normalized mean-square-error (*NMSE*) deviations between output plant variables and desired values and is defined as

$$NMSE_{V_{\mathrm{DC-bus}}} = \frac{\sum \left(V_{\mathrm{DC-bus}} - V_{\mathrm{DC-bus-ref}}\right)^2}{\sum \left(V_{\mathrm{DC-bus-ref}}\right)^2} \tag{38.44}$$

$$NMSE_{\omega_m} = \frac{\sum \left(\omega_m - \omega_{m-ref}\right)^2}{\sum \left(\omega_{m-ref}\right)^2} \tag{38.45}$$

The digital simulation results validated the effectiveness of both GA- and PSO-based tuned controllers in providing effective speed tracking minimal steady-state errors. Transients are also damped with minimal overshoot, settling time, and fall time. The GA- and PSO-based self-tuned controllers are more effective and dynamically advantageous in comparison with the artificial neural network (ANN) controller, the fuzzy logic controller (FLC), and fixed-type controllers. The self-regulation is based on minimal value of absolute total/global error of each regulator shown in Figs. 38.18–38.21. The control system comprising the three dynamic multiloop error-driven regulators is coordinated to minimize the selected objective functions. SOO obtains a single global or near-optimal solution based on a single-weighted objective function. The weighted single-objective function combines several objective functions using specified or selected weighting factors as follows:

$$\text{weighted objective function} = \alpha_1 J_1 + \alpha_2 J_2 + \alpha_3 J_3 + \alpha_4 J_4 + \alpha_5 J_5 \tag{38.46}$$

where $\alpha_1 = 0.20$, $\alpha_2 = 0.20$, $\alpha_3 = 0.20$, $\alpha_4 = 0.20$, and $\alpha_5 = 0.20$ are selected weighting factors. J_1, J_2, J_3, J_4, and J_5 are the selected objective functions. On the other hand, the MO finds the set of

acceptable (trade-off) optimal solutions. This set of accepted solutions is called Pareto front. These acceptable trade-off multilevel solutions give more ability to the user to make an informed decision by seeing a wide range of near-optimal selected solutions.

Table 38.5 shows the optimal solutions of the main objective functions versus the tuned variable structure sliding mode controller gain-based SOGA and MOGA control schemes. On the other hand, Table 38.6 shows the optimal solutions of the main objective functions versus the tuned variable structure sliding mode controller gain-based SOPSO and MOPSO control schemes. Table 38.7 shows the DC bus behavior comparison using the GA-based tuned variable structure sliding mode controller for the three selected reference tracks. In addition, Table 38.8 shows the system behavior using the PSO-based tuned variable structure sliding mode controller. Figs. 38.25–38.30 show the effectiveness of MOPSO and MOGA search and optimized control gains in tracking the PMDC-EV motor three reference speed trajectories. Comparing the PMDC-EV dynamic response results of the two study cases, with GA and PSO tuning algorithms and traditional controllers with constant controller gain results shown in Table 38.9, ANN controller in Table 38.10 (Figs. 38.31–38.33) and FLC in Table 38.11 (Figs. 38.34–38.36), it is quite apparent that the GA and PSO tuning algorithms highly improved the PMDC-EV system dynamic performance from a general power quality point of view. The GA and PSO tuning algorithms had a great impact on the system efficiency improving it from 0.906631 (constant gains controller), 0.928253 (ANN controller), and 0.937334 (FLC) to around 0.948156 (GA-based tuned controller) and 0.930708 (PSO-based tuned controller) that is highly desired. Moreover, the normalized mean square error ($NMSE\text{-}V_{\text{DC-Bus}}$) of the DC bus voltage is reduced from 0.08443 (constant gains controller), 0.04827 (ANN controller), and 0.03022 (FLC) to around 0.007304 (GA-based tuned controller) and 0.005854 (PSO-based tuned controller). In addition, the normalized mean square error ($NMSE_\omega_m$) of the PMDC motor is reduced from 0.053548 (constant gains controller), 0.02627 (ANN controller), and 0.02016 (FLC) to around 0.0076308 (GA-based tuned controller) and 0.006309 (PSO-based tuned controller). Maximum transient DC voltage over/undershoot (pu) is reduced from 0.054604 (constant gains controller), 0.04186 (ANN controller), and 0.03126 (FLC) to around 0.009302 (GA-based tuned controller) and 0.007259 (PSO-based tuned controller). Maximum transient DC current—over/undershoot (pu) is reduced from 0.087336 (constant gains controller), 0.07355 (ANN controller), and 0.04383 (FLC) to around 0.00292 (GA-based tuned controller) and 0.005987 (PSO-based tuned controller). DC bus voltage (pu) is improved from 0.917020 (constant gains controller), 0.932736 (ANN controller), and 0.94745 (FLC) to around

38.8.3 Novel Self Regulating Green Plug/Energy Management/Energy Economizer GP-EM-EE Schemes for Wind Driven Induction Generation

The application presents a novel self-adjusting wind energy utilization scheme using a modified single-phase operation of the three-phase induction generator supplemented by a voltage stabilization switched filter compensation scheme developed by the first author. The series-parallel switched capacitor filter scheme is controlled by a dynamic particle swarm optimization (PSO) and GA error-driven self-adjusting controller to ensure voltage stabilization, minimum impact of the electric load excursions, and wind variations on terminal voltage. The sinusoidal pulse-width modulation complementary switching scheme is dynamically controlled using online minimal global error search that continuously adjusts and modifies the controller gains. The application presents a family of novel switched smart filter compensated devices using green plug/energy management/energy economizer GP-EM-EE devices for small single-phase induction motors used in residential/commercial motor drives used in water pumping, ventilation, air conditioning, compressors, and refrigeration applications. The GP-EM-EE devices are equipped with a dynamic online error-driven optimally tuned controller that ensures improved power factor, reduced feeder losses, stabilized voltage, minimal current ripples, and efficient energy utilization/conservation with minimal impact on the host electric grid security and reliability. The proposed schemes can enhance the power quality and extend induction motor life span by reducing overheating due to inrush currents and

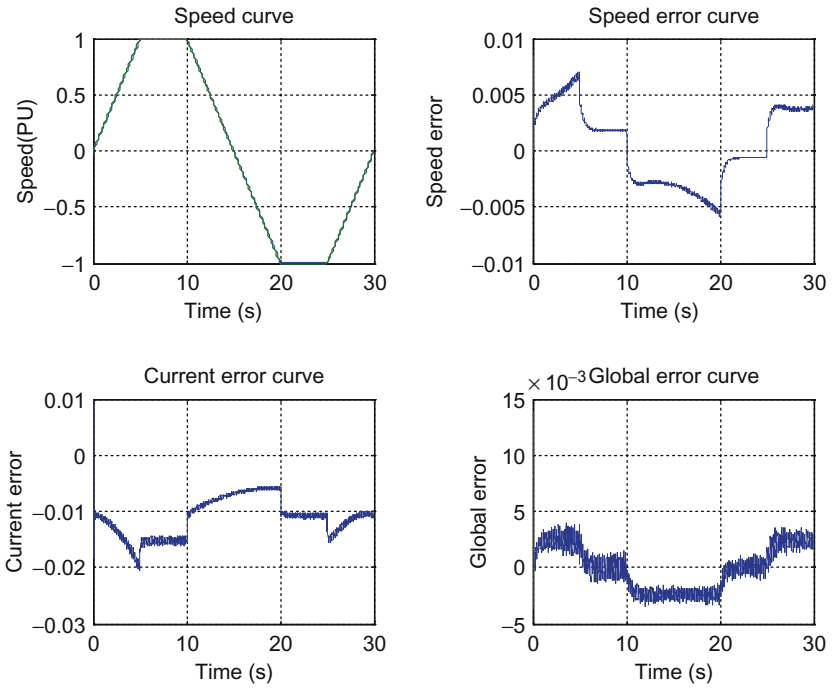

FIG. 38.34 EV-PMDC motor speed response for the first speed track using FLC-based controller.

harmonics. They prevent overheating and possible motor damage. The scheme is suitable for small-scale applications of wind energy utilization in the range from 5 to 25 kVA.

Wind energy conversion systems (WECS) are increasing their number as an environmentally friendly power generation system. Small-sized wind turbine systems in the output power range of 5–25 kVA to be used for the residential houses or small-sized business complex are extending their application fields. There are various advantages of the small-sized wind turbine system. The rotational speed of the smaller sized wind turbines can more rapidly follow the change of the wind speed than the large-scale wind turbines system due to their smaller inertia. This feature contributes higher power generation efficiency of the wind turbines in the case that the wind speed frequently changes [34]. Induction generators are being increasingly utilized in a WECS since they are relatively inexpensive, rigid, and require low maintenance [35]. Small-scale induction motor drives consume over 50% of the total electric energy generated in the developed countries [36]. The electric utility industry and consumers of electric energy around the world are facing new challenges for cutting electric energy cost, improving energy utilization, enhancing energy efficiency, demand-side management, improving supply waveform power quality, reducing safety hazards to personnel, and protecting sensitive computer and automatic data processing networks [37]. There is a mushrooming use of nonlinear electric loads especially in large motor drives, arc furnaces, and power electronic converter loads. All these nonlinear loads are by-products of analog (saturation or limiter-type) or digital (converter, solid-state switching-type) nonlinearities [38]. Nonlinear-type loads cause severe waveform distortion, power quality problem interference, and extra feeder losses due to excessive inrush currents and severe voltage sags. The extended use of power electronic switching conveners and devices in motor drives and process industries such as mining, oil, and gas industries and industrial DC and AC arc-type furnaces has resulted in a polluted grid and unreliable radial distribution/utilization system with serious inherent voltage and power quality problems [39]. These nonlinear-type electric loads are used with ventilation, air conditioning, water pumping, and low-power factor industries such as sewing, printing, shear and press machinery, and food processing plants. These nonlinear loads also fall in the category of inrush or arc-type motorized loads and combined with fluorescent lighting can cause waveform distortion, harmonic interference, and voltage flickering [40–42]. Generally, direct online motor starting is an economic method for starting induction motors. But direct starting will result in severe voltage sags and extra heating. When starting large induction motors, excessive voltage dips result in overheating and loss of motor life expectancy [43].

38.8.3.1 Sample Study Motorized System

Fig. 38.37 depicts the block diagram of the utilization (single-phase induction motor SPIM) and the connection of switched smart filter compensated device using green plug/energy management/energy economizer GP-EM-EE devices and the speed control drive system to the SPIM load. Figs. 38.38 and 38.39 show the proposed triloop dynamic tracking controller to ensure both objectives of (energy/power) saving and power quality enhancement of the supply system current and load bus voltage. The novel PSO and GA self-tuned multiregulators and coordinated controller are used for the following purposes: (1) green plug filter compensator GPFC-SPWM regulator for pulse-width switching scheme to regulate the DC bus voltage and minimize inrush current transients and load excursions and (2) the SPIM drive with the speed regulator that ensures speed reference tracking with minimum inrush conditions and ensure reduced voltage transients and improved energy

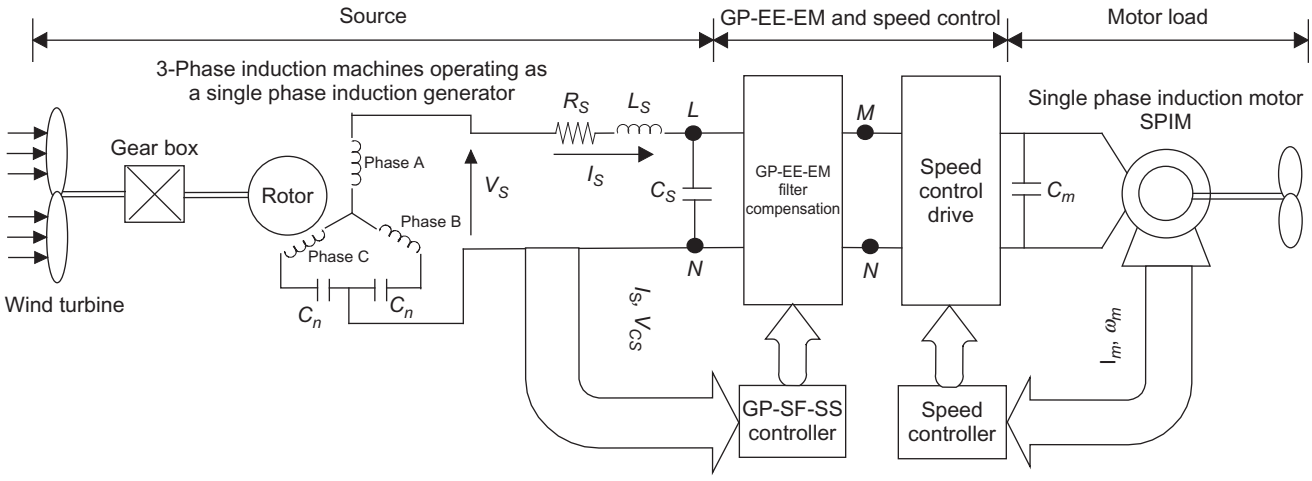

FIG. 38.37 The proposed switched smart filter compensated devices using green plug/energy management/energy economizer GP-EM-EE devices for single-phase induction motor SPIM drive system.

utilization. Figs. 38.40–38.44 depict the proposed family of switched smart filter compensated devices using green plug/energy management/energy economizer GP-EM-EE devices. All filters objectives can be either (a) harmonic reduction and power quality (PQ) enhancement or (b) electric power/energy savings and dynamic reactive compensation for the single-phase induction motor loads. The proposed utilization scheme is fully validated using the Matlab/Simulink software environment under normal conditions, load excursion, SPIM

motor torque changes to assess the control system robustness, effective energy utilization, and speed reference tracking.

The common concerns of power quality are the long-duration voltage variations (overvoltage, undervoltage, and sustained interruptions), short-duration voltage variations (interruption, sags, and swells), voltage imbalance (voltage unbalance), waveform distortion (DC offset, harmonics, inter-harmonics, notching, and noise), voltage fluctuation (voltage flicker), and power frequency variations. To prevent the undesirable states and to reduce the power consumption, a GPF scheme is used to stabilize the system.

Dynamic error driven control

The proposed control system comprises two subregulators or controllers named as DC side green plug filter compensator GPFC-SPWM regulator and the SPIM drive speed controller. Figs. 38.38 and 38.39 depict the proposed multiloop dynamic self-regulating controllers based on multiobjective optimization search and optimization technique based on soft computing PSO and GA. The global error is the summation of the three loop individual errors including voltage stability, current limiting, and synthesize dynamic power loops. Each multiloop dynamic control scheme is used to reduce a global error based on a triloop dynamic error summation signal and to mainly track a given speed reference trajectory loop error in addition

to other supplementary motor current limiting, and dynamic power loops are used as auxiliary loops to generate a dynamic global total error signal that consists of not only the main loop speed error but also the current ripple, overcurrent limit, and dynamic over load power conditions.

The global error signal is input to the self-tuned controllers shown in Fig. 38.38. The (per unit) three-dimensional-error vector (e_{vs}, e_{Is}, and e_{ps}) of the diesel engine controller scheme is governed by the following equations:

$$e_{vs}(k) = V_s(k)\left(\frac{1}{1+ST_s}\right)\left(\frac{1}{1+SD}\right) - V_s(k)\left(\frac{1}{1+ST_s}\right) \tag{38.47}$$

$$e_{Is}(k) = I_s(k)\left(\frac{1}{1+ST_s}\right)\left(\frac{1}{1+SD}\right) - I_s(k)\left(\frac{1}{1+ST_s}\right) \tag{38.48}$$

$$\begin{aligned} e_{Ps}(k) = {} & I_s(k) \times V_s(k)\left(\frac{1}{1+ST_s}\right)\left(\frac{1}{1+SD}\right) \\ & - I_s(k) \times V_s(k)\left(\frac{1}{1+ST_g}\right) \end{aligned} \tag{38.49}$$

The total or global error $e_{ts}(k)$ for the GP-EM-EE side scheme at a time instant

$$e_{ts}(k) = \gamma_{vs} e_{vs}(k) + \gamma_{is} e_{is}(k) + \gamma_{ps} e_{ps}(k) \tag{38.50}$$

In the same manner, the (per unit) three-dimensional-error vector ($e_{\omega m}$, e_{Im}, and e_{pm}) of the SPIM motor scheme is governed by the following equations:

$$e_{\omega m}(k) = \omega_m(k)\left(\frac{1}{1+ST_m}\right)\left(\frac{1}{1+SD}\right) - \omega_m(k)\left(\frac{1}{1+ST_m}\right) \tag{38.51}$$

$$e_{Im}(k) = I_m(k)\left(\frac{1}{1+ST_m}\right)\left(\frac{1}{1+SD}\right) - I_m(k)\left(\frac{1}{1+ST_m}\right) \tag{38.52}$$

$$\begin{aligned} e_{Pm}(k) = {} & I_m(k) \times \omega_m(k)\left(\frac{1}{1+ST_m}\right)\left(\frac{1}{1+SD}\right) \\ & - I_m(k) \times \omega_m(k)\left(\frac{1}{1+ST_m}\right) \end{aligned} \tag{38.53}$$

and the total or global error $e_{tm}(k)$ for the MPFC scheme at a time instant

$$e_{tm}(k) = \gamma_{\omega m} e_{\omega m}(k) + \gamma_{im} e_{im}(k) + \gamma_{pm} e_{pm}(k) \tag{38.54}$$

A number of conflicting objective functions are selected to optimize using the PSO algorithm. These functions are defined by the following:

$$J_1 = \text{Minimize the total harmonic distortion of the load current } (THDi) \tag{38.55}$$

$$J_2 = \text{Minimize the total harmonic distortion of the load voltage } (THDv) \tag{38.56}$$

$$J_3 = \text{Maximize the electric energy efficiency} \tag{38.57}$$

$$J_4 = \text{Maximize the power factor} \tag{38.58}$$

$$J_5 = \text{Minimize the KWh consumption} \tag{38.59}$$

In general, to solve this complex optimality search problem, there are two possible optimization techniques based on particle swarm optimization (PSO): single aggregate selected objective optimization (SOO), which is explained, and multiobjective optimization (MOO). The main procedure of the SOO is based on selecting a single aggregate objective function with weighted single-objective parameters scaled by a number of weighting factors. The objective function is optimized (either minimized or maximized) using either GA or particle swarm optimization search algorithm (PSO) methods to obtain a single global or near-optimal solution. On the other hand, the main objective of the multiobjective (MO) problem is finding the set of acceptable (trade-off) optimal solutions. This set of accepted solutions is called Pareto front. These acceptable trade-off multilevel solutions give more ability to the user to make an informed decision by seeing a wide range of near-optimal selected solutions that are feasible and acceptable from an "overall" standpoint. Single-objective (SO) optimization may ignore this trade-off viewpoint, which is crucial. The main advantages of the proposed MOO method are the following: It doesn't require a priori knowledge of the relative importance of the objective functions, and it provides a set of acceptable trade-off near-optimal solutions. This set is called Pareto front or optimality trade-off surfaces. Both SOO and MOO searching algorithms are tested, validated, and compared.

The dynamic error-driven controller regulates the controllers' gains using the particle swarm optimization (PSO) and GA to minimize the system total error and the selected objective functions. The proposed dynamic triloop error-driven controller, developed by the first author, is a novel advanced regulation concept that operates as an adaptive dynamic-type multipurpose controller capable of handling sudden parametric changes, load and/or source excursions. By using the triloop error-driven controller, it is expected to have a smoother, less dynamic overshoot and fast and more robust controller when compared with those of classical control schemes.

Self tuned conventional PID controller

Fundamentally, the conventional PID controller comprises three basic control actions. They are simple to implement and they provide good performance. The tuning process of the gains of PID controllers can be complex because it is iterative: first, it is necessary to tune the "proportional" mode, then the "integral," and then add the "derivative" mode to stabilize

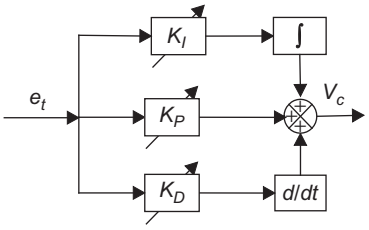

FIG. 38.45 Optimally tuned conventional PID controller block diagram.

the overshoot, then add more "proportional," and so on. The PID controller has the following form in the time domain as shown in Fig. 38.45:

$$u(t) = K_p e(t) + K_i \int_0^t e(t)\,dt + K_d \frac{de(t)}{dt} \tag{38.60}$$

where $e(t)$ is the selected system error, $u(t)$ the control variable, K_p the proportional gain, K_i the integral gain, and K_d is the derivative gain. Each coefficient of the PID controller adds some special characteristics to the output response of the system. Because of this, choosing the right parameters becomes a crucial decision. In this scheme, the triloop error-driven controller is utilized with traditional PID controller. PID controller gains (K_P, K_I, and K_D) are dynamically self-tuned using the PSO and GA dynamic search and optimization criterion based on total error minimization, steady-state error, maximum overshoot, and settling time and rising time.

38.8.3.2 Digital Simulation Results

The family of (GP-EM-EE) devices system performance is compared for two cases; with (as shown in Table 38.12) and without the (GP-EM-EE) devices, the second case is studied with fixed (as shown in Table 38.13) and self-tuned-type controllers using either GA or PSO. In addition, the second case is studied to compare the performance with artificial neural network (ANN) controller (as shown in Table 38.14) and fuzzy logic controller (FLC) (as shown in Table 38.15) with the self-tuned-type controllers using either GA or PSO. The self-tuned-type controllers based either GA or PSO is tuned conventional PID controller and has been applied to the speed tracking control of the same system parameters for performance comparison. Matlab/Simulink software was used to design, test, and validate the effectiveness of the (GP-EM-EE) devices for small motors used in household appliances, washers, dryers, fans, water pumps, ventilation systems, air conditions, and other applications in dispersing machines, actuators, and small converters with induction motor size from 5 to 25 kVA. The digital dynamic simulation model using Matlab/Simulink software environment allows for low-cost assessment and prototyping, system parameter selection, and optimization of control settings. The use of GA and PSO search algorithms is utilized in online gain adjusting to minimize

controller absolute value of total error. This is required before full-scale prototyping that is both expensive and time-consuming. The effectiveness of dynamic simulators brings on detailed submodels selections and tested submodels Matlab library of power system components already tested and validated. The dynamic simulation conditions are identical for all tuned controllers. To compare the global performances of tuned conventional PID controller, the normalized mean-square-error (*NMSE*) deviations between output plant variables and desired values and is defined as

$$\mathrm{NMSE}_{V_S} = \frac{\sum (V_S - V_{S-\mathrm{ref}})^2}{\sum (V_{S-\mathrm{ref}})^2} \tag{38.34}$$

$$\mathrm{NMSE}_{\omega_m} = \frac{\sum (\omega_m - \omega_{m-\mathrm{ref}})^2}{\sum (\omega_{m-\mathrm{ref}})^2} \tag{38.35}$$

$$\mathrm{NMSE}_{I_s} = \frac{\sum (I_S - I_{S-\mathrm{ref}})^2}{\sum (I_{S-\mathrm{ref}})^2} \tag{38.36}$$

The control system comprises the three dynamic multiloop error-driven regulator is coordinated to minimize the selected objective functions. SOO obtains a single global or near-optimal solution based on a single-weighted-objective function. The weighted single-objective function combines several objective functions using specified or selected weighting factors as follows:

$$\text{weighted objective function} = \alpha_1 J_1 + \alpha_2 J_2 + \alpha_3 J_3 + \alpha_4 J_4 + \alpha_5 J_5 \tag{38.37}$$

where $\alpha_1 = 0.20$, $\alpha_2 = 0.20$, $\alpha_3 = 0.20$, $\alpha_4 = 0.20$, and $\alpha_5 = 0.20$ are selected weighting factors. J_1, J_2, J_3, J_4, and J_5 are the selected

objective functions. On the other hand, the MO finds the set of acceptable (trade-off) optimal solutions. This set of accepted solutions is called Pareto front. These acceptable trade-off multilevel solutions give more ability to the user to make an informed decision by seeing a wide range of near-optimal selected solutions. Table 38.16 shows the system behavior using traditional controllers with constant controller gains for the (GP-EM-EE) schemes. In addition, Table 38.10 shows system behavior comparison using the SOGA-based tuned conventional PID controller, and Table 38.17 shows the system behavior comparison using the MOGA-based tuned conventional PID controller. Finally, Tables 38.18 and 38.19) show system behavior comparison using the SOPSO- and MOPSO-based tuned conventional PID controller, respectively. Comparing the system dynamic response results of the two study cases, with GA and PSO tuning algorithms and traditional controllers with constant controller gain results, ANN controller and FLC, it is quite apparent that the GA and PSO tuning algorithms highly improved the system dynamic performance from a general power quality point of view. The GA and PSO tuning algorithms had a great impact on motor RMS voltage (pu) improving it from 0.8578 (without the (GP-EM-EE) device), 0.9762 (constant gains controller), 0.9790 (ANN controller), and 0.9598 (FLC) to around 0.9804 (SOGA-based tuned controller), 0.9865 (MOGA-based tuned controller), 0.9887 (SOPSO)-based tuned controller, and 0.9852 (MOPSO-based tuned controller). Motor RMS current (pu) is reduced from 0.8724 (without the (GP-EM-EE) device), 0.7029 (constant gains controller), 0.6837 (ANN controller), and 0.6863 (FLC) to around 0.6247 (SOGA-based tuned controller), 0.6304 (MOGA-based tuned controller), 0.6358 (SOPSO)-based tuned controller, and 0.6471 (MOPSO-based tuned controller). Maximum transient motor voltage over/undershoot (pu) is reduced from 0.1797 (without the (GP-EM-EE) device),

Total

harmonic distortion (THD) (%) of the supply voltage is reduced from 19.647 (without the (GP-EM-EE) device), 7.8228 (constant gains controller), 10.4023 (ANN controller), and 8.2175 (FLC) to around 6.2535 (SOGA-based tuned controller), 4.8408 (MOGA-based tuned controller), 4.2581 (SOPSO)-based tuned controller, and 4.1081 (MOPSO-based tuned controller). THD (%) of the supply current is reduced from 20.346 (without the (GP-EM-EE) device), 7.3532 (constant gains controller), 9.3573 (ANN controller), and 7.5181 (FLC) to around 4.1530 (SOGA-based tuned controller), 4.0103 (MOGA-based tuned controller), 5.2433 (SOPSO)-based tuned controller, and 5.1378 (MOPSO-based tuned controller). THD (%) of the motor voltage is reduced from 21.675 (without the (GP-EM-EE) device), 8.0566 (constant gains controller), 8.5408 (ANN controller), and 9.9806 (FLC) to around 5.7887 (SOGA-based tuned controller), 4.9313 (MOGA-based tuned controller), 4.5873 (SOPSO)-based tuned controller, and 4.3629 (MOPSO-based tuned controller). THD (%) of the motor current is reduced from 21.675 (without the (GP-EM-EE) device), 10.8589 (constant gains controller), 9.3120 (ANN controller), and 11.0353 (FLC) to around 3.9572 (SOGA-based tuned controller), 3.9998 (MOGA-based tuned controller), 5.1673 (SOPSO)-based tuned controller, and 5.1216 (MOPSO-based tuned controller). The system efficiency is improved from 0.7853 (without the (GP-EM-EE) device), 0.8577 (constant gains controller), 0.8943 (ANN controller), and 0.9195 (FLC) to around 95.4132 (SOGA-based tuned controller), 95.4882 (MOGA-based tuned controller), 95.4999 (SOPSO)-based tuned controller, and 90.7467 (MOPSO-based tuned controller). Motor power factor is improved from 0.7167 (without the (GP-EM-EE) device), 0.9082 (constant gains controller), 0.8609 (ANN controller), and 0.9169 (FLC) to around 95.1040 (SOGA-based tuned controller), 90.8137 (MOGA-based tuned controller), 91.7450 (SOPSO)-based tuned controller, and 91.4433 (MOPSO-based tuned controller). Reduction in kWh consumption (%) is reduced from 0.000 (without the (GP-EM-EE) device), 14.4937 (constant gains controller), 12.3129 (ANN controller), and 11.4634 (FLC) to around 18.3913 (SOGA-based tuned controller), 16.5388 (MOGA-based tuned controller), 15.9691 (SOPSO)-based tuned controller, and 16.5328 (MOPSO-based tuned controller).

The application validated the operation of a novel wind-driven squirrel cage induction generator fed from single-phase supply. The scheme utilizes a simple but effective series-parallel switched capacitor filter to ensure dynamic terminal voltage stabilization, effective energy utilization, and minimal impact of electric load switching and dynamic excursions and wind velocity changes. The novel error-driven self-regulating multiloop dynamic controller utilizes random search optimization algorithms using particle swarm optimization (PSO) and GA to continuously search for effective and optimized controllers gains that can cope with specified objective function restrictions of minimum voltage deviations, limited generated current and power excursions due to terminal load changes, and wind velocity excursions and gusting. The application presents a family of novel low-cost green plug electricity saving devices/energy management/energy economizer (GP-EM-EE) devices equipped with a dynamic online error-driven optimally tuned controller. The (GP-EM-EE) are small low-cost energy conservation devices in the form add-on dynamic switched capacitor filter compensator schemes for low horsepower motors used in household appliances, washers, dryers, fans, water pumps, ventilation systems, air conditioners, and other cyclic motorized loads used in dispersing machines, actuators, and small converters with induction motor size from 5 to 25 kVA. The (GP-EM-EE) devices family can be used with all types of small horsepower motors with billions of small motors used in multitude of applications that consumes over 50%–60% of total electric energy generated in the world. The (GP-EM-EE) device can save 10–20% of the electricity cost of operating the small motor over the estimated motor life span of 7–10 years. This translates into millions of dollars in daily electricity savings, reduced electric utility overloading conditions, blackouts, brownouts, and enhanced, secure, and reliable operation with additional sizable power capacity release due to reduced electric demand and feeder losses.

38.9 Conclusion

The chapter covers novel techniques for the dynamic control of industrial motor drives. The use of AI soft computing PSO and GA random search techniques is presented. The specific use of PSO and GA single-objective and multiobjective controller optimization and dynamic gains adjusting is illustrated using three key applications of optimal operation of induction motor drives, hybrid photovoltaic-fuel cell-diesel-battery electric vehicle drive system, and finally, the novel self-regulating green plug-energy management energy economizer schemes developed by the first author as a number of an extended family of modulated power filters, switched capacitor compensators, and dynamic electric energy management devices and system. The control strategies are all based on multiloop error-driven regulation with online dynamic gain adjusting based on PSO and GA search algorithm. The use of AI self-regulating dynamic controllers based on AI soft computing allows meeting a multitude of conflicting objective functions of effective speed reference tracking, minimal losses, efficient utilization, limited inrush currents under parametric variations, supply source excursions, inertia, and mechanical load nonlinear loads. The other added benefit is targeting the use of power electronic devices and switched capacitor compensator/filters in ensuring efficient operation of motors and motor drives especially in future applications using renewable and green energy system.

He completed a MSc degree in electrical engineering in 1976 and PhD degree in 1979 from the University of Manitoba, Canada. He joined the University of New Brunswick in 1981 to start a tenure-track academic career as an assistant professor and was promoted to associate professor in 1983, awarded tenure in 1986, and the full professorship in 1987. Dr. Sharaf has extensive industrial and consulting experience with electric utilities in Canada and abroad. He is currently the vice provost of graduate studies and research and professor of energy systems at the University of Trinidad and Tobago, West Indies. He authored and coauthored over 580 scholarly technical journal, refereed conference applications, and engineering reports. Dr. Sharaf holds a number of US and international patents (pending) in electric energy and environmental devices. He supervised over (50) graduate student (37 MSc and 13 PhD) since joining the academia in July 1981. His current research areas include power systems and electrotechnology, motor drives, FACTS technology, renewable/alternate energy systems, and harmonics and power quality.

Dr. **Adel A. A.** is currently an associate professor at the University of Trinidad and Tobago (UTT), Centre for Energy Studies. He received his BSc degree in electrical power engineering from Helwan University, Egypt, in 1996. He completed his MSc degree in electric drives and machines engineering in 2002 and PhD degree in January 2007 from the faculty of engineering (Helwan University, Egypt). He joined the University of Helwan, Egypt, in January 2007 as an assistant professor. He authored and coauthored over 12 scholarly technical journal and over 37 refereed conference publications and one engineering chapter. In May 2008, Dr. El-Gammal joined UTT as assistant professor at Center of Energy Studies, and he was promoted to associate professor in May 2010 at the Centre of Energy Studies, the University of Trinidad and Tobago (UTT). His current research areas include power systems and electrotechnology, motor drives, FACTS technology, renewable/alternate energy systems, harmonics and power quality, application of intelligent systems (particle swarm optimization (PSO), fuzzy logic, neutral networks, and genetic algorithms) to power systems, renewable/green energy systems and electric drives, application of power electronics to power systems, and computer-based controllers. Dr. El-Gammal has gained industrial and academic experience and participated in several technical consultations and professional experience in Egypt.

39.1 Introduction

High-performance motor drives are characterized by the need for smooth rotation down to stall, full control of torque at stall, and fast accelerations and decelerations. In the past, variable speed drives employed predominantly dc motors because of their excellent controllability. However, modern high-performance motor drive systems are usually based on three-phase ac motors, such as the ac induction motor (ACIM) or the permanent-magnet synchronous motor (PMSM). These machines have supplanted the dc motor as the machine of choice for variety of applications because of their simple robust construction, low inertia, high power density, high torque density, and good performance at high speeds of rotation.

The vector-control techniques are established for controlling these ac motors, and most modern high-performance drives now implement digital closed-loop current control. In such systems, the achievable closed-loop bandwidths are directly related to the rate at which the computationally intensive vector-control algorithms and associated vector rotations can be implemented in real time. Because of this computational burden, many high-performance drives now use digital signal processors (DSPs) to implement the embedded motor- and vector-control schemes. The DSPs are special microprocessors used where real-time manipulation of large amounts of digital data is required in order to implement complicated control algorithms. The inherent computational power of the DSP permits very fast cycle times and closed-loop current control bandwidths to be achieved.

The complete current control scheme for these machines also requires a high-precision pulse-width modulation (PWM) voltage-generation scheme and high-resolution analog-to-digital (A/D) conversion (ADC) for the measurement of the motor currents. In order to maintain a smooth control of torque to zero speed, rotor position feedback is essential for modern vector controllers. Therefore, many systems include rotor-position transducers, such as resolvers and incremental encoders.

The Texas Instruments TMS320LF2407 DSP Controller (referred to as the LF2407 in this chapter) is a programmable digital controller with a C2xx DSP central processing unit (CPU) as the core processor. The LF2407 contains the DSP core processor and useful peripherals integrated onto a single piece of silicon. The LF2407 combines the powerful CPU with

http://dx.doi.org/10.1016/B978-0-12-811407-0.00043-X

on-chip memory and peripherals. With the DSP core and control-oriented peripherals integrated into a single chip, users can design very compact and cost-effective digital control systems.

The LF2407 DSP controller offers 40 million instructions per second (MIPS) performance. This high processing speed of the C2xx CPU allows users to compute parameters in real time rather than lookup approximations from tables stored in memory. This fast performance is well suited for processing control parameters in applications such as notch filters or sensorless motor-control algorithms where a large amount of calculations must be computed quickly.

While the "brain" of the LF2407 DSP is the C2xx core, the LF2407 contains several control-orientated peripherals on board (see Fig. 39.1). The peripherals on the LF2407 make virtually any digital control requirement possible. Their applications range from analog-to-digital conversion to pulse-width modulation (PWM) generation. Communication peripherals make possible the communication with external peripherals,

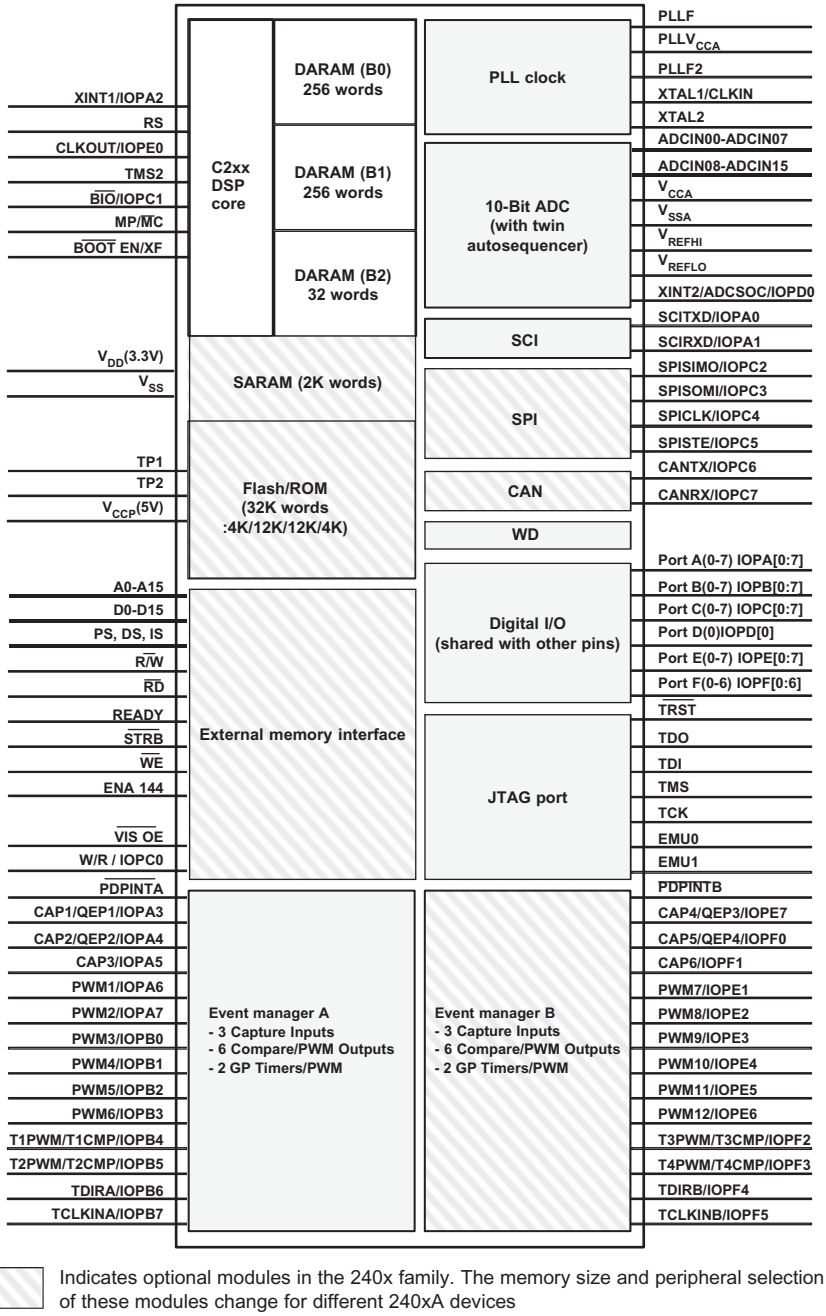

FIG. 39.1 Graphic overview of DSP core and peripherals on the LF2407. Courtesy of Texas Instruments.

personal computers, or other DSP processors. Below is a graphic listing of the different peripherals on board the LF2407 depicted in Fig. 39.1.

We describe here the fundamental principles behind the implementation of high-performance controllers for three-phase ac motors—combining an integrated DSP controller, LF2407, flexible PWM generation, high-resolution A/D conversion, and embedded encoder interface.

39.2 Variable Speed Control of AC Machines

Efficient variable speed control of three-phase ac machines requires the generation of a balanced three-phase set of variable voltages with variable frequency. The variable-frequency supply is typically produced by conversion from dc using power semiconductor devices (typically MOSFETs or IGBTs) as solid-state switches. A commonly used converter configuration is shown in Fig. 39.2A. It is a two-stage circuit, in which the fixed-frequency 50 or 60 Hz ac supply is first rectified to provide the dc-link voltage, V_d, stored in the dc-link capacitor. This voltage is then supplied to an inverter circuit that generates the variable-frequency ac power for the motor. The power switches in the inverter circuit permit the motor terminals to be connected to either V_d or ground.

This mode of operation gives high efficiency because, ideally, the switch has zero loss in both the open and closed positions. By rapid sequential opening and closing of the six switches (Fig. 39.2A), a three-phase ac voltage with an average sinusoidal waveform can be synthesized at the output terminals. The actual output voltage waveform is a pulse-width modulated (PWM) high-frequency waveform, as shown in Fig. 39.2B. In practical, inverter circuits using solid-state switches and high-speed switching of about 20 kHz are possible. Therefore, sophisticated PWM waveforms with fundamental frequencies, nominally in the range of 0–250 Hz, can be generated. The inductive reactance of the motor increases with frequency. Thus, higher-order harmonic currents are very small, and near-sinusoidal currents flow in the stator windings. The fundamental voltage and output frequency of the inverter, as indicated in Fig. 39.2B, are adjusted by changing the PWM waveform using an appropriate controller. When controlling the fundamental output voltage, the PWM process inevitably modifies the harmonic content of the output voltage waveform. A proper choice of modulation strategy can minimize these harmonic voltages and, in result, harmonic losses in the motor.

39.3 General Structure of a Three-Phase AC Motor Controller

Accurate control of any motor drive process may ultimately be reduced to the problem of accurate control of both the torque and speed of the motor. In general, motor speed is controlled directly by measuring the motor's speed or position using appropriate transducers, and torque is controlled indirectly by suitable control of the motor phase currents. Fig. 39.3 shows

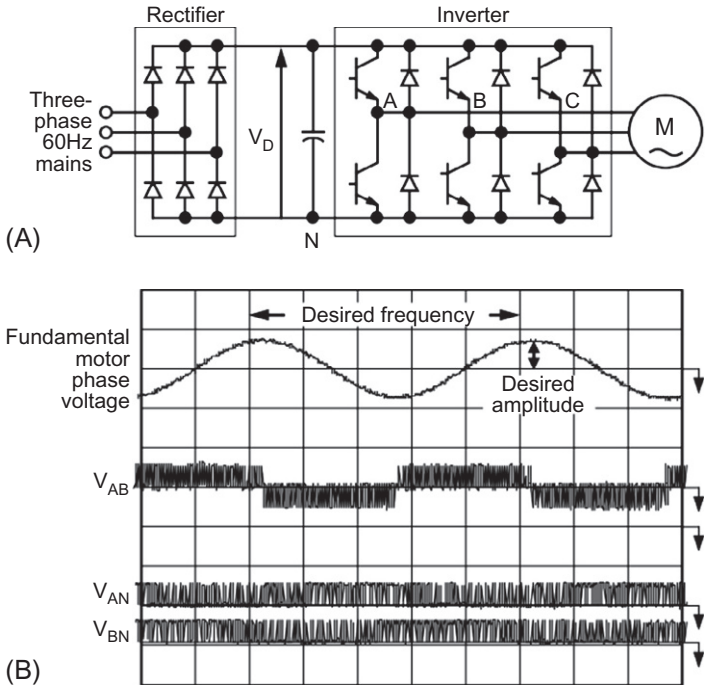

FIG. 39.2 (A) Typical configuration of power converter used to drive three-phase ac motors and (B) typical PWM waveforms in the generation of a variable-voltage, variable-frequency supply for the motor.

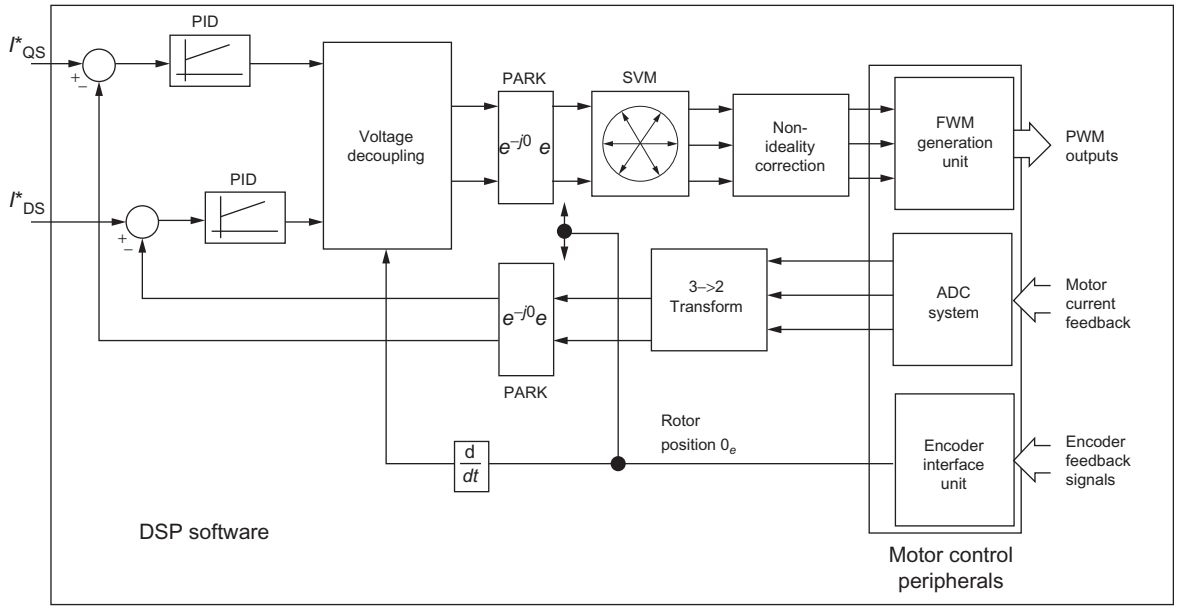

FIG. 39.3 Configuration of typical control system for three-phase ac motor.

a block diagram of a typical synchronous frame current controller for a three-phase motor. The figure also shows the proportioning of tasks between software code modules and the dedicated motor-control peripherals of a motor controller such as the LF2407. The controller consists of two proportional-plus-integral-plus-differential (PID) current regulators that are used to control the motor current vector in a reference frame that rotates synchronously with the measured rotor position.

Sometimes, it may be desirable to implement a decoupling between voltage and speed that removes the speed dependencies and associated axes cross coupling from the control loop. The reference voltage components are then synthesized on the inverter using a suitable PWM strategy, such as space-vector modulation (SVM). It is also possible to incorporate some compensation schemes to overcome the distorting effects of the inverter switching dead time, finite inverter device on-state voltages, and dc-link voltage ripple. The two components of the stator current vector are known as the direct-axis and quadrature-axis components. The direct-axis current controls the motor flux and is usually controlled to be zero with permanent-magnet machines. The motor torque may then be controlled directly by regulation of the quadrature-axis component. Fast, accurate torque control is essential for high-performance drives in order to ensure rapid acceleration and deceleration and smooth rotation down to zero speed under all load conditions.

The actual direct and quadrature current components are obtained by first measuring the motor phase currents with suitable current-sensing transducers and converting them to digital, using an on-chip ADC system. It is usually sufficient to simultaneously sample just two of the motor line currents: since the sum of the three currents is zero, the third current can, when necessary, be deduced from simultaneous measurements of the other two currents. The controller software makes use of mathematical vector transformations, known as Park transformations that ensure that the three-phase set of currents applied to the motor is synchronized to the actual rotation of the motor shaft, under all operating conditions. This synchronism ensures that the motor always produces the optimal torque per ampere—that is, operates at optimal efficiency. The vector rotations require real-time calculation of the sine and cosine of the measured rotor angle, plus a number of multiply-and-accumulate operations. The overall control-loop bandwidth depends on the speed of implementation of the closed-loop control calculations and the resulting computation of new duty-cycle values. The inherent fast computational capability of the 40 MIPS, 16-bit fixed-point DSP core makes it the ideal computational engine for these embedded motor-control applications.

39.3.1 Pulse Width Modulation Generation

In typical ac motor-controller design, both hardware and software considerations are involved in the process of generating the PWM signals that are ultimately used to turn on or off the power devices in the three-phase inverter. In typical digital control environments, the controller generates a regularly timed interrupt at the PWM switching frequency (nominally 10–20 kHz). In the interrupt service routine, the controller software computes new duty-cycle values for the PWM signals used to drive each of the three legs of the inverter. The computed duty cycles depend on both the measured state of the motor (torque and speed) and the desired operating state.

The duty cycles are adjusted on a cycle-by-cycle basis in order to make the actual operating state of the motor follow the desired trajectory.

Once the desired duty-cycle values have been computed by the processor, a dedicated hardware PWM generator is needed to ensure that the PWM signals are produced over the next PWM and controller cycle. The PWM generation unit typically consists of an appropriate number of timers and comparators that are capable of producing very accurately timed signals. Typically, 10- to 12-bit performance in the generation of the PWM timing waveforms is desirable.

Fig. 39.4 shows a typical PWM waveform for a single-leg inverter. In general, there is a small delay required between turning off one power device like A-phase lower device and turning on the complementary power device A-phase upper device. This dead time is required to ensure that the device being turned off has sufficient time to regain its blocking capability before the other device is turned on. Otherwise, a short circuit of the dc voltage could result.

In LF2407, the compare units have been used to generate the PWM signals. The PWM output signal is high when the output of current PI regulation matches the value of T1CNT and is set to low when the timer underflow occurs. The switch states are controlled by the ACTR register. In order to minimize the switching losses, the lower switches are always kept on, and the upper switches are chopped on/off to regulate the phase current.

39.3.2 Analog-to-Digital Conversion Requirements

For the control of high-performance motor drives, fast, high-accuracy, simultaneous-sampling A/D conversion of the measured current values is required. The drives have a rated operation range—a certain power level that they can sustain continuously, with an acceptable temperature rise in the motor and power converter. They also have a peak rating—the ability to handle a current far in excess of the rated current for short periods of time. This allows a large torque to be applied transiently, to accelerate or decelerate the drive very quickly, and then to revert to the continuous range for normal operation. This also means that in the normal operating mode of the drive, only a small percentage of the total input range is being used.

At the other end of the scale, in order to achieve the smooth and accurate rotations desired in these machines, it is wise to compensate for small offsets and nonlinearities such as core saturation and parameter detuning. In any current-sensor electronics, the analog signal processing is often subject to gain and offset errors. Gain mismatches, for example, can exist between the current-measuring systems for different windings. These effects combine to produce undesirable oscillations in the torque. To meet both of these conflicting resolution requirements, modern motor drives use 10-bit A/D converters, depending on the cost/performance trade-off required by the application.

The bandwidth of the system is essentially limited by the amount of time it takes to input information and then perform the calculations. The A/D converters that take many microseconds to convert can produce intolerable delays in the system. A delay in a closed-loop system will degrade the achievable bandwidth of the system, and bandwidth is one of the most important figures of merit in these high-performance drives. Therefore, fast analog-to-digital conversion is a necessity for these applications.

A third important characteristic of the A/D converter used in these applications is timing. In addition to high resolution and fast conversion, simultaneous sampling is needed. In any three-phase motor, it is necessary to measure the currents in the three windings of the motor at exactly the same time in order to get an instantaneous "snapshot" of the torque in the machine. Any time skew (time delay between the measurements of the different currents) is an error factor that is artificially inserted by the means of measurement. Such a nonideality translates directly into a ripple of the torque—a very undesirable characteristic.

The analog-to-digital converter (ADC) on the LF2407 allows the DSP to sample analog or "real-world" voltage signals. The output of the ADC is an integer number that represents the voltage level sampled. The integer number may be used for calculations in an algorithm. The resolution of the ADC is 10 bits, meaning that the ADC will generate a 10-bit number for every conversion it performs. However, the ADC stores the conversion results in registers that are 16-bit wide. The 10 most significant bits are the ADC result, while the least significant bits

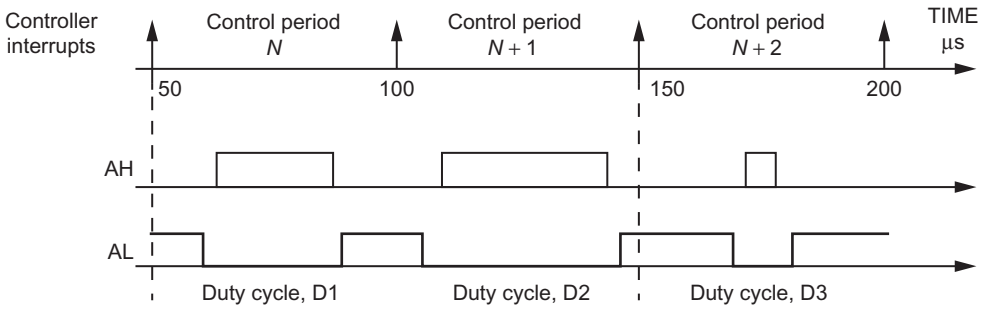

FIG. 39.4 Typical PWM waveforms for a single inverter leg.

(LSBs) are filled with "0"s. There are a total of 16 input channels to the single input ADC. The control logic of the ADC consists of autosequencers, which control the sampling of the 16 input channels to the ADC. The autosequencers control not only which channels (input channels) will be sampled by the ADC but also the order of the channels that the ADC performs conversions on. The two 8-conversion autosequencers can operate independently or cascade together as a "virtual" 16-conversion ADC.

39.3.3 Position Sensing and Encoder Interface Units

Usually, the motor position is measured through the use of an encoder mounted on the rotor shaft. The incremental encoder produces a pair of quadrature outputs (A and B), each with a large number of pulses per revolution of the motor shaft. For a typical encoder with 1024 lines, both signals produce 1024 pulses per revolution. Using a dedicated quadrature counter, it is possible to count both the rising and falling edges of both the A and B signals so that one revolution of the rotor shaft may be divided into 4096 different values. In other words, a 1024-line encoder allows the measurement of rotor position to 12-bit resolution. The direction of rotation may also be inferred from the relative phasing of quadrature signals A and B.

Fig. 39.5 shows the structure of an encoder. It consists of a light source, a radially slotted disk, and the photoelectric sensors. The disk rotates with the rotor. The two photosensors detect the light passing through the slots in the disk. When the light is hidden, a logic "0" is generated by the sensors. When the light passes through the slots of the disk, a logic "1" is produced. These logic signals are shown in Fig. 39.5. By counting the number of pulses, the motor speed can be calculated. The direction of rotation can be determined by detecting the leading signal between signals A and B.

This is all very well, but there is an increasing class of cost-sensitive motor drive applications with lower performance demands that can afford neither the cost nor the space requirements of the rotor position transducer. In these cases, the same motor-control algorithms can be implemented with estimated rather than measured rotor position.

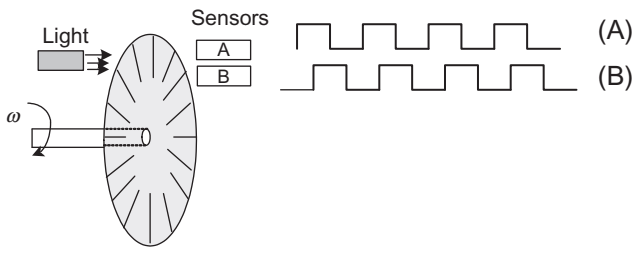

FIG. 39.5 The structure of an optical encoder showing sensor A and B outputs.

The DSP core is quite capable of computing rotor position using sophisticated rotor-position estimation algorithms, such as extended Kalman estimators that extract estimates of the rotor position from measurements of the motor voltages and currents. These estimators rely on the real-time computation of a sufficiently accurate model of the motor in the DSP. In general, these sensorless algorithms can be made to work and the sensored algorithms at medium to high speeds of rotation. But as the speed of the motor decreases, the extraction of reliable speed-dependent information from voltage and current measurements becomes more difficult. In general, sensorless motor control is applicable principally to applications such as compressors, fans, and pumps, where continuous operation at zero or low speeds is not required.

39.3.4 The PI Regulator

An electric drive based on the field-orientated control (FOC) needs two constants as control parameters, the torque component reference i_{qs}^{e*} and the flux component reference i_{ds}^{e*}. The classical PI regulator is well suited to regulate the torque and flux feedback to the desired values. This is because it is able to reach constant references by correctly setting both the proportional term (K_p) and the integral term (K_i), which are, respectively, responsible for the error sensibility and for the steady-state error. The numerical expression of the PI regulatoris as follows:

$$Y_{(k)} = K_p e_{(k)} + K_i e_{(k)} + \sum_{n=0}^{k-1} e_{(n)} \tag{39.1}$$

which is represented in Fig. 39.6.

During normal operation, large reference value variations or disturbances may occur that result in the saturation and overflow of the regulator variables and output. To solve this problem, one solution is to add a correction of the integral component as depicted in Fig. 39.7.

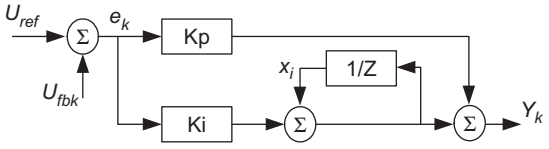

FIG. 39.6 Classical PI regulator structure in discrete domain.

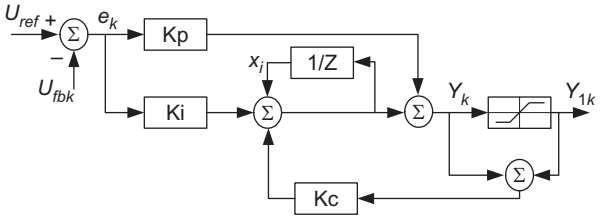

FIG. 39.7 Numerical PI regulator with correction.

The constants K_p, K_i, and K_c, proportional, integral, and integral correction components, respectively, are selected based on the sampling period and on the motor parameters. After defining the DSP-controlled motor drive requirements, in the following, we describe the digital control algorithms for permanent-magnet motors and induction motors.

39.4 DSP-Based Control of Permanent Magnet Brushless DC Machines

Permanent-magnet alternating current (PMAC) motors are synchronous motors that have permanent magnets mounted on the rotor and polyphase, usually three-phase, armature windings located on the stator. Since the field is provided by the permanent magnets, the PMAC motor has higher efficiency than induction- or switched-reluctance motors. The advantages of PMAC motors, combined with a rapidly decreasing cost of permanent magnets, have led to their widespread use in many variable speed drives such as robotic actuators, computer disk drives, appliances, automotive applications, and air-conditioning (HVAC) equipment.

In general, PMAC motors are categorized into two types. The first type of motor is referred to as PM synchronous motor (PMSM). These motors produce a sinusoidal back EMF, shown in Fig. 39.8A, and should be supplied with sinusoidal current/voltage. The PMSM's electronic control and drive system uses continuous rotor position feedback and PWM to supply the motor with the sinusoidal voltage or current. With this, constant torque is produced with very little ripple.

The second type of PMAC motor has a trapezoidal back EMF and is referred to as the brushless DC (BLDC) motor. The back EMF of the BLDC motor is shown in Fig. 39.8B. The BLDC motor requires that quasi-rectangular-shaped currents are fed into the machine. Alternatively, the voltage may be applied to the motor every 120 degrees, with a current limit to hold the currents within the motor's capabilities.

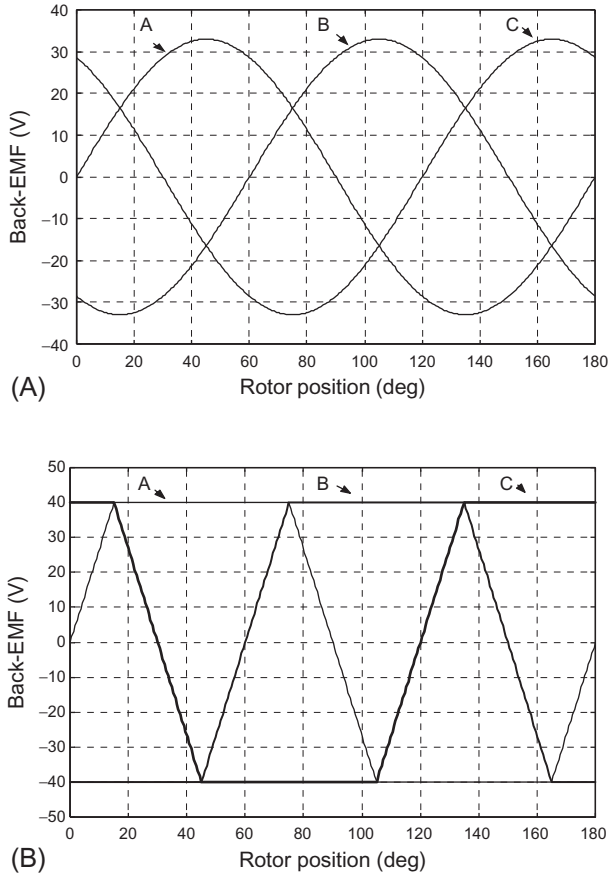

FIG. 39.8 The back EMF of PMAC motors: (A) three-phase back EMF of PMSM and (B) three-phase back EMF of BLDC motors.

39.4.1 Mathematical Model of the BLDC Motor

The phase variables are used to model the BLDC motor due to its nonsinusoidal back EMF and phase current. The terminal voltage equation of the BLDC motor can be written as

$$\begin{bmatrix} v_a \\ v_b \\ v_c \end{bmatrix} = \begin{bmatrix} R+pL_s & 0 & 0 \\ 0 & R+pL_s & 0 \\ 0 & 0 & R+pL_s \end{bmatrix} \cdot \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} e_a \\ e_b \\ e_c \end{bmatrix} \quad (39.2)$$

where v_a, v_b, and v_c are the phase voltages; i_a, i_b, and i_c are the phase currents; e_a, e_b, and e_c are the phase back-EMF voltages; R is the phase resistance; L_s is the synchronous inductance per phase and includes both leakage and armature reaction inductances; and p represents d/dt. The electromagnetic torque is given by

$$T_e = \frac{(e_a i_a + e_b i_b + e_c i_c)}{\omega_m} \quad (39.3)$$

where ω_m is the mechanical speed of the rotor. The equation of motion is

$$\frac{d}{dt}\omega_m = \frac{(T_e - T_L - B\omega_m)}{J} \quad (39.4)$$

where T_L is the load torque, B is the damping constant, and J is the moment of inertia of the rotor shaft and the load.

39.4.2 Torque Generation

From Eq. (39.3), the electromagnetic torque of the BLDC motor is related to the product of the phase back EMF and current. The back EMFs in each phase are trapezoidal in shape and are displaced by 120 electrical degrees with respect to each other in a three-phase machine. A rectangular current pulse is injected into each phase so that current coincides with the crest of the back-EMF waveform; hence, the motor develops

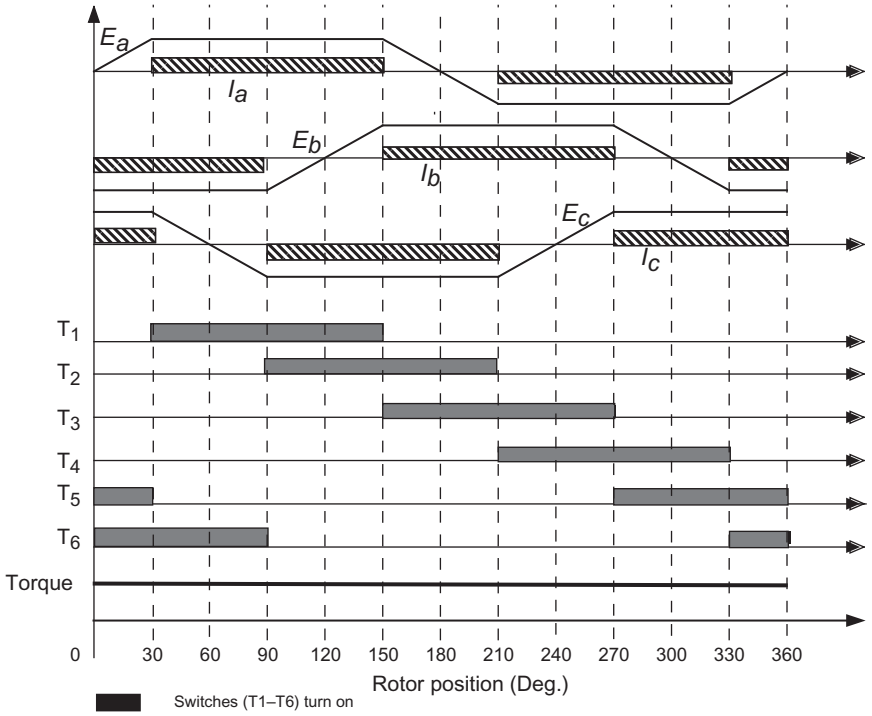

FIG. 39.9 The principle of the six-step current control algorithm. T_1–T_6 are the gate signals; E_a, E_b, and E_c are the motor phase back EMF; and I_a, I_b, and I_c are the motor phase currents.

an almost constant torque. This strategy, commonly called six-step current control, is shown Fig. 39.9. The amplitude of each phase's back EMF is proportional to the rotor speed and is given by

$$E = k\phi\omega_m \tag{39.5}$$

where k is a constant and depends on the number of turns in each phase, φ is the permanent-magnet flux, and ω_m is the mechanical speed. In Fig. 39.9, during any 120 degrees interval, the instantaneous power converted from electric to mechanical, P_o, is the sum of the contributions from two phases in series and is given by

$$P_0 = \omega_m T_e = 2EI \tag{39.6}$$

where T_e is the output torque and I is the amplitude of the phase current. From Eqs. (39.4) and (39.6), the expression for output torque can be written as

$$T_e = 2k\phi I = k_t I \tag{39.7}$$

where K_t is the torque constant. Since the electromagnetic torque is only proportional to the amplitude of the phase current in Eq. (39.7), torque control of the BLDC motor is essentially accomplished by phase current control.

39.4.3 BLDC Motor Control Topology

Based on the previously discussed concept, a BLDC motor drive system is shown in Fig. 39.10. It can be seen that the total

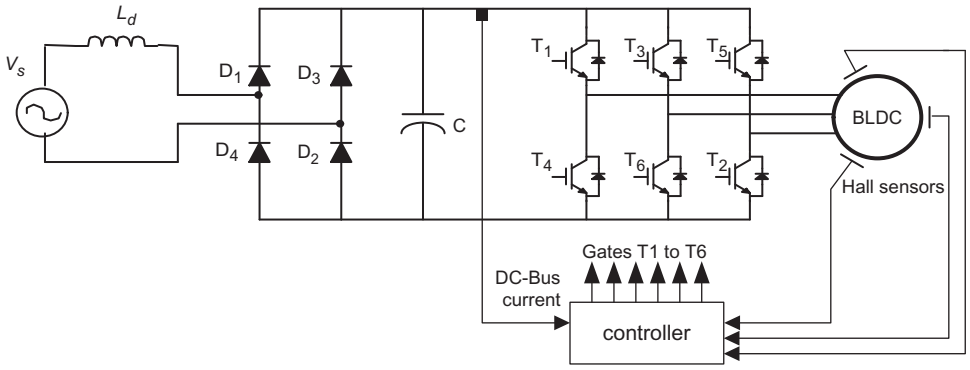

FIG. 39.10 BLDC motor-control system.

drive system consists of the BLDC motor, power electronic converter, sensor, and controller.

The BLDC motors are predominantly surface-magnet machines with wide magnet pole arcs. The stator windings are usually concentrated windings, which produce a square waveform distribution of flux density around the air gap. The design of the BLDC motor is based on the crest of each half cycle of the back-EMF waveform. In order to obtain a smooth output torque, the back-EMF waveform should be wider than 120 degrees electrical degrees. A typical BLDC motor with 12 stator slots and 4 poles on the rotor is shown in Fig. 39.11. The inverter is usually responsible for the electronic commutation and current regulation. For the six-step current control, if the motor windings are Y-connected without the neutral connection, only two of the three-phase currents flow through the inverter in series. This results in the amplitude of the DC-link current always being equal to that of the phase currents. The PWM current controllers are typically used to regulate the actual machine currents in order to match the rectangular current reference waveforms shown in Fig. 39.9. For example, during one 60 degrees interval, when switches T_1 and T_6 are active, phases A and B conduct. The lower switch T_6 is always turned on, and the upper switch T_1 is chopped on/off using either a hysteresis current controller with variable switch frequency or a PI controller with fixed switch frequency.

When T_1 and T_6 are conducting, current builds up in the path as shown in Fig. 39.12A with dashed line. When switch T_1 is turned off, the current decays through diode D_4 and switch T_6 as depicted in Fig. 39.12B. In the next interval, switch T_2 is on, and T_1 is chopped so that phase A and phase C conduct. During the commutation interval, the phase-B current rapidly decreases through the freewheeling diode D_3 until it becomes zero and the phase C current builds up.

From the above analysis, each of the upper switches is always chopped for one 120 degrees interval, and the corresponding lower switch is always turned on per interval. The freewheeling diodes provide the necessary paths for the currents to circulate when the switches are turned off and during the commutation intervals. There are two types of sensors for the BLDC drive system: a current sensor and a position sensor. Since the amplitude of the dc-link current is always equal to the motor phase current in six-step current control, the dc-link current is measured instead of the phase current. Thus, a shunt resistor, which is in series with the inverter, is usually used as the current sensor. Hall-effect position sensors typically provide the position information needed to synchronize the stator excitation with rotor position in order to produce constant torque. Hall-effect sensors detect the change in magnetic field. The rotor magnets are used as triggers for the Hall sensors. A signal-conditioning circuit is needed for noise cancellation in Hall-effect sensor circuits. In six-step current control algorithm, rotor position needs to be detected at only six discrete points in each electric cycle. The controller tracks these six points so that the proper switches are turned on or off for the correct intervals. Three Hall-effect sensors, spaced 120 electrical degrees apart, are mounted on the stator frame. The digital signals from the Hall sensors are then used to determine the rotor position and switch gating signals for the inverter switches.

39.4.4 DSP Controller Requirements

The controller of BLDC drive systems reads the current and position feedback, implements the speed or torque control algorithm, and finally generates the gate signals. The connectivity of the LF2407 in this application is illustrated in Fig. 39.13. Three capture units in the LF2407 are used to detect both the rising and falling edges of Hall-effect signals. Hence, in every 60 electrical degrees of motor rotation, one capture unit interrupt is generated that ultimately causes a change in the gating signals and the motor to move to the next position. One input channel of the 10-bit A/D converter reads the dc-link current. The output pins PWM1–PWM6 are used to supply the gating signals to the inverter.

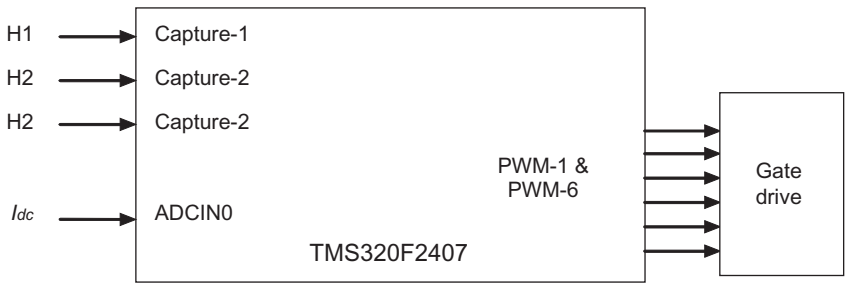

FIG. 39.13 The interface of LF2407.

39.4.5 Implementation of the BLDC Motor Control Algorithm Using LF2407

A block diagram of the BLDC motor-control system is shown in Fig. 39.14. The dashed line separates the software from the hardware components introduced in the previous section. It is necessary to choose hardware components carefully in order to ensure high processing speed and precision in the overall control system. The overall control algorithm of the BLDC motor consists of nine modules:

- Initialization procedure
- Detection of Hall-effect signals
- Speed control subroutine
- Measurement of current
- Speed profiling
- Calculation of actual speed
- PID regulation
- PWM generation
- DAC output

The flowchart of the overall control algorithm is illustrated in Fig. 39.15.

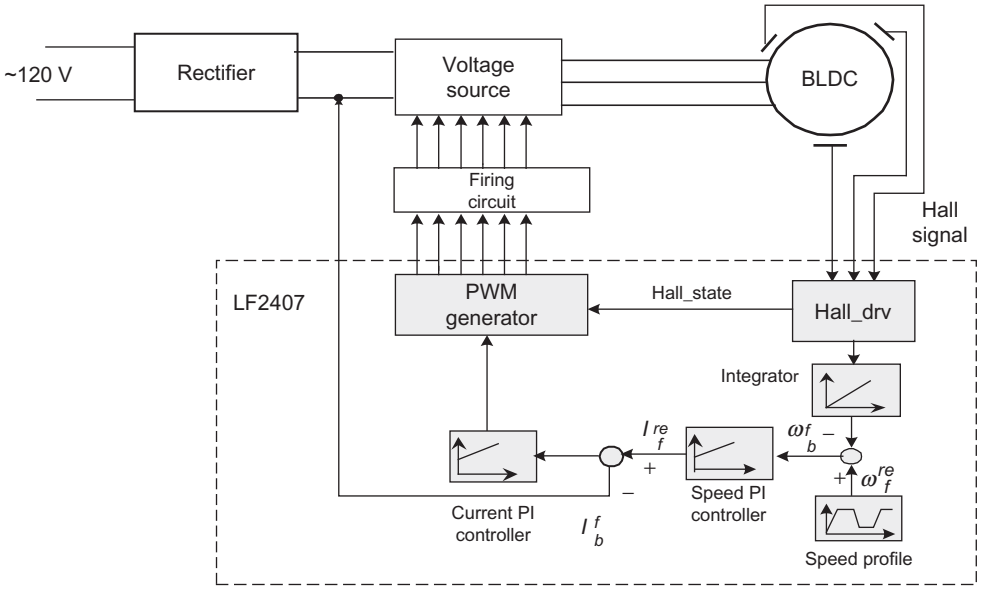

FIG. 39.14 The block diagram of BLDC motor-control algorithm.

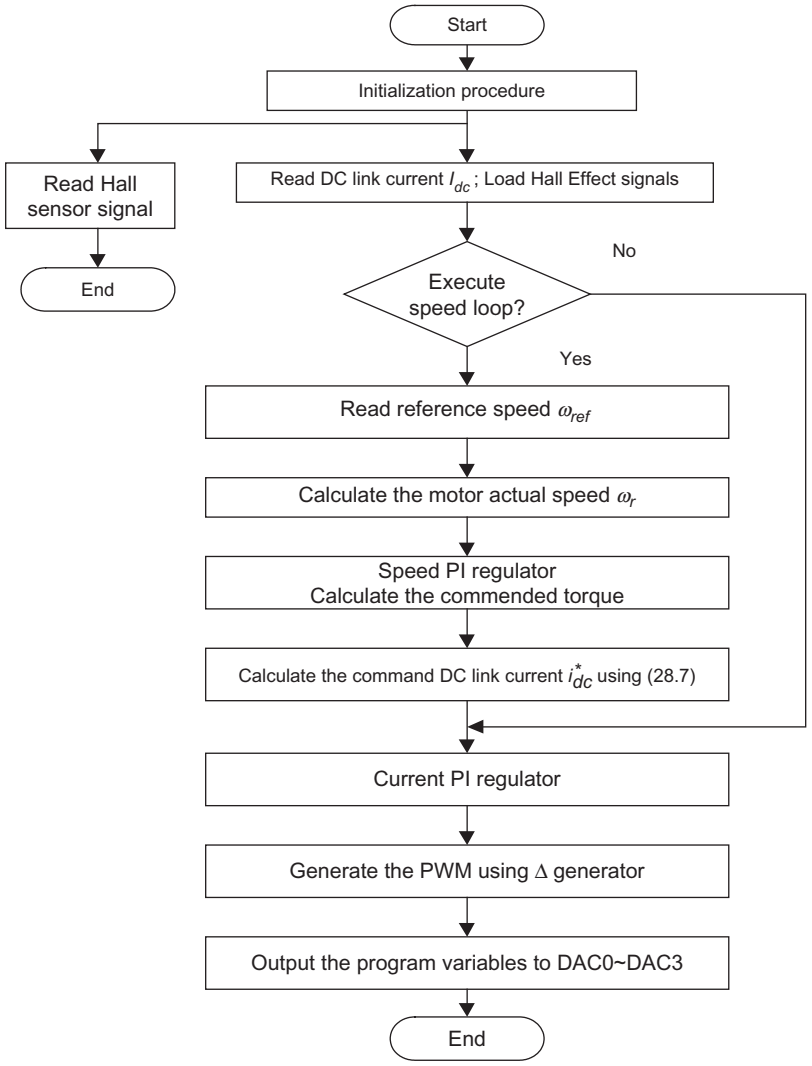

FIG. 39.15 BLDC algorithm flowchart.

39.5 DSP-Based Control of Permanent Magnet Synchronous Machines

As previously described, the permanent-magnet synchronous motor (PMSM) is a PM motor with a sinusoidal back EMF. Compared with the BLDC motor, it has less torque ripple because the torque pulsations associated with current commutation do not exist. A carefully designed machine in combination with a good control technique can yield a very low level of torque ripple (<2% rated), which is attractive for high-performance motor-control applications such as machine tool and servo applications.

In this section, following the same procedures used in the previous section, the principles of the PMSM drive system will be introduced. Later, the control implementation using the LF2407 DSP will be described in detail.

39.5.1 Mathematical Model of PMSM

Fig. 39.16 depicts the simplified three-phase surface-mounted PMSM motor for our discussion. The stator windings, *as-as'*, *bs-bs'*, and *cs-cs'*, are shown as lumped windings for simplicity but are actually distributed around the stator. The rotor has two poles. Mechanical rotor speed and position are denoted as ω_{rm} and θ_{rm}, respectively. Electric rotor speed and position, ω_r and θ_r, are defined as $P/2$ times the corresponding mechanical quantities, where P is the number of poles.

Based on the above motor definition, the voltage equation in the abc stationary reference frame is given by

$$V_{abcs} = R_s i_{abcs} + \frac{d}{dt}\lambda_{abcs} \tag{39.8}$$

where

$$f_{abcs} = [f_{as} f_{bs} f_{cs}]^T \tag{39.9}$$

and the stator resistance matrix is given by

$$R_s = \mathrm{diag}[r_s \quad r_s \quad r_s] \tag{39.10}$$

The flux linkages equation can be expressed by

$$\lambda_{abcs} = L_s i_{abcs} + \lambda'_m \begin{bmatrix} \sin\vartheta_r \\ \sin\left(\vartheta_r - \frac{2\pi}{3}\right) \\ \sin\left(\vartheta_r - \frac{4\pi}{3}\right) \end{bmatrix} \tag{39.11}$$

where λ'_m denotes the amplitude of the flux linkages established by the permanent magnet as viewed from the stator phase windings. Note that in Eq. (39.11), the back EMFs are sinusoidal waveforms that are 120 degrees apart from each other.

The stator self-inductance matrix, L_s, is given as

$$L_s = \begin{Bmatrix} L_{ls} + L_A - L_B\cos 2\theta_r & -\frac{1}{2}L_A - L_B\cos 2(\theta_r - \pi/3) & -\frac{1}{2}L_A - L_B\cos 2(\theta_r + \pi/3) \\ -\frac{1}{2}L_A - L_B\cos 2(\theta_r - \pi/3) & L_{ls} + L_A - L_B\cos 2(\theta_r - 2\pi/3) & -\frac{1}{2}L_A - L_B\cos 2(\theta_r + \pi) \\ -\frac{1}{2}L_A - L_B\cos 2(\theta_r + \pi/3) & -\frac{1}{2}L_A - L_B\cos 2(\theta_r + \pi) & L_{ls} + L_A - L_B\cos 2(\theta_r + 2\pi/3) \end{Bmatrix} \tag{39.12}$$

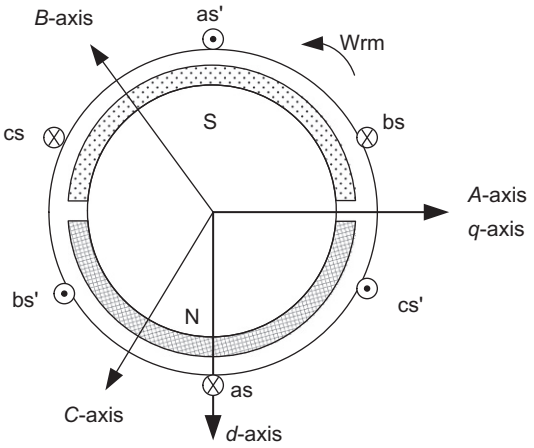

FIG. 39.16 The cross section of PMSM.

The electromagnetic torque may be written as

$$T_e = \frac{P}{2}\left\{\lambda'_m\left[\left(i_{as} - \frac{1}{2}i_{bs} - \frac{1}{2}i_{cs}\right)\cos\theta_r - \frac{\sqrt{3}}{2}(i_{bs} - i_{cs})\sin\vartheta_r\right] + \frac{L_{md} - L_{mq}}{3}\left[\left(i_{as}^2 - \frac{1}{2}i_{bs}^2 - \frac{1}{2}i_{cs}^2 - i_{as}i_{bs} - i_{as}i_{cs} + 2i_{bs}i_{cs}\right)\sin 2\theta_r + \frac{\sqrt{3}}{2}\left(i_{bs}^2 i_{cs}^2 - 2i_{as}i_{bs} + 2i_{as}i_{cs}\right)\cos 2\theta_r\right]\right\} + T_{cog}(\theta_r) \tag{39.13}$$

In Eq. (39.13), $T_{cog}(\theta_r)$ represents the cogging torque, and the d- and q-axes magnetizing inductances are defined by

$$L_{md} = \frac{3}{2}(L_A - L_B)$$

and

$$L_{md} = \frac{3}{2}(L_A + L_B) \tag{39.14}$$

The torque and speed are related by the electromechanical motion equation

$$J\frac{d}{dt}\omega_{rm} = \frac{P}{2}(T_e - T_L) - B_m\omega_{rm} \tag{39.15}$$

where J is the rotational inertia, B_m is the approximated mechanical damping due to friction, and T_L is the load torque.

39.5.2 Mathematical Model of PMSM in Rotor Reference Frame

The voltage and torque equations can be expressed in the rotor reference frame in order to transform the time-varying variables into steady-state constants. The transformation of the three-phase variables in the stationary reference frame to the rotor reference frame is defined as

$$f_{qd0r} = K_r f_{abcs} \tag{39.16}$$

where

$$k_r = \frac{2}{3}\begin{bmatrix} \cos\theta_r & \cos\left(\theta_r - \frac{2\pi}{3}\right) & \cos\left(\theta_r + \frac{2\pi}{3}\right) \\ \sin\theta_r & \sin\left(\theta_r - \frac{2\pi}{3}\right) & \sin\left(\theta_r + \frac{2\pi}{3}\right) \\ \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \end{bmatrix}$$

If the applied stator voltages are given by

$$\begin{cases} V_{as} = \sqrt{2}V_s\cos\theta_{ev} \\ V_{bs} = \sqrt{2}V_s\cos\left(\theta_{ev} = \frac{2\pi}{3}\right) \\ V_{cs} = \sqrt{2}V_s\cos\left(\theta_{ev} + \frac{2\pi}{3}\right) \end{cases} \tag{39.17}$$

then applying Eq. (39.16) to Eqs. (39.8), (39.11), and (39.17) yields

$$v_{qs}^r = r_s i_{qs}^r + \omega_r\lambda_{ds}^r + \frac{d}{dt}\lambda_{qs}^r \tag{39.18}$$

$$v_{ds}^r = r_s i_{ds}^r - \omega_r\lambda_{qs}^r + \frac{d}{dt}\lambda_{ds}^r \tag{39.19}$$

$$\lambda_{qs}^r = L_{qs} i_{qs}^r \tag{39.20}$$

$$\lambda_{ds}^r = L_{ds} i_{ds}^r + \lambda_m^{'r} \tag{39.21}$$

where the q- and d-axes self-inductances are given by $L_{qs} = L_{ls} + L_{mq}$ and $L_{ds} = L_{ls} + L_{md}$, respectively.

The electromagnetic torque can be written as

$$T_e = \frac{3}{2}\frac{P}{2}\left[\lambda_m^{'r} i_{qs}^r + (L_{ds} - L_{qs}) i_{qs} i_{ds}\right] \tag{39.22}$$

From Eq. (39.22), it can be seen that torque is related only to the d- and q-axes currents. Since $L_q \geq L_d$ (for surface-mounted PMSM, both inductances are equal), the second item contributes a negative torque if the flux-weakening control has been used. In order to achieve the maximum torque/current ratio, the d-axis current is set to zero during the constant torque control so that the torque is proportional only to the q-axis current. Hence, this results in the control of the q-axis current for regulating the torque in rotor reference frame.

39.5.3 PMSM Control Topology

Based on the above analysis, a PMSM drive system is developed as shown in Fig. 39.17. The total drive system looks similar to that of the BLDC motor and consists of a PMSM, power electronic converter, sensors, and controller. These components are discussed in detail in the following sections.

The design consideration of the PMSM is to first generate the sinusoidal back EMF. Unlike the BLDC, which needs concentrated windings to produce the trapezoidal back EMF, the stator windings of PMSM are distributed in as many slots per pole

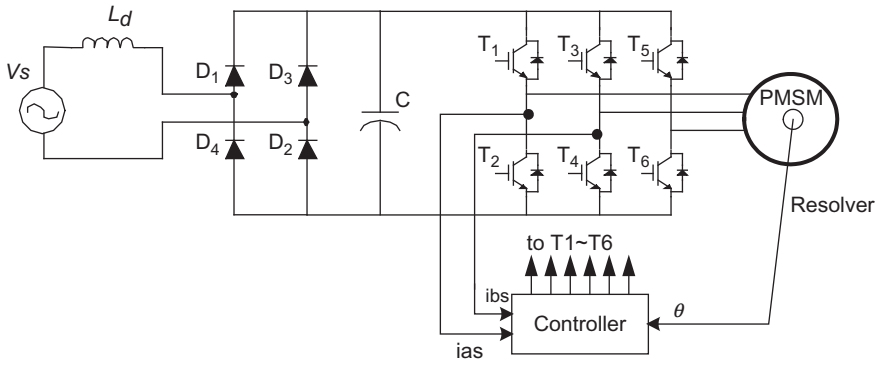

FIG. 39.17 The PMSM speed control system.

as deemed practical to approximate a sinusoidal distribution. To reduce the torque ripple, standard techniques such as skewing and chorded windings are applied to the PMSM. With the sinusoidally excited stator, the rotor design of the PMSM becomes more flexible than the BLDC motor where the surface-mounted permanent magnet is a favorite choice. Besides the common surface-mounted nonsalient pole PM rotor, the salient pole rotors, like inset and buried magnet rotors, are often used because they offer appealing performance characteristics during the flux-weakening region. A typical PMSM with 36 stator slots in stator and 4 poles on the rotor is shown in Fig. 39.18.

Due to the sinusoidal nature of the PMSM, control algorithms such as V/f and vector control, developed for other AC motors, can be directly applied to the PMSM control system. If the motor windings are Y-connected without a neutral connection, three-phase currents can flow through the inverter at any moment. With respect to the inverter switches, three switches, one upper and two lower in three different legs, conduct at any moment as shown in Fig. 39.19. The PWM current control is still used to regulate the actual machine current. Either a hysteresis current controller, a PI controller with sine triangle, or an SVPWM strategy is employed for this purpose. Unlike the BLDC motor, the three switches are switched at any time.

39.5.4 DSP Controller Requirements

The LF2407 is used as the controller to implement speed control of the PMSM system. The interface of the LF2407 is illustrated in Fig. 39.20. Similar to the BLDC motor-control system, three input channels are selected to read the two-phase currents and resolver signal. Because a resolver is used in one case, the quadrature-encoder-pulse (QEP) inputs are not used. The QEP inputs work only with a QEP signal that a rotary encoder supplies. The DSP output pins PWM1–PWM6 are used to supply the gating signals to the switches and form the output of the control part of the system.

39.5.5 Implementation of the PMSM Algorithm Using the LF2407

The block diagram of the PMSM drive system is displayed in Fig. 39.21.

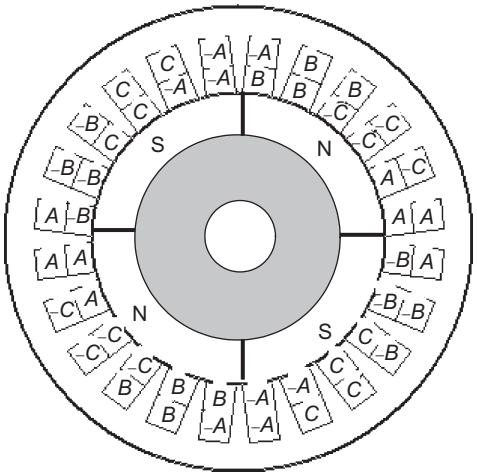

FIG. 39.18 A 4-pole 24-slot PMSM.

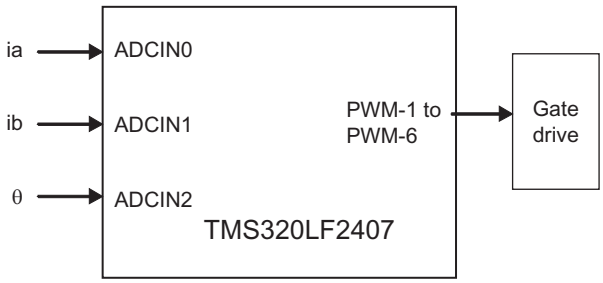

FIG. 39.20 The interface of LF2407.

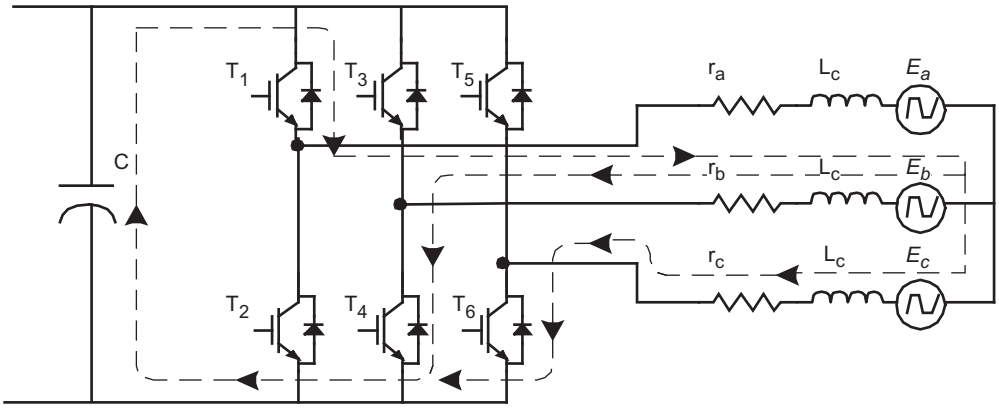

FIG. 39.19 The current path when the three phases are chopped.

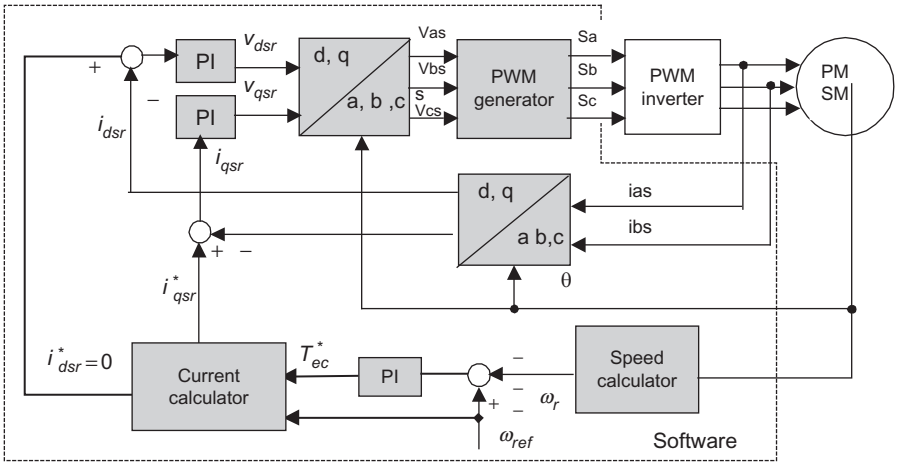

FIG. 39.21 Block diagram of PMSM speed control system.

The flowchart of the developed software is shown in Fig. 39.22. The control program of the PMSM has one main routine and includes four modules:

- Initialization procedure
- DAC module
- ADC module
- Speed control module

In the following section, speed control module is discussed.

39.5.5.1 The Speed Control Algorithm

The requirement for speed control algorithm can be itemized as follows:

- Reading the current and position signal and then generating the commanded speed profile
- Calculating the actual motor speed and transferring the variables in the abc model to the *d-q* model and reverse
- Regulating the motor speed and currents using the vector-control strategy
- Generating the PWM signal based on the calculated motor phase voltages

The PWM frequency is determined by the time interval of the interrupt, with the controlled phase voltages being recalculated every interrupt.

39.6 DSP-Based Vector Control of Induction Motors

For many years, induction motors have been preferred for a variety of industrial applications because of their robust and rugged construction. Compared to dc motors, induction motors are not as easy to control. They typically draw large starting currents, about six to eight times their full-load values, and operate with lagging power factor when loaded. However, with the advent of the vector-control concept for motor control, it is possible to decouple the torque and the flux, thus making the control of the induction motor very similar to that of the dc motor.

The most popular type of induction motor used is the squirrel-cage induction motor. The rotor consists of a laminated core with parallel slots for carrying the rotor conductors, which are usually heavy bars of copper, aluminum, or alloys. One bar is placed in each slot, or rather, the bars are inserted from the end when the semiclosed slots are used. The rotor bars are brazed, electrically welded, or bolted to two heavy and stout short-circuiting end rings, thus completing the squirrel-cage construction. The rotor bars are permanently short-circuited on themselves. The rotor slots are usually not parallel to the shaft but are given a slight angle, called a skew, which increases the rotor resistance due to increased length of rotor bars and an increase in the slip for a given torque. The skew is also advantageous because it reduces the magnetic hum while the motor is operating and reduces the locking tendency or cogging of the rotor teeth.

When the three-phase stator windings are fed by a three-phase supply, a magnetic flux of a constant magnitude rotating at synchronous speed is created in the air gap. Due to the relative speed between the rotating flux and the stationary conductors, an electromagnetic force (EMF) is induced in the rotor in accordance with Faraday's laws of electromagnetic induction. The frequency of the induced EMF is the same as the supply frequency, and the magnitude is proportional to the relative velocity between the flux and the conductors. Therefore, the rotor current develops in the same direction as the flux and tries to catch up with the rotating flux.

39.6.1 Induction Motor Field-oriented Control

The term "vector" control refers to the control technique that controls both the amplitude and the phase of ac excitation voltage. Vector control controls the spatial orientation of the EMF

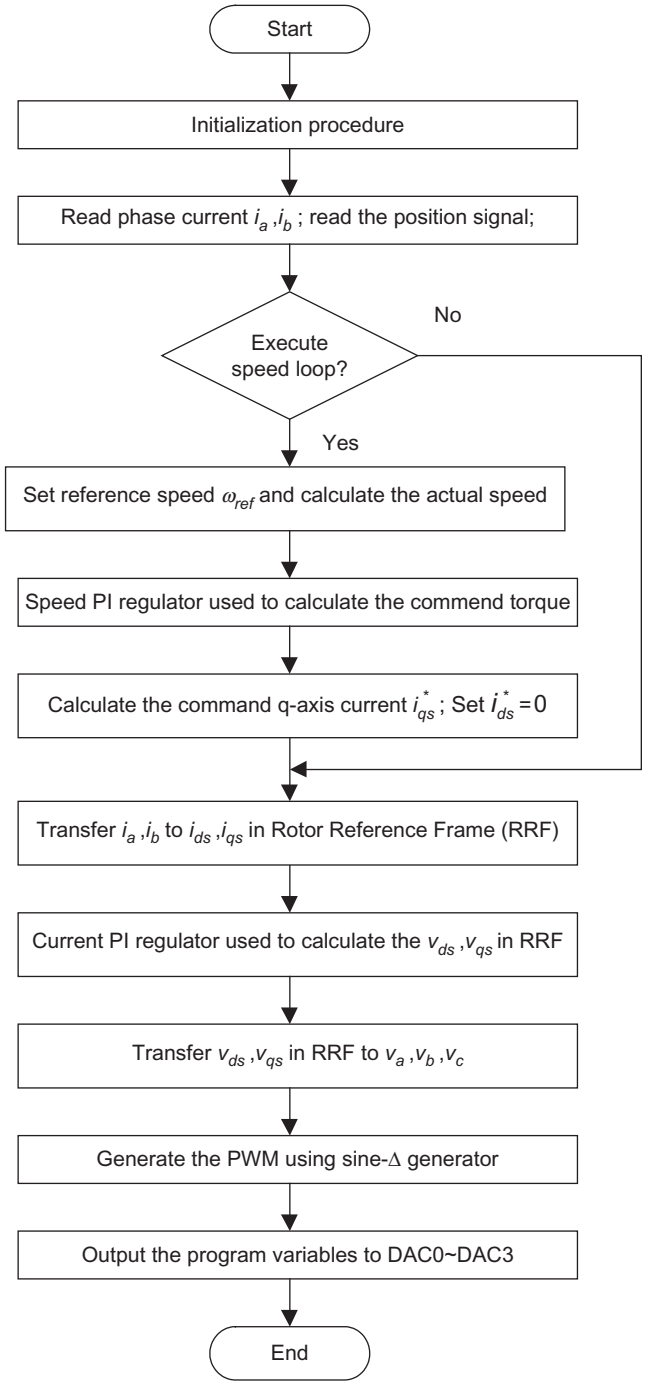

FIG. 39.22 The flowchart of PMSM control system.

in the machine. This has led to the coining of the term FOC, which is used for controllers that maintain a 90 degrees spatial orientation between the critical field components.

The required 90 degrees of spatial orientation between key field components can be compared with the dc motor, where the armature winding magnetic field and the field winding magnetic field are always in quadrature. The objective is to force the control of the induction machine to be similar to the control of a dc motor, that is, torque control. In dc machines, the field and the armature winding axes are orthogonal to one another, making the magnetomotive forces (MMFs) established orthogonal. If the iron saturation is ignored, then the orthogonal fields can be considered to be completely decoupled.

It is important to maintain a constant field flux for proper torque control. It is also important to maintain an independently controlled armature current in order to overcome the effects of the detuning of resistance of the armature winding and leakage inductance. A spatial angle of 90 degrees between the flux and MMF axes has to be maintained in order to limit the interaction between the MMF and the flux. If these conditions are met at every instant of time, the torque will always follow the current.

With vector control, the mechanically robust induction motors can be used in high-performance applications where dc motors were previously used. The key feature of the control scheme is the orientation of the synchronously rotating q-d-0 frame to the rotor flux vector. The d-axis component is aligned with the rotor flux vector and regarded as the flux-producing current component. On the other hand, the q-axis current, which is perpendicular to the d-axis, is solely responsible for torque production.

In order to apply a rotor flux field-orientation condition, the rotor flux linkage is aligned with the d-axis, so the q-axis rotor flux in excitation reference frame λ_{qr}^e will be zero, and the d-axis rotor flux in the excitation reference frame will be the rotor flux, $\lambda_{dr}^e = \hat{\lambda}_r$. Therefore, we have

$$i_{ds}^e = \frac{\lambda_{dr}^e}{L_m} \tag{39.23}$$

$$\omega_{slip} = \frac{r_r}{\hat{\lambda}_r}\left(\frac{L_m}{L_r}\right) i_{qs}^e = \frac{L_m i_{qs}^e}{\tau_r \lambda_r} \tag{39.24}$$

$$T_e = \frac{3}{2}\frac{P}{2}\frac{L_m}{L_r}\hat{\lambda}_d i_{qs}^e \tag{39.25}$$

where τ_r is rotor time constant, L_m magnetizing inductance, L_r, rotor leakage inductance, r_r, rotor resistance, i_{qs}^e q-axis stator current in excitation frame, i_{ds}^e d-axis stator current in excitation frame, and ω_{slip} angular frequency of slip. We can find out that in this case, i_{ds}^e controls the rotor flux linkage and i_{qs}^e controls the electromagnetic torque. The reference currents of the q-d-0 axis (i_{qs}^{e*}, i_{ds}^{e*}) are converted to the reference phase voltages (v_{ds}^{e*}, v_{qs}^{e*}) as the commanded voltages for the control loop. Given the position of the rotor flux and two-phase currents, this generic algorithm implements the instantaneous direct torque and flux control by means of coordinate transformations and PI regulators, thereby achieving accurate and efficient motor control.

It is clear that for implementing vector control, we have to determine the rotor flux position. This usually is performed by measuring the rotor position and utilizing the slip relation to compute the angle of the rotor flux relative to the rotor axis.

Equations (39.23) and (39.24) show that we can control torque and field by i_{ds} and i_{qs} in the excitation frame. However, in the implementation of FOC, we need to know i_{ds} and i_{qs} in the stationary reference frame. So, we have to know the angular position of the rotor flux to transform i_{ds} and i_{qs} from the excitation frame to the stationary frame. By using ω_{slip}, which is shown in Eq. (39.24), and using actual rotor speed, the rotor flux position is obtained:

$$\int_0^t \omega_{slip} dt + \theta_{re}(t) = \theta_r(t) \tag{39.26}$$

where $\theta_{re}(t)$ is electric angular rotor position and $\theta_r(t)$ angular rotor flux position.

The current model takes i_{ds} and i_{qs} as inputs and the rotor mechanical speed and gives the rotor flux position as an output. Fig. 39.23 shows the block diagram of the vector-control strategy in which speed regulation is possible using a control loop.

As shown in Fig. 39.23, two-phase currents are measured and fed to the Clarke transformation block. These projection outputs are indicated as i^s_{ds} and i^s_{qs}. These two components of the current provide the inputs to Park's transformation, which gives the currents in the qds^e excitation reference frame. The i^e_{ds} and i^e_{qs} components, which are outputs of the Park transformation block, are compared with their reference values i^{e*}_{ds}, the flux reference, and i^{e*}_{qs}, the torque reference. The torque command, i^{e*}_{qs}, comes from the output of the speed controller. The flux command, i^{e*}_{ds}, is the output of the flux controller that indicates the right rotor flux command for every speed reference. For i^{e*}_{ds}, we can use the fact that the magnetizing current is usually between 40% and 60% of the nominal current. For operating in speeds above the nominal speed, a field-weakening section should be used in the flux controller section. The current regulator outputs, v^{e*}_{ds} and v^{e*}_{qs}, are applied to the inverse Park transformation. The outputs of this projection are v^e_{ds} and v^s_{qs}, which are the components of the stator voltage vector in the dqs^s orthogonal reference frame. They form the inputs of the space-vector PWM block. The outputs of this block are the signals that drive the inverter.

Note that both the Park and the inverse Park transformations require the exact rotor flux position, which is given by the current model block. This block needs the rotor resistance or rotor time constant as a parameter. Accurate knowledge of the rotor resistance is essential to achieve the highest possible efficiency from the control structure. The lack of this knowledge results in the detuning of the FOC. In Fig. 39.23, a space-vector PWM has been used to emulate v^s_{ds} and v^s_{qs} in order to implement current regulation.

39.6.2 DSP Controller Requirements

The controller of the induction motor-control system is used to read the feedback current and position signals, to implement the speed or torque control algorithm, and to generate the gate signals based on the control signal. Analog controllers or digital signal processors, such as LF2407, can perform these tasks.

The interface of the LF2407 is illustrated in Fig. 39.24. Two quadrature counters detect the rising and falling edges of the encoder signals. Two input channels related to the 10-bit ADC are selected to read the two-phase currents. The pins PWM1–PWM6 output the gating signals to the gate drive circuitry.

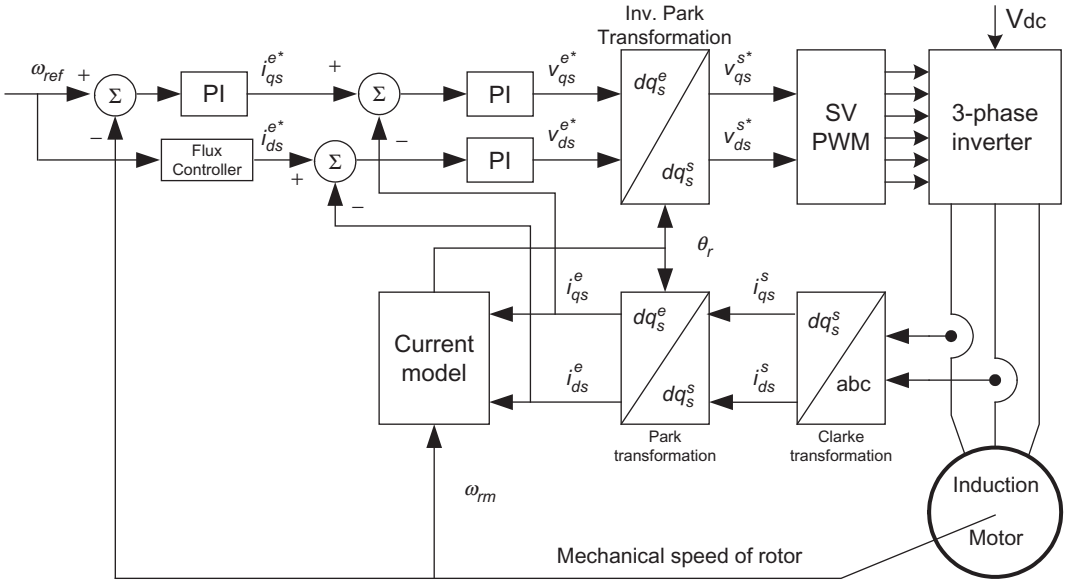

FIG. 39.23 Vector-control algorithm for induction motor.

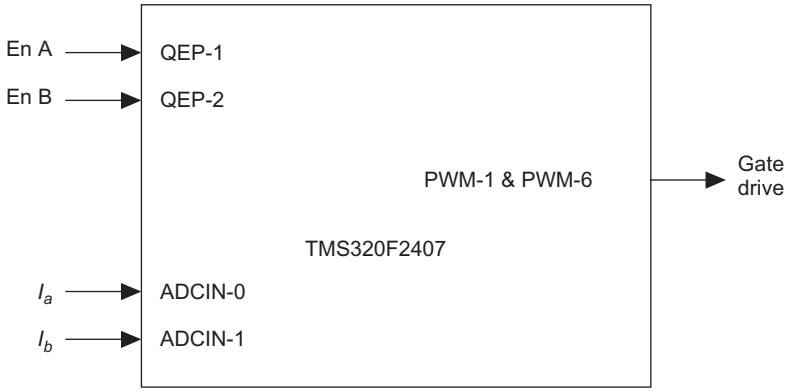

FIG. 39.24 The interface of LF2407.

39.6.3 Implementation of Field-Oriented Speed Control of Induction Motor

Some practical aspects of implementing the block diagram of Fig. 39.24 are discussed in this section and subsections. The software organization, the utilization of different variables, and the handling of the DSP controller resources are described. In addition, the control structure for the per-unit model is presented. Next, some numerical considerations have been made in order to address the problems inherent within the fixed-point calculation. As described, current model is one of the most important blocks in the block diagram depicted in Fig. 39.23. The inputs of this block are the currents and mechanical speed of rotor. In the next sections, technical points that should be considered during current and speed measurement and their scaling are discussed.

39.6.3.1 Software Organization

The body of the software consists of two main modules: the initialization module and the PWM interrupt service routine (ISR) module. The initialization model is executed only once at start-up. The PWM ISR module interrupts the waiting infinite loop when the timer underflows. When the underflow interrupt flag is set, the corresponding ISR is served. Fig. 39.25 shows the general structure of the software. The complete FOC algorithm is executed within the PWM ISR so that it runs at the same frequency as the switching frequency or at a fraction of it. The wait loop could be easily replaced with a user interface.

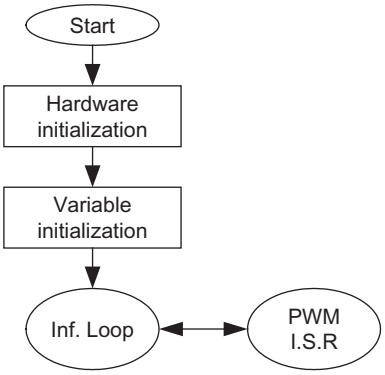

FIG. 39.25 General structure of software.

39.6.3.2 Base Values and Per-Unit Model

It is often convenient to express machine parameters and variables of per-unit quantities. Moreover, the LF2407 is a fixed-point DSP, so using a normalized per-unit model of the induction motor is easier than using real parameters. In this model, all quantities refer to the base values. Base power and base voltage are selected, and all parameters and variables are normalized using these base quantities. Although one might violate this convention from time to time when dealing with instantaneous quantities, the rms values of the rated phase voltage and current are generally selected as the base voltage for the *a-b-c* variables, while the peak value is generally selected as the base voltage for *d-q* variables. The base values are determined from the nominal values by using Eq. (39.27), where I_n, V_n, and f_n are the nominal phase current, the nominal phase-to-neutral voltage, and the nominal frequency in a star-connected induction motor, respectively. The base value definitions are as follows:

$$\begin{aligned} I_b &= \sqrt{2} I_n \\ V_b &= \sqrt{2} V_n \\ \omega_b &= 2\pi f_n \\ \psi_b &= \frac{V_b}{\omega_b} \end{aligned} \tag{39.27}$$

where I_b and V_b are the maximum values of the nominal phase current and voltage, ω_b is the electric nominal rotor flux speed, and ψ_b is the base flux.

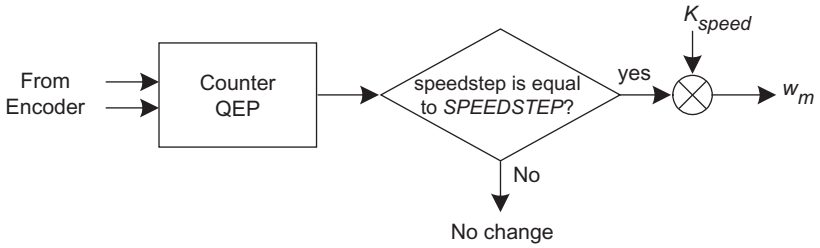

FIG. 39.26 Block diagram of speed feedback calculator.

39.6.3.3 Speed Estimation During High-Speed Region

As previously mentioned, this method is based on counting the number of encoder pulses in a specified time interval. The QEP assigned timer counts the number of pulses and records it in the timer counter register (TxCNT). As the mechanical time constant is much slower than the electric one, the speed regulation loop frequency might be lower than the current loop frequency. The speed regulation loop frequency is obtained in this algorithm by means of a software counter. This counter accepts the PWM interrupt as input clock, and its period is the software variable called SPEEDSTEP. The counter variable is named speedstep. When speedstep is equal to SPEEDSTEP, the number of pulses counted is stored in another variable called n_p, and thus, the speed can be calculated. The scheme depicted in Fig. 39.26 shows the structure of the speed feedback generator.

Assuming that n_p is the number of encoder pulses in one SPEEDSTEP period when the rotor turns at the nominal speed, a software constant K_{speed} should be chosen as follows:

$$01000h = K_{speed} \cdot n_p$$

The speed feedback can then be transformed into a Q4.12 format, which can be used in the control software. In the proposed control system, the nominal speed is 1800 rpm, and SPEEDSTEP is set to 125. The n_p can be calculated as follows:

$$n_p = \frac{1800 \times 64 \times 4}{60} \times \text{SPEEDSTEP} \times T_p = 288 \qquad (39.28)$$

where $T_p = \frac{3}{f_{pwm}} = 3 \times 10^{-4}$ (PWM frequency is 10 kHz, but the program is running at 3333 Hz) and hence K_{speed} is given by

$$K_{speed} = \frac{4096}{288} = 14.22 \Leftrightarrow 0E38h \qquad \text{Q8.8}$$

Note that K_{speed} is out of the Q4.12 format range. The most appropriate format to handle this constant is the Q8.8 format. The speed feedback in Q4.12 format is then obtained from the encoder by multiplying n_p by K_{speed}. The flowchart of speed measurement is presented in Fig. 39.27.

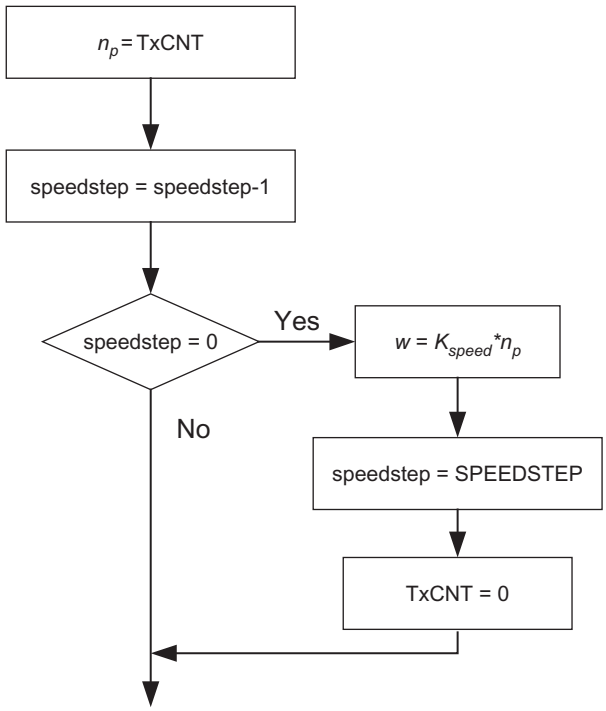

FIG. 39.27 Complete flowchart of speed measurement block during high-speed region.

39.6.3.4 Speed Measurement During Low-Speed Region

To detect the edges of two successive encoder pulses, the developed program can use either the QEP counter or the capture unit input pins. The program has to measure the time between two successive pulses; therefore, it must utilize another GP timer. In this program, timer 3 has been dedicated to the time measurement. During the interrupt service routine of the capture unit or counter QEP, speed can be calculated. To obtain the actual speed of the motor, the appropriate number is divided by the value in the count register of timer 3.

As it can be inferred, at very low speeds, an overflow may occur in timer 3. The counter would then reset itself to zero and start counting up again. This event results in a large error

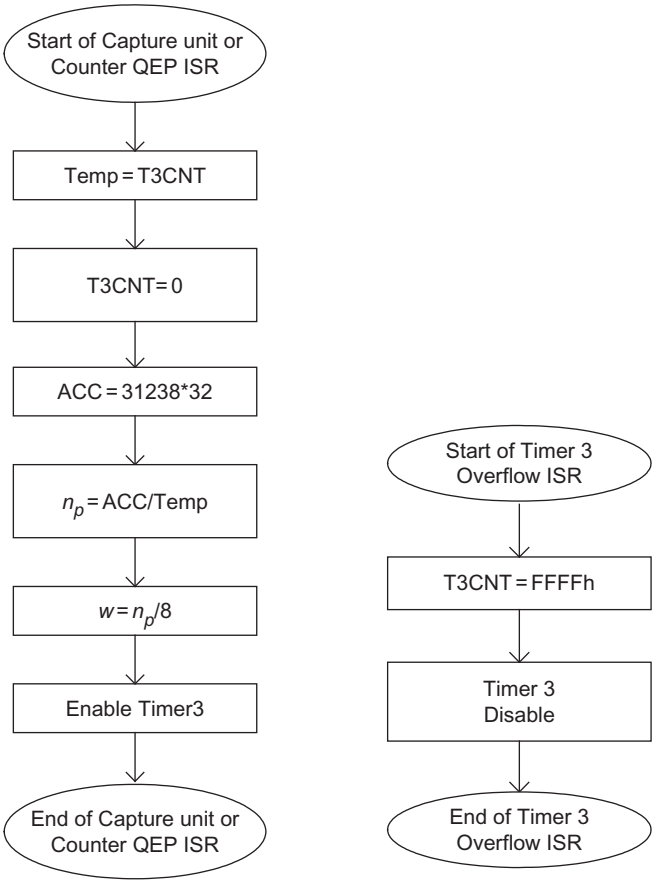

FIG. 39.28 Flowchart of speed measurement at low speed.

in speed measurement. To avoid this event, timer 3 will be disabled in the overflow interrupt service routine. However, this timer is enabled in the capture unit (counter QEP) interrupt.

The flowchart of this implementation is presented in Fig. 39.28.

39.6.3.5 The Current Model

The current model is used to find the rotor flux position. This module takes i_{ds} and i_{qs} as inputs plus the rotor electric speed and then calculates the rotor flux position. The current model is based on Eqs. (39.23) and (39.24). Eq. (39.23) in transient form can be written as

$$\frac{L_r}{r_r L_m}\frac{d\lambda_{dr}}{dt}+\frac{\lambda_{dr}}{L_m}=i_{ds} \tag{39.29}$$

Assume $\lambda_{dr}/L_m = i_m$ where i_m is the magnetizing current; therefore, Eq. (39.29) can be written as follows:

$$T_r\frac{d}{dt}i_m+i_m=i_{ds} \tag{39.30}$$

Rotor flux speed in a per-unit system can be shown by

$$f_s=\frac{1}{\omega_b}\frac{d\theta}{dt}=\omega_{re}+\frac{i_{qs}}{T_r i_m \omega_b} \tag{39.31}$$

where θ is the rotor flux position and $T_r = L_r/r_r$ and ω_{re} are the rotor time constant and rotor electric speed, respectively. The rotor time constant is critical to the correct functionality of the current model. This system outputs the rotor flux speed, which in turn will be integrated to get the rotor flux position. Assuming that $i_{qs_{(k+1)}} \approx i_{qs_{(k)}}$, Eqs. (39.30) and (39.31) can be discretized as follows:

$$\begin{aligned} i_{mr_{(k+1)}} &= i_{mr_{(k)}}+\frac{T_p}{T_r}\left(i_{ds_{(k)}}-i_{mr_{(k)}}\right)\\ f_{S_{(k+1)}} &= n_{(K+1)}+\frac{1}{T_r\omega_b}\frac{i_{qs_{(k)}}}{i_{mr_{(k+1)}}} \end{aligned} \tag{39.32}$$

For example, let the constants T_p/T_r and $1/T_r\omega_b$ be renamed to K_t and K_t, respectively. Here, $L_r = 73.8$ mH, $r_r = 0.73\ \Omega$, and $f_n = 60$ Hz. So for K_t and K_r, we have

$$\begin{aligned} K_r &= \frac{T_p}{T_r}=\frac{(10000/3)^{-1}}{101.09\times10^{-3}}\\ &= 2.967\times10^{-3}\Leftrightarrow 000Ch \end{aligned} \tag{Q4.12}$$

$$\begin{aligned} K_t &= \frac{1}{T_r\omega_b}=\frac{1}{30.232\times10^{-3}\times377}\\ &= 26.237\times10^{-3}\Leftrightarrow 006Bh \end{aligned} \tag{Q4.12}$$

By knowing the rotor flux speed (f_s), the rotor flux position (θ_{cm}) is computed by the integration formula in the per-unit system:

$$\theta_{cm_{(k+1)}}=\theta_{cm_{(k)}}+\omega_b\cdot f_{s_{(k)}}\cdot T \tag{39.33}$$

In Eq. (39.33), let $\omega_b f_s T$ be called θ_{inc}. This variable is the rotor angle variation within one sampling period. Thus, the current model module has three input variables i_{ds}, i_{ds}, and ω_{re} and one output, which is the rotor flux position θ_{cm} represented as a 16-bit integer value. The flowchart of the field-oriented speed control of induction motor is presented in Fig. 39.29. This routine is placed inside the PWM interrupt service routine.

40.1 Introduction

In recent years, power electronic converters have been involved in many applications from industrial level (motor drives, renewable energy technologies, etc.) to home level (PCs, home appliances, etc.). Therefore, the widespread use of power electronic converters puts their control requirements at the forefront. Traditionally, the control techniques in such converters are supposed to have good dynamic response and high reference tracking accuracy. In addition to these requirements, modern control methods should take into account some technical specifications and constraints to meet national and international standards and grid codes. Although these requirements often can be met with the hardware modifications, this results in extra cost. Thus, this shift in trend has driven the development of more advanced control methods, which should fulfill many control objectives at the same time [1].

One of these control methods is predictive control that has appeared as an attractive solution for the control of power converters due to its fast dynamic response and increased control accuracy [1–3]. Originally, this method was introduced in the process industry, but a very innovative and early paper applied predictive control for power electronics [4]. The main approach is based on the computation of the future system dynamic to calculate optimal actuation variables. Therefore, this technique requires a high amount of calculations, compared with classic control schemes; fortunately, parallel computational capable microprocessors are available in the current market to make possible the implementation of predictive control [5].

Furthermore, predictive control brings considerable benefits to power electronics systems. First of all, concepts are intuitive and easy to understand and implement, it can be applied to a variety of systems, it allows for nonlinearities and constraints to be incorporated into the control law in a straightforward manner, a multivariable case can be considered, and the resulting controller is easy to implement. However, the method requires a high amount of calculations, compared with a classic control scheme; however, the fast microprocessors available today make possible the implementation of predictive control. Generally, the quality of the controller depends on the quality of the model [6].

The aim of this chapter is to provide a comprehensive overview of predictive control and to illustrate its use in power electronic converters. It starts with an overview of predictive control theory. Then, predictive control types are presented along with a description of advantages and disadvantages of each type of predictive control. After that, implementation of MPC for power electronic converters is described. Finally, two case studies are given with simulation and experimental results.

40.2 Theory of Predictive Control

The main idea of the predictive control can be roughly explained as follows: it uses a discrete-time model of the system

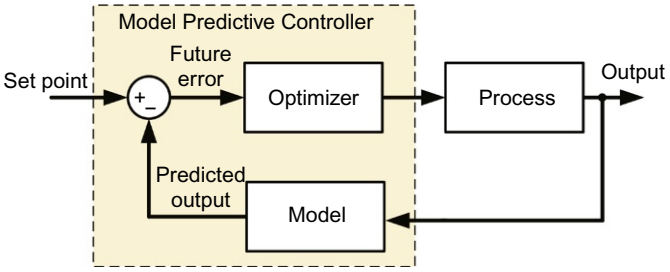

FIG. 40.1 A principle block diagram of predictive control.

to forecast the future behavior of the controlled parameters during a certain time window called a receding horizon. A basic block diagram of this control technique is given in Fig. 40.1 [7]. It can be seen that predictive control consists of two main blocks: model and optimizer. To predict behavior of the system at the next sampling time, the system discrete-time model is used. Then, the future error between predicted output and the reference value is minimized by using predefined cost function in the optimizer. To sum up briefly, the basic idea of MPC can be explained as follows:

- A discrete-time model of the system should be obtained in order to predict system output at the next sampling instant.
- To obtain the optimal actuation, the cost function is used in the optimizer block.

The system prediction model can be defined as state space model as follows:

$$x(k+1) = Ax(k) + Bu(k) \tag{40.1}$$

$$y(k) = Cx(k) + Du(k) \tag{40.2}$$

where $x(k+1)$, $u(k)$, and y(k) are the state variable vector, the input vector, and the output vector, respectively. Furthermore, A is the system matrix, B is the control matrix, C is the output matrix, and D is the feedthrough matrix. The prediction model can be obtained by combining N equations at $k+1$th through $k+N$th instants as follows [8]:

$$\begin{bmatrix} x(k+1) \\ x(k+2) \\ .. \\ x(k+N) \end{bmatrix} = \begin{bmatrix} A \\ A^2 \\ .. \\ A^N \end{bmatrix} x(k) + \begin{bmatrix} B & 0 & 0 & 0 \\ AB & B & 0 & 0 \\ .. & .. & .. & .. \\ A^{N-1}B & A^{N-2}B & .. & B \end{bmatrix} \begin{bmatrix} u(k) \\ u(k+1) \\ .. \\ u(k+N-1) \end{bmatrix} \tag{40.3}$$

This prediction model can be expressed as

$$x(k+1:k+N) = \hat{A}x(k) + \hat{B}u(k:k+N-1) \tag{40.4}$$

$$x(:) = \hat{A}x(k) + \hat{B}u(:) \tag{40.5}$$

A cost function (g) is needed to be determined to select an optimal actuation in the next sampling time. Since the objective of the controller is to guide the system state toward zero from any given initial conditions, the cost function can be defined as follows:

$$\begin{aligned} g &= \|x(:)\|^2 + \lambda\|u(:)\|^2 = \left\|\hat{A}x(k) + \hat{B}u(:)\right\|^2 + \lambda\|u(:)\|^2 \\ &= u(:)^T\left(\hat{B}^T\hat{B} + \lambda I\right)u(:) + u(:)^T\hat{B}^T\hat{A}x(k) + x(k)^T\hat{A}^T\hat{B}u(:) \\ &\quad + x(k)^T\hat{A}^T\hat{A}x(k) \end{aligned} \tag{40.6}$$

where λ is a weighting factor. Taking the derivative of the cost function with respect to $u(:)$ and setting it to zero, one obtains

$$\frac{dg}{du(:)} = 2\left(\hat{B}^T\hat{B} + \lambda I\right)u(:) + 2\hat{B}^T\hat{A}x(k) = 0 \tag{40.7}$$

whose solution is

$$u(:) = -\left[\left(\hat{B}^T\hat{B} + \lambda I\right)^{-1}\hat{B}^T\hat{A}\right]x(k) \tag{40.8}$$

Following the fundamental concept behind predictive control, only the first vector from the array of the optimally predicted future control inputs in Eq. (40.8) is utilized. Hence, the control input vector at the kth time instant can be found to be

$$u(k) = [I \;\; 0 \;\; \ldots \;\; 0]u(:) \tag{40.9}$$

Fig. 40.2 illustrates the working principle of predictive control. The future values of the system states are predicted until a predefined horizon in time $k+$N using the system model and the available measured data until time k. The sequence of the optimal actuation is calculated by minimizing the cost function. This process is repeated taking into account the new measured data for each sampling time [9].

40.3 Types of Predictive Control

The classification of predictive control in power electronic converters can be divided into four main categories, as shown in Fig. 40.3 [10]. The deadbeat control consists of determining which input signal must be applied to the system to ensure the output reaches steady state in the smallest number of time steps. Although deadbeat control requires a modulator, it provides constant switching frequency and requires low computation burden to be implemented in digital platforms. The optimization criterion in the hysteresis-based predictive control is to keep the controlled variable within the boundaries of a hysteresis area, while in the trajectory based, the variables are forced to follow a predefined trajectory. Furthermore, hysteresis-based and trajectory-based predictive controls can be accepted as direct control technique, which means that it doesn't need modulator stage; however, switching frequency is variable. Model predictive control (MPC), which is the most significant predictive control technique for power electronic converters among the others, can be classified in two categories: continuous control set MPC (CCS-MPC) and finite control set

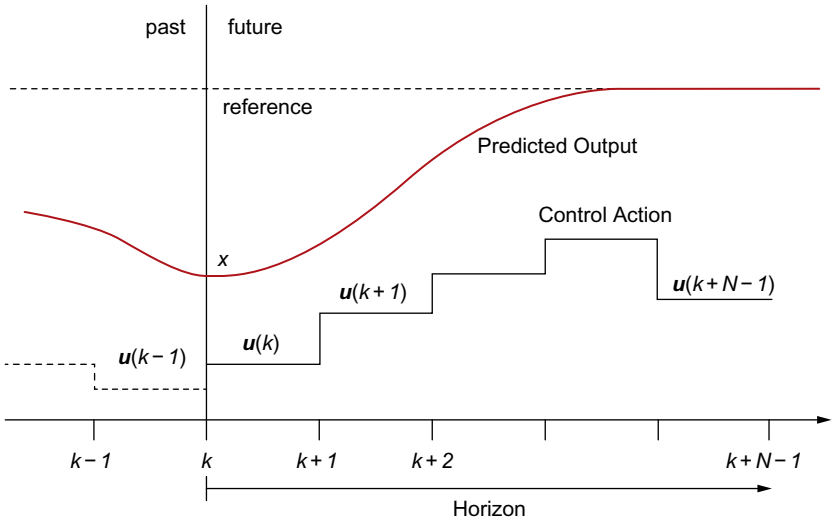

FIG. 40.2 Working principle of predictive control.

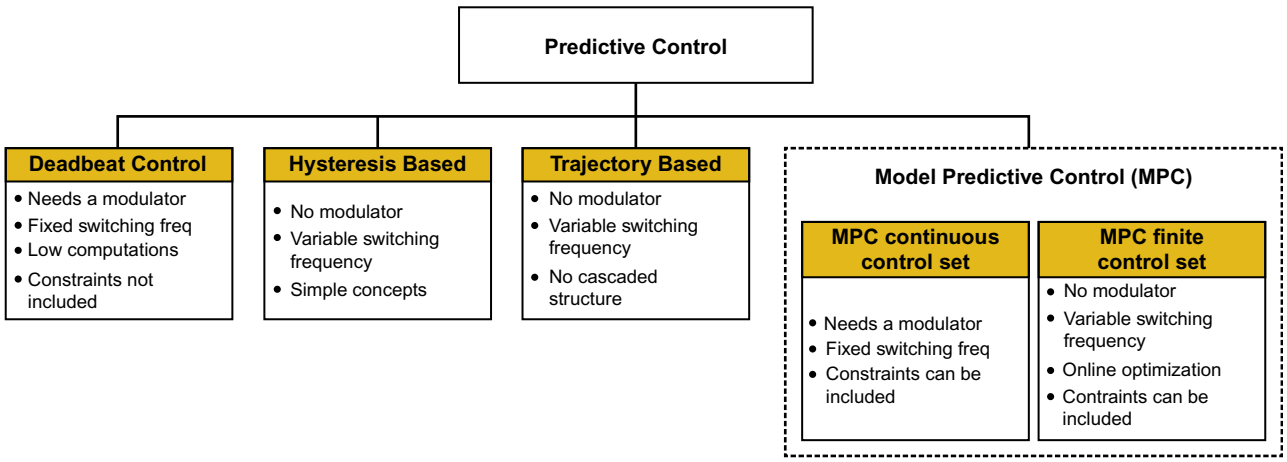

FIG. 40.3 The classification of predictive control techniques.

MPC (FCS-MPC). CCS-MPC requires a modulator to generate the switching states, while in FCS-MPC, the switching state can be generated without modulator stage. In FCS-MPC approach, to solve the optimization problem, the power converters' finite number of switching states is used. To do that, a discrete-time model of the system should be employed to predict the future behavior of the system. Then, an optimal control actuation is selected by the predefined cost function. Although FCS-MPC can generate switching signals without a modulator, switching frequency is variable.

Simplicity and easy implementation concept are the most important advantages of predictive control. Using predictive control technique also allows avoiding the cascaded control structure, which results in fast dynamic response in control. Furthermore, some constraints can be included in the control in order to improve the system performance. Although these advantages can be easily implemented in some predictive control techniques such as MPC, but it is very difficult to add in deadbeat control.

40.4 Model Predictive Control for Power Electronics

In this subsection, the implementation of MPC for power electronic converters will be explained step by step. Although this technique is suitable for all power electronic converters, traditional three-phase three-leg voltage source inverter (VSI) will be taken as an example to explain the MPC idea for power converters.

The block diagram of the MPC for three-phase VSI is shown in Fig. 40.4. This control technique can be summarized by the following steps:

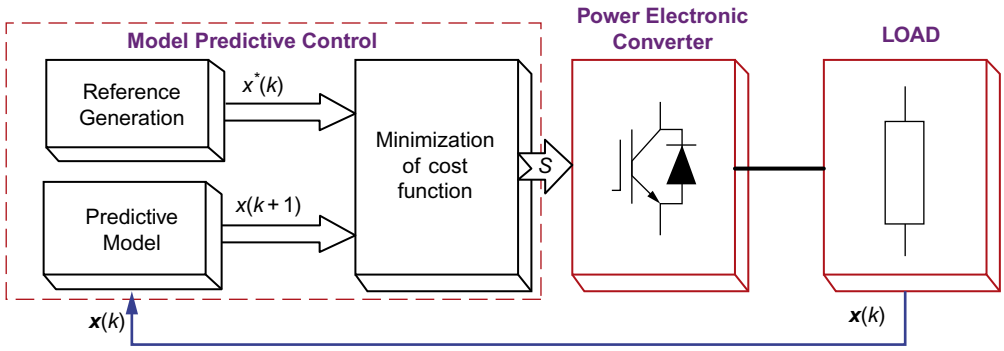

FIG. 40.4 Model predictive control block diagram for three-phase VSI.

- Build a model of the converter and determine the possible switching states.
- Build a model of the load for the predictive model.
- Define a cost function to minimize the error.

40.4.1 Converter Model

The traditional three-phase VSI with *RL* load and VSI equivalent circuits are shown in Fig. 40.5 [11]. As shown, each leg can be represented as a dual-way switch, so only one switch can be active simultaneously in the same leg in order to avoid short circuit. The switching states S_a, S_b, S_c are controlled as follows:

$$S_a = \begin{cases} 1, & \text{if } S_1 \text{ on and } S_4 \text{ off} \\ 0, & \text{if } S_1 \text{ off and } S_4 \text{ on} \end{cases} \tag{40.10}$$

$$S_b = \begin{cases} 1, & \text{if } S_2 \text{ on and } S_5 \text{ off} \\ 0, & \text{if } S_2 \text{ off and } S_5 \text{ on} \end{cases} \tag{40.11}$$

$$S_c = \begin{cases} 1, & \text{if } S_3 \text{ on and } S_6 \text{ off} \\ 0, & \text{if } S_3 \text{ off and } S_6 \text{ on} \end{cases} \tag{40.12}$$

These switching states can be expressed as

$$S = \frac{2}{3}\left(S_a + \mathrm{a}S_b + \mathrm{a}^2 S_c\right) \tag{40.13}$$

where **a** is called as a unitary vector and is equal to $e^{j2\pi/3}$. Finally, the inverter output voltage vector can be defined as a function of the switching state vector ***S*** by

$$\mathrm{v} = V_{dc}\mathrm{S} \tag{40.14}$$

where V_{dc} is the dc-link voltage.

Considering all the possible combinations of the switches (S_a, S_b, S_c), eight switching states and consequently eight voltage vectors can be obtained, as shown in Fig. 40.6. Six of these vectors (v_1–v_6) are defined as active vectors, while the other two (v_0, v_7) are defined as zero vector. Consequently, seven different voltage vectors are obtained as shown in Fig. 40.6.

40.4.2 Discrete-Time Model of Load for Prediction

The equivalent circuit of the three-phase VSI with *RL* load is shown in Fig. 40.7. The continuous-time model of the system can be expressed as

$$\begin{bmatrix} v_{aN} \\ v_{bN} \\ v_{cN} \end{bmatrix} = \begin{bmatrix} R & 0 & 0 \\ 0 & R & 0 \\ 0 & 0 & R \end{bmatrix} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} L & 0 & 0 \\ 0 & L & 0 \\ 0 & 0 & L \end{bmatrix} \frac{d}{dt} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} e_a \\ e_b \\ e_c \end{bmatrix} + \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} v_{nN} \tag{40.15}$$

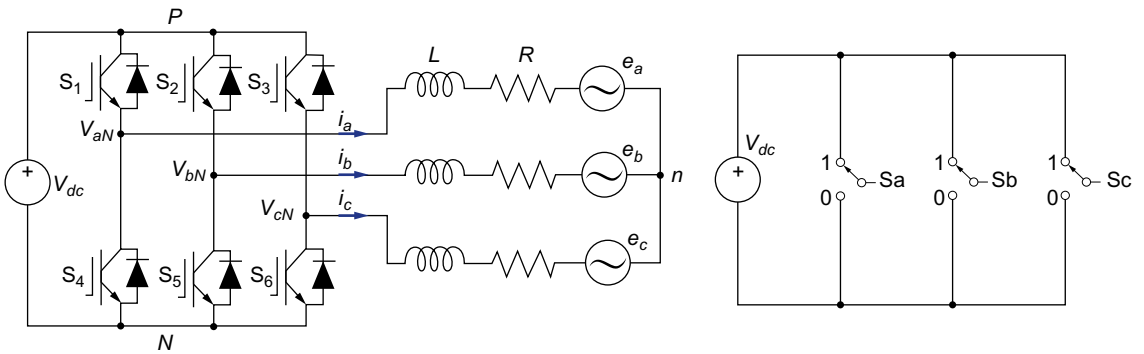

FIG. 40.5 Three-phase three-leg voltage source inverter circuit with *RL* load and its equivalent circuit.

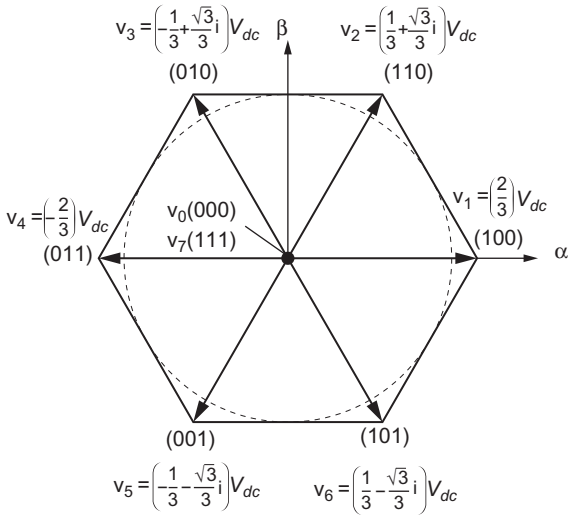

FIG. 40.6 Voltage vectors of the three-phase three-leg inverter.

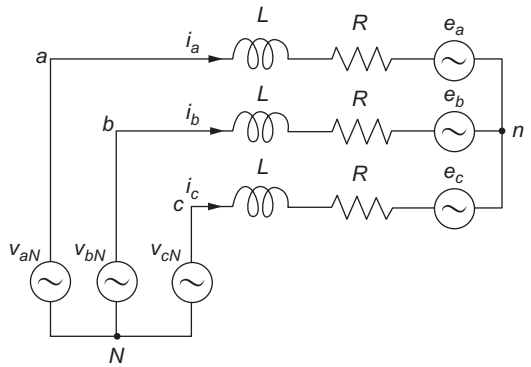

FIG. 40.7 Equivalent circuit of the three-phase VSI with *RL* load.

where R and L are the load resistance and the load inductance, respectively. This equation can be simplified as

$$\mathbf{v} = R\mathbf{i} + L\frac{d\mathbf{i}}{dt} + \mathbf{e} \tag{40.16}$$

where $\mathbf{v}$ is inverter output voltage vector, $\mathbf{i}$ is the load current vector, and $\mathbf{e}$ the load back-emf vector. The derivative of the output current vector can be obtained from

$$\frac{d\mathbf{i}}{dt} = \frac{1}{L}[(\mathbf{v} - \mathbf{e}) - R\mathbf{i}] \tag{40.17}$$

To use mathematical equations in the prediction model, discrete-time equations of the system must be obtained from continuous-time equations. To do that, the general structure of forward-difference Euler equation (40.18) can be used in order to compute the differential equations of the output current [12,13]:

$$\frac{df}{dt} \asymp \frac{f(x_0 + h) - f(x_0)}{h} \tag{40.18}$$

To estimate these variables in the next sampling time, the discretization equation can be defined as

$$\frac{\Delta f(k)}{\Delta t} \asymp \frac{f(k+1) - f(k)}{T_s} \tag{40.19}$$

The continuous-time expression for the i_{abc} is given in (40.17). By substituting (40.19) into (40.17), the discrete-time model of the i_{abc} can be obtained as

$$\mathbf{i}(k+1) = \left(1 - \frac{RT_s}{L}\right)\mathbf{i}(k) + \frac{T_s}{L}(\mathbf{v}(k) - \hat{\mathbf{e}}(k)) \tag{40.20}$$

where $\mathbf{i}(k+1)$ is the predicted output current vector at the next sampling time and $\hat{e}(k)$ denotes the estimated back emf that can be calculated from (40.16) considering the measurements of the load voltage and current with the following expression;

$$\hat{\mathbf{e}}(k-1) = \mathbf{v}(k-1) - \frac{L}{T_s}\mathbf{i}(k) - \left(R - \frac{L}{T_s}\right)\mathbf{i}(k-1) \tag{40.21}$$

where $\hat{e}(k-1)$ is the estimated value of $e(k-1)$.

40.4.3 Cost Function Optimization

The objective of the cost function is to minimize the error between the reference currents ($i_{abc}{}^{*}(k)$) and the predicted output currents ($i_{abc}(k+1)$) at the next sampling time. The cost function can be expressed in orthogonal coordinates as

$$\begin{aligned} g &= \left|i^*_{abc}(k) - i^p_{abc}(k+1)\right| \\ &= \left|i^*_{\alpha}(k) - i^P_{\alpha}(k+1)\right| + \left|i^*_{\beta}(k) - i^P_{\beta}(k+1)\right| \end{aligned} \tag{40.22}$$

where $i^P_{\alpha}(k+1)$ and $i^P_{\beta}(k+1)$ are the real and imaginary parts of the predicted load current vector, while $i^*_{\alpha}(k+1)$ and $i^*_{\beta}(k+1)$ are the real and imaginary parts of the reference load current. To simplify the analysis, it is assumed that the reference current does not change immediately in one sampling time. Thus, $i^*_{abc}(k+1) = i^*_{abc}(k)$ can be considered. On the other hand, this may introduce a one sample delay in the reference tracking, which can be neglected in high sampling frequency conditions. In general, the reference current is generated from an external control loop, for example, maximum power point tracking control loop.

The sketch map of the reference and predicted rotor currents is shown in Fig. 40.8 to illustrate how the proposed MPC strategy works. Here, the measured output current i_a(k) and voltage vectors $\mathbf{v_{0\text{-}7}}$, which are given in Table 40.1, have been evaluated together to estimate the future output current $i_a(k+1)$ values. As shown in Fig. 40.8, there are eight different predicted rotor current values at time $k+1$ and $k+2$. However, it can be seen from the figure that only v_2 and v_3 voltage vectors minimize the error of the output current at $k+1$ and $k+2$ instants, respectively. Thus, voltage vectors that minimize the cost function g are v_2 at $k+1$ and v_3 at $k+2$ are selected. In other words,

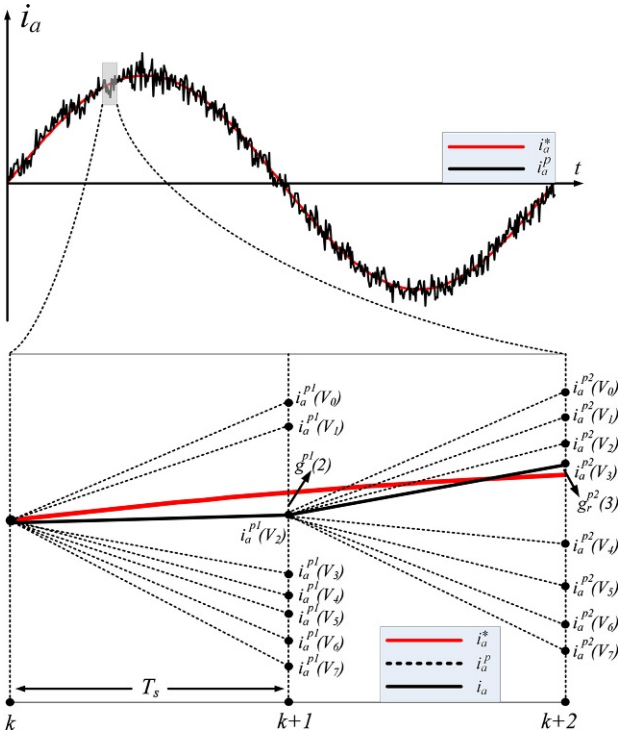

FIG. 40.8 The sketch map of the reference and predicted currents.

2	1	1	0	$\mathbf{V}_2=\frac{1}{3}V_{dc}+j\frac{\sqrt{3}}{3}V_{dc}$
3	0	1	0	$\mathbf{V}_3=-\frac{1}{3}V_{dc}+j\frac{\sqrt{3}}{3}V_{dc}$
4	0	1	1	$\mathbf{V}_4=-\frac{2}{3}V_{dc}$
5	0	0	1	$\mathbf{V}_5=-\frac{1}{3}V_{dc}-j\frac{\sqrt{3}}{3}V_{dc}$
6	1	0	1	$\mathbf{V}_6=\frac{1}{3}V_{dc}-j\frac{\sqrt{3}}{3}V_{dc}$
7	1	1	1	$\mathbf{V}_7=0$

corresponding voltage vector at each sample time is determined by the cost function according to the minimum error or distance between reference and predicted currents. As a result, it can be shown that v_2 and v_3 voltage vectors produce the lowest value of the cost function at $k+1$ and $k+2$ instants, respectively.

40.4.4 Control Algorithm

The MPC algorithm can be implemented as a "*for*" loop to predict future behavior of the system output, minimize the error between the reference and predicted output using predefined cost function, and store the index value of the corresponding switching state [14,15]. The flowchart of the MPC algorithm is given in Fig. 40.9. The control algorithm can be summarized by the following steps:

- Measure the output currents (i_{abc}).
- Estimate the back emf using Eq. (40.21).
- These measured and estimated values are used to predict output currents using the predictive model in Eq.(40.20).
- All predictions are evaluated using the predefined cost function.
- The optimal switching state that corresponds to the optimal voltage vector that minimizes the cost function is selected to be applied at the next sampling time.

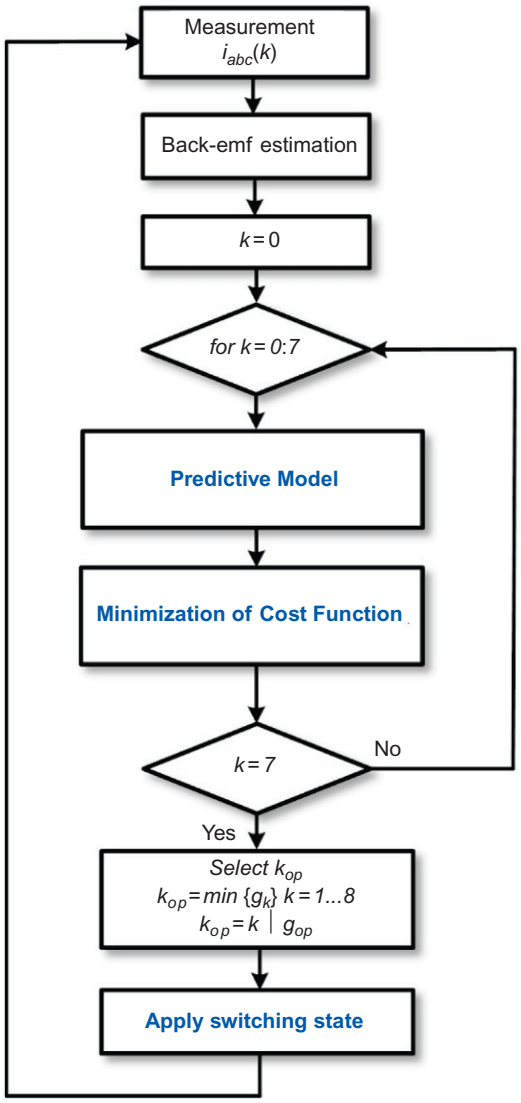

FIG. 40.9 Flowchart of the model predictive control of three-phase VSI.

40.5 MPC Applications in Power Electronic

40.5.1 Three-Level Neutral-Point-Clamped Inverter

Motivated by the aforementioned advantages of MPC and considering the multiobjective control requirements of neutral-point-clamped (NPC) inverter, in this subsection, MPC-based control technique for three-phase NPC inverter is presented. Here, two parameters, the output current and the capacitor voltages, are controlled by the MPC technique. Thus, multiobjective control requirement is solved with simple technique.

A. System Model

The used three-phase NPC inverter topology is illustrated in Fig. 40.10. Each leg of the inverter consists of four power switches with two diodes that allow the output terminal to be connected to the middle point of the split dc-link capacitors. This circuit configuration allows to generate three voltage levels at the output of the inverter according to the neutral point. The switching combinations are given in Table 40.2 [16]. Switching state variable S_x represents the switching state of phase x, with $x = a, b, c$, and it has three possible values denoted by positive, zero, and negative that represent the switching combinations that generate $V_{dc}/2$, 0, and $-V_{dc}/2$, respectively, at the output of the inverter phase.

The NPC inverter applies to the load 19 voltage vectors, which are generated from 27 switching states, as shown in Fig. 40.11 [16]. In addition to these switching states, for this application, one extra switching state is required to ensure shoot-through state. During this state, dc link must be short-circuited by single or multiple inverter legs.

TABLE 40.2 Switching states for one phase of the NPC inverter

S_x	S_{x1}	S_{x2}	S_{x3}	S_{x4}	v_{x0}
+	1	1	0	0	$V_{dc}/2$
0	0	1	1	0	0
−	0	0	1	1	$V_{dc}/2$

The continuous-time expression for the output current (i_o) can be described by the following equation:

$$L\frac{d\mathbf{i}(t)}{dt} = \mathbf{v}(t) - R\mathbf{i}(t) - \mathbf{e}(t) \tag{40.23}$$

where R and L are the load resistance and inductance, respectively, $\mathbf{v}$ is the voltage vector generated by the inverter, $\mathbf{e}$ is the electromotive force of the load, and $\mathbf{i}$ is the load current vector. These vectors are defined as

$$\left.\begin{aligned} \mathbf{v} &= \frac{2}{3}\left(V_a + aV_b + a^2V_c\right) \\ \mathbf{i} &= \frac{2}{3}\left(i_a + ai_b + a^2i_c\right) \\ \mathbf{e} &= \frac{2}{3}\left(e_a + ae_b + a^2e_c\right) \end{aligned}\right\} \tag{40.24}$$

where $a = e^{j(2\pi/3)}$.

B. MPC-based control algorithm

The proposed MPC algorithm applied to the three-level NPC inverter is shown in Fig. 40.12. To predict the output current ($\mathbf{i}_o$) and the capacitor voltages (v_{C1} and v_{C2}) at the next sampling time, discrete-time model of the inverter must be defined. One way to obtain discrete-time models is to use the forward-difference Euler equation due to its simplicity. The derivative form $dx(t)/dt$ is approximated by

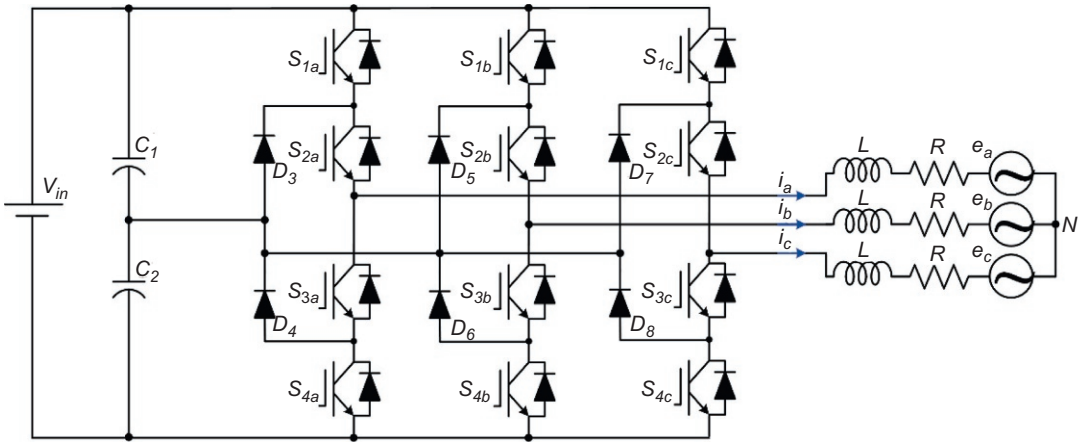

FIG. 40.10 Three-phase three-level NPC inverter topology.

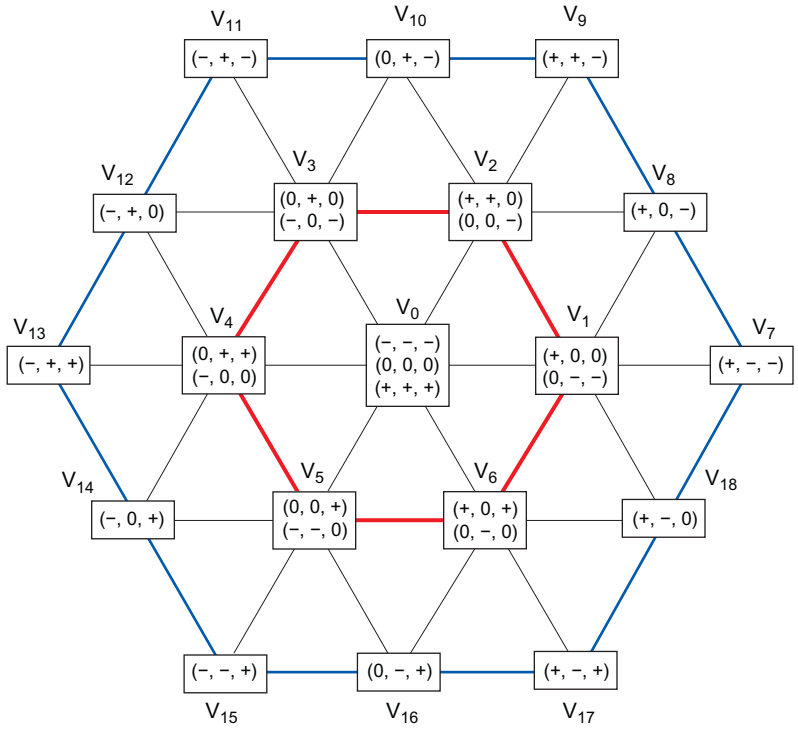

FIG. 40.11 Possible voltage vectors and switching states generated by a three-level NPC inverter.

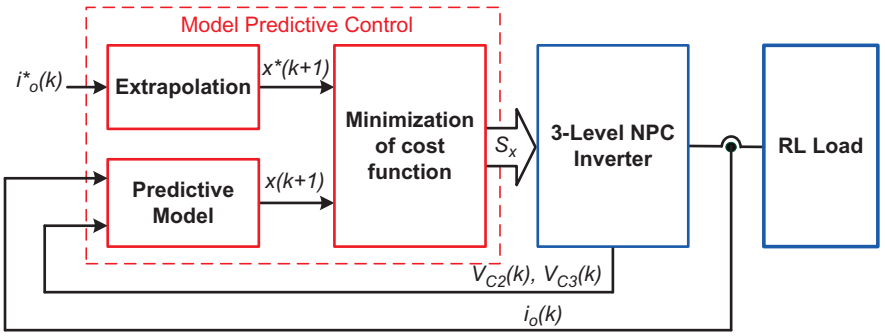

FIG. 40.12 Block diagram of the proposed MPC technique.

$$\frac{dx(k)}{dt} \approx \frac{x(k+1)-x(k)}{T_s} \tag{40.25}$$

where T_s is the sampling time and x is one of the control parameters such as $\mathbf{i}$ and v_{c12}.

By substituting (40.23) into (40.25), the discrete-time model of the output current vector is

$$\mathbf{i}(k+1) = \frac{T_s}{RT_s + L}\left[\frac{L}{T_s}\mathbf{i} + \mathbf{v}(k+1) - \mathbf{e}(k+1)\right] \tag{40.26}$$

where $\mathbf{i}$ $(k+1)$ is the predicted output current vector at the next sampling time.

The current prediction in (40.26) also requires an estimation of the future load back EMF $\mathbf{e}$ (k+1). It can be estimated by using a second-order extrapolation from present and past values. From (40.25) and the output voltage and current, resulting in the following expression:

$$\hat{\mathbf{e}}(k) = \mathbf{v}(k) + \frac{L}{T_s}\mathbf{i}(k-1) - \frac{RT_s + L}{T_s}\mathbf{i}(k) \tag{40.27}$$

where $\hat{e}(k)$ is the estimated value of $\mathbf{e}(k)$.

Furthermore, the discrete-time equations of the capacitor voltage can be expressed by using (40.25):

$$v_{C12}(k+1) = v_{C12}(k) + \frac{T_s}{C} i_{C12}(k) \tag{40.28}$$

where v_{C12}(k+1) is the predicted capacitor voltages, at the next sampling time.

To use reference value in the cost function, this value must be extrapolated to $k+1$ instant. To do that, Lagrange's extrapolation can be used [17]. Once the extrapolated reference values obtained, they are applied in the cost function optimization block as can be seen in Fig. 40.12. To handle the desired control objectives, two terms are required to be defined in the cost function. The terms are responsible for minimizing the error between the reference and predicted values. The defined cost function is

$$g(k+1) = \left|i_\alpha^*(k+1) - i_\alpha(k+1)\right| + \left|i_\beta^*(k+1) - i_\beta(k+1)\right| + \lambda\left|v_{C1}(k+1) - v_{C2}(k+1)\right| \tag{40.29}$$

where λ is the weighting factor.

C. Simulation Results

The simulation of the proposed system was performed using Matlab/Simulink environment. The NPC inverter topology, shown in Fig. 40.10, is used in the simulation. The parameters used in the simulation are summarized in Table 40.3.

The simulation result of steady-state analysis is shown in Fig. 40.13. The reference output currents track their references with high accuracy, while the dc-link voltage is kept balanced by the MPC. Fig. 40.14 shows the simulation result of the transient response of the proposed control technique. The output reference current is step changed from 10 to 15 A. It can be seen that the dc-link voltage remains balanced at 150 V, with small deviations during the transient.

40.5.2 33-Level Input Switched Inverter

The control of multilevel inverters (MIs) is quite challenging and requires a flexible approach to success multiple control objectives. The MPC technique is extremely effective to control MIs due to its considerable advantages over the traditional linear controller. This subsection presents MPC technique for 33-level input switched multilevel inverter (ISMI) to verify MPC's effectiveness in the high-level MI topologies.

TABLE 40.3 System parameters

Parameters	Values
Input DC voltage, V_{DC}	300 V

Load resistance, R	10 Ω
Load inductance, L	10 mH
Sampling time, T_s	100 μs

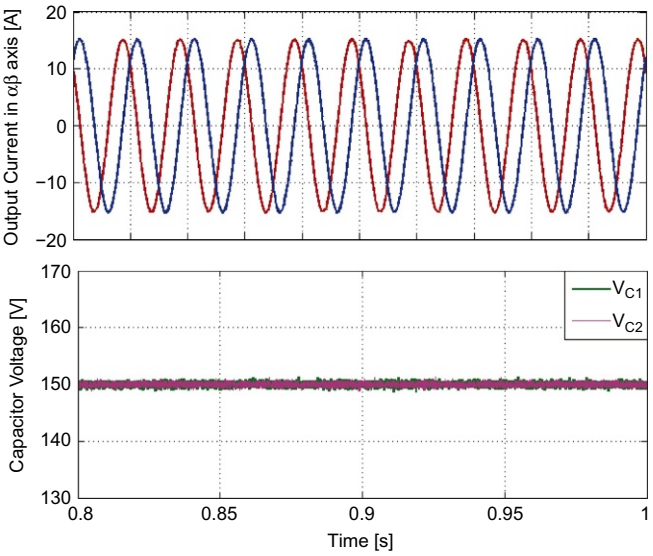

FIG. 40.13 Simulation results of steady-state operation.

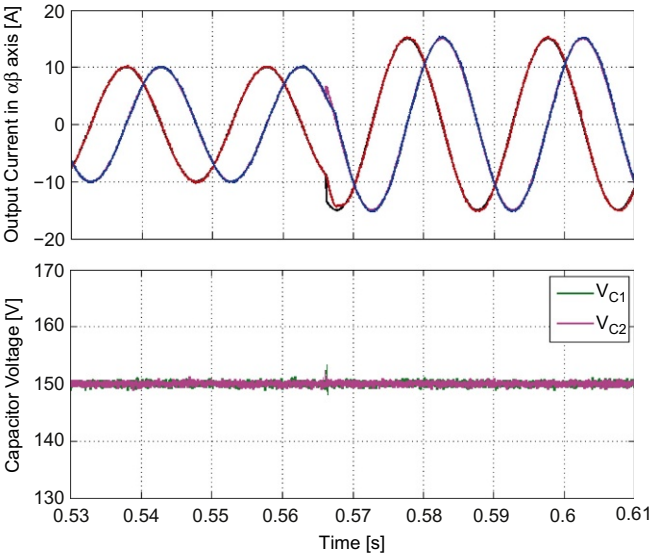

FIG. 40.14 Simulation results of transient response.

A. Overview of the ISMI

The circuit diagram of the single-phase 33-level ISMI with PV generation system is shown in Fig. 40.15 [18]. The ISMI topology has two stages, consisting of the multilevel module and H-bridge inverter. Output voltage level of this topology is given by $N_{level} = 2n+1$, where n represents the number of power legs. In order to obtain 33 voltage level, n should be 16 for this application.

In the first stage, each leg includes two power switches that allow bidirectional current flow. Sixteen capacitors are also employed to divide the dc-link voltage equally to

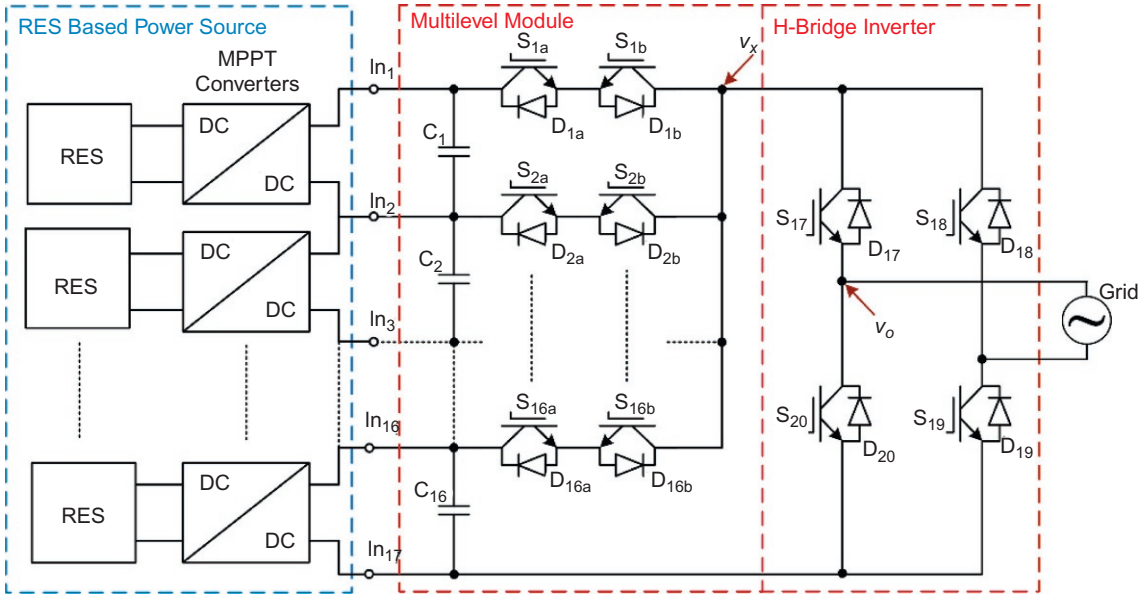

FIG. 40.15 The block diagram of single-phase 33-level ISMI in PV generation system.

V_{dc}/16, as seen in Fig. 40.15. The bidirectional power switches of each leg should be gated on sequentially to obtain desired voltage level. It is noticeable that more than one leg switches cannot be turned on at the same time because input dc source would be short circuit. Moreover, the switching state of the multilevel module is determined by the output current direction and the voltage level of the multilevel module. For example, when the first leg (S_{1ab}) is turned on and other legs are turned off, the output voltage (v_x) of the multilevel module is V_{dc}, the current flows through S_{1a} and D_{1b}. The proposed ISMI has 64 switching states that produce thirty-three voltage levels. However, it should be noted that the voltage level of the multilevel module is only 16 positive levels. Therefore, to obtain positive and negative levels, the traditional H-bridge inverter is employed in the second stage of this topology, as seen in Fig. 40.15. The H-bridge inverter provides voltage gains, which are +1, 0, −1, to ensure positive, zero, and negative voltage on the output. The switching states of 33-level ISMI are given in Table 40.4.

B. MPC-based control algorithm for 33-level ISMI

The block diagram of the MPC strategy applied to the current control for the 33-level grid-connected ISMI is shown in Fig. 40.16. The predictive model of the system needs output current information in order to generate

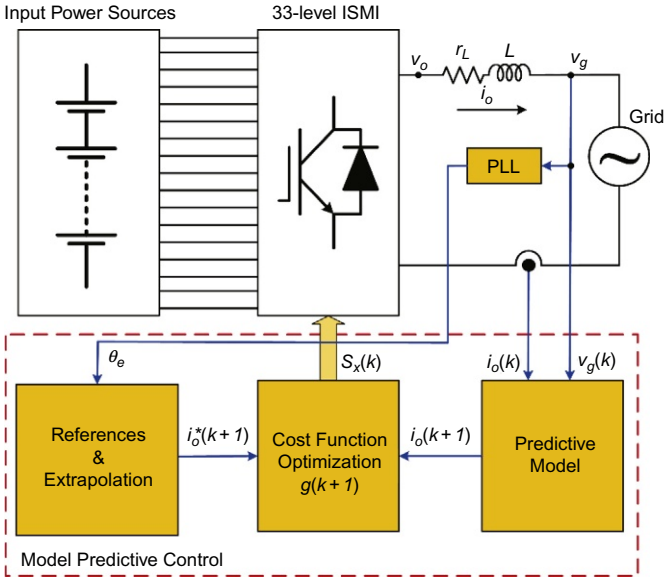

FIG. 40.16 Block diagram of the proposed model predictive control scheme.

reference current. Grid phase angle information is also required to generate reference current in same phase with the grid voltage. In this case, the output current i_o(k) and the grid voltage v_g(k) need to be measured. The phase angle (θ_e) of the reference current is obtained from PLL block. Thus, generated reference current will be in same phase and frequency with the grid voltage.

To control the output current (i_o) of the ISMI, a discrete-time model of the i_o must be defined. To do that, the averaged model of the system, which is defined in (40.30), can be used:

$$\frac{d}{dt}i_o(t) = \frac{-r_L}{L}.i_o(t) + \frac{1}{L}v(t) \tag{40.30}$$

where r_L and L are the resistance and inductance of the filter inductor, respectively, $i_o(t)$ is the average inverter output current, and $v(t)$ is the voltage, averaged in a switching period and applied to the inductor. The voltage on the inductor can be written as $v(t) = v_o(t) - v_g(t)$, where $v_g(t)$ is the grid voltage and $v_o(t)$ is the averaged value of the inverter voltage.

The general solution of the differential equation is

$$i_o(t) = e^{\frac{-r_L}{L}(t-t_0)}i_o(t_0) + \int_{t_0}^{t} e^{\frac{-r_L}{L}(t-\tau)}\frac{1}{L}v(\tau)d\tau \tag{40.31}$$

where lower (t_0) and upper (t) limits of integration can be defined as kT_s and (k+1)T_s, respectively, to obtain discrete-time model with sampling period T_s.

$$i_o(k+1) = e^{\frac{-r_L}{L}T_s}i_o(k) + \frac{1}{L}\int_{kT_s}^{(k+1)T_s} e^{\frac{-r_L}{L}((k+1)T_s-\tau)}v(\tau)d\tau \tag{40.32}$$

where i_o(k) $\equiv i_o$(kT_s). T_s is usually small enough to satisfy ($r_L Ts/L$) <<l; thus, (40.32) can be approximated as

$$i_o(k+1) = e^{\frac{-r_L}{L}T_s}.i_o(k) + \frac{1}{L}\int_{kT_s}^{(k+1)T_s} \left(v_o(\tau) - v_g(\tau)\right)d\tau \tag{40.33}$$

Since $d(t)$ is actualized every sampling period, we can assume that $v_o(t)$ is constant between two sampling instants:

$$v_o(t) = v_o(kT_s) \equiv v_o(k) \tag{40.34}$$

if $t \in$ [kT_s,(k+1)T_s]. On the other hand, as the sampling frequency is much higher than the grid frequency, we can approximate $v_g(t)$ linearly between two sampling instants:

$$v_g(t) \asymp v_g(kT) + \frac{v_g((k+1)T_s) - v_g(kT_s)}{T_s} \tag{40.35}$$

if $t \epsilon$ [kT_s,(k+1)T_s]. Discrete-time model of the output current can be obtained from substituting (40.34) and (40.35) into (40.33):

$$i_o(k+1) = e^{\frac{-r_L}{L}T_s}.i_o(k) + \frac{T_s}{L}\left(v_o(k) - \overline{v}_g(k)\right) \tag{40.36}$$

where $\overline{v}_g(k) = (1/2).\left(v_g(k+1) + v_g(k)\right)$ is the averaged value of the grid voltage between two samples.

The cost function is an important stage of the MPC technique. To minimize the error between the reference and the predicted values in the next sampling time, the cost function must be selected according to specific design criteria. In this study, in order to control the output current, the cost function is defined as

$$g = \left[i_o^*(k+1) - i_o(k+1)\right]^2 \tag{40.37}$$

where i_o*(k+1) is the reference output current and i_o(k+1) is the predicted output current in the next sampling time.

C. Implantation results

To verify the proposed MPC scheme for 33-level ISMI, experimental studies have been carried out for different operating conditions. The parameters of the system are summarized in Table 40.5.

Fig. 40.17A and B shows the experimental results of steady-state performance of the MPC-based current controller under normal and poor grid conditions. The results show that even with poor grid condition, the MPC-based current controller has an excellent steady-state performance.

TABLE 40.5 System parameters

Parameters	Values
Input DC voltage, V_{in}	16*62.5 = 1000 V
dc-link capacitor, C_n	470 μF (each)
Filter inductance, L_f	10 mH
Filter resistance, R_f	0.02 Ω
Nominal output voltage, v_{ln}	800 V max
Sampling time, T_s	50 μs

Fig. 40.18 shows the transient response results of the proposed MPC. The reference current is changed from 30 to 10 A and vice versa in order to observe the response of the proposed control technique. It can be seen that the transient time is very short, controller response is very fast, and the output current tracks its reference with high accuracy.

As the proposed control method is based on the system model, the algorithm is also tested to verify the robustness

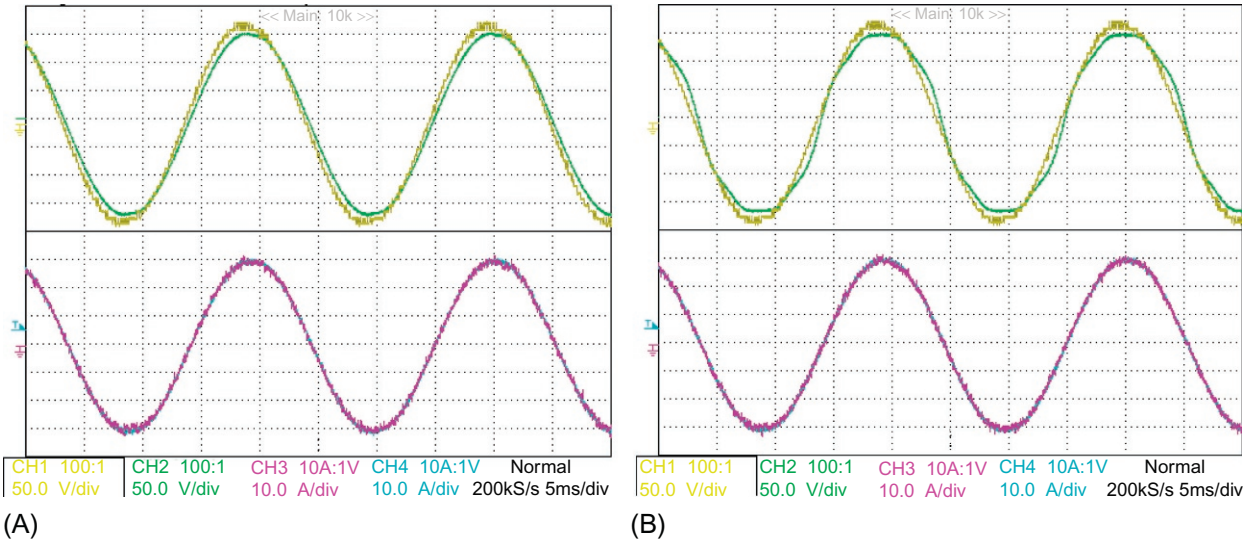

FIG. 40.17 Steady-state results of the proposed algorithm. (A) Normal grid condition. (B) Poor grid condition. CH1, inverter output voltage; CH2, grid voltage; CH3, output current; CH4, reference current.

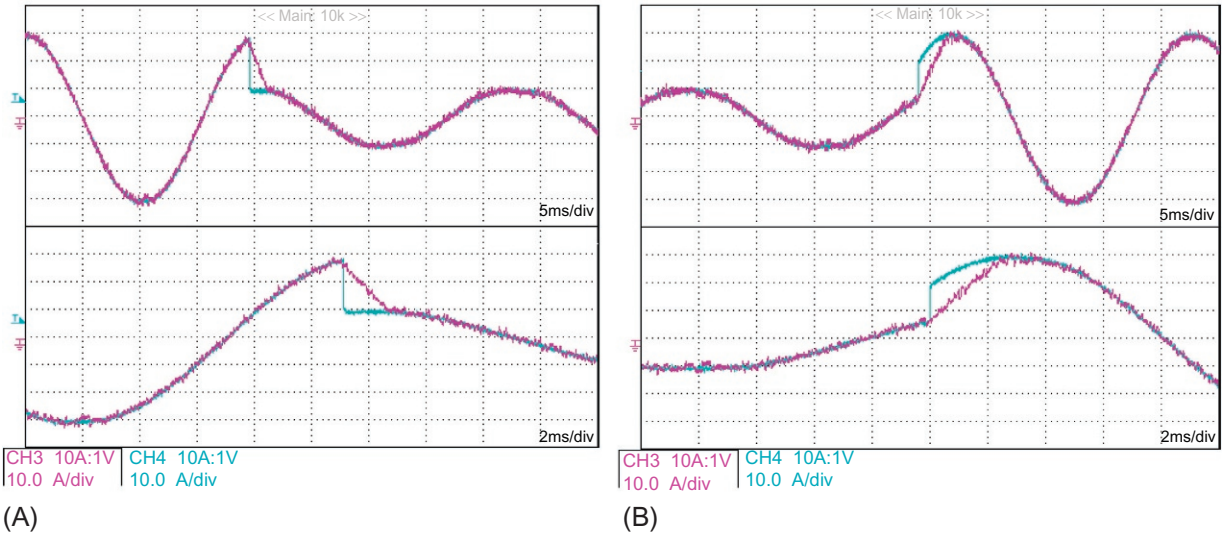

FIG. 40.18 Transient response of the proposed algorithm. (A) Step changes from 30 to 10 A. (B) Step changes from 10 to 30 A. CH3, output current; CH4, reference current.

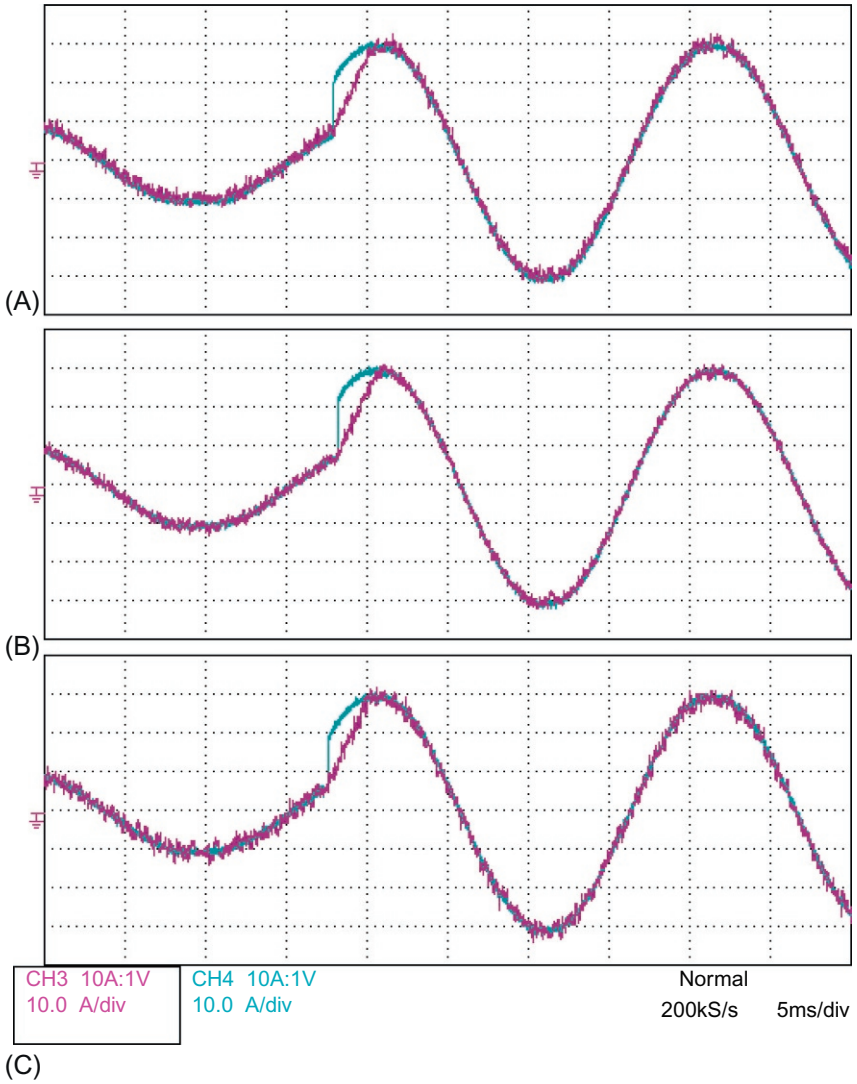

FIG. 40.19 Effect of mismatch filter inductance errors. (A) −50% error $L = 0.5^*L$, (B) no error $L = L$, (C) +50% error $L = 1.5^*L$. CH3, output current; CH4, reference current.

against the mismatch with filter parameter. To do that, the filter inductance (L_f) is consecutively set at 0.5^*L, L, and 1.5^*L, which is the typical case in distributed generation systems where the power system impedance changes randomly. It is remarkable that the new filter inductance value is not entered to the controller. The control algorithm uses a rated filter inductance value ($L = 10$ mH). Results are shown in Fig. 40.19A–C. It is clear that, when the modeled inductance value is smaller than selected value (0.5^*L), the mismatch causes steady-state errors, and when the modeled inductance value is bigger than selected value (1.5^*L), the mismatch causes current oscillation. However, it can be observed from results that the mismatch of the filter model slightly affects the system performance.

41.1 Introduction

The growing number of power-electronics-based equipment has produced an important impact on the quality of electric power supply. Both high-power industrial loads and domestic loads cause harmonics in the network voltages. At the same time, much of the equipment causing the disturbances is quite sensitive to deviations from the ideal sinusoidal line voltage. Therefore, power quality problems may originate in the system or may be caused by the consumer itself. Moreover, in the last years, the growing concern related to power quality comes from the following:

- Consumers that are becoming increasingly aware of the power quality issues and being more informed about the consequences of harmonics, interruptions, sags, switching transients, etc. Motivated by deregulation, they are challenging the energy suppliers to improve the quality of the power delivered.
- The proliferation of load equipment with microprocessor-based controllers and power electronic devices that are sensitive to many types of power quality disturbances.
- Emphasis on increasing overall process productivity that has led to the installation of high-efficiency equipment, such as adjustable speed drives and power factor correction equipment. This in turn has resulted in an increase in harmonics injected into the power system, causing concern about their impact on the system behavior.

For an increasing number of applications, conventional equipment is proving insufficient for the mitigation of power quality problems. Harmonic distortion has traditionally been dealt with the use of passive LC filters. However, the application of passive filters for harmonic reduction may result in parallel resonances with the network impedance, over compensation of reactive power at fundamental frequency, and poor flexibility for dynamic compensation of different frequency harmonic components.

The increased severity of power quality in power networks has attracted the attention of power engineers to develop dynamic and adjustable solutions to the power quality problems. Such equipment, generally known as active filters, are also called active power line conditioners and are able to compensate current and voltage harmonics and reactive power, regulate terminal voltage, suppress flicker, and improve voltage balance in three-phase systems. The advantage of active filtering is that it automatically adapts to changes in the network and load fluctuations. They can compensate for several harmonic

http://dx.doi.org/10.1016/B978-0-12-811407-0.00046-5

orders, and are not affected by major changes in network characteristics, eliminating the risk of resonance between the filter and network impedance. Another plus is that they take up very little space compared with traditional passive compensators.

41.2 Types of Active Power Filters

The technology of active power filter has been developed during the past two decades reaching maturity for harmonic compensation, reactive power, and voltage balance in ac power networks. All active power filters are developed with pulse-width-modulated (PWM) converters (current-source or voltage-source inverters). The current-fed PWM inverter bridge structure behaves as a nonsinusoidal current source to meet the harmonic current requirement of the nonlinear load. It has a self-supported dc reactor that ensures the continuous circulation of the dc current. They present good reliability but have important losses and require higher values of parallel capacitor filters at the ac terminals to remove unwanted current harmonics. Moreover, they cannot be used in multilevel or multistep mode configurations to allow compensation in higher power ratings.

The other converter used in active power filter topologies is the PWM voltage-source inverter (PWM-VSI). This converter is more convenient for active power filtering applications since it is lighter, cheaper, and expandable to multilevel and multistep versions, to improve its performance for high power rating compensation with lower switching frequencies. The PWM-VSI has to be connected to the ac mains through coupling reactors. An electrolytic capacitor keeps a dc voltage constant and ripple-free.

Active power filters can be classified based on the type of converter, topology, control scheme, and compensation characteristics. The most popular classification is based on the topology such as shunt, series, or hybrid. The hybrid configuration is a combination of passive and active compensation. The different active power filter topologies are shown in Fig. 41.1.

Shunt active power filters (Fig. 41.1A) are widely used to compensate current harmonics, reactive power, and load current unbalanced. It can also be used as a static var generator in power system networks for stabilizing and improving voltage profile. Series active power filters (Fig. 41.1B) is connected before the load in series with the ac mains, through a coupling transformer to eliminate voltage harmonics and to balance and regulate the terminal voltage of the load or line. The hybrid

Series	Current harmonic filtering Reactive current compensation Current unbalance Voltage flicker Voltage unbalance	Voltage sag/swell Voltage unbalance Voltage distortion Voltage interruption Voltage flicker Voltage notching

configuration is a combination of series active filter and passive shunt filter (Fig. 41.1C). This topology is very convenient for the compensation of high-power systems, because the rated power of the active filter is significantly reduced (about 10% of the load size), since the major part of the hybrid filter consists of the passive shunt LC filter used to compensate lower-order current harmonics and reactive power at fundamental frequency.

Due to the operation constraint, shunt or series active power filters can compensate only specific power quality problems. Therefore, the selection of the type of active power filter to improve power quality depends on the source of the problem as can be seen in Table 41.1.

The principles of operation of shunt, series, and hybrid active power filters are described in the following sections.

41.2.1 Shunt Active Power Filters

Shunt active power filters compensate current harmonics by injecting equal but opposite harmonic compensating current. In this case, the shunt active power filter operates as a current source injecting the harmonic components generated by the load but phase shifted by 180 degrees. As a result, components of harmonic currents contained in the load current are canceled by the effect of the active filter, and the source current remains sinusoidal and in phase with the respective phase-to-neutral voltage. This principle is applicable to any type of load considered as a harmonic source. Moreover, with an appropriate control scheme, the active power filter can also compensate the load power factor. In this way, the power distribution system sees the nonlinear load and the active power filter as an ideal resistor. The compensation characteristics of the shunt active power filter are shown in Fig. 41.2.

41.2.2 Power Circuit Topologies

Shunt active power filters are normally implemented with PWM-VSIs. In this type of application, the PWM-VSI operates as a current-controlled voltage source. Traditionally, two-level PWM-VSIs have been used to implement such system connected

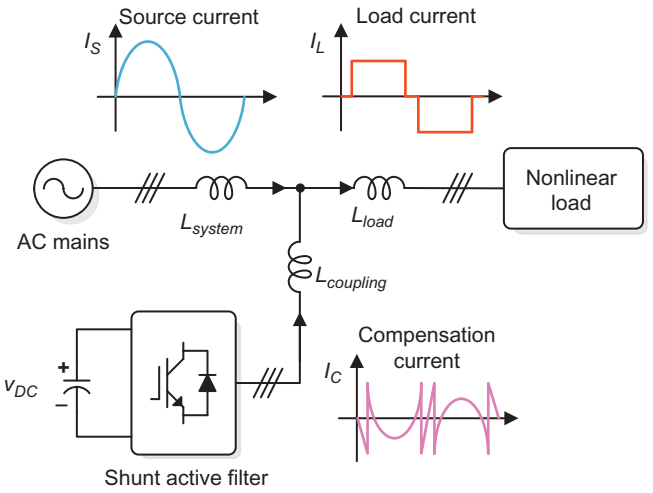

FIG. 41.2 Compensation characteristics of a shunt active power filter.

to the ac bus through a transformer. This type of configuration is aimed to compensate nonlinear load rated in the medium power range (hundreds of kilovolt-amperes) due to semiconductor rated value limitations. However, in the last years, multilevel PWM-VSIs have been proposed to develop active power filters for medium-voltage and higher rated power applications. Also, active power filters implemented with multiple VSIs connected in parallel to a dc bus but in series through a transformer or in cascade have been proposed in the technical literature. The different power circuit topologies are shown in Fig. 41.3.

The use of VSI connected in cascade is an interesting alternative to compensate high-power nonlinear loads. The use of two PWM-VSI with different rated power allows the use of different switching frequencies, reducing switching stresses and commutation losses in the overall compensation system. The power circuit configuration of such a system is shown in Fig. 41.4.

The VSI connected closer to the load compensates for the displacement power factor and lower-frequency current harmonic components (Fig. 41.5B), while the second compensates only high-frequency current harmonic components. The first converter requires higher rated power than the second and can operate at lower switching frequency. The compensation characteristics of the cascade shunt active power filter are shown in Fig. 41.5.

In recent years, there has been an increasing interest in using multilevel inverters for high-power energy conversion, especially for drives and reactive power compensation. The use of neutral-point-clamped (NPC) inverters (Fig. 41.6) allows equal voltage shearing of the series-connected semiconductors in each phase. Basically, multilevel inverters have been developed for applications in medium-voltage ac motor drives and static var compensation. For these types of applications, the output voltage of the multilevel inverter must be able to generate an almost sinusoidal output current. In order to generate a near sinusoidal output current, the output voltage should not contain low-frequency harmonic components.

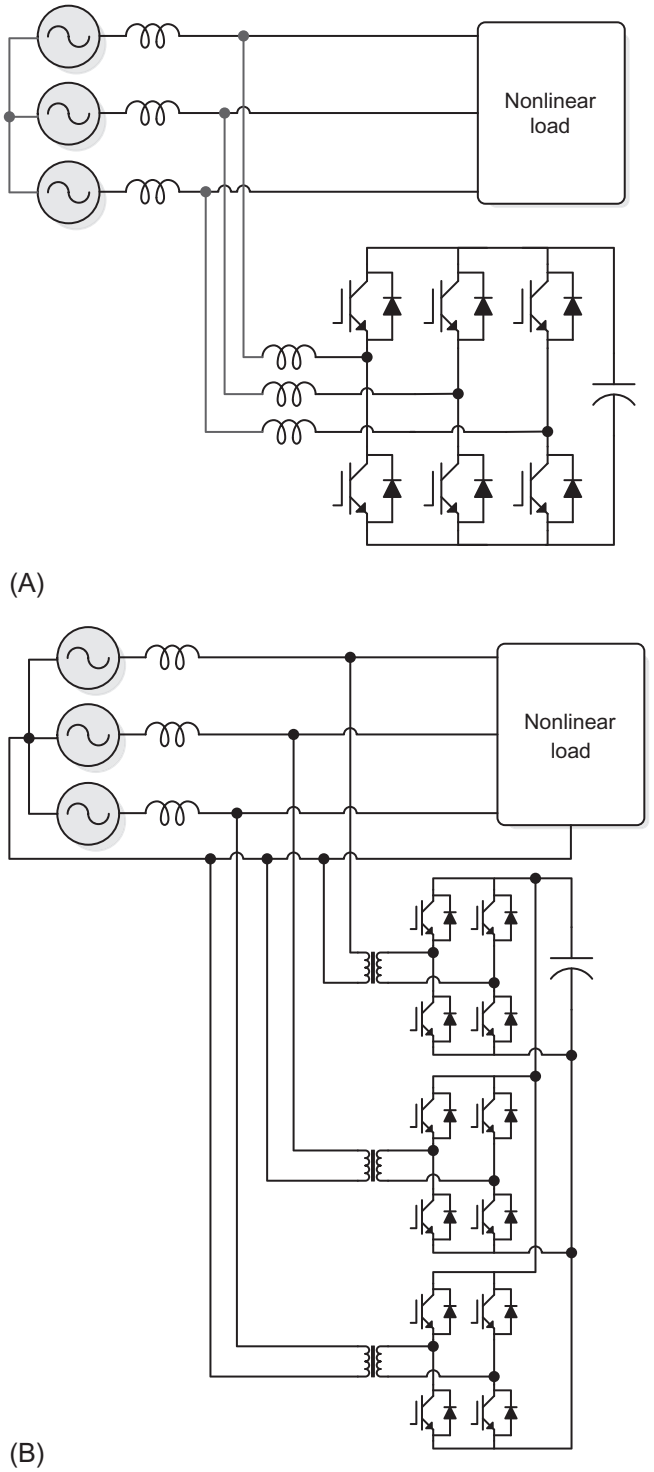

FIG. 41.3 Shunt active power filter topologies implemented with PWM-VSIs: (A) a three-phase PWM unit and (B) three single-phase units in parallel to a common dc bus.

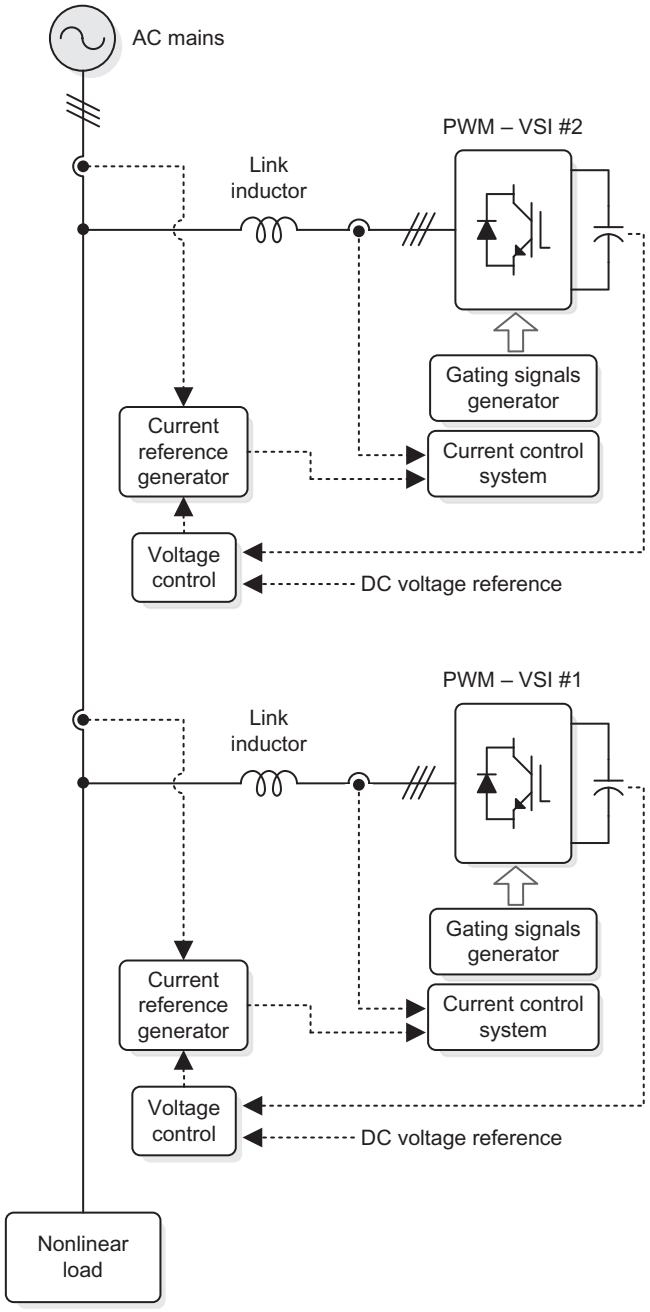

FIG. 41.4 A shunt active power filter implemented with two PWM-VSI connected in cascade.

However, for active power filter applications, the three-level NPC inverter output voltage must be able to generate an output current that follows the respective reference current containing the harmonic and reactive component required by the load. Current and voltage waveforms obtained for a shunt active power filter implemented with a three-level NPC-VSI are shown in Fig. 41.7.

41.2.3 Control Scheme

The control scheme of a shunt active power filter must calculate the current reference waveform for each phase of the inverter, maintain the dc voltage constant, and generate the inverter gating signals. The block diagram of the control scheme of a shunt active power filter is shown in Fig. 41.8.

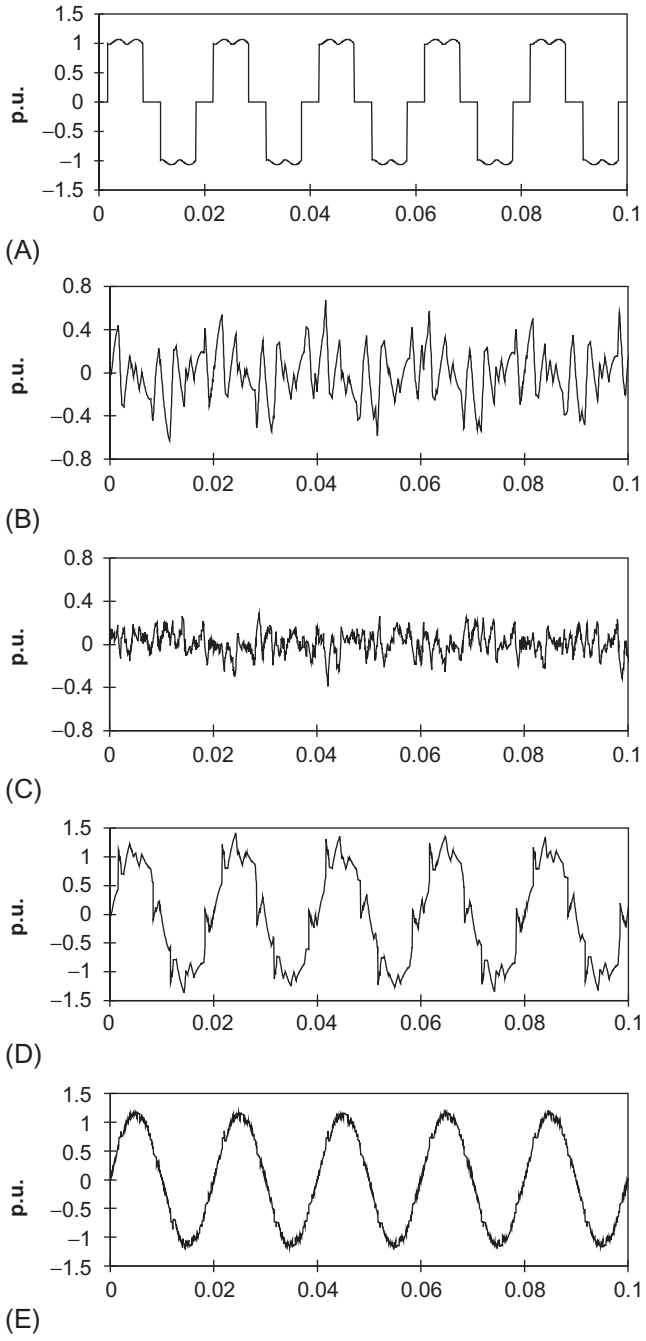

FIG. 41.5 Current waveforms of active power filter implemented with two PWM-VSI in cascade: (A) load current waveform, (B) current waveform generated by PWM-VSI no. 1, (C) current waveform generated by PWM-VSI no. 2, (D) power system current waveform between the two inverters ($THD_i = 13.7\%$), and (E) power system current waveform ($THD_i = 4.5\%$).

The current reference circuit generates the reference currents required to compensate the load current harmonics and reactive power and also try to maintain constant the dc voltage across the electrolytic capacitors. There are many possibilities to implement this type of control, and the most popular of them will be explained in this chapter. Also, the compensation effectiveness of an active power filter depends on its ability to follow with a minimum error and time delay the reference signal calculated to compensate the distorted load current. Finally, the dc voltage control unit must keep the total dc bus voltage constant and equal to a given reference value. The dc voltage control is achieved by adjusting the small amount of real power absorbed by the inverter. This small amount of real power is adjusted by changing the amplitude of the fundamental component of the reference current.

41.2.3.1 Current Reference Generation

There are many possibilities to determine the reference current required to compensate the nonlinear load. Normally, shunt active power filters are used to compensate the displacement power factor and low-frequency current harmonics generated by nonlinear loads. One alternative to determine the current reference required by the VSI is the use of the instantaneous reactive power theory, proposed by Akagi [1], the other one is to obtain current components in *d-q* or synchronous reference frame [2], and the third one is to force the system line current to follow a perfectly sinusoidal template in phase with the respective phase-to-neutral voltage.

Instantaneous reactive power theory

This concept is very popular and useful for this type of application and basically consists of a variable transformation from the *a*, *b*, *c* reference frame of the instantaneous power, voltage, and current signals to the α, β reference frame. The transformation equations from the *a*, *b*, *c* reference frame to the α, β coordinates can be derived from the phasor diagram shown in Fig. 41.9.

The instantaneous values of voltages and currents in the α, β coordinates can be obtained from the following equations:

$$\begin{bmatrix} v_\alpha \\ v_\beta \end{bmatrix} = [A] \cdot \begin{bmatrix} v_a \\ v_b \\ v_c \end{bmatrix} \begin{bmatrix} i_\alpha \\ i_\beta \end{bmatrix} = [A] \cdot \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} \tag{41.1}$$

where *A* is the transformation matrix, derived from Fig. 41.9 and is equal to

$$[A] = \sqrt{\frac{2}{3}} \begin{bmatrix} 1 & -1/2 & -1/2 \\ 0 & \sqrt{3}/2 & -\sqrt{3}/2 \end{bmatrix} \tag{41.2}$$

This transformation is valid if and only if $v_a(t) + v_b(t) + v_c(t)$ is equal to zero and also if the voltages are balanced and sinusoidal. The instantaneous active and reactive power in the α, β coordinates are calculated with the following expressions:

$$p(t) = v_\alpha(t) \cdot i_\alpha(t) + v_\beta(t) \cdot i_\beta(t) \tag{41.3}$$

$$q(t) = -v_\alpha(t) \cdot i_\beta(t) + v_\beta(t) \cdot i_\alpha(t) \tag{41.4}$$

It is evident that *p(t)* becomes equal to the conventional instantaneous real power defined in the *a*, *b*, *c* reference frame. However, in order to define the instantaneous reactive power, Akagi

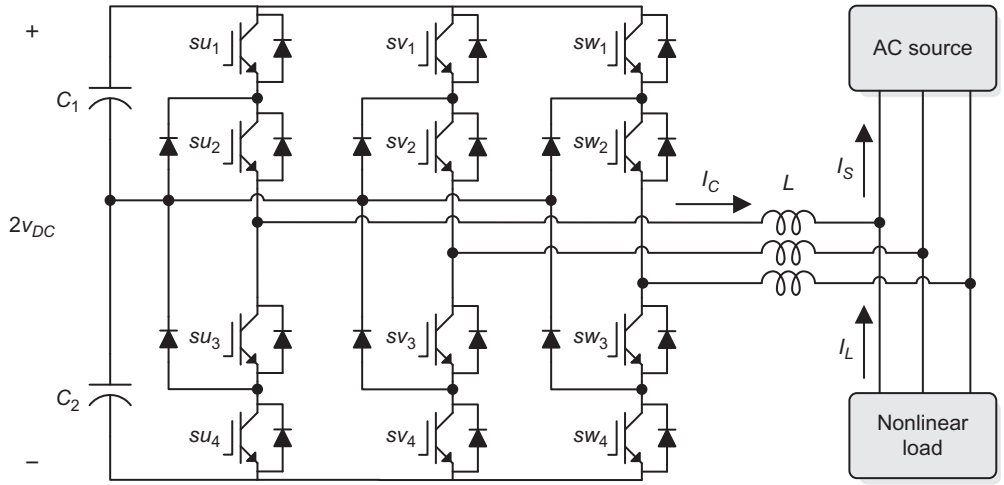

FIG. 41.6 A shunt active power filter implemented with a three-level neutral-point-clamped VSI.

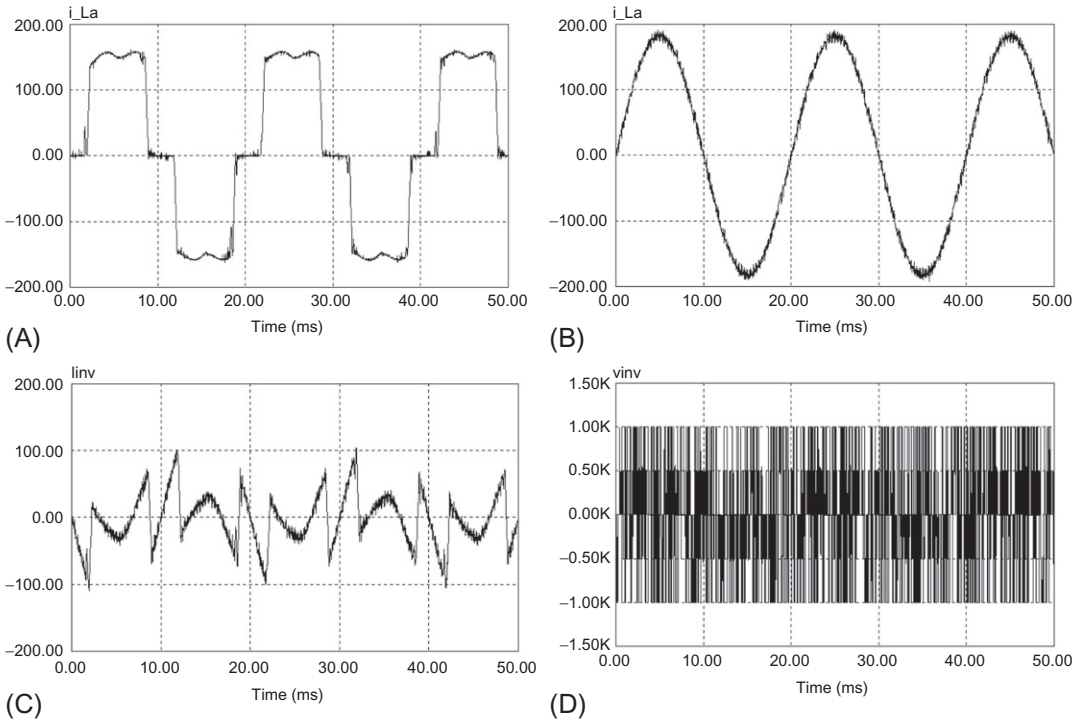

FIG. 41.7 Current and voltage waveforms for a shunt active power filter implemented with a three-level NPC-VSI: (A) load current, (B) compensated system current ($THD_i = 3.5\%$), (C) current generated by the shunt active power filter, and (D) inverter output voltage.

introduces a new instantaneous space vector defined by expression (41.4) or by the vector equation:

$$q = v_\alpha x i_\beta + v_\beta x i_\alpha \tag{41.5}$$

where the vector q is perpendicular to the plane of α, β coordinates, to be faced in compliance with a right-hand rule; v_α is perpendicular to i_β; and v_β is perpendicular to i_α. The physical meaning of the vector q is not "instantaneous power" because of the product of the voltage in one phase and the current in the other phase. On the contrary, $v_\alpha i_\alpha$ and $v_\beta i_\beta$ in Eq. (41.3) obviously mean "instantaneous power" because of the product of the voltage in one phase and the current in the same phase. Akagi named the new electric quantity defined in Eq. (41.5)

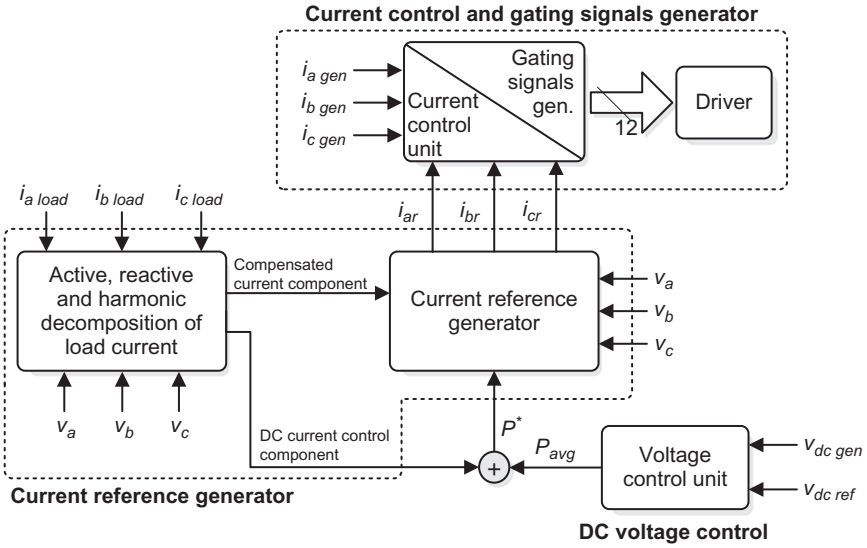

FIG. 41.8 The block diagram of a shunt active power filter control scheme.

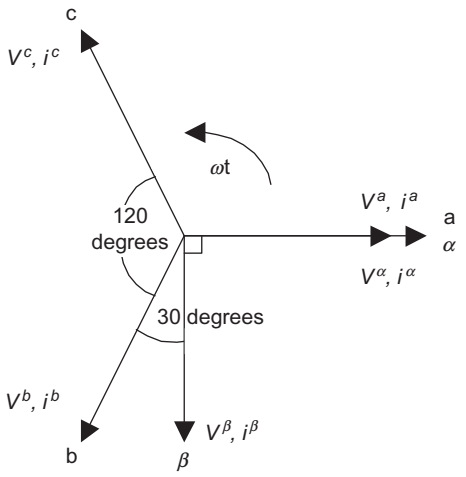

FIG. 41.9 Transformation diagram from the a, b, c reference frame to the α, β coordinates.

"instantaneous imaginary power," which is represented by the product of the instantaneous voltage and current in different axes, but cannot be treated as a conventional quantity.

The expression of the currents in the $\alpha-\beta$ plane, as a function of the instantaneous power, is given by the following equation:

$$\begin{bmatrix} i_\alpha \\ i_\beta \end{bmatrix} = \frac{1}{v_\alpha^2 + v_\beta^2} \cdot \left\{ \begin{bmatrix} v_\alpha & v_\beta \\ v_\beta & -v_\alpha \end{bmatrix} \cdot \begin{bmatrix} p \\ 0 \end{bmatrix} + \begin{bmatrix} v_\alpha & v_\beta \\ v_\beta & -v_\alpha \end{bmatrix} \cdot \begin{bmatrix} 0 \\ q \end{bmatrix} \right\} \equiv \begin{bmatrix} i_{\alpha p} \\ i_{\beta p} \end{bmatrix} + \begin{bmatrix} i_{\alpha q} \\ i_{\beta q} \end{bmatrix} \tag{41.6}$$

and the different components of the currents in the $\alpha-\beta$ plane are shown in the following expressions:

$$i_{\alpha p} = \frac{v_\alpha p}{v_\alpha^2 + v_\beta^2} \tag{41.7}$$

$$i_{\alpha q} = \frac{v_\beta q}{v_\alpha^2 + v_\beta^2} \tag{41.8}$$

$$i_{\beta p} = \frac{v_\beta p}{v_\alpha^2 + v_\beta^2} \tag{41.9}$$

$$i_{\beta q} = \frac{-v_\alpha q}{v_\alpha^2 + v_\beta^2} \tag{41.10}$$

From Eqs. (41.3) and (41.4), the values of p and q can be expressed in terms of the dc components and the ac components, that is,

$$p = \overline{p} + \widetilde{p} \tag{41.11}$$

$$q = \overline{q} + \widetilde{q} \tag{41.12}$$

where

$\overline{p}$ is the dc component of the instantaneous power p and is related to the conventional fundamental active current,

$\widetilde{p}$ is the ac component of the instantaneous power p; it does not have average value and is related to the harmonic currents caused by the ac component of the instantaneous real power.

$\overline{q}$ is the dc component of the imaginary instantaneous power q and is related to the reactive power generated by the fundamental components of voltages and currents.

$\widetilde{q}$ is the ac component of the instantaneous imaginary power q and it is related to the harmonic currents caused by the ac component of instantaneous reactive power.

In order to compensate reactive power (displacement power factor) and current harmonics generated by nonlinear loads, the reference signal of the shunt active power filter must include the values of $\widetilde{p}$, $\overline{q}$, and $\widetilde{q}$. In this case, the reference currents required by the shunt active power filters are calculated with the following expression:

$$\begin{bmatrix} i^*_{c,\alpha} \\ i^*_{c,\beta} \end{bmatrix} = \frac{1}{v_\alpha^2 + v_\beta^2} \cdot \begin{bmatrix} v_\alpha & v_\beta \\ v_\beta & -v_\alpha \end{bmatrix} \cdot \begin{bmatrix} \widetilde{p}_L \\ \overline{q}_L + \widetilde{q}_L \end{bmatrix} \tag{41.13}$$

The final compensating currents including the zero-sequence components in a, b, c reference frame are the following:

$$\begin{bmatrix} i^*_{c,a} \\ i^*_{c,b} \\ i^*_{c,c} \end{bmatrix} = \sqrt{\frac{2}{3}} \cdot \begin{bmatrix} \frac{1}{\sqrt{2}} & 1 & 0 \\ \frac{1}{\sqrt{2}} & \frac{-1}{2} & \frac{\sqrt{3}}{2} \\ \frac{1}{\sqrt{2}} & \frac{-1}{2} & \frac{-\sqrt{3}}{2} \end{bmatrix} \cdot \begin{bmatrix} -i_0 \\ i^*_{c,\alpha} \\ i^*_{c,\beta} \end{bmatrix} \tag{41.14}$$

where the zero-sequence current component i_0 is equal to $\frac{1}{\sqrt{3}}(i_a + i_b + i_c)$. The block diagram of the circuit required to generate the reference currents defined in Eq. (41.14) is shown in Fig. 41.10.

The advantage of instantaneous reactive power theory is that real and reactive power associated with fundamental components are dc quantities. These quantities can be extracted with a low-pass filter. Since the signal to be extracted is dc, filtering of the signal in the $\alpha - \beta$ reference frame is insensitive to any phase-shift errors introduced by the low-pass filter, improving compensation characteristics of the active power filter. The same advantage can be obtained by using the *synchronous reference frame method*, proposed in [2]. In this case, transformation from a, b, c axes to d-q synchronous reference frame is done.

Effects of the low-pass filter design characteristics in compensation performance: A Butterworth filter is normally used due to the adequate frequency response. A second-order filter offers an appropriate relation between the transient response and the required attenuation characteristic. Higher-order filters achieve better filtering characteristic, but the settling time is increased. Since the low-pass filter cannot eliminate completely the low-frequency harmonic contained in the p and q signals, the shunt active power filter cannot compensate the entire low-frequency harmonic contained in the load current. Normally, the cutoff frequency is equal to 127 Hz with an attenuation factor of 15 dB for the first ac component to be eliminated, which means an 82.2% attenuation of the fifth and seventh harmonic components (Fig. 41.11). The expression that relates the system line current harmonic distortion with the LPF cutoff frequency and load power factor is shown in Eq. (41.15):

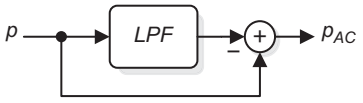

FIG. 41.11 The low-pass filter block diagram used to extract the ac component of p.

$$THD_{isys} = \frac{\sqrt{\sum_{h=6k}^{\infty} \frac{1}{(f_n/f_c)^4 + 1} \left[\left(\left(h^2+1\right)/\left(h^2-1\right) \right) - \left(1/\left(h^2-1\right)\right) \cos(2\varphi) \right]}}{\cos(\varphi)} \tag{41.15}$$

with $k = 1, 2, 3, \ldots$ and f_h is the frequency of the harmonic component of order h and f_c is the LPF cutoff frequency.

Fig. 41.12 shows the total harmonic distortion (THD) in the line currents introduced by the second-order Butterworth filtering characteristics, as a function of the cutoff frequency and considering a 50 Hz ac mains frequency. The harmonic distortion of the compensated line current depends on the load displacement power factor, as shown in Eq. (41.15). If the cutoff frequency of the low-pass filter is changed, the active power filter compensation performance is affected and the transient response of the control scheme.

Effects of the supply voltage distortion in compensation performance: One of the most important characteristics of the instantaneous imaginary power concept is that in order to obtain the current reference signal required to compensate reactive and harmonic current components, the system phase-to-neutral voltages are used. In general, purely sinusoidal voltages

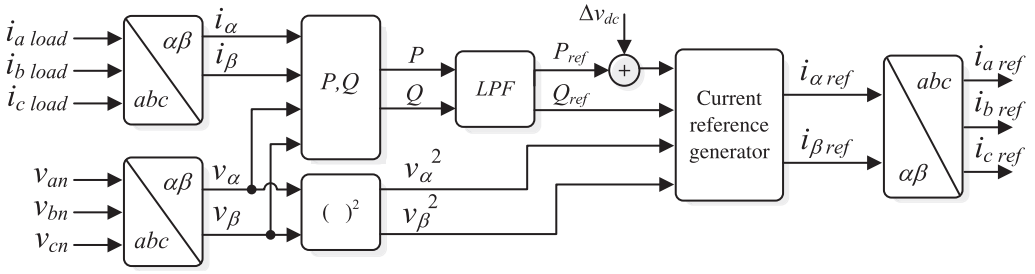

FIG. 41.10 The block diagram of the current reference generator using p-q theory.

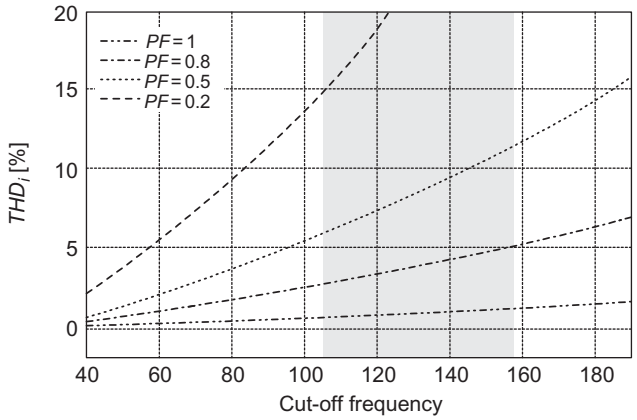

FIG. 41.12 Harmonic distortion of the compensated line current as a function of the low-pass filter cutoff frequency, $PF = \cos(\varphi)$.

are considered in previously reported analysis. In case voltage is purely sinusoidal, the dc components of p and q in the α–β plane are related with the fundamental components in the real a, b, c reference system. This is not the case if the system voltages are distorted or unbalanced, as it is demonstrated below.

It is assumed that the supply voltages have harmonic distortion, and these are represented by

$$\begin{aligned} v_a(t) &= V_1 \cos(\omega t) + V_h \cos[h(\omega t - \delta_h)] \\ v_b(t) &= V_1 \cos\left(\omega t - \frac{2\pi}{3}\right) + V_h \cos\left[h\left(\omega t - \delta_h - \frac{2\pi}{3}\right)\right] \\ v_c(t) &= V_1 \cos\left(\omega t + \frac{2\pi}{3}\right) + V_h \cos\left[h\left(\omega t - \delta_h + \frac{2\pi}{3}\right)\right] \end{aligned} \tag{41.16}$$

Since the harmonic voltage component introduces a dc component in p and q, compensation performance of the shunt active power filter is reduced, as shown in Fig. 41.13. The larger the harmonic distortion in the system voltage is, the active power filter performance is more affected.

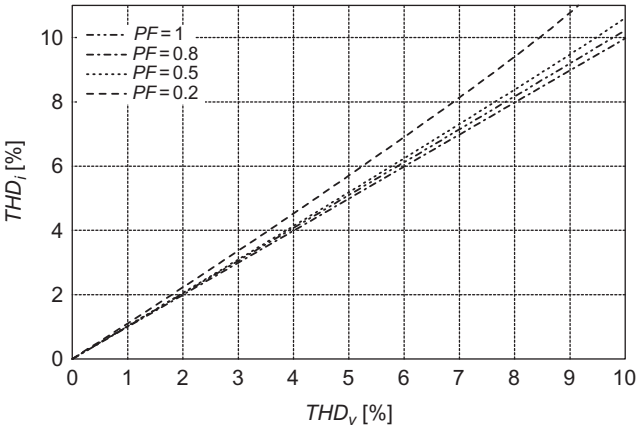

FIG. 41.13 Harmonic distortion in the compensated line current as a function of the harmonic distortion in the system voltages, $PF = \cos(\varphi)$.

Effects of the supply voltage unbalance in compensation performance: Voltage unbalance also affects the active power filter compensation performance. In this analysis, the phase-to-neutral voltages of the ac supply are equal to

$$\begin{aligned} v_a(t) &= V_1 \cos(\omega t) \\ v_b(t) &= V_1(1+m) \cos\left(\omega t - \frac{2\pi}{3}\right) \\ v_c(t) &= V_1(1-m) \cos\left(\omega t + \frac{2\pi}{3}\right) \end{aligned} \tag{41.17}$$

with $0 < m < 1$.

If the low-pass filter is considered as ideal and the active filter follows exactly the current references, the compensated supply current (phase a) is

$$\begin{aligned} i_{Sa} = & I_1 \cos(\varphi) \cos(\omega t) + \frac{\sqrt{3}}{3} m [I_1 \sin(\varphi) \cos(3\omega t) \\ & + I_1 \cos(3\omega t - \varphi)] \end{aligned} \tag{41.18}$$

In this case, the active power filter is not able to fully compensate the system line current, since compensation performance depends on the voltage unbalance magnitude.

The unbalance is defined as a function of the positive and negative-sequence component as

$$\begin{aligned} V_{a1} &= \frac{1}{3}\left[V_a + a^2 V_b + a V_c\right] \\ V_{a2} &= \frac{1}{3}\left[V_a + a V_b + a^2 V_c\right], \quad a = 1\angle 120 \text{ degrees} \\ \text{Unbalance} &= \frac{|V_{a2}|}{|V_{a1}|} = \frac{\sqrt{3}}{3} m \end{aligned} \tag{41.19}$$

The harmonic distortion is equal to

$$THD_i = \frac{\sqrt{3}}{3} m \tag{41.20}$$

The relation between line current harmonic distortion and voltage unbalance is shown in Fig. 41.14.

Effects of the time delay introduced by the dsp in compensation performance: If a DSP is used to derive the reference generation signals, a time delay, T, associated with the processing time is introduced in the calculation of the reference signals. Considering a simultaneous sampling, the ac mains compensated line current with an ideal low-pass filter in the control scheme (phase a) is

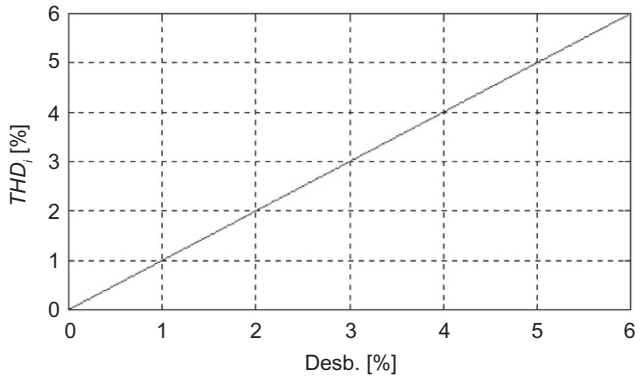

FIG. 41.14 Harmonic distortion in the compensated line current as a function of the system voltages unbalance.

$$\begin{aligned} i_{Sa} =& I_1 \cos(\omega t)[\cos(\varphi) + \sin(\omega T)] + \Delta V_{DC} \cos(\omega t) \\ &+ \sum_{n=2k-1}^{\infty} I_n[1 - \cos(n\omega T)] \cos[n(\omega t - \varphi)] \\ &+ \sum_{n=2k-1}^{\infty} I_n \sin(n\omega T) \sin[n(\omega t - \varphi)] \end{aligned} \tag{41.21}$$

The time delay introduced by the DSP affects the compensation performance, especially when fast changes are present in the load current. Nevertheless, when T is small ($T > 50$ s), the effect in compensation performance is negligible.

In four-wire systems, unbalances in the load current also affect the generation of the adequate current reference signal that will assure high-performance active power filter compensation. This assumption can be proved by considering the following load currents:

$$\begin{aligned} i_{La} &= I_1 \cos(\omega t - \varphi) + \sum_{n=2k-1}^{\infty} I_n \cos[n(\omega t - \varphi)] \\ i_{Lb} &= I_1(1 + l) \cos\left(\omega t - \varphi - \frac{2\pi}{3}\right) \\ &+ \sum_{n=2k-1}^{\infty} I_n(1 + l) \cos\left[n\left(\omega t - \varphi - \frac{2\pi}{3}\right)\right] \\ i_{Lc} &= I_1(1 - l) \cos\left(\omega t - \varphi + \frac{2\pi}{3}\right) \\ &+ \sum_{n=2k-1}^{\infty} I_n(1 - l) \cos\left[n\left(\omega t - \varphi + \frac{2\pi}{3}\right)\right] \\ i_{LN} &= i_{La} + i_{Lb} + i_{Lc} \end{aligned} \tag{41.22}$$

with $0 < l < 1$, $k = 1, 2, 3, \ldots$

Eq. (41.23) shows the presence of low-frequency even harmonics in the active power expression introduced by the load current unbalanced. These low-frequency current components force to reduce the cutoff frequency of the low-pass filter, close to 100 Hz, which affects the transient response of the active power filter:

$$\begin{aligned} p = \frac{3}{2} V_1 \Bigg[& I_1 \cos(\varphi) + \sum_{n=2k-1}^{\infty} I_n \cos[(n+1)\omega t - n\varphi] \\ & + \sum_{m=2k-1}^{\infty} I_m \cos[(m-1)\omega t - m\varphi] \Bigg] \quad \text{with} \quad k = 1, 2, 3, \ldots \end{aligned} \tag{41.23}$$

Synchronous reference frame algorithm

The block diagram of a current reference generator that uses the synchronous reference frame algorithm is shown in Fig. 41.15.

In this case, the real currents are transformed into a synchronous reference frame [2]. The reference frame is synchronized with the ac mains voltage and is rotating at the same frequency. The transformation is defined by

$$\begin{bmatrix} i_d \\ i_q \end{bmatrix} = \begin{bmatrix} \cos(\omega t) & \sin(\omega t) \\ \sin(\omega t) & \cos(\omega t) \end{bmatrix} \begin{bmatrix} i_\alpha \\ i_\beta \end{bmatrix} \tag{41.24}$$

As for the instantaneous reactive power theory, d and q terms are composed by a dc and multiple ac components, such as $i_d = i_{ddc} + i_{dac}$ and $i_q = i_{qdc} + i_{qac}$. The compensation reference signals are obtained from the following expressions: $i_{dref} = -i_{dac}$ and $i_{qref} = -i_{qdc} - i_{qac}$. The compensated currents generated by the shunt active power filter are obtained from Eq. (41.25):

$$\begin{bmatrix} i_{aref} \\ i_{bref} \\ i_{cref} \end{bmatrix} = \sqrt{\frac{2}{3}} \begin{bmatrix} \frac{1}{\sqrt{2}} & 1 & 0 \\ \frac{1}{\sqrt{2}} & -\frac{1}{2} & \frac{\sqrt{3}}{2} \\ \frac{1}{\sqrt{2}} & -\frac{1}{2} & -\frac{\sqrt{3}}{2} \end{bmatrix} \begin{bmatrix} -1 & 0 & 0 \\ 0 & \cos(\omega t) & -\sin(\omega t) \\ 0 & \sin(\omega t) & \cos(\omega t) \end{bmatrix} \begin{bmatrix} i_0 \\ i_{dref} \\ i_{qref} \end{bmatrix} \tag{41.25}$$

One of the most important characteristics of this algorithm is that the reference currents are obtained directly from the load currents without considering the source voltages. This is an

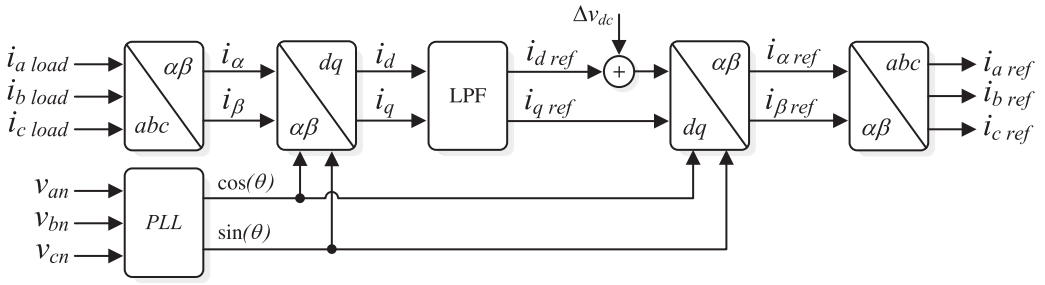

FIG. 41.15 The circuit block diagram required to obtain current reference waveforms using the synchronous reference frame theory.

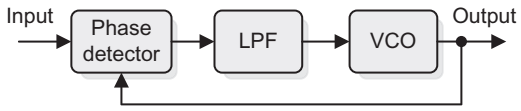

FIG. 41.16 The PLL circuit block diagram.

important advantage since the generation of the reference signals is not affected by voltage unbalance or voltage distortion, therefore increasing the compensation robustness and performance. However, in order to transform from the $\alpha-\beta$ plane to the d-q synchronous reference frame, sine and cosine signals synchronized with the respective phase-to-neutral voltages are required. A phase-locked loop (PLL) per each phase, as the one shown in Fig. 41.16, must be used.

Since the algorithm used to obtain the reference current presents the same mathematical procedure and operations that the ones required in the instantaneous reactive power concept, the effects introduced by the filter and DSP time delay are similar. Unbalanced load currents generate a different harmonic spectrum in the synchronous reference frame, and low-order harmonic components appear in the reference signal. In order to separate these uncharacteristic low-frequency current components, the cutoff frequency of the low-pass filter must be reduced.

Peak detection method

There are other possibilities to generate the current reference signal required to compensate reactive power and current harmonics. Basically, all the different schemes try to obtain the current reference signals that include the reactive components required to compensate the displacement power factor and the current harmonics generated by the nonlinear load. Fig. 41.17 shows another scheme used to generate the current reference signals required by a shunt active power filter. In this case, the ac current generated by the inverter is forced to follow the reference signal obtained from the current reference generator. In this circuit, the distorted load current is filtered, extracting the fundamental component, i_{l1}. The band-pass filter is tuned at the fundamental frequency (50 or 60 Hz), so that the gain attenuation introduced in the filter output signal is zero and the phase-shift angle is 180 degrees. Thus, the filter output current is exactly equal to the fundamental component of the load current but phase shifted by 180 degrees. If the load current is added to the fundamental current component obtained from the second-order band-pass filter, the reference current waveform required to compensate only harmonic distortion is obtained. In order to provide the reactive power required by the load, the current signal obtained from the second-order band-pass filter I_{l1} is synchronized with the respective phase-to-neutral source voltage (see Fig. 41.17) so that the inverter ac output current is forced to lead the respective inverter output voltage, thereby generating the required reactive power and absorbing the real power necessary to supply the switching losses and also to maintain the dc voltage constant.

The real power absorbed by the inverter is controlled by adjusting the amplitude of the fundamental current reference waveform, I_{l1}, obtained from the reference current generator. The amplitude of this sinusoidal waveform is equal to the amplitude of the fundamental component of the load current plus or minus the error signal obtained from the dc voltage control unit. In this way, the current signal allows the inverter to supply the current harmonic components, the reactive power required by the load, and to absorb the small amount of active power necessary to cover the switching losses and to keep the dc voltage constant (Fig. 41.18).

The main characteristic of this method is the direct derivation of the compensating component from the load current, without the use of any reference frame transformation [1,2]. Nevertheless, this technique presents a low-frequency oscillation problem in the active power filter dc bus voltage. To improve this technique, a modification of the previous scheme (Fig. 41.17) is shown in Fig. 41.19. The scheme is necessary for each phase. The expression for i_{Ma} is

$$i_{Ma}=\frac{I_1\cos(\varphi)}{2}+\frac{I_1\cos(2\omega t-\varphi)}{2}+\sum_{n=2k-1}^{\infty}\frac{I_n}{2}\{\cos[(n-1)\omega t-n\varphi]+\cos[(n+1)\omega t-n\varphi]\} \tag{41.26}$$

with $k=1, 2, 3,\ldots$

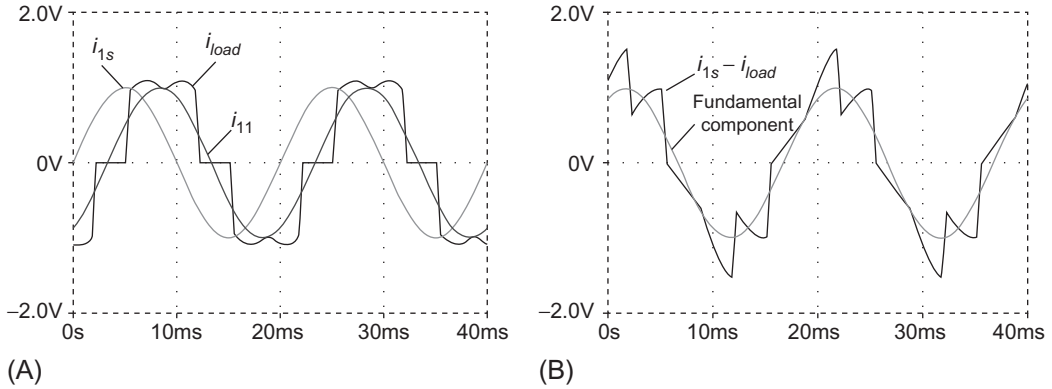

FIG. 41.18 The procedure for the generation of the current reference waveform: (A) the load current i_{load}, its fundamental component, i_{l1}, and the fundamental current component synchronized with the respective phase-to-neutral source voltage, i_{ls}, and (B) the synchronized fundamental current signal minus the load current, $i_{ls} - i_{load}$, and its fundamental component.

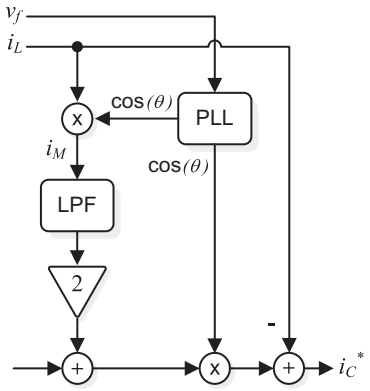

FIG. 41.19 Modified version of the original peak detection method.

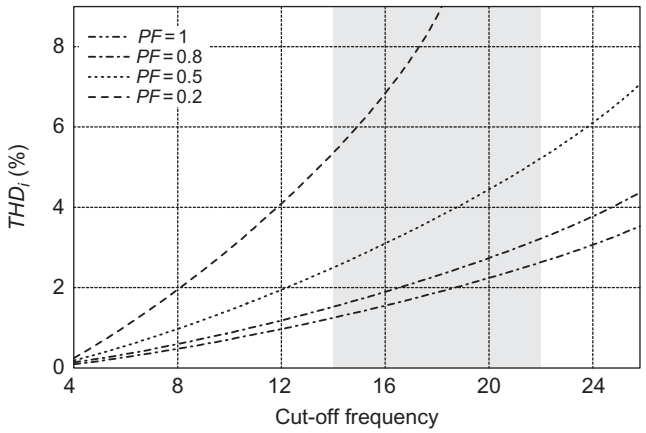

FIG. 41.20 Harmonic distortion of the system line current as a function of the cutoff frequency of the low-pass filter and the load displacement power factor.

Fig. 41.20 shows the current harmonic distortion introduced by the low-pass filter used in the control scheme and the associated cutoff frequency. The current distortion of the compensated current depends on the phase angle of the fundamental load current component.

The supply voltage has no effect on the reference current generation. Synchronization with the ac mains voltage is the important issue in this scheme and in the synchronous reference frame theory. Unbalanced loads do not affect the reference generation. Nevertheless, the method cannot achieve active power balance in four-wire systems. The control circuit implementation of the peak detection method is simple and does not require complex calculation, so the processing time on a DSP is lower than the required in the two previous implementations, ($T < 10$ s). The use of this method minimizes the distortion introduced on current harmonics.

Technical comparison of the three different techniques: In order to validate the effectiveness of the proposed analysis, a common industrial system is considered. The results are obtained using the previous equations and Matlab simulation results. The DSP delay introduced is using the processing time according to the DSP ADSP2187. The parameters considered are

$$THD_{iL} = 29\%$$
$$THD_V = 5\%$$
$$\cos(\varphi) = 0.87$$
$$\text{Unbalance} = 3\%$$

Table 41.2 shows the numeric results.

Table 41.3 shows a comparison of the three different techniques analyzed. The effects of the nonideal conditions are described for each technique.

In conclusion, it can be mentioned that the compensation performance of the different techniques is similar under ideal conditions, but under the presence of unbalanced and voltage

TABLE 41.2 Results of the considered case

Technique	THD_{iS}(%)	FP	Transient delay t_d (ms)

DSP delay time introduced	Minimum	Minimum	≈ 0

distortion, the synchronous reference frame algorithm presents the best performance, since it is insensitive to voltage perturbations. It is fundamental to consider adequately the cutoff frequency in the filter used to extract the ac component in the different techniques. If the frequency is changed, the compensation performance is affected as well as the transient response of the control scheme. In four-wire systems, unbalance in the load current also affects the generations of the adequate current reference. Unbalanced load currents generate a different harmonic spectrum in the dc reference frame, and low-order harmonic components appear in the reference signal; then, the cutoff frequency of the filter must be reduced.

41.2.3.2 Current Modulator

The effectiveness of an active power filter depends basically on the design characteristics of the current controller, the method implemented to generate the reference template and the modulation technique used. Most of the modulation techniques used in active power filters are based on PWM strategies. In this chapter, four of these methods, whose characteristics are their simplicity and effectiveness, are analyzed: periodical sampling control, hysteresis band control, triangular carrier control, and vector control. The first three methods have been tested with different waveform templates sinusoidal, quasisquare, and rectifier compensation current and were compared in terms of the harmonic content and distortion at the same switching frequency [3]. The analysis shows that for sinusoidal current generation the best method is triangular carrier, followed by hysteresis band and periodical sampling. For other types of references, however, one strategy may be better than the others. Also, it was shown that each control method is affected in a different way by the switching time delays present in the driving circuitry and in the power semiconductors.

Periodical sampling

The periodical sampling method switches the power transistors of the converter during the transitions of a square-wave clock of fixed frequency (the sampling frequency). As shown in Fig. 41.21, this type of control is very simple to implement since it requires a comparator and a D-type flip-flop per phase. The main advantage of this method is that the minimum time between switching transitions is limited to the period of the sampling clock. However, the actual switching frequency is not clearly defined.

Hysteresis band

The hysteresis band method switches the transistors when the current error exceeds a fixed magnitude: the hysteresis band. As can be seen in Fig. 41.22, this type of control needs a single comparator with hysteresis per phase. In this case, the switching frequency is not determined, but it can be estimated.

Triangular carrier

The triangular carrier method, shown in Fig. 41.23, compares the current error with fixed-amplitude and fixed-frequency

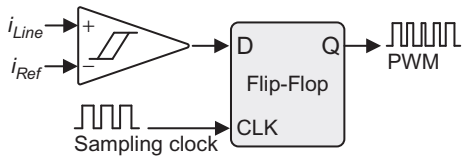

FIG. 41.21 Control modulator block for periodical sampling method.

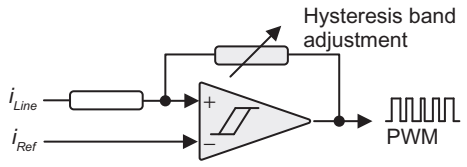

FIG. 41.22 Control modulator block for hysteresis band.

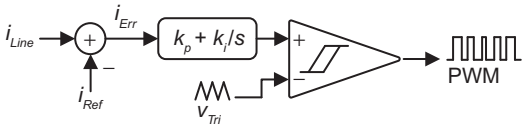

FIG. 41.23 Control modulator block for triangular carrier method.

triangular wave (the triangular carrier). The error is processed through a proportional-integral (PI) gain stage before the comparison with the triangular carrier takes place. As can be seen, this control scheme is more complex than the periodical sampling and hysteresis band. The values for the PI control gain k_p and k_i determine the transient response and steady-state error of the triangular carrier method. It was found empirically that the values for k_p and k_i shown in Eqs. (41.27) and (41.28) give a good dynamic performance under transient- and steady-state operating conditions:

$$k_p^* = \frac{(L + L_o) \cdot \omega_c}{2V_{dc}} \tag{41.27}$$

$$k_i^* = \omega_c k_p^* \tag{41.28}$$

where $L + L_o$ is the total series inductance seen by the converter; ω_c is the triangular carrier frequency, whose amplitude is 1 V peak-peak; and V_{dc} is the dc supply voltage of the inverter.

Vector control technique

This current control technique proposed in [4] divides the $\alpha - \beta$ reference frame of currents and voltages in six regions, phase shifted by 30 degrees (Fig. 41.24); identifies the region where the current vector error Δi is located; and selects the inverter output voltage vector V_{inv} that will force Δi to change in the opposite direction, keeping the inverter output current close to the reference signal.

Fig. 41.25 shows the single-phase equivalent circuit of the shunt active power filter connected to a nonlinear load and to the power supply.

The equation that relates the active power filter currents and voltages is obtained by applying Kirchhoff law to the equivalent circuit shown in Fig. 41.25:

$$V_{inv} = L\frac{di_{gen}}{dt} + E_0 \tag{41.29}$$

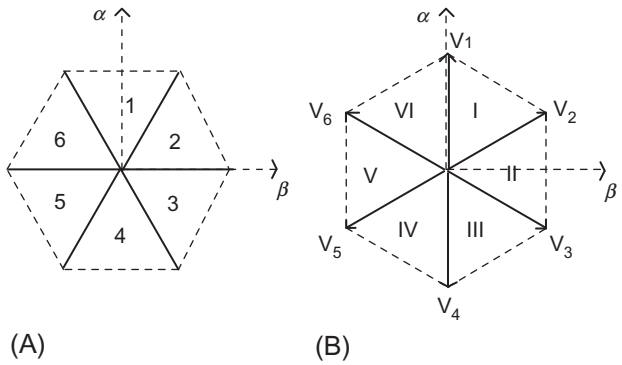

FIG. 41.24 The hexagons defined in the $\alpha - \beta$ reference frame by the current control scheme: (A) the hexagon defined by the inverter output current vector and (B) the hexagon defined by the inverter output voltage vector.

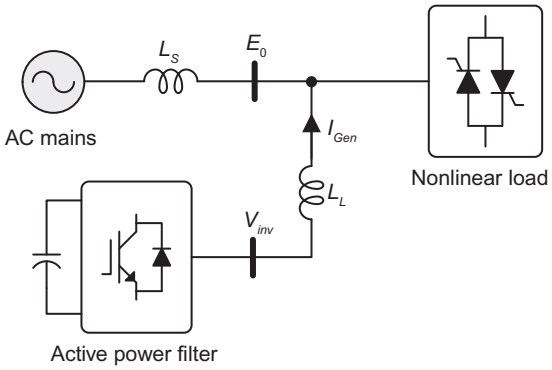

FIG. 41.25 The single-phase equivalent circuit of a shunt active power filter connected to the power system.

The current error vector Δi is defined by the following expression:

$$\Delta i = i_{ref} - i_{gen} \tag{41.30}$$

where i_{ref} represents the inverter reference current vector defined by the instantaneous reactive power concept. By replacing Eq. (41.30) in Eq. (41.29),

$$V_{inv} = L\frac{d}{dt}\left(i_{ref} - \Delta i\right) + E_0 \Rightarrow L\frac{d\Delta i}{dt} = L\frac{di_{ref}}{dt} + E_0 - V_{inv} \tag{41.31}$$

If $E = L\left(di_{ref}/dt\right) + E_0$, then Eq. (41.31) becomes

$$L\frac{d\Delta i}{dt} = E - V_{inv} \tag{41.32}$$

Eq. (41.32) represents the active power filter state equation and shows that the current error vector variation $d\Delta i/dt$ is defined by the difference between the fictitious voltage vector E and the inverter output voltage vector V_{inv}. In order to keep $d\Delta i/dt$ close to zero, V_{inv} must be selected near E_0.

The selection of the inverters' gating signals is defined by the region in which Δi is located and by its amplitude. In order to improve the current control accuracy and associate time response, depending on the amplitude of Δi, the following actions are defined:

- If $\Delta i \leq \delta$, the gating signals of the inverter are not changed.
- If $h \leq \Delta i \leq \delta$, the inverter gating signals are defined following mode a.
- If $\Delta i > h$, the inverter gating signals are defined following mode b.

where δ and h are reference values that define the accuracy and the hysteresis window of the current control scheme.

Mode a: Small changes in $\Delta i (h \leq \Delta i \leq \delta)$

The selection of the inverter switching mode a can be explained with the following example. Assuming that the voltage vector E

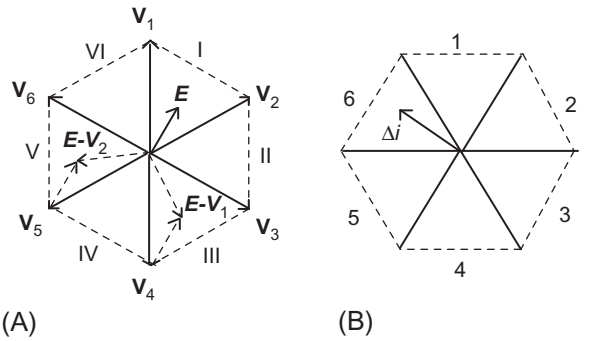

FIG. 41.26 Selection of the inverter switching pattern according to the region where Δi and E are located: (A) the regions where $Ld\Delta i/dt$ is located and (B) the region where Δi is located.

is located in region I (Fig. 41.26A) and the current error vector Δi is in region 6 (Fig. 41.26B), the inverter voltage vectors, V_{inv}, located closest to E are V_1 and V_2. The vectors $E - V_2$ and $E - V_1$ define two vectors $Ld\Delta i/dt$, located in regions III and V, respectively, as shown in Fig. 41.26A, so in order to reduce the current vector error Δi, $Ld\Delta i/dt$ must be located in region III. Thus, the inverter output voltage has to be equal to V_1. In this way, Δi will be forced to change in the opposite direction reducing its amplitude faster. By doing the same analysis for all the possible combinations, the inverter switching modes for each location of Δi and E can be defined (Table 41.4).

V_k represents the inverter switching functions defined in Table 41.5.

Mode b: Large changes in Δi ($\Delta i > h$)

If Δi becomes larger than h in a transient state, it is necessary to choose the switching mode in which the $d\Delta i/dt$ has the largest opposite direction to Δi. In this case, the best inverter output voltage V_{inv} corresponds to the value located in the same region of Δi.

The switching frequency may be fixed by controlling the time between commutations and not applying a new switching pattern if the time between two successive commutations is lower than a selected value ($t = 1/2f_c$).

Fig. 41.27 shows the block diagram of the inverter vector current control scheme implemented in a microcontroller. In Fig. 41.27, $^*E$ represents the region where the vector E is located, $^*\Delta i$, the region of Δi, k_1 keeps the same value of k (no commutation in the inverter), k_2 selects the new inverter output voltage from Table 41.4, and k_3 selects V_{inv} in the same region of Δi.

41.2.3.3 Control Loop Design

Active power filters based on self-controlled dc bus voltage require two control loops, one to control the inverter output current and the other to regulate the inverter dc voltage. Different design criteria have been presented in the technical literature; however, a classic design procedure using a PI controller will be presented in this chapter. In general, the design procedure for the current and voltage loops is based on the respective time-response requirements. Since the transient response of the active power is determined by the current control loop, its time response has to be fast enough to follow the current reference waveform closely. On the other hand, the time response of the dc voltage does not need to be fast and is selected to be at least 10 times slower than the current control loop time response. Thus, these two control systems can be decoupled and designed as two independent systems.

A PI controller is normally used for the current and the voltage control loops since it contributes to zero steady-state error in tracking the reference current and voltage signals, respectively.

Design of the current control loop

The design of the current control loop gains depends on the selected current modulator. In the case of selecting the triangular carrier technique, to generate the gating signals, the error between the generated current and the reference current is processed through a PI controller, and then, the output current error is compared with a fixed-amplitude and fixed-frequency triangular wave (Fig. 41.23). The advantage of this current modulator technique is that the output current of the converter has well-defined spectral line frequencies for the switching frequency components.

Since the active power filter is implemented with a voltage-source inverter, the ac output current is defined by the inverter

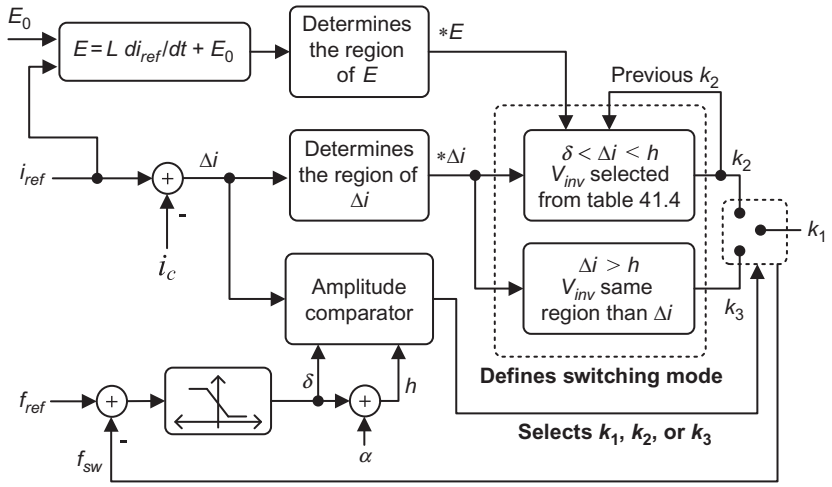

FIG. 41.27 The current control block diagram.

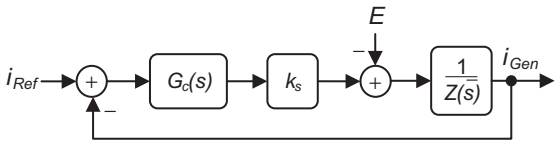

FIG. 41.28 The block diagram of the current control loop.

ac output voltage. The block diagram of the current control loop for each phase is shown in Fig. 41.28 where

E	phase-to-neutral source voltage,
$Z(s)$	impedance of the link reactor,
K_s	gain of the converter, and
$Gc(s)$	gain of the controller.

The values of K_s and $Gc(s)$ are given in Eqs. (41.33) and (41.34):

$$K_s = \frac{V_{dc}}{2\xi} \tag{41.33}$$

$$G_c(s) = K_p + \frac{K_i}{s} \tag{41.34}$$

From Fig. 41.27 and Eq. (41.34), the following expression is obtained:

$$I_{gen} = \frac{\left[K_s\left(K_p + (K_i/s)\right)\right]/(R_r + sL_r)}{1 + \left[K_s\left(K_p + (K_i/s)\right)/(R_r + sL_r)\right]} I_{ref} - \frac{1/(R_r + sL_r)}{1 + \left(K_s\left(K_p + K_i/s\right)/(R_r + sL_r)\right)} E \tag{41.35}$$

The characteristic equation of the current loop is given by

$$1 + \frac{\left(K_p s + K_i/s\right)}{s(R_r + sL_r)} \tag{41.36}$$

The analysis of the characteristic equation proves that the current control loop is stable for all values of K_p and K_i. Also, this analysis shows that K_p determines the speed response and K_i defines the damping factor of the control loop. If K_p is too big, the error signal can exceed the amplitude of the triangular waveform, affecting the inverter switching frequency, and if K_i is too small, the gain of the PI controller decreases, which means that the generated current will not be able to follow the reference current closely. The active filter transient response can be improved by adjusting the gain of the proportional part (K_p) to equal one and the gain of the integrator (K_i) to equal the frequency of the triangular waveform.

DC voltage control loop

Voltage control of the dc bus is performed by adjusting the small amount of real power flowing into the dc capacitor, thus compensating for the conduction and switching losses. The voltage loop is designed to be at least 10 times slower than the current loop, hence the two loops can be considered decoupled. The dc voltage control loop needs not to be fast, since it only responds for steady-state operating conditions. Transient changes in the dc voltage are not permitted and are taken into consideration with the selection criteria of the appropriate electrolytic capacitor value.

41.2.4 Power Circuit Design

The selection of the ac link reactor and the dc capacitor values affects directly the performance of the active power filter. Static var compensators implemented with voltage-source inverters present the same power circuit topology, but for this type of application, the criteria used to select the values of L_r and C are different. For reactive power compensation, the design of the synchronous link inductor, L_r, and the dc capacitor, C, is performed based on harmonic distortion constrain. That is, L_r must reduce the amplitude of the current harmonics generated by the inverter, while C must keep the dc voltage ripple factor below a given value. This design criteria cannot be

applied in the active power filter since it must be able to generate distorted current waveforms. However, L_r must be specified so that it keeps the high-frequency switching ripple of the inverter ac output current smaller than a defined value.

41.2.4.1 Design of the Synchronous Link Reactor

The design of the synchronous link reactor depends on the current modulator used. The design criteria presented in this section are based considering that the triangular carrier modulator is used. The design of the synchronous reactor is performed with the constraint that for a given switching frequency the minimum slope of the inductor current is smaller than the slope of the triangular waveform that defines the switching frequency. In this way, the intersection between the current error signal and the triangular waveform will always exist. In the case of using another current modulator, the design criteria must allow an adequate value of L_r in order to ensure that the di/dt generated by the active power filter will be able to follow the inverter current reference closely. In the case of the triangular carrier technique, the slope of the triangular waveform, λ, is defined by

$$\lambda = 4\xi f_t \tag{41.37}$$

where ξ is the amplitude of the triangular waveform, which has to be equal to the maximum permitted amount of ripple current, and f_t is the frequency of the triangular waveform (i.e., the inverter switching frequency). The maximum slope of the inductor current is equal to

$$\frac{di_L}{dt} = \frac{V_{an} + 0.5V_{dc}}{L_r} \tag{41.38}$$

Since the slope of the inductor current (di_L/dt) has to be smaller than the slope of the triangular waveform (λ) and the ripple current is defined, from Eqs. (41.37) and (41.38), as

$$L_r = \frac{V_{an} + 0.5V_{dc}}{4\xi f_t} \tag{41.39}$$

41.2.4.2 Design of the DC Capacitor

Transient changes in the instantaneous power absorbed by the load generate voltage fluctuations across the dc capacitor. The amplitude of these voltage fluctuations can be controlled effectively with an appropriate dc capacitor value. It must be noticed that the dc voltage control loop stabilizes the capacitor voltage after a few cycles, but is not fast enough to limit the first voltage variations. The capacitor value obtained with this criteria is bigger than the value obtained based on the maximum dc voltage ripple constraint. For this reason, the voltage across the dc capacitor presents a smaller harmonic distortion factor. The maximum overvoltage generated across the dc capacitor is given by

$$V_{C\max} = \frac{1}{C}\int_{\theta_1/\omega}^{\theta_2/\omega} i_C(t)dt + V_{dc} \tag{41.40}$$

where $V_{C\max}$ is the maximum voltage across the dc capacitor, V_{dc} is the steady-state dc voltage, and $i_c(t)$ is the instantaneous dc bus current. From Eq. (41.40),

$$C = \frac{1}{\Delta V}\int_{\theta_1/\omega}^{\theta_2/\omega} i_C(t)dt \tag{41.41}$$

Eq. (41.41) defines the value of the dc capacitor, C, that will maintain the dc voltage fluctuation below ΔV p.u. The instantaneous value of the dc current is defined by the product of the inverter line currents with the respective switching functions. The mean value of the dc current that generates the maximum overvoltage can be estimated by

$$\int_{\theta_1/\omega}^{\theta_2/\omega} i_C(t)dt = I_{inv}\int_{\theta_1/\omega}^{\theta_2/\omega} [\sin(\omega t) + \sin(\omega t + 120 \text{ degrees})]dt \tag{41.42}$$

In this expression, the inverter ac current is assumed to be sinusoidal. These operating conditions represent the worst case.

41.2.5 Technical Specifications

The standard specifications of shunt active power filters are the following:

- Number of phases: three phases and three wires or three phases and four wires (in case neutral currents need to be compensated)
- Input voltage: 200, 210, 220 ± 10%, 400, 420, 440 ± 10%, 6600 ± 10%
- Frequency: 50/60 Hz ± 5%
- Number of restraint harmonic orders: 2nd–25th
- Harmonic restraint factor: 85% or more at the rated output
- Type of rating: continuous
- Response: 1 ms or less

For shunt active power filter, the harmonic restraint factor is defined as $[1 - (I_{H_2}/I_{H_1})] \times 100\%$, where I_{H_1} is the harmonic currents flowing on the source side when no measure is taken for harmonic suppression and I_{H_2} is the harmonic currents flowing on the source side when harmonics are suppressed using an active filter.

41.3 Series Active Power Filters

Series active power filters were introduced by the end of the 1980s [5] and operate mainly as a voltage regulator and harmonic isolator between the nonlinear load and the utility system. The series-connected active power filter is more preferable to protect the consumer from an inadequate supply voltage quality. This type of approach is specially recommended for the compensation of voltage unbalances, voltage distortion,

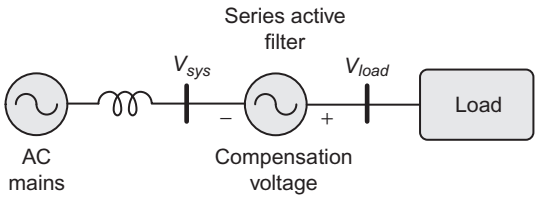

FIG. 41.29 The series active power filter operating as a voltage compensator.

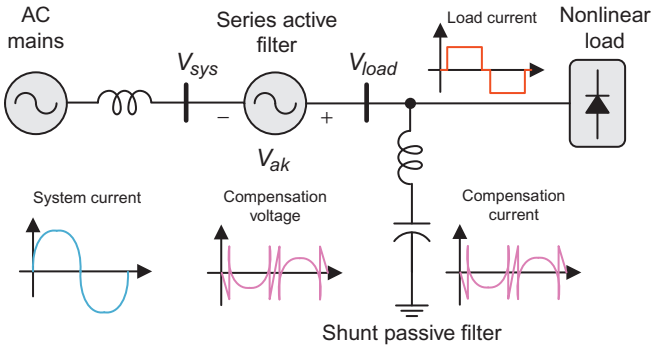

FIG. 41.30 Combination of series active power filter and passive filter for current harmonic compensation.

and voltage sags from the ac supply and for low-power applications represents an economically attractive alternative to UPS, since no energy storage (battery) is necessary and the overall rating of the components is smaller. The series active power filter injects a voltage component in series with the supply voltage and therefore can be regarded as a controlled voltage source, compensating voltage sags and swells on the load side (Fig. 41.29).

If passive LC filters are connected in parallel to the load, the series active power filter operates as a harmonic isolator forcing the load current harmonics to circulate mainly through the passive filter rather than the power distribution system (hybrid topology) (Fig. 41.30). The main advantage of this scheme is that the rated power of the series active power filter is a small fraction of the load kilovolt-ampere rating, typically 5%. However, the rated apparent power of the series active power filter may increase, in case voltage compensation is required.

41.3.1 Power Circuit Structure

The topology of the series active power filter is shown in Fig. 41.31. In most cases, the power circuit configuration is based on a three-phase PWM voltage-source inverter connected in series with the power lines through three single-phase coupling transformers. For certain type of applications, the three-phase PWM voltage-source converter can be replaced by three single-phase PWM inverters. However, this type of approach requires more power components, which increases the cost.

In order to operate as a harmonic isolator, a parallel LC filter must be connected between the nonlinear loads and the coupling transformers (Fig. 41.30). Current harmonic and voltage compensation are achieved by generating the appropriate voltage waveforms with the three-phase PWM voltage-source inverter, which are reflected in the power system through three

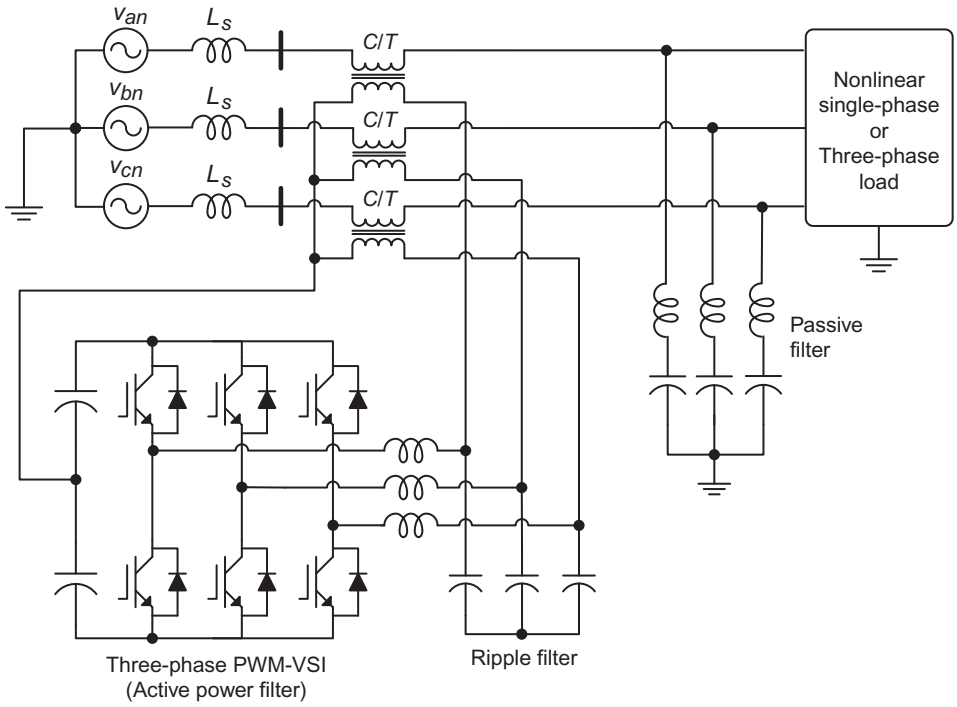

FIG. 41.31 The series active power filter topology.

coupling transformers. With an adequate control scheme, series active power filters can compensate for current harmonics generated by nonlinear loads, voltage unbalances, voltage distortion, and voltage sags or swells at the load terminals. However, it is very difficult to compensate the load power factor with this type of topology. In four-wire power distribution systems, series active power filters with the power topology can also compensate the current harmonic components that circulate through the neutral conductor.

41.3.2 Principles of Operation

Series active power filters compensate current system distortion caused by nonlinear loads by imposing a high-impedance path to the current harmonics, which forces the high-frequency currents to flow through the LC passive filter connected in parallel to the load (Fig. 41.30). The high impedance imposed by the series active power filter is created by generating a voltage of the same frequency that the current harmonic component needs to be eliminated. Voltage regulation or voltage unbalance can be corrected by compensating the fundamental frequency positive, negative, and zero-sequence voltage components of the power distribution system (Fig. 41.29). In this case, the series active power filter injects a voltage component in series with the supply voltage and therefore can be regarded as a controlled voltage source, compensating voltage regulation on the load side (sags or swells) and voltage unbalance. Voltage injection of arbitrary phase with respect to the load current implies active power transfer capabilities that increases the rating of the series active power filter and in most cases requires an energy storage element connected in the dc bus. Voltage and current waveforms shown in Figs. 41.32–41.34 illustrate the compensation characteristics of a series active power filter operating with a shunt passive filter.

41.3.3 Power Circuit Design

The power circuit topology of the series active power filter is composed by the three-phase PWM voltage-source inverter, the second-order resonant LC filters, the coupling transformers, and the secondary ripple frequency filter (Fig. 41.30). The design characteristics for each of the power components are described below.

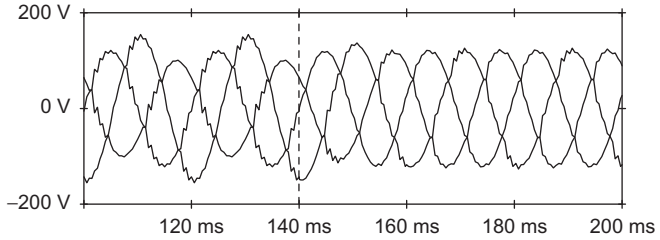

FIG. 41.32 Load voltage waveforms for voltage unbalance compensation. Phase-to-neutral voltages at the load terminals before and after series compensation. (Compensation starts at 140 ms, current harmonic compensator not operating.)

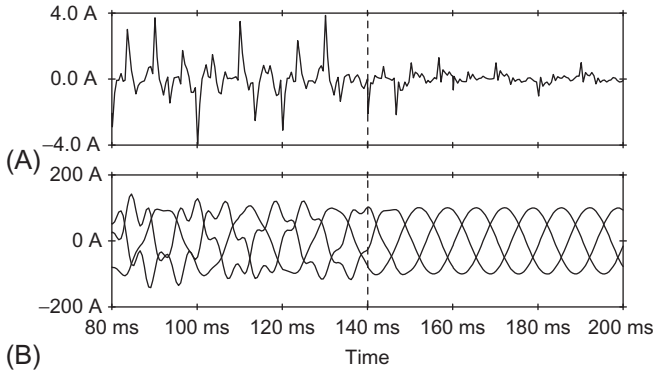

FIG. 41.33 System current waveforms for current harmonic compensation: (A) neutral current flowing to the ac mains before and after compensation and (B) line currents flowing to the ac mains before and after compensation. (Voltage unbalance compensator is not operating.)

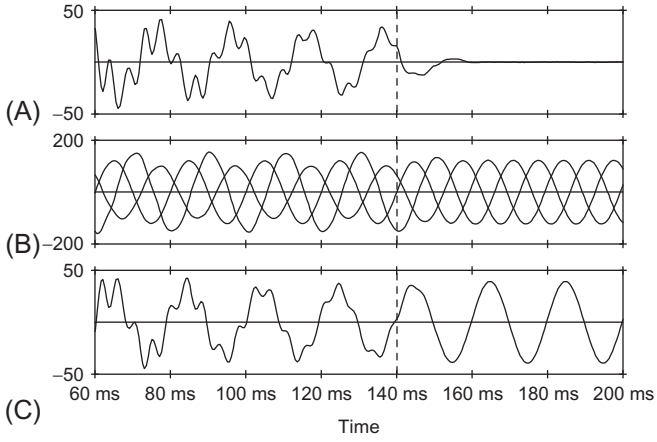

FIG. 41.34 Load voltages and system currents for voltage unbalance and current harmonic compensation, before and after compensation: (A) power system neutral current, (B) phase-to-neutral load voltages, and (C) power system line current.

41.3.3.1 PWM Voltage-Source Inverter

Since series active power filter can compensate voltage unbalance and current harmonics simultaneously, the rated power of the PWM voltage-source inverter increases compared with other approaches that compensate only current harmonics, since voltage injection of arbitrary phase with respect to the load current implies active power transfer from the inverter to the system. Also, the transformer leakage inductance entails fundamental voltage drop and apparent power, which has to be supported by the inverter, reducing the series active filter inverter rating available for harmonic and voltage compensation. The rated apparent power required by the inverter can be obtained by calculating the apparent power generated in

the primary of the coupling transformers. The voltage reflected across the primary winding of each coupling transformer is defined in Eq. (41.43):

$$V_{series} = \left[K_1^2 \left\{ \sum_{k \neq 1} I_{sk}^2 \right\}^{1/2} + K_2^2 \{ V_2 + V_0 \}^2 \right]^{1/2} \tag{41.43}$$

where V_{series} is the root-mean-square voltage across the primary winding of the coupling transformer. Eq. (41.43) shows that the voltage across the primary winding of the transformer is defined by two terms. The first one is inversely proportional to the quality factor of the passive LC filter, while the second one depends on the voltage unbalance that needs to be compensated. K_1 depends on the LC filter values, while K_2 is equal to one. The current flowing through the primary winding of the coupling transformer, due to the harmonic currents (Eq. 41.44), can be obtained from the equivalent circuit shown in Fig. 41.35:

$$I_{sk} = \frac{Z_{fk} I_{lk}}{Z_{fk} + Z_{sk} + K_1} \tag{41.44}$$

where $V_{series} = -K_1 I_{sk}$. The fundamental component of the primary current depends on the amplitude of the negative- and zero-sequence component of the source voltage due to the system unbalance.

41.3.3.2 Coupling Transformer

The purpose of the three coupling transformers is not only to isolate the PWM inverters from the source but also to match the voltage and current ratings of the PWM inverters with those of the power distribution system. The total apparent power required by each coupling transformer is one-third the total apparent power of the inverter. The turn ratio of the current transformer is specified according to the inverter dc bus voltage, K_1 and V_{ref}. The correct value of the turn ratio "a" must be specified according to the overall series active power filter performance. The turn ratio of the coupling transformer must be optimized through the simulation of the overall active power filter, since it depends on the values of different related parameters. In general, the transformer turn ratio must be high in order to reduce the amplitude of the inverter output current and to reduce the voltage induced across the primary winding. Also, the selection of the transformer turn ratio influences the performance of the ripple filter connected at the output of the PWM inverter. Taking into consideration all these factors, in general, the transformer turn ratio is selected equal to 1:20.

41.3.3.3 Secondary Ripple Filter

The design of the ripple filter connected in parallel to the secondary winding of the coupling transformer is performed following the method presented by Akagi in [6]. However, it is important to notice that the design of the secondary ripple filter depends mainly on the coupling transformer turn ratio and the current modulator used to generate the inverter gating signals. If the triangular carrier is used, the frequency of the triangular waveform has to be considered in the design of the ripple filter. The ripple filter connected at the output of the inverter avoids the induction of the high-frequency ripple voltage generated by the PWM inverter switching pattern at the terminals of the primary winding of the coupling transformer. In this way, the voltage applied in series to the power system corresponds to the components required to compensate voltage unbalanced and current harmonics. The single-phase equivalent circuit is shown in Fig. 41.36.

The voltage reflected in the primary winding of the coupling transformer has the same waveform as that of the voltage across the filter capacitor. For low-frequency components, the inverter output voltage must be almost equal to the voltage across C_{fr}. However, for high-frequency components, most of the inverter output voltage must drop across L_{fr}, in which case the voltage at the capacitor terminals is almost zero. Moreover, C_{fr} and L_{fr} must be selected in order not to exceed the burden of the coupling transformer. The ripple filter must be designed for the carrier frequency of the PWM voltage-source inverter. To calculate C_{fr} and L_{fr}, the system equivalent impedance at the carrier frequency, Z_{sys}, reflected in the secondary must be known. This impedance is equal to

$$Z_{sys(secondary)} = a^2 \cdot Z_{sys(primary)} \tag{41.45}$$

For the carrier frequency, the following design criteria must be satisfied:

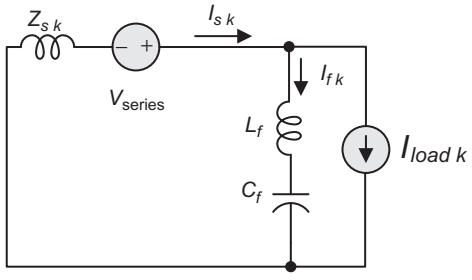

FIG. 41.35 The equivalent circuit of the series active power filter for harmonic components.

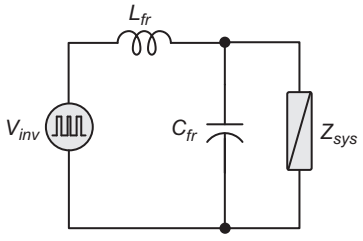

FIG. 41.36 The single-phase equivalent circuit of the inverter output ripple filter.

(i) $X_{Cfr} \ll X_{Lfr}$ to ensure that at the carrier frequency most of the inverter output voltage will drop across L_{fr}

(ii) X_{Cfr} and $X_{Lfr} \ll Z_{sys}$ to ensure that the voltage divider is between L_{fr} and C_{fr}

The small-rated LC passive filter exhibits a high-quality-factor circuit because of the high impedance on the output side. Oscillation between the small-rated inductor and capacitor may occur, causing undesirable high-frequency voltage across the ripple filter capacitor, which is reflected in the primary winding of the coupling transformer generating high-frequency current to flow through the power distribution system. It is important to note that this oscillation is very difficult to eliminate through the design and selection of the L_{fr} and C_{fr} values. However, it can be eliminated with the addition of a new control loop. The cause of the output voltage oscillation is explained with the help of Fig. 41.37. The transfer function $G_p(s)$ between the input voltage $V_i(s)$ and the output voltage $V_C(s)$ is given by the following equation:

$$G_p(s) = \frac{\omega_n^2}{s^2 + 2\xi\omega_n s + \omega_n^2} \tag{41.46}$$

where $\omega_n = \sqrt{1/L_{fr}C_{fr}}$ and $\xi = r_L/2\sqrt{C_{fr}/L_{fr}}$.

Normally, the damping factor ξ is smaller than one, causing the voltage oscillation across the capacitor ripple filter, C_{fr}. Generally, relatively low impedance loads are connected to the output terminals of voltage-source PWM inverters. In these cases, the quality factor of the LC filter can be low, and the oscillation between the inductor L_{fr} and the capacitor C_{fr} is avoided [7].

41.3.3.4 Passive Filters

Passive filters connected between the nonlinear load and the series active power filter play an important role in the compensation of the load current harmonics. With the connection of the passive filters, the series active power filter operates as a harmonic isolator. The harmonic isolation feature reduces the need for precise tuning of the passive filters and allows their design to be insensitive to the system impedance and eliminates the possibility of filter overloading due to supply voltage harmonics. The passive filter can be tuned to the dominant load current harmonic and can be designed to correct the load displacement power factor.

However, for industrial loads connected to stiff supply, it is difficult to design passive filters that can absorb a significant part of the load harmonic current, and therefore, its effectiveness deteriorates. Specially, for compensation of diode rectifier type of loads, where a small kilovolt-ampere passive filter is required, it is difficult to achieve the required tuning to absorb significant percentage of the load harmonic currents. For this type of application, the passive filter cannot be tuned exactly to the harmonic frequencies because they can be overloaded due to the system voltage distortion and/or system current harmonics.

The single-phase equivalent circuit of a passive LC filter connected in parallel to a nonlinear current source and to the power distribution system is shown in Fig. 41.38. From this figure, the design procedure of this filter can be derived. The harmonic current component flowing through the passive filter i_{fh} and the current component flowing through the source i_{sh} are given by the following expressions:

$$i_{fh} = \frac{Z_s}{Z_s + Z_f} i_h; \quad i_{sh} = \frac{Z_f}{Z_s + Z_f} i_h \tag{41.47}$$

At the resonant frequency, the inductive reactance of the passive filter is equal to the capacitive reactance of the filter, that is,

$$2\pi frL = \frac{1}{2\pi frC} \tag{41.48}$$

Therefore, the resonant frequency of the passive filter is equal to

$$fr = \frac{1}{2\pi\sqrt{LC}} \tag{41.49}$$

The passive filter bandwidth is defined by the upper and lower cutoff frequency, at which values the filter current gain is −3 dB, as shown in Fig. 41.39.

The magnitude of the passive filter impedance as a function of the frequency is shown in Fig. 41.40.

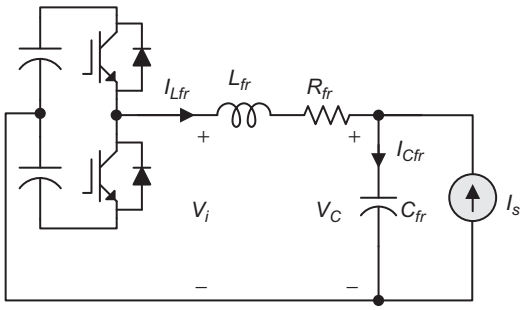

FIG. 41.37 Single-phase equivalent circuit of series active power filter connected to the ripple filter.

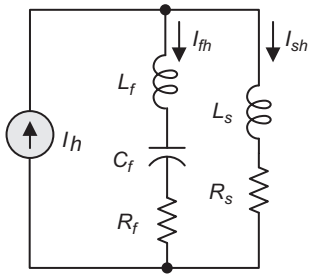

FIG. 41.38 The single-phase equivalent circuit of the passive filter connected to a nonlinear load.

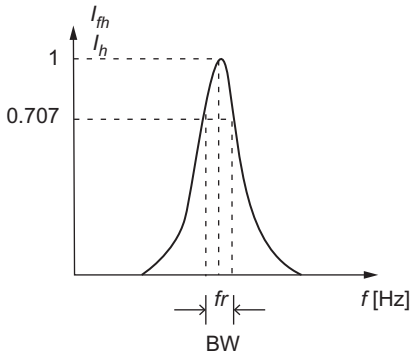

FIG. 41.39 The passive filter bandwidth.

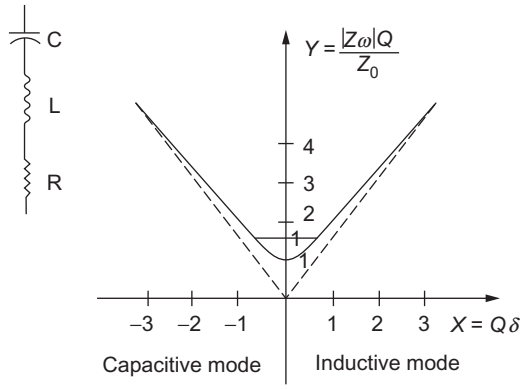

FIG. 41.40 The frequency response of the passive LC filter.

At the resonant frequency, the passive filter magnitude is equal to the resistance. If the resistance is zero, the filter is in short circuit. The quality factor of the passive filter is defined by the following expression:

$$Q = \frac{\omega_n L}{R} \tag{41.50}$$

It is important to note that the operation of the series active power filter with off-tuned passive filter has an adverse impact on the inverter power rating compared with the normal case. The more off-tuned the passive filter, the more rated apparent power is required by the series active power filter.

41.3.3.5 Protection Requirements

Short circuits in the power distribution system generate large currents that flow through the power lines until the circuit breaker operates clearing the fault. The total clearing time of a short circuit depends on the time delay imposed by the protection system. The clearing time cannot be instantaneous due to the operating time imposed by the overcurrent relay and by the total interruption time of the power circuit breaker. Although power system equipment, such us power transformers and cables, are designed to withstand short-circuit currents during at least 30 cycles, the active power filter may suffer severe damage during this short time. The withstand capability of the series active power filter depends mainly on the inverter power semiconductor characteristics.

Since the most important feature of series active power filters is the small-rated power required to compensate the power system, typically 10%–15% of the load rated apparent power, the inverter semiconductors are rated for low values of blocking voltages and continuous currents. This makes series active power filters more vulnerable to power system faults.

The block diagram of the protection scheme described in this section is shown in Fig. 41.41. It consists of a varistor connected in parallel to the secondary winding of each coupling transformer and a couple of antiparallel thyristors [8]. A special circuit detects the current flowing through the varistors and generates the gating signals of the antiparallel thyristors. The protection circuit of the series active power filter must protect only the PWM voltage-source inverter connected to the secondary of the coupling transformers and must not interfere with the protection scheme of the power distribution system. Since the primary of the active power filter coupling transformers is connected in series to the power distribution system, they operate as current transformers, so that their secondary windings cannot operate in open circuit. For this reason, if a short circuit is detected in the power distribution system, the PWM voltage-source inverter cannot be disconnected from the secondary of the current transformer. Therefore, the protection scheme must be able to limit the amplitude of the currents and voltages generated in the secondary circuits. This task is performed by the varistors and by the magnetic saturation characteristic of the transformers.

The main advantages of the series active power filter protection scheme described in this section are the following:

(i) It is easy to implement and has a reduced cost.
(ii) It offers full protection against power distribution short-circuit currents.
(iii) It does not interfere with the power distribution system.

When short-circuit currents circulate through the power distribution system, the low saturation characteristic of the

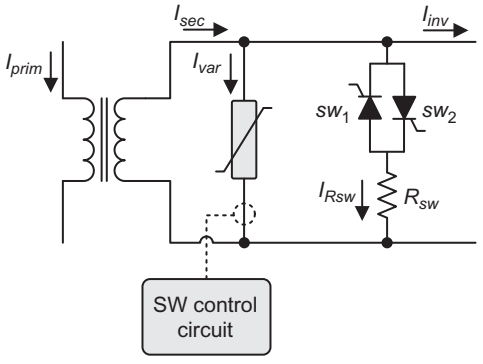

FIG. 41.41 The series active power filter protection scheme.

transformers increases the current ratio error and reduces the amplitude of the secondary currents. The larger secondary voltages induced by the primary short-circuit currents are clamped by the varistors, reducing the amplitude of the PWM voltage-source inverter currents. After a few cycles of duration of the short circuit, the PWM voltage-source inverter is bypassed through a couple of antiparallel thyristors, and at the same time, the gating signals applied to the PWM voltage-source inverter are removed. In this way, the PWM voltage-source inverter can be turned off. The principles of operation and the effectiveness of the protection scheme are shown in Fig. 41.42.

The secondary short-circuit currents will circulate through the antiparallel thyristors and the varistors until the fault is cleared by the protection equipment of the power distribution system.

By using the protection scheme described in this subsection, the voltage and currents reflected in the secondary of the coupling transformers are significantly reduced. When short-circuit currents circulate through the power distribution system, the low saturation characteristic of the coupling transformers increases the current ratio error and reduces the amplitude of the secondary voltages and currents. Moreover, the saturated high secondary voltages induced by the primary short-circuit currents are clamped by the varistors, reducing the amplitude of the PWM voltage-source inverter ac currents. Once the secondary current exceeds a predefined reference value, the PWM voltage-source inverter is bypassed through a couple of antiparallel thyristors, and then, the gating signals applied to the PWM voltage-source inverter are removed. The effectiveness of the protection scheme is shown in Fig. 41.43.

By increasing the current ratio error due to the magnetic saturation, the energy dissipated in the secondary of the coupling transformer is significantly reduced. The total energy dissipated in the varistor for the different protection conditions is shown in Fig. 41.44.

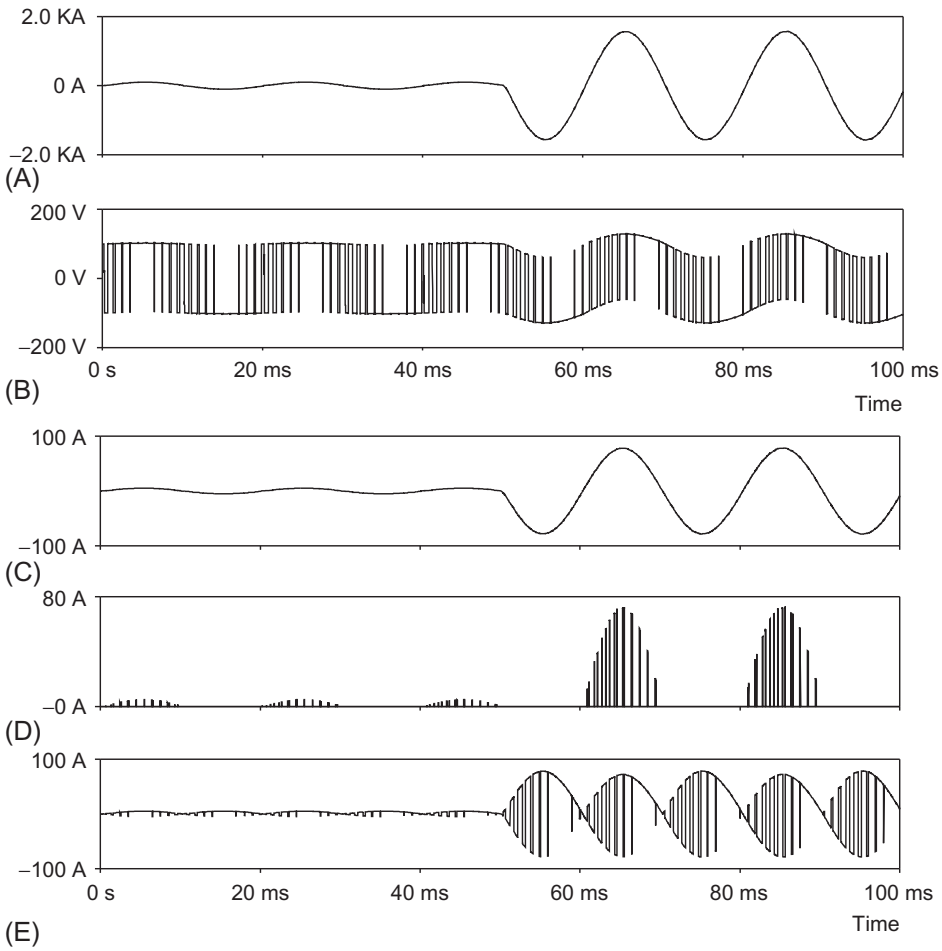

FIG. 41.42 Current waveforms of the series active power filter during a three-phase short circuit in the power distribution system set at 50 ms: (A) power distribution system line current, (B) current transformer secondary voltage, (C) inverter ac current, (D) current through an inverter leg, and (E) inverter dc bus current.

41.3.4 Control Issues

The block diagram of a series active power filter control scheme that compensates current harmonics and voltage unbalance simultaneously is shown in Fig. 41.45.

Current and voltage reference waveforms are obtained by using the Park transformation (instantaneous reactive power theory) voltage unbalance that is compensated by calculating the negative- and zero-sequence fundamental components of the system voltages. These voltage components are added to the source voltages through the coupling transformers compensating the voltage unbalance at the load terminals. In order to reduce the amplitude of the current flowing through the neutral conductor, the zero-sequence components of the line currents are calculated. In this way, it is not necessary to sense the current flowing through the neutral conductor.

41.3.4.1 Reference Signals Generator

The compensation characteristics of series active power filters are defined mainly by the algorithm used to generate the reference signals required by the control system. These reference signals must allow current and voltage compensation with minimum time delay. Also, it is important that the accuracy of the information contained in the reference signals allows the elimination of the current harmonics and voltage unbalance present in the power system. Since the voltage and current control schemes are independent, the equations used to calculate the voltage reference signals are the following:

$$\begin{bmatrix} v_{a0} \\ v_{a1} \\ v_{a2} \end{bmatrix} = \frac{1}{\sqrt{3}} \begin{bmatrix} 1 & 1 & 1 \\ 1 & a & a^2 \\ 1 & a^2 & a \end{bmatrix} . \begin{bmatrix} v_a \\ v_b \\ v_c \end{bmatrix} \tag{41.51}$$

The voltages v_a, v_b, and v_c correspond to the power system phase-to-neutral voltages before the current transformer. The reference voltage signals are obtained by making the positive-sequence component, v_{a1}, zero and then applying

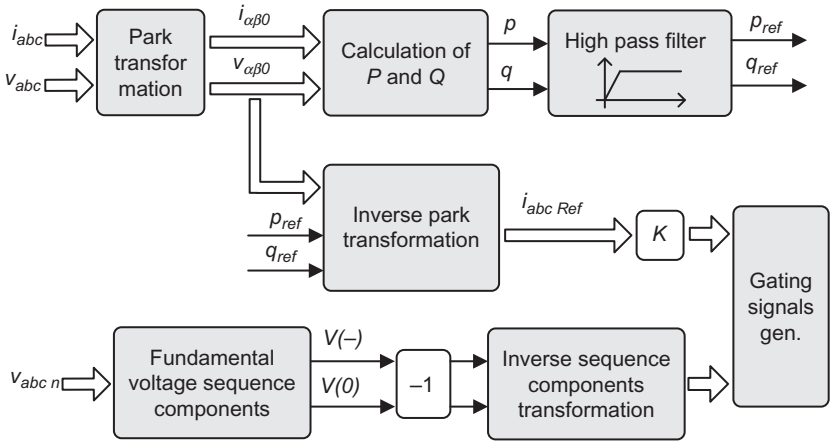

FIG. 41.45 Compensation scheme for voltage unbalance correction.

the inverse of the Fortescue transformation. In this way, the series active power filter compensates only voltage unbalance and not voltage regulation. The reference signals for the voltage unbalance control scheme are obtained by applying the following equations:

$$\begin{bmatrix} v_{refa} \\ v_{refb} \\ v_{refc} \end{bmatrix} = \frac{1}{\sqrt{3}} \begin{bmatrix} 1 & 1 & 1 \\ 1 & a^2 & a \\ 1 & a & a^2 \end{bmatrix} \cdot \begin{bmatrix} -v_{ao} \\ 0 \\ -v_{a2} \end{bmatrix} \tag{41.52}$$

In order to compensate current harmonics generated by the nonlinear loads, the following equations are used:

$$\begin{bmatrix} i_{aref} \\ i_{bref} \\ i_{cref} \end{bmatrix} = \sqrt{\frac{2}{3}} \cdot \begin{bmatrix} 1 & 0 \\ \frac{-1}{2} & \frac{\sqrt{3}}{2} \\ \frac{-1}{2} & \frac{-\sqrt{3}}{2} \end{bmatrix} \cdot \begin{bmatrix} v_\alpha & v_\beta \\ -v_\beta & v_\alpha \end{bmatrix}^{-1} \begin{bmatrix} p_{ref} \\ q_{ref} \end{bmatrix} + \frac{1}{\sqrt{3}} \begin{bmatrix} i_0 \\ i_0 \\ i_0 \end{bmatrix} \tag{41.53}$$

where i_0 is the fundamental zero-sequence component of the line current and is calculated using the Fortescue transformation Eq. (41.50):

$$i_0 = \frac{1}{\sqrt{3}}(i_a + i_b + i_c) \tag{41.54}$$

In Eq. (41.40), p_{ref}, q_{ref}, v_α, and v_β are defined according to the instantaneous reactive power theory. In order to avoid the compensation of the zero-sequence fundamental frequency current, the reference signal i_0 must be forced to circulate through a high-pass filter generating a current i_0' that is used to create the reference signal required to compensate current harmonics. Finally, the general equation that defines the references of the PWM voltage-source inverter required to compensate voltage unbalance and current harmonics is the following:

$$\begin{bmatrix} V_{refa} \\ V_{refb} \\ V_{refc} \end{bmatrix} = K_1 \left\{ \sqrt{\frac{2}{3}} \begin{bmatrix} 1 & 0 \\ \frac{-1}{2} & \frac{\sqrt{3}}{2} \\ \frac{-1}{2} & \frac{-\sqrt{3}}{2} \end{bmatrix} \cdot \begin{bmatrix} v_\alpha & v_\beta \\ -v_\beta & v_\alpha \end{bmatrix}^{-1} \begin{bmatrix} P_{ref} \\ q_{ref} \end{bmatrix} + \frac{1}{\sqrt{3}} \begin{bmatrix} i_0' \\ i_0' \\ i_0' \end{bmatrix} \right\} + K_2 \left\{ \frac{1}{\sqrt{3}} \begin{bmatrix} 1 & 1 & 1 \\ 1 & a^2 & a \\ 1 & a & a^2 \end{bmatrix} \cdot \begin{bmatrix} -v_{a0} \\ 0 \\ -v_{a2} \end{bmatrix} \right\} \tag{41.55}$$

where K_1 is the gain of the coupling transformer that defines the magnitude of the impedance for high-frequency current components and K_2 defines the degree of compensation for voltage unbalance, ideally K_2 equals 1.

41.3.4.2 Gating Signals Generator

This circuit provides the gating signals of the three-phase PWM voltage-source inverter required to compensate voltage unbalance and current harmonic components. The current and voltage reference signals are added, and then, the amplitude of the resultant reference waveform is adjusted in order to increase the voltage utilization factor of the PWM inverter for steady-state operating conditions. The gating signals of the inverter are generated by comparing the resultant reference signal with a fixed-frequency triangular waveform. The triangular waveform helps to keep the inverter switching frequency constant (Fig. 41.46).

A higher voltage utilization of the inverter is obtained if the amplitude of the resultant reference signal is adjusted for the steady-state operating condition of the series active power filter. In this case, the reference current and reference voltage waveforms are smaller. If the amplitude is adjusted for transient operating conditions, the required reference signals will have a

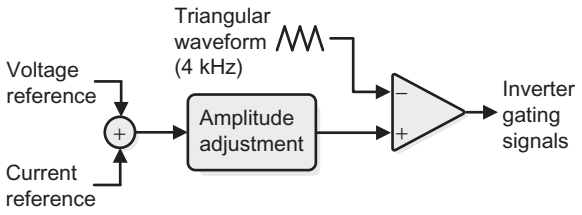

FIG. 41.46 The block diagram of the gating signal generator.

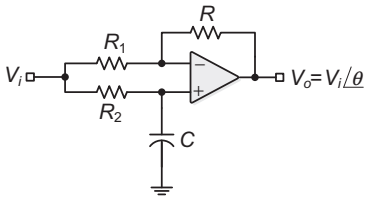

FIG. 41.48 The all-pass filter used as a phase shifter.

larger value, creating a higher dc voltage in the inverter and defining a lower voltage utilization factor for steady-state operating conditions. The inverter switching frequency must be higher in order not to interfere with the current harmonics that need to be compensated.

41.3.5 Control Circuit Implementation

Since the control scheme of the series active power filter must translate the current harmonic components that need to be compensated in voltage signals, a proportional controller is used. The use of a PI controller is not recommended since it would modify the reference waveform and generate new current harmonic components. The gain for proportional controller depends on the load characteristics, and its value fluctuates between one and two.

Another important element used in the control scheme is the filter that allows to generate p_{ref} and q_{ref} (Fig. 41.35). The frequency response of this filter is very important and must not introduce any phase shift or attenuation to the low-frequency harmonic components that must be compensated. A high-pass first-order filter tuned at 15 Hz is adequate. This corner frequency is required when single-phase nonlinear loads are compensated. In this case, the dominant current harmonic is the third. An example of the filter that can be used is shown in Fig. 41.47.

The operator "a" required to calculate the sequence components of the system voltages (Fortescue transformation) can be obtained with the all-pass filter shown in Fig. 41.48.

The phase shift between V_o and V_i is given by the following expression:

$$\theta = 2\arctan\left(2\pi f R_2 C\right) \tag{41.56}$$

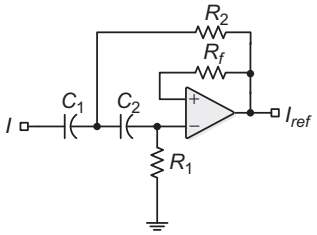

FIG. 41.47 The first-order high-pass filter implemented for the calculation of p_{ref} and q_{ref} ($C_1 = C_2 = 0.1\,\mu F$, $R_1 = R_f = 150\,k\Omega$, and $R_2 = 50\,k\Omega$).

Since the phase shift is negative, the operator "a" is obtained by using an inverter (180 degrees) and then by tuning $\theta = -60$ degrees. The operator "a^2" is obtained by phase shifting V_i by -120 degrees. V_i is synchronized with the system phase-to-neutral voltage V_{an}.

41.3.6 Experimental Results

The viability and effectiveness of series active power filters used to compensate current harmonics was proved in an experimental setup of 5 kVA. Current waveforms generated by a nonlinear load and using only passive filters and the combination of passive and the series active power filter are shown in Figs. 41.49 and 41.50.

These figures show the effectiveness of the series active power filter, which reduces the overall *THD* of the current that flows through the power system from 28.9% (with the operation of only the passive filters) to 9% with the operation of the passive filters with the active power filter connected in series. The compensation of the current that flows through the neutral conductor is shown in Fig. 41.51.

41.4 Hybrid Active Power Filters

Hybrid topologies composed of passive LC filters connected in series to an active power filter have already been proposed by the end of the 1980s [2,5,6,9,10]. Hybrid topology improves significantly the compensation characteristics of simple passive filters, making the use of active power filter available for high-power applications, at a relatively lower cost. Moreover, the compensation characteristics of already installed passive filters can be significantly improved by connecting a series active power filter at its terminals, giving more flexibility to the compensation scheme. Most of the technical disadvantages of passive filters described before can be effectively attenuate if an active power filter is connected in series to the passive approach as shown in Fig. 41.52.

The hybrid active power filter topology is shown in Fig. 41.52. The active power filter is implemented with a three-phase PWM voltage-source inverter operating at fixed switching frequency and connected in series to the passive filter through a coupling transformer. Basically, the active power filter forces the utility line currents to become sinusoidal and in

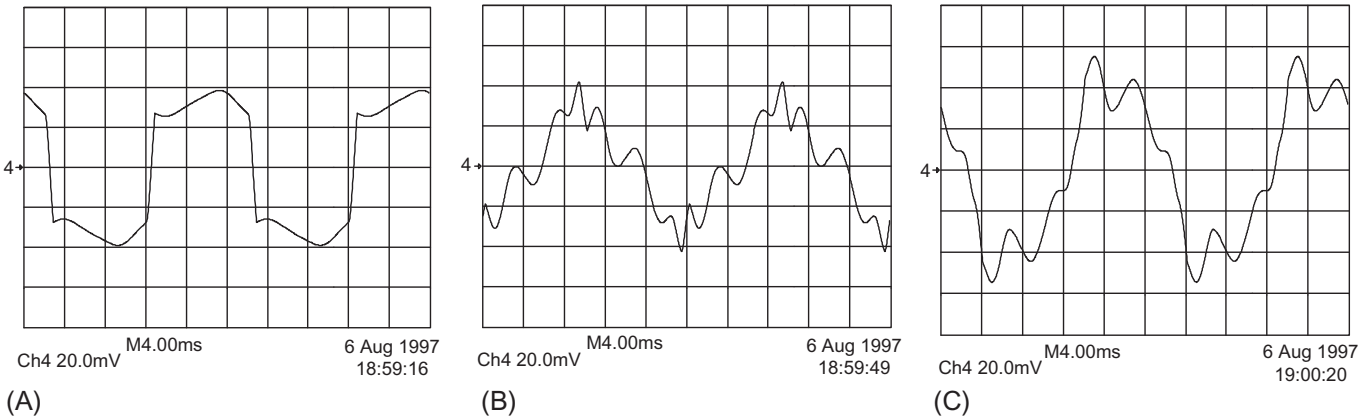

FIG. 41.49 Experimental results without the operation of the series active power filter: (A) load current, (B) current flowing through the passive filter, and (C) current through the power supply.

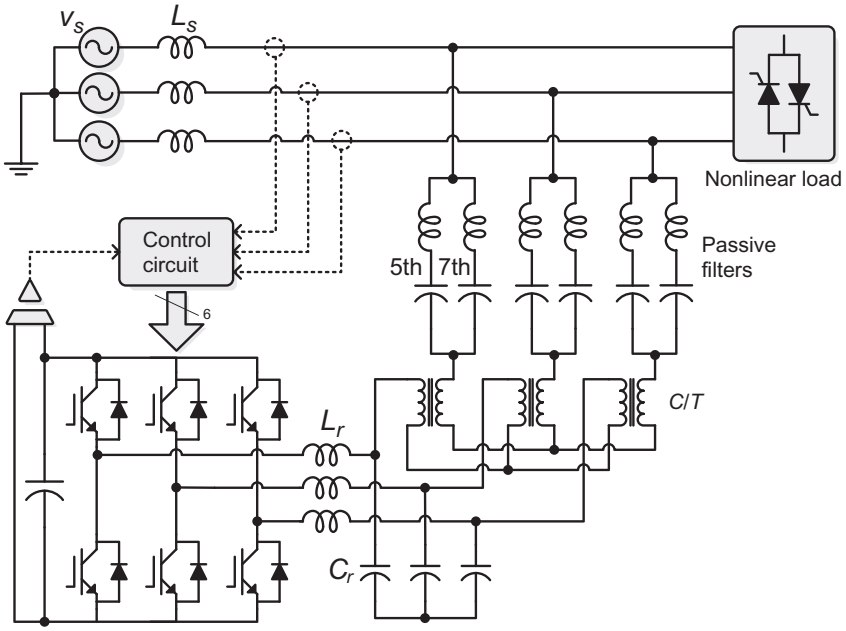

FIG. 41.52 The hybrid active power filter configuration.

phase with the respective phase-to-neutral voltage, improving the compensation characteristics of the passive filter.

41.4.1 Principles of Operation

Since the active power filter is connected in series to the passive filter through a coupling transformer, it imposes a voltage signal at its primary terminals that forces the circulation of current harmonics through the passive filter, improving its compensation characteristics, independently of the variations in the selected resonant frequency of the passive filter. The block diagram of the proposed control scheme shown in Fig. 41.53 consists of three modules: the dc voltage control, the voltage reference generator, and the inverter gating signal generator.

The voltage reference waveform required by the inverter control scheme is obtained by adjusting the amplitude of a

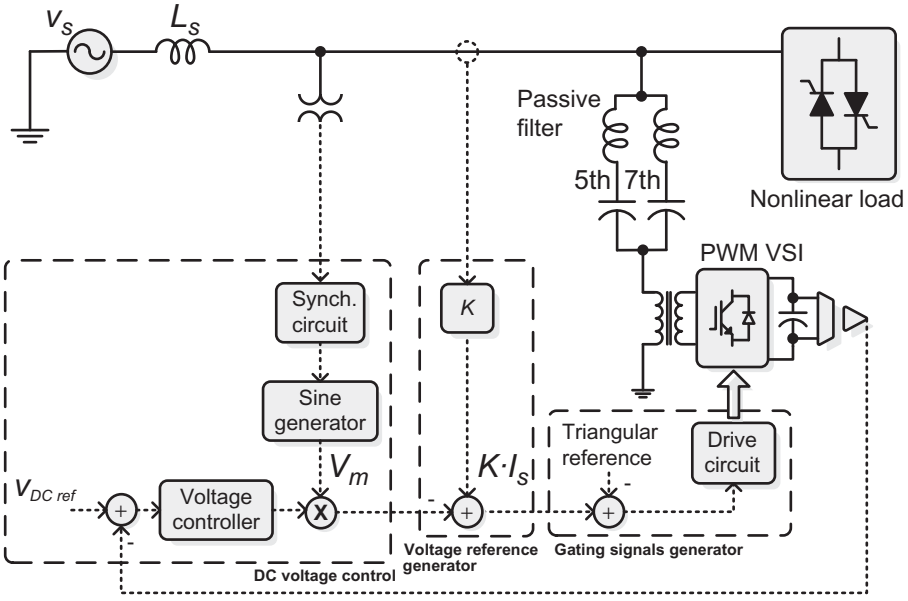

FIG. 41.53 The hybrid active power filter topology and associated control scheme.

sinusoidal reference waveform in phase with the respective phase-to-neutral voltage and then subtracting the respective ac line current (Fig. 41.53). The sinusoidal reference signal can be obtained from the voltage system (in case of low voltage distortion), or it can be generated from an EPROM synchronized with the respective phase-to-neutral voltage. The amplitude of this reference waveform controls the inverter dc voltage and the ac mains displacement power factor. The inverter dc voltage varies according with the amount of real power absorbed by the inverter, while the ac mains power factor depends on the amount of reactive power generated by the hybrid filter, which can be controlled by changing the amplitude of the fundamental component of the inverter output voltage.

The principles of operation for current harmonic and power factor compensation are explained with the help of the single-phase equivalent circuit shown in Fig. 41.54. In the current harmonic compensation mode, the active filter improves the filtering characteristic of the passive filter by imposing a voltage harmonic waveform at its terminals with an amplitude value equals to

$$V_{Ch} = K \cdot I_{Sh} \tag{41.57}$$

where I_{Sh} is the harmonic content of the line current to be compensated and K is the active power filter gain. If the ac mains voltage is purely sinusoidal, the ratio between the harmonic component of the nonlinear load current and the harmonic component of the ac line current (attenuation factor) is obtained from Fig. 41.54A and is equal to

$$\frac{I_{Sh}}{I_{Lh}} = \frac{Z_F}{K + Z_F + Z_S} \tag{41.58}$$

Eq. (41.58) shows that the filtering characteristics of the hybrid topology (I_{Sh}/I_{Lh}) depend on the value of the passive filter equivalent impedance, Z_F. Moreover, since the tuned factor, δ, and the quality factor, Q, can modify the filter bandwidth and the passive filter harmonic equivalent impedance (Fig. 41.55), their values must be carefully selected in order to maintain the compensation effectiveness of the hybrid topology. In particular, a high value of the quality factor, Q, defines a large bandwidth of the passive filter, improving the compensation characteristics of the hybrid topology. On the other hand, a low value in the quality factor and/or a large value in the tuned factor increases the required voltage generated by the active power filter necessary to keep the same compensation effectiveness, which increases the active power filter rated power.

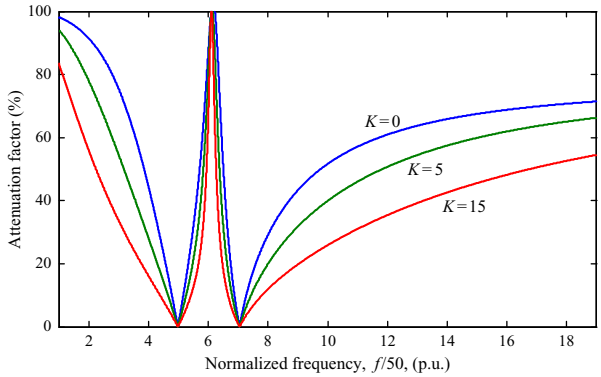

FIG. 41.55 The attenuation factor of the line current harmonics for different frequency values.

Fig. 41.55 shows how the active power filter gain, K, in Eq. (41.57) affects the harmonic attenuation factor of the line currents. The attenuation factor of the line current harmonics expressed in percentage is obtained from Eq. (41.59) and is shown in Fig. 41.56, for a power distribution system with two passive filters tuned at fifth and seventh harmonics.

$$THD_i = \frac{\sqrt{\sum_{h=2} [I_{Lh} \cdot (Z_F/(Z_S + Z_F + K))]^2}}{I_{S1}} \tag{41.59}$$

Eq. (41.59) indicates that the total harmonic distortion of the line current decreases if K increases. In other words, a better hybrid filter compensation is obtained for larger values of voltage harmonic components generated by the active power filter. Also, it is shown that the compensation capability of the hybrid

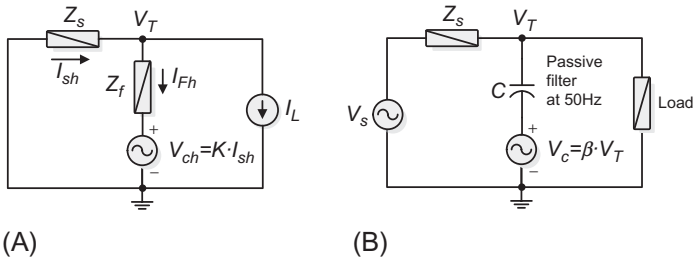

FIG. 41.54 Single-phase equivalent circuits of the hybrid active power filter scheme: (A) for current harmonic compensation and (B) for displacement power factor compensation.

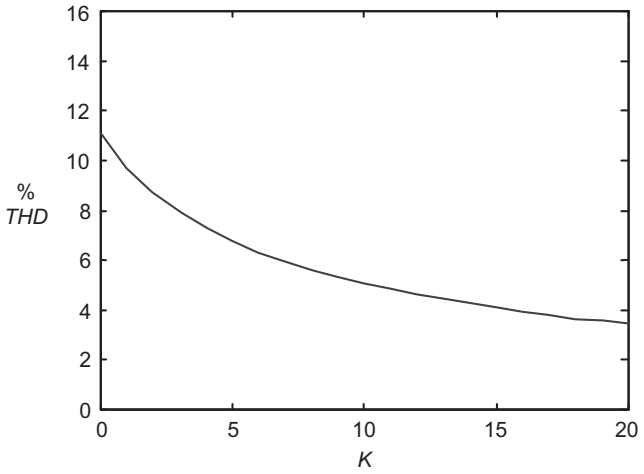

FIG. 41.56 System line current *THD* vs *K* factor.

filter depends on the compensation characteristic of the passive filter, that is, the filter impedance value and tuned frequency will affect the active filter rated power required to satisfy the system line current compensation requirements.

Displacement power factor correction can be achieved by controlling the voltage drop across the passive filter capacitor. In order to do that, a voltage at fundamental frequency is generated at the inverter ac terminals, with an amplitude equals to

$$V_C = \beta \cdot V_T \tag{41.60}$$

Displacement power factor control can be achieved since at fundamental frequency the passive filter equivalent impedance is capacitive. The reactive power generated by the passive filter is obtained by changing the voltage imposed by the active power filter across the passive filter capacitor terminals. The passive filter fundamental current component is defined by the following expression:

$$i_F = C\frac{d}{dt}(v_T - \beta v_T) = (1-\beta)C\frac{dv_T}{dt} = C_\gamma \beta \frac{dv_T}{dt} \tag{41.61}$$

Eq. (41.61) proves that the equivalent capacitance at fundamental frequency $C\gamma$ can be modified by changing β. The reactive power generated by the active filter is β times the reactive power generated by the passive filter and can be defined by

$$Q_\gamma = V_C \cdot I_F = \beta V_T I_F \tag{41.62}$$

Eq. (41.62) shows that if $\beta > 0$, the active power filter generates a voltage at fundamental frequency in phase with V_T, reducing the reactive power that flows to the load. If $\beta < 0$, the active power filter generates a voltage at fundamental frequency phase shifted by 180 degrees with respect to V_T, increasing the reactive power that flows to the load. In other words, by selecting a β positive or negative, the hybrid topology can generate or absorb reactive power at fundamental frequency, compensating for leading or lagging displacement power factor of the nonlinear load. This is achieved by changing the voltage across the passive filter capacitor C_F.

41.4.2 The Hybrid Filter Compensation Performance

The design characteristics of the passive filters have an important influence on the compensation performance of the hybrid topology. The tuned frequency and quality factor of the passive filter directly influence the compensation characteristics of the hybrid topology. If these two factors are not properly selected, the rated power of the active filter must be increased in order to get the required compensation performance. The tuned factor, δ, in per unit with respect to the resonant frequency is defined by Eq. (41.63):

$$\delta = \frac{\omega - \omega_n}{\omega_n} \tag{41.63}$$

Here, δ defines the magnitude in which the passive filter resonant frequency changes due to the variations in the power system frequency and modifications in the values of the passive filter parameters L and C. The values of L and C can change due to aging conditions, temperature, or design tolerances. The tuning factor, δ, can also be defined as

$$\delta = \frac{\Delta f}{f_n} + \frac{1}{2}\left(\frac{\Delta L}{L_n} + \frac{\Delta C}{C_n}\right) \tag{41.64}$$

The quality factor, Q, of the passive filter is defined by Eq. (41.65):

$$Q = \frac{X_0}{R} \tag{41.65}$$

where X_0 is equal to

$$X_0 = \omega_n L = \frac{1}{\omega_n C} = \sqrt{\frac{L}{C}} \tag{41.66}$$

The passive filter quality factor, Q, defines the ratio between the passive filter reactance with respect to its resistance. In order to have a passive filter low impedance value in a limited frequency bandwidth, defined by the maximum expected changes of the rated power system frequency, it is necessary to reduce X_0 or increase the passive filter resistance R, reducing the value of Q. However, if R increases, the equivalent impedance of the passive filter at the resonant frequency will increase, with the associated power losses, increasing the overall passive filter operational cost. On the other hand, the larger the value of Q, the lower is the passive filter equivalent impedance at the resonant frequency, increasing the currents harmonic components across the filter, at the resonant operating point.

41.4.2.1 Effects of the Power System Equivalent Impedance

The influence of the power system equivalent impedance on the hybrid filter compensation performance is related with its effects on the passive filter, since if the system equivalent impedance is lower than the passive filter equivalent impedance at the resonant frequency, most of the load current harmonics will flow mainly to the power distribution system. In order to compensate this negative effect on the hybrid filter compensation performance, K must be increased, as shown in Eq. (41.57), increasing the active power filter rated power.

Fig. 41.57 shows how the system equivalent impedance affects the relation between the system current *THD* with the active filter gain, K, in a power distribution system with passive filters tuned at the fifth and seventh harmonics. If Z_s decreases, the current system *THD* increases, so in order to keep the same compensation performance of the hybrid scheme, the active power filter gain, K, must be increased. On the other hand, if Z_s is high, it is not necessary to increase K in order to ensure a low *THD* value in the system current.

41.4.2.2 Effects of the Passive Filter Quality Factor

The quality factor, Q, defines the passive filter bandwidth. A passive filter with a high quality factor, Q, presents a larger bandwidth and better compensation characteristics. Eq. (41.67) defines the quality factor value in terms of the passive filter parameters L, R, and C. This equation shows that if R or C decreases, Q increases, and the filter bandwith becomes larger, improving the hybrid scheme compensation characteristics:

$$Q = \frac{1}{R}\sqrt{\frac{L}{C}} \tag{41.67}$$

Although by decreasing R or C the passive filter quality factor is improved, each element produces a different effect in the hybrid filtering behavior. For example, by increasing R, the filter equivalent impedance at the resonant frequency becomes bigger, affecting the current harmonic compensation characteristics at this specific frequency.

Fig. 41.58 illustrates how the system current *THD* changes with different values of C while keeping the filter tuned factor, δ, constant. It is important to note that the larger the value of C, the better is the compensation characteristic of the hybrid scheme. An appropriate value of C must be selected, since C cannot be increased too much. If C is too big, the fundamental component of the filter current will increase, overloading the hybrid filter and generating a large amount of reactive power to the power distribution system. A similar analysis is made for the value of the resistance, showing the results in Fig. 41.59.

41.4.2.3 Effects of the Passive Filter Tuned Factor

The tuned factor, δ, is defined in Eq. (41.63). This factor affects the hybrid scheme performance especially at the passive filter

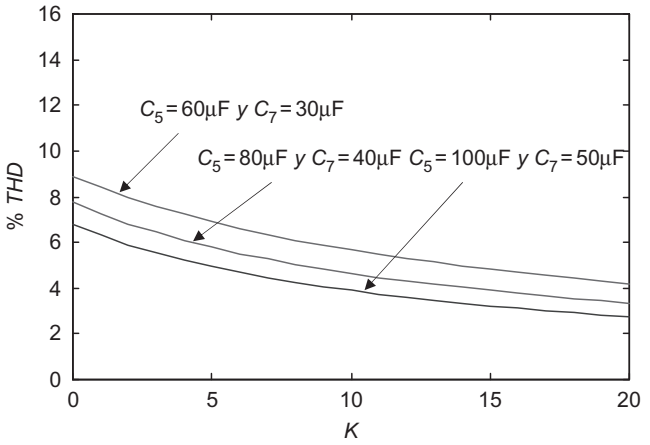

FIG. 41.58 *THD* of the system line current vs the K factor for different values of filter capacitor.

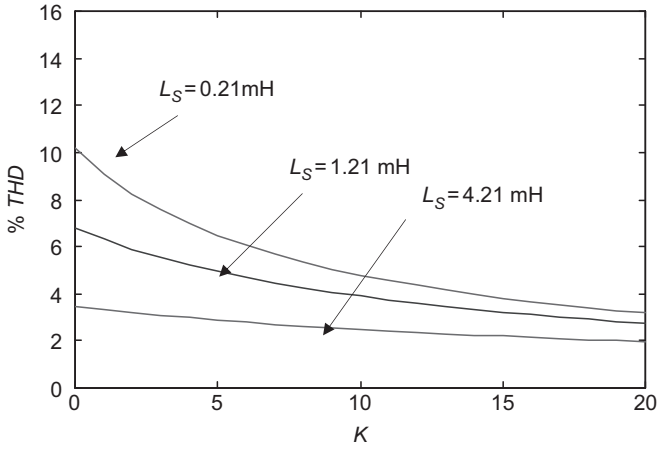

FIG. 41.57 Relation between the *THD* of the line current vs the active power filter gain, K, for different values of the system equivalent impedance.

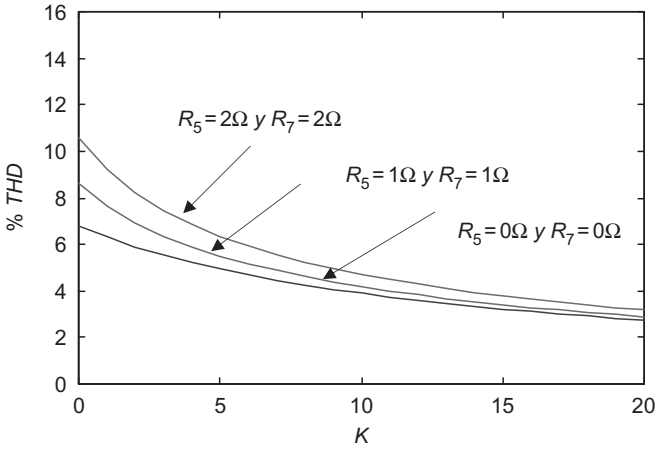

FIG. 41.59 *THD* of the system line current vs the K factor for different values of filter resistor.

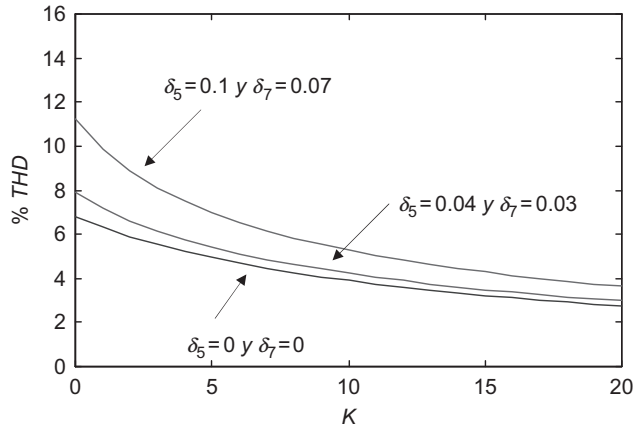

FIG. 41.60 *THD* of the system line current vs the *K* factor for different values of tuned factor.

resonant frequency, since δ defines the changes in the system frequency, affecting the value of the passive filter resonant frequency. Fig. 41.60 shows how the system current *THD* changes with respect to the active power filter gain, *K*, for different values of passive filter tuned factors. The larger the value of δ, the filtering performance of the hybrid filter becomes worst.

41.4.3 Experimental Results

A laboratory prototype using IGBT switches was implemented and tested in the compensation of a six-pulse controlled rectifier. The inverter was operated at 4 kHz switching frequency. Steady-state experimental results are illustrated in Figs. 41.61 and 41.62.

In case resonance is generated between the passive filter and system equivalent reactance, the system current *THD* increases to 60%. By connecting the active power filter, the line current *THD* is reduced to 4.9%, as shown in Figs. 41.63 and 41.64.

41.5 Predictive Control in Active Power Filters

Traditionally, active power filters have been controlled using pretuned controllers, such as PI-type or adaptive, for the current and for the dc voltage loops. PI controllers must be designed based on the equivalent linear model, while predictive controllers use the nonlinear model, which is closer to real operating conditions. Providing an accurate model is used, a predictive controller improves the performance of the active power filter, especially during transient operating conditions, because it can quickly follow the current reference signal while maintaining a constant dc voltage.

Fig. 41.65 shows the equivalent circuit of a shunt APF application. One advantage of using model-based predictive control in active power filter applications is that the power converter model and parameter are well-known or can be easily determined. These parameters are obtained from the converter output ripple filter (Z_f) and the power system equivalent impedance (Z_s). The former is known from the design stage of the active power filter, and the latter can be determined using well-known standard procedures of calculation or online estimation.

41.5.1 Predictive Current Control

The block diagram of the proposed digital predictive current control scheme is shown in Fig. 41.66. This control scheme

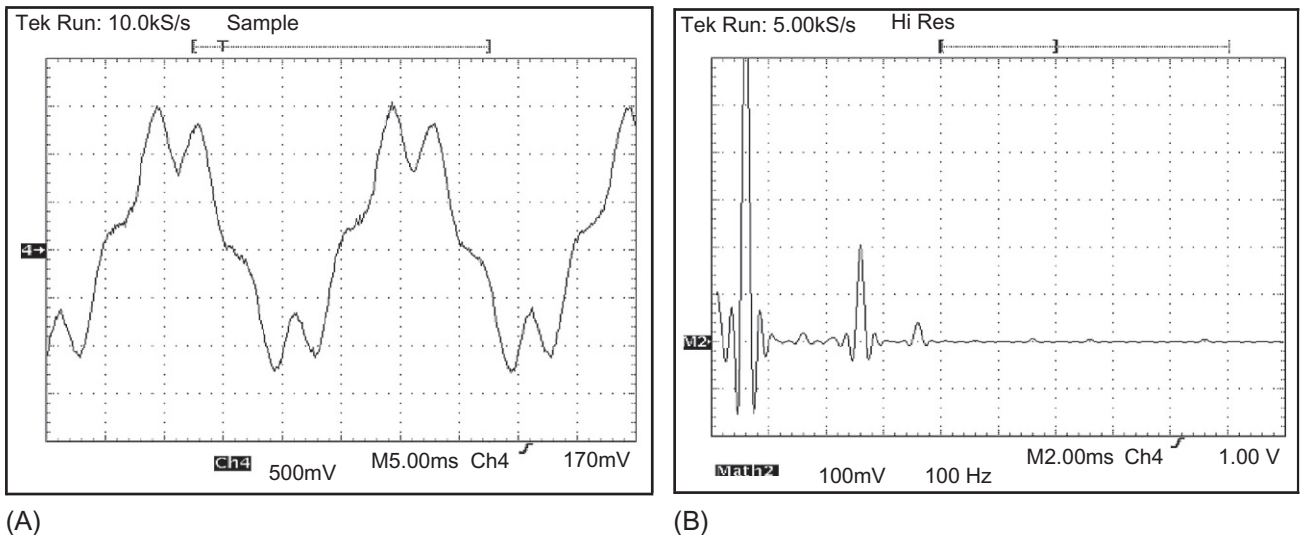

FIG. 41.61 Experimental ac line current waveform with passive filtering compensation: (A) line current waveform (*THD* = 24%) and (B) line current frequency spectrum.

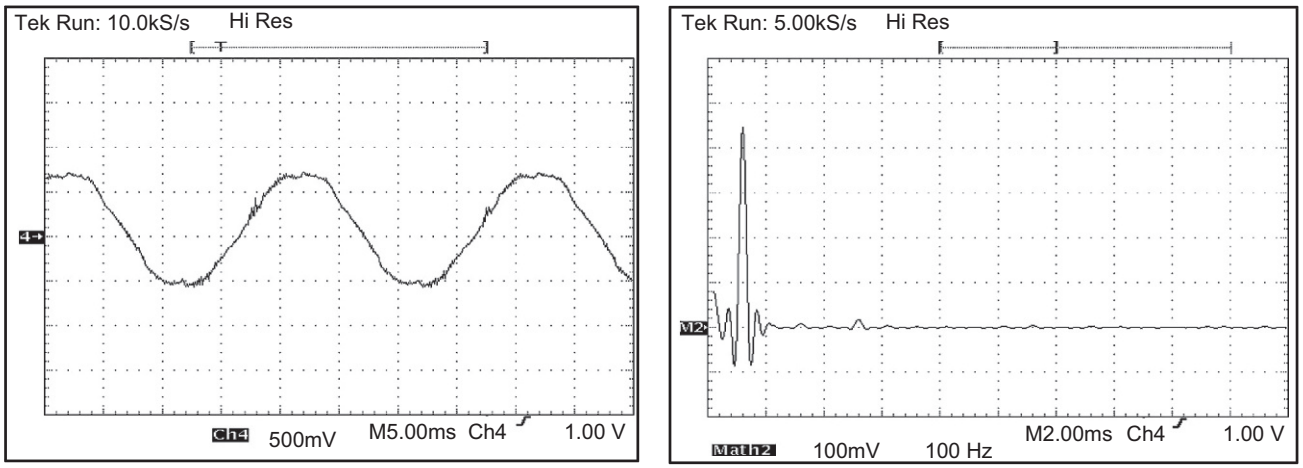

FIG. 41.62 Experimental ac line current waveform with hybrid filter compensation: (A) line current waveform ($THD = 6.3\%$) and (B) associated frequency spectrum.

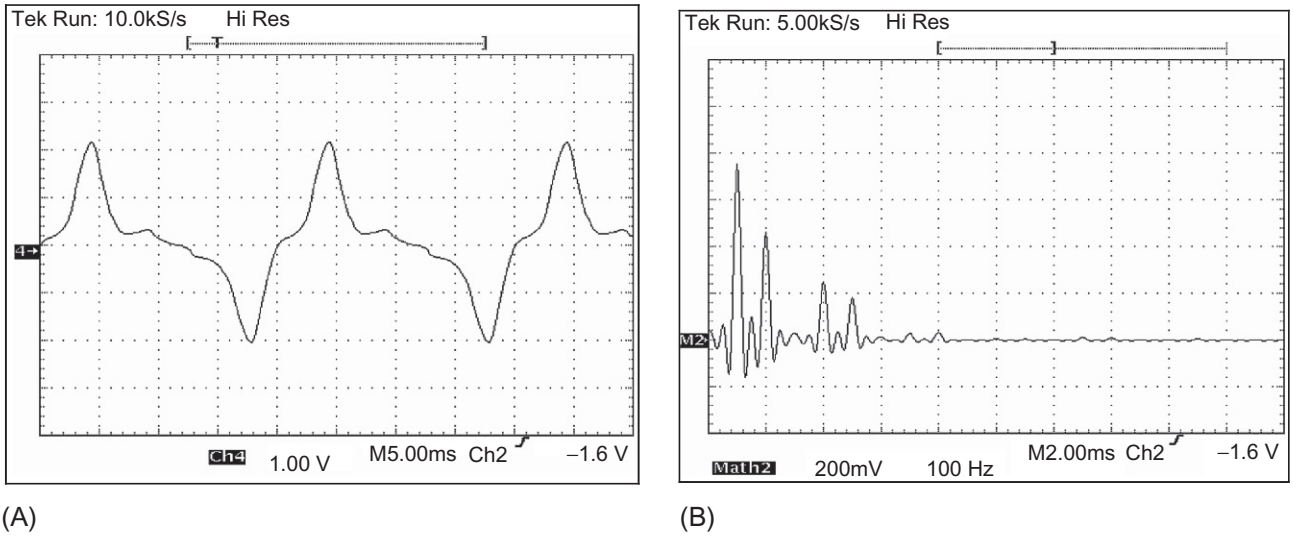

FIG. 41.63 Experimental ac line current waveform for resonant compensation: (A) line current waveform ($THD = 60\%$) and (B) associated frequency spectrum.

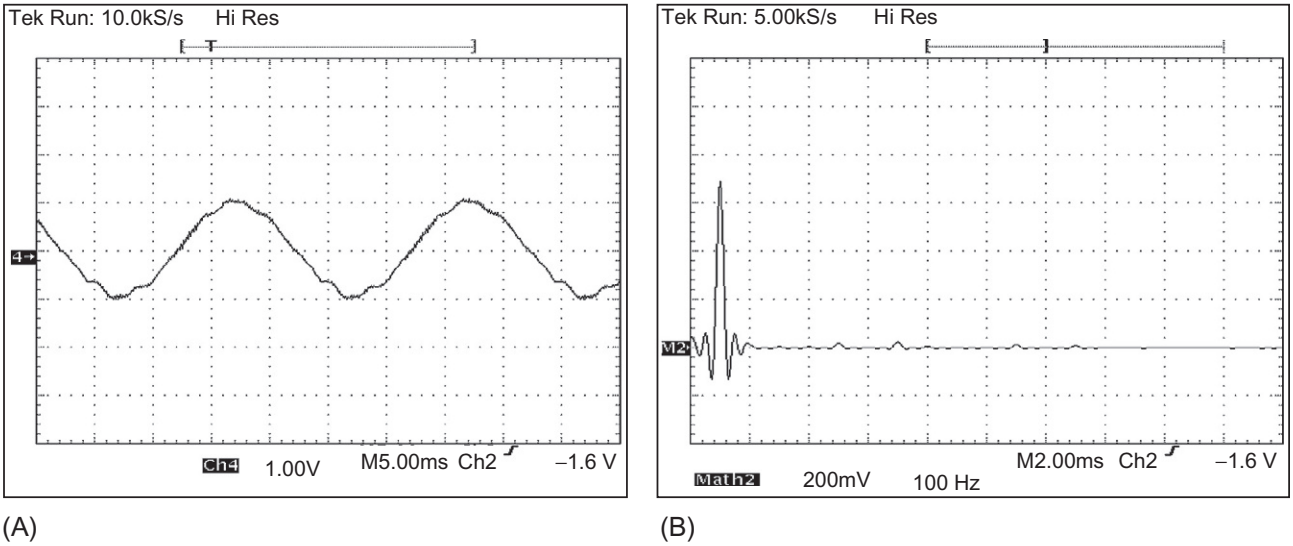

FIG. 41.64 Experimental ac line current waveform with hybrid topology compensation: (A) line current waveform ($THD = 4.9\%$) and (B) associated frequency spectrum.

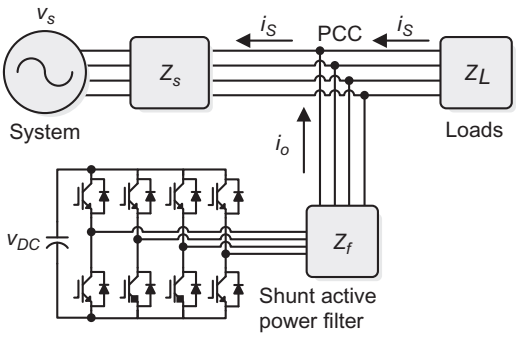

FIG. 41.65 Three-phase equivalent circuit of the proposed shunt APF.

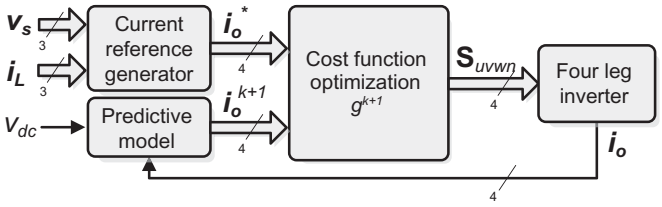

FIG. 41.66 Block diagram of the proposed predictive current control.

entails an optimization algorithm that is implemented in a microprocessor. Consequently, the analysis has to be developed using discrete mathematics in order to consider additional restrictions such as time delays and approximations. The essence of model-based predictive control is the use of the model of the system to be controlled to predict the future state of some of its variables. The controller then, according to a predefined optimization criterion, selects the optimum switching pattern that has to be applied to the power converter in order for it to achieve the future state with minimum error. The predictive control algorithm can be implemented with three main blocks, as shown in Fig. 41.66.

41.5.1.1 Current Reference Generator

This unit is designed to generate the required current reference that is used to compensate the undesirable load current components. In this case, the system voltages, the load currents, and the dc voltage converter are measured, while the neutral output current and neutral load current are generated directly from these signals.

41.5.1.2 Prediction Model

The converter model is used to predict the output converter current. Since the controller operates in discrete time, both the controller and the system model must be represented in a discrete-time domain. The discrete-time model consists of a recursive matrix equation that represents this prediction system. This means that for a given sampling time T_s, knowing the converter switching states and control variables at instant kT_s, it is possible to predict the next states at any instant $[k+1]$ T_s. Due to the first-order nature of the state equations that describe the model in (41.68) and (41.69), a sufficiently accurate first-order approximation of the derivative is considered:

$$v_o = v_{xn} - R_{eq} i_o - L_{eq} \frac{di_o}{dt} \tag{41.68}$$

$$v_{xn} = S_x - S_n v_{dc}\,, x = u, v, w, n. \tag{41.69}$$

Therefore, the 16 possible output current predicted values can be obtained from (41.68) as

$$i_o[k+1] = \frac{T_s}{L_{eq}}(v_{xn}[k] - v_o[k]) + \left(1 - \frac{R_{eq} T_s}{L_{eq}}\right) i_o[k] \tag{41.70}$$

41.5.1.3 Cost Function

In order to select the optimal switching state that must be applied to the power converter, the 16 predicted values obtained for $i_o[k+1]$ are compared with the reference using a cost function g, as follows:

$$\begin{aligned} g[k+1] = &\left(i_{ou}^*[k+1] - i_{ou}[k+1]\right)^2 \\ &+ \left(i_{ov}^*[k+1] - i_{ov}[k+1]\right)^2 \\ &+ \left(i_{ow}^*[k+1] - i_{ow}[k+1]\right)^2 \\ &+ \left(i_{on}^*[k+1] - i_{on}[k+1]\right)^2 \end{aligned} \tag{41.71}$$

The output current (i_o) is equal to the reference (i_o^*) when $g=0$. Therefore, the optimization goal of the cost function is to achieve a g-value close to zero. During each sampling state, the voltage vector v_{xn} that minimizes the cost function is found and then applied to the converter in the next sampling state.

41.5.2 Current Reference Generator

A dq-based current reference generator scheme is used to obtain the active power filter current reference signals (see "Synchronous Reference Frame Algorithm" section). This scheme presents a fast and accurate signal-tracking capability. This characteristic avoids voltage fluctuations that deteriorate the current reference signal affecting compensation performance. The current reference signals are obtained from the corresponding load currents as shown in Fig. 41.67. The cutoff frequency of the LPF used in this example is 20 Hz.

The current that flows through the neutral of the load is compensated by injecting the same instantaneous value obtained from the phase currents but with a phase shift of 180 degrees as shown in (41.72):

$$i_{on}^* = -(i_{Lu} + i_{Lv} + i_{Lw}) \tag{41.72}$$

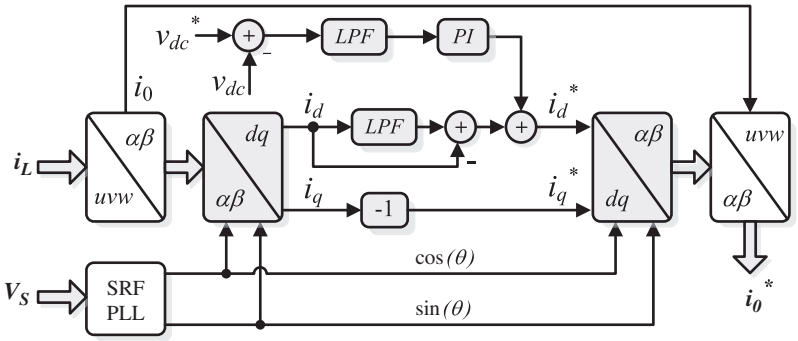

FIG. 41.67 A *dq*-based current reference generator block diagram.

41.5.3 DC Voltage Control

The dc voltage converter is controlled with a traditional PI controller. This is an important issue in the evaluation, since the cost function (41.71) is designed using only current references, in order to avoid the use of weighting factors. Generally, these weighting factors are obtained experimentally, and they are not well defined when different operating conditions are required. Additionally, the slow dynamic response of the voltage across the electrolytic capacitor does not affect the current transient response. For this reason, the PI controller represents a simple and effective alternative for the dc voltage control.

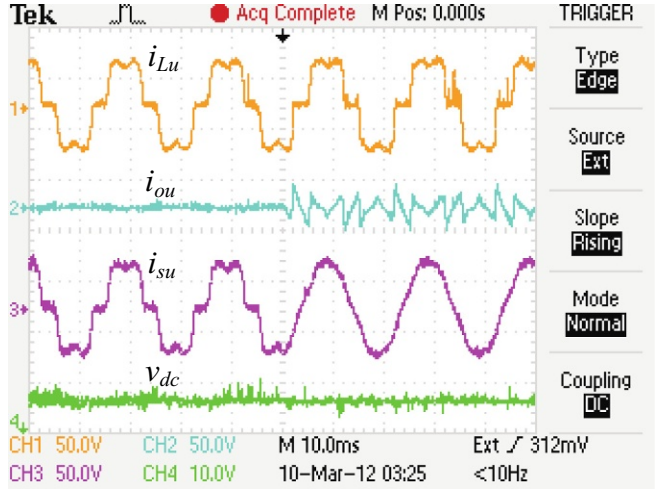
The dc voltage remains constant (with a minimum value of $\sqrt{6}v_{s(rms)}$) until the active power absorbed by the converter decreases to a level where it is unable to compensate for its losses. The active power absorbed by the converter is controlled by adjusting the amplitude of the active power reference signal i_e, which is in phase with each phase voltage. The equivalent closed-loop transfer function of the given system with a PI controller is

$$\frac{v_{dc}}{i_e} = \frac{\frac{\omega_n^2}{a}(s+a)}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{41.73}$$

Since the time response of the dc voltage control loop does not need to be fast, a damping factor $\zeta = 1$ and a natural angular speed $\omega_n = 2\pi 100$ rad/s are used to obtain a critically damped response with minimal voltage oscillation. The corresponding integral time $T_i = 1/a$ and proportional gain K_p can be calculated as

$$\zeta = \sqrt{\frac{3}{8}\frac{K_P v_s \sqrt{2} T_i}{C_{dc} v_{dc}^*}} \tag{41.74}$$

$$\omega_n = \sqrt{\frac{3}{2}\frac{K_P v_s \sqrt{2}}{C_{dc} v_{dc}^* T_i}} \tag{41.75}$$



41.5.4 Performance Evaluation

The compensation effectiveness of the active power filter is corroborated in a 2 kVA experimental setup. In order to verify the effectiveness of the current harmonic compensation, a six-pulse rectifier was selected as a nonlinear load. A step load change was applied to evaluate the transient response of the dc voltage loop. Finally, an unbalanced load was used to validate the performance of the neutral current compensation. The proposed predictive control algorithm was programmed using an S-function block that allows simulation of a discrete model that can be easily implemented in a real-time interface (RTI) on the dSPACE DS1103 R&D control board. The complete control loop is executed by the controller every 20 μs, while the selected switching state is available at 16 μs. An average switching frequency of 4.64 kHz is obtained.

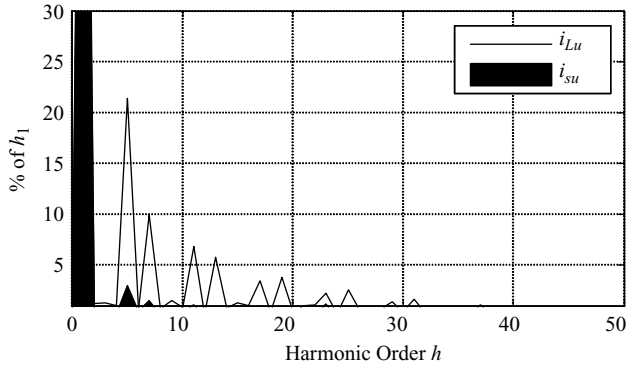


Fig. 41.68 shows the transient response of the compensation scheme. Fig. 41.68A shows that the line current becomes sinusoidal when the active power filter starts compensating and the dc voltage behaves as expected. Fig. 41.68B indicates that the total harmonic distortion of the line current (THDi) is reduced from 27.1% to 4.5%. This is a consequence of the good tracking characteristic of the current references, as shown in Fig. 41.68D.

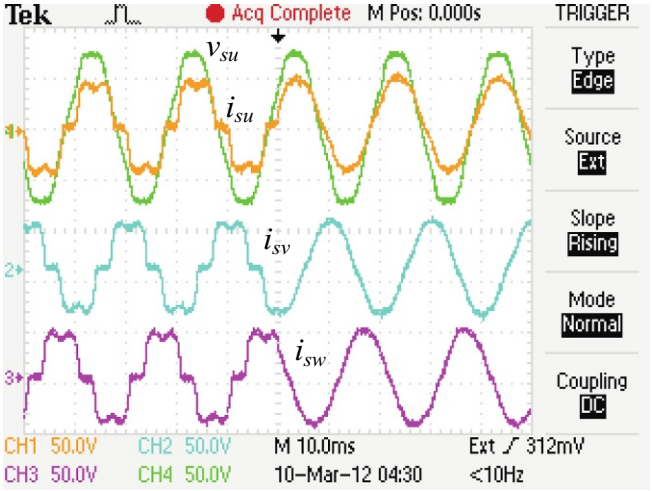
In Fig. 41.69, the transient response of the active power filter under a step load change is shown. In this case, a step load change is applied from 0.6 to 1.0 p.u. The line currents remain sinusoidal, and the dc voltage returns to its reference with a typical transient response of an underdamped second-order system (maximum overshoot of 5% and two grid cycles of settling time).



Finally, the load connected to phase u was increased from 1.0 to 1.3 p.u. The corresponding waveforms are shown in Fig. 41.70. Fig. 41.70A shows that the active filter is capable of compensating the current in the neutral conductor with a fast transient response. Moreover, Fig. 41.70B shows that the system neutral current ion is effectively compensated and eliminated and system currents remain balanced even if an 11% current imbalance is applied.

42.1 Introduction

The term "electromagnetic interference" (EMI) refers to the disturbance in operation of an engineering system due to an electromagnetic impact of the same system or other systems. Conducted electric noise and radiated electromagnetic noise are typical culprits. Watching TV during work hours in industrial centers of Western Europe in the late 1960s was virtually impossible, due to operation of large dc drives and inadequate efforts to fight the EMI threat. Today, proliferation of power electronic converters and communication devices makes EMI mitigation as important as ever, because of the high and growing number of both the potential perpetrators and victims of EMI. To ensure electromagnetic compatibility (EMC), various EMI norms have been established. The issue of EMI is closely linked to that of susceptibility of an electronic circuit to external disturbances. Considering a multicircuit system, if each constituent circuit does not emit above-limit EMI and is immune to below-limit EMI, then each circuit is electromagnetically compatible with the system.

The institution historically entrusted with development of international EMC standards is Comité International Special des Perturbations Radioelectriques (CISPR), founded in 1933, and now forming part of International Electrotechnical Commission (IEC). Drawing on CISPR expertise, numerous other international and national organizations issue norms pertaining to various aspects of EMC. Specific EMI limits are set for internal use by individual countries and organizations, such as armed forces or large corporations. Manufacturers of electric apparatus and systems must comply with the EMC standards to have an access to the market.

In this chapter, EMI effects of power electronic converters are illustrated, and basic terms and units are introduced. EMI measurement techniques and preventive measures are described, and EMC standardization efforts are examined.

42.2 Power Converters as Sources of EMI

The switch-mode operation of power electronic converters results in rippled currents. Also, rapid changes of the switched voltages induce currents in parasitic (stray) capacitances that couple the converter with other closely spaced circuits. Distorted currents drawn from the power grid produce distorted voltage drops generating pervasive voltage noise. In general, the voltage disturbances can be divided into three classes: (1) noise, (2) short-duration impulses superimposed on the mains voltage, and (3) transients.

Electromagnetic disturbances travel by conduction on wiring (conducted EMI), radiation in space (radiated EMI), and intercircuit capacitive or inductive coupling. Below 10 MHz, the EMI spreads mainly by conduction, whereas at higher frequencies mostly by radiation. The frequency range of 0.15–30 MHz occupies an important place in EMC norms because it covers the radio and TV broadcast. According to those norms, in that range, it is the conducted EMI that must be measured and suppressed, whereas measurements of the radiated EMI are required only under special circumstances. Power electronic equipment typically produces EMI that is broadband and contained within a frequency range from the operating frequency to several megahertz. Recently, the very

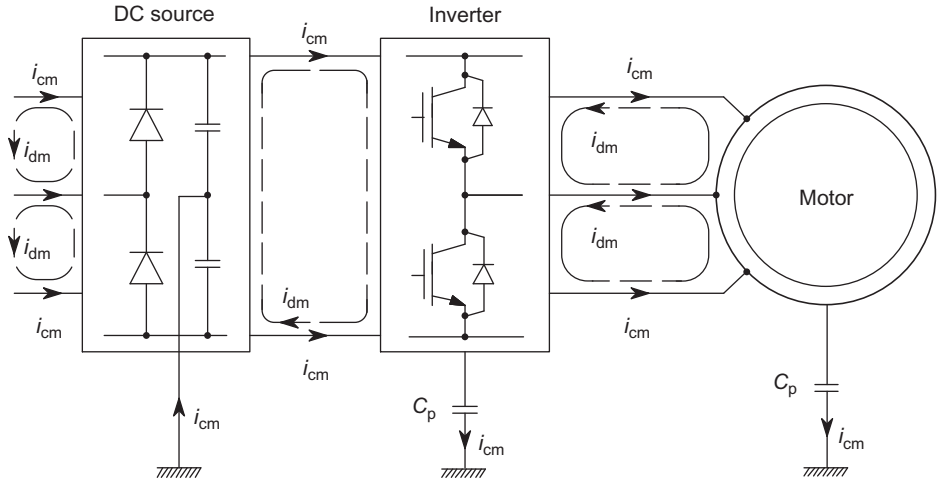

FIG. 42.1 AC drive system with PWM voltage-source inverter.

low-frequency range of 10–150 kHz has been receiving an increased attention. Consequently, with respect to most power electronic converters, it is the conducted EMI that is considered a major nuisance.

Conducted EMI appears in the form of common-mode (CM) and differential-mode (DM) voltages and currents. These two modes are illustrated in Fig. 42.1, which depicts an adjustable-speed ac drive with a PWM voltage-source inverter. CM currents, i_{cm}, flow to the ground through parasitic capacitances, C_p, whereas DM currents, i_{dm}, flow only in the wires of the system. Considering the two-wire dc line supplying the inverter, the rms CM voltage, $V_{cm(2)}$, is defined as

$$V_{cm(2)} = \frac{V_1 + V_2}{2} \tag{42.1}$$

and the rms DM voltage, $V_{dm(2)}$, as

$$V_{dm(2)} = V_1 - V_2 \tag{42.2}$$

where V_1 and V_2 are line-to-ground voltages of the two wires. The rms CM and DM currents, $I_{cm(2)}$ and $I_{dm(2)}$, are defined as

$$I_{cm(2)} = I_1 + I_2 \tag{42.3}$$

$$I_{dm(2)} = \frac{I_1 - I_2}{2} \tag{42.4}$$

For the three-wire supply and load ac lines, the rms CM voltage, $V_{cm(3)}$, and current, $I_{cm(3)}$, are defined as

$$V_{cm(3)} = \frac{V_1 + V_2 + V_3}{3} \tag{42.5}$$

$$I_{cm(3)} = I_1 + I_2 + I_3 \tag{42.6}$$

where subscript "3" applies to the third wire. The DM voltage and current, if measured with respect to ac wires 1 and 2, are defined by Eqs. (42.2) and (42.4) as for the two-wire system.

To illustrate EMI generation by PWM power converters, a typical waveform of output current of the inverter in Fig. 42.1 is shown in Fig. 42.2. The fundamental sine wave dominates, but the high-frequency current ripple is also observable. As seen in Fig. 42.3, numerous clusters of higher harmonics appear in the frequency spectrum of the current. Their locations coincide with multiples of the switching frequency (here 2 kHz), which, as in all PWM converters, is much higher than the fundamental frequency (here 9 Hz) of the ac output (or input) voltage.

The range of frequency in Fig. 42.3 is narrow (24 kHz). A wide-range frequency spectrum of current of another inverter is shown in Fig. 42.4. It can be seen that the harmonics become progressively less prominent when the frequency increases. This observation justifies the already mentioned focus on the frequencies below 30 MHz.

The fast ON-OFF and OFF-ON state transition of switches, whose switching times are typically in the order of a fraction of microsecond, also causes EMI. It is due to the high dv/dt ratios, which generate transient charge currents in the inter-wire capacitances of cables, intrawinding capacitances of transformers and p-n junctions of power diodes. Transient circuit-to-ground currents through parasitic capacitances also produce EMI. If not filtered out, the transients appear in current waveforms as spikes on top of the fundamental sinusoid. The circuit-to-ground current spikes constitute CM emissions, whereas the ripple current and periodic current spikes, coincident with the switching pattern of the converter, comprise DM emissions.

Power electronic converters tend to generate current-related interference at their input, injecting noise to the power grid, and voltage-related interference at their outputs. It may disturb operation of communication and control systems in proximity to the converter. Considering the popular low-power dc-to-dc converters, the flyback and buck converters produce particularly noisy input currents because the semiconductor switch

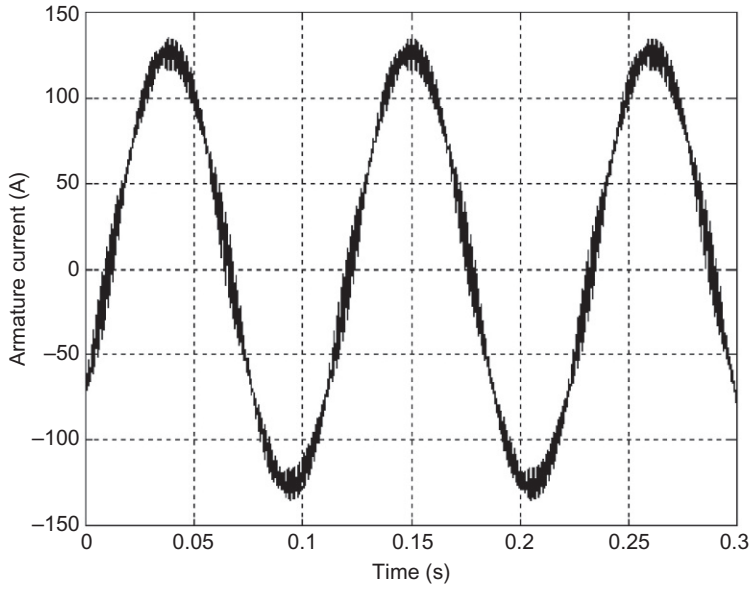

FIG. 42.2 Waveform of output current of PWM voltage-source inverter.

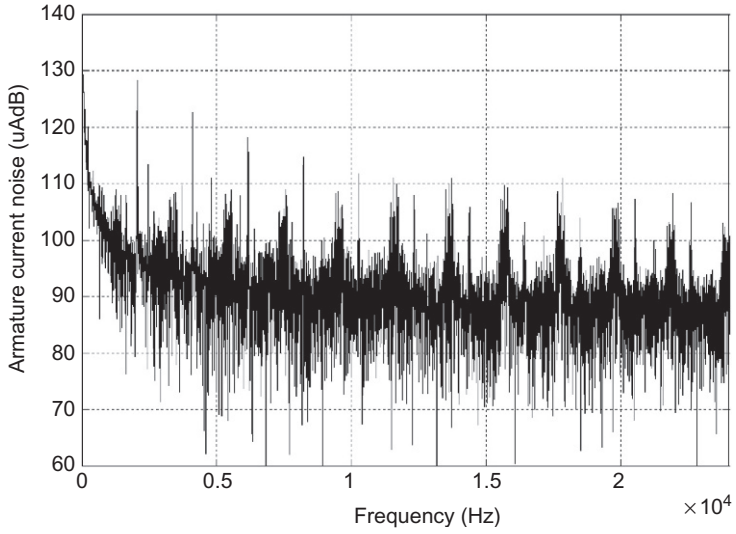

FIG. 42.3 Frequency spectrum of current in Fig. 42.2.

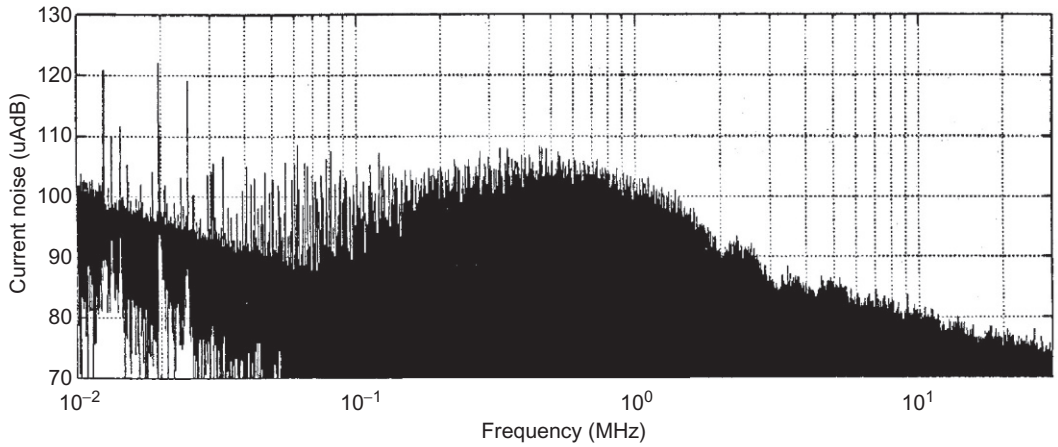

FIG. 42.4 Wide-range frequency spectrum of inverter current.

is directly in series with the input power line. In conjunction with the finite source impedance, the EMI from dc-to-dc converters conducted by the line can cause disturbance of operation of system operating from a common power bus. Disturbances can also be caused by emissions radiated from converters with very high switching frequencies. The radiated EMI is most often a magnetic field, due to the typically low voltages and high currents involved, but electric fields can sometimes also be a nuisance, especially with respect to the own control circuitry of the converter. Power lines can also radiate EMI produced by the current noise drawn from converters.

42.3 Measurements of Conducted EMI

Mitigation of conducted EMI is of major practical importance in power electronic systems. Therefore, the topic of EMI measurements in this chapter is limited to the 10 kHz–30 MHz frequency range. The related terms, units, instruments, and techniques are subsequently described. Concerning the radiated interference, the reader is referred to one of many publications covering the radio-frequency (RF) aspects of EMC, for example [1–5].

The basic quantity of a signal is power. Because of the potentially wide magnitude ranges involved, the decibel (dB) system is often used in which 1 W serves as the reference. In the dB system, signal power, $P_{(\mathrm{dBW})}$, expressed in dBW, is calculated from the power in watts, $P_{(\mathrm{W})}$, as

$$P_{(\mathrm{dBW})} = 10\log P_{(\mathrm{W})}\,\mathrm{dBW} \tag{42.7}$$

If milliwatts, mW, often abbreviated as "m," is considered; then

$$P_{(\mathrm{dBm})} = P_{(\mathrm{dBW})} + 30\,\mathrm{dBm} \tag{42.8}$$

However, in EMI measurements, it is voltage that is commonly used, and voltage probes are employed. Power is proportional to the square of voltage. Thus, taking 1 V as reference, voltage in the logarithmic scale, $V_{(\mathrm{dbV})}$, is defined as

$$V_{(\mathrm{dBV})} = 20\log V_{(\mathrm{V})}\,\mathrm{dBV} \tag{42.9}$$

In practice, the reference voltage is usually 1 μV, and

$$V_{(\mathrm{dB}\mu\mathrm{V})} = 20\log V_{(\mu\mathrm{V})}\,\mathrm{dB}\mu\mathrm{V} = V_{(\mathrm{dBV})} + 120\,\mathrm{dB}\mu\mathrm{V} \tag{42.10}$$

If the commonly used resistance of 50 Ω is employed in the measurements, conversions of $P_{(\mathrm{dBm})}$ into $V_{(\mathrm{dB}\mu\mathrm{V})}$ and vice versa can be made from the equation:

$$V_{(\mathrm{dB}\mu\mathrm{V})} + P_{(\mathrm{dBm})} = 107 \tag{42.11}$$

Current probes for EMI measurements are used when limits on conducted EMI are expressed in units of current. Denoting the terminal-pair transfer impedance of a current probe by Z_{T}, current expressed in dBμA, is given by

$$I_{(\mathrm{dB}\mu\mathrm{A})} = V_{(\mathrm{dB}\mu\mathrm{V})} - Z_{\mathrm{T}(\mathrm{dB}\Omega)} \tag{42.12}$$

where

$$Z_{(\mathrm{dB}\Omega)} = 20\log Z_{(\Omega)}\,\mathrm{dB}\Omega \tag{42.13}$$

To characterize broadband coherent (continuous spectrum) signals, an amplitude density function, A, is used in place of a discrete amplitude measure. The so-called broadband unit is 1 V/Hz. In EMC techniques, the 1 μV/MHz unit is more convenient. The conversion equations are

$$A_{(\mathrm{dB}\mu\mathrm{V/MHz})} - A_{(\mathrm{dBV/Hz})} = 240 \tag{42.14}$$

and

$$V_{(\mathrm{dB}\mu\mathrm{V})} - A_{(\mathrm{dB}\mu\mathrm{V/MHz})} = 20\log B_{(\mathrm{MHz})} \tag{42.15}$$

where $B_{(\mathrm{MHz})}$ is the measurement bandwidth, usually 9 kHz, that is, 0.009 MHz.

Conducted emissions are measured using EMI receivers, which usually measure voltage from an appropriate probe. Basically, the EMI receiver is a tunable voltmeter; its block diagram is shown in Fig. 42.5. Modern EMI receivers cover extremely wide frequency ranges, for example, from 9 kHz to 18 GHz.

To allow comparison of EMI measurement results, precise specifications for the detector have been established. The most common types are peak, quasi-peak, and average detectors. They are based on RC circuits having different charging and discharging time constants. It must be mentioned that the displays are usually calibrated to the rms value of an equivalent sinusoidal signal, whereas the actual detector often measures a different characteristic of the culprit noise.

Measurement of the peak EMI is important because of the ubiquity of impulsive sources and sensitivity of many types

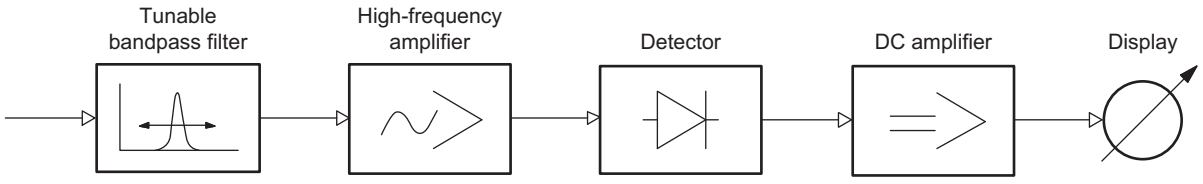

FIG. 42.5 Block diagram of EMI receiver.

of electronic circuits to impulses. The peak detectors have a short charging time constant, in the order of a fraction of microsecond, and a very long discharging time constant, in the order of tens of seconds. The quasi-peak detectors, strongly recommended by CISPR, have been primarily developed to emulate the human ear acting as a broadcast disturbance sensor. The charging and discharging time constants are 1 and 160 ms, respectively. The average detector is characterized by a long integration time constant, in the order of a second. For the 0.15–30 MHz frequency range, CISPR requires that an EMI measuring instrument have a 9 kHz bandwidth of the filter at 6 dB (from −5 to +4 kHz from the central frequency value) and that the measurement accuracy for a sinusoidal signal be less than 2 dB.

To increase the accuracy within wide ranges of the frequency and magnitude of signals, modern EMI receivers have several measuring channels. Each channel contains an independent quasi-peak detector, and the saturation and threshold levels of individual channels differ from each other. Output signals of the detectors are added in a circuit operating the display.

For comparability of EMI measurements, an interface circuit is inserted between the EMI source and the mains. This circuit is called a line impedance stabilization network (LISN) or artificial mains. The LISN produces a standard load impedance for the EMI source and filters out high-frequency disturbances on the mains, which could distort measurement results. An example of single-phase LISN recommended by CISPR 16—a publication devoted to proper EMI testing—is shown in Fig. 42.6. In the equipment under test (EUT) block, the positive and negative line terminals are denoted by P and N, respectively, whereas grounded terminal is denoted by G. The load resistance, R_L, specified by CISPR 16 is 50 Ω. The switch, S, allows transition from the CM to DM measurements. Three-phase LISNs are also available. Refer to the manual of a given LISN for operating instructions.

For quick qualitative EMI measurements, for example, when developing an EMI filter, a spectrum analyzer can be employed. A direct view of the interference levels over a wide frequency range is very convenient. The frequency axis can be switched to a linear or logarithmic scale, whereas the magnitude is usually displayed in dBm. True peak and average detectors are available. Spectrum analyzers are rms calibrated, so that the reading is correct for sinusoidal waveforms only, such as discrete harmonics of the measured noise. For impulse disturbances, correct peak values are obtained. For broadband measurements, corrections must be made to convert the true peak to quasi-peak and to account for the difference in measurement bandwidths. For help, refer to the manual of a given spectrum analyzer.

Technical details of EMI measurements for EMC compliance are too vast, a topic to be fully covered here. The reader is referred to such authoritative sources as the already mentioned CISPR publication 16 and books [1–6].

42.4 EMI Filters

EMI generated in power electronic systems usually exceeds the allowable levels, so it must be reduced. The most common means of EMI mitigation are low-pass filters, often called radio-frequency (RF) filters. They are installed on the input and output sides of power converters. The filters are simple capacitive (C) or inductive-capacitive (LC) circuits. Resistors are sometimes added to dampen possible resonances caused by converters with high switching frequencies.

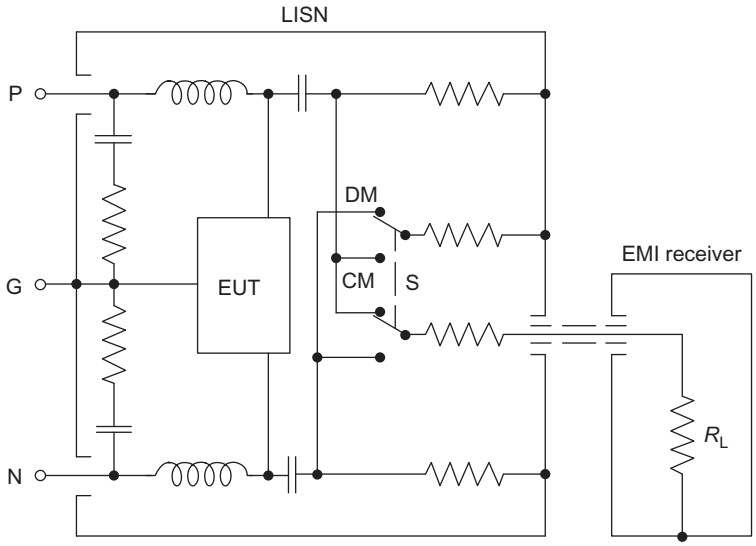

FIG. 42.6 Simplified circuit diagram of a LISN.

Choke coils are employed as the inductive components of the filters. They are usually single-layer solenoid structures with relatively low coefficients of inductance. In the case of CM EMI filters, two or three windings are placed on the same closed iron core. The windings are so arranged that the coil impedance for the CM noise is high, but that for the load current and DM noise is low. A single-phase CM choke coil is shown in Fig. 42.7. Again, letters P, N, and G denote the positive, negative, and ground terminals of the mains. It can be seen that magnetomotive forces $\mathcal{F}_L$ and $\mathcal{F}_{dm}$ produced by the load current i_L and DM noise current i_{dm} in the upper and lower parts of the coil cancel each other. As a result, the magnetic flux Φ_{cm12} in the core is generated only by magnetomotive forces $\mathcal{F}_{cm1}$ and $\mathcal{F}_{cm2}$ produced by the CM noise currents i_{cm1} and i_{cm2}.

Capacitors employed in EMI filters must have low parasitic series inductance, low dielectric and ohmic losses, and stable capacitance versus frequency characteristics. Paper, metalized paper, polystyrene, and ceramic capacitors are widely used. The so-called multifunction ceramic (MFC) capacitors can suppress the high-frequency noise and absorb impulse-type transients. According to their electric connection mode, capacitors in power line filters can be classified as X and Y capacitors, the former posing no threat of electric shock to personnel, even in the case of a breakdown. Y capacitors are typically used for attenuation of the CM noise in power line filters, but they require stricter safety standards and higher reliability than X capacitors.

To reduce the parasitic inductance, contributed mostly by the leads, the so-called feedthrough capacitors have been developed for use in EMI filters. The wire conducting the load current passes through the capacitor structure, instead of the capacitor being connected between it and the ground. This is illustrated in Figs. 42.8 and 42.9. Fig. 42.8A shows the structure of the feedthrough capacitor, and its electric symbol is shown in Fig. 42.8B. Fig. 42.9A shows that in a conventional capacitor, the parasitic inductances, L_p, of the leads are in series with the capacitance, C. The total inductance is thus $2L_p$. In contrast, as seen in Fig. 42.9B, in the feedthrough capacitor, lead inductances are connected in parallel to each other, so that the total inductance is $L_p/2$.

From the very beginning of modern power electronics, capacitors have been employed in the so-called snubbers. In the simplest embodiment, a snubber circuit consists of a capacitor with a resistor connected in series to dampen possible resonance with parasitic inductances. The snubber is placed across a semiconductor power switch to improve the switching conditions and keep the switch within its safe operating area. Snubbers reduce the EMI, which is particularly strong when the switch turns off and interrupts the load current.

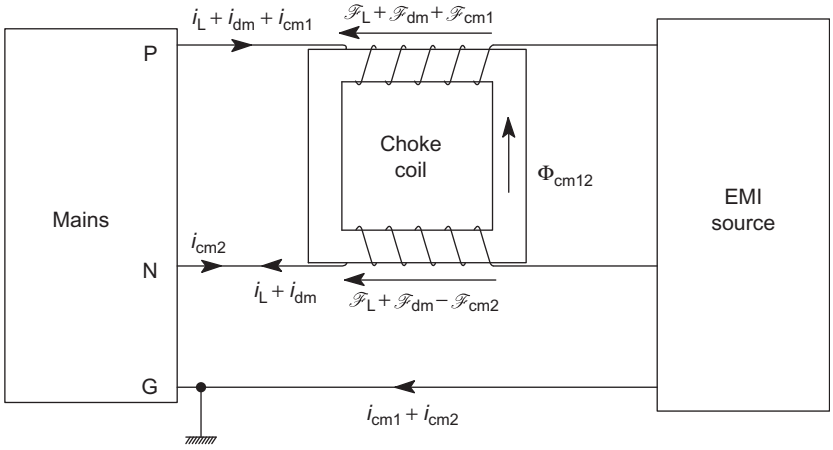

FIG. 42.7 Single-phase CM choke coil.

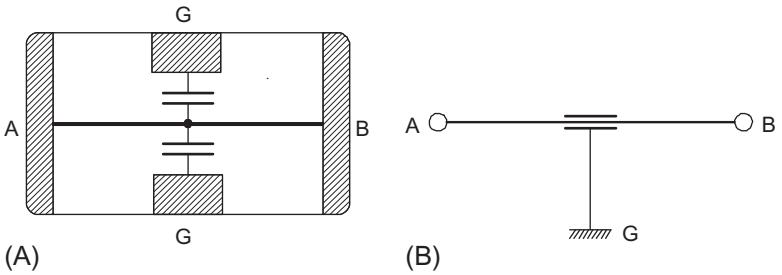

FIG. 42.8 Feedthrough capacitor: (A) structure and (B) electric symbol.

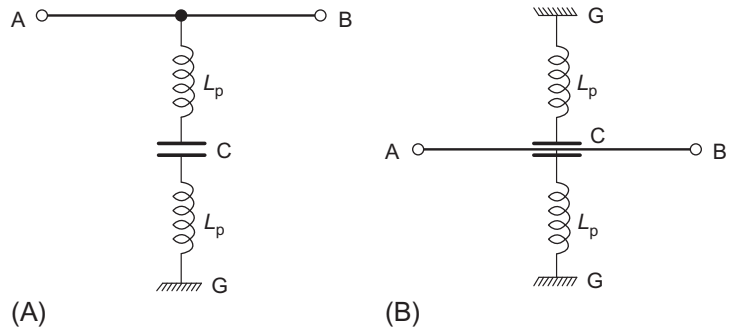

FIG. 42.9 Parasitic inductances of the leads: (A) conventional capacitor and (B) feedthrough capacitor.

Noise suppression capacitors connected to various other points in a power electronic system are also widely used, although they do not mitigate the EMI as effectively as LC filters with choke coils. Capacitive filters most often appear at the input and output of power electronic converters. They can be connected between lines or line to ground.

Basic topologies of low-pass LC filters are illustrated in Fig. 42.10. It must be stressed that EMI filters must be placed in all wires of a power electronic system. Most common configurations are shown in Fig. 42.11 for a two-wire system. The filters attenuate both the CM and DM conducted EMI. An extension of the T-type filter on a three-wire system is shown in Fig. 42.12. Similar extension can be made with respect to the other topologies of filters.

An example arrangement of the CM and DM EMI filters in the ac drive system of Fig. 42.1 is shown in Figs. 42.13 and 42.14, respectively. In the actual system, both types of filters are installed, and the two separate circuit diagrams have been used for an instructional purpose only.

The main parameter of EMI filters is the insertion loss (IL). For a given frequency, f, IL can be determined by measuring the voltage, V_G, of a sinusoidal signal generator and then connecting the filter to the generator and measuring the voltage, V_F, at the filter's output. Then,

$$\mathrm{IL} = 20\log\left(\frac{V_G}{V_F}\right)\mathrm{dB} \tag{42.16}$$

The insertion loss is usually given as an IL(f) graph with logarithmic coordinates. For filter design, the two-port network theory is employed, using the transmission, A, parameters expressing the dynamic relations between the input and output variables of a two-port network. Specifically,

$$\begin{bmatrix} V_1(s) \\ I_1(s) \end{bmatrix} = \begin{bmatrix} A_{11}(s) & A_{12}(s) \\ A_{21}(s) & A_{22}(s) \end{bmatrix} \begin{bmatrix} V_2(s) \\ I_2(s) \end{bmatrix} \tag{42.17}$$

where V_1 denotes the input (EMI-source side) voltage of the network, I_1 is the input current, V_2 is the output voltage, and I_2 is the output current, whereas s denotes the Laplace variable (complex frequency). The transmission parameters are defined as

$$A_{11}(s) = \frac{V_1(s)}{V_2(s)}\Big|I_2 = 0 \tag{42.18}$$

$$A_{12}(s) = \frac{V_1(s)}{I_2(s)}\Big|V_2 = 0 \tag{42.19}$$

$$A_{21}(s) = \frac{I_1(s)}{V_2(s)}\Big|I_2 = 0 \tag{42.20}$$

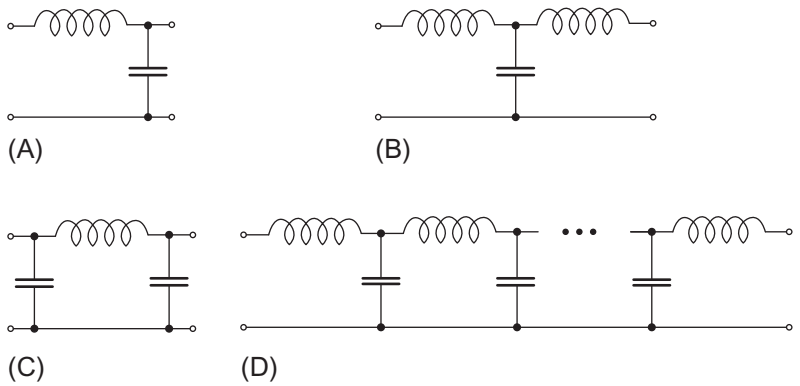

FIG. 42.10 Basic topologies of low-pass LC filters: (A) inverted gamma (Γ'), (B) pi (Π), (C) tee (T), and (D) multistage.

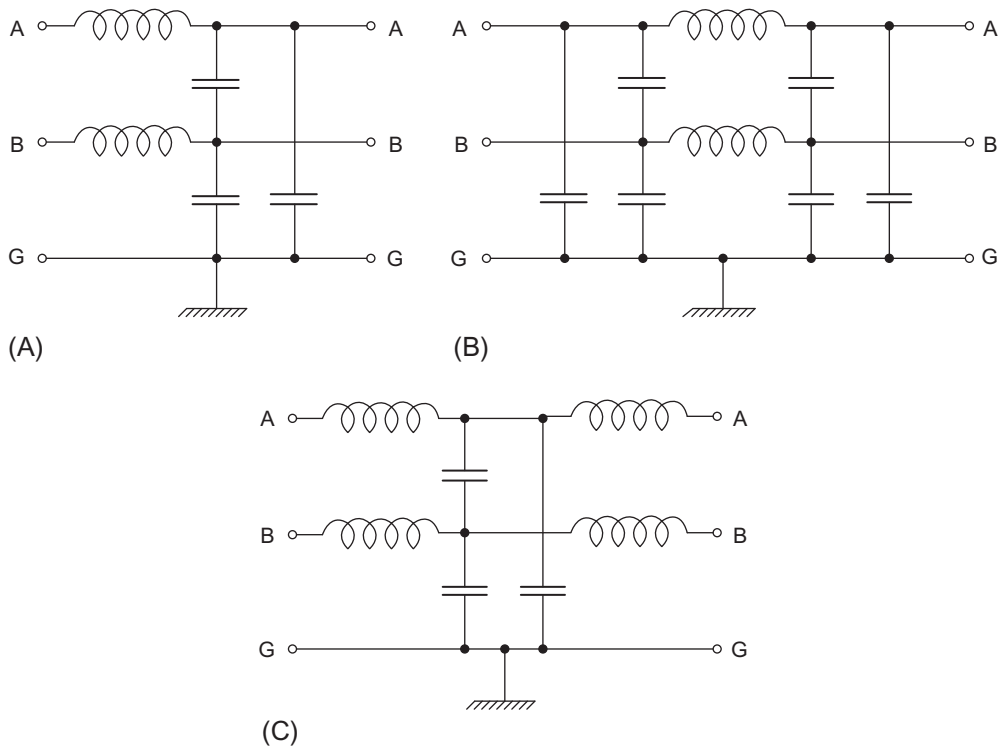

FIG. 42.11 EMI filters in a two-wire power electronic system: (A) inverted gamma (Γ′), (B) pi (*Π*), and (C) tee (T).

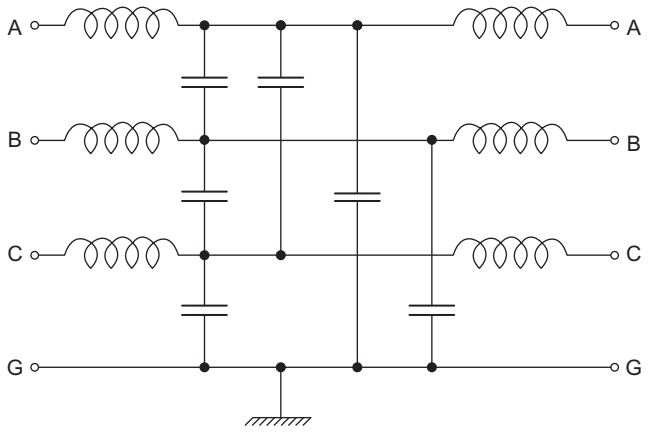

FIG. 42.12 T-type EMI filter in a three-wire power electronic system.

$$A_{22}(s) = \frac{I_1(s)}{I_2(s)} \Big| V_2 = 0 \tag{42.21}$$

Once the transmission parameters for a given filter are determined using the transient analysis of its circuit, the insertion loss can be found from the following equation:

$$\mathrm{IL}(f) = 20\log \left| \frac{[A_{21}(j\omega)Z_\mathrm{L}(j\omega) + A_{22}(j\omega)Z_\mathrm{S}(j\omega) + A_{11}(j\omega)Z_\mathrm{L}(j\omega), + A_{11}(j\omega)]}{Z_\mathrm{S}(j\omega) + Z_\mathrm{L}(j\omega)} \right| \tag{42.22}$$

where $\omega = 2\pi f$. Then, the IL(f) graph can be plotted, as illustrated in Fig. 42.15 for an actual commercial EMI filter.

The insertion loss is approximately proportional to the total inductance and capacitance (total LC) and square of the frequency. Because of the cost and size associated with the total LC value of the filter, an optimal filter is the one with a minimum total LC value, which still mitigates the EMI sufficiently to satisfy the pertaining norm. A difficulty in optimizing the EMI filter design consists in the mismatched impedance conditions under which the filters operate. From the point of view of a manufacturer of the filters, the source and load impedances are unknown. However, from the user's viewpoint, estimating the source and load impedances allows for better selection of the filter configuration. Specifically, for low source and load impedance, the "T" filter is recommended. The "*Π*" configuration is best for high source and load impedance, whereas for low source and high load impedance, the "Γ′" (LC) filter is preferred. Finally, for high source and low load impedance, the "*Γ*" (CL) topology is favored. If possible, multiple-stage filter topologies should be employed.

Practical design of EMI filters is complicated by the fact that there are no ideal inductors and capacitors. Considering the equivalent electric circuit of an inductor in Fig. 42.16A and that of a capacitor in Fig. 42.16B, it can be seen that at very high frequencies, the impedance of the parasitic components, marked by the subscript "p," may dominate that of the main component. Thus, the reactance of the parasitic capacitance, C_p, of the inductor can make the overall impedance to decrease with the frequency, and the reactance of the parasitic

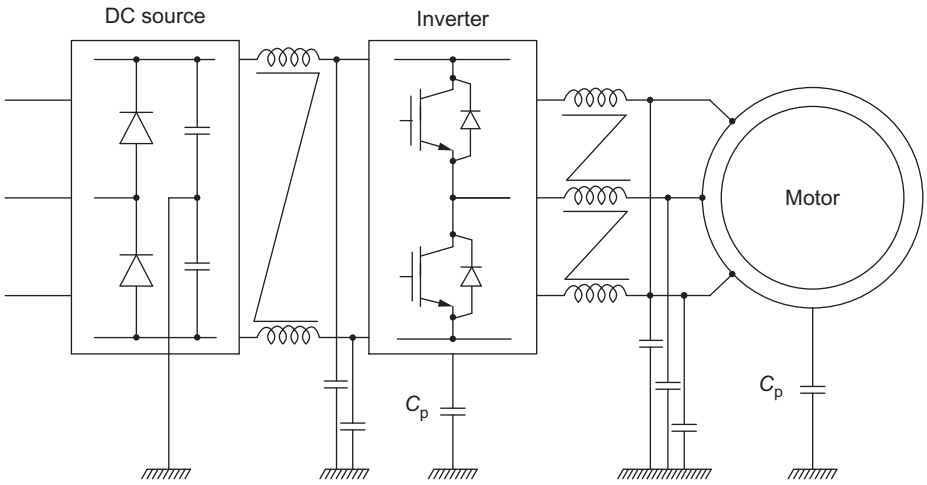

FIG. 42.13 Placement of CM EMI filters in the drive system of Fig. 42.1.

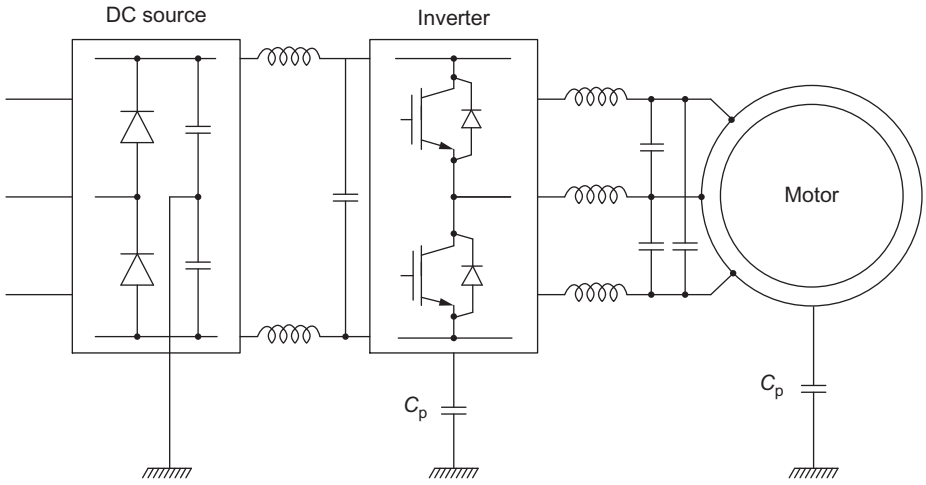

FIG. 42.14 Placement of DM EMI filters in the drive system of Fig. 42.1.

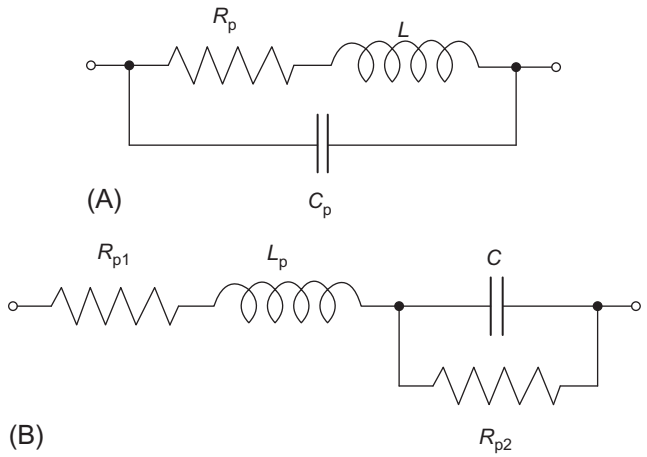

FIG. 42.16 High-frequency equivalent circuits of (A) capacitor and (B) inductor.

inductance, L_p, of the capacitor can make the overall impedance of the capacitor to increase. That is why manufacturers of EMI filters and their components go to great lengths to minimize the parasitics.

In the common case of power electronic converters fed from the grid, the so-called power line filter is installed between the grid and converter. It protects the converter and its load from external disturbances and, vice versa, screens out the grid from EMI generated in the converter. Voltage impulses originated within the grid are particularly hazardous for the converter, and varistors are used in the filter to attenuate the impulses. An example of commercial power line filter is shown in Fig. 42.17. In the drive system in Fig. 42.1, the filter would be connected to the three-phase input terminals of the dc source (rectifier).

Numerous vendors offer a variety of power line and EMI filters with a wide range of voltage and current ratings. Thus, designers of power converters and converter-fed systems have a choice of quality products, without the need for designing their own filters. Useful details of the process of EMI filters design can be found in [7,8].

Active EMI filters, although very effective, are less common than the passive filters described because of their increased complexity and cost. They are based on the feedback principle, generating currents that neutralize the noise currents. In the dc-to-dc converters, they are also employed to limit inrush currents, for example, during the so-called hot swapping, when a faulty electronic board is replaced without interrupting operation of the system. In certain three-phase systems with power converters such as ac drives, the CM voltage noise, apart from producing external interference, causes internal problems, for example, accelerated wear of bearings. The so-called CM voltage cancellers are one of the means to mitigate those problems. Such a voltage canceller in the drive system of Fig. 42.1 is shown in Fig. 42.18.

42.5 Random Pulse Width Modulation

Suppression of the low-frequency noise originating from the PWM operating mode of most power converters is particularly difficult. As already pointed out in Section 42.1, the noise, mostly harmonics of the voltages and currents, appears in the frequency spectra as harmonic clusters around multiples of the switching frequency, f_{sw}. As seen in Fig. 42.3, the highest magnitudes of the harmonics appear at the lower end of the frequency range, while the insertion loss of EMI filters progressively increases with the frequency, as shown in Fig. 42.15. Thus, at low frequencies, effectiveness of the filters decreases. Increasing the total LC value helps, but it results in corresponding increase of the cost and bulk of the filters. Therefore, mitigation of harmonics by means of special PWM strategies is the best solution for filter minimization.

Most of the commercial PWM power converters are characterized by a fixed switching frequency, f_{sw}, defined here as a reciprocal of the switching period, T_{sw}. The switching period constitutes the length of a switching interval, which houses pulses of switching variables of the converter, one pulse per variable. Duty ratio of a given pulse varies from 0 to 1; that is, the width (duration) of the pulse is in the range of $0 - T_{sw}$. It has been demonstrated in many publications, for example, [9] that

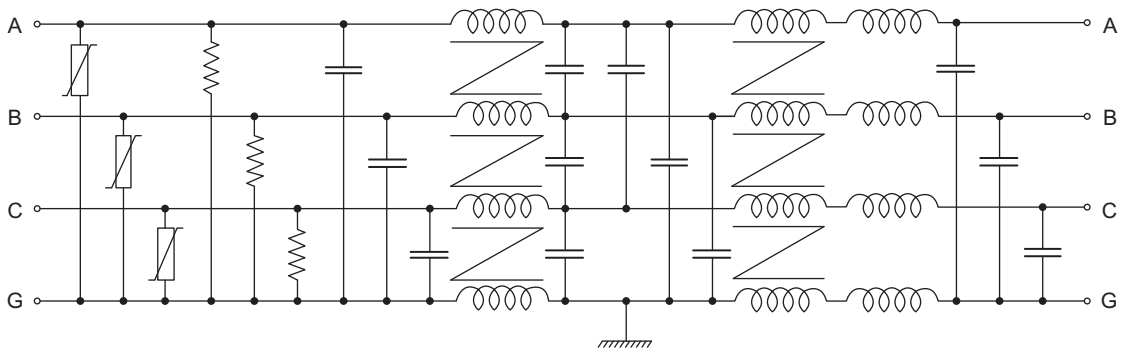

FIG. 42.17 Power line filter.

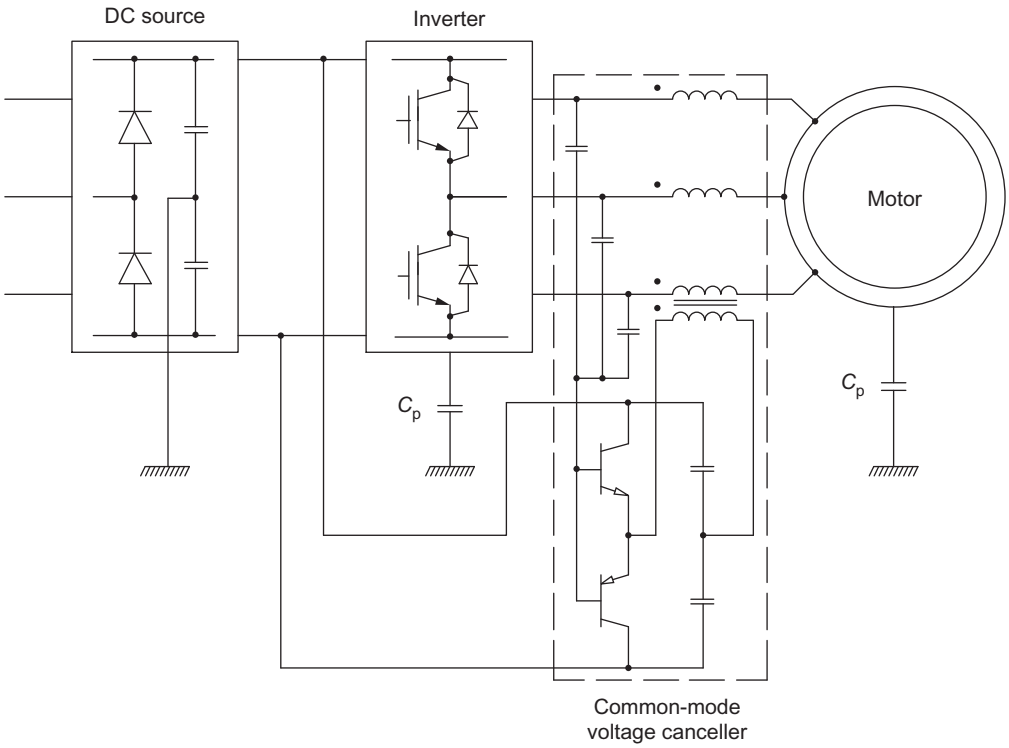

FIG. 42.18 Common-mode voltage canceller.

if individual switching periods are randomly varied, then the discrete harmonic power (watts) of spectra of the voltages and currents of the converter is transferred to continuous power spectral density (watts/hertz). This strategy of random pulse-width modulation (RPWM) results in significant mitigation of both the acoustic and electromagnetic noise associated with the current harmonics [10,11]. Accumulated experience and theoretical considerations show that varying T_{sw} from 0.5 to 1.5 of the average switching period, $T_{sw,ave}$, is sufficient. Thus, the nth switching period is determined as

$$T_{sw,n} = (r_n + 0.5)T_{sw,ave} \tag{42.23}$$

where r_n is a uniform-probability random number in the 0–1 range.

For convenience, in practical digital modulators for PWM converters, the switching cycles coincide with the sampling cycles of the modulator, that is, $f_{sw} = f_{smp}$, where f_{smp} denotes the sampling frequency (not to be confused with the much higher clock frequency). Consequently, the varying switching rate is associated with identically varying sampling rate. When a single digital system performs more tasks than just PWM, the random sampling rate is a disadvantage. For instance, in a control system, the sampling rate defines the control bandwidth, and it is selected at a specific trade-off level. Therefore, an RPWM technique with a fixed sampling rate but variable switching frequency is more practical. Fig. 42.19 illustrates (A) the most common, nonrandom PWM technique with

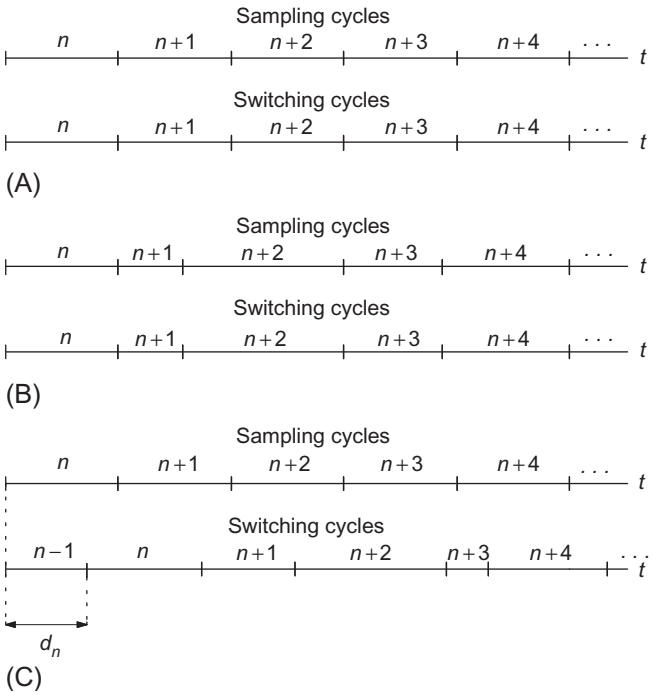

FIG. 42.19 Illustration of PWM techniques: (A) fixed-period and coinciding sampling and switching cycles, (B) randomly varied and coinciding sampling and switching cycles, and (C) fixed-period sampling cycles and variable-period switching cycles (VD-RPWM).

fixed-period and coinciding sampling and switching cycles; (B) RPWM with randomly varied and coinciding sampling and switching cycles; and (C) RPWM with fixed sampling periods and randomly varied switching periods, subsequently referred to as variable-delay RPWM (VD-RPWM).

As seen in Fig. 42.19C, the switching cycles in the VD-RPWM method are delayed with respect to the corresponding sampling cycles by a randomly varied time delay, d. The value of d for the nth switching cycle is calculated as

$$d_n = r_n T_{\text{smp}} \tag{42.24}$$

where $T_{\text{smp}} = 1/f_{\text{smp}}$ denotes the sampling period. When in two consecutive switching cycles, denoted by k and $k+1$, r_{k} is close to 1, and $r_{\text{k}+1}$ is close to 0; the second, $k+1$, switching cycle may be too short; that is, its length, $T_{\text{sw},k+1}$, may be lower than the minimum allowable length, $T_{\text{sw,min}}$. Therefore, in case of such occurrence, $T_{\text{sw},k+1}$ is set to $T_{\text{sw,min}}$, or another value of r_{k} is selected. As a result, the switching periods vary from T_{min} to $2T_{\text{smp}}$. The average switching period, $T_{\text{sw,ave}}$, equals the sampling period, T_{smp}.

Any PWM strategy based on the concept of switching cycles can be employed within the RPWM method. For instance, the popular space-vector modulation can be used in three-phase voltage-source inverters. As long as the average switching period is sufficiently short, the quality of output current is similar to that in a converter with a fixed switching frequency having the same period. An example spectrum of the output current of a voltage-source inverter controlled using the VD-RPWM is shown in Fig. 42.20. It is the same converter whose current spectrum, with fixed-period PWM, was shown in Fig. 42.3. The noise suppression by 10 dBμA is easily observable. A spectrum corresponding to that in Fig. 42.4 is shown in Fig. 42.21. Here, the EMI mitigation, by about 20 dBμA, is even stronger.

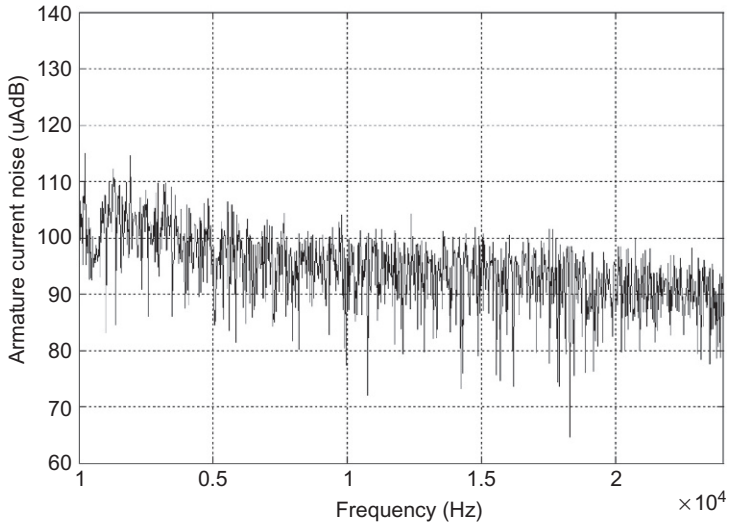

FIG. 42.20 Frequency spectrum of output current of a voltage-source inverter with VD-RPWM.

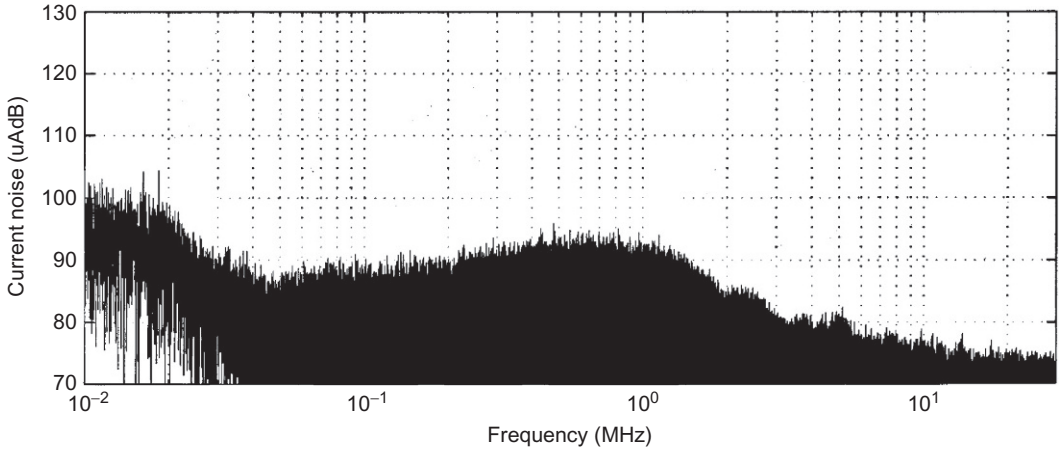

FIG. 42.21 Wide-range frequency spectrum of inverter current with VD-RPWM.

Although RPWM is not a perfect tool for EMI mitigation, it effectively eliminates high harmonics of the input and output currents and output voltages in PWM power converters. The EMI filters are usually still needed for the suppression of transients, impulses, and high-frequency noise. However, their total LC value can be greatly reduced. The RPWM technique with random switching and sampling periods is a little more effective than the VD-RPWM because of the somewhat greater freedom of randomization, and it is recommended for converters whose pulse-width modulator operates independently of the rest of the system.

It is worth mentioning that PWM techniques have been developed that reduce the CM noise in three-phase inverters by elimination (or significant reduction) of the so-called zero states, in which all the three-phase terminals are clamped by the inverter switches to one of the dc buses. Other solutions involve addition of a fourth leg to the inverter or use of multilevel inverters.

42.6 Other Means of Noise Suppression

In addition to filters and PWM methods, means of mitigation of EMI effects in systems with power electronic converters include grounding, shielding, and minimization of electromagnetic coupling. When skillfully used, they can significantly reduce the EMI and circuit susceptibility at a low extra cost.

Effects of grounding on the EMI must be considered in the context of the whole system employing power electronic converters. Grounding of electric equipment has historically been based on the requirements of safe and reliable power distribution, maximum protection against overvoltages (including lightning strikes and electrostatic buildup), and safe-touch conditions for personnel during ground faults. The so-called safety ground (green wire in the United States) protects personnel and equipment by conducting fault current, operating a circuit breaker or fuse, and limiting the voltage to ground during faults. This type of grounding can be termed low-frequency grounding. The earth ground is made using buried rods, plates, or grids. Note that the ground wiring for lightning protection must be isolated from other grounding conductors, and the lightning current may not pass through any circuit breaker or fuse. Considering the drive system in Fig. 42.1 and assuming the "Y" connection of the secondary windings of the supplying transformer, the neutral of the transformer can be ungrounded, directly grounded, or connected to the ground through a resistor. Each of these arrangements has advantages and disadvantages, but the resistance-grounded system has gained the greatest popularity because the line-to-ground faults do not cause immediate shutdown of the system. Proper selection of the grounding resistance allows sufficient limitation of the ground fault currents and the voltage to ground to avoid equipment failures.

The high-frequency grounding, which should be considered separately from the low-frequency scheme, has a strong impact on the CM EMI. The general rule for proper high-frequency grounding design is to understand the CM noise path and to reroute the noise away from the sensitive electronics. A single-point grounding scheme is theoretically the best, although the existence of many stray system-to-ground capacitances makes it practically a multipoint grounding above certain frequencies. Physical capacitors are often used to augment the stray capacitances, for example, between the chassis and the grounding wire, to reduce the CM noise voltage. High-power parts of a system should be connected the closest to the single-point ground, with the most sensitive circuits the furthest from it.

Most practical systems with power converters include cables, for example, those connecting the inverter to the motor in the drive in Fig. 42.1. The cables act as antennas for the radiated EMI, and they are receptors in the electromagnetic coupling. Shielding the cables significantly reduces those unwanted phenomena. Such types of cables as the aluminum-armor or braided-shield ones offer very good protection from EMI. In particular, they prevent interference with sensitive equipment by providing an isolated and predictable metallic path for the CM noise. The shield is usually bonded with the ground wire at both ends of the cable. For industrial installations, such as drive systems in a factory, use of grounded steel conduits to carry cables is a convenient and effective solution. Shielding can also be applied to other than cables, parts of the electronic circuitry, such as circuit enclosures.

As illustrated in Fig. 42.22, the electromagnetic noise coupling can be capacitive (electric field) or inductive (magnetic field). The noise source voltage is denoted by v_n, and the stray capacitance, C_{12}, and mutual inductance, M_{12}, link wires 1 and 2 transmitting noise from the source. The coupling capacitances and inductances should therefore be minimized. The simplest, but not always practical, approach is to increase the distances between noise sources and receivers. Shielding is a good protection from electromagnetic noise coupling, and the unshielded leads extending beyond the shield should be possibly short [12].

Electromagnetic noise coupling can also be minimized by proper circuit geometry. The potential noise source should not be placed in parallel to the potential noise receiver. Perpendicular placement is best. Twisting two interconnecting wires helps as well because currents in individual wires flow in opposite directions, producing magnetic fields that cancel each other.

EMI reduction techniques should also be considered at the printed circuit board (PCB) level. Proper grounding, power distribution, and interconnection techniques, depending on whether the PCB contains analog or digital circuitry, improve immunity to both the internal and external noise sources. This highly specialized topic extends the tutorial scope of this publication.

A thorough compendium of various means of EMI mitigation in inverter-fed ac drive systems can be found in [12]. It should be stressed that EMI suppression techniques should be considered in early stages of the design. Otherwise, the

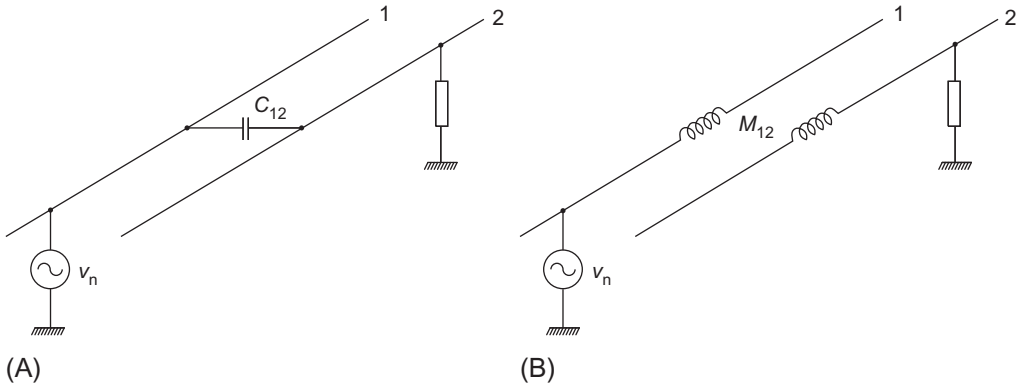

FIG. 42.22 Electromagnetic coupling: (A) capacitive and (B) inductive.

designed system would be likely to have serious and expensive to fix noise problems.

42.7 EMC Standards

The number of institutions involved in regulations and recommendations that concern EMI is quite large, and to an average person, the issue of EMC standards can be somewhat confusing. EMC is defined as the ability of equipment to function satisfactorily in its electromagnetic environment without introducing intolerable disturbances to anything in that environment. EMC requirements entail two major items: emissions and susceptibility or its opposition—the immunity. Electromagnetic disturbance is any phenomenon that may degrade the performance of a device or system or adversely affect the living and inert matter. The term "EMI" pertains to that performance degradation. It is worth mentioning that in the colloquial engineering language, EMI is often meant as emissions and EMC as immunity, which is inexact. In the important US military standard, MIL-STD 461, the emissions and immunity requirements are referred to as conducted/radiated emissions (CE/RE) and conducted/radiated susceptibility (CS/RS).

In the United States, it is the Federal Communications Commission (FCC) that sets the general EMC requirements, but medical products are regulated by the Food and Drug Administration (FDA). The FCC rules and regulations, title 47, part 15, subpart B concerns *any unintentional radiator (device or system) that generates and uses timing pulses at a rate in excess of 9000 pulses (cycles) per second and uses digital techniques.* Clearly, that mandatory requirement applies to almost every product that employs a microprocessor. It is illegal to sell or advertise for the sale of any product regulated under part 15, subpart B until its emissions have been measured and found to be in compliance. Products regulated by part 15, subpart B are divided in two classes. Class A devices are those marketed for use in commercial applications, whereas the domestic applications belong to class B. As illustrated in Fig. 42.23, class B limits are more stringent than those for class A products, and the class B administrative *certification* process is more rigorous than the class A *verification* process. The American National Standards Institute (ANSI) standard C63.4 defines the required emission test procedures. However, there are no FCC regulations pertaining to product immunity to electromagnetic fields.

EMC requirements for products used by the US military are listed in the already mentioned MIL-STD-461. This standard is applicable to a wide range of systems, from power tools to computer workstations. Unlike the FCC regulations, MIL-STD-461 specifies limits for both the emissions and immunity. The ANSI and Institute of Electrical and Electronics Engineers (IEEE) also publish EMC standards, as do, for internal use, private organizations, such as the Society of Automotive Engineers (SAE) and automobile manufacturers.

Under provisions of the General Agreement on Tariffs and Trade (GATT) and its successor, the World Trade Organization (WTO), member countries are obliged to adopt international standards for national use. With respect to the EMC, international standards are primarily developed by the International Electrotechnical Commission (IEC) and its International Special Committee on Radio Interference (CISPR); both were already mentioned in the introduction to this chapter. The series of IEC standards, IEC 61000-1 through IEC 61000-6, covers all aspects of EMC. The FCC standards are harmonized to IEC standards, as are the European Norms (EN) used in the European Union (EU). Some specific EMC standards have also been published by the International Organization for Standardization (ISO).

In 1992, the EU eliminated internal borders, necessitating a common system for establishing EMC standards and accreditation, testing, and certification procedures. The "new approach" and "global approach" have been initiated; their goal are to include EU directives into national laws of EU states, harmonize national standards with the European standards, and ensure validity of test reports and conformity certificates between all member states.

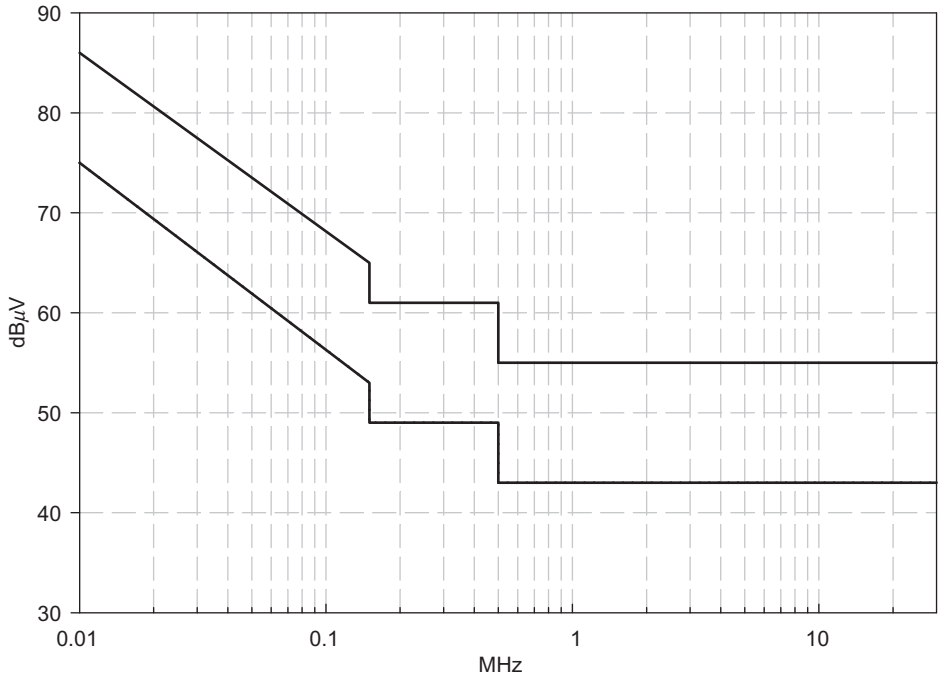

FIG. 42.23 FCC conducted emissions limits. Upper trace, class A, and lower trace, class B.

According to the "new approach," technical contents have been removed from the European directives and entrusted to the European standard bodies, which are Comitè Europèen de Normalization (CEN), Comitè Europèen de Normalization Electrotechnique (CENELEC), and European Telecommunication Standards Institute (ETSI). The key European directive 89/336/EEC "electromagnetic compatibility" gives only a general definition of the *essential protection requirements* for all electric and electronic equipment and systems while referring to CENELEC and ETSI standards for technical details. The "global approach" requires every product on the European market to have the permanent "CE" marking, which indicates that the affixer declares and takes full responsibility of the conformity to all applicable European directives.

The EMC directive 89/336/EEC sets up emission and immunity requirements. It defines (a) components, (b) systems, and (c) installations. The directive applies only to components performing direct function and to the systems. Standards referred to the directive are divided into basic standards, generic standards, and product standards. The basic standards define general EMC requirements and testing procedures, without specifying any limit values or assessment criteria. Generic standards specify the requirements for products in specific electromagnetic environments. For instance, EN 50081-1 applies to emissions in residential, commercial, and light industrial equipment, including power supplies for industrial equipment, and EN 50081-2 to emissions in industrial environments. Respective immunity norms are EN 50082-1 and EN 50082-2. Product standards address EMC requirements for certain products and product families, such as household appliances, information technology equipment, or generic light industrial equipment; various European norms are employed as the product standards.

The IEC 555-2 (EN 60555-2), IEC 1000-3-2 (EN 61000-3-2), and IEC 1000-3-4 are emission standards for low-frequency harmonics, closely associated with operation of power electronic converters. Voltage fluctuations and flicker (*impression of unsteadiness of visual sensation induced by a light stimulus whose luminance or spectral distribution fluctuates in time*) emission limits are defined in IEC 555-3 (EN 555-3), IEC 1000-3-3 (EN 61000-3-3), and IEC 1000-3-5. IEC 61000-4-7 and IEC 61000-4-15 define the required instrumentation for EMI measurements. Radio-frequency conducted and radiated emissions are dealt with in EN 55011, EN 55014, and EN 55022, whereas CISPR 16 is the basic standard for radio-interference measurements. Finally, IEC 1000-4-1 through IEC 1000-4-12 are immunity standards.

EMC standards are continuously being developed and revised. Therefore, it is important to keep track of standards' publication dates (DoP) and dates of withdrawal (DoW) of conflicting earlier standards. Temporary EN standards are called ENV. Numerous Internet resources are available, in particular:

- American National Standards Institute (ANSI)
- Canadian Standards Association
- Electronic Industries Association (EIA)
- European Telecommunications Standards Institute (ETSI)
- Federal Communications Commission (FCC)

- IEEE Standards Association
- International Electrotechnical Commission (IEC)
- International Organization for Standardization (ISO)
- National Institute of Standards and Technology (NIST)
- NSSN, A National Resource for Global Standards
- Society of Automotive Engineers (SAE)
- Standards Australia
- VCCI (Japanese EMC Regulation and Certification)
- Verband Deutscher Elektrotechniker e. V. (VDE–German standards)

For more EMC information links, go to http://www.dbtechnology.co.uk/links.htm and https://en.wikipedia.org/wiki/List_of_common_EMC_test_standards. A comprehensive treatment of contemporary EMC issues in power electronic and power distribution systems can be found in [13,14].

43.1 Introduction

Famous admiral Rickover often made the point that what was needed to get things done in the world of technology was engineering more than science. He also said: "Engineering is a profession which affects the material basis of everyone's life. To practice a profession one must have acquired mastery of an academic discipline as well as a technique for applying this special knowledge to the problems of everyday life. A profession is therefore intellectual in content, practical in application."

Dr. Henry Petroski, specialist in failure analysis and professor of civil engineering at Duke University, put it in these words: "Engineers are not superhuman. That they make mistakes is forgivable; that they catch them is imperative. Thus it is the essence of modern engineering not only to be able to check one's own work but also to have one's work checked and to be able to check the work of others."

As in any rapidly advancing technology, power electronics standards are the risk mitigation tool, which allow using collective practical experience of many generations of engineers. Knowledge of the standards accelerates acceptance of power electronics and allows doing things right from the first time. Typically, standards formulate what is required and should be considered leaving to user decisions how requirements of the standards are implemented.

43.2 General Review of Power Electronics Standards

All power electronics standards are application-specific and could be categorized as follows:

1. Recommended professional engineering standards developed by engineering societies, manufacturing associations, and testing laboratories
2. Mandatory regulation standards developed or adapted by country or local authorities for operation of power electronics in their area of jurisdiction
3. End user- or customer-specific standards mutually agreed by user and manufacturer.

The major international developers of power electronics engineering standards are the Institute of Electrical and Electronics Engineers (IEEE), International Electrotechnical Commission (IEC), National Electrical Manufacturers Association (NEMA), and Underwriters Laboratories (UL). Each standard organization has its own procedures for developing standards:

- IEEE Working Groups develop standards through a consensus development process, which brings together volunteers representing varied viewpoints and interests to achieve the final product. These standards are approved only when a 75% consensus is reached. IEEE standards

Copyright © 2018 Elsevier Inc. All rights reserved.
http://dx.doi.org/10.1016/B978-0-12-811407-0.00048-9

are creating technical base for customer's selection and acceptance of products and the technical base for codes, rules, and regulations by different enforcing and regulating authorities.
- IEC technical committees by specialists from participating countries develop IEC standards expressing an international consensus of opinion on the relevant subjects from all interested IEC National Committees having equal voting rights. Each participating country is responsible for enforcement of standards.
- NEMA technical committees of representatives from members of association develop NEMA standards. NEMA members are responsible for compliance with standards.
- UL specialists develop UL standards with inputs from manufacturers and consumers. Compliance with standards required for power electronics products liability insurance or by end users and consumers.

There are many standards for power electronics components, but the list of power electronics standards as an equipment is relatively short:

- IEEE Std 1100 (Emerald Book), IEEE Recommended Practice for Powering and Grounding Electronic Equipment
- IEEE Std 1303 Guide for Static Var Compensator Field Tests
- IEEE Std 1409 Guide for Application of Power Electronics for Power Quality Improvement on Distribution Systems Rated 1 kV Through 38 kV
- IEEE Std 1566 IEEE Standard for Performance of Adjustable Speed AC Drives Rated 375 kW and Larger
- IEEE Std 1515 IEEE Recommended Practice for Electronic Power Subsystems: Parameter Definitions, Test Conditions, and Test Methods
- IEEE Std. 1573 IEEE Recommended Practice for Electronic Power Subsystems: Parameters, Interfaces, Elements, and Performance
- IEEE Std 1585 IEEE Guide for the Functional Specification of Medium Voltage (1–35 kV) Electronic Series Devices for Compensation of Voltage Fluctuations
- IEEE Std 1662-2008 Guide for the Design and Application of Power Electronics in Electrical Power Systems on Ships
- IEEE Std 1676 IEEE Guide for Control Architecture for High Power Electronics (1 MW and Greater) Used in Electric Power Transmission and Distribution Systems
- IEEE Std 1688 Standard for requirements for the Control of Electromagnetic Interference Characteristics of Replaceable Electronic Modules
- IEC 60146, Semiconductor converters—Basic requirements: Part 1-1: Line Commutated converters and Part 1-2: Self-commutated semiconductor converters including d. c. converters
- IEC 61800 all parts, Adjustable speed electrical power drive systems
- ANSI/UL 347A Medium Voltage Power Conversion Equipment
- ANSI/UL 508C-2008 Power Conversion Equipment
- ANSI/UL 61800-5 all parts, Adjustable Speed Electrical Power Drive Systems
- NEMA Standards Publication ICS 1.1 Safety Guidelines for the Application, Installation, and Maintenance of Solid-State Control
- NEMA ICS 7.2 Application Guide for AC Adjustable Speed Drive Systems
- NEMA Standards Publication IC 10 Industrial Control and Systems Part 2: Static AC Transfer Equipment
- UL 1008S Standard for Solid-State Transfer Switches

43.3 Examples of IEEE Power Electronics Standards

43.3.1 IEEE Std 1662-2016 "Recommended Practice for the Design and Application of Power Electronics in Electrical Power Systems"

This standard was sponsored by the Industrial Applications Society (IAS) and cosponsored by the Power Electronics Society (PELS). The standard recommends that power electronics equipment should do the following:

- Take self-protection actions regardless of the status of communications by reflexive actions to maintain continuity of power.
- Respond to internal and downstream faults.
- Sustain communications and ability to perform control actions following a loss of input voltage to permit detection, isolation, and system reconfiguration following a casualty condition.
- Latch parameter values at the time of the fault and communicate status to higher-level outside controllers.
- Interact with other power electronics equipment for power flow management and fault handling.
- High-resistance grounding preferable on the source side of isolated and otherwise ungrounded three-wire, three-phase distribution systems with voltages over 1000 V and aggregated power above 1.5 MW.
- PE should have a minimum efficiency of 95% (5% total losses) at rated load condition. PE should be provided with an overload rating of 150% for 1 min.

Three sets of test recommended to be conducted on power electronics equipment:

- Type test—Test of one or more devices made to a certain design to demonstrate that the design meets certain specifications.

- Production test—A test conducted on every unit of equipment prior to shipment.
- Commissioning test—A test conducted when the equipment is installed to verify correct operation.

43.3.2 IEEE Std 1676-2010 "Guide for Control Architecture for High Power Electronics (1 MW and Greater) in Electric Power Transmission and Distribution Systems"

This standard sponsored by the IEEE Power Engineering Society (PES) recommends the use of Power Electronics Building Block (PEBB) concept in electric power systems. It recommends PEBB multilayer control architecture and states, for example:

- The interface between layers should be designed to enable layer modularity such that replacement of any layer should not induce modifications in other layers.
- The communication speed requirements at the lowest or hardware layer are the greatest and decline with each higher control layer.
- In order to preserve the hierarchical architecture, horizontal communication between layers should be avoided.
- It is also recommended that each converter have its own independent switch control to serve its hardware control.

43.3.3 IEEE Std 1826-2012 "IEEE Standard for Power Electronics Open System Interfaces in Zonal Electrical Distribution Systems Rated Above 100 kW"

This standard was sponsored by the Industrial Applications Society (IAS) and cosponsored by the Power Electronics Society (PELS). The standard applies in cases where power electronics is the interface between the zones and extends application of IEEE Standards 1662 and 1676. It states that each power electronics device attached to the power bus shall meet following criteria:

1. Each device shall conform to standard control and power interfaces.
2. Each device shall have functionality that lets it "play well" with other power electronics devices including having the same protection and safety features.
3. Each device shall be capable of information exchange and reconfiguration of the system in response to load demands, changes of the mission, or new technologies insertion.

Any standard is always available from standard publishers.

43.4 Conclusions

- The best definition of the importance of standards is the famous saying by Admiral Rickover: "You have to learn from the mistakes of others. You won't live long enough to make them all yourself."
- Standards establish baseline for customer's selection and acceptance of products.
- Standards are collective practical experience of many generations of engineers. They are the best tools to avoid mistakes and do things right from the first attempt.
- Standards are risk reduction in applying new power electronics technologies by combining established industrial practices with the latest innovations and modern analytic tools.
- Standards are best defense from outrageous regulators demands and frivolous lawsuits.
- The latest editions of any standard are always available from the standard publisher.

44.1 Introduction

This chapter shows how power electronics, electric motors, and drives can be simulated with modern spice-based software simulation tools. The focus will be on LTspice, which is widely used and available for free download for all contemporary (2016) Windows 7, 8, and 10 PCs. The LTspice examples have been developed for the current LTspice IV version of the software [1]. LTspice lends itself especially well to simulations of switch-mode power electronics circuits since it was designed to support Linear Technologies' family of products. This product line includes a large number of switch-mode power conversion parts. This manifests itself in the stability of the simulator during switching transitions. The author found the use of these examples is very beneficial in an educational environment, since the examples can be shared with students to enhance their understanding of the lecture material. The concepts and examples presented here can also be used for serious professional work. In fact, the author has used these tools with great success in many research projects. In addition to LTspice, PTC Mathcad [2] has been used to derive and present the underlying equations. Equations created in Mathcad look as perfect as in the best typesetting software, but they can also be evaluated numerically and manipulated symbolically to derive additional equations and to validate the underlying theory.

The software examples have been developed to illustrate advanced techniques for the simulation of power electronics and motor drives but not to teach the basic features of LTspice. For that, the reader shall be referred to the online documentation [1]. In addition, it is assumed that the reader is familiar with the basics of power electronics and electric machines, specifically AC induction machines. For a review, the reader shall be referred to [3] for power electronics and [4,5] for induction machines.

44.2 Use of Simulation Tools for Design and Analysis

It is appropriate to reflect upon the value of simulations and its place in the design and analysis process before any in-depth discussion of specific simulation examples. Computer simulations enable engineers to study the behavior of complex and powerful systems without actually building or operating them. Simulations therefore have a place in the analysis of existing equipment and the design of new systems. In addition, computer simulations enable engineers to safely study high-power circuits including abnormal operating conditions without actually creating such conditions in a real environment.

However, even the most advanced simulation software cannot perfectly represent all effects in real hardware. The accuracy of the results depends on the accuracy of the component models and the proper identification and inclusion of parasitic circuit elements such as parasitic inductance, capacitance, and mutual coupling. Discrepancies between simulation and experimental results often occur if the underlying assumptions for the device model have been exceeded. For example, an attempt to model transformer inrush with a transformer model that assumes linear magnetics would not yield useful results.

Copyright © 2018 Elsevier Inc. All rights reserved.
http://dx.doi.org/10.1016/B978-0-12-811407-0.00049-0

In particular, the precise prediction of voltage and current traces during fast switching transitions in power electronics circuits has been proven to be difficult. To obtain useful results, extensive experimental validation, advanced device models (and the values for their parameters!), and detailed knowledge of parasitic elements, including the ones associated with the packaging of the circuit elements, are necessary. Therefore, the exact prediction of waveforms during switching transitions shall be excluded from the discussions in this chapter. Consequently, the author prefers to measure parameters such as voltage rise and fall times and over- and undershoot on actual circuitry in the laboratory.

Sometimes, users of spice-based simulators claim that the simulations of power electronics circuits with steep signal transitions are difficult due to convergence problems. However, with the proper techniques of gate signal generation, we can simulate just about any given circuit with little or no convergence problems in many spice-based tools. In addition, if convergence problems are avoided, simulations run much faster and larger numbers of individual transitions can be studied. This is achieved by generating gate signals using dependent sources with mathematical functions that produce switching signals that are differentiable throughout the transition. Being able to run simulations with a large number of transitions fast and without convergence problems gives a lot of insight into the cycle-by-cycle and the system level behavior of a power electronics circuit. An excellent application for these cycle-by-cycle simulations is the development and verification of control strategies for the power semiconductors in power electronics circuits.

Dependent voltage and current sources included in LTspice can be used to study large and complex systems like field-oriented (also called vector) control of induction machines if the proper mathematical control functions are used. Details are given below. In the examples for vector control of induction motors, the power electronics inverter is replaced with a dependent voltage source that represents the short-term average (filtering away the high-frequency voltage components associated with the switching frequency) of the output of a three-phase inverter. These examples represent system level simulations, which could have also been done using programs like MatLab/Simulink. However, circuit simulation software also provides the option of studying actual circuit level details in complex systems. To demonstrate this capability, the start-up of an induction motor, fed by a three-phase inverter with actual switch-mode operation, is presented.

In all modeling cases, the user needs to define the goal of the simulation effort. In other words, the user must answer the question "What information shall be obtained through the simulation of the circuit or system?" The user must then select the appropriate simulation software and the appropriate models. This process requires a detailed understanding of the properties and limitations of the device models and the sensitivity of the results to the limitations of the models. In order to obtain such an understanding, it is often recommended and necessary to perform numerous simulation test runs, carefully scrutinize the results, and compare them with measured data, results from other simulation packages, or otherwise known facts.

44.3 Simulation of Power Electronics Circuits With LTspice

The first example of a power electronics circuit is a step-down (also called buck) converter with synchronous rectification. For the purpose of synchronous rectification, the diode, which connects the inductor to ground in the regular circuit, is replaced with a power MOSFET transistor. The benefit of this circuit is that the power MOSFET represents a purely resistive channel in the on state. This channel does not have a residual, current independent, voltage drop like the p-n junction of a diode. Therefore, the voltage drop across the MOSFET can be much lower than what can be achieved with diodes. The results are reduced losses and increased efficiency. To achieve this, the lower MOSFET must be turned on whenever the upper MOSFET is turned off.

Fig. 44.1 shows a simulation setup for a synchronous buck converter. This converter steps down from 12 V input voltage to 3.3 V at the output. As mentioned before, the key element of this example is the circuit for the generation of the gate-drive signals for the MOSFETs. The basic principle of the operation of the gate-drive circuit is the well-known carrier-based scheme [3], where a control voltage is compared with a triangular carrier with fixed amplitude. The dependent voltage source *tri* on the left border of Fig. 44.1 generates the triangular carrier. Eq. (44.1) shown below gives the closed form equation for the triangular carrier wave. The output range of the function shown in Eq. (44.1) is between 0.0 and 1.0:

$$E_{\mathrm{tri}}(t) := \frac{1}{2} + \frac{1}{\pi} \cdot a\sin\left(\sin\left(2 \cdot \pi \cdot F_{\mathrm{SW}} \cdot t\right)\right) \tag{44.1}$$

For the generation of the gate-drive signals, the carrier wave is compared with a control signal that can have values between 0.0 and 1.0, corresponding to a duty cycle input between 0% and 100%. Dependent voltage sources *E_PWMa* and *E_PWMb* in Fig. 44.1 generate the PWM signals for the MOSFETs *M1* and *M2*, which are included in the LTspice library. A hyperbolic tangent function is used to create a PWM waveform with smooth transitions to aid in convergence. Fig. 44.2 shows a plot of a hyperbolic tangent function to illustrate the concept. The *Gain* parameter is used to steepen the curve to resemble realistic PWM signal transitions. In Fig. 44.2, the *Gain* is varied between 1 and 5. In the control functions for *E_PWMa* and *E_PWMb*, the factor 15 in front of the tanh function generates an output voltage that varies between −15 and +15 V. Note the inverse polarities on the inputs of sources *Dr1* and *Dr2* generate the complementary gate-drive signals.

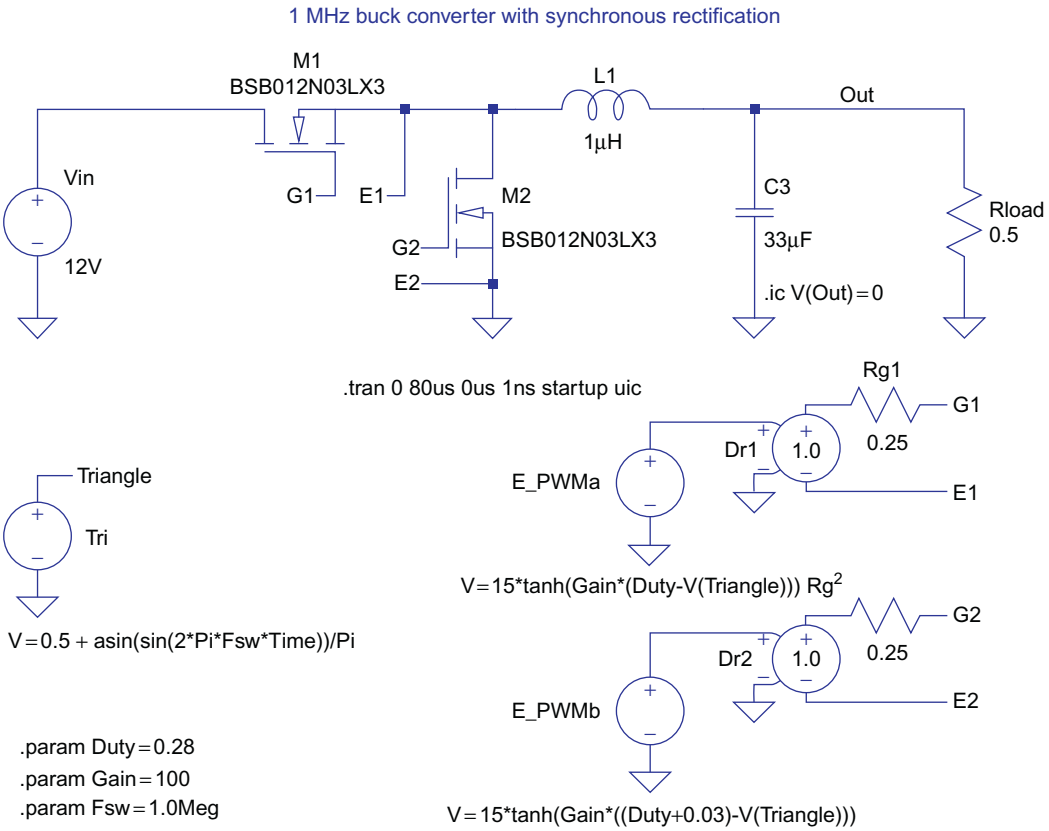

FIG. 44.1 LTspice simulation setup for a synchronous buck converter.

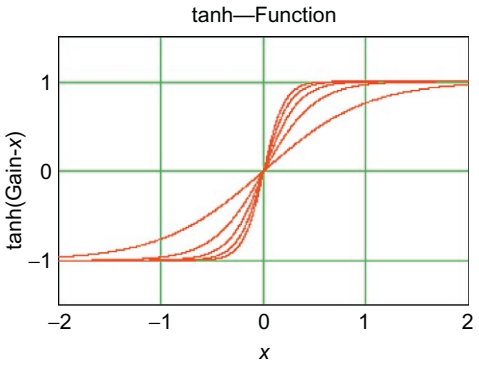

FIG. 44.2 Plot of a hyperbolic tangent function used to generate smooth PWM signals.

Careful inspection of Fig. 44.1 shows that 3% duty cycle *0.03* is added to generate the gate-drive signal of the lower (synchronous rectification) MOSFET to create some blanking time between the drive signals and avoid cross conduction between the MOSFETs *M1* and *M2*.

Fig. 44.3 shows the calculated voltage and current traces for the synchronous buck converter. The top-level pane shows the generated triangle carrier. It has a frequency (Fsw; see parameter statement in Fig. 44.1) of 1.0 MHz. The graph below the triangle signal shows the inductor current and the current in the load resistor. The bottom trace shows the capacitor voltage, which has a steady-state value of 3.3 V.

In addition to the cycle-by-cycle simulation of a DC-DC converter, it is also possible to use a time-averaged replacement for the MOSFET transistors used in the circuit in Fig. 44.1. In fact, a common time-averaged model can be used for the buck, the boost, the buck-boost, and the Cuk converter as long as they operate with continuous inductor current. The time-averaged model has the advantage that it can run much faster since it does not have to follow each switching transition. It is also possible to perform DC and AC sweep analyses. A DC sweep would sweep the duty cycle over a wide range and show the output voltage as a function of the duty cycle. An AC sweep analysis would sweep the frequency of an AC signal, which is superimposed on top of the duty cycle bias signal. The AC sweep allows the study of the behavior of the converter, including a feedback control system, in the frequency domain for traditional stability analysis and system tuning. A detailed description of this time-averaged modeling technique, including detailed examples, is given in [6].

To illustrate the capabilities of the LTspice simulation program, the next example shows a complete three-phase inverter using six power MOSFETs. This circuit is shown in Fig. 44.4.

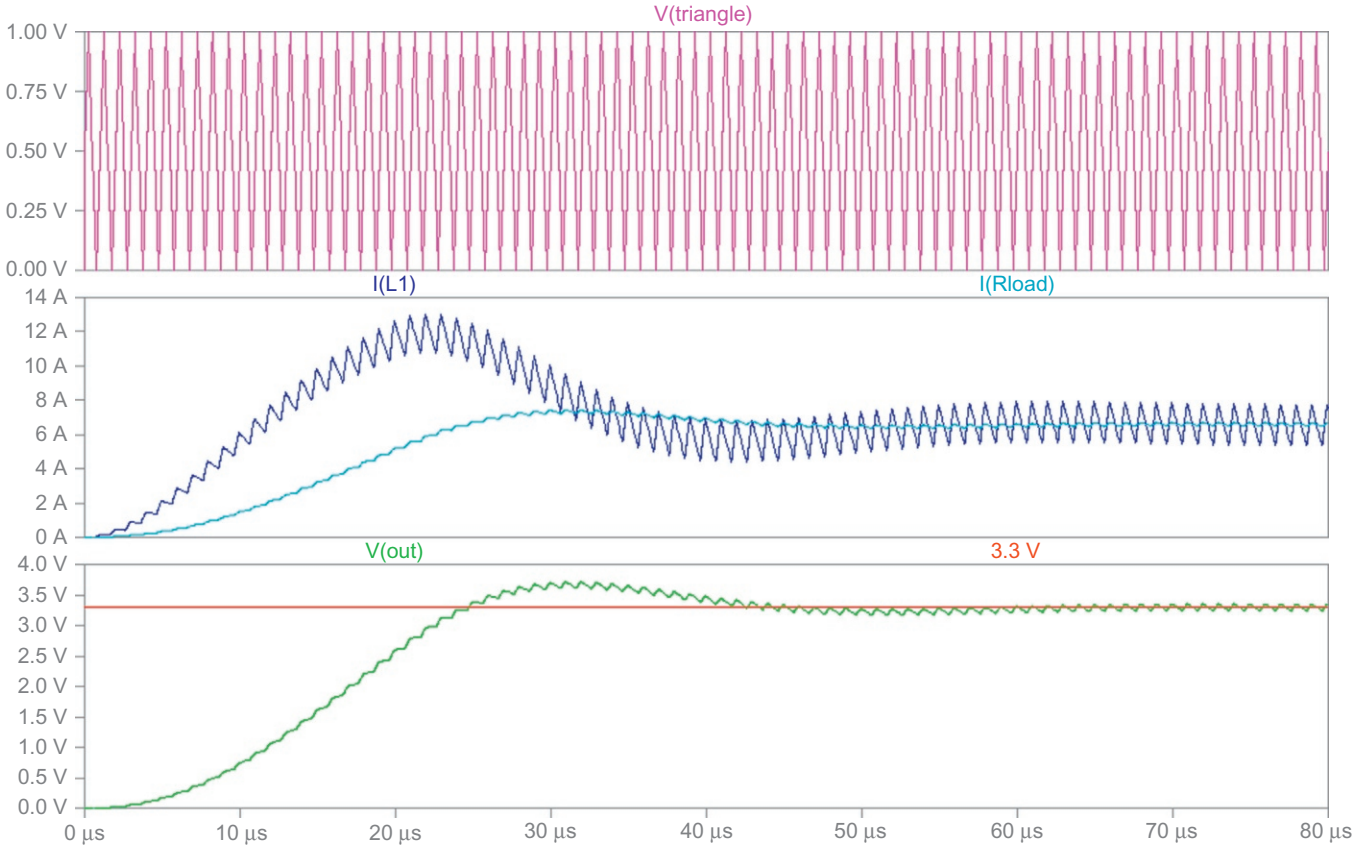

FIG. 44.3 Output waveforms for the synchronous buck converter.

Such an inverter needs antiparallel diodes connected across each power semiconductor to ensure that the load current can flow continuously. These diodes are often called freewheeling diodes. Here, the freewheeling diodes are an integral part of every power MOSFETs (body diodes) and are therefore not visible. The inverter drives a three-phase load, which represents the 5 hp induction motor used later. The R and L values represent rated load conditions. The load is connected to the inverter output terminals via labels (A,B,C).

Due to the number of elements involved, the circuit for the gate-drive signal generation is contained in a custom part named *PWM1*. Custom parts like this can easily be generated using the "Hierarchy—Create a New Symbol" menu path in the LTspice schematic editor. Double-clicking on the part reveals the associated subcircuit that is shown in Fig. 44.5. The arrow-shaped symbols on the right side of Fig. 44.5 named *G1*, *E1*, *G2*, etc. are called interface ports and are the outputs of the gate-drive circuit to the MOSFETs. These interface ports provide the connection between the subcircuit and the ports of the custom part. These ports on the custom part are created using the "Edit—Add Pin/Port" menu path in the LTspice schematic editor. The arrow-shaped symbols on the left side of Fig. 44.5 are inputs for the fundamental output frequency and the modulation index. The names of these ports in the subcircuit (must!) correspond to the names of the ports of the custom symbol.

The circuit shown in Fig. 44.5 is similar to the gate-drive generation circuit discussed before. As in the PWM generation circuitry shown in Fig. 44.1, a triangular carrier is compared with a reference signal. In this case, three reference signals, one for each phase, are compared with 3 PWM sources (*E_PWM_A*, *E_PWM_B*, and *E_PWM_C*) to create the gate-drive signals for all three phases. Again, the factor 15 in front of the tanh functions generates an output voltage that varies between −15 and +15 V for driving the gates of the MOSFETs. Here, the triangular carrier signal is symmetrical with respect to the time axis and covers the range from −1.0 to 1.0. The closed form expression for the triangular carrier is given by Eq. (44.2):

$$E_{\text{tri}}(t) := \frac{2}{\pi} \cdot a\sin\left(\sin\left(2 \cdot \pi \cdot F_{\text{SW}} \cdot t + \frac{\pi}{2}\right)\right) \tag{44.2}$$

The three reference signals are sinusoidal signals with equal amplitude and a relative phase shift of 120°. For linear modulation, the amplitude range of the reference signals is limited to the amplitude of the triangular carrier, for example, 1 V. The ratio of the reference wave amplitude and the (fixed) carrier amplitude is called amplitude modulation ratio *Mod*. In the

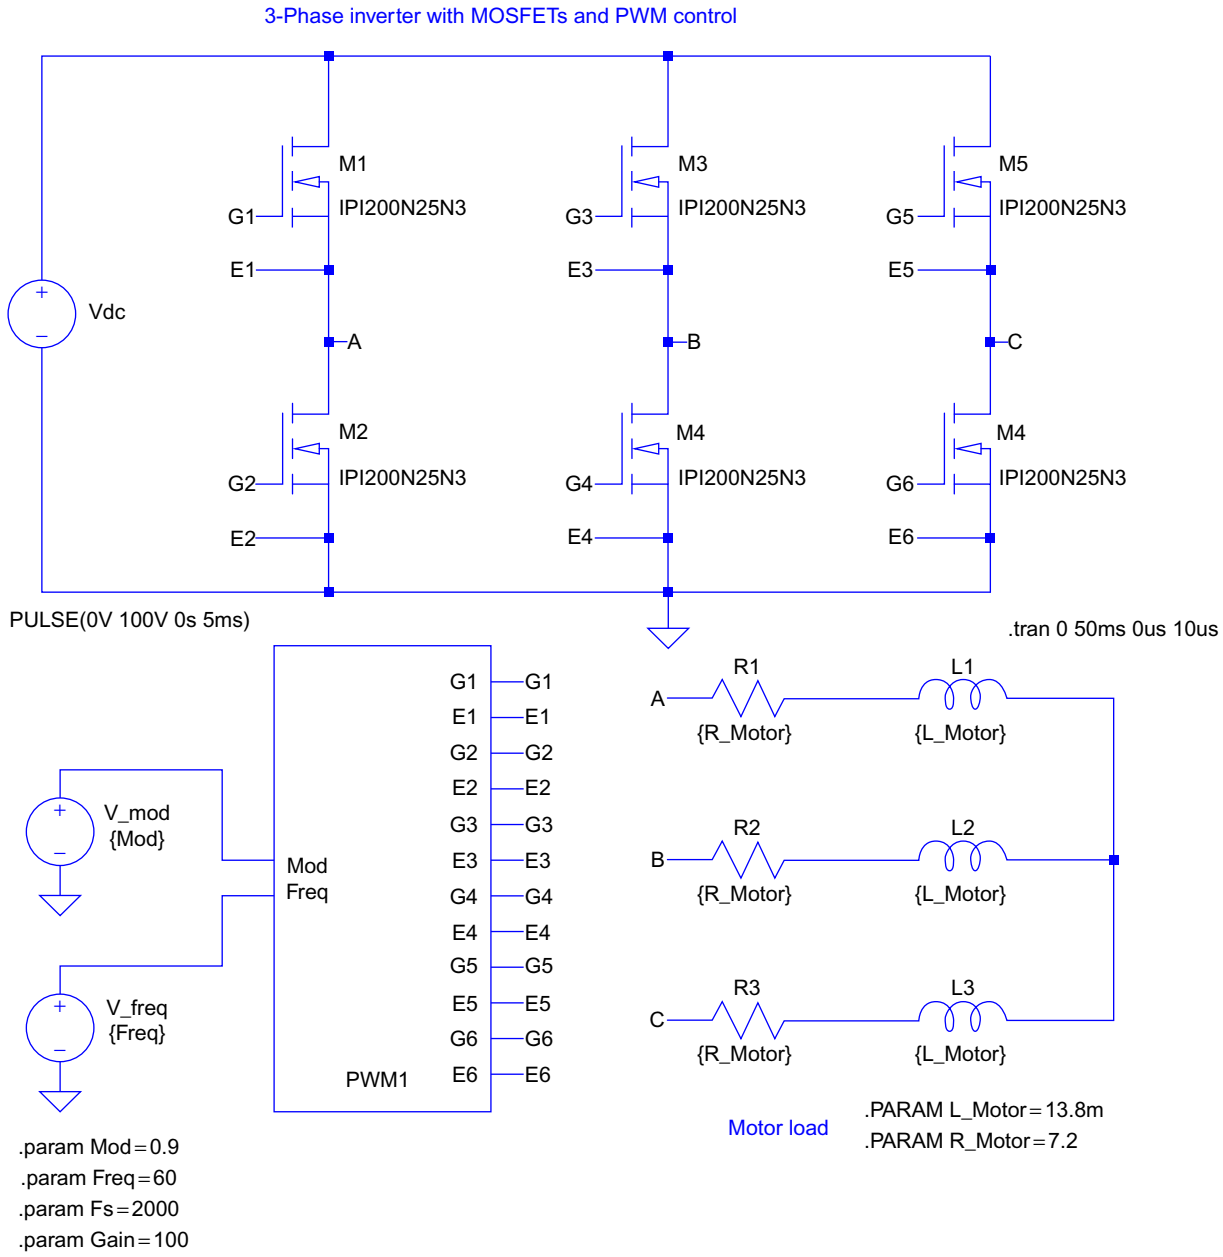

FIG. 44.4 Circuit for a three-phase inverter with MOSFETs.

circuit shown in Fig. 44.4, *Mod* has a value of 0.9. This value is defined by a parameter symbol at the top level and therefore represents a global parameter, which is visible throughout all levels of the hierarchy. The amplitude of the phase-to-neutral voltage of each inverter leg is equal to half of *Vdc* (shown in Fig. 44.4) multiplied with the amplitude modulation ratio. The frequency and wave shape of the phase-to-neutral voltage of each phase leg is equal to the reference waveform if the high-frequency components resulting from the carrier wave are filtered away. Each inverter leg can be viewed as a power amplifier for its reference voltage. In fact, in drive applications, inverters are often called "servo-amplifiers." The load typically reacts only to the low-frequency components of the inverter output voltage. The high-frequency components, which include the triangular carrier frequency (also called switching frequency) and its harmonics, are typically "just a blur" for the load. These are especially true in recent times, where switching frequencies of 20 kHz and above are possible. As an added benefit, audible noise is avoided at these frequency levels.

The complementary sources *Dr1/Dr2*, *Dr3/Dr4*, and *Dr5/Dr5* in combination with the gate resistors will generate the control voltages for the transistor pairs of each leg. Using this circuitry will ensure that during switching transitions in each

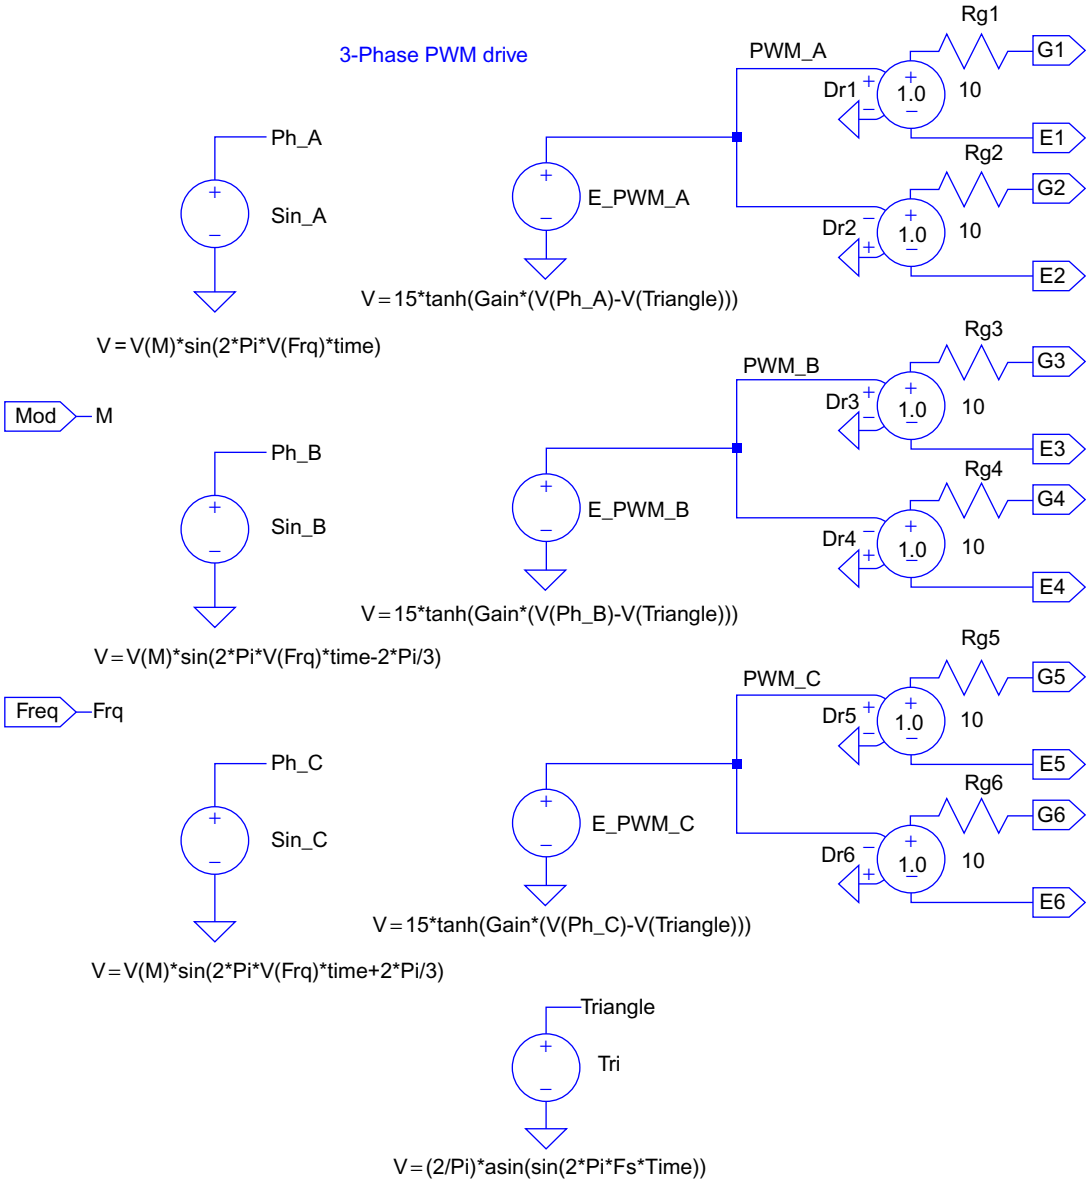

FIG. 44.5 PWM generation subcircuit for a three-phase MOSFET inverter.

phase leg, the gate voltage of the transistor that is turning off will fall below the turn-on threshold before the gate voltage of the transistor that is turning on reaches that threshold. Therefore, a shoot through, meaning a short circuit between the positive and negative bus, is avoided.

Fig. 44.6 shows the simulation results for the three-phase inverter. The timescale is slightly stretched, to better show the details of the PWM signals. The line-to-line voltage V_{AB} and the load current in all three phases are shown. Due to the inductors contained in the load, the current cannot instantaneously change and follow the PWM signal. Therefore, the load currents are almost pure sinusoids with very little ripple. This is representative of the real line currents in induction motors.

Fig. 44.7 shows an example where the MOSFETs in Fig. 44.4 have been replaced with insulated gate bipolar transistors (IGBTs). The spice model of the particular IGBTs shown here is included on the right side of the schematic. Note that freewheeling diodes are needed, if IGBTs are used. The freewheeling diodes carry the load current when the IGBTs are turned off to provide a continuous path for the current. This is very important, since the load can have a substantial inductive component. Whenever the diodes are conducting, energy flows momentarily back to the source. In the case of power MOSFETs, the diodes (often called body diodes) are an integral part of the device. In the symbol graphic of LTspice, these body diodes are not shown for MOSFETs. For this circuit, the gate-drive circuit and the results are the same as for the

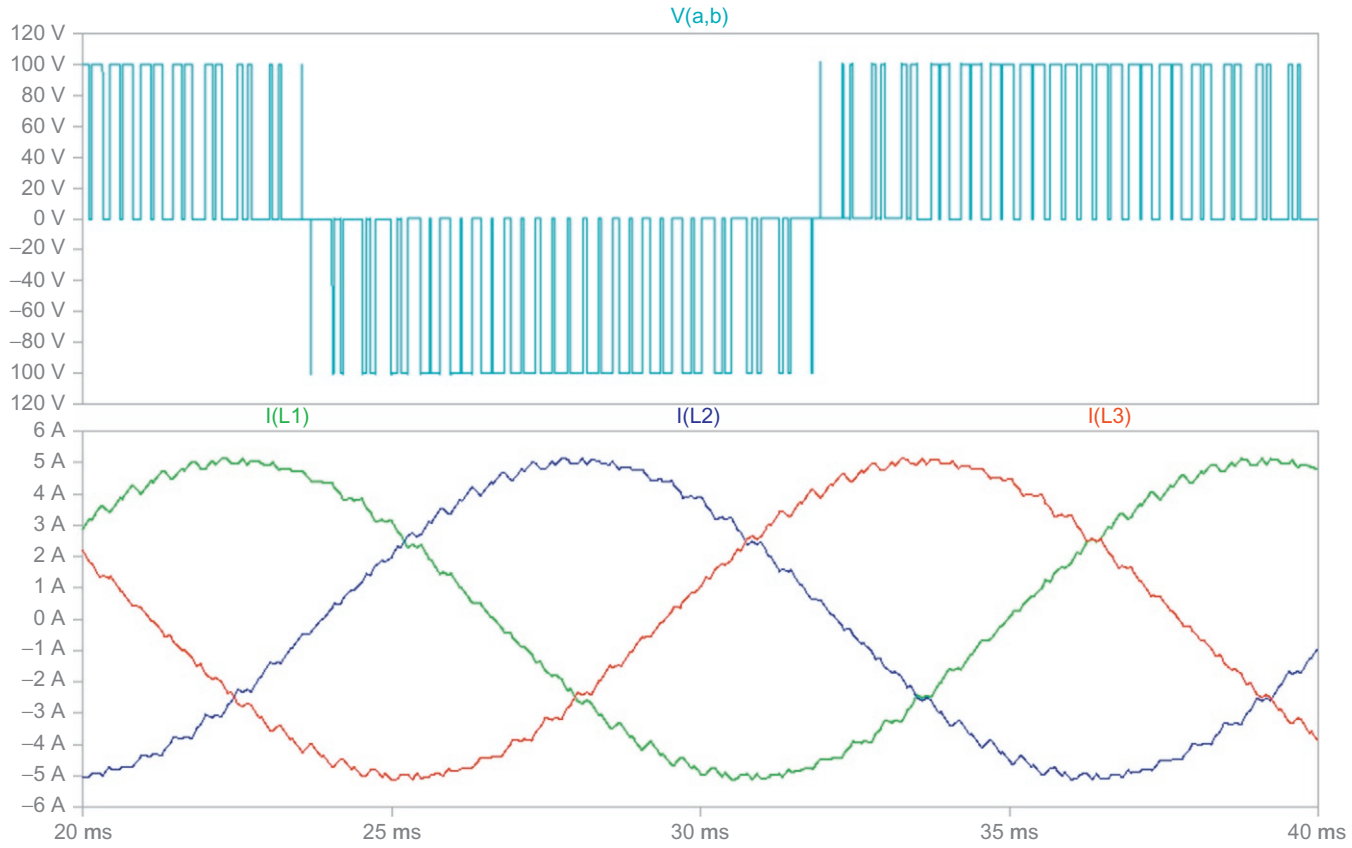

FIG. 44.6 Output waveforms of the three-phase inverter with MOSFETs.

three-phase inverter with power MOSFETs. This circuit returns the same results than the one shown in Fig. 44.6 except that the simulation runs a lot longer (minutes rather than seconds) due to the complexity of the IGBT models.

44.4 Simulations of Power Electronic Circuits and Electric Machines

In the following, the start-up of an induction motor, fed by a three-phase inverter similar to the ones shown in Figs. 44.4 and 44.7, is presented. For this purpose, the simple passive load in Figs. 44.4 and 44.7 has been replaced by a complete dynamic model of an induction motor. Also, the MOSFETs or IGBTs from Figs. 44.4 and 44.7, respectively, have been replaced by generic voltage-controlled switches. This will increase the simulation speed even more dramatically compared with the case with IGBTs with very little effect on accuracy since this simulation is meant to study the start-up behavior of an induction motor. For this and further discussions, it is assumed that the reader is familiar with the theory of induction machines and in particular their dynamic behavior. A number of excellent references are given at the end of this chapter [4,5,7,8]. The induction motor symbol represents the electromechanical model of an induction motor. The model is suitable for studies of electric and mechanical transients and steady-state conditions. The output pin on the motor shaft represents the mechanical output. The voltage on this pin represents the mechanical angular velocity using the relation 1 V = 1 rad/s. In addition, any current drawn from or fed into this terminal represents applied motor or generator torque according to the relation 1 A = 1 N m. Due to these definitions, the electric power associated with the voltage of the motor shaft (with respect to ground) is identical to the mechanical power. Following the well-known theory, the induction motor model has been derived for a two-phase (direct and quadrature, D, Q) equivalent motor. Attached to the motor is a bidirectional two-phase to three-phase converter module. This module is voltage and current invariant. This means that the voltage and current levels in the two-phase and the three-phase machine are equal. Consequently, the power in the two-phase machine is only two-thirds of the power in the three-phase circuit. This is accounted for in the calculation of the electromagnetic torque (factor 3/2; see Eq. (44.4)). The internally generated torque can be monitored on the output labeled *Torque* on top of the sleeve around the motor shaft. The linear load in Fig. 44.8 is a symbol that represents an appropriately

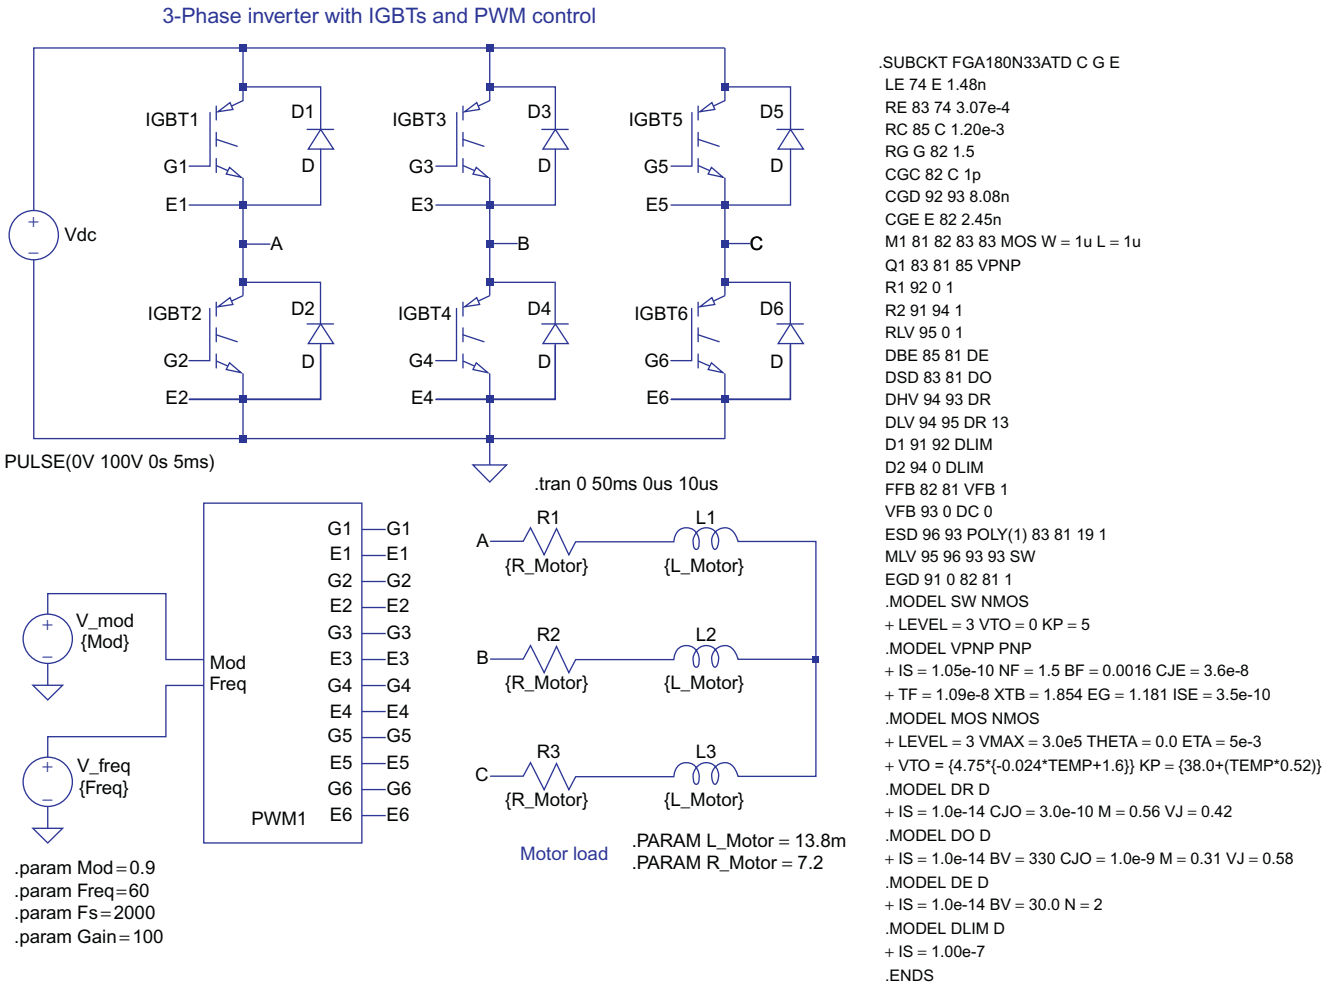

FIG. 44.7 Three-phase inverter circuit with IGBTs.

sized resistor to the ground representing rated power that is 5 hp for this example.

In Fig. 44.8, the motor is represented by a custom symbol called *induction machine*. The symbol can be easily created using the "Hierarchy—Create a New Symbol" menu path in the LTspice schematic editor. The editor provides standard graphic elements (lines, rectangles, circles, etc.) so that professional-looking symbols can easily be created.

Double-clicking on the motor symbol reveals the associated subcircuit that implements its function. This subcircuit is shown in Fig. 44.9. The left part of this subcircuit represents the electric model. The electric model calculates the stator and rotor currents, with the stator voltages and the mechanical speed of the machine being input parameters. However, it is also possible without any changes to feed stator currents (with controlled current sources) into the D and Q inputs. This option is useful for vector control applications, which are discussed later.

The equation system for the electric model of a two-phase induction machine is given by Eq. (44.3). The theory for this equation system is derived in [4,5,7,8]. The equation system and the model are formulated for the stationary reference frame. This reference frame assumes that the frame of the machine is stationary and the voltages and currents of the rotor are equivalent AC values with stator frequency.

From machine theory, we know that the actual rotor currents have slip frequency. Another reference frame is the synchronous (also called excitation) reference frame. In this reference frame, the stator of a fictitious machine is assumed to rotate with synchronous speed. The advantage of this reference frame is that the input frequency is zero (DC), which makes it easy to derive the principle of vector control by extending the theory of DC machines to AC machines:

$$\begin{bmatrix} V_d \\ V_q \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} R_{stat}+pL_s & 0 & pL_m & 0 \\ 0 & R_{stat}+pL_s & 0 & pL_m \\ pL_m & \omega_e L_m & R_{rot}+pL_r & \omega_e L_r \\ -\omega_e L_m & pL_m & -\omega_e L_r & R_{rot}+pL_r \end{bmatrix} \begin{bmatrix} I_{sd} \\ I_{sq} \\ I_{rd} \\ I_{rq} \end{bmatrix}$$

$$L_s = L_m + L_{s1} \qquad L_r = L_m + L_{r1} \quad p = \frac{d}{dt} \tag{44.3}$$

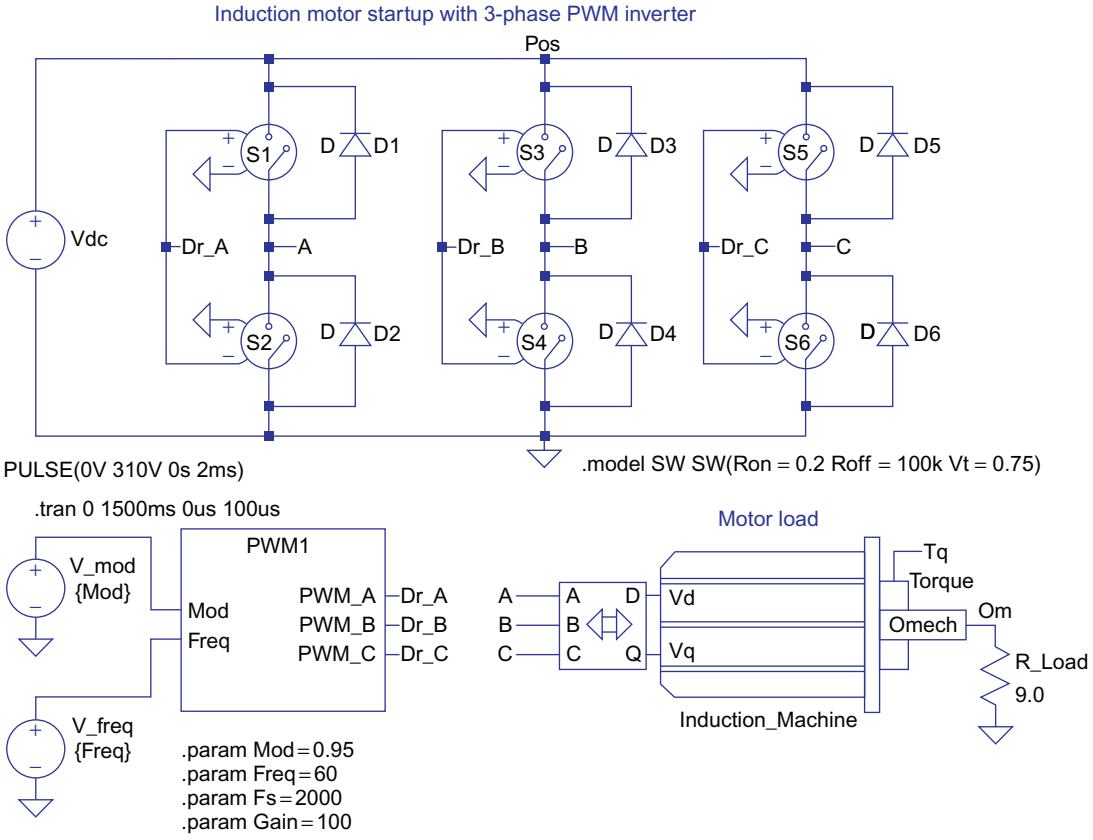

FIG. 44.8 Induction motor start-up with three-phase inverter circuit.

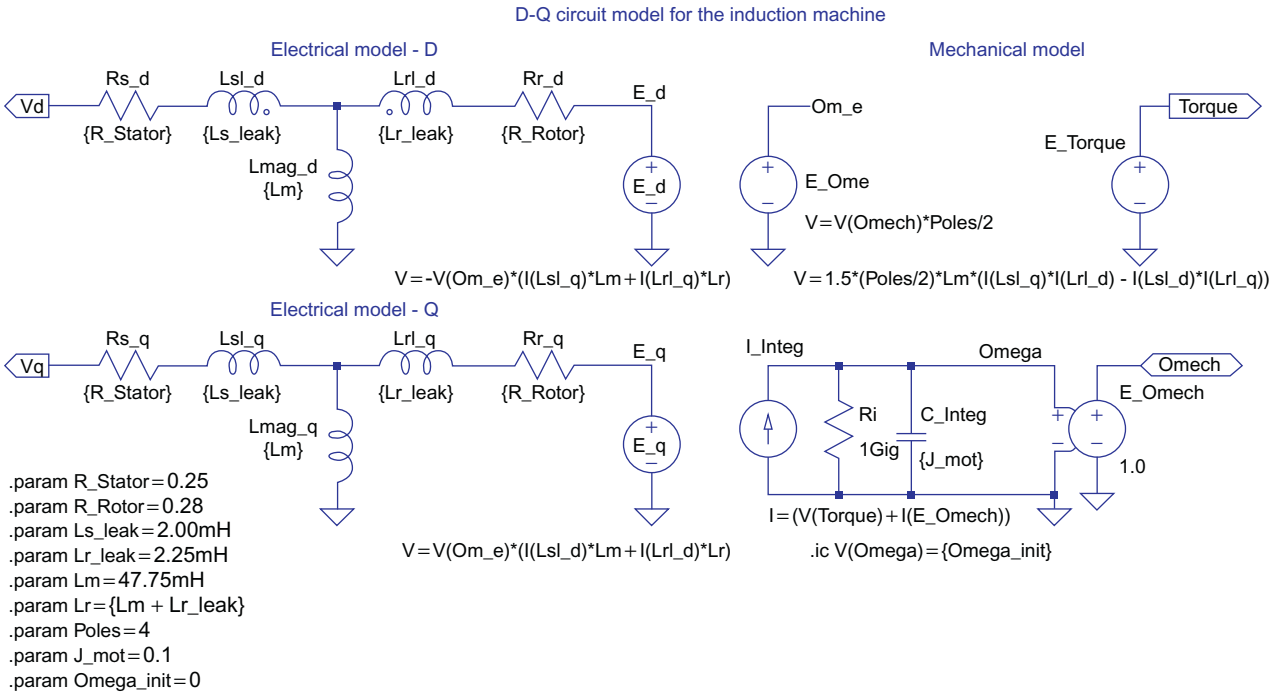

FIG. 44.9 Subcircuit for induction motor model.

In typical implementations of vector control using digital signal processors (DSPs), the synchronous reference frame is used internally to calculate the reference values for the currents in the D- and Q-axis. These values are then transformed to the stationary reference frame in an additional step. Sometimes, still other reference frames are used, and it is possible to generate a universal electric model with a reference frame speed input. This model could then be used for any reference frame.

The electric model in Fig. 44.9 implements the equation system shown in Eq. (44.3). The circuit closely resembles the well-known T-equivalent circuit for the steady-state analysis of induction machines. Two instances of the T-equivalent circuit are necessary to implement the two-phase (D, Q) model. The right part of the schematic in Fig. 44.9 represents the mechanical model. This circuitry calculates the internally generated electromagnetic torque, using the rotor and stator currents as input values. The equation for the internal electromagnetic torque of the induction machine is given by Eq. (44.4) [4,5,7,8]. The factor 3/2 accounts for the fact that the real motor is a three-phase machine. The generated torque is used to calculate the angular acceleration of the motor shaft considering the load torque and the moment of inertia. Integration of the angular acceleration yields the rotor speed, which is used in the electric model:

$$T = \frac{3}{2}\frac{P}{2} L_m \left(I_{sq} I_{rd} - I_{sd} I_{rq}\right) \tag{44.4}$$

Since almost all induction machines are three-phase machines, it is often desirable to have a machine model with a three-phase input. Therefore, a bidirectional two-phase to three-phase converter module, which can be attached to the motor, has been developed. A subcircuit for this module is shown in Fig. 44.10.

This circuit is truly bidirectional, meaning that the circuit can be fed with voltage or current sources from either side. The equation system for this voltage and current-invariant transformation is given by Eq. (44.5). This transformation is sometimes called "Clark" or "ABC-DQ" transformation. The voltage V_0 in Eq. (44.5) denotes a zero-sequence voltage, which is assumed to be zero and not implemented in the subcircuit shown in Fig. 44.10. This voltage would only have nonzero values for unbalanced conditions. An interesting detail of the subcircuit in Fig. 44.10 is the addition of high-value resistors on each input. These resistors provide a small current path from the three-phase input to the ground and ensure stable operation if the module is fed with current sources;

$$\begin{bmatrix} V_d \\ V_q \\ V_o \end{bmatrix} = \frac{1}{3}\begin{bmatrix} 2 & -1 & -1 \\ 0 & \sqrt{3} & -\sqrt{3} \\ 1 & 1 & 1 \end{bmatrix}\begin{bmatrix} V_a \\ V_b \\ V_c \end{bmatrix}$$
$$\begin{bmatrix} V_a \\ V_b \\ V_c \end{bmatrix} = \frac{1}{2}\begin{bmatrix} 2 & 0 & 2 \\ -1 & \sqrt{3} & 2 \\ -1 & -\sqrt{3} & 2 \end{bmatrix}\begin{bmatrix} V_d \\ V_q \\ V_o \end{bmatrix} \tag{44.5}$$

Fig. 44.11 shows the result for the start-up of the induction motor for the circuit of Fig. 44.8. The motor is a 5 hp, 208 V, 4-pole machine. The detailed parameters are shown in Table 44.1. The PWM generation was derived from the example shown in Fig. 44.4. The top trace in Fig. 44.11 shows the mechanical angular velocity with a scale of 1 V = 1 rad/s. The middle trace shows the developed electromagnetic torque, including the level for the rated steady-state torque (20 N m as commanded by the load in Fig. 44.8) and the zero level. This graph shows the typical oscillatory torque production of the induction machine for an uncontrolled line start. The scale for this graph is 1 V = 1 N m. The bottom trace of Fig. 44.11 shows the input current for phase A.

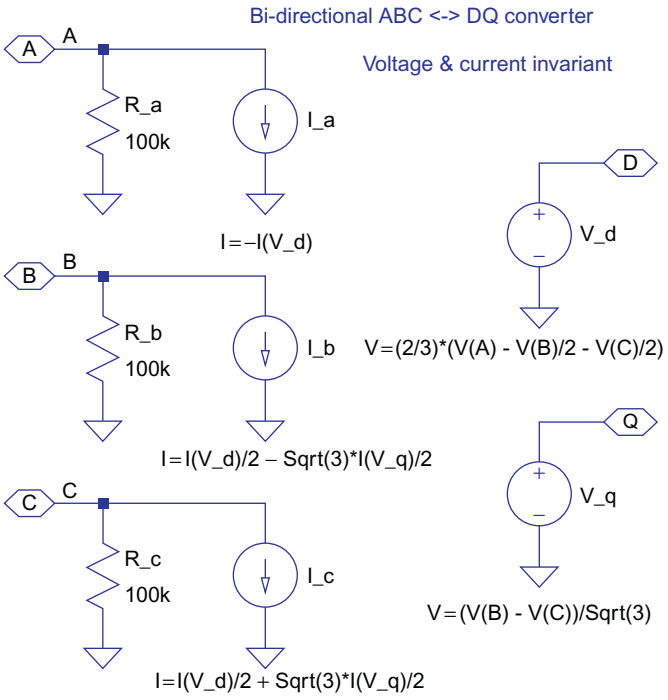

FIG. 44.10 Subcircuit for the ABC-DQ transformation module.

It is evident that the current trace is an almost perfect sinusoid, despite the fact that the input voltage is a PWM waveform. Also, the trace for the torque shows only a small high-frequency ripple. The reason is, of course, that the motor windings are inductive and represent a low-pass filter for the applied voltages. Nevertheless, recent research suggests that filtering the output voltage of the inverter is advantageous anyway, because it significantly reduces the voltage stress on the windings and suppresses displacement currents through the bearings [9].

44.5 Simulations of AC Induction Machines Using Field Oriented (Vector) Control

The following examples will demonstrate the use of LTspice for simulations of field-oriented control (FOC) of AC induction machines. Again, it is assumed that the reader is familiar with the basics of induction machine theory. Often times, FOC is

FIG. 44.11 Induction motor start-up with three-phase inverter circuit.

TABLE 44.1 List of all attributes used for the 5 hp, 208 V, 4-pole induction motor

Attributes
R_Stator = 0.25 Ω
R_Rotor = 0.28 Ω
Ls_leak = 2.00 mH
Lr_leak = 2.25 mH
Lm = 47.75 mH
Ls = Lm + Ls_leak
Lr = Lm + Lr_leak
kT = 1.5*(Poles/2)*Lm/Lr
Tau_r = Lr/R_Rotor
Sigma = 1 − Lm*Lm/(Ls*Lr)
Poles = 4
J_mot = 0.1 kg m^2
Omega_init = 0

also called vector control, and both expressions can be used interchangeably. The theory of vector control is described in detail in [4,7,8]. The idea was originally proposed in the 1960s by Hasse and Blaschke, working at the Technical University of Darmstadt [10]. The author had the privilege of taking one of Prof. Hasse's classes on machine control as an undergraduate student. The basic idea of FOC is to inject currents into the stator of an induction machine such that the magnetic flux level and the production of electromagnetic torque can be independently controlled and the dynamics of the machine resembles that of a separately excited DC machine. The previously discussed two-phase model for the induction machine is very helpful for studies of vector control and shall be used in all examples. If a two-phase induction motor model for the synchronous (or excitation) reference frame is used, the similarities between the control of a separately excited DC machine and vector control of an AC induction machine will be most evident. In this case, the D input corresponds to the field excitation input of the DC machine, and both inputs are fed with DC current. Assuming unsaturated machines, the current into the D input of the induction machine or the field current in the DC machine directly controls the flux level. The Q input of the induction machine would correspond to the armature winding input of the DC machine, and again, both inputs would receive DC current. These currents would directly control the production of electromagnetic torque with a linear relation (constant k_T) between the current level and the torque level. Furthermore, the Q component of the current would not change the flux level established by the D component (no cross coupling). To make such a simulation work, it would finally be necessary to calculate the slip value that corresponds to the commanded torque and use this value to calculate the speed of the synchronous reference frame of the machine model.

Of course, this is very interesting from an academic standpoint, and the author uses this example in a semester-long lecture on machines and drives. However, it should again be noted that a machine represented by a model with a synchronous reference frame would have a stator, which rotates with synchronous speed. Of course, this is not realistic, and therefore, it is more interesting to generate a simulation example that uses the previously discussed motor model for the stationary reference frame. This motor must be supplied with AC voltages and currents with a frequency determined mostly by the rotor speed and to a small extent (slip value) by the commanded torque. We still compute DC values representing the commanded flux and torque, but we transform these DC values to appropriate AC values. In the following example, we will assume that we can measure the actual rotor speed with a sensor. For this purpose, many types of sensors are available on the market. If we add the slip speed to the measured rotor speed, we obtain the synchronous speed for the given operating point. We determine the slip speed from the torque command. With this synchronous speed, we can transform the DC flux and torque command values from the synchronous reference frame to the stationary reference frame. We accomplish this by using a rotational transformation according to the matrix equations in Eq. (44.6). This rotational transformation is also called "Park" transformation. As shown in Eq. (44.6), the transformation is bidirectional, and the product of the transformation matrices yields the unity matrix:

$$\begin{bmatrix} V_{Dout} \\ V_{Qout} \end{bmatrix} = \begin{bmatrix} \cos(\rho) & -\sin(\rho) \\ \sin(\rho) & \cos(\rho) \end{bmatrix} \begin{bmatrix} V_{Din} \\ V_{Qout} \end{bmatrix}$$
$$\begin{bmatrix} V_{Dout} \\ V_{Qout} \end{bmatrix} = \begin{bmatrix} \cos(\rho) & \sin(\rho) \\ -\sin(\rho) & \cos(\rho) \end{bmatrix} \begin{bmatrix} V_{Din} \\ V_{Qout} \end{bmatrix} \tag{44.6}$$
$$\begin{bmatrix} \cos(\rho) & -\sin(\rho) \\ \sin(\rho) & \cos(\rho) \end{bmatrix} \begin{bmatrix} \cos(\rho) & \sin(\rho) \\ -\sin(\rho) & \cos(\rho) \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

For the following discussion, we shall define the transformation that produces AC values from DC inputs as a positive vector transformation and the reverse operation consequently a negative vector transformation. The matrix equation for the positive vector transformation is shown on the left side of Eq. (44.6). The negative transformation is very useful to extract DC values from AC voltages and currents for diagnostic and feedback control purposes. Both rotational transformations use the angle, α, in the equations. This angle can be interpreted as the momentary rotational displacement angle between two Cartesian coordinate systems, one containing the input values and the other the output values. This angle is obtained by integration of the angular velocity with which the coordinate systems are rotating (typically the synchronous speed).

In summary, we replaced a theoretical motor model using a synchronous reference frame by a reference frame transformation of the supply voltages and currents. In fact, modern DSPs are capable to perform both the Clark and the Park transformations in both directions at very high speeds. These DSPs are well supported with proved reference designs, including free software examples.

Fig. 44.12 shows the top level of a simulation example that implements vector control for an induction machine with a stationary reference frame model. The motor model and the associated subcircuits (Fig. 44.9) are identical to the ones used for the circuit shown in Fig. 44.8. As discussed above, the actual speed of the rotor is used as an input signal for the control unit. This scheme is known as indirect vector control and represents one of the most often used control methods. The symbol for the controller uses the same parameters as the motor. This is necessary to achieve correct field orientation. In real systems, the controller must be told or somehow determine the machine parameters. The machine parameters are contained in *.param* statements. If these *.param* statements are used at the top level of the hierarchy, they are global to the simulation, but if they are contained in a subcircuit, they are local to that subcircuit. Here, the vector controller and the induction motor

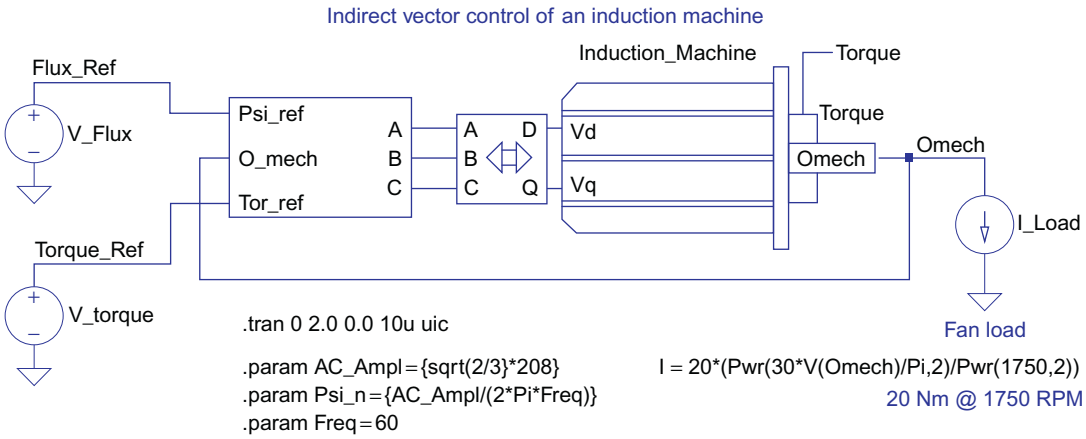

FIG. 44.12 Top-level circuit for indirect vector control of induction motors.

both have local parameters, which enables us to study the influence of parameter mismatch on the performance of the control.

Fig. 44.12 shows a dependent current source that represents a fan load for the motor. The current of this source represents the load torque and is proportional to the square of the mechanical speed of the motor shaft. That speed is represented by the voltage on the *Omech* terminal. The controlling equation is scaled such that the load draws the rated torque (20 A = 20 N m) at rated speed (1750 RPM). In this fashion, many more mechanical properties and devices can be modeled. For example, a mechanical flywheel is simply represented by a capacitor to the ground. Due to the scaling factors for the angular velocity and the torque, a flywheel with $J = 1$ kg m^2 would be a capacitor with a value of $C = 1$ F. The compliance of a driveshaft (elastic twisting by the applied torque) can be modeled by a series inductor. By including both capacitors and inductors, effects like mechanical resonance can be included in a model.

Fig. 44.13 shows the subcircuit for the vector control unit. The central part is a vector rotator for positive direction. This element transforms the DC reference values for the flux (D-axis) and the torque (Q-axis) to the stationary reference frame. The input angle for the vector rotator is the integral of the synchronous angular velocity. The signal called *Omech* is the measured rotor speed. The subcircuit for the vector rotator is shown in Fig. 44.14.

This speed is multiplied with the number of pole pairs (*poles*/2) to obtain the electric angular velocity. Then, the slip value (see Eq. (44.7) for slip frequency calculation for vector

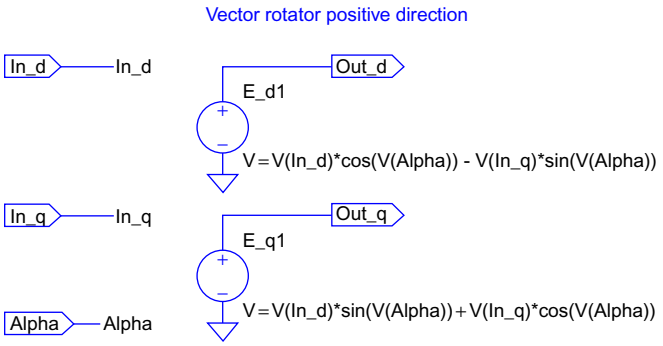

FIG. 44.14 Schematic for subcircuit for vector rotator.

control) appropriate to the torque command is added, and the resulting signal is routed through an integrator to generate the input angle for the vector rotator.

In the D-axis, a differentiator function *DDT(V(Id_ref))* is used in a compensation element (see Eq. (44.8) for D-axis reference current for vector control) that assures that the actual flux in the machine follows the commanded signal without delay. The input and output values of the vector rotator are voltage signals that correspond 1:1 to current signals. (In a real controller, the currents are typically scaled values in the memory of a DSP.) The vector controller calculates the appropriate currents that need to be injected into the machine to perform as desired. The currents are then transformed into three-phase values using the equations of (44.5) and fed into three voltage

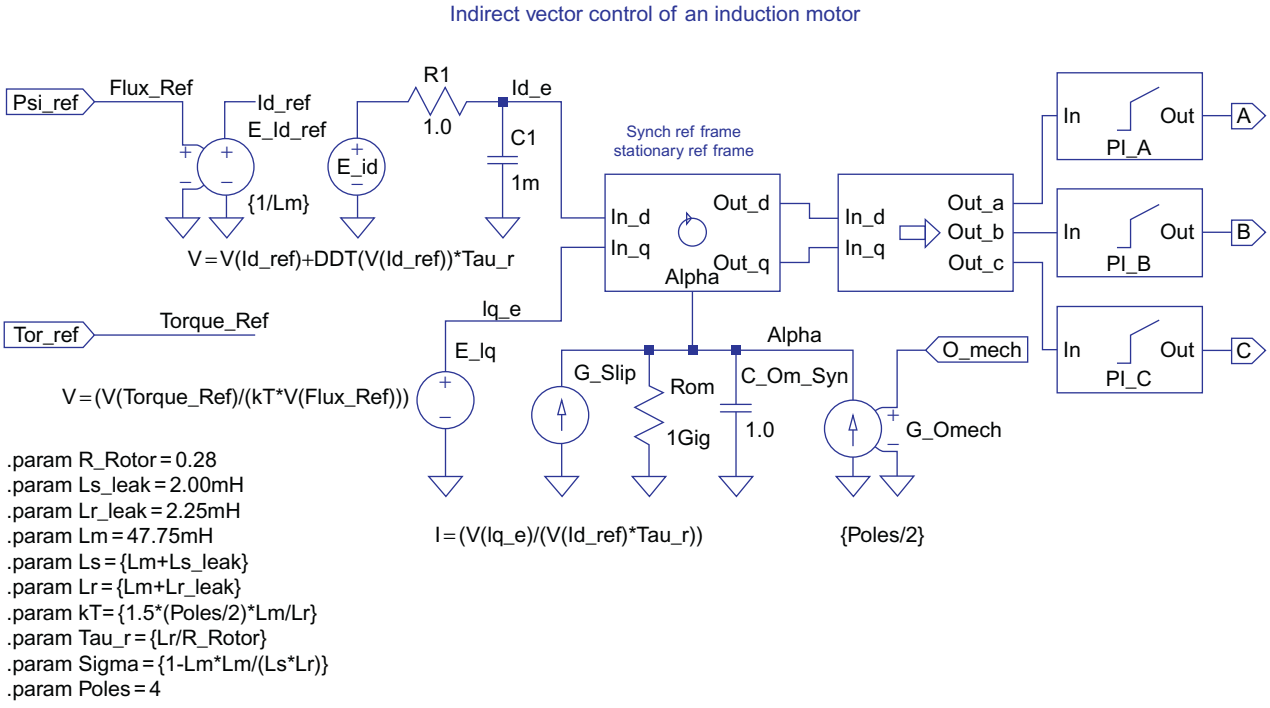

FIG. 44.13 Subcircuit for indirect vector control of induction motors.

sources with PI current loop feedback that represents a realistic implementation using a voltage-source PWM inverter. Alternatively, the PI current loops could be replaced with ideal current sources that are available in LTspice:

$$\omega_{slip} = L_m \frac{I_{sq}}{\tau_r \lambda_{rd}} \tag{44.7}$$

$$I_{sd} = \frac{(\lambda_{rd} + \tau_r \lambda_{rd} p)}{L_m} = \frac{1 + \tau_r p}{L_m} \lambda_{rd} \quad p = \frac{d}{dt} \tag{44.8}$$

Fig. 44.15 shows the results obtained for the circuit shown in Fig. 44.12 with perfect tuning of the vector controller. Perfect tuning means that the controller precisely knows all motor parameters at all times (including resistance changes due to heating of the windings). The two traces in the pane at the top of Fig. 44.15 represent the traces for the D and Q input signals of the vector rotator. The upper trace in the bottom pane of Fig. 44.15 shows the reference value for the flux scaled by a factor of 50. It is evident that the flux level is being changed at the same time when 20 N m of torque is commanded (and produced). This proves that with exact tuning the torque and the flux can be independently controlled, which is true for correct FOC. Below the trace for the flux reference are the traces for the torque reference and the actual torque, which are perfectly on top of each other. This provides the easiest way to judge the quality of the correct field orientation.

The center pane shows the trace for the mechanical angular velocity. It can be seen that the machine accelerates whenever torque is developed and slows down due to the load when the torque command is driven to zero.

Fig. 44.16 is an example of the results obtained from a detuned vector controller. The circuit is identical to the circuit in Fig. 44.12, except for the fact that the rotor resistance value in the controller was increased to 125%, which is thought to be attributed to heating of the rotor bars. It is obvious that the traces for the commanded and the actually produced torque are no longer identical. This is especially true, during times when the flux is changing. Detuning is actually a real problem in industrial vector control applications. Detuning is caused by the fact that the machine parameters are not precisely known to begin with and/or are changing during the operation of the machine. The values of the winding resistance are most commonly increasing due to heating of the machine during operation at high load.

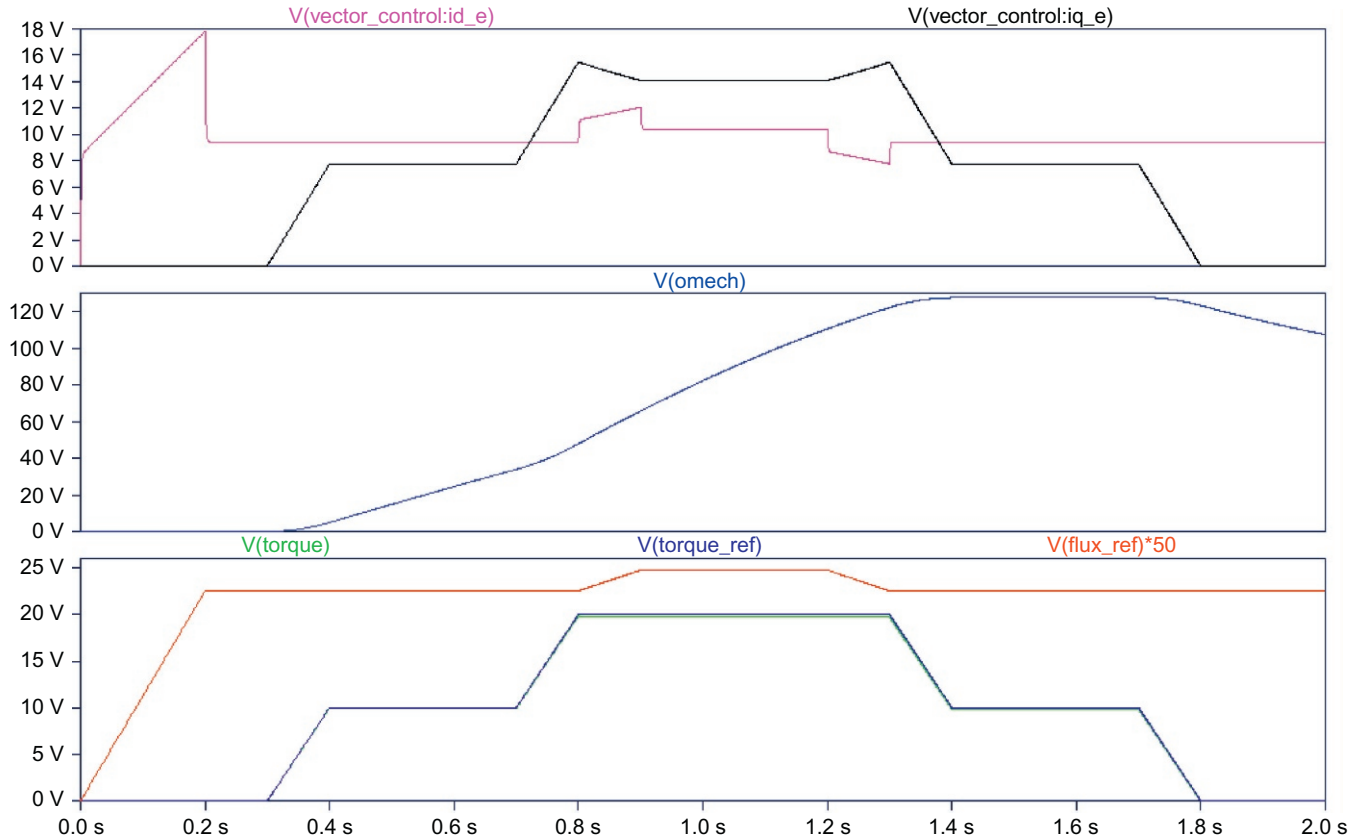

FIG. 44.15 Results for indirect vector control with perfect tuning.

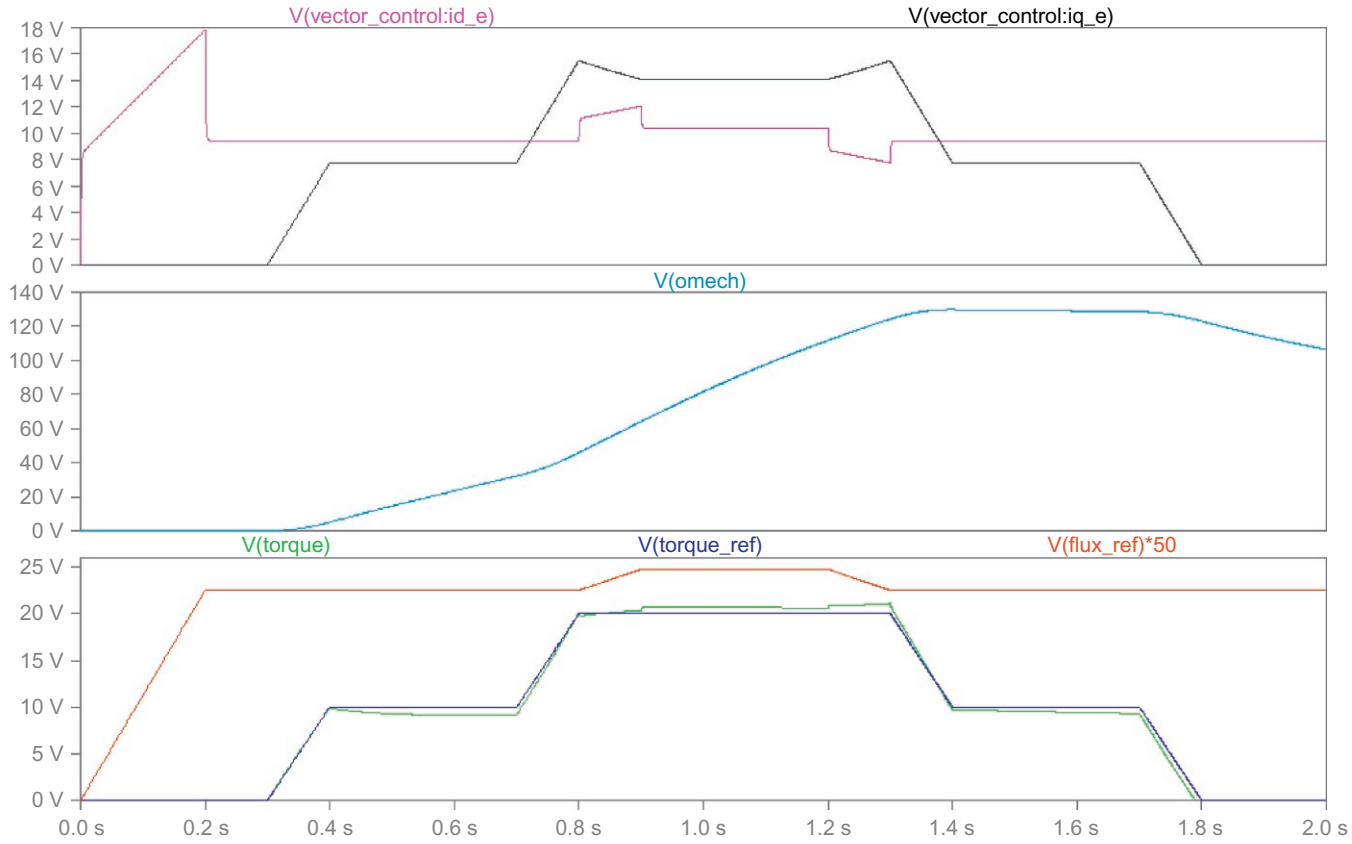

FIG. 44.16 Results for indirect vector control with 125% rotor resistance resulting in imperfect tuning.

44.6 Simulation of Sensorless Vector Control Using LTspice

In the previous example, the advantages of vector control have been shown. However, for the implementation of the control scheme, a sensor for the mechanical speed was used. This poses a problem for applications where a vector drive is to be retrofitted into existing equipment. The motor installation may not easily allow the installation of a mechanical speed sensor. Therefore, engineers have thought to replace the mechanical speed sensor with a speed observer, which is a mathematical model that is evaluated by the control processor (typically a DSP), which is also performing the standard vector control computations. The algorithm for the observer uses the measured stator voltages and currents for the D- and Q-axes as input parameters. It also relies on the knowledge of the machine model and on the correct machine parameters (rotor and stator resistance, mutual and leakage inductance, etc.). The following example shows a vector control implementation using a speed observer. The vector controller has been derived from the previous example shown in Fig. 44.13. However, the speed sensor signal was replaced by a speed observer. Careful examination of the derivation [4] of the speed observer reveals that it is easier to calculate the synchronous angular velocity, which is ultimately desired, than the angular velocity of the rotor. Therefore, the observer was modified, and the calculation of the rotor speed and the subsequent addition of the slip speed were foregone. The speed observer used here basically solves the D, Q equation system of the induction machine shown in Eq. (44.3), with the only difference that some of the dependent variables are now independent and vice versa. In addition to the synchronous angular velocity, the observer provides the values of the rotor flux, which could be used in the D-axis signal path.

Fig. 44.17 shows the top level of a simulation project for sensorless vector control. The top view of this circuit is very similar to the circuit for the indirect vector control represented by Fig. 44.12 except for the missing motor-speed feedback. The model for the motor and the motor's parameters are precisely the same as in the example for the indirect vector control. Double-clicking the control block reveals the associated subcircuit, which is shown in Fig. 44.18. As mentioned before, this subcircuit is similar to the subcircuit for the indirect vector control. However, the signal from the motor-speed sensor is replaced by the speed observer. In our case, the speed observer directly provides the synchronous angular velocity. Therefore,

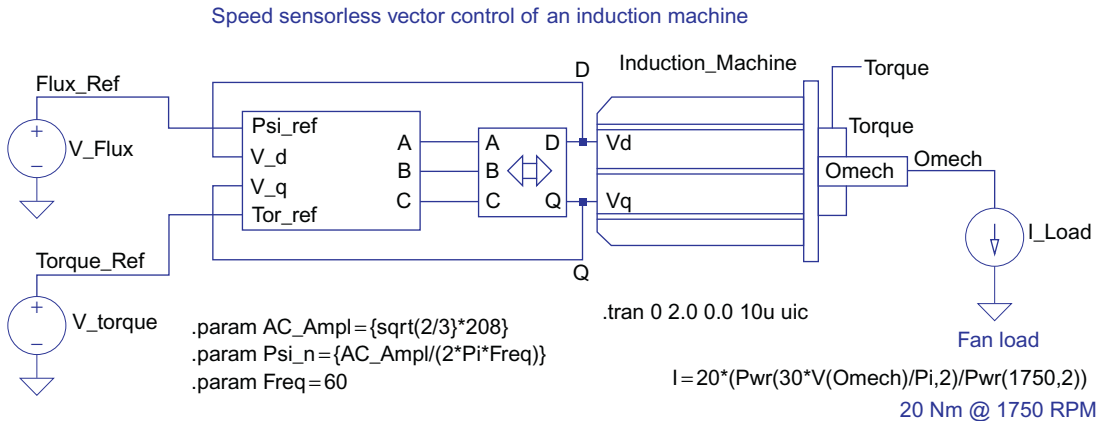

FIG. 44.17 Top level of simulation circuit for sensorless vector control.

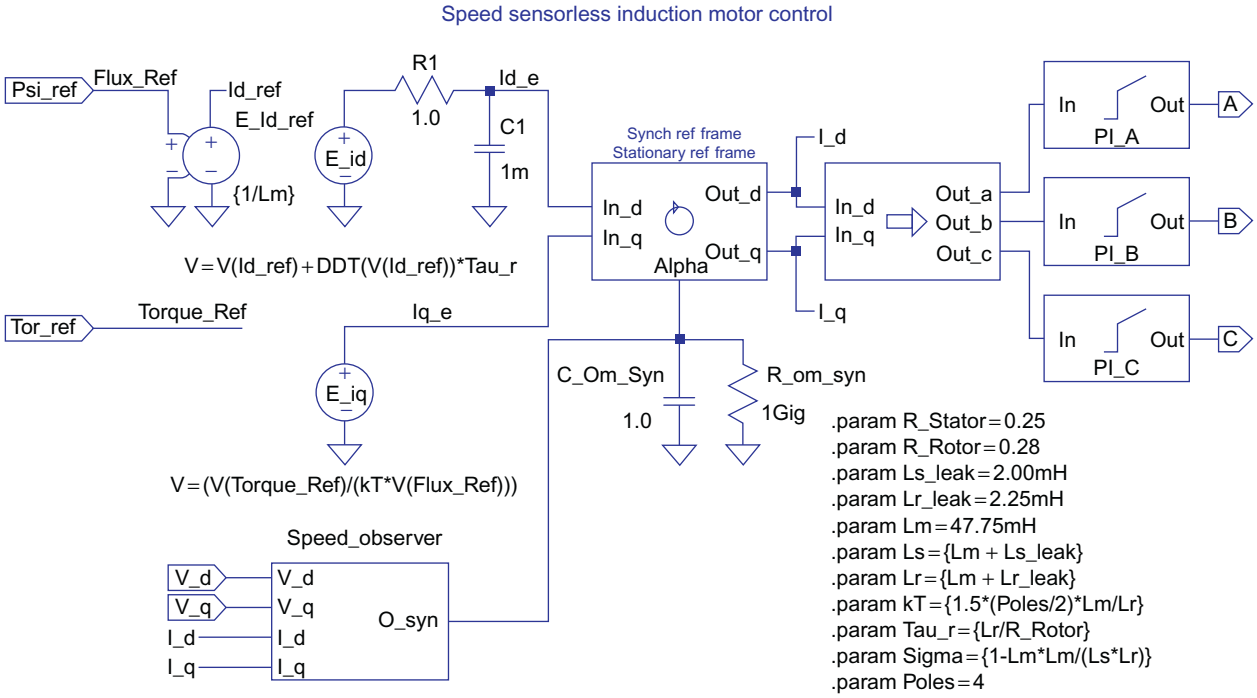

FIG. 44.18 Subcircuit for sensorless vector controller.

it is not necessary to calculate the slip speed and add it to the rotor speed to obtain the synchronous speed.

Fig. 44.19 shows the subcircuit for the speed observer. The speed observer uses the stator voltages and currents for the D- and Q-axis as input variables. After subtracting the voltage drop across the winding resistance and the leakage inductance of the stator from the stator input voltage and scaling the result by *Lr/Lm*, the observer calculates the D and Q components of the rotor flux by integration. Since the input values are in the stationary reference frame, so are the results. The observer also calculates the magnitude of the rotor flux (Eq. (44.9)) and then calculates the synchronous angular velocity (Eq. 44.10) by evaluating the rate of change of the ratio of the D and Q components. The mathematical relationships are given by Eqs. (44.9) and (44.10) [4]:

$$p\begin{bmatrix}\lambda_{rd}\\ \lambda_{rq}\end{bmatrix}=\frac{L_r}{L_m}\left[\begin{bmatrix}V_{sd}\\ V_{sq}\end{bmatrix}-\begin{bmatrix}R_s+\sigma L_s p & 0\\ 0 & R_s+\sigma L_s p\end{bmatrix}\begin{bmatrix}I_{sd}\\ I_{sq}\end{bmatrix}\right] \qquad (44.9)$$

$$\sigma=\left[1-\frac{L_m^2}{(L_r L_s)}\right] \quad \sigma=\text{Leakage factor}$$

$$\frac{d}{dt}a\tan\left(\frac{\lambda_{rq}(t)}{\lambda_{rd}(t)}\right)=\omega_s=\frac{\left(\frac{d}{dt}\lambda_{rq}(t)\lambda_{rd}(t)-\lambda_{rq}(t)\frac{d}{dt}\lambda_{rd}(t)\right)}{\left(\lambda_{rd}(t)^2+\lambda_{rq}(t)^2\right)} \qquad (44.10)$$

Fig. 44.20 shows the output for the speed sensorless vector control project as it presents itself in the LTspice waveform display for perfect tuning of the speed observer. A comparison of the traces for the torque and the torque command (they are

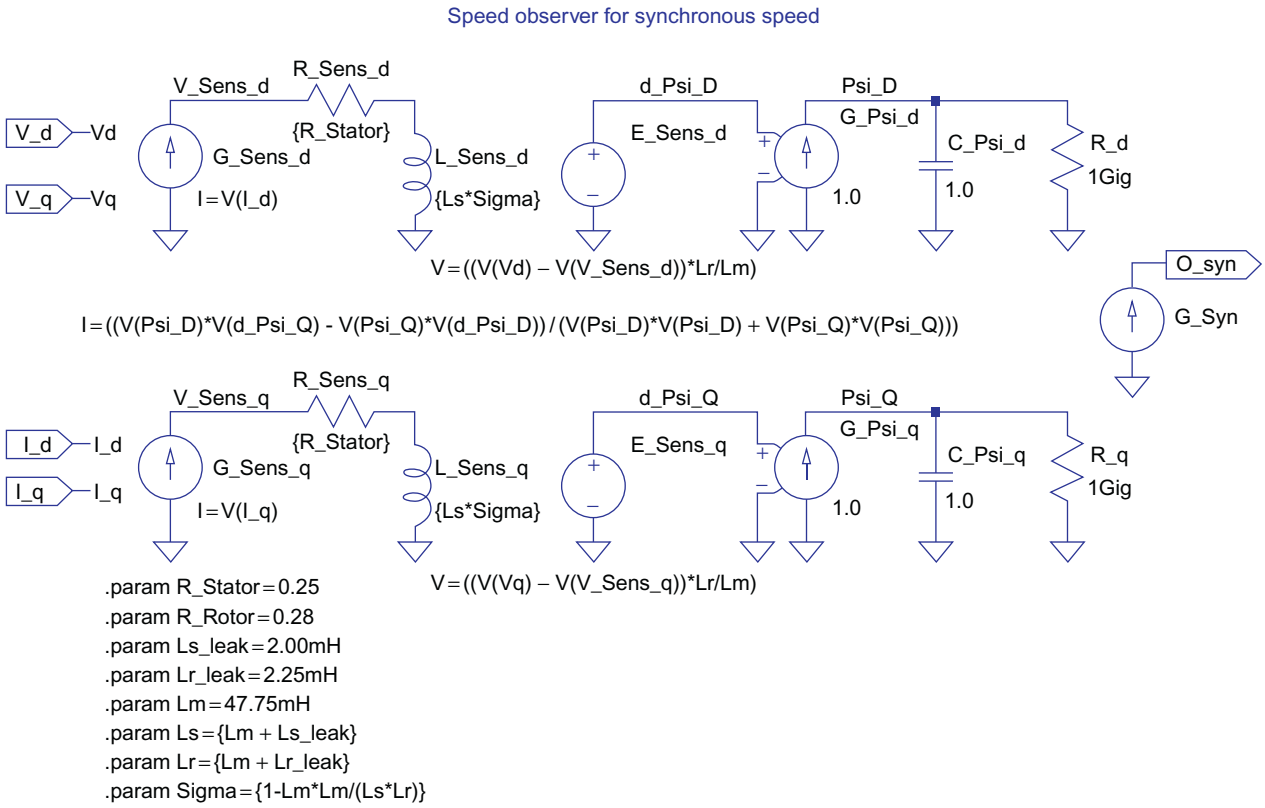

FIG. 44.19 Subcircuit for speed observer for sensorless vector controller.

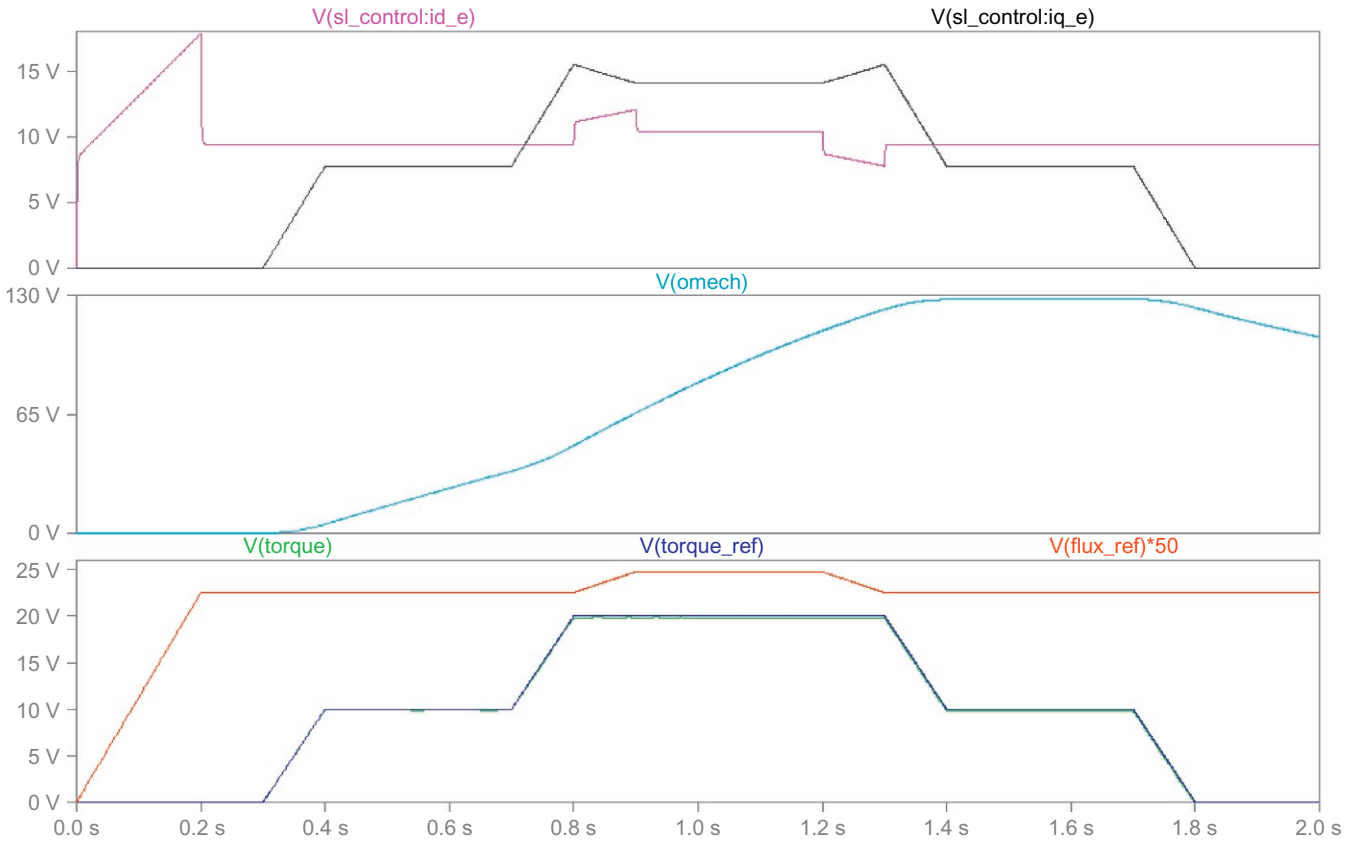

FIG. 44.20 Simulation results for sensorless vector control with perfect observer tuning.

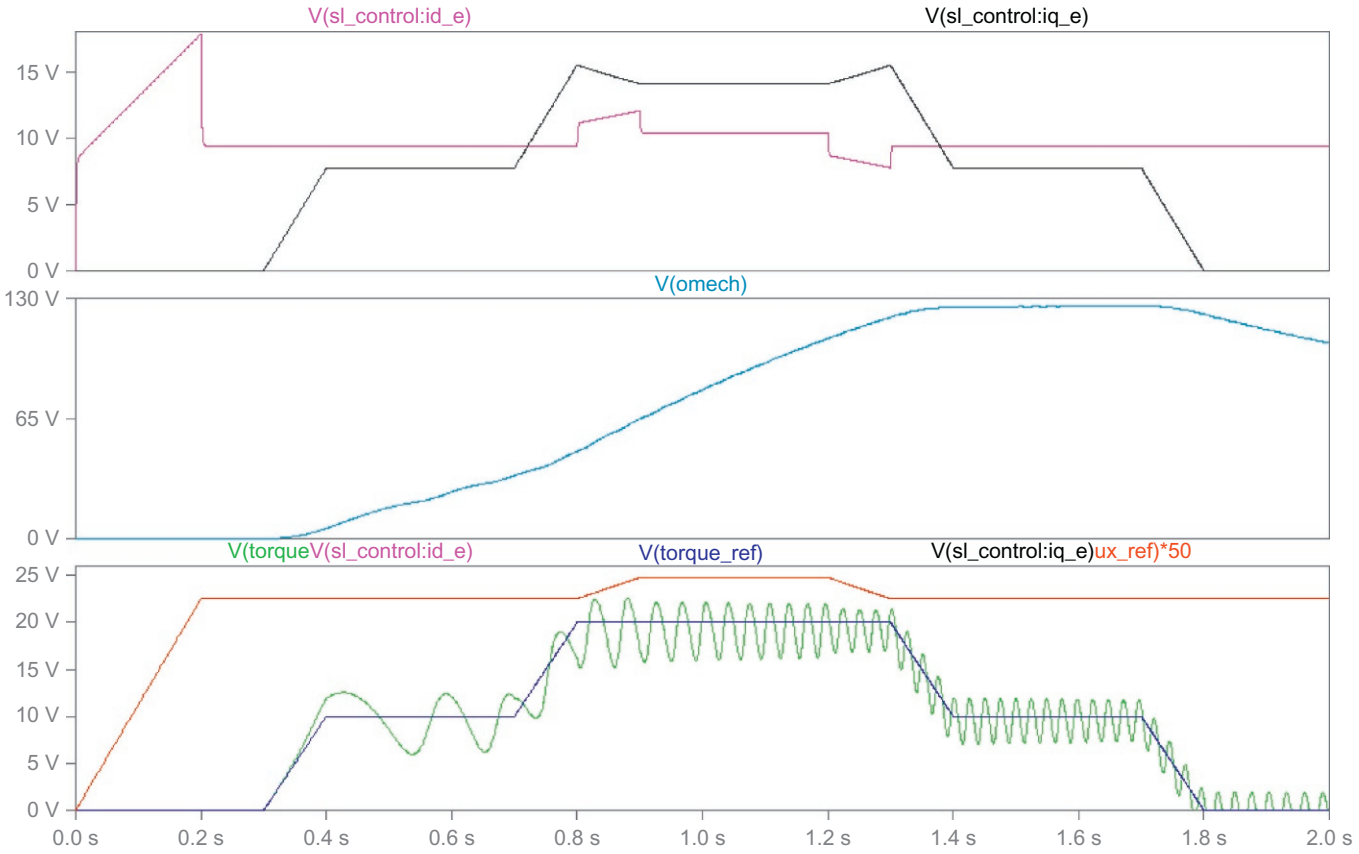

FIG. 44.21 Simulation results for sensorless vector control with detuned stator resistance.

perfectly on top of each other) shows that the scheme works extremely well. It even works for a start from zero speed, which is typically not the case in real systems. The reason is that the uncertainties of the winding resistance values (note that they change with temperature) create errors in observers like this one. The problem is worst at low speeds, because at low speeds and associated low stator frequencies, the uncertain winding resistance represents the largest part of the total machine impedance.

Fig. 44.21 shows the output for the speed sensorless vector control example with increased values for the stator resistance (0.28 Ω instead of 0.25 Ω). A comparison of the traces for the torque and the torque command now shows that the control does not work well in this case. This confirms that at low speeds including zero speed, an actual speed sensor is required for proper field-oriented control.

44.7 Conclusions

In this chapter, the capabilities of LTspice [1] have been used to simulate a number of examples from the power electronics, machines, and drive area. The advantage of LTspice is that it is based on the almost universal spice simulation language, which can be seen as the worldwide de facto standard for circuit simulation. The reader should always validate any model before it is used for critical engineering decisions. It was pointed out in the introduction that model validation often means verification that the limitations of the model are not exceeded.

In addition to the detailed examples, some general guidelines on the uses of simulation for analysis and design have been developed. All tested simulations yielded excellent results. The simulation time for each project shown was typically less than a minute on a contemporary (2016) PC. The author hopes that the reader has gotten an insight and appreciation of the power of modern circuit simulation codes and some useful ideas and inspirations for projects of his/her own.

45.1 Introduction

Due to the foreseen exhaustion of fossil-based energies, many countries are turning to the renewable energy technologies [1,2]. Among those, wind and solar photovoltaic (PV) systems have attracted more attentions in the past decades [2]. However, the incompatibility of renewable sources and loads requires an intermediate processing stage, which is typically achieved by power electronics [2–4,4a]. In conventional electric systems (e.g., motor drive systems), the role of power electronics is also obvious, as they are heavily involved in controlling the loads—motors. That is, the power electronic technology is the key to optimal energy harvesting and also friendly energy system integration. Moreover, this technology is developing with new and emerging power devices [5,6] with extraordinary performances in terms of switching speed and efficiency. In all, power electronics will be extensively used in many applications in the future.

In practice, the design of power electronic systems is mainly cost-driven, and thus there are three major concerns: power density, efficiency, and reliability [7,8]. Efficiency improvements can be achieved through developing power-lossless topologies (also, including soft-switching techniques) and advancing the power semiconductor devices. As an intuitive way, minimizing the number of conversion stages can contribute to high efficiencies. Notably, the topological simplification also has adverse impacts (e.g., the leakage current issue in transformerless PV inverters), which thus requires new dedicated control strategies. Alternatively, the latest advancements in power semiconductor technologies, for example, wide bandgap power devices like silicon carbide (SiC) transistors, offer much room to improve the efficiency of power electronic systems [6–10]. For instance, as reported in [11–13], the PV power electronic systems with wide bandgap devices have achieved a remarkable efficiency of above 99%, meaning that very few losses exist. The high-efficiency performance has boosted the PV market, where commercial PV inverters employing new devices are available. Furthermore, the wide bandgap power semiconductors feature a high-switching frequency operation capability, and thus, incorporating soft-switching techniques can further improve the efficiency [14].

As discussed above, higher power density and efficiency of power electronic systems are relatively achievable. However, according to a survey [15], the power electronic converter itself has become one of the most fragile parts in the entire system. For instance, in that study, the unscheduled maintenance events due to power electronics account for 37% of the total events in a utility-scale PV power plants, as shown in

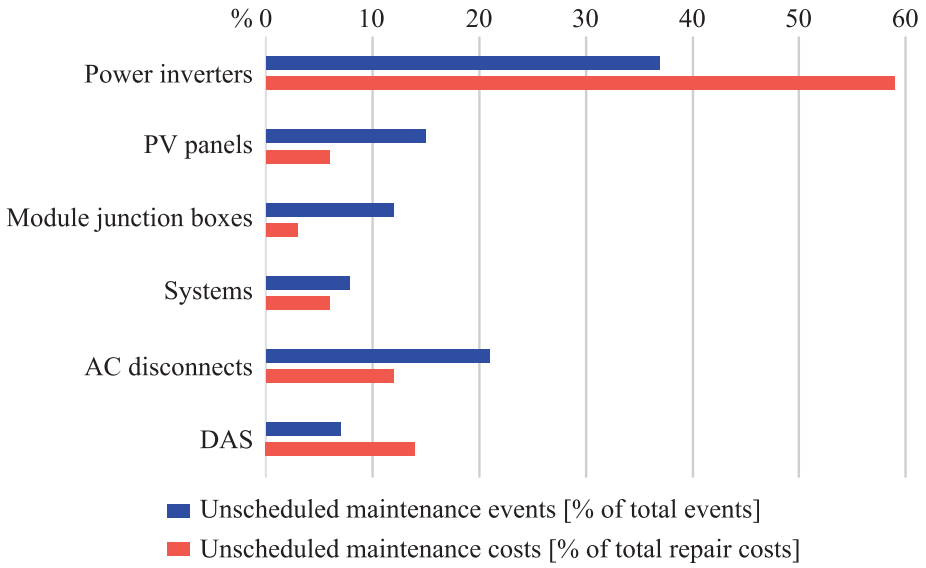

FIG. 45.1 Five years of real-field experience in failures of a utility-scale PV power plants (data acquisition systems (DAS)) [15].

Fig. 45.1. Those unscheduled maintenance events require human intervention (system repairing or maintenance), thus affecting the overall production and the maintenance costs, as observed in Fig. 45.1. In the end, the cost of PV energy will go up drastically due to the high failure rate of power inverters in PV systems. Hence, as aforementioned, high reliability of power electronics is in urgent need on top of efficiency.

As for reliability, more challenging issues should be addressed [16–23]. Prediction in lifetime of the power electronics is the first task so that the reliability can be taken as a performance factor in the design phase of power electronic systems, which is referred to as the design for reliability (DfR) [24–26]. In the past, the statistical analysis has been the dominant approach for lifetime prediction, where the reliability models (typically, constant failure rates) of subsystems are defined. For instance, a handbook—MIL-HDBK-217 F [27]—has been widely adopted to predict the lifetime of electronic equipment for decades. However, in this handbook, the models are outdated, and the associated failure rates are considered as constants. Thus, this handbook has been revoked. It is also worth to point out that the predicted lifetime or reliability based on this handbook has limited or no direct guiding value for the system design [28]. It is difficult to use the predicted reliability data to design new products or systems with higher reliability, not to mention the control to enhance the reliability performance. With the still increasing demands for high reliability, the analysis approach has to be shifted to the physics-of-failure (PoF) analysis [19–22], where the root causes, failure mechanisms, and mission profiles are in focus [20,29,30]. This (i.e., the PoF-based DfR) enables more predictable and controllable power electronic systems with high reliability.

In light of the above discussion, this chapter briefly discusses the mainstream power electronic converters for wind and PV power systems. More importantly, the DfR approach is explained in detail, including a short description of the failure mechanisms. Case studies on a 6-kW single-phase grid-connected PV inverter system have been provided to better illustrate the DfR approach considering mission profiles. Finally, concluding remarks and discussions on future research trends in the reliability of power electronics are provided.

45.2 Power Electronic Converters and Mission Profiles

Design and operation of power electronic systems for both wind and PV power systems are strongly dependent on the grid requirements. Fig. 45.2 shows the general demands for grid-connected PV and wind power systems, where the power electronic system is the key component, acting as “the brain” of the entire system. The objectives of those power electronic systems are to manage the power demand from the local operators and end customers [31,32]. A very common requirement is to transfer the PV and wind energy to the grid, according to its inherent characteristics (i.e., applying maximum power point tracking techniques). Other specific demands can be summarized as (a) reliable/secure power supply; (b) high efficiency, low cost, small volume, and effective protection; (c) control of active and reactive power injected into the grid; (d) dynamic grid support (e.g., fault ride-through operation); and (e) system monitoring and communication. In all, as the core of power conversion systems, the reliability of power electronic systems is of strong concern. In the following, some of the state-of-the-art power electronic converter solutions for wind and PV systems are introduced.

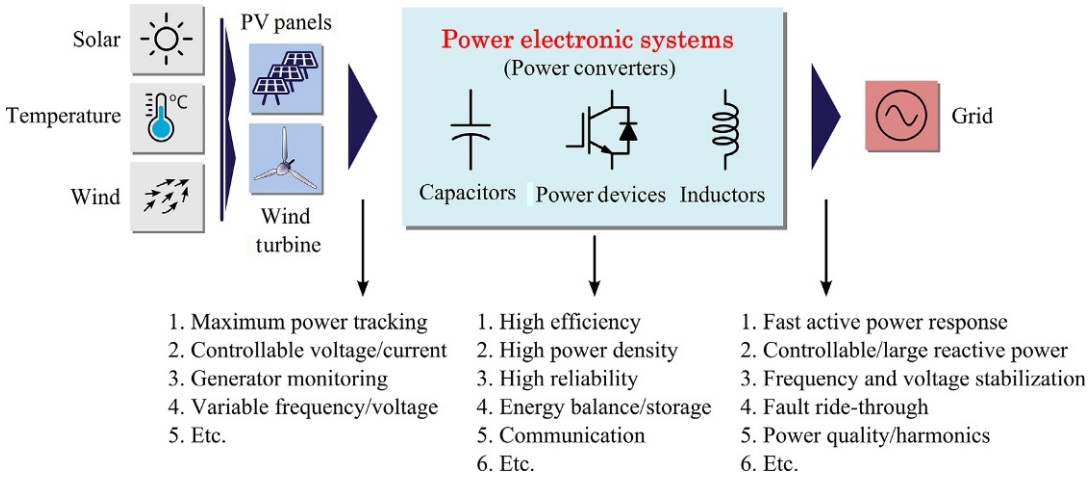

FIG. 45.2 Demands for grid-connected PV and wind power systems at different stages in the system.

45.2.1 Power Electronic Converters for Wind Power Systems

According to the types of generator, power electronics, speed controllability, and the way in which the aerodynamic power is limited, the wind-turbine system (WTS) designs can be categorized into four types:

- Fixed speed wind turbine (WT) systems
- Partial variable speed WT with variable rotor resistance
- Variable speed WT with partial-scale frequency converter
- Variable speed WT with full-scale power converter

Among those configurations, the latter two shown in Fig. 45.3 currently dominate the markets, which will be further employed in future wind power systems. As observed in Fig. 45.3 and aforementioned, the power electronic converters are very important, and they have various power ratings. In the past, the doubly fed induction generator (DFIG) with partial-scale power electronic converters was the most favorable concept (see Fig. 45.3A). However, the synchronous generator (SG) or asynchronous generator (AG) with full-scale power electronic converters (see Fig. 45.3B) has taken over today's wind power markets [33,34].

For the power electronic converters, there are many ways to configure. The most commonly adopted three-phase converter is the two-level voltage source converter (2L-VSC), as shown in Fig. 45.4. The popularity of this converter topology lies in its structural and control simplicity. However, the continuous increase in power capacity of an individual wind turbine [35,36] highly stressed the 2L-VSC and thus leading to a lower efficiency. From this standpoint, the multilevel converter technology is getting more and more attentions in wind power applications, since they can achieve more output voltage levels,

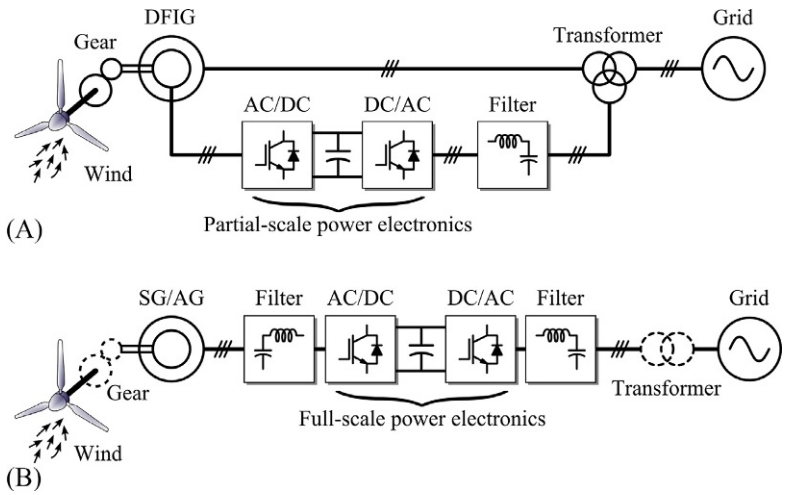

FIG. 45.3 Two dominant power-electronic-based WTS configurations: (A) partial-scale back-to-back power-converter-based wind turbine system with a doubly fed induction generator (DFIG) and (B) full-scale back-to-back power-converter-based wind turbine system with a synchronous or asynchronous generator (SG/AG).

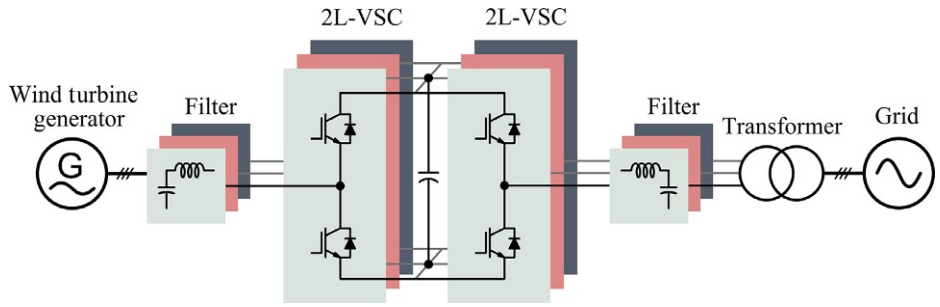

FIG. 45.4 Two-level VSC back-to-back (2L-VSC BTB) power electronic converters for wind turbine power systems.

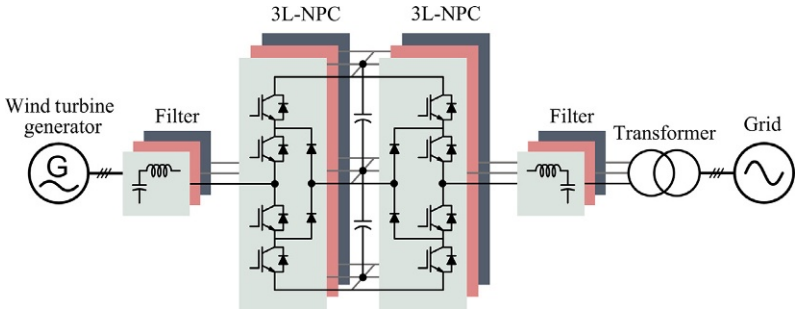

FIG. 45.5 Three-level neutral-point-clamped back-to-back (3L-NPC BTB) converter for wind turbine power systems.

higher voltage, and larger output power [33–37]. Fig. 45.5 shows the power converter schematics of the most successfully commercialized multilevel converter, that is, the three-level neutral-point-clamped (3L-NPC) converter. As mentioned, the 3L-NPC enables the use of smaller filters (reduced system volume), while the major drawback is the unequal power loss distribution. This in return may challenge the reliability of the entire power electronic converter system. To tackle this issue, multicell converter topologies by connecting converter cells in parallel or in series are developed and also commercially adopted in practice (e.g., Gamesa and Siemens) [38,39].

45.2.2 Power Electronic Converters for PV Power Systems

According to the state-of-the-art technologies, there are certain concepts [26,39a] to organize and deliver the PV power to the grid, as shown in Fig. 45.6. Each of the concepts consists of a couple of power electronic converters (e.g., dc-dc converters and dc-ac inverters) that are configured in different structures, depending on the applications and power ratings. For instance, modular PV converters (Fig. 45.6A) of small volume and high scalability are commonly adopted in small energy conversion systems. However, in order to connect modular PV converters to the grid, high conversion ratio dc-dc converters may be required, or a dc grid is necessary (see Fig. 45.6A and B). In contrast, string, multistring, or central inverters can directly be connected to the grid and they are developed as shown in Fig. 45.6B and C. Nevertheless, when compared with wind power systems, the PV utilization is still at a residential level with lower power ratings. Hence, string and multistring inverters with the exemplified configuration of Fig. 45.6B are dominant on the markets, and the single-phase connection is more often to see [40,41].

Fig. 45.7 exemplifies a single-phase grid-connected PV system with an LCL filter, where a full-bridge inverter has been employed. Additionally, to have a higher efficiency, transformerless PV inverters are preferred [40]. However, the side effects (e.g., leakage currents) brought by the removal of isolation transformers have to be addressed. Although single-phase configurations are more common, increasing demands in power and voltage also push the ratings of PV systems higher, as demonstrated in Fig. 45.6. Those large PV power plants, rated over tens and even hundreds of megawatts (MW), adopt many central inverters with the power rating of up to 900 kW. A typical large-scale PV power plant is shown in Fig. 45.8, in which the traditional three-phase full-bridge inverter can be adopted. Notably, the cables and power devices may have to bear large currents, and seen from this point, multilevel power electronic converter technologies might be more promising to large-scale PV systems [42–44]. In that case, disconnecting a large amount of dc currents is yet challenging.

45.2.3 Mission Profiles for Power Electronic Converters

A mission profile is normally referred to as a simplified representation of relevant conditions under which the system is operating [45,46]. As a result, the mission profiles for power electronic converters determine the loading of power electronic

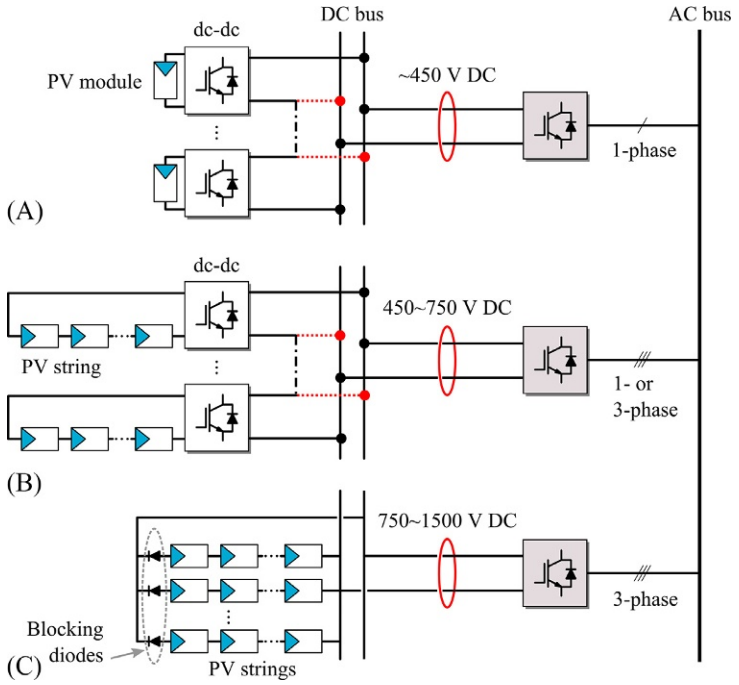

FIG. 45.6 Different grid-connected photovoltaic conversion systems: (A) module converters (low-power applications); (B) string or multi-string inverters (medium-power applications), where the dc-dc converters are optional; and (C) central inverters (high-power applications, e.g., commercial and utility-scale systems).

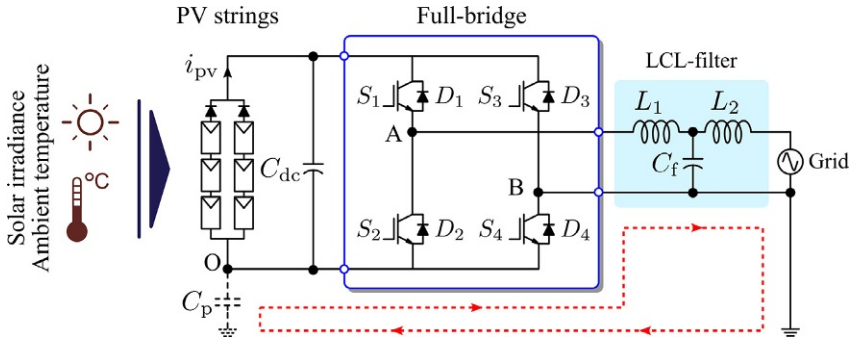

FIG. 45.7 Single-phase single-stage transformerless full-bridge string inverter with an LCL filter, where i_{pv} represents the PV output current and C_p is the parasitic capacitor between the PV panels (strings) and the ground. The dashed line with arrows indicates possible leakage currents circulating through the parasitic capacitor C_p.

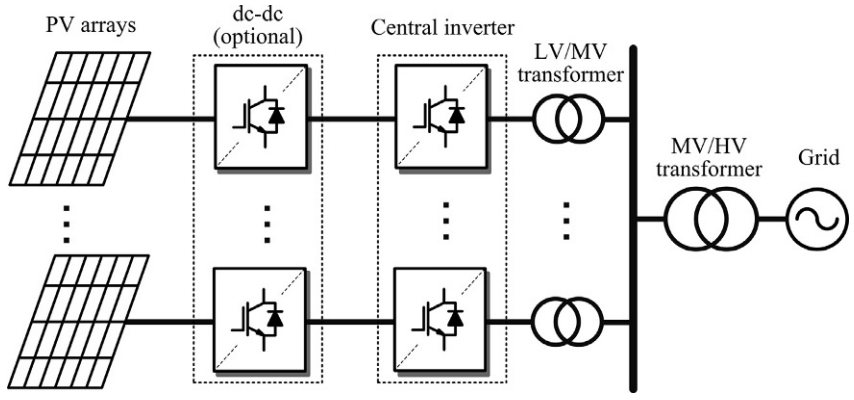

FIG. 45.8 Typical large-scale PV power plant based on central inverters for utility applications in the MW range (low voltage (LV); medium voltage (MV); high voltage (HV)).

components, and thereby, they are closely related to the cost and reliability performances. In renewable energy applications, the mission profiles are relatively tough: they need to withstand a large amount of power (even up to a few MWs) and perform a series of complicated functions required from the grid, and meanwhile, they also operate under harsh environments like day-night temperature swings, dust, vibration, humidity, and salty ambience. Moreover, the operating hours for wind turbines can be up to 120,000 h, and for a PV inverter, they might be operating 80,000 h in a 20-year life span [19,20]. Notably, today, even longer operation hours are discussed. In this section, typical mission profiles for wind and PV applications are exemplified, including wind speed, solar irradiance level, and ambient temperature.

45.2.3.1 Wind Speed

As the input of the entire wind power system, the wind energy quantified by the wind speed is an important factor that can determine the design, control, maintenance, energy yield, and eventually also the system cost. During the construction and design phases, assumptions have to be made about the wind conditions that the wind turbines will be exposed to. Typically, wind classes are used that are determined by three parameters—the average wind speed, extreme 50-year gust, and turbulence. Because the loading of power electronic converters are mainly caused by wind speed level and its variations, the knowledge of the wind class is of crucial importance for the reliability calculation and performances. The commonly adopted classifications of wind conditions are from an IEC standard [47]. Fig. 45.9 shows the distribution under different wind classes, where the Weibull function is used to describe the distribution characteristics.

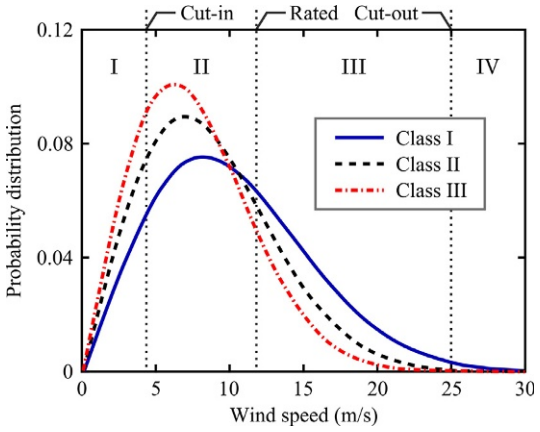

FIG. 45.9 Distributions of the wind speeds under different wind classes and operation of wind turbines (region I, no power generation below cut-in wind speed; region II, maximum power point tracking generation; region III, constant power generation; and region IV, no power generation above cut-out wind speed) [47].

Additionally, a field-recorded annual wind speed profile is illustrated in Fig. 45.10 [48], which is based on 1-h averaged at 80-m hub height for a wind farm located near Germany with the latitude of 54.25° and the longitude of 8.20°. The shown wind speed belongs to the IEC class I—high with an average wind speed of 8.5–10 m/s. It can be seen in Fig. 45.10 that the wind speed fluctuates significantly. Without proper controls of the mechanical and electrical parts, the fluctuations may be transferred to the grid and cause grid stability problems. Moreover, the power electronic components may suffer from largely cyclical loadings and thus accelerating the degradation and challenging the lifetime. As a result, the roughness class and fluctuation of wind speeds should be considered in the control and design of the power electronics for wind power systems [34].

45.2.3.2 Solar Irradiance

Wind speeds directly affect the power outputs of wind power systems, while solar irradiance level and ambient temperature are determining the output power of PV power systems. Actually, the mission profile (i.e., solar irradiance and ambient temperature) is a reflection of the intermittent nature of the solar PV energy, and consequently, it has an inherent relationship with the entire system performance. Figs. 45.11 and 45.12 show annual solar irradiance and ambient temperature profiles for PV systems in Aalborg, Denmark, respectively. It can be observed that both the solar irradiance level and the ambient temperature vary significantly through a year. It is thus required to develop dedicated MPPT control

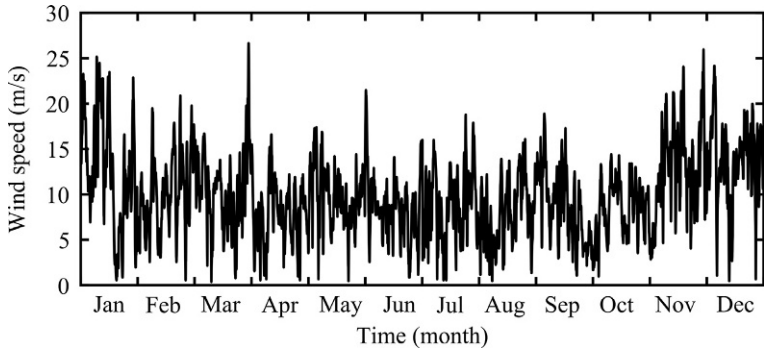

FIG. 45.10 One-year wind speed profile at a wind farm near Germany (recorded at 80-m height and 1-h averaged).

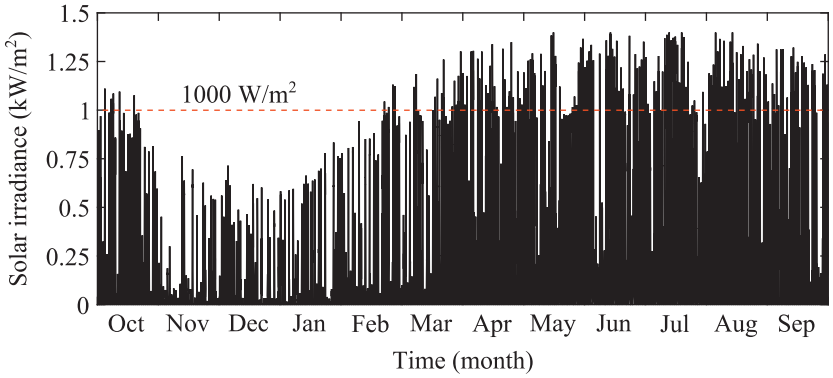

FIG. 45.11 Yearly solar irradiance level from recorded data (5 min per sampling data) for PV systems.

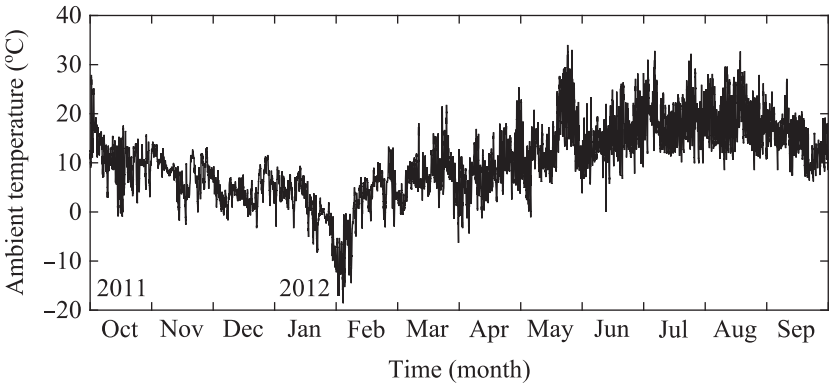

FIG. 45.12 Yearly ambient temperature profile from recorded data (5 min per sampling data) for PV systems.

systems in order to increase the energy yield. Moreover, like the case for wind power systems, the resultant fluctuating power from a PV power system may incur stability issues—especially when the PV penetration is getting larger and larger.

45.2.3.3 Ambient Temperature

In many applications, the power electronic systems are exposed to a harsh environment, where the ambient temperature is also time-varying, as shown in Fig. 45.12. The ambient temperature variation inevitably imposes thermal stresses on the power electronic systems, and thus, the reliability is affected by the ambient temperature. For PV power systems, as mentioned previously, the ambient temperature also affects the power outputs. Consequently, those aspects related to mission profiles have to be carefully considered in the control and design phases of power electronic systems.

45.3 Design for Reliability (DfR) of Power Electronic Systems

As discussed in Section 45.2, the power electronic system is the core of the energy conversion or processing system. Hence, the design of the entire system is centered on the power electronic systems, including power density, efficiency, and reliability. All those considered parameters aim to further reduce the cost but increase the manufacturability. For the design of high power density and high efficiency, technological achievements are dictated by topological innovations and semiconductor advancements, as mentioned at the beginning of this chapter.

To design a power electronic system with a specific reliability target, a top-down reliability allocation to the component level is necessary. Fig. 45.13 shows a typical architecture to illustrate this concept. The failure causes of a power electronic system could be hardware, software, and human errors. While this chapter focuses on the hardware reliability, the failure from software and human errors can be considered according to the software reliability modeling and the field operation experiences in human error rates. A certain level of the reliability budget should be allocated for the software failure and human errors accordingly. For the hardware part, there are long-term degradation related wear-out failures and single-event-related catastrophic failures. The wear-out failure of power electronic components usually can be modeled based on long-term operation conditions and their respective lifetime models, which contribute partially to the failure events. The single-event-related catastrophic failure does have associated failure mechanisms, while it is difficult to predict accurately by models. Instead, it can be obtained based on field operation experiences of the products or similar products. An ideal design is to avoid

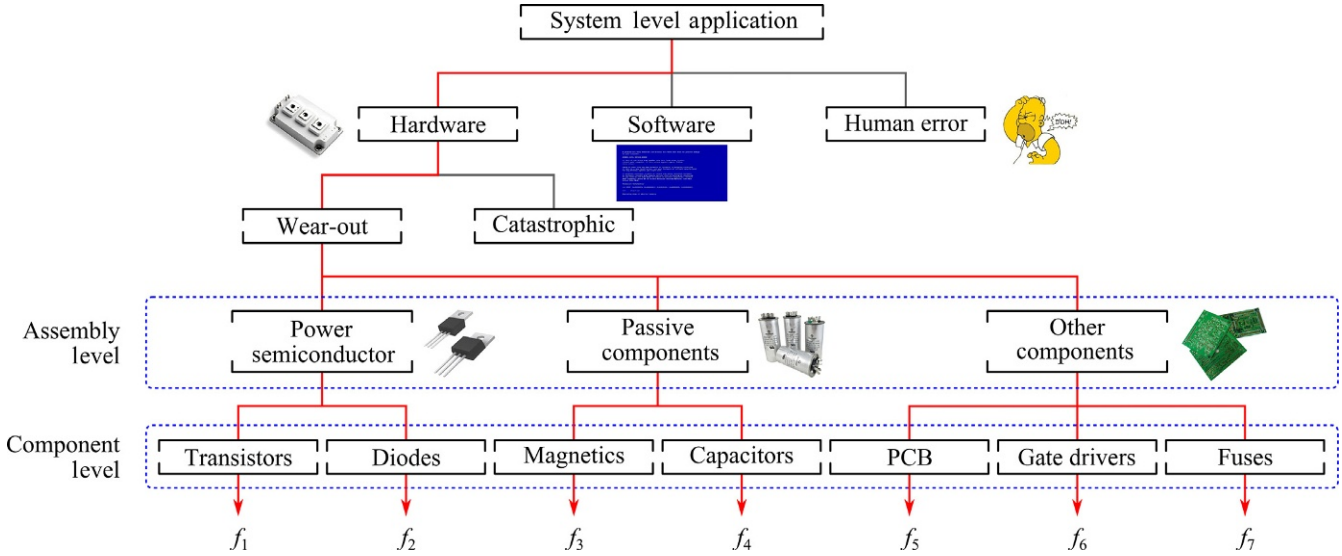

FIG. 45.13 From system-level reliability specification to component-level reliability design budgets (printed circuit board (PCB); f_k stands for failures with k being 1, 2, 3, ..., 7).

any wear-out failure of power electronic components within the specified service life of the power electronic system of interest. However, it is usually not feasible due to both design cost constraints and component property uncertainties to a certain degree. Based on the budgets for software failures, human errors, single-event-related catastrophic failures, and the system-level reliability target, the reliability design budget of hardware assemblies associated with wear-out failure mechanisms can be determined. The component-level reliability design target can then be allocated. The wear-out failure mechanisms of key power electronic components and the lifetime prediction methods have been well discussed in [20]. As an example, Section 45.4 demonstrates how to size the IGBT power devices to achieve a specific reliability target.

Fig. 45.14A shows the influencing factors in the design and operation phases of power electronic systems, where it can be observed that the design involves many factors. More important, it is seen in Fig. 45.14A that unexpected failures will occur during the operation, resulting in costly maintenance [24]. Accordingly, the design of high reliability is becoming mission critical in power electronic systems, as it is the key parameter affecting the levelized cost of energy (LCOE) [49,50]:

$$\mathrm{LCOE} = \frac{C_{\mathrm{int}} + C_{\mathrm{cap}} + C_{\mathrm{o\&m}}}{E_{\mathrm{annual}}} \tag{45.1}$$

where C_{int} is the initial development cost, C_{cap} represents the capital cost, $C_{\mathrm{o\&m}}$ indicates the operational and maintenance cost, and E_{annual} denotes the average annual energy production in the lifetime cycle of the system. More specifically, a power electronic system of high reliability will reduce the cost for operational and maintenance and also increase the service time (i.e., more energy production). Eventually, the cost of energy is lowered.

In order to lower the unscheduled maintenance cost, potential failures should be anticipated as early as possible and input into the design flow. This initiates a more promising solution to improving the reliability of power electronic systems, as shown in Fig. 45.14B, being the DfR approach. The inclusion of reliability enables a quick identification of design flaws or weakness and thus feeds back to the design for corrections (e.g., reselection of components). After a few iterations, the reliability demands can be fulfilled before the installation/construction of the power electronic system. As a consequence, significant cost reduction in the design phase and shorter development cycles can be attained while also targeting for higher reliability. Clearly, the failures or downtimes of the designed power electronic systems are predictable, demonstrated in Fig. 45.14B.

It should be pointed out that the reliability prediction is the first task for the DfR process, and it involves in multiple disciplines from the PoF point of view. Fig. 45.15 depicts the detailed reliability evaluation process of the DfR approach, which shows that the reliability analysis has three major tasks:

- Failure identification
- Stress analysis and strength modeling
- Reliability mapping.

More specifically, the critical components and the major failure mechanisms of power electronics are identified through physics analysis and real-field experience. Accordingly, the corresponding stresses and the ability of power electronic components to withstand the stresses are tested and modeled. Finally, counting algorithms and statistical distributions are adopted to map the stress and strength information to the reliability metrics of the power electronic system. The reliability indicators can be direct performances like the B_x lifetime, robustness, and failure probability or indirect performances [24]. Here, the B_x lifetime indicates the time by which x percent of a population of the system under study will have failed.

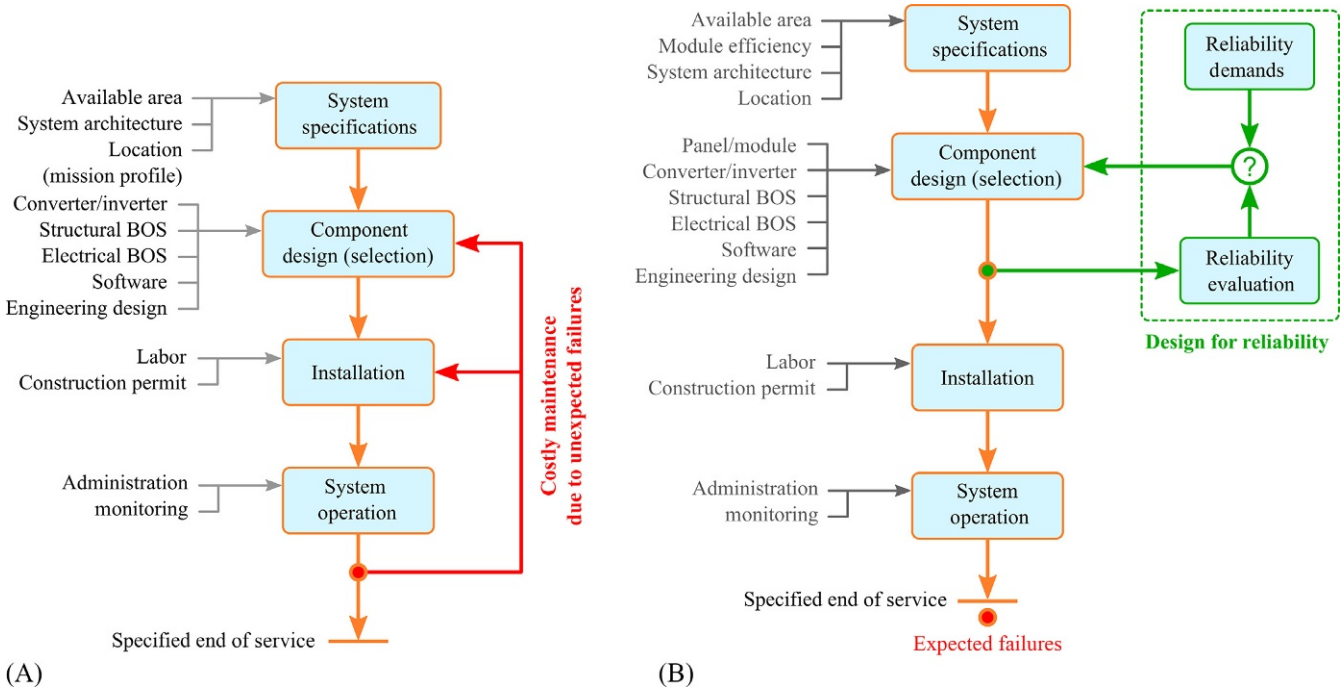

FIG. 45.14 Factors considered in the design and operation phases of power electronic systems (e.g., PV systems; balance of system (BOS)): (A) conventional design and (B) with reliability demands.

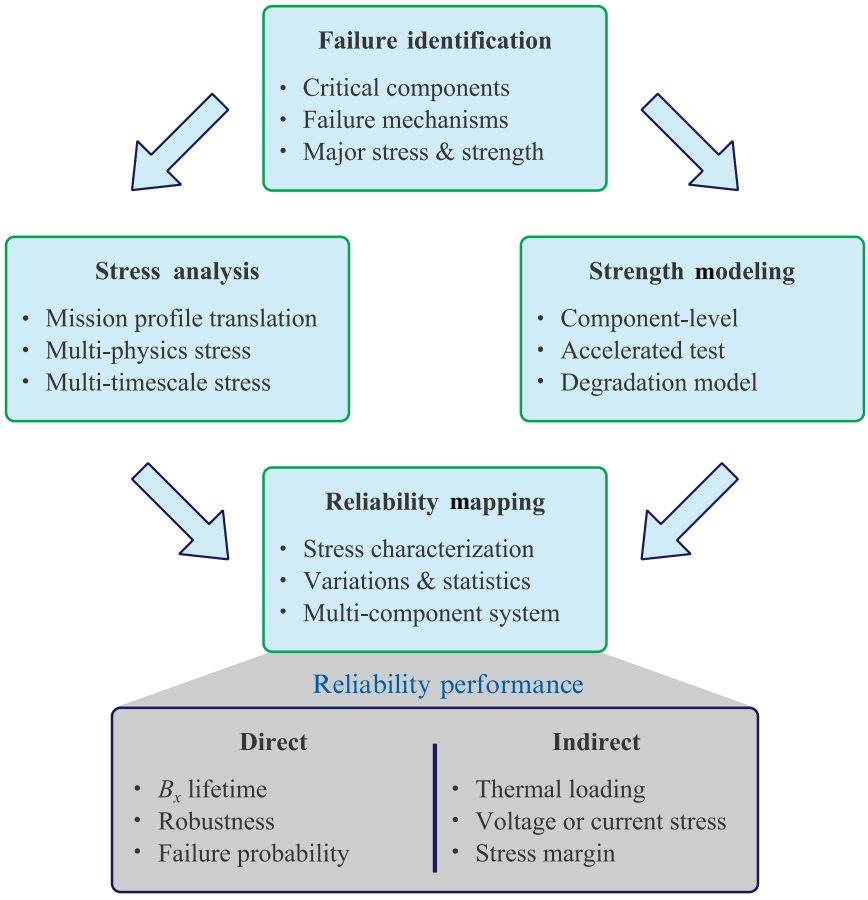

FIG. 45.15 Reliability prediction process of the design for reliability (DfR) approach for power electronic systems, where the B_x lifetime indicates the time by which x percent of a population of the evaluated system will have failed.

For a specific power electronic system, the DfR approach included in the Fig. 45.14 and the reliability predication process detailed in Fig. 45.15 enable analyzing the power converter candidates in terms of reliability. Here, the failure mechanisms have to be identified first. As discussed in [20], for power electronic converters, the major failures are related to the temperature in power devices. Nevertheless, on condition that the failure mechanisms are identified, it is possible to directly translate mission profiles into thermal loading on the power electronic components of the selected candidates. As a result, the reliability is obtained and can be compared with the demand. The process is further summarized as follows:

- Mission profile translation
- Thermal loading interpretation
- Lifetime model of power devices
- Monte Carlo reliability assessment
- System-level reliability analysis

which is also discussed in detail in the following.

45.3.1 Mission Profile Translation

In the DfR approach, the knowledge of the power converter operating conditions during the entire operation is essential [20,51]. In this respect, a mission profile of the power electronic converters, which represents the operating condition of the system, is needed. Then, the mission profiles have to be translated into thermal loading of power electronic systems (e.g., junction temperature variations of the devices), which can be done in the following way.

Once the mission profiles are obtained, the power production of the power electronic system can be estimated considering the electrical characteristic model. Taking into account the conversion efficiency, the power losses dissipated in the power devices can be estimated. Notably, this loss calculation is usually implemented with a lookup table (LUT), in order to assist the long-term simulation (e.g., an annual mission profile). In that case, the power losses are calculated for a certain set of operating conditions (e.g., the input power from 0 to 100% of the rated power), and the power losses under other operating conditions can be interpolated from the constructed LUT. Then, the thermal model of the power devices in the power electronic converter is required in order to obtain the device junction temperature loading.

45.3.2 Thermal Loading Interpretation

By applying the previous process, the junction temperature of the power electronic device T_j under a specific mission profile can be obtained. However, the device junction temperature is usually an irregular loading profile, due to the dynamics of mission profiles (e.g., the solar irradiance and ambient temperature for PV power systems). Thus, a cycle-counting algorithm such as a rainflow analysis is usually employed, in order to divide the irregular thermal loading cycle into several regular thermal loading cycles [52]. By doing so, the information such as the mean junction temperature T_{jm}, the cycle amplitude ΔT_j, and the cycle period t_{on} can be obtained, which can then be applied to the lifetime (degradation) model of the selected power electronic devices of the converter candidates.

45.3.3 Lifetime Model of Power Devices

Any component in a power electronic system (e.g., power semiconductors and capacitors) can cause failures of the entire system. In that regard, it leads to a complicated analysis, as the components may have a cross effect of the reliability on each other. For simplicity, only the temperature-related failure mechanisms of the power device are considered. In fact, the power device has been reported as one of the most critical components in power electronic systems [15,16]. Hence, it is a natural thought to consider temperature-related lifetime models [53,54].

Normally, the lifetime of the power device is expressed by considering the life consumption (LC), which indicates how much life of the device has been consumed (or damaged) during operations. The LC is calculated by using the Miner's rule as [52]

$$\text{LC} = \sum_i \frac{n_i}{N_{fi}} \tag{45.2}$$

where n_i is the number of cycles (obtained from the thermal loading interpretation) for a certain T_{jm}, ΔT_j, and $t_{\text{on,}}$ and N_{fi} is the number of cycles to failure calculated at that specific stress condition. For instance, if the number of cycles n_{i} is counted from an annual mission profile, the LC calculated in (45.2) will represent a yearly LC of the power device. When the LC accumulates to unity, the power electronic device is considered to reach its end of life, and the lifetime for the single power electronic device is predicted.

45.3.4 Monte Carlo Reliability Assessment

Actually, the lifetime prediction of the power device obtained from (45.2) can be taken as an ideal case, where all the power devices fail at the same rate. In reality, there are uncertainties in the time to failure of the power devices, mainly introduced by parametric variations in the lifetime model and changes in the stresses. Therefore, it is more common to express the lifetime prediction in terms of statistical values (e.g., using the probability of failures), rather than the fixed values. In order to do so, a Monte Carlo analysis should be performed, which is aimed to introduce variations in the system parameters, and simulate the

result with a large number of samples. With the large enough number of samples, the results will converge to the expected value.

This approach can be employed for estimating the power devices lifetime [55–57]. In this method, all the parameters in the lifetime model have to be modeled by a distribution function with a certain range of variations. Then, following the Monte Carlo simulation approach, a certain number of samples from each parametric distribution are randomly taken to calculate the lifetime of the power electronic device. Accordingly, a set of results is obtained, which can then be represented with a certain distribution function (e.g., Weibull distribution) [58]. The probability density function (PDF) of this lifetime prediction result is usually referred to as a lifetime distribution (failure distribution) $f(x)$, while its cumulative distribution function (CDF) is considered as an unreliability function $F(x)$. Eventually, the B_x lifetime can be obtained from the unreliability function of the power electronic device.

45.3.5 System-Level Reliability Analysis

A power electronic system usually has many power devices, and each power electronic device has its own unreliability function $F(x)$. In order to perform the system-level reliability assessment, the reliability block diagram of the entire system should be constructed [16]. The reliability block diagram represents how the reliability of components in the system interacts with each other. For a system with n components and the entire power electronic system cannot function if any of the n components fails, the total unreliability of system $F_{\text{tot}}(x)$ can be calculated as

$$F_{tot}(x) = 1 - \prod_{n} (1 - F_n(x)) \tag{45.3}$$

where $F_n(x)$ is the unreliability function of the n-th component. Once the total unreliability function of the inverter system $F_{\text{tot}}(x)$ is obtained, the B_x lifetime of the entire power electronic system can be estimated in a similar way as it has been done for a single power electronic component. However, it should be pointed out that the system-level reliability analysis approach (i.e., the reliability block diagram) can be applied to any power electronic system. For different converter topologies, the reliability block diagram may be different from (45.3), depending on the number of power devices and their operational principles.

Following the above steps, the reliability of a power electronic system can be predicted, and then, it can be compared with the design target (i.e., the reliability demand). This DfR flow especially includes the reliability in the design and thus avoids slow and expensive feedbacks or iterations. From this standpoint, the DfR approach can significantly accelerate the power electronic system design, while maintaining lower design costs and also better reliable products.

45.4 Case Study

In the DfR approach, the reliability target (i.e., the reliability demand) has to be specified at the beginning of the design phase, as shown in Fig. 45.14B. The reliability target is considered as a design objective, which should be fulfilled in the end of the design process. Following the diagram in Fig. 45.14B, the DfR approach is demonstrated on a single-phase 6 -kW PV power system referring to Fig. 45.7. To recap, the entire DfR flow for the PV power electronic system is represented in Fig. 45.16. As the PV power production is mainly affected by the solar irradiance level and the ambient temperature conditions, these two parameters are considered as the mission profile of the PV power electronic system, as also shown in Fig. 45.16. In the case study, the mission profiles in Figs. 45.11 and 45.12 are adopted. The targeted lifetime for the power electronic system is above 25 years. Three power electronic devices with the rated current of 15, 30, and 50 A from leading manufacturers are selected for comparison.

45.4.1 Mission Profile Translation

From the given mission profile, the PV power production (P_{pv}) can be determined by using the PV panel electrical characteristic model. Then, the actual input power seen by the PV inverter (P_{in}) is obtained by taking the MPPT algorithm efficiency (η_{MPPT}) into account. In order to estimate the power losses in the power devices (P_{loss}), a PV inverter loss model is employed. This can be obtained by considering the switching losses and conduction losses of the power devices in the inverter. After that, the thermal model of the power devices can be applied in order to obtain the junction temperature profile of the power devices (T_j) during the entire operation, which is implemented by using an LUT, as mentioned previously, in order to enable a long-term mission profile translation (e.g., yearly mission profiles) [59]. Fig. 45.17 summarizes the above process.

As an example (for the 600 V/30 A device), one of the translated thermal loading profiles under the mission profile (Figs. 45.11 and 45.12) is shown in Fig. 45.18. The cycle amplitude ($\triangle T_j$) and the mean junction temperature (T_{jm}) are presented in Fig. 45.18A and B, respectively. The impact of the mission profile can be observed in Fig. 45.18 from the thermal loading of the power device, where the cycle amplitude profile follows the variation in the solar irradiance profile (i.e., part of the mission profile). The long-term variation in the mean junction temperature has the similar tendency as the ambient temperature profile in Fig. 45.12 with a short-term variation imposed by the variation in the solar irradiance profile in Fig. 45.11.

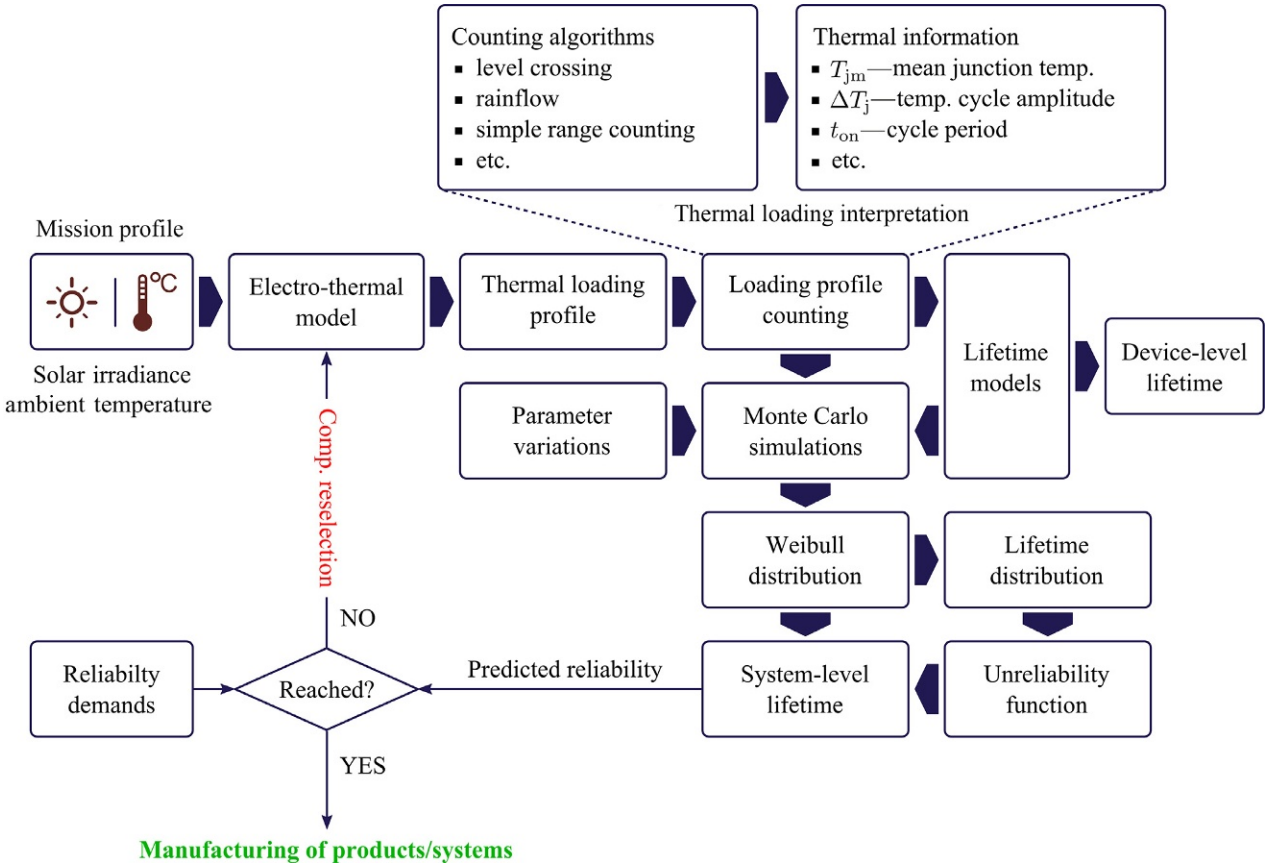

FIG. 45.16 Complete DfR structure for the power electronic systems in PV applications.

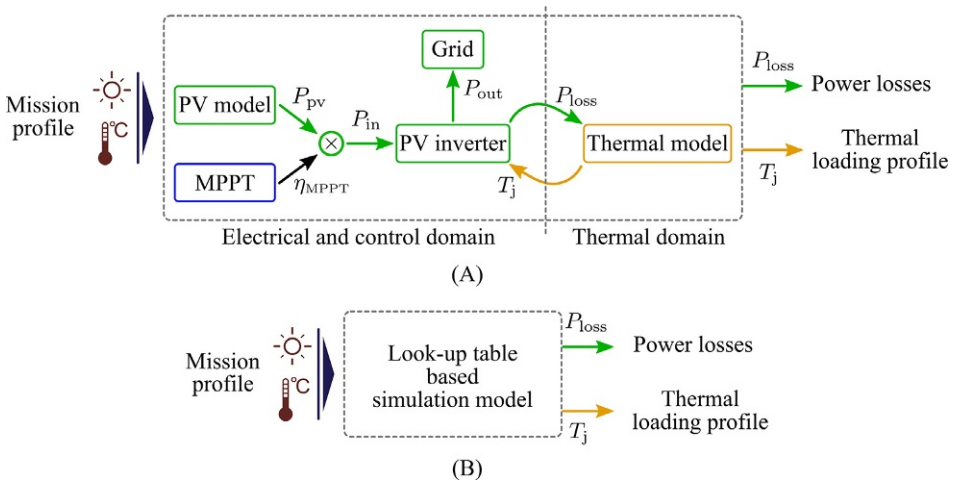

FIG. 45.17 Mission profile translation to power losses P_{loss} and thermal loading T_j: (A) for short-term mission profiles and (B) for long-term mission profiles.

45.4.2 Thermal Loading Interpretation

The junction temperature profile shown in Fig. 45.18 reflects the impact of mission profiles on the thermal loading of the power electronic system. However, it provides limited qualitative information about the thermal loading of the power devices, as the cycle amplitude ($\triangle T_j$) and the mean value of the junction temperature (T_{jm}) are an irregular profile due to the mission profile dynamics. In other words, it

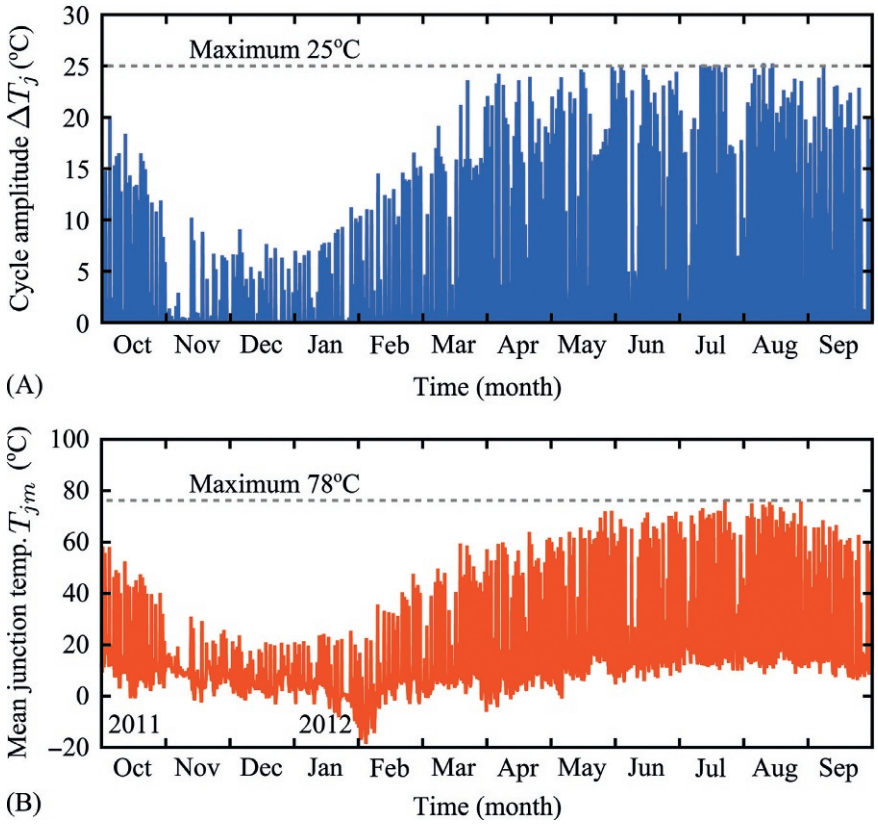

FIG. 45.18 Thermal loading of the power device in the single-phase full-bridge PV inverter under a yearly mission profile: (A) cycle amplitude and (B) mean junction temperature.

cannot be directly applied to an empirical lifetime model. Thus, a cycle-counting algorithm such as rainflow analysis is normally employed in order to divide the irregular profile into several regular thermal cycles [52]. With this analysis, the qualitative information such as the number of cycles n_i at a certain cycle amplitude $\triangle T_j$, mean junction temperature T_{jm}, and cycle period t_{on} can be obtained and applied to the lifetime model. Details of the rainflow algorithm can be found in [30,60,61].

45.4.3 Lifetime Model of Power Devices

The lifetime model of the interested power component is required for the lifetime prediction. In the case study, the lifetime of the power electronic systems (devices) is considered. Several lifetime models of the power electronic devices, components, or modules have been developed. A recently developed IGBT lifetime model that considers the thermal cycle period t_{on} is adopted [53], and it is expressed as

$$N_f = A \times (\Delta T_j)^{\alpha} \times (ar)^{\beta_1 \Delta T_j + \beta_0} \times \left[\frac{C + (t_{\text{on}})^{\gamma}}{C+1}\right] \times \exp\left(\frac{E_a}{k_b \times T_{\text{jm}}}\right) \times f_d \quad (45.4)$$

where N_f, $\triangle T_j$, T_{jm}, and t_{on} are defined previously. The other parameters are constants that are given in Table 45.1. Using the interpreted thermal loading information and (45.4), the LC of the power electronic components can be obtained according to (45.2). When the LC is accumulated to unity, the power electronic device reaches its end of life, as mentioned previously.

45.4.4 Monte Carlo Reliability Assessment

The reliability metric is usually expressed in terms of statistical values, rather than a fixed value obtained previously, due

TABLE 45.1 Parameters of the lifetime model of an IGBT module [53]

Parameter	Value	Experimental Condition
A	3.4368×10^{14}	
α	-4.923	$64 \le \triangle T_j \le 113$ K
β_1	-9.012×10^{-3}	
β_0	1.942	$0.19 \le ar \le 0.42$
C	1.434	
γ	-1.208	$0.07 \le t_{\text{on}} \le 63$ s
f_d	0.6204	
E_a	0.06606 eV	$32.5 \le T_j \le 122$ °C
k_B	8.6173324×10^{-5} eV/K	

to the uncertainties in the lifetime prediction. The uncertainties can be introduced by the component-parametric variations (e.g., due to the manufacturing process), lifetime-parametric variations (e.g., due to the test data), and variations in the stresses (e.g., variations in the PV power production due to the PV panel aging). In order to include the impact of those uncertainties into the lifetime prediction, a Monte Carlo analysis is employed [26,62], according to the flow shown in Fig. 45.16.

In the Monte Carlo analysis, variations are introduced to the lifetime model of (45.4) and also the stressors, where the parameters can be modeled with a certain distribution function (e.g., a normal distribution), as illustrated in Fig. 45.19. Following the Monte Carlo approach, a large set of populations are taken randomly from the distribution in Fig. 45.19 and applied to the lifetime model. Therefore, the lifetime distribution (or time-to-failure distribution) can be obtained and fitted with a specific distribution function. Normally, the lifetime distribution of the wear-out failure follows the Weibull distribution, and the Weibull probability density function (Weibull PDF) is shown in Fig. 45.20A. Notably, it is also possible to analyze the influence of an individual parametric variation by using the sensitivity study. This can be used for identifying the crucial parameter that limits the lifetime of the component (which may be redesigned). For instance, a controlled cooling unit may be required, if the lifetime is sensitive to the mean junction temperature.

From the lifetime distribution (i.e., the Weibull PDF), the reliability of one single power device (e.g., component level) can be determined by considering the CDF of the lifetime distribution. The Weibull CDF distribution (Weibull CDF) shown in Fig. 45.20B is referred to as the unreliability function, as it represents the percentage of failure population overtime. The B_x lifetime can be obtained from the unreliability function. For instance, the B_1 and B_{10} lifetime of the power device, which indicates the time when 1% and 10% of the population have failed, are the commonly used reliability metrics.

45.4.5 System-Level Reliability Analysis

In many cases, the system under consideration consists of several components, where each component has its own unreliability function. The B_x lifetime of one single component may not accurately reflect the B_x lifetime of the overall power electronic system. Thus, the system-level reliability assessment is performed using the reliability block diagram. For the full-bridge PV inverter shown in Fig. 45.7, the system-level reliability block diagram consists of a series connection of four components, as the failure of any power device (e.g., S_1, S_2, S_3, or S_4) will lead to the loss of functionality of the entire power electronic system. Thus, according to (45.3), the system-level unreliability function can be calculated as

$$F_{\text{sys}}(x) = 1 - \prod_{n=1}^{4} (1 - F_n(x)) \tag{45.5}$$

where $F_{\text{sys}}(x)$ is the system-level unreliability function and $F_n(x)$ is the component-level unreliability function of the n-th component. The system-level unreliability function of the PV inverter (e.g., four devices) is shown in Fig. 45.20B, where it can be noticed that the system-level unreliability is in general higher than the component-level unreliability (i.e., $F_{\text{sys}}(x) \geq F_n(x)$), resulting in the lower B_x lifetime for the system level.

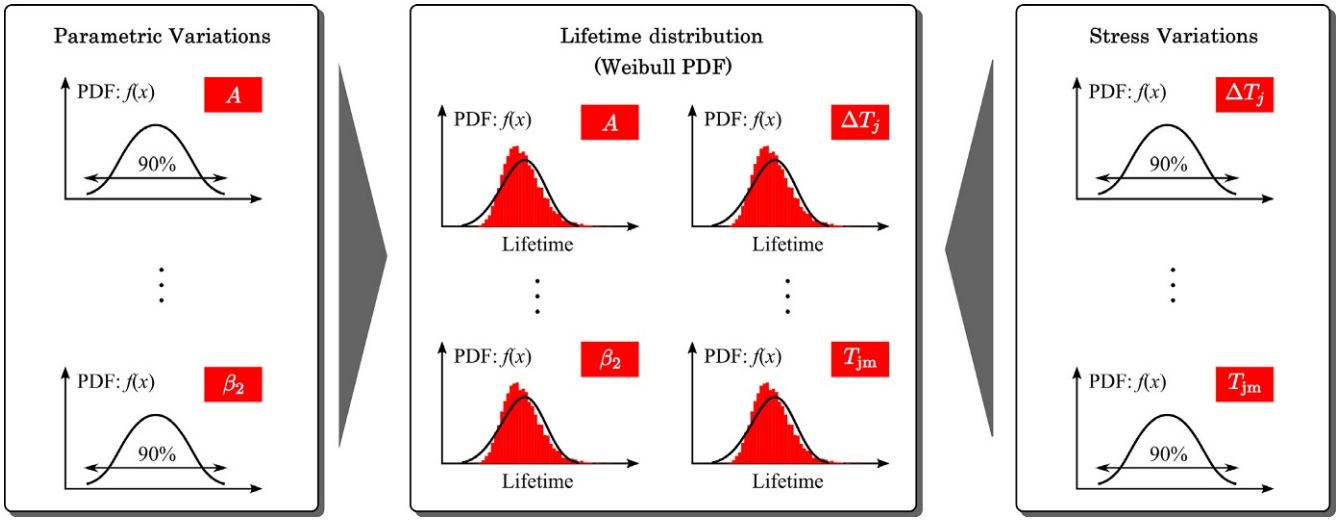

FIG. 45.19 Sensitivity analysis of the parametric variations by using the Monte Carlo analysis (probability density function (PDF)).

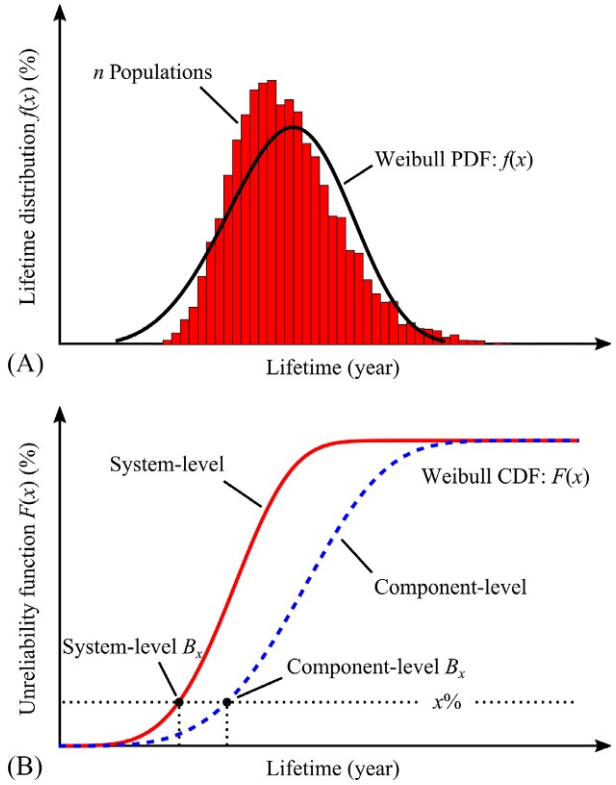

FIG. 45.20 Results from the Monte Carlo simulation (probability density function (PDF) and cumulative distribution function (CDF)): (A) lifetime distribution of one single power device (i.e., the Weibull PDF) with n populations and (B) unreliability function (i.e., the Weibull CDF) of one single power device (component level) and full-bridge inverter with four power devices (system level).

45.4.6 Design for Reliability (DfR) Results

The reliability analysis is carried out with three selected power devices following the above. As specified in the reliability target, the system-level lifetime of the PV power electronic system should be higher than 25 years. This is the benchmark for selecting the most suitable power electronic device among the three candidates. The DfR results are shown in Fig. 45.21. The lifetime distribution of each device obtained from the Monte Carlo analysis is shown in Fig. 45.21A, where it can be seen that the lifetime distribution of the three power electronic devices shows significant difference. A majority of the population with the 15-A power devices fail after 10 years of operation, while most of the population with the 30- and 50-A power devices can survive after 100 and 250 years of operation, respectively. However, it should be noted that in such cases other parameters will determine the lifetime. Additionally, the ratings of the two devices are over designed compared with the rating of the system under study (i.e., 6-kW). Both lead to the relatively long lifetime.

Based on the lifetime distribution in Fig. 45.21A, the unreliability function can be obtained, as it is shown in Fig. 45.21B, where the B_x lifetime is also indicated. For example, it can be seen from Fig. 45.21B that the system-level B_1 lifetime of the PV inverter is 2 years if the 15-A power devices are selected. This means that the power electronic system with 15-A power devices did not meet the reliability target of 25 years under the given mission profile. On the other hand, the PV inverter with 30- and 50-A power devices has the system-level B_1 lifetime of 30 and 61 years, respectively. Therefore, either the 30- or 50-A power device can be used in the full-bridge power electronic system that fulfills the reliability target. In most cases, the cost of the power devices with the current rating of 30 A will be lower than that of the 50-A power devices. Thus, the 30-A power electronic device is considered to be the most suitable candidate to be used in the PV power system in order to achieve the system-level B_1 lifetime higher than 25 years. However, it is also worth mentioning that the predicted lifetime is relatively long, since there are many other factors influencing the reliability. In this case study, only the failure mechanism related the junction temperature is considered. To improve the reliability prediction, more failure mechanisms as well as possible coupling effects should be taken into account. It in return may make the analysis become more complicated. Nevertheless, the above demonstrates a way to lifetime prediction, and thus enables the DfR in power electronic systems.

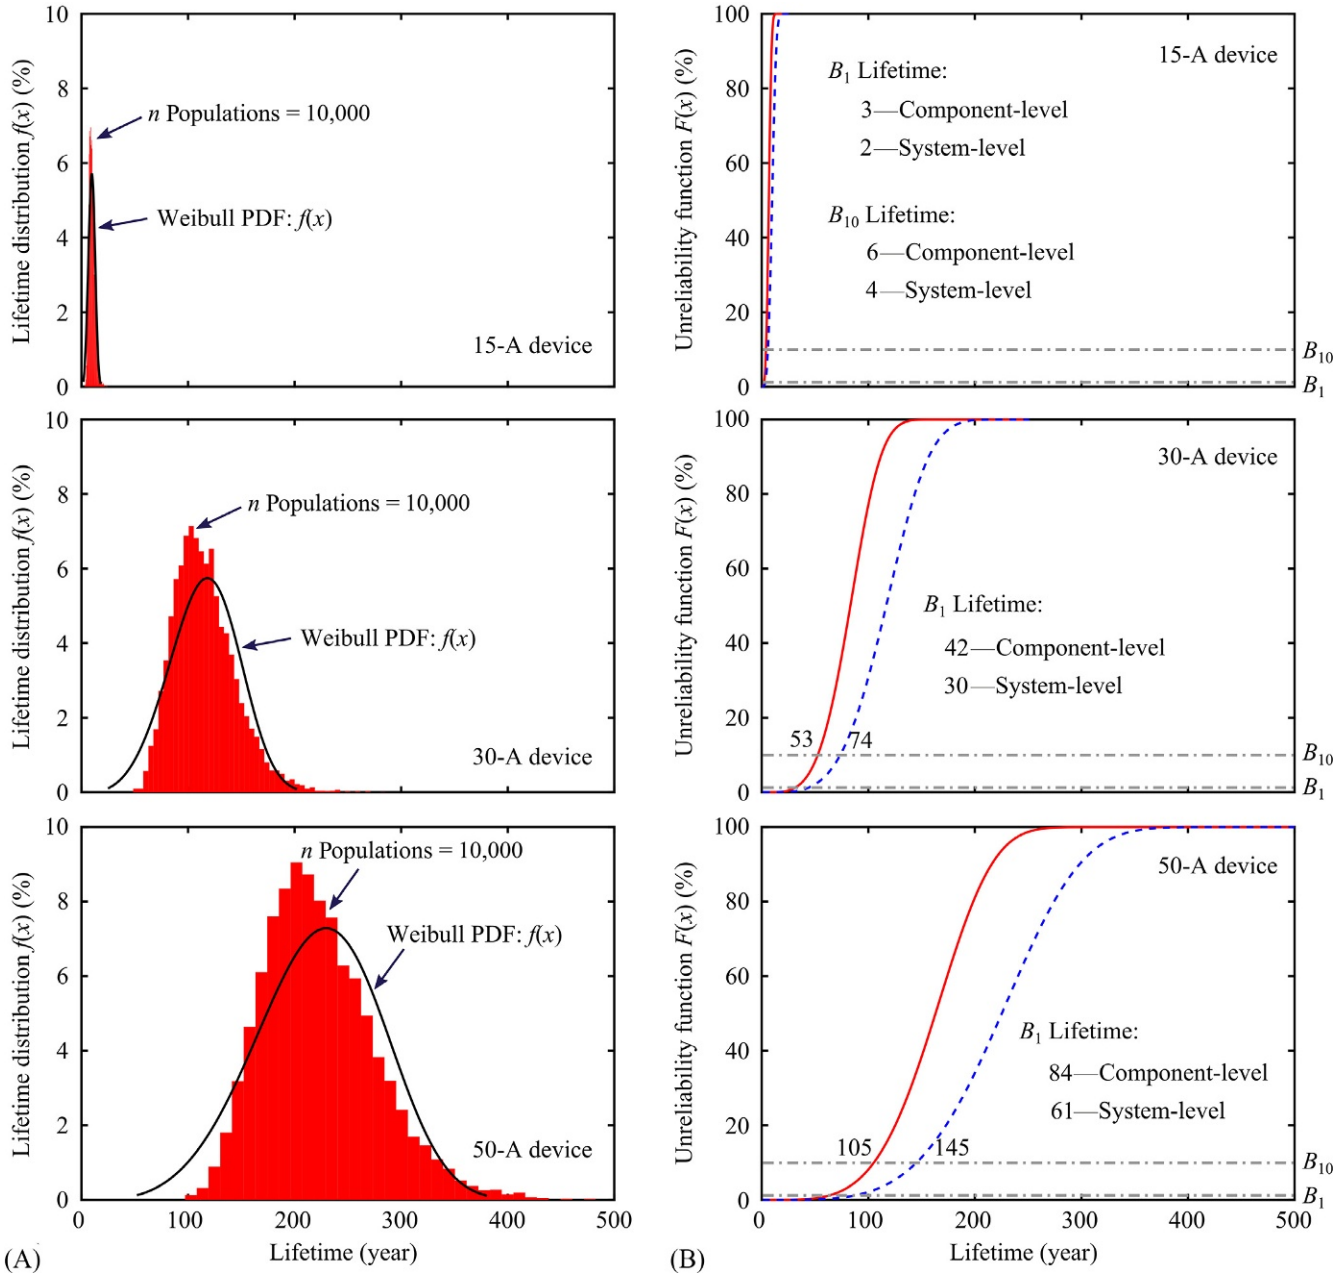

FIG. 45.21 Design for reliability (DfR) results of the power electronic system for single-phase PV applications obtained from the Monte Carlo simulation with 10,000 populations: (A) lifetime distribution of one single power device (i.e., the Weibull PDF function) and (B) unreliability function (i.e., the Weibull CDF function) of one single power device (component level) and full-bridge inverter with four power devices (system level). Note that there are other factors leading to the so long lifetime.

45.5 Summary

The reliability demands for power electronic systems have been identified in this chapter. The state of the art in power electronic converters for wind and PV power systems have been briefly reviewed, from which it is known that the power electronic systems play a vital role in the power conversion. The conventional design of power electronic systems focuses on power density and efficiency. However, the power electronic system is also one of the most life-limiting parts, and thus, the reliability should be included in the design phase, being the design for reliability (DfR) approach, as demonstrated in this chapter. Multidisciplinary efforts in component physics, reliability engineering, system engineering, and power electronics are necessary to implement the DfR approach. Many challenges still exit in mission profile modeling, lifetime modeling, reliability data in software, human errors, single-event catastrophic failures, and reliability-oriented design tools as

discussed in [20]. Other relevant studies related to this chapter have been collectively presented in [63], which provides an overview of the recent advancements in the area of reliability of power electronic converter systems and also reliability testing.

46.1 Introduction

In the field of power electronics, most of the challenges arise from the thermal management and our ability to predict the behavior of circuits under varied and extreme temperature conditions. It is particularly important in power electronics to understand the effects of temperature as this fundamentally affects so many aspects of the design from component values to tolerances, reliability, performance, and robustness. This chapter will therefore focus on understanding how to model and analyze thermal models relating to power electronic components and systems.

Heat is transported by three main mechanisms, conduction, convection, and radiation [1], and all three mechanisms can be important in power electronics, although the first two are generally the most significant. Heat transport occurs in three dimensions, which can make detailed analysis difficult; therefore one objective in modeling thermal behavior in power electronic systems is to reduce the problem to a simpler level and make it easier for the designer to get approximate but sufficiently accurate answers to design questions. A particular issue for the power electronics designer is that not only is the thermal behavior a requirement to accurately model the system but also is the interdependence with the device behavior. Power devices contribute heat due to losses and switching behavior, and this also contributes to self-heating effects that fundamentally affect their behavior. In some devices, this can become a serious problem. In power electronic circuits, there are also significant effects due to the variability of passive components such as resistance, capacitance, and magnetic components due to temperature, and these must all be taken into account when understanding the overall circuit behavior in this context. Finally, the environment temperature will also have a major impact on the performance of the power electronic circuit, and an effective and efficient approach is required to modeling such thermal effects.

46.2 Background

Modeling and simulation of thermal effects has been at the heart of power electronics for many years, with engineers attempting to understand fundamental device behavior needing to understand specific thermal behavior to provide model parameters that would accurately reflect the true model behavior [2,3]. Using simple thermal resistance and capacitance models (discussed in more detail later in this chapter) either integrated in the device models [4] or extending the SPICE simulator to include thermal effects directly in the models [5], the use of equivalent "lumped element" models has been used for more than 25 years to improve our understanding of temperature and its effect on semiconductor device operation. This has been a particular issue for the bipolar device community due to the "thermal runaway" characteristics of these devices; however, the use of similar techniques by the power electronics community has become common [6]. This is still an ongoing research issue primarily due to the difficulty of accurately obtaining thermally dependent parameters for the device and package thermal circuit and also making empirical measurements that can confirm the validity of the approach. In this chapter, we will look at some techniques that can be applied to modeling thermal behavior and some approaches to implement some form of modeling to understand at least the basic thermal behavior of power electronic devices and systems.

46.3 Semiconductor Device Modelling

Simulation Program with Integrated Circuit Emphasis (SPICE) building block models exist for diodes and MOSFETs in most circuit simulators already, but they were generally designed for low-voltage and small current integrated circuit applications as the name of the program suggests. They do not (usually) have bulk effects or dynamic thermal behavior, which is essential for power electronics. Like any semiconductor device power diode, MOSFETS and IGBTs are highly nonlinear and depend fundamentally on temperature. If we consider the humble diode equation (46.1),

$$i_d = I_{SAT}\left(e^{\frac{V_d}{nV_T}} - 1\right) \tag{46.1}$$

Eq. (46.1) relates the diode current in a nonlinear fashion to the diode voltage where I_{SAT} is the saturation current, V_d is the junction voltage, $V_T = kT/q$ is the thermal voltage, and n is the emission coefficient. It is obvious that the thermal voltage depends directly on the temperature. This type of approach has been used in SPICE (and other circuit simulators for many years), where the simulator temperature is defined as a global variable and used in semiconductor device models, with the assumption being that the circuit will be in a thermal steady state and this can be defined precisely by the designer. In some simulators, such as SABER, the temperature can be defined hierarchically so that a circuit or even device can have a unique temperature, but this is still effectively static. A breakthrough was to make the temperature of the device a dynamic variable that could be modeled using a thermal circuit at the same time as the electric circuit, and by using electric analogies, the integrated device behavior could be made more accurate.

Another key issue with the modeling power devices was to take a different approach to that of the low-power IC designers and to create models of power devices such as diodes, MOSFETs, and IGBTs that were more appropriate to this context. This was the "lumped-charge" approach [7], and this model handles the forward and reverse recovery characteristics much better than the basic low-voltage model. It has been implemented in Saber for more than 20 years, and the general approach has been extended to a wide variety of power semiconductor models [8] and to other simulators such as Modelica [9].

Often, power electronics designers do not understand the detail of model that is required to solve their design problem, and this relates directly to the implementation of a thermal model too. This can be encapsulated in a series of questions such as the following:

- Do you need a detailed physics model?
- Do you need cycle by cycle accuracy?
- Can you characterize the data well enough to achieve the accuracy?

These questions (and the answers to them) will often dictate the type of model to be used and the resulting complexity of system to analyze.

46.4 Magnetic Components

Magnetic components that include a nonlinear ferrite core are some of the most difficult to model in a power electronic system. The nonlinear BH curve that defines the magnetic behavior of the inductors and transformers in a power electronic system has a profound effect on the behavior of the system as a whole. It is also highly thermally dependent, and therefore, it is useful to be able to model this.

A basic BH curve is shown in Fig. 46.1, and this illustrates the effect of high magnetic field strength (causing saturation) and the remanence effect that leads to hysteresis. This is difficult enough to model without thermal effects (e.g., see the Jiles-Atherton approach [10–12]), and this has been implemented in most circuit simulators; however, the problem for power electronic circuit designers is that the BH curve can vary with temperature as shown in Fig. 46.2.

This can be managed in a simulation model by not only including a thermal pin, in a similar manner to the power semiconductor devices, but also making it self-heating to take into account eddy currents or losses that contribute to the overall thermal behavior [13].

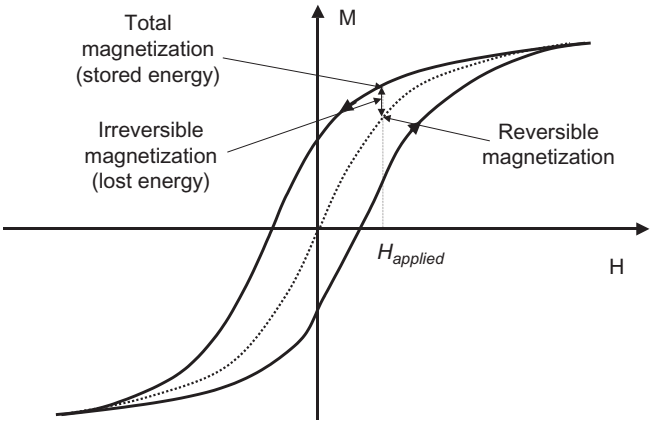

FIG. 46.1 Basic magnetic material BH curve.

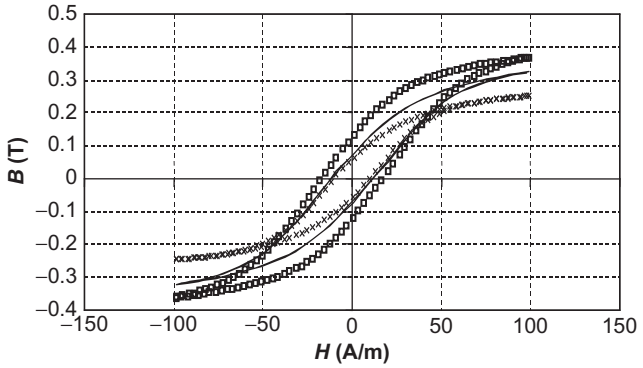

FIG. 46.2 BH curve temperature variation (□ = 27°C, − = 95°C, and × = 125°C).

In order to understand the methods of integrating thermal behavior into power electronic circuits, it is useful to first review the principles in thermal modeling.

46.5 Thermal Conduction

The conduction of heat through materials is by far the simplest transport mechanism to analyze. The transport of heat with conduction is described by the Fourier heat equation given in Eq. (46.1):

$$\frac{\delta T}{\delta t} = \frac{\sigma_\theta}{d\rho c} \times \nabla^2 T \tag{46.2}$$

where ρ is the density and c is the specific heat. The heat flux (power flow per unit area) can be found at any point using Eq. (46.3):

$$Q_\theta = -\sigma_\theta \nabla T \tag{46.3}$$

As with all partial differential equations, the solution of the Fourier equation can only be performed exactly for a few

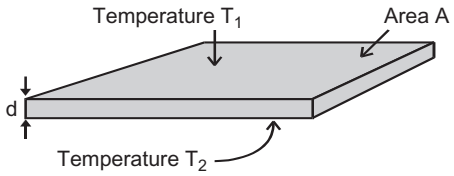

FIG. 46.3 Block of material for thermal conduction.

simple sets of boundary and initial conditions. Solutions can be found numerically or using approximate methods if we consider the conduction of heat through a square plate of area A and thickness d as shown in Fig. 46.3.

The two surfaces are at uniform temperatures T_1 and T_2. If it is the case that $d \ll A$, then we can make the assumption that the heat loss from the edges may be neglected and the resulting heat flow is in one dimension. The heat flow through the plate can therefore be calculated using Eq. (46.4):

$$P_\theta = \frac{(T_1 - T_2) \times A \times \sigma_\theta}{d} \times W \tag{46.4}$$

where σ_θ is the thermal conductivity. Notice the use of the subscript θ to emphasize that both the power and conductivity are thermal. Eq. (46.4) is often written in the form shown in Eq. (46.5):

$$P_\theta = \frac{(T_1 - T_2)}{R_\theta} \tag{46.5}$$

where R_θ is the *thermal resistance* of the plate, given by Eq. (46.6):

$$R_\theta = \frac{d}{A \times \sigma_\theta} \text{ K/W} \tag{46.6}$$

It is useful to see that the magnitude of thermal resistances for commonly used materials (in this case assuming a plate of area 10^{-4} m^2 (1 cm × 1 cm) and thickness 1 mm) is shown in Table 46.1.

TABLE 46.1 Thermal conductivity and resistance of a range of materials

Material	Thermal conductivity (W/K/m)	Thermal resistance (K/W)
Aluminum	217	0.046
Copper	394	0.025
Gold	291	0.034
Lead	34.3	0.29
Tin	63	0.16
PCB (FR4)	0.3	33
Alumina	27.6	0.36
Diamond	630	0.016
Silicon	150	0.067
GaN	130	0.077
Silicon carbide	500	0.02

Table 46.1 is interesting in that as we might expect, copper is an extremely good conductor; however, it is particularly interesting to look at three common materials for power electronic devices, silicon, gallium nitride, and silicon carbide. They all have excellent thermal properties; however, silicon carbide is particularly good making it advantageous for power electronic applications where thermal management is crucial.

The equation for conduction of heat has the same form as Ohm's law, making it easy to draw a direct analogy between the thermal and electric resistance equations:

$$P_\theta = \frac{\Delta T}{R_\theta} \Leftrightarrow I = \frac{\Delta V}{R} \tag{46.7}$$

The analogy is drawn that P is equivalent to I, T is equivalent to V, and R_θ is equivalent to R. T in the thermal model is defined as an *across* variable, that is, only differences between points are specified. This means that as for voltage, there must be a reference node. This is usually the ambient temperature, T_a. P is a through variable in the same that in an electric circuit, current must flow around a closed loop.

46.6 Convection

Convection is the process by which heat is transferred from a solid surface to a nonsolid, such as air or water. The convection process involves the motion of the fluid relative to the solid surface and the processes by which heat is transferred across the interface.

There are two main forms of convection, *natural* or *free* convection, where the motion of the fluid is produced by the change in density with temperature, and *forced* convection, where the motion is generated by an external mechanism, a fan or a pump.

Convection is most effective where the hot surface is vertical. The air is heated by the plate and rises by the "chimney effect." Forced airflow parallel to the plate will increase heat transfer. Heat transfer will depend on surface area, height, and temperature difference (Fig. 46.4). The process of convection is complex and not readily amenable to analysis; therefore, empirical methods have been developed, allowing models to be created based on these measurements.

46.7 Radiation

The final concept of heat transfer is radiation. In this context, radiation refers to the transfer of heat by electromagnetic radiation. The basic equation for heat transfer by radiation is the Stefan-Boltzmann law that is given in Eq. (46.8):

$$P_{rad} = 5.7 \times 10^{-7}\left(T^4 - T_a^4\right) \times E \times A \tag{46.8}$$

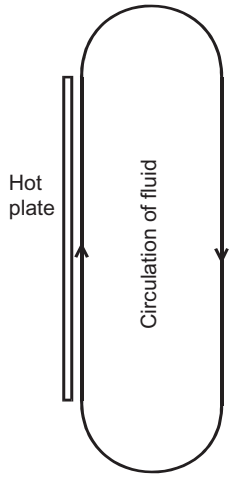

FIG. 46.4 Convection concept of fluid circulation.

where T is the absolute temperature of the radiating surface (K), T_a is the ambient temperature of the surrounding objects (K), A is the area (m^2), and E is a constant known as the emissivity. The emissivity may vary from as low as 0.05 for polished aluminum to 0.9 for black oxidized aluminum.

In order to put the power loss by radiation into context, consider a 1 cm^2 black anodized aluminum plate. The plate is at a temperature of 373 K, and the ambient temperature is at 323 K.

Taking into account the heat loss from both sides of the plate, the power loss is given by Eq. (46.9):

$$P = 5.7 \times 10^{-7} \times 0.8 \times 10^{-4} \times \left(373^4 - 323^4\right) \times 2 = 0.87 \text{ W} \tag{46.9}$$

With a heat sink using natural convection, radiation will play a role in removing heat. The difference between a shiny aluminum heat sink and the same sink anodized black is of order 5%–25%, and the advantage rises with temperature.

Now, we have covered the basics of thermal behavior; we can investigate how to implement useful models for inclusion in power electronic circuits.

46.8 Steady State Thermal Circuit Modeling

For the thermal circuit model to be of use, it must be possible to define the temperature at well-defined points that are defined as the nodes of the thermal circuit. It must also be possible to define the heat flux and thermal resistance between these points, which implies that we therefore have a *lumped* model. At this stage, we are considering the steady state only, where the temperatures have stabilized into an equilibrium condition.

It is essentially the same as describing an electric circuit in terms of nodes connected by electric components, which is valid as long as it is not necessary to consider distributed effects

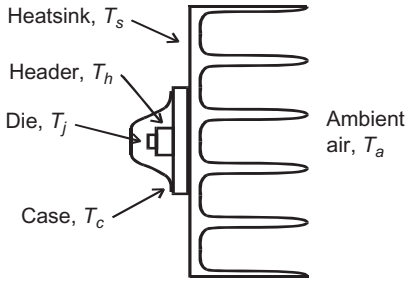

FIG. 46.5 Transistor bolted to a heat sink.

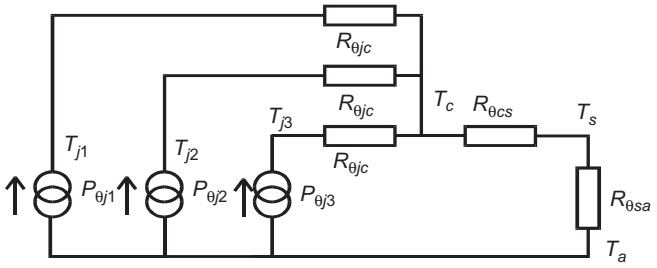

FIG. 46.7 Several transistors mounted on the same heat sink.

(such as a transmission line). The lumped components in the thermal circuit are generally less well defined than their electric counterparts, due to the uncertainty in characterization of the thermal parameters and approximations made to obtain the parameters.

If we consider the example of a transistor that is bolted to a heat sink, as shown in Fig. 46.5, we can see that there are five temperatures to consider in this model, starting from the junction temperature of the device (T_j), the header temperature (T_h), the case temperature (T_c), the heat sink (T_s), and finally the ambient temperature (T_a).

The heat flow into the thermal circuit from the device is the power dissipation (in watts) from the power device, which is analogous to current in the electric domain. At this point, the obvious question is how do we model this thermal circuit in such a way that we can calculate all the intermediate temperatures based on a power dissipation value from the power transistor? We can represent each of the individual thermal elements as a thermal resistance connected in series with a thermal heat source as shown in Fig. 46.6.

In this example, the thermal circuit has been represented by four resistors with five nodes. In practice, R_{qjh} and R_{qhc} would not readily be measured separately and so would be grouped together as R_{qjc}, a parameter measured by the manufacturer. The heat-sink supplier would specify R_{qsa}, and the contact resistance between case and heat sink would depend on mounting method surface conditions. The junction temperature can be estimated using Eq. (46.10):

$$T_j = \left(R_{\theta jh} + R_{\theta jc} + R_{\theta cs} + R_{\theta sa}\right) \times P_{\theta j} + T_a \tag{46.10}$$

and the heat-sink temperature can also be estimated from Equation (46.11):

$$T_s = R_{\theta sa} \times P_{\theta j} + T_a \tag{46.11}$$

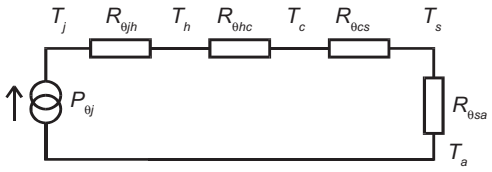

FIG. 46.6 Equivalent thermal circuit of power device and heat sink.

This lumped approach starts to become very effective when the situation becomes more complex as it can be easily modeled using SPICE or other circuit simulators, such as the case when there are several devices mounted on the same heat sink as shown in Fig. 46.7.

This circuit can quickly be solved and the resulting heatsink temperature estimated.

46.9 Dynamic Thermal Circuit Modeling

So far, only steady-state thermal circuits have been considered. There are however many situations where it is required to model the transient behavior, such as when the dynamic electric behavior changes (say under peak inrush current conditions or a failure current). When heat is applied to an object, the temperature will increase at a rate determined by the heat input and the *thermal capacity* of the object. Although the scenario has moved from steady state to dynamic, the assumption is still being made that a single temperature may be assigned to the object, that is, a lumped model rather than a distributed one. This will not necessarily be the case, but it is a necessary assumption for the lumped component model. Generally, some kind of average temperature will be used. The thermal capacity of a lumped component of the thermal circuit is given by Eq. (46.12):

$$C_\theta = m \times c_s \tag{46.12}$$

where m is the mass of the component and c_s the specific heat of the material. In terms of the circuit model, the thermal capacity is analogous to an electric capacitor. A transistor on a heat sink may therefore be represented by Fig. 46.8.

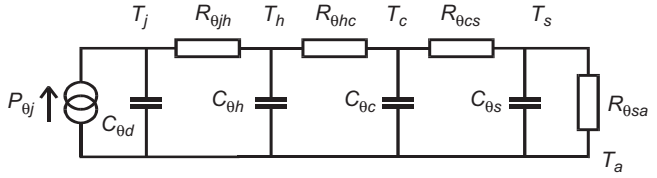

FIG. 46.8 Adding thermal capacitance to the thermal model.

This model is useful, but there are still issues to resolve. If we consider the heat sink, a thermal capacity $R_{\theta s}$ has been ascribed to it, and this is relatively well defined. In the model, the temperature drop across the heat sink itself has been neglected. The thermal resistances either side of the capacitor are interface resistances, with no significant thermal capacity. Similarly, the case presents a relatively large thermal capacity but little thermal resistance. The header and the die however are different. Here, they have both been considered as two lumped components. This is not a very good assumption as in reality the thermal resistance and thermal capacity in both header and die are distributed.

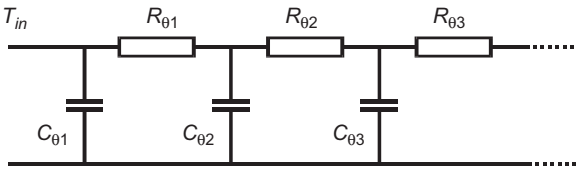

FIG. 46.9 Thermal ladder network.

46.10 Approximating Distributed Thermal Behaviour Using Ladder Networks

One solution to the problem of approximating a distributed thermal network is to use a thermal ladder network. The thermal resistance is divided into n sections of R_θ/n and the capacitance into n capacitances of value C_θ/n. This is exactly the same problem that arises in distributed electric networks (such as transmission lines), and the same approach may be taken as shown in Fig. 46.9. However, it should be noted that there is no obvious equivalent to an inductance in the thermal domain.

46.11 Transient Thermal Impedance

The ladder network approach is useful but is a hard work to analyze. A simpler approach is needed and that approach is the transient thermal impedance. When considering active devices mounted on a heat sink, the external part can be adequately described by the simple thermal resistance—thermal capacity concept. The problem area is the internal behavior of the device. The central idea is to replace the internal thermal resistance by a thermal impedance that depends on the temporal variation of the power dissipated. The objective is to accurately estimate the maximum junction temperature.

A typical data sheet graph (for the International Rectifier IRF 450 n-type power MOSFET in a modified TO-3 package, a 500 V 12 A device) of thermal impedance is shown in Fig. 46.10, with the thermal impedance plotted against the pulse duration on the x-axis and the family of curves showing how the duty ratio affects the effective thermal impedance, normalized to the thermal resistance. For this device, the thermal resistance is found on the data sheet as the parameter R_{thJC} and is 0.83°C/W, and the junction to ambient thermal resistance is 30°C/W. (For comparison, a TO-240 package—device is denoted by IRFM450—has a junction to ambient thermal resistance of 48°C/W.)

The starting point is the response of the junction temperature to a unit step of input power, when the case temperature is constant. The temperature after a time t is the equivalent of the maximum temperature reached by the junction for a single

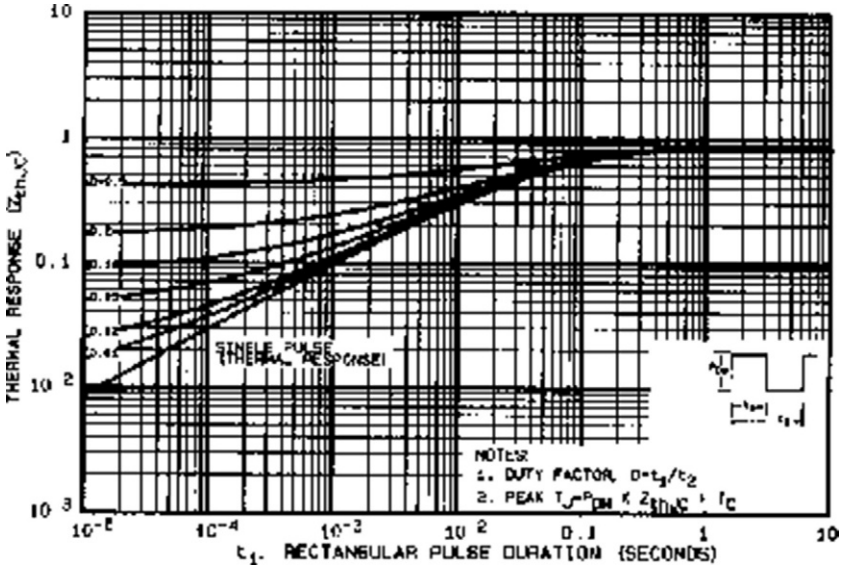

FIG. 46.10 Thermal impedance for International Rectifier IRF450.

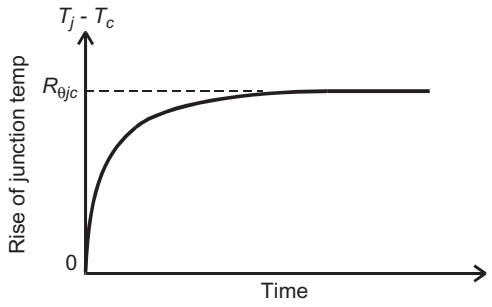

FIG. 46.11 Response of junction temperature over time.

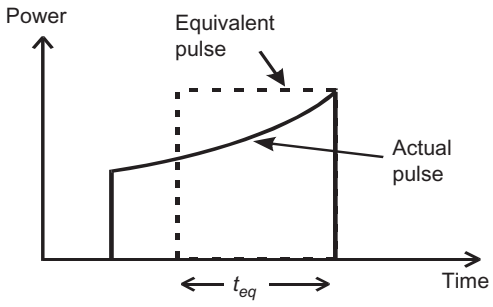

FIG. 46.13 Equivalent pulse based on actual pulse shape.

pulse of duration t. The steady-state response is a rise of temperature equal to the thermal resistance R_{qjc}.

The dynamic response of the junction temperature can be seen in Fig. 46.11, where the temperature will rise smoothly to the steady-state value.

The rise of junction temperature above the case temperature for a pulse of length t is defined as the thermal impedance for a pulse of length t. This is for a pulse of unit height. If the pulse has an amplitude P_m and duration t, the maximum junction temperature is given by Eq. (46.13):

$$T_{jmax} = T_a + Z_{\theta jc}(t) \times P_m \tag{46.13}$$

If the pulses are repetitive with a duration t and duty ratio D (Period t/D), the maximum temperature will rise above the value for a single pulse of duration t as shown in Fig. 46.12.

With multiple pulses, the temperature oscillates, the magnitude of the oscillation decreasing with increasing frequency. In the limit, the ripple will approach zero, with a temperature rise corresponding to the mean power ($P_m \times D$) multiplied by the thermal resistance. Measured values for thermal impedance can be seen on manufacturer's data sheets. The graphs show the thermal impedance normalized to the thermal resistance, as a function of pulse width and duty ratio.

46.12 Procedure to Calculate the Transient Thermal Impedance

The procedure to use thermal impedance to calculate the temperature difference between junction and case starts by calculating the approximate power pulse by an equivalent square pulse of equal area and same height based on the actual pulse as shown in Fig. 46.13. From this figure, it is possible to deduce equivalent pulse width, t_{eq}. The way to do this is to estimate the area under the actual curve (using a trapezoidal approach) and from the maximum value calculate the equivalent pulse width based on the rectangular area required. The duty ratio can then be calculated based on the ratio of the equivalent pulse width and the switching period.

With the equivalent pulse width and the derived duty ratio, the graph of thermal impedance can be used to look up the appropriate value.

The maximum difference (effectively the steady state) can then be calculated by multiplying the peak pulse power by the value of thermal impedance obtained from the data sheet. In practice, the pulsing thermal behavior we see in Fig. 46.12 will be filtered out by the time the case is taken into account, and the calculation of case temperature may be made using the average power and the external thermal resistances.

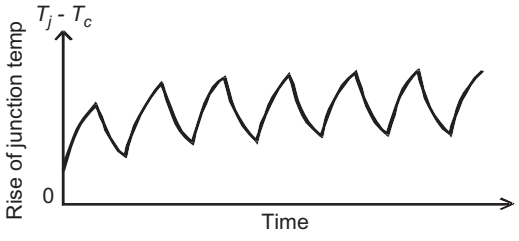

FIG. 46.12 Response of junction temperature to repeated pulses.

46.13 Finite Element Numerical Methods

The solution of the Fourier heat equation in anything but the simplest cases requires the use of numerical methods such as the finite element method. For the steady state, the Fourier equation reduces to the Laplace equation in Eq. (46.14):

$$\nabla^2 T = 0 \tag{46.14}$$

and the heat flux (power per unit area) at any point is given by Eq. (46.15):

$$Q_\theta = \sigma \nabla(T) \tag{46.15}$$

The Laplace equation occurs in many physical systems, and the solution of it is a standard problem; however, due to the complexity of most real-world systems, finite element techniques are the preferred technique to obtain a numerical solution. Solutions for the temperature distribution in physical geometries can be obtained using commercial software packages designed to implement the finite element method. In most cases, this will give the equilibrium or steady-state solution rather than the transient behavior. In order to calculate, the

transient thermal distribution requires the use of repeated finite element simulations for different initial conditions and applied heat flow values (as in the pulsed example shown in Fig. 46.13). This can take a high level of computation to complete and for complex geometries can take a long time to complete.

46.14 Dynamic Thermal Equivalent Circuit Models

When the calculations get more complex than a simple junction to case and junction to ambient calculation, then the choice for the power electronics design engineer is to either create a complex geometric model for the device, case, heat sink, and environment and then conduct extensive, repeated finite element analyses or more commonly use equivalent circuit models instead.

One obvious circuit that is often used to provide an increased level of detail, which effectively approximates the finite element model in one dimension, is the ladder circuit. For example, if we take the IRF450 device we have looked at previously, we can see that the junction to case thermal resistance R_{thJC} is 0.83°C/W; therefore, if we create a 10-section RC ladder network, then each individual thermal resistance will be 0.083 C/W (one-tenth of the overall thermal resistance). In the steady state, this will be identical to the lumped model we looked at previously in this chapter (Fig. 46.14). It is possible to calculate an appropriate value for the ladder capacitances; however, in most cases, it is just as quick (and certainly easier) to use a simulation to experiment with the capacitance values to obtain the best matching of time dependence with the data for the device.

If a heat flow (current in an electric analogous circuit) is applied, then the voltage will represent the thermal impedance over time, and this can be matched to the data sheet transient thermal impedance. For example, using the Saber simulator, we can define a thermal circuit using dedicated thermal resistance and capacitance models (although we could equally well use SPICE models for electric analogues), as shown in Fig. 46.15.

Varying the capacitance value allows the response of the transient thermal impedance to be obtained from the temperature across the whole ladder network. In this case, we can vary the capacitance on each leg from 200 to 2000 μF, with the resulting responses as shown in Fig. 46.16.

The same circuit can be used to test the behavior of the thermal circuit to a pulsed heat source, much as would be the case when a power device is switched on and off, and we can simulate this using the same test circuit, but with a pulse heat source (Fig. 46.17). Using a period of 1 ms and a duty ratio of 0.2, we can see the temperature response as follows (when the capacitance is defined as 400 μF).

When the heat source pulse period is reduced to 100 μs (i.e., 10 kHz), the ripple on the temperature reduces significantly (Fig. 46.18).

One of the limitations with the ladder network is that it will tend to underestimate the thermal impedance for higher duty ratios, and while it is certainly very useful, it must be used with caution. It is possible to increase the accuracy by increasing the number of thermal RC stages; however, obviously, there will be a price to pay in terms of simulation speed as a result.

It is also very useful to note that the thermal models can be linked directly to the electric simulations with the power electronics, either using electric analogy models (i.e., electric resistance to represent thermal resistance) or more commonly in modern multiple-domain simulators directly as thermal models. It is, however, true to say that in most cases, the time constants of the thermal circuits are much longer than the switching periods of the power electronics and the user should

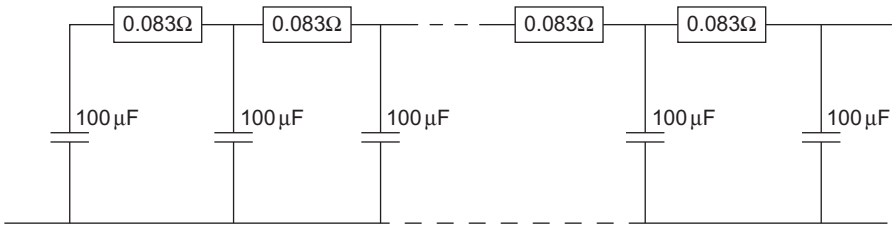

FIG. 46.14 Dynamic thermal ladder model example.

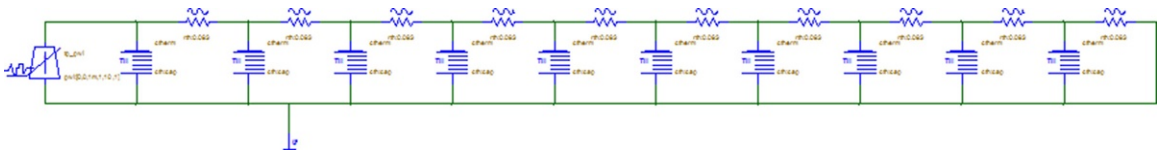

FIG. 46.15 Thermal ladder simulation test circuit.

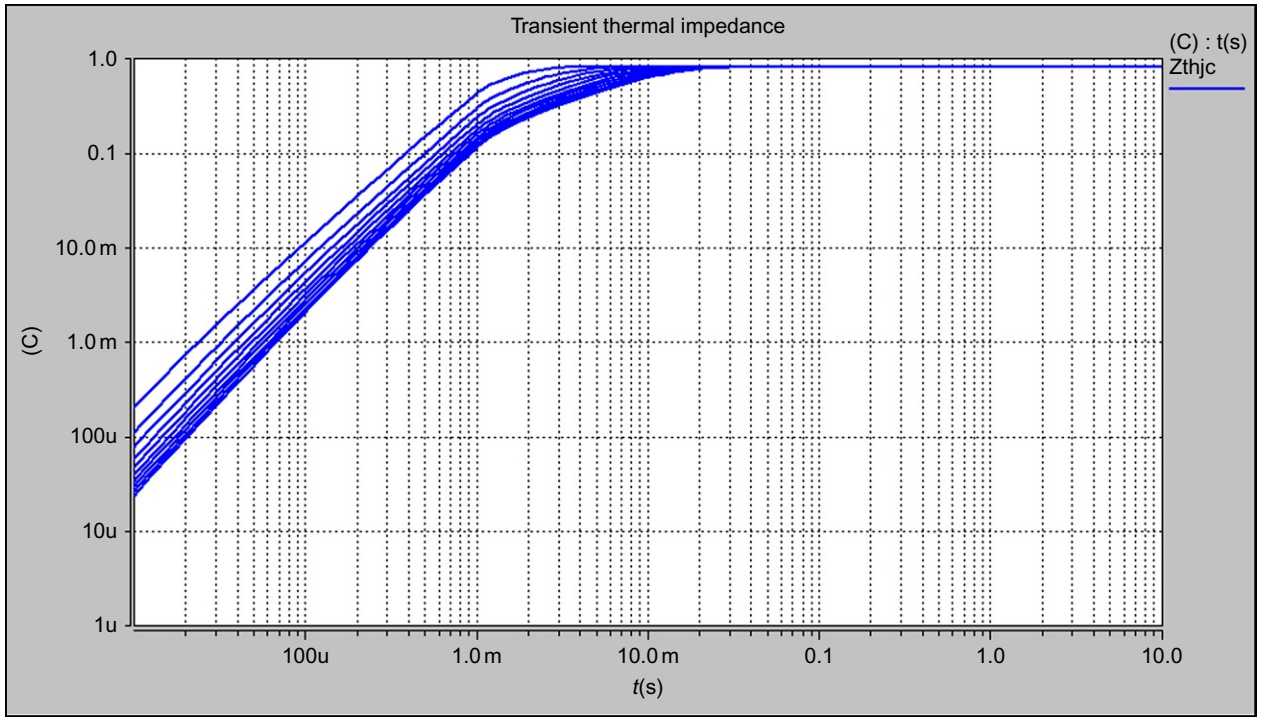

FIG. 46.16 Transient thermal impedance variation due to ladder capacitance.

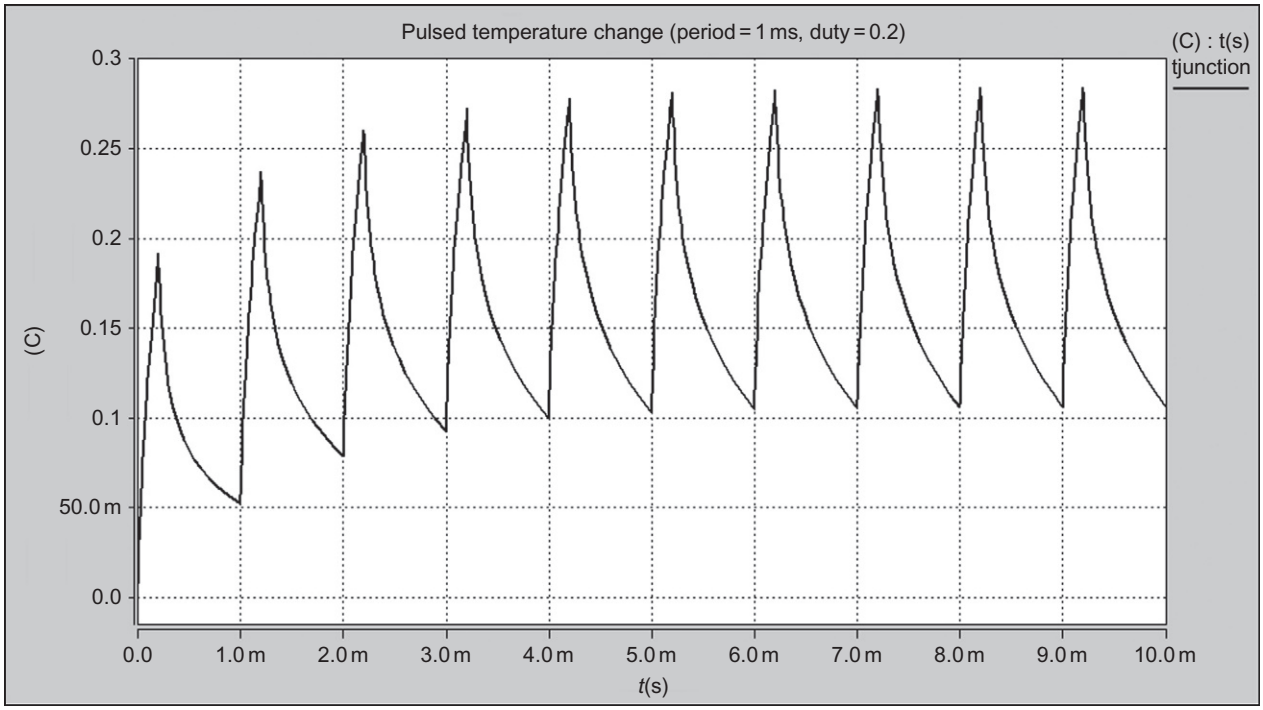

FIG. 46.17 Pulsed heat source temperature change at 1 kHz and duty ratio = 0.2.

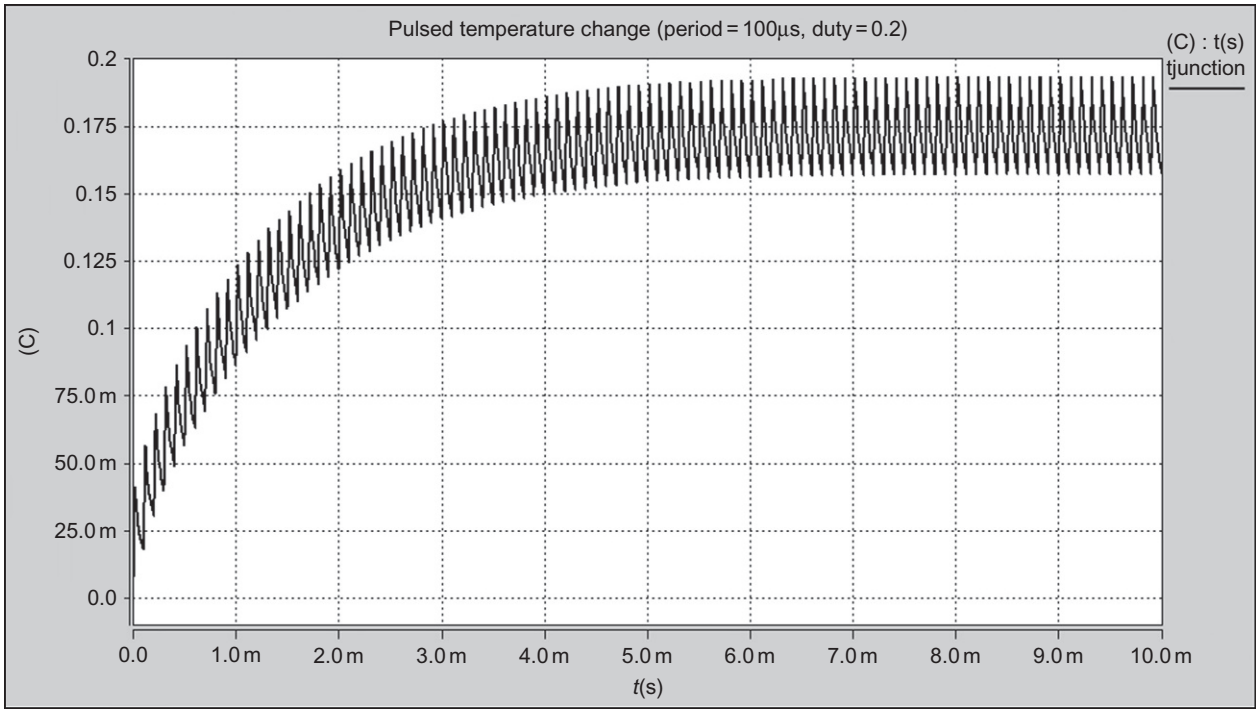

FIG. 46.18 Pulsed heat source temperature change at 10 kHz duty ratio = 0.2.

therefore be prepared for running long simulations to achieve the steady-state temperature changes. Nevertheless, it can be extremely illuminating and helpful in understanding the true thermal state of the power electronics.

46.15 Summary

Thermal properties of devices, packages, and heat sinks can be modeled in a relatively simple and efficient manner using a number of simple lumped-model techniques. While this gives a good starting point for estimating the thermal impact on circuit performance, it is clearly a complex and interlinked area that requires detailed analysis to gain highly accurate solutions. However, the use of such models can help the designer gain an insight as to the effect of temperature on device and circuit behavior and as a result can profoundly improve the ultimate design. If the designer takes a "worst-case-scenario" approach to modeling thermal behavior, then they greatly increase their chances of obtaining a robust and efficient design that can cope with extremes of temperature in the environment or due to the device behavior.
